Table of Contents

1. Glossary Shirlyn B. McKenzie/J. Lynne Williams	1
2. Introduction Shirlyn B. McKenzie/J. Lynne Williams	29
3. Cellular Homeostasis Shirlyn B. McKenzie/J. Lynne Williams	37
4. Hematopoiesis Shirlyn B. McKenzie/J. Lynne Williams	61
5. Structure and Function of Hematopoietic Organs Shirlyn B. McKenzie/J. Lynne Williams	81
6. The Erythrocyte Shirlyn B. McKenzie/J. Lynne Williams	97
7. Hemoglobin Shirlyn B. McKenzie/J. Lynne Williams	123
8. The Leukocyte Shirlyn B. McKenzie/J. Lynne Williams	143
9. Introduction to Anemia Shirlyn B. McKenzie/J. Lynne Williams	189
10. Anemias of Disordered Iron Metabolism and Heme Synthesis Shirlyn B. McKenzie/J. Lynne Williams	219
11. Hemoglobinopathies: Qualitative Defects Shirlyn B. McKenzie/J. Lynne Williams	259
12. Thalassemia Shirlyn B. McKenzie/J. Lynne Williams	283
13. Megaloblastic and Nonmegaloblastic Macrocytic Anemias Shirlyn B. McKenzie/J. Lynne Williams	311

14. Hypoproliferative Anemias Shirlyn B. McKenzie/J. Lynne Williams	341
15. Introduction to Hemolytic Anemia Shirlyn B. McKenzie/J. Lynne Williams	359
16. Hemolytic Anemia: Membrane Defects Shirlyn B. McKenzie/J. Lynne Williams	371
17. Hemolytic Anemia: Enzyme Deficiencies Shirlyn B. McKenzie/J. Lynne Williams	393
18. Hemolytic Anemia: Immune Anemias Shirlyn B. McKenzie/J. Lynne Williams	409
19. Hemolytic Anemia: Nonimmune Defects Shirlyn B. McKenzie/J. Lynne Williams	441
20. Nonmalignant Granulocyte and Monocyte Disorders Shirlyn B. McKenzie/J. Lynne Williams	459
21. Nonmalignant Lymphocyte Disorders Shirlyn B. McKenzie/J. Lynne Williams	483
22. Introduction to Hematopoietic Neoplasms Shirlyn B. McKenzie/J. Lynne Williams	503
23. Myeloproliferative Disorders Shirlyn B. McKenzie/J. Lynne Williams	527
24. Myelodysplastic Syndromes Shirlyn B. McKenzie/J. Lynne Williams	567
25. Acute Myeloid Leukemias Shirlyn B. McKenzie/J. Lynne Williams	593
26. Acute Lymphoblastic Leukemias Shirlyn B. McKenzie/J. Lynne Williams	619
27. Lymphoid Malignancies: Chronic Lymphoid Leukemias, Lymphomas, and Plasma Cell Neoplasms Shirlyn B. McKenzie/J. Lynne Williams	637
28. Hematopoietic Stem Cell Transplantation Shirlyn B. McKenzie/J. Lynne Williams	663
29. Morphologic Analysis of Body Fluids in the Hematology Laboratory Shirlyn B. McKenzie/J. Lynne Williams	681
30. Primary Hemostasis Shirlyn B. McKenzie/J. Lynne Williams	713
31. Secondary Hemostasis and Fibrinolysis Shirlyn B. McKenzie/J. Lynne Williams	743

32. Disorders of Primary Hemostasis Shirlyn B. McKenzie/J. Lynne Williams	777
33. Disorders of Secondary Hemostasis Shirlyn B. McKenzie/J. Lynne Williams	809
34. Thrombophilia Shirlyn B. McKenzie/J. Lynne Williams	843
35. Hematology Procedures Shirlyn B. McKenzie/J. Lynne Williams	875
36. Bone Marrow Examination Shirlyn B. McKenzie/J. Lynne Williams	913
37. Automation in Hematology and Hemostasis Shirlyn B. McKenzie/J. Lynne Williams	929
38. Flow Cytometry Shirlyn B. McKenzie/J. Lynne Williams	955
39. Chromosome Analysis of Hematopoietic and Lymphoid Disorders Shirlyn B. McKenzie/J. Lynne Williams	975
40. Molecular Analysis of Hematologic Diseases Shirlyn B. McKenzie/J. Lynne Williams	999
41. Laboratory Testing in Coagulation Shirlyn B. McKenzie/J. Lynne Williams	1017
42. Quality Assessment in the Hematology Laboratory Shirlyn B. McKenzie/J. Lynne Williams	1053
Index	1075

GLOSSARY

▶ A

Abetalipoproteinemia (hereditary acanthocytosis) - rare, autosomal recessive disorder characterized by the absence of serum β -lipoprotein, low serum cholesterol, low triglyceride, and low phospholipid and an increase in the ratio of cholesterol to phospholipid.

Acanthocyte - abnormally shaped erythrocyte with spicules of varying length irregularly distributed over the cell membrane's outer surface; also known as *spur cell*. There is no central area of pallor.

Achlorhydria - absence of hydrochloric acid in stomach gastric secretions.

Acquired aberration - chromosome aberration (either numerical or structural) that occurs at some time after birth and involves only one cell line.

Acquired immune deficiency syndrome (AIDS) - disease caused by infection with human immunodeficiency virus type I (HIV-1). The virus selectively infects helper T lymphocytes (CD4+) causing rapid depletion of these cells. This causes a deficiency in cell-mediated immunity. The patients have repeated infections with multiple opportunistic organisms and an increase in malignancies.

Acquired inhibitors - See Circulating anticoagulants.

Acrocentric - description of a chromosome that has the centromere close to the terminal end so that the short arm is much shorter than the long arm. The short arm consists only of a stalk and a small amount of DNA called a *satellite*.

Acrocyanosis - See Raynaud's phenomenon.

Activated partial thromboplastin time (APTT) - screening test used to detect deficiencies in the intrinsic and common pathway of the coagulation cascade.

Activated lymphocyte - See Reactive lymphocyte.

Activated protein C resistance (APCR) - condition in which activated protein C is not able to inactivate F-V, which may cause or contribute to thrombosis. In most cases, it is due to a mutation in F-V in which Arg 506 is replaced with Gln (F-V_{Leiden}).

Acute leukemia - malignant hematopoietic stem cell disorder characterized by proliferation and accumulation of immature and non-functional hematopoietic cells in the bone marrow and other organs.

Acute lymphocytic leukemia (ALL) - malignant lymphoproliferative disorder characterized by proliferation and accumulation of lymphoid cells in the bone marrow. Peripheral blood smear reveals the presence of many undifferentiated or minimally differentiated cells.

Acute myeloid leukemia (AML) - malignant myeloproliferative disorder characterized by proliferation and accumulation of primarily undifferentiated or minimally differentiated myeloid cells in the bone marrow.

Acute phase reactant - plasma protein that rises rapidly in response to inflammation, infection, or tissue injury.

Acute undifferentiated leukemia (AUL) - acute leukemia in which the morphology, cytochemistry, and immunophenotype of the pro-

liferating blasts lack sufficient information to classify them as myeloid or lymphoid origin.

ADAMTS-13 - metalloprotease enzyme responsible for cleavage of the ultralarge multimers of VWF released from endothelial cells into the VWF multimer sizes normally found in the circulation.

Adaptive immune response - interaction of the T lymphocyte, B lymphocyte, and macrophage in a series of events that allows the body to attack and eliminate foreign antigens.

ADCC - antibody-dependent cell cytotoxicity that describes the recognition and lysis of cells by NK cells. This occurs by binding IgG to the NK cell CD 16 receptor. Any target cell coated with IgG can be bound to NK cells and lysed. Monocytes, macrophages, and neutrophils also have this receptor and act in a similar manner.

Adipocyte - cell whose cytoplasm is largely replaced with a single fat vacuole; fat cell.

Adsorbed plasma - platelet-poor plasma that is adsorbed with either barium sulfate or aluminum hydroxide to remove the coagulation factors II, VII, IX, X (the prothrombin group). Factors V, VIII, XI, XII, and fibrinogen (I) are present in adsorbed plasma. This plasma is one of the reagents used in the substitution studies to determine a specific factor deficiency.

Afibrinogenemia - condition in which there is absence of fibrinogen in the peripheral blood. It may be caused by a mutation in the gene controlling the production of fibrinogen or by an acquired condition in which fibrinogen is pathologically converted to fibrin.

Aged serum - serum that lacks coagulation factors fibrinogen (I), prothrombin (II), V, VIII. Aged serum is prepared by incubating normal serum for 24 hours at 37°C. Factors VII, IX, X, XI, and XII are present in aged serum. This serum is one of the reagents used in the substitution studies to determine a specific factor deficiency.

Agglutinate - clumping together of erythrocytes as a result of interactions between membrane antigens and specific antibodies.

Aggregating reagent - chemical substance (agonist) that promotes platelet activation and aggregation by attaching to a receptor on the platelet's surface.

Agonist - chemical substance that can attach to a platelet membrane receptor and activate platelets causing them to aggregate (e.g., collagen, ADP). These agonists are used in the laboratory to test platelet function using a platelet aggregometer or platelet function analyzer.

Agranulocytosis - absence of granulocytes in the peripheral blood.

AIDS related complex (ARC) - second recognized clinical stage of a person infected with the HIV virus. Immune-compromised patients with mild symptoms of weight loss, fever, lymphadenopathy, thrush, chronic rash, or intermittent diarrhea are included in this category.

Alder-Reilly anomaly - benign condition characterized by the presence of leukocytes with large purplish granules in their cytoplasm when stained with a Romanowsky stain. These cells are functionally normal.

Aleukemic leukemia - disorder in which the abnormal malignant cells are found only in the bone marrow.

Allele - one of two or more genes that correspond to the same trait and occupy the same position on paired chromosomes.

Alloantibodies - antibodies produced in one individual in response to the antigens of another individual of the same species.

Allogeneic - pertaining to an allograft in which donor and host belong to the same species but are not genetically identical.

Allogeneic stem cell transplantation - transplantation of stem cells between genetically dissimilar animals of the same species.

Alloimmune hemolytic anemia - hemolytic disorder generated when blood cells from one person are infused into a genetically unrelated person. Antigens on the infused donor cells are recognized as foreign by the recipient's lymphocytes, stimulating the production of antibodies. The antibodies react with donor cells and cause hemolysis.

Alpha granules - platelet storage granules containing a variety of proteins that are released into an area after platelet activation.

Analytical sensitivity - ability to detect small amounts of the analyte.

Analytical specificity - ability to detect only the analyte in question.

Analytical time - period between specimen entry into the test system and the reporting of the result by the instrument.

Anemia - disorder characterized by decrease in the normal concentration of hemoglobin or erythrocytes. This may be caused by increased erythrocyte loss or decreased erythrocyte production. Anemia may result in hypoxia.

Aneuploid - number of chromosomes per cell that does not equal a multiple of the haploid number, n , for example, in human cells a chromosome count of 45, 47, 48, etc.

Anisocytosis - term used to describe a general variation in erythrocyte size.

Antibody - immunoglobulin produced in response to an antigenic substance.

Anticardiolipin antibody (ACA) - autoantibody directed against negatively charged phospholipids. *See* Antiphospholipid antibody.

Anticoagulant - chemical substance added to whole blood to prevent blood from coagulating. Depending on the type of anticoagulant, in vitro coagulation is prevented by the removal of calcium (EDTA) or the inhibition of the serine proteases such as thrombin (heparin).

Antigen - any foreign substance that evokes antibody production (an immune response) and reacts specifically with that antibody.

Antigen-dependent lymphopoiesis - development of immunocompetent lymphocytes into effector T and B lymphocytes that mediate the immune response through production of lymphokines and antibodies. The process is initiated when mature lymphocytes come into contact with an antigen. This process occurs in secondary lymphoid tissue.

Antigen-independent lymphopoiesis - development of lymphoid stem cells into immunocompetent T and B lymphocytes (virgin lymphocytes). This process occurs in the primary lymphoid tissue under the regulation of hematopoietic growth factors.

Antigen presenting cell (APC) - term used to describe the macrophage in the immune response; the macrophage phagocytizes substances foreign to the host and presents its antigenic determinants on its membrane to antigen-dependent T lymphocytes.

Antihuman globulin (AHG) - globulin used in a laboratory procedure that is designed to detect the presence of antibodies directed against erythrocyte antigens on the erythrocyte membrane.

Antioncogene - gene that codes for a normal substance that suppresses tumor formation. Maturation and/or absence of both alleles allows tumor growth. Also called *tumor-suppressor gene*.

Antiphospholipid antibody - autoantibody directed against antigens that consist of a negatively charged phospholipid. Clinically important antiphospholipid antibodies include anticardiolipin antibody (ACA) and lupus anticoagulant (LA). In some individuals, these antibodies are associated with thrombosis and other hemostatic defects.

Antiphospholipid antibody syndrome - clinical condition characterized by the presence of high titers of antiphospholipid antibodies, thrombocytopenia, and recurrent arterial and venous thromboses, often affecting young males.

Aperture - small opening through which blood cells are drawn into an electronic cell counter. Electrodes are located on either side of the aperture, and electrical resistance is detected as the cell passes through the aperture.

Apheresis - separation or removal. Whole blood is withdrawn from the donor or patient and separated into its components. One of the components is retained, and the remaining constituents are recombined and returned to the individual.

Aplasia - failure of hematopoietic cells to generate and develop in the bone marrow.

Aplastic anemia - anemia characterized by peripheral blood pancytopenia and hypoplastic marrow. It is considered a pluripotential stem cell disorder.

Aplastic crisis - abrupt, transient cessation of erythropoiesis that occurs in some hemolytic anemias and infections.

Apo ferritin - cellular protein that combines with iron to form ferritin. It is found attached only to iron, not in the free form.

Apoptosis - programmed cell death resulting from activation of a predetermined sequence of intracellular events; "cell suicide."

APSAC - anisoylated plasminogen streptokinase activator complex; a modification of the enzyme streptokinase that is a chemically altered complex of streptokinase and plasminogen and is used as a thrombolytic agent in the treatment of thrombosis.

APTT - laboratory test that measures fibrin-forming ability of coagulation factors in the intrinsic coagulation cascade.

Arachidonic acid (AA) - unsaturated essential fatty acid, usually attached to the second carbon of the glycerol backbone of phospholipids, released by phospholipase A_2 and a precursor of prostaglandins and thromboxanes.

Arachnoid mater - delicate membrane that covers the central nervous system; middle layer of the meninges.

Artificial oxygen carrier (AOC) - two groups of AOCs including hemoglobin-based oxygen carriers (HBOCs) in solution and perfluorocarbons (PFCs). The HBOCs consist of purified human or bovine hemoglobin and recombinant hemoglobin. The oxygen dissociation curve of HBOCs is similar to that of native human blood. Hemoglobin tests based on colorimetric analysis could give erroneous results. PFCs are fluorinated hydrocarbons with high gas-dissolving capacity. They do not mix in aqueous solution and must be emulsified. In contrast to HBOCs, a linear relationship exists between pO_2 and oxygen content in PFCs. Thus, relatively high O_2 partial pressure is required to maximize delivery of O_2 by PFCs.

Ascites - effusion and accumulation of fluid in the peritoneal cavity.

Ascitic fluid - fluid that has abnormally collected in the peritoneal cavity of the abdomen.

Atypical lymphocyte - See Reactive lymphocyte.

Auer rods - reddish-blue staining needlelike inclusions within the cytoplasm of leukemic myeloblasts that occur as a result of abnormal cytoplasmic granule formation. Their presence on a Romanowsky-stained smear is helpful in differentiating acute myeloid leukemia from acute lymphoblastic leukemia.

Autoantibodies - antibodies in the blood capable of reacting with the subject's own antigens.

Autohemolysis - lysis of the subject's own erythrocytes by hemolytic agents in the subject's serum.

Autoimmune hemolytic anemia (AIHA) - anemia that results when individuals produce antibodies against their own erythrocytes. The antibodies are usually against high-incidence antigens.

Autologous stem cell transplantation - transplantation or infusion of a person's own stem cells.

Autosome - chromosome that does not contain genes for sex differentiation; in humans, chromosome pairs 1–22.

Autosplenectomy - extensive splenic damage secondary to infarction. This is often seen in older children and adults with sickle cell anemia.

Azurophilic granules - granules (primary granules) within myelocytic leukocytes that have a predilection for the aniline component of a Romanowsky-type stain. These granules appear bluish purple or bluish black when observed microscopically on a stained blood smear. They first appear in the promyelocyte.

► B

Backlighting - highlighting a parameter that falls outside its reference interval or a user-defined action limit. Backlighting alerts the clinical laboratory professional of a potential problem or error that requires further investigation.

Band neutrophil - immediate precursor of the mature granulocyte. This cell type can be found in either the bone marrow or peripheral blood. The nucleus is elongated and nuclear chromatin is condensed. The cytoplasm stains pink, and there are many specific granules. The cell is 9–15 μm in diameter. Also called *stab* or *unsegmented neutrophil*.

Basophil - mature granulocytic cell characterized by the presence of large basophilic granules. These granules are purple blue or purple black with Romanowsky stain. The cell is 10–14 μm in diameter, and the nucleus is segmented. Granules are cytochemically positive with periodic acid-schiff (PAS) and peroxidase. The granules contain histamine and heparin peroxidase. Basophils constitute $<0.2 \times 10^9/\text{L}$ or 0–1% of peripheral blood leukocytes. The basophil functions as a mediator of inflammatory responses. The cell has receptors for IgE.

Basophilia - increased concentration of circulating basophils.

Basophilic normoblast - nucleated precursor of the erythrocyte that is derived from a pronormoblast. The cell is 10–16 μm in diameter. The nuclear chromatin is coarser than the pronormoblast, and nucleoli are usually absent. Cytoplasm is more abundant, and it stains deeply basophilic. The cell matures to a polychromatophilic normoblast. Also called *prorubricyte*.

Basophilic stippling - precipitating ribonucleoproteins and mitochondrial remnants that compose erythrocyte inclusions. Observed

on Romanowsky-stained blood smears as diffuse or punctate bluish-black granules in toxic states such as drug (lead) exposure. Diffuse, fine basophilic stippling may occur as an artifact.

B cell ALL - immunologic type of ALL in which the neoplastic cell is a B lymphoid cell. There are subtypes.

B cell receptor (BCR) - specific antigen receptor on the B lymphocyte membrane.

bcl-2 gene - gene on chromosome 18 producing bcl-2 protein. The translocation t(14;18) found in follicular lymphoma leads to bcl-2 overexpression and inhibition of lymphocyte cell death.

Beer Lambert's law - law that forms the mathematical basis for colorimetry. The equation is $A = C \times L \times K$. A is absorbance, C is the concentration of the colored substance, L is the depth of the solution through which the light travels, and K is a constant.

Bence-Jones protein - excessive immunoglobulin light chain in the urine.

Benign - Description of tissue that is nonmalignant. Formed from highly organized, differentiated cells that do not spread or invade surrounding tissue.

Bernard-Soulier disease - rare hereditary platelet disorder characterized by a genetic mutation in the gene coding for platelet glycoprotein Ib resulting in platelets' inability to adhere to collagen.

BFU-E - burst forming unit-erythroid; a committed erythroid progenitor cell. It gives rise to the unipotential CFU-E stem cell. It is relatively insensitive to EPO except in high concentrations. GM-CSF stimulates it to enter the cell cycle.

Bilineage leukemia - leukemia that has two separate populations of leukemic cells, one of which phenotypes as lymphoid and the other as myeloid.

Bilirubin - breakdown product of the heme portion of the hemoglobin molecule. Initial steps in the degradation of hemoglobin result in a lipid-soluble form (unconjugated or indirect bilirubin) that travels in the blood stream to the liver, where it is converted into a water-soluble form (conjugated or direct bilirubin) that can be excreted into the bile.

Bioavailability - degree and rate at which a free drug is available to produce its effect.

Biphasic antibody - antibody that binds to erythrocytes at room temperature or below and causes hemolysis when the blood warms to 37°C.

Biphenotypic leukemia - acute leukemia that has myeloid and lymphoid markers on the same population of neoplastic cells.

Birefringent - description of a substance that can change the direction of light rays that are directed at the substance; can be used to identify crystals.

2,3-bisphosphoglycerate (2,3-BPG) - product of the glycolytic pathway that affects the oxygen affinity of hemoglobin. It serves in the biochemical feedback system that regulates the amount of oxygen released to the tissues. As the concentration of 2,3-BPG increases, hemoglobin's affinity for oxygen decreases and more oxygen is released to the tissue. Also referred to as *2,3-diphosphoglycerate (2,3-DPG)*.

Bite cells - erythrocytes with a portion of the cell missing; seen in G6PD deficiency and drug-induced oxidant hemolysis.

Bleeding time and PFA 100 - screening test that measures platelet function.

Blinded preanalyzed samples - previously analyzed samples that are integrated randomly into a specimen run and possess no identifying feature (e.g., number or designation) to indicate that they are different from current patient specimens. These samples used as a part of a quality control program can be identified only by the individual who selected and relabeled them.

Blister cell - cell with a clear area next to the membrane on one side of the cell. It is thought to be formed when the phagocyte removes a Heinz body in the cell and is seen in G6PD deficiency.

Blood coagulation - formation of a blood clot, usually considered a normal process.

Bohr effect - effect of pH on hemoglobin-oxygen affinity. This is one of the most important buffer systems in the body. As the H⁺ concentration in tissues increases, the affinity of hemoglobin for oxygen is decreased, permitting unloading of oxygen.

Bone marrow aspirate - fluid withdrawn from the bone marrow by aspiration using a special needle (e.g., Jamshidi needle) and syringe. It represents the specialized soft tissue that fills the medullary cavities between the bone trabeculae. Examination of the bone marrow aspirate is useful in evaluating hematopoietic cellular morphology, distribution, and development; observing for presence of abnormal cells; and estimating cellularity.

Bone marrow trephine biopsy - removal of a small piece of the bone marrow core that contains marrow, fat, and trabecula. Examination of the trephine biopsy is useful in observing the bone marrow architecture and cellularity and allows interpreting the spatial relationships of bone, fat, and marrow cellularity.

Bordetella pertussis - gram-negative aerobic coccobacilli that is the cause of whooping cough. The hematologic picture in whooping cough is leukocytosis with lymphocytosis. The lymphocytes are small cells with folded nuclei.

Buffy coat - layer of white blood cells and platelets that lies between the plasma and erythrocytes in centrifuged blood sample.

Burkitt cell - lymphoblast that is found in Burkitt's lymphoma.

Butt cell - circulating neoplastic lymphocyte with a deep indentation (cleft) of the nuclear membrane. Butt cells may be seen when follicular lymphoma involves the peripheral blood.

Cabot ring - reddish-violet erythrocyte inclusion resembling the figure 8 on Romanowsky-stained blood smears that can be found in some cases of severe anemia.

Capitated payment - reimbursement method for health care by third-party payers in which the insurer contracts with certain health care providers who agree to provide services for a defined population on a per-member fee schedule. The insurer determines who the providers will be.

Carboxyhemoglobin - compound formed when hemoglobin is exposed to carbon monoxide; it is incapable of oxygen transport.

Carboxylation - addition of a carboxyl group to a coagulation factor (II, VII, IX, X, Proteins C, S, Z). This occurs in the liver. The factor is not functional until it is carboxylated. Vitamin K is required for this reaction.

Cardiac tamponade - critical clinical condition in which the pericardial sac fills with fluid and restricts the heartbeat and venous return to the heart.

Caspase - cysteine protease responsible for cell alterations in apoptosis.

Catalytic domain - molecular area of a molecule that is common to all serine proteases involved in blood clotting. Cleavage of a peptide bond occurs here and converts the proenzyme to its active form.

CD designation - cluster of differentiation; refers to a group of monoclonal antibodies recognizing the same protein marker antigen on a cell. The antibodies are used to classify cell types and stages of maturation.

Cell cycle - biochemical and morphological stages a cell passes through leading up to cell division; includes G1, S, G2, and M phases.

Cell cycle checkpoint - point in the cell cycle at which progress through the cycle can be halted until conditions are suitable for the cell to proceed to the next stage.

Cell-mediated immunity - immune response mediated by T lymphocytes. The event requires interaction between histocompatible T lymphocytes and macrophages with antigen. At least three important T lymphocyte subsets are involved: helper, suppressor, and cytotoxic.

Cellular hemoglobin concentration mean (CHCM) - erythrocyte index that represents the average hemoglobin concentration of the individual cells analyzed. CHCM is derived from the hemoglobin histogram. Interference with the hemoglobin determination due to turbidity or lipemia can be identified by comparing the CHCM to the MCHC.

Central nervous system (CNS) - part of the nervous system that consists of the brain and spinal cord.

Centriole - cytoplasmic organelle that is the point of origin for the contractile protein known as *spindle fiber*.

Centromere - primary constriction that attaches sister chromatids in a chromosome, dividing the chromatids into long and short arms.

Cerebrospinal fluid (CSF) - fluid that is normally produced to protect the brain and spinal cord. Produced by the choroid plexus cells and absorbed by the arachnoid pia, it circulates in the subarachnoid space.

CFU-E - colony-forming unit-erythroid; unipotential stem cell derived from the BFU-E. It has a high concentration of EPO membrane receptors and with EPO stimulation transforms into the earliest recognizable erythroid precursor, the pronormoblast.

CH50 - functional hemolytic titration assay to measure lysis, the endpoint of complement activation. It measures the amount of patient serum required to lyse 50% of a standardized concentration of antibody-sensitized SRBC. Because all complement proteins are required for lysis to occur, any single complement factor deficiency causes a negative reaction (no lysis).

Charcot-Leyden crystals - crystals formed from eosinophil granules; found in tissues with large numbers of eosinophils.

Cheidak-Higashi anomaly - multisystem disorder inherited in an autosomal recessive fashion and characterized by recurrent infections, hepatosplenomegaly, partial albinism, and CNS abnormalities; neutrophil chemotaxis and killing of organisms is impaired. There are giant cytoplasmic granular inclusions in leukocytes and platelets.

Chemotaxins - chemical messengers that cause migration of cells in one direction. Also called *chemokines*.

Chimerism - state of being of cells from two different zygotes expressed in one individual.

Chloride shift - phenomenon in which a plasma Cl⁻ diffuses into the erythrocyte when a free bicarbonate iron diffuses out of the erythrocyte into the plasma.

Cholecystitis - inflammation of the gallbladder.

Cholelithiasis - formation of calculi or bilestones in the gallbladder or bile duct.

Chromatid - structure of DNA during G₀ and G₁ of the cell cycle. After S-phase, DNA has replicated, and the chromosome consists of two parallel, identical chromatids held together at the centromere.

Chromogenic assay - spectrophotometric measurement of an enzyme's activity based on the release of a colored pigment following enzymatic cleavage of the pigment-producing substrate (chromogen).

Chromosome - nuclear structure seen during mitosis and meiosis consisting of supercoiled DNA with histone and nonhistone proteins. It consists of two identical (sister) chromatids attached at the centromere.

Chronic basophilic leukemia - rare myeloproliferative disease (MPD), also referred to as *atypical MPD*. There is an extreme increase in basophils in the peripheral blood. Cell of origin is a bipotential progenitor cell capable of differentiation into either basophil or eosinophil lineages or differentiation into basophil or mast cell lineages

Chronic eosinophilic leukemia - clonal eosinophilia with an HES phenotype. It is Ph chromosome and has a persistent eosinophilia of $>1.5 \times 10^9/L$. There is no evidence of clonality or $>2\%$ blasts in the peripheral blood.

Chronic idiopathic thrombocytopenic purpura (ITP) - immune form of thrombocytopenia that occurs most often in young adults and lasts longer than 6 months.

Chronic lymphocytic leukemia (CLL) - lymphoproliferative disorder characterized by a neoplastic growth of lymphoid cells in the bone marrow and an extreme elevation of these cells in the peripheral blood. It is characterized by leukocytosis, $<20\%$ blasts, and a predominance of mature lymphoid cells.

Chronic idiopathic myelofibrosis (CIMF) - myeloproliferative disorder characterized by excessive proliferation of all cell lines as well as progressive bone marrow fibrosis and blood cell production at sites other than the bone marrow, such as the liver and spleen. Also called *agnogenic myeloid metaplasia, myelofibrosis with myeloid metaplasia, and primary myelofibrosis*.

Chronic myelogenous leukemia (CML) - myeloproliferative disorder characterized by a neoplastic growth of primarily myeloid cells in the bone marrow and an extreme elevation of these cells in the peripheral blood. There are two phases to the disease: chronic and blast crisis. In the chronic phase, there are less than 20% blasts in the bone marrow or peripheral blood, whereas in the blast crisis phase, there are more than 20% blasts. Individuals with this disease have the BCR/ABL translocation, which codes for a unique P210 protein. Also referred to as *chronic granulocytic leukemia (CGL)*.

Chronic myelomonocytic leukemia (CMML) - subgroup of the myelodysplastic syndromes. There is anemia and a variable total leukocyte count. An absolute monocytosis ($>1 \times 10^9/L$) is present;

immature erythrocytes and granulocytes may also be present. There are less than 5% blasts in the peripheral blood. The bone marrow is hypercellular with proliferation of abnormal myelocytes, promonocytes, and monoblasts, and there are $<20\%$ blasts.

Chronic neutrophilic leukemia - myeloproliferative disorder (MPD) characterized by a sustained increase in neutrophils in the peripheral blood with a slight shift to the left. The Ph chromosome and BCR/ABL translocation are absent.

Chronic nonspherocytic hemolytic anemia - group of chronic anemias characterized by premature erythrocyte destruction. Spherocytes are not readily found when differentiating these anemias from hereditary spherocytosis.

Chylous - body effusion that has a milky, opaque appearance due to the presence of lymph fluid and chylomicrons.

Circulating inhibitor (anticoagulant) - acquired pathologic protein, primarily immunoglobulins (IgG or IgM) with antibody specificity toward a factor involved in fibrin formation. Circulating inhibitors interfere with the activity of the factor. The inhibitors are associated with a number of conditions, such as hemophilia, autoimmune diseases, malignancies, certain drugs, and viral infections.

Circulating leukocyte pool - population of neutrophils actively circulating within the peripheral blood stream.

Clinical Laboratory Improvement Amendments (CLIA) - regulations that mandate standards in clinical laboratory operations and testing signed into federal law in 1988.

Clonality - presence of identical cells derived from a single progenitor. It can be detected by the identification of only one of the immunoglobulin light chains (kappa or lambda) on B cells or the presence of a population of cells with a common phenotype.

Clonogenic - giving rise to a clone of cells.

Clot - extravascular coagulation whether occurring in vitro or in blood shed into the tissues or body cavities.

Clot retraction - cohesion of a fibrin clot that requires adequate, functionally normal platelets. Retraction of the clot occurs over a period of time and results in the expression of serum and a firm mass of cells and fibrin.

Cluster analysis - analysis in which floating thresholds cluster specific cell populations together based on size and staining or absorption characteristics. With cluster analysis, an instrument is able to accommodate for shifts in abnormal cell populations from one sample to another sample.

CLSI - organization whose mission is "to develop best practices in clinical and laboratory testing and promote their use throughout the world using a consensus-driven process that balances the viewpoints of industry, government, and the healthcare professions." (http://www.clsi.org/Content/NavigationMenu/AboutCLSI/Vision-MissionandValues/Vision_Mission_Value.htm)

Coagulation factors - soluble inert plasma proteins that interact to form fibrin after an injury.

Cobalamin - cobalt-containing complex that is common to all subgroups of the vitamin B₁₂ group.

Codocytes - See Target cell.

Codon - sequence of three nucleotides that encodes a particular amino acid.

Coefficient of determination (r^2) - statistic that represents the square of the correlation coefficient. It is a measure of the strength of the relationship between two data sets.

Coefficient of variation - relative standard deviation or standard deviation expressed as a percentage of the mean for a set of data.

Cofactor - a substance of coagulation factors V and VII that function as cofactors. It is required for the conversion of specific zymogens to the active enzyme form.

Coincidence - in an electronic cell counter, a phenomenon of two or more cells crossing the sensing zone at the same time and evaluated as only one cell.

Cold agglutinin disease - condition associated with the presence of cold-reacting autoantibodies (IgM) directed against erythrocyte surface antigens. This causes clumping of the red cells at room or lower temperatures.

Colony-forming unit - visible aggregation (seen in vitro) of cells that developed from a single stem cell.

Colony-stimulating factor - cytokine that stimulates the growth of immature leukocytes in the bone marrow.

Column chromatography - laboratory separation method based on the differential distribution of a liquid or gaseous sample (mobile phase) that flows through a column of specific substance (stationary phase). Depending on the chemical characteristics of the stationary phase, the substance of interest may bind to the stationary phase and remain in the column or directly pass through the column and remain in the mobile phase. If the substance remains in the column, a second mobile phase (elution buffer) is used to release the substance from the stationary phase and allow it to pass through the column.

Committed/progenitor cells - parent or ancestor cells that differentiate into one cell line.

Common coagulation pathway - one of the three interacting pathways in the coagulation cascade. The common pathway includes three rate-limiting steps: (1) activation of factor X by the intrinsic and extrinsic pathways, (2) conversion of prothrombin to thrombin by activated factor X, and (3) cleavage of fibrinogen to fibrin.

Comparative genomic hybridization (CGH) - assay that can be used for the analysis of changes in chromosome copy number (copy number variants); also designed to analyze critical regions of the DNA for well-defined genetic abnormalities.

Compensated hemolytic disease - disorder in which the erythrocyte life span is decreased but the bone marrow is able to increase erythropoiesis enough to compensate for the decreased erythrocyte life span; anemia does not develop.

Compensation - process of adjusting the settings on the flow cytometer or performing a mathematical correction for overlap of light emitted by several fluorochromes. This is done either before or after the data are collected.

Competency assessment - mechanism of assessing the requisite ability of testing personnel to perform a given laboratory procedure. This includes recognition of specimen collection errors, interpretation of test results to detect possible instrument or specimen problems, interpretation of quality control results, troubleshooting of instrument or specimen problems, and proper reporting of results.

Complement - any of the 11 serum proteins that causes lysis of the cell membrane when sequentially activated.

Complementary DNA - synthetic DNA transcribed from an RNA template by the enzyme reverse transcriptase. Also known as *cDNA*.

Complete blood count (CBC) - hematology screening test that includes the white blood cell (WBC) count, red blood cell (RBC) count, hemoglobin, hematocrit, and, often, platelet count. It may also include red cell indices.

Compression syndrome - altered physiological function of an organ or tissue due to impingement by an abnormal mass.

Compound heterozygote - individual possessing two different abnormal alleles of a gene.

Conditioning regimen - high-dose chemotherapy and/or irradiation given to the patient before stem cell transplantation.

Congenital - present at birth.

Congenital aberration - chromosome aberration (either numerical or structural) that is present at the time of birth in all cell lines or in several cell lines in the case of mosaicism.

Congenital amegakaryocytic thrombocytopenia (CAMT) - condition present at birth with decreased marrow megakaryocytes and peripheral blood thrombocytopenia, which eventually converts into bone marrow failure and aplastic anemia. Most cases are caused by mutations of the gene for the thrombopoietin receptor (*c-mpl*).

Congenital Heinz body hemolytic anemia - inherited disorder characterized by anemia due to decreased erythrocyte life span. Erythrocyte hemolysis results from the precipitation of hemoglobin in the form of Heinz bodies, which damage the cell membrane and causes cell rigidity.

Congenital thrombocytopenia with radioulnar synostosis (CTRUS) - congenital disorder presenting with decreased marrow megakaryocytes and peripheral blood thrombocytopenia, which eventually converts into bone marrow failure and aplastic anemia. Most cases caused by mutations within the *HOXA11* gene (which codes for a regulatory protein involved in the development of hematopoietic and bone tissue).

Consolidation therapy - second phase of cancer chemotherapy whose function is to damage or kill those malignant cells that were not destroyed during the induction phase.

Constitutional aberrations - genetic aberrations present in every cell in a patient's body.

Consumption coagulopathy - See Disseminated intravascular coagulation

Contact group - group of coagulation factors in the intrinsic pathway involved with the initial activation of the coagulation system. It requires contact with a negatively charged surface for activity. These factors include factors XII, XI, prekallikrein, and high-molecular-weight kininogen.

Continuous flow analysis - automated method of analyzing blood cells that allows measurement of cellular characteristics as the individual cells flow singly through a laser beam.

Contour gating - subclassification of cell populations based on two characteristics such as size (x-axis) and nuclear density (y-axis) and the frequency (z-axis) of that characterized cell type. This information is used to create a three-dimensional plot. A line is drawn along the valley between two peaks to separate two cell populations.

Correlation coefficient (r) - determines the distribution of data about the estimated linear regression line.

Coverglass smear - blood smear prepared by placing a drop of blood in the center of one cover glass, then placing a second cover glass on top of the blood at a 45° angle to the first cover glass. The two cover glasses are pulled apart, creating two cover glass smears.

CRM- - cross-reacting material negative; a clotting factor that is defective and can be identified both by abnormal functional and immunologic tests.

CRM+ - cross-reacting material positive; a functionally defective clotting factor that can, however, be identified by immunologic means.

Crossover - reciprocal exchange of genetic material between chromatids that normally occurs in meiosis to increase the diversity of the species.

Cryoprecipitate - preparation of proteins containing fibrinogen, von Willebrand factor, and factor VIII prepared by freezing and thawing plasma and used for replacement therapy in patients with hemophilia A and von Willebrand disease.

Cryopreservation - maintenance of the viability of cells by storing them at very low temperatures.

Cryosupernatant - product that lacks large VWF multimers that are present in fresh frozen plasma yet still contains the VWF cleaving protease missing in thrombotic thrombocytopenic purpura (TTP) patients.

Culling - filtering and destroying senescent/damaged red cells by the spleen.

Cyanosis - bluish color of the skin and mucous membranes that develops as a result of excess deoxygenated hemoglobin in the blood.

Cyclins/Cdks - kinase proteins that regulate the transition between the various phases of the cell cycle.

Cytochemistry - chemical staining procedures used to identify various constituents (enzymes and proteins) within white blood cells. It is useful in differentiating blasts in acute leukemia, especially when morphologic differentiation on Romanowsky-stained smears is impossible.

Cytogenetic remission - absence of recognized cytogenetic abnormalities associated with a given neoplastic disease (previously identified in a patient) after therapy.

Cytokine - protein produced by many cell types that modulates the function of other cell types. The group includes interleukins, colony-stimulating factors, and interferons.

Cytomegalovirus (CMV) - herpes virus that replicates only in human cells. The virus has a widespread distribution and is spread by close contact with an infected person.

Cytoplasm - protoplasm of a cell outside the nucleus.

► D

DcytB - duodenal cytochrome β reductase; ferric reductase that reduces ferric iron to the ferrous state at the enterocyte brush border.

D-dimer - cross-linked fibrin degradation product that is the result of plasmin's proteolytic activity on a fibrin clot. The presence of D-dimers is specific for fibrinolysis.

Decay accelerating factor - regulating complement protein found on cell membranes that accelerates decay (dissociation) of membrane bound complement (C3bBb). An absence of this factor leads to excessive sensitivity of these cells to complement lysis.

Deep vein thrombosis (DVT) - formation of a thrombus, or blood clot, in the deep veins (usually a leg vein).

Delayed bleeding - symptom of severe coagulation factor disorders in which a wound bleeds a second time after initial stoppage of

bleeding. This occurs because the primary hemostatic plug is not adequately stabilized by the formation of fibrin.

Delta check - comparison of current hematology results to the most recently reported previous result for a given patient. This check helps detect certain random errors.

Delta (δ) storage pool disease - autosomal dominant disease characterized by a decrease in dense granules in the platelets.

Demarcation membrane system - cytoplasmic membrane system in the megakaryocyte that separates small areas of the cell's cytoplasm. These areas eventually become the platelets.

Demyelination - destruction, removal, or loss of the lipid substance that forms a myelin sheath around the axons of nerve fibers. It is a characteristic finding in vitamin B₁₂ deficiency.

Dense bodies - platelet storage granules containing nonmetabolic ADP, calcium, and serotonin along with other compounds that are released from activated platelets.

Dense tubular system (DTS) - membrane in the platelet that originates from the smooth endoplasmic reticulum of the megakaryocyte. It is one of the storage sites for calcium ions within platelets. The channels of the DTS do not connect with the surface of the platelet.

Densitometry - laboratory testing method that determines the pattern and concentration of protein fractions separated by electrophoresis. It measures the amount of light absorbed by each dye-bound protein fraction as the fraction passes a slit through which light is transmitted. The amount of light absorbed (optical density) is directly proportional to the protein's concentration.

Deoxyhemoglobin - hemoglobin without oxygen.

Diamond-Blackfan anemia - congenital, progressive erythrocyte hypoplasia that occurs in very young children. There is no leukopenia or thrombocytopenia.

Diapedese - passage of blood cells through the unruptured capillary wall. For leukocytes, this involves active locomotion.

Differentiation - appearance of different properties in cells that were initially equivalent.

2,3-diphosphoglycerate (2,3-DPG) - product of the glycolytic pathway that affects the oxygen affinity of hemoglobin. It serves in the biochemical feedback system that regulates the amount of oxygen released to the tissues. As the concentration of 2,3-DPG increases, hemoglobin's affinity for oxygen decreases and more oxygen is released to the tissue. See *2,3-bisphosphoglycerate (2,3-BPG)*.

Diploid - number of chromosomes in somatic cells that is $2n$. For human cells, $2n = 46$.

Direct antiglobulin test (DAT) - laboratory test used to detect the presence of antibody and/or complement that is attached to the erythrocyte. The test uses antibody directed against human immunoglobulin and/or complement. Also called the antihuman globulin (AHG) test.

Disseminated intravascular coagulation (DIC) - complex condition in which the normal coagulation process is altered (resulting in systemic rather than localized activation) by an underlying condition. Resulting complications may include thrombotic occlusion of vessels, bleeding, and ultimately organ failure. DIC is initiated by multiple triggers, most involving damage to the endothelial lining of vessels.

DMT1 - integral membrane protein that transports ferrous iron across the apical enterocyte plasma membrane.

DNA (deoxyribonucleic acid) - blueprint that cells use to catalog, express, and propagate information. DNA is the fundamental substance of heredity that is carried from one generation to the next. It is a double-stranded molecule composed of complementary nucleotide sequences. The two strands of DNA are held together by hydrogen bonds formed according to the following rules of complementary nucleotide pairing: G bonds with C; A bonds with T; other combinations cannot bond.

DNA index (DI) - DNA content of tumor cells relative to a diploid population of cells. It is calculated as the DNA content of cells in the tumor in the G0/G1 phase of the cell cycle relative to the DNA content of G0/G1 cells in a diploid control.

DNA sequencing - Determining the nucleotide sequence in a segment of DNA by replicating the DNA strands and monitoring the order in which labeled nucleotides are added to the new strands.

Döhle bodies - oval aggregates of rough endoplasmic reticulum that stains light gray blue (with Romanowsky stain) found within the cytoplasm of neutrophils and eosinophils. It is associated with severe bacterial infection, pregnancy, burns, cancer, aplastic anemia, and toxic states.

Donath-Landsteiner antibody - biphasic IgG antibody associated with paroxysmal cold hemoglobinuria. The antibody reacts with erythrocytes in capillaries at temperatures below 15°C and fixes complement to the cell membrane. Upon warming, the terminal complement components on erythrocytes are activated, causing cell hemolysis.

Downey cell - outdated term used to describe morphologic variations of the reactive lymphocyte.

Drug-induced hemolytic anemia - hemolytic anemia precipitated by ingestion of certain drugs. The process may be immune mediated or nonimmune mediated.

Dry tap - description of situation when bone marrow cannot be aspirated. This can be caused by inadequate technique or alterations in the bone marrow architecture such as extensive fibrosis or very increased cellularity.

Dura mater - dense membrane covering the central nervous system; outermost layer of the meninges.

Dutcher bodies - intranuclear membrane-bound inclusion bodies found in plasma cells. The body stains with periodic acid-Schiff (PAS) indicating it contains glycogen or glycoprotein. The appearance is finely distributed chromatin, nucleoli, or intranuclear inclusions.

Dysfibrinogenemia - hereditary condition in which the fibrinogen molecule has a structural alteration.

Dyshematopoiesis - abnormal formation and/or development of blood cells within the bone marrow.

Dyspepsia - symptoms due to abnormalities in the process of digestion.

Dysplasia - abnormal cell development.

Dyspoiesis - abnormal development of blood cells frequently characterized by asynchrony in nuclear to cytoplasmic maturation and/or abnormal granule development.

▶ E

Ecchymosis - bruise (bluish-black discoloration of the skin) that is larger than 3mm in diameter caused by bleeding from arterioles into subcutaneous tissues without disruption of intact skin.

Echinocyte - spiculated erythrocyte with short, equally spaced projections over the entire outer surface of the cell.

Edematous - the swelling of body tissues due to the accumulation of tissue fluid.

Effector lymphocytes - antigen-stimulated lymphocytes that mediate the efferent arm of the immune response.

Efficacy - ability to produce the desired effect (e.g., anticoagulation).

Effusion - abnormal accumulation of fluid.

Egress - act of going out or exiting. The term is used to describe the exit of blood cells from the blood to the tissue.

ELISA (Enzyme linked immunosorbent assay) - immunological examination that employs an enzyme linked to an antibody or antigen as a marker for the detection of a specific protein. When a substrate specific for the enzyme label is added to the test system, the colored product that results is proportional to the concentration of the protein in the test sample.

Elliptocyte - abnormally shaped erythrocyte. The cell is an oval to elongated ellipsoid with a central area of pallor and hemoglobin at both ends. Also known as *ovalocyte*, *pencil cell*, and *cigar cell*.

Embolism - blockage of an artery by embolus, usually by a portion of blood clot but can be other foreign matter, resulting in obstruction of blood flow to the tissues.

Embolus - piece of blood clot or other foreign matter that circulates in the blood stream and usually becomes lodged in a small vessel obstructing blood flow.

Endomitosis - rounds of nuclear DNA synthesis without nuclear or cytoplasmic division.

Endoplasmic reticulum (ER) - cytoplasmic organelle in eukaryotic cells that consists of a network of interconnected tubes and flattened membranous sacs. If the ER has ribosomes attached, it is known as *granular* or *rough endoplasmic reticulum (RER)*, and if ribosomes are not attached, it is known as *smooth endoplasmic reticulum (SER)*.

Endosteum - membrane that lines the bone medullary cavity that contains the bone marrow.

Endothelial cells - flat cells that line the cavities of the blood and lymphatic vessels, heart, and other related body cavities.

Endothelial cell protein C receptor (EPCR) - receiver on the membrane of endothelial cells of larger vessels that binds and immobilizes protein C, augmenting the activation of protein C by the thrombin:thrombomodulin complex.

Engraftment - homing of infused stem cells into the bone marrow microenvironment resulting in hematopoietic recovery.

Enzyme - protein that catalyzes a specific biochemical reaction but is not itself altered in the process.

Eosinophil - mature granulocyte cell characterized by the presence of large acidophilic granules. These granules are pink to orange pink

with Romanowsky stains. The cell is 12–17 μm in diameter, and the nucleus has 2–3 lobes. Granules contain acid phosphatase, glycuronidase cathepsins, ribonuclease, arylsulfatase, peroxidase, phospholipids, and basic proteins. Eosinophils have a concentration of less than $0.45 \times 10^9/\text{L}$ in the peripheral blood. The cell membrane has receptors for IgE and histamine.

Eosinophilia - increase in the concentration of eosinophils in the peripheral blood ($>0.5 \times 10^9/\text{L}$). It is associated with parasitic infection, allergic conditions, hypersensitivity reactions, cancer, and chronic inflammatory states.

Epigenetics - heritable changes in gene expression not due to changes in DNA sequence.

Epistaxis - hemorrhage from the nose.

Epitope - structural portion of an antigen that reacts with a specific antibody. Also called *antigenic determinant*.

Estein-Barr virus (EBV) - agent that attaches to B lymphocytes by a specific receptor designated CD21 on the B lymphocyte membrane surface.

Error detection - laboratory's multirule quality control procedure to detect a true error in the testing system and reject the control run.

Erythroblastic island - composite of erythroid cells in the bone marrow that surrounds a central macrophage. These groups of cells are usually disrupted when bone marrow smears are made but may be found in erythroid hyperplasia. The central macrophage is thought to transfer iron to the developing cells. The least mature cells are closest to the center of the island and the more mature cells are on the periphery.

Erythroblastosis fetalis - hemolytic anemia occurring in newborns as a result of fetal-maternal blood group incompatibility involving the Rh factor of ABO blood groups. It is caused by an antigen-antibody reaction in the newborn when maternal antibodies traverse the placenta and attach to antigens on the fetal cells.

Erythrocyte - red blood cell (RBC) that has matured to the nonnucleated stage. The cell is about 7 μm in diameter. It contains the respiratory pigment hemoglobin, which readily combines with oxygen to form oxyhemoglobin. The cell develops from the pluripotential stem cell in the bone marrow under the influence of the hematopoietic growth factor erythropoietin and is released to the peripheral blood as a reticulocyte. The average life span is about 120 days, after which the cell is removed by cells in the mononuclear-phagocyte system. The average concentration is about $5 \times 10^{12}/\text{L}$ for males and $4.5 \times 10^{12}/\text{L}$ for females.

Erythrocytosis - abnormal increase in the number of circulating erythrocytes as measured by the erythrocyte count, hemoglobin, or hematocrit.

Erythron - summation of the stages of erythrocytes in the marrow, peripheral blood, and within vascular areas of specific organs such as the spleen.

Erythrophagocytosis - phagocytosis of an erythrocyte by a histiocyte; the erythrocyte can be seen within the cytoplasm of the histiocyte as a pink globule or, if digested, as a clear vacuole on stained bone marrow or peripheral blood smears.

Erythropoiesis - formation and maturation of erythrocytes in the bone marrow. It is under the influence of the hematopoietic growth factor erythropoietin.

Erythropoietin - hormone secreted by the kidney that regulates erythrocyte production by stimulating the stem cells of the bone mar-

row to mature into erythrocytes. Its primary effect is on the committed stem cell CFU-E.

Essential thrombocythemia - myeloproliferative disorder affecting primarily the megakaryocytic element in the bone marrow. There is extreme thrombocytosis in the blood (usually $>1,000 \times 10^9/\text{L}$). Also called *primary thrombocythemia*, *hemorrhagic thrombocythemia*, and *megakaryocytic leukemia*.

Euchromatin - region of the chromosome that contains genetically active DNA, is lighter staining, and replicates early in S phase of the cell cycle. See heterochromatin.

Evan's syndrome - condition characterized by a warm autoimmune hemolytic anemia and concurrent severe thrombocytopenia.

Exchange transfusion - simultaneous withdrawal of blood and infusion with compatible blood.

Exon - protein-coding DNA sequence of a gene.

Extracellular matrix - noncellular components of the hematopoietic microenvironment in the bone marrow.

Extramedullary erythropoiesis - red blood cell production occurring outside the bone marrow.

Extramedullary hematopoiesis - formation and development of blood cells at a site other than the bone marrow.

Extravascular - occurring outside of the blood vessels.

Extrinsic pathway - one of the three interacting pathways in the coagulation cascade. The extrinsic pathway is initiated when tissue factor comes into contact with blood and forms a complex with factor VII. The complex activates factor X. The term *extrinsic* is used because the pathway requires tissue factor, a factor extrinsic to blood.

Extrinsic Xase - complex of tissue factor and factor VIIa that forms when a vessel is injured.

Exudate - effusion that is formed by increased vascular permeability and/or decreased lymphatic resorption. This indicates a true pathologic state in the anatomic region, usually either infection or tumor.

▶ F

FAB classification - current internationally accepted scheme for the classification of the acute leukemias. Cell identification is based on cell identification by a combination of bright-light microscopy and cytochemical testing. (FAB = French-American-British)

Factor V_{Leiden} - mutant form of F-V in which Arg 506 is replaced with Gln. This makes the molecule resistant to inactivation by activated protein C.

Factor VIII:C assay - method that determines the amount of F-VIII.

Factor VIII concentrate - lyophilized preparation of concentrated F-VIII used for replacement therapy of F-VIII in patients with hemophilia A.

Factor VIII inhibitor - IgG immunoglobulin with antibody specificity to F-VIII. The inhibitor inactivates the factor. The antibodies are time and temperature dependent. F-VIII inhibitors are associated with hemophilia.

Factor VIII/vWF complex - plasma form of VWF associated with F-VIII.

Faggot cell - cell in which there is a large collection of Auer rods and/or phi bodies.

False rejection - rejection of a control run that is not truly out of control. The result falling outside the control limits or violating a Westgard rule is due to the inherent imprecision of the test method.

Fanconi anemia (FA) - autosomal recessive disorder characterized by chromosomal instability. Patients have a complex assortment of congenital anomalies in addition to a progressive bone marrow hypoplasia.

Favism - sensitivity to a species of bean, *Vicia faba*. The condition is commonly found in Sicily and Sardinia in individuals who have inherited glucose-6-phosphate dehydrogenase deficiency. It is characterized by fever, acute hemolytic anemia, vomiting, and diarrhea after ingestion of the bean or inhalation of the plant pollen.

Fee for service - payment method for health care in which consumers choose their own health care providers and the provider determines the fees for the services. The fees may be paid by the patient or a third-party payer.

Ferritin - iron-phosphorus-protein compound formed when iron complexes with the protein apoferritin. It is a storage form of iron found primarily in the bone marrow, spleen, and liver. Small amounts can be found in the peripheral blood proportional to that found in the bone marrow.

Ferroportin - basolateral transporter protein of ferrous iron across the basolateral membrane (also known as *IREG1*). It is the only known cellular exporter of iron.

Fibrin degradation products (FDP) - breakdown products of fibrin or fibrinogen that are produced when plasmin's proteolytic action cleaves these molecules. The four main products are fragments X, Y, D, and E. The presence of fibrin degradation products indicates either fibrinolysis or fibrinogenolysis.

Fibrin monomer - structure resulting when thrombin cleaves the A and B fibrinopeptides from the α and β chains of fibrinogen.

Fibrinogen group - group of coagulation factors that are activated by thrombin and are consumed during the formation of fibrin and therefore absent from serum. It includes factors I, V, VIII, and XIII. Also called *consumable group*.

Fibrinolysis - breakdown of fibrin.

Fibrin polymer - complex of covalently bonded fibrin monomers. The bonds between glutamine and lysine residues are formed between terminal domains of γ chains and polar appendages of α chains of neighboring residues.

Fibronectin - extracellular-matrix glycoprotein capable of binding heparin.

Fibrosis - abnormal formation of fibrous tissue.

Flame cell - plasma cell with reddish-purple cytoplasm. The red tinge is caused by the presence of a glycoprotein and the purple by ribosomes.

Flow chamber - specimen handling area of a flow cytometer where cells are forced into single file and directed in front of the laser beam.

Fluorescence in situ hybridization (FISH) - technique in which whole chromosomes (metaphase or interphase) are hybridized to a complementary probe that is labeled with a fluorochrome and visualized by microscopy.

Fluorochrome - molecule excited by light of one wavelength and emits light of a different wavelength.

Forward light scatter - laser light scattered in a forward direction in a flow cytometer. Forward light scatter is related to particle size (e.g., large cells produce more forward scatter).

Free erythrocyte protoporphyrin (FEP) - protoporphyrin within the erythrocyte that is not complexed with iron. The concentration of FEP increases in iron-deficient states. It is now known that in the absence of iron, erythrocyte protoporphyrin combines with zinc to form zinc protoporphyrin (ZPP).

Fresh frozen plasma (FFP) - colorless fluid portion of blood that is frozen at -18°C or colder within 6 hours of collection. It is formed by removal of all cellular components.

F-test - statistical tool used to compare features of two or more sets of data.

Functional hyposplenism - reduced splenic function due not to the loss of splenic tissue but to the accumulation of cells sequestered in the spleen.

Gammopathy - abnormal condition in which there is an increase in serum immunoglobulins.

Gating - in flow cytometry, isolating cells with the same light scattering or fluorescence properties by placing a gate around them electronically.

Gene - functional segment of DNA that serves as a template for RNA transcription and protein translation. Regulatory sequences control gene expression so that only a small fraction of the estimated 100,000 genes is ever transcribed by a given cell.

Gene cluster - group of closely linked genes that can be affected as a group.

Gene promoter - DNA sequence that RNA polymerase binds to in order to begin transcription of a gene.

Gene rearrangement - process in which segments of DNA are cut and spliced to produce new DNA sequences. During normal lymphocyte development, rearrangement of the immunoglobulin genes and the T cell receptor genes results in new gene sequences that encode the antibody and surface antigen receptor proteins necessary for immune function.

Gene therapy - introduction of a normally functioning gene into the appropriate target cell of an affected individual.

Genome - total aggregate of inherited genetic material. In humans, the genome consists of 3 billion base pairs of DNA divided among 46 chromosomes including 22 pairs of autosomes numbered 1–22 and the two sex chromosomes.

Genomics - study of all nucleotide sequences, including structural genes, regulatory sequences, and noncoding DNA segments, in the chromosomes of an organism.

Genotype - genetic constitution of an individual, often referring to a particular gene locus.

Germinal center - lightly staining center of a lymphoid follicle where B cell activation occurs.

Germline - cell lineage that consists of germ cells.

Glanzmann's thrombasthenia - rare hereditary platelet disorder characterized by a genetic mutation in one of the genes coding for

the glycoproteins IIb or IIIa and resulting in the inability of platelets to aggregate.

Global testing - specialized global instrumentation that provides analysis on the entire hemostatic process including coagulation, anticoagulant effects, fibrin formation and stabilization, clot retraction, and fibrinolysis on a whole blood sample.

Globin - protein portion of the hemoglobin molecule.

Glossitis - inflammation of the tongue.

Glucose-6-phosphate-dehydrogenase (G6PD) - enzyme within erythrocytes that is important in carbohydrate metabolism. It dehydrogenates glucose-6-phosphate to form 6-phosphogluconate in the hexose monophosphate shunt. This reaction produces NADPH from NADP and provides reducing power to the erythrocyte, protecting the cell from oxidant injury.

Glutathione - tripeptide that takes up and gives off hydrogen and prevents oxidant damage to the hemoglobin molecule. A deficiency of glutathione is associated with hemolytic anemia.

Glycocalin - portion of glycoprotein Ib of the platelet membrane that is external to the platelet surface and contains binding sites for von Willebrand factor and thrombin.

Glycocalyx - amorphous coat of glycoproteins and mucopolysaccharides covering the surface of cells, particularly the platelets and endothelial cells.

Glycolysis - anaerobic conversion of glucose to lactate and pyruvic acid resulting in the production of energy (ATP).

Glycoprotein Ib - glycoprotein of the platelet surface that contains the receptor for von Willebrand factor and is critical for initial adhesion of platelets to collagen after an injury.

Glycoprotein IIb/IIIa complex - complex of membrane proteins on the platelet surface that is functional only after activation by agonists and then becomes a receptor for fibrinogen and von Willebrand factor. It is essential for platelet aggregation.

Glycosylated hemoglobin - hemoglobin that has glucose irreversibly attached to the terminal amino acid of the beta chains. Also called *HbA_{1c}*.

Golgi apparatus - cytoplasmic organelle composed of flattened sacs or cisternae arranged in stacks. In secretory cells, it functions in concentrating and packaging secretory products. It does not stain with Romanowsky stains and appears as a clear area usually adjacent to the nucleus.

Gower hemoglobin - embryonic hemoglobin detectable in the yolk sac for up to 8 weeks gestation. It is composed of two zeta (ζ) chains and two epsilon (ϵ) chains.

Graft-versus-host disease (GVHD) - tissue injury secondary to HLA-mismatch grafts resulting from immunocompetent donor T lymphocytes that recognize HLA antigens on the host cells and initiate a secondary inflammatory response.

Graft versus leukemia - favorable effect seen when immunocompetent donor T cells present in the allograft destroy the recipient's leukemic cells.

Granulocytopenia - decrease in granulocytes below $1.8 \times 10^9/L$.

Granulocytosis - increase in granulocytes above $7.0 \times 10^9/L$. It is usually seen in bacterial infections, inflammation, metabolic intoxication, drug intoxication, and tissue necrosis.

Granulomatous - distinctive pattern of chronic reaction in which the predominant cell type is an activated macrophage with epithelial-like (epithelioid) appearance.

Gray platelet syndrome (alpha storage pool disease) - rare hereditary platelet disorder characterized by the lack of platelet alpha granules.

▶ H

Hairy cell - neoplastic cell of hairy cell leukemia characterized by circumferential, cytoplasmic, hairlike projections.

Ham test - specific laboratory test for paroxysmal nocturnal hemoglobinuria (PNH). When erythrocytes from a patient with PNH are incubated in acidified serum, the cells lyse due to complement activation. Also called *acid-serum lysis test*.

Haploid - number of chromosomes in a gamete that is n ; consists of one of each of the autosomes and one of the sex chromosomes. For human cells, $n = 23$.

Haplotype - one of the two alleles at a genetic locus.

Haptoglobin - serum α_2 -globulin glycoprotein that transports free plasma hemoglobin to the liver.

HDFN - *See* hemolytic disease of the fetus and newborn.

Health Insurance Portability and Accountability Act (HIPAA) - law that mandates health care entities to establish measures that ensure the confidentiality of patient information.

Heinz bodies - inclusions in the erythrocyte composed of denatured or precipitated hemoglobin. It appears as purple-staining body on supravital stained (crystal violet) smears.

HELLP syndrome - obstetric complication characterized by hemolysis (H), elevated liver enzymes (EL), and a low platelet count (LP). The etiology and pathogenesis are not well understood.

Helmet cell - abnormally shaped erythrocyte with one or several notches and projections on either end that look like horns. The shape is caused by trauma to the erythrocyte. Also called *keratocyte* and *horn-shaped cells*.

Hematocrit - packed cell volume of erythrocytes in a given volume of blood following centrifugation of the blood. It is expressed as a percentage of total blood volume or as a liter of erythrocytes per liter of blood (L/L). Also referred to as *packed cell volume (PCV)*.

Hematogones - precursor B lymphocytes present normally in the bone marrow.

Hematologic remission - absence of neoplastic cells in the peripheral blood and bone marrow and the return to normal levels of hematologic parameters.

Hematology - study of formed cellular blood elements.

Hematoma - localized collection of blood under the skin or in other organs caused by a break in the wall of a blood vessel.

Hematopoiesis - production and development of blood cells normally occurring in the bone marrow under the influence of hematopoietic growth factors.

Hematopoietic microenvironment - specialized, localized environment in hematopoietic organs that supports the development of hematopoietic cells.

Hematopoietic progenitor cell - hematopoietic precursor cell developmentally located between stem cells and the morphologically recognizable blood precursor cells; includes multilineage and unilineage cell types.

Hematopoietic stem cell - hematopoietic precursor cell capable of giving rise to all lineages of blood cells.

Heme - nonprotein portion of hemoglobin and myoglobin that contains iron nestled in a hydrophobic pocket of a porphyrin ring (ferroprotoporphyrin). It is responsible for the characteristic color of hemoglobin.

Hemochromatosis - clinical condition resulting from abnormal iron metabolism characterized by accumulation of iron deposits in body tissues.

Hemoconcentration - increased concentration of blood components due to loss of plasma from the blood.

Hemoglobin - intracellular erythrocyte protein that is responsible for the transport of oxygen and carbon dioxide between the lungs and body tissues.

Hemoglobin distribution width - measure of the distribution of hemoglobin within an erythrocyte population. It is derived from the hemoglobin histogram generated by the Bayer/Technicon instruments.

Hemoglobin electrophoresis - method of identifying hemoglobins based on differences in their electrical charges.

Hemoglobinemia - presence of excessive hemoglobin in the plasma.

Hemoglobinopathy - disease that results from an inherited abnormality of the structure or synthesis of the globin portion of the hemoglobin molecule.

Hemoglobinuria - presence of hemoglobin in the urine.

Hemojuvelin (HJV) - glycosylphosphatidylinositol-anchored protein that has been shown to regulate hepcidin expression.

Hemolysis - destruction of erythrocytes resulting in the release of hemoglobin. In hemolytic anemia, this term refers to the premature destruction of erythrocytes.

Hemolysis, elevated liver enzymes and low platelet (HELLP) syndrome - severe form of preeclampsia characterized by hemolysis, elevated liver enzymes, and low platelet count. It may be a cause of microangiopathic hemolytic anemia.

Hemolytic anemia - disorder characterized by a decreased erythrocyte concentration due to premature destruction of the erythrocyte.

Hemolytic disease of the fetus and newborn (HDFN) - alloimmune disease characterized by fetal red blood cell destruction as a result of incompatibility between maternal and fetal blood groups.

Hemolytic transfusion reaction - interaction of foreign (nonself) erythrocyte antigens and plasma antibodies due to the transfusion of blood. There are two types of transfusion reactions: immediate (within 24 hours) and delayed (occurring 2 to 14 days after transfusion).

Hemolytic uremic syndrome (HUS) - disorder characterized by a combination of microangiopathic hemolytic anemia, acute renal failure, and thrombocytopenia.

Hemopexin - plasma glycoprotein (β -globulin) that binds the heme molecule in plasma in the absence of haptoglobin.

Hemophilia A - sex-linked (X-linked) hereditary hemorrhagic disorder caused by a genetic mutation of the gene coding for coagulation F-VIII.

Hemophilia B - sex-linked (X-linked) hereditary hemorrhagic disorder caused by a genetic mutation of the gene coding for coagulation F-IX.

Hemorrhage - loss of a large amount of blood either internally or externally.

Hemorrhagic disease of the newborn - severe bleeding disorder in the first week of life caused by deficiencies of the vitamin K-dependent clotting factors due to vitamin K deficiency.

Hemosiderin - water insoluble, heterogeneous iron-protein complex found primarily in the cytoplasm of cells (normoblasts and histiocytes in the bone marrow, liver, and spleen); the major long-term storage form of iron. It is readily visible microscopically in unstained tissue specimens as irregular aggregates of golden yellow to brown granules. It may be visualized with Prussian-blue stain as blue granules. The granules are normally distributed randomly or diffuse.

Hemosiderinuria - presence of iron (hemosiderin) in the urine as a result of intravascular hemolysis and disintegration of renal tubular cells.

Hemostasis - localized, controlled process that results in arrest of bleeding after an injury.

Heparin - polysaccharide that inhibits coagulation of blood by preventing thrombin from cleaving fibrinogen to form fibrin. It is commercially available in the form of a sodium salt for therapeutic use as an anticoagulant.

Heparin associated thrombocytopenia (HAT) - thrombocytopenia associated with heparin therapy in some patients due to a nonimmune-mediated direct platelet activation effect.

Heparin-induced thrombocytopenia (HIT) - thrombocytopenia associated with heparin therapy in some patients due to an immune-mediated destruction of platelets due to heparin-dependent platelet-activating IgG antibodies produced against the platelet factor 4 (PF4)-heparin complex.

Hepcidin - master iron-regulating protein that regulates iron recycling/balance via interaction with ferroportin 1. It is a negative regulator of intestinal iron absorption.

Hephaestin - facilitates export of iron and oxidizes Fe^{++} iron to Fe^{+++} for binding to apotransferrin.

Hereditary elliptocytosis - autosomal-dominant condition characterized by the presence of increased numbers of elongated and oval erythrocytes. The abnormal shape is due to a horizontal interaction defect with abnormal spectrin, deficiency, or defect in band 4.1 or deficiency of glycophorin C and abnormal band 3.

Hereditary erythroblastic multinuclearity with positive acidified serum test (HEMPAS) - type II congenital dyserythropoietic anemia (CDA). CDA is characterized by both abnormal and ineffective erythropoiesis. Type II is distinguished by a positive acidified serum test but a negative sucrose hemolysis test.

Hereditary pyropoikilocytosis (HPP) - rare but severe hemolytic anemia inherited as an autosomal recessive disorder. It is characterized by marked erythrocyte fragmentation. The defect is most likely a spectrin abnormality in the erythrocyte cytoskeleton.

Hereditary spherocytosis - chronic hemolytic anemia caused by an inherited erythrocyte membrane disorder. The vertical interaction

defect is most commonly due to a combined spectrin and ankyrin deficiency. The defect causes membrane instability and progressive membrane loss. Secondary to membrane loss, the cells become spherocytes and are prematurely destroyed in the spleen. The condition is usually inherited as an autosomal dominant trait.

Hereditary stomatocytosis - rare hemolytic anemia inherited in an autosomal dominant fashion. The erythrocyte membrane is abnormally permeable to sodium and potassium. The cell becomes overhydrated, resulting in the appearance of stomatocytes. The specific membrane abnormality has not been identified.

Hereditary xerocytosis - hereditary disorder in which the erythrocyte is abnormally permeable to sodium and potassium with an increased potassium efflux. The erythrocyte becomes dehydrated and appears as either target or spiculated cells. The cells are rigid and become trapped in the spleen.

Heterochromatin - region of the chromosome that contains genetically inactive DNA, is dark staining, and replicates late in S phase of the cell cycle.

Heterologous - refers to morphologically nonidentical chromosomes that have different gene loci.

Heterophile antibodies - antibodies that can react against a heterologous antigen that did not stimulate the antibody's production. In infectious mononucleosis, heterophile antibodies are produced in response to infection with Epstein-Barr virus and react with sheep, horse, and beef erythrocytes.

Heterozygous - different genes at a gene locus.

Hexose-monophosphate shunt - metabolic pathway that converts glucose-6-phosphate to pentose phosphate. This pathway couples oxidative metabolism with the reduction of nicotinamide adenine dinucleotide-phosphate (NADPH) and glutathione. This provides the cell with reducing power and prevents injury by oxidants.

HFE - transmembrane protein that associates with beta2-microglobulin. It binds to the transferrin receptor (TfR) on cells and regulates the interaction of the receptor with transferrin. When bound to TfR, it reduces the affinity of the receptor for iron-bound transferrin (Tf-Fe) by 5- to 10-fold. Mutations are associated with hereditary hemochromatosis.

Histogram - graphical representation of the number of cells within a defined parameter such as size.

HIV-I (human immunodeficiency virus type-I) - virus that causes acquired immunodeficiency syndrome (AIDS).

Hodgkin lymphoma (disease) - malignancy that most often arises in lymph nodes and is characterized by the presence of Reed-Sternberg cells and variants with a background of varying numbers of benign lymphocytes, plasma cells, histiocytes, and eosinophils. The origin of the malignant cell is still controversial.

Homologous - having two morphologically identical chromosomes that have identical gene loci but may have different gene alleles because one member of a homologous pair is of maternal origin and the other is of paternal origin.

Homozygous - identical genes at a gene locus.

Horizontal interactions - side-by-side interactions involving the proteins of the erythrocyte membrane.

Howell-Jolly bodies - erythrocyte inclusions composed of nuclear remnants (DNA). On Romanowsky-stained blood smears, they appear as a dark purple spherical granule usually near the periphery of

the cell. They are commonly associated with megaloblastic anemia and splenectomy.

Humoral immunity - immunity imparted as a result of B lymphocyte activation. The B lymphocyte differentiates to a plasma cell that produces antibodies specific to the antigen that stimulated the response.

Hybridization - process in which one nucleotide strand binds to another strand by formation of hydrogen bonds between complementary nucleotides.

Hydrodynamic focusing - phenomenon that allows cells/particles to flow in a single column due to differences in the pressures of two columns of fluid in a flow chamber of a flow cytometer. The particles are contained in an inner column of sample fluid that is surrounded by a column of stream sheath fluid. The gradient between the sample and sheath fluid keeps the fluids separate (laminar flow) and is used to control the diameter of the column of sample fluid. The central column of sample fluid is narrowed to isolate single cells that pass through a laser beam like a string of beads.

Hydrops fetalis - genetically determined hemolytic disease (thalassemia) resulting in production of an abnormal hemoglobin (hemoglobin Bart's, γ_4) that is unable to carry oxygen. No alpha(α) globin chains are synthesized.

Hypercoagulable state - condition associated with an imbalance between clot-promoting and clot-inhibiting factors. This leads to an increased risk of developing thrombosis.

Hyperdiploid - number of chromosomes per cell that is more than 2n. For human cells, this would be >46 .

Hyper eosinophilic syndrome - persistent blood eosinophilia over $1.5 \times 10^9/L$ with tissue infiltration, absence of clonal genetic aberrations, and no apparent cause of the increase in eosinophils.

Hyperhomocysteinemia - elevated levels of homocysteine in the blood as a result of impaired homocysteine metabolism. It can be due to acquired or congenital causes. It is associated with premature atherosclerosis and arterial thrombosis.

Hyperplasia - increase in the number of cells per unit volume of tissue. This can be brought about by an increase in the number of cells replicating, an increase in the rate of replication, or prolonged survival of cells. The cells usually maintain normal size, shape, and function. The stimulus for the proliferation may be acute injury, chronic irritation, or prolonged, increased hormonal stimulation. In hematology, a hyperplastic bone marrow is one in which the proportion of hematopoietic cells to fat cells is increased.

Hypersplenism - disorder characterized by enlargement of the spleen and pancytopenia in the presence of a hyperactive bone marrow.

Hypocellularity - decreased cellularity of hematopoietic precursors in the bone marrow.

Hypochromic - lack of color; used to describe erythrocytes with an enlarged area of pallor due to a decrease in the cell's hemoglobin content. The mean corpuscular hemoglobin concentration (MCHC) and mean corpuscular hemoglobin (MCH) are decreased.

Hypodiploid - number of chromosomes per cell that is less than 2n. For human cells, this would be <46 .

Hypofibrinogenemia - condition in which there is an abnormally low fibrinogen level in the peripheral blood. It may be caused by a mutation in the gene controlling the production of fibrinogen or an acquired condition in which fibrinogen is pathologically converted to fibrin.

Hypogammaglobulinemia - condition associated with a decrease in resistance to infection as a result of decreased γ -globulins (immunoglobulins) in the blood.

Hypoplasia - condition of underdeveloped tissue or organ usually caused by a decrease in the number of cells. A hypoplastic bone marrow is one in which the proportion of hematopoietic cells to fat cells is decreased.

Hypoproliferative - decreased production of any cell type.

Hypoxia - deficiency of oxygen to the cells.

Idiopathic - pertaining to disorders or diseases in which the pathogenesis is unknown.

Idiopathic (or immune) thrombocytopenic purpura (ITP) - acquired condition in which the platelets are destroyed by immune mechanisms faster than the bone marrow is able to compensate. Platelets are decreased.

Immature reticulocyte fraction (IRF) - index of reticulocyte maturity provided by flow cytometry. The IRF may be helpful in evaluating bone marrow erythropoietic response to anemia, monitoring anemia, and evaluating response to therapy.

Immune hemolytic anemia - disorder caused by premature, immune-mediated destruction of erythrocytes. Diagnosis is confirmed by the demonstration of immunoglobulin (antibodies) and/or complement on the erythrocytes.

Immune thrombocytopenic purpura (ITP) - autoimmune disorder in which autoreactive antibodies bind to platelets, shortening the platelet life span.

Immune response - body's defense mechanism that includes producing antibodies to foreign antigens.

Immunoblast - T or B lymphocyte that is mitotically active as a result of stimulation by an antigen. The cell is morphologically characterized by a large nucleus with prominent nucleoli, a fine chromatin pattern, and an abundant, deeply basophilic cytoplasm.

Immunocompetent - having the ability to respond to stimulation by an antigen.

Immunoglobulin - molecule produced by B lymphocytes and plasma cells. It reacts with antigen. It consists of two pairs of polypeptide chains: two heavy and two light chains linked together by disulfide bonds. Also called *antibody*.

Immunohistochemical stains - stains applied using immunologic principles and techniques to study cells and tissues. Usually a labeled antibody is used to detect antigens (markers) on a cell.

Immunophenotyping - identifying antigens using detection antibodies.

Immunosuppressed - suppressed ability to produce antibodies to antigens.

Immunotherapy - form of therapy in which different immune cells are manipulated in vivo or in vitro and later infused to alter the immune function of other cells.

Indirect antiglobulin test (IAT) - laboratory test used to detect the presence of serum antibodies against specific erythrocyte antigens.

Induction therapy - initial phase of cancer chemotherapy. Its function is to rapidly drop the tumor burden and induce a remission back to a normal state.

Ineffective erythropoiesis - premature death of erythrocytes in the bone marrow preventing release into circulation.

Infectious lymphocytosis - A condition found in young children. The most striking hematologic finding is a leukocytosis of $40\text{--}50 \times 10^9/\text{L}$ with 60–97% small, normal-appearing lymphocytes. It is thought to be a reactive immune response to a viral infection and is no longer considered a unique disease.

Infectious mononucleosis - self-limiting lymphoproliferative disease caused by infection with Epstein-Barr virus (EBV). The usually increased leukocyte count is related to an absolute lymphocytosis. Various forms of reactive lymphocytes are present. Serologic tests to detect the presence of heterophil antibodies are helpful in differentiating this disease from more serious diseases. Also known as the *kissing disease*.

Innate immune response - body's first response to common classes of invading pathogens. It is rapid but limited. The leukocyte receptors that participate in it are always available and do not require cell activation in order to be expressed. Once a pathogen is recognized, effector cells can attack, engulf, and kill it. Neutrophils, monocytes, and macrophages play a major role in the innate immune system.

In situ hybridization - detection of specific DNA or RNA sequences in tissue sections or cell preparations using a labeled complementary nucleic acid sequence or probe.

Integral proteins - proteins embedded between phospholipids within a cell membrane.

Internal quality control program - system designed to verify the validity of laboratory test results that is followed as part of the daily laboratory operations. Typically, it is monitored using Levey-Jennings plots and Westgard rules.

International normalized ratio (INR) - method of reporting prothrombin time results when monitoring long-term oral anticoagulant therapy. Results are independent of the reagents and methods used.

International Sensitivity Index (ISI) - value provided by the manufacturer of thromboplastin reagents. It indicates the responsiveness of the particular lot of reagent compared to the international reference thromboplastin.

Intrinsic coagulation pathway - one of the three interacting pathways in the coagulation cascade. The intrinsic pathway is initiated by exposure of the contact coagulation factors (F-XII, F-XI, prekallikrein, and high-molecular-weight kininogen) with vessel subendothelial tissue. The intrinsic pathway activates F-X. The term *intrinsic* is used because all intrinsic factors are contained within the blood.

Intrinsic factor - glycoprotein secreted by the parietal cells of the stomach that is necessary for binding and absorption of dietary vitamin B₁₂.

Intrinsic Xase - complex of F-IXa, F-VIIIa, phospholipid, and calcium that assembles on membrane surfaces.

Intron - DNA base sequence interrupting the protein coding sequence of a gene; this sequence is transcribed into RNA but is cut out of the message before it is translated into protein.

IRE - stem-loop-stem structure in either the 5' or 3' noncoding regions of mRNA recognized and bound by iron-binding proteins

(IRE-BP or IRP). The binding affinity of IRP for the IRE is determined by the amount of cellular iron. The IRP binds to the IRE region when iron is scarce and dissociates when iron is plentiful. When bound, the IRP modulates the translation of the mRNA. The translation of the proteins involved in iron metabolism including ferritin, ferroportin, ALA synthase2, transferrin, and DMT1 are regulated by this mechanism.

IRP - protein that binds to a stem-loop structure of ferritin and transferrin receptor mRNA. The stem-loop structure of mRNA is known as the iron-responsive element (IRE). It is also referred to as *IRE-BP* (*iron-responsive element-binding protein*). The binding affinity of IRE-BP for the IRE is determined by the amount of cellular iron. The IRE-BP is involved in the regulation of transferrin receptors and ferritin.

Irreversibly sickled cells (ISC) - rigid cells that have been exposed to repeated sickling events and cannot revert to a normal discoid shape. They are ovoid or boat-shaped and have a high MCHC and low MCV.

Ischemia - deficiency of blood supply to a tissue caused by constriction of the vessel or blockage of the blood flow through the vessel.

Isoelectric focusing - technique of moving charged particles through a support medium with a continuous pH gradient. Individual proteins will move until they reach the pH that is equal to their isoelectric point.

Isopropanol precipitation - technique that identifies the presence of unstable hemoglobins due to their insolubility in isopropanol as compared to normal hemoglobins.

Isovolumetric sphering - method employed by the Bayer/Technicon instruments in which a specific buffered diluent is used to sphere and fix the blood cells without altering their volume.

▶ J

JAK2 gene - Janus kinase 2, codes for a tyrosine kinase closely associated with cytokine receptors. A gain in function mutation that gives the cell a proliferative advantage is common in the myeloproliferative disorders, especially polycythemia vera.

Jaundice - condition characterized by yellowing of the skin, mucous membranes, and the whites of the eye caused by accumulation of bilirubin.

Juvenile myelomonocytic leukemia - clonal hematopoietic neoplasm of childhood characterized by proliferation of the granulocytic and monocytic lineages. There is a peripheral blood monocyto-sis ($>1 \times 10^9/L$), with $<20\%$ blasts (including promonocytes).

▶ K

Karyolysis - destruction of the nucleus.

Karyorrhexis - disintegration of the nucleus resulting in the irregular distribution of chromatin fragments within the cytoplasm.

Karyotype - systematic display of a cell's chromosomes that determines the number of chromosomes present and their morphology.

Kernicterus - toxic buildup of bilirubin in brain tissue; associated with hyperbilirubinemia.

Keratocytes - abnormally shaped erythrocytes with one or several notches and projections on either end that look like horns. Also

called *helmet cells* and *horn-shaped cells*. The shape is caused by trauma to the erythrocyte.

Killer cell - population of cytolytic lymphocytes identified by monoclonal antibodies. Involved in several activities such as resistance to viral infections, regulation of hematopoiesis, and activities against tumor cells.

Knizocytes - abnormally shaped erythrocyte that appears on stained smears as a cell with a dark stick-shaped portion of hemoglobin in the center and a pale area on either end. The cell has more than two concavities.

▶ L

L&H/popcorn cell - See Popcorn cell.

Lacunar cell - neoplastic cell variant found in NS Hodgkin lymphoma characterized by abundant pale-staining cytoplasm. It is also characterized by cytoplasmic clearing and delicate, multilobated nuclei.

Large granular lymphocyte - null cell with a low nuclear-to-cytoplasmic ratio, pale blue cytoplasm, and azurophilic granules. It does not adhere to surfaces or phagocytose.

Latex immunoassay (LIA) test - immuno-turbidimetric assay using microlatex particles coated with specific antibodies. In the presence of the antigen to be tested, the particles agglutinate producing an adsorption of light proportional to the antigen level present in the sample.

Laurell "rocket" technique (EIA-Electroimmunoassay) - agarose plates containing antibody are electrophoresed with an antigen (in PPP) until a "rocket" of precipitated antigen-antibody forms (measured following the staining of the gel). The height of the rocket is proportional to the quantity of antigen present in the PPP.

Lecithin:cholesterol acyl transferase (LCAT) deficiency - rare autosomal disorder that affects metabolism of high-density lipoproteins. It is characterized by a deficiency of an enzyme that catalyzes the formation of cholesterol esters from cholesterol. Its onset is usually during young adulthood.

Leptocyte - abnormally shaped erythrocyte that is thin and flat with hemoglobin at the periphery. It is usually cup shaped.

Leukemia - progressive, malignant disease of the hematopoietic system characterized by unregulated, clonal proliferation of the hematopoietic stem cells. The malignant cells eventually replace normal cells. It is generally classified as chronic or acute, and lymphoid or myelogenous.

Leukemic hiatus - gap in the normal maturation pyramid of cells with many blasts and some mature forms but very few intermediate maturational stages. Eventually, the immature neoplastic cells fill the bone marrow and spill over into the peripheral blood producing leukocytosis (e.g., acute leukemia).

Leukemic stem cell - rare cell with infinite proliferative potential that drives the formation and growth of tumors.

Leukemoid reaction - transient, reactive condition resulting from certain types of infections or tumors characterized by an increase in the total leukocyte count to more than $25 \times 10^9/L$ and a shift to the left in leukocytes (usually granulocytes).

Leukocyte - white blood cell (WBC) of which there are five types: neutrophils, eosinophils, basophils, lymphocytes, and monocytes.

The function of these cells is to defend against infection and tissue damage. The normal reference range for total leukocytes in peripheral blood is $4.5\text{--}11.0 \times 10^9/\text{L}$.

Leukocyte alkaline phosphatase (LAP) - enzyme present within the specific (secondary) granules of granulocytes (from the myelocyte stage onward). It is useful in distinguishing leukemoid reaction/reactive neutrophilia (high LAP) from chronic myelogenous leukemia (low LAP).

Leukocytosis - increase in WBCs in the peripheral blood; WBC count over $11 \times 10^9/\text{L}$.

Leukoerythroblastic reaction - condition characterized by the presence of nucleated erythrocytes and a shift to the left in neutrophils in the peripheral blood; often associated with myelophthisis.

Leukopenia - decrease in leukocytes below $4 \times 10^9/\text{L}$.

Leukopoiesis - production of leukocytes.

Linearity - range of concentration over which the test method can be used without modifying the sample (i.e., diluting the sample).

Linearity check material - commercially available matter with known concentrations of the analytes and no interfering substances or conditions. Linearity check material is used to determine an instrument's or method's linearity.

Linear regression analysis - statistical tool used to determine a single line through a data set that describes the relationship between two methods, X and Y . General equation is $Y = a + bx$, where a denotes the y -intercept; b is the slope; and Y is the predicted mean value of Y for a given x value.

Linkage analysis - process of following the inheritance pattern of a particular gene in a family based on its tendency to be inherited with another locus on the same chromosome.

Locus - specific position on the chromosome.

Low-molecular-weight heparin (LMWH) - heparin molecules of M.W. 2,000–12,000 Daltons.

LRP receptor (LDL receptorlike protein) - receiver on hepatocytes that removes plasmin/antiplasmin, plasminogen activator/plasminogen activator inhibitor, and thrombin/antithrombin complexes from the circulation.

Lupuslike anticoagulant - circulating substance that arises spontaneously in patients with a variety of conditions (originally found in patients with lupus erythematosus) and directed against phospholipid components of the reagents used in laboratory tests for clotting factors. See Antiphospholipid antibody.

Lymphadenopathy - abnormal enlargement of lymph nodes.

Lymphoblast - lymphocytic precursor cell found in the bone marrow. The cell is $10\text{--}20 \mu\text{m}$ in diameter and has a high nuclear/cytoplasmic ratio. The nucleus has a fine (lacy) chromatin pattern with one or two nucleoli. The cytoplasm is agranular and scant. It stains deep blue with Romanowsky stain. The cell contains terminal deoxynucleotidyltransferase (TdT) but no peroxidase, lipid, or esterase.

Lymphocyte - mature leukocyte with variable size depending on the state of cellular activity and amount of cytoplasm. The nucleus is usually round with condensed chromatin and stains deep, dark purple with Romanowsky stains. The cytoplasm stains a light blue. Nucleoli are usually not visible. A few azurophilic granules may be present. These cells interact in a series of events that allow the body to attack and eliminate foreign antigen. They have a peripheral blood

concentration in adults from 1.0 to $4.8 \times 10^9/\text{L}$ (20–40% of leukocytes). The concentration in children less than 10 years old is higher.

Lymphocytic leukemoid reaction - response characterized by an increased lymphocyte count with the presence of reactive or immature appearing lymphocytes. It is associated with whooping cough, chicken pox, infectious mononucleosis, infectious lymphocytosis, and tuberculosis.

Lymphocytopenia - decrease in the concentration of lymphocytes in the peripheral blood ($<1.0 \times 10^9/\text{L}$). Also called *lymphopenia*.

Lymphocytosis - increase in peripheral blood lymphocyte concentration ($>4.8 \times 10^9/\text{L}$ in adults or $>9 \times 10^9/\text{L}$ in children).

Lympho-epithelial lesion - infiltration of epithelium by groups of lymphocytes. Infiltration of mucosal epithelium by neoplastic lymphocytes is characteristic of MALT lymphoma.

Lymphoid follicle - sphere of B cells within lymphatic tissue.

Lymphokines - substances released by sensitized lymphocytes and responsible for activation of macrophages and other lymphocytes.

Lymphoma - malignant proliferation of lymphocytes. Most cases arise in lymph nodes, but it can begin at many extranodal sites. The lymphomas are classified as to B or T cell and low, intermediate, or high grade.

Lymphoma classification - process of dividing (grading) lymphomas into groups, each with a similar clinical course and response to treatment. Current schemes use a combination of morphologic appearance, phenotype, and genotype.

Lyonization - process in which all but one X chromosome in a cell are randomly inactivated.

Lyophilized - serum or plasma sample that has been freeze dried. The sample is reconstituted with a diluent, typically distilled or deionized water.

Lysosomal granules - granules containing lysosomal enzymes.

Lysosome - membrane-bound sacs in the cytoplasm that contain various hydrolytic enzymes.

► M

Macrocyte - abnormally large erythrocyte. The MCV is $>100 \text{ fL}$. Oval macrocytes are characteristically seen in megaloblastic anemia.

Macro-ovalocyte - abnormally large erythrocyte with an oval shape. This cell is characteristically seen in megaloblastic anemia.

Macrophage - large tissue cell ($10\text{--}20 \mu\text{m}$) derived from monocytes. The cell secretes a variety of products that influence the function of other cells. It plays a major role in both nonspecific and specific immune responses.

Maintenance therapy - third and final phase of cancer chemotherapy whose function is to prevent the repair and/or return of the malignant clone, thus allowing the normal immune system to clear away all remaining disease.

Malignant neoplasm - clone of identical, anaplastic (dedifferentiated), proliferating cells. Malignant cells can metastasize.

Marginating pool - population of neutrophils that are attached to or marginated along the vessel walls and not actively circulating. This is about one-half of the total pool of neutrophils in the vessels.

Material safety data sheet (MSDS) - document that provides safety information for clinical laboratory professionals who use hazardous materials; includes pertinent safety information regarding the proper storage and disposal of a chemical, precautions that should be taken in handling the chemical, potential health hazards associated with exposure to it, and whether the chemical is a fire or explosive hazard.

Mastocytosis - heterogeneous group of mast cell diseases characterized by the abnormal proliferation of mast cells in one or more organ systems. It is suggested that mast cell disorders be classified as myeloproliferative disorders. Two major groups of mast cell disorders are cutaneous and systemic.

Maturation - process of attaining complete development of the cell.

Maturation index - mathematical expression that attempts to separate AML-M5 and AML-M1 with and without maturation.

Mean cell hemoglobin (MCH) - indicator of the average weight of hemoglobin in individual erythrocytes reported in picograms. The reference interval for MCH is 28–34 pg. This parameter is calculated from the hemoglobin and erythrocyte count: $MCH (pg) = \text{Hemoglobin (g/dL)} \div \text{Erythrocyte count} (\times 10^{12}/L) \times 10$.

Mean cell hemoglobin concentration (MCHC) - measure of the average concentration of hemoglobin in grams per deciliter of erythrocytes. The reference interval is 32–36 g/dL. The MCHC is useful when evaluating erythrocyte hemoglobin content on a stained smear. This parameter correlates with the extent of chromasia exhibited by the stained cells and is calculated from the hemoglobin and hematocrit. $MCHC (g/dL) = \text{hemoglobin (g/dL)} \div \text{hematocrit (L/L)}$.

Mean cell volume (MCV) - average volume of individual erythrocytes reported in femtoliters. The reference interval for MCV is 80–100 fL. This parameter is useful when evaluating erythrocyte morphology on a stained blood smear. The MCV usually correlates with the diameter of the erythrocytes observed microscopically. The MCV can be calculated from the hematocrit and erythrocyte count: $MCV (fL) = \text{Hematocrit (L/L)} \div \text{Erythrocyte Count} (\times 10^{12}/L) \times 1000$.

Mean platelet volume - mean volume of a platelet population; analogous to the MCV of erythrocytes.

Medical decision level - concentration of an analyte indicating that medical intervention is required for proper patient care.

Medullary hematopoiesis - blood cell production and development in the bone marrow.

Megakaryocyte - large cell found within the bone marrow characterized by the presence of large or multiple nuclei and abundant cytoplasm. It gives rise to the blood platelets.

Megaloblastic - asynchronous maturation of any nucleated cell type characterized by delayed nuclear development in comparison to the cytoplasmic development. The abnormal cells are large and are characteristically found in pernicious anemia and other megaloblastic anemia.

Metacentric - chromosome that has the centromere near center so that the short arm and long arms are equal in length.

Meninges - three membranes covering the brain and spinal cord.

Metamyelocyte - granulocytic precursor cell normally found in the bone marrow. The cell is 10–15 μm in diameter. The cytoplasm stains pink and there is a predominance of specific granules. The nucleus is indented with a kidney bean shape. The nuclear chromatin is condensed and stains dark purple.

Methemoglobin - hemoglobin with iron that has been oxidized to the ferric state (Fe^{+++}); is incapable of combining with oxygen.

Methemoglobin reductase pathway - metabolic pathway that uses methemoglobin reductase and NADH to maintain heme iron in the reduced state (Fe^{+}).

Microangiopathic hemolytic anemia (MAHA) - any hemolytic process that is caused by prosthetic devices or lesions of the small blood vessels.

Microcyte - abnormally small erythrocyte. The MCV is typically less than 80 fL and its diameter is less than 7.0 μm on a stained smear.

Microenvironment - unique environment in the bone marrow where orderly proliferation and differentiation of precursor cells take place.

Micromegakaryocyte - small, abnormal megakaryocyte sometimes found in the peripheral blood in MDS and the myeloproliferative syndromes.

Microtubule - cylindrical structure (20–27 μm in diameter) composed of protein subunits. It is a part of the cytoskeleton, helping some cells maintain shape. Microtubules increase during mitosis and form the mitotic spindle fibers. They also assist in transporting substances in different directions. In the platelet, a band of tubules located on the circumference is thought to be essential for maintaining the disc shape in the resting state.

Minimal (minimum) residual disease - condition with the presence of malignant cells detected by molecular tests when all other tests are negative.

Mitotic pool - population of cells within the bone marrow that is capable of DNA synthesis. Also called *proliferating pool*.

Mixed lineage acute leukemia - acute leukemia that has both myeloid and lymphoid populations present or blasts that possess myeloid and lymphoid markers on the same cell.

Molecular remission - absence of detectable molecular abnormalities using PCR or related molecular technologies in patients who had identifiable abnormalities before therapy. This is the most sensitive test for detecting minimal residual disease.

Monoblast - monocytic precursor cell found in bone marrow. It is about 14–18 μm in diameter with abundant agranular, blue-gray cytoplasm. The nucleus may be folded or indented. The chromatin is finely dispersed, and several nucleoli are visible. The monoblast has nonspecific esterase activity that is inhibited by sodium fluoride.

Monoclonal gammopathy - alteration in immunoglobulin production that is characterized by an increase in one specific class of immunoglobulin.

Monocyte - mature leukocyte found in bone marrow or peripheral blood. Its morphology depends on its activity. The cell ranges in size from 12–30 μm with an average of 18 μm . The blue-gray cytoplasm is evenly dispersed with fine dustlike granules. There are two types of granules. One contains peroxidase, acid phosphatase, and arylsulfatase. Less is known about the content of the other granule. The nuclear chromatin is loose and linear forming a lacy pattern. The nucleus is often irregular in shape.

Monocytopenia - decrease in the concentration of circulating monocytes ($<0.1 \times 10^9/L$).

Monocytosis - increase in the concentration of circulating monocytes ($>0.8 \times 10^9/L$).

Mononuclear phagocyte (MNP) system - collection of monocytes and macrophages found both intravascularly and extravascularly. It plays a major role in initiating and regulating the immune response.

Monosomy - one daughter cell with a missing chromosome (one copy instead of two).

Morulae - basophilic, irregularly shaped granular, cytoplasmic inclusions found in leukocytes in an infectious disease called *ehrlichiosis*.

Mosaic - process that occurs in the embryo shortly after fertilization, resulting in congenital aberrations in some cells and some normal cells.

Mott cell - pathologic plasma cell whose cytoplasm is filled with colorless globules. These globules most often contain immunoglobulin (Russell bodies) and form as a result of accumulation of material in the RER, SER, or Golgi complex due to an obstruction of secretion. The cell is associated with chronic plasmocyte hyperplasia, parasitic infection, and malignant tumors. Also called *grape cell*.

Multimer analysis - analysis that determines the structure of VWF multimers.

Multiple myeloma - plasma cell malignancy characterized by increased plasma proteins.

Mutation - any change in the nucleotide sequence of DNA. In instances in which large sequences of nucleotides are missing, the alteration is referred to as a *deletion*.

Myeloblast - first microscopically identifiable granulocyte precursor. It is normally found in the bone marrow. The cell is large (15–20 μm) with a high nuclear/cytoplasmic ratio. The nucleus has a fine chromatin pattern with a nucleoli. There is moderate amount of blue, agranular cytoplasm.

Myelocyte - granulocytic precursor cell normally found in the bone marrow. The cell is 12–18 μm in diameter with a pinkish granular cytoplasm. Both primary and secondary granules are present.

Myelodysplastic syndromes (MDS) - group of primary neoplastic pluripotential stem cell disorders characterized by one or more cytopenias in the peripheral blood with prominent maturation abnormalities (dysplasia) in the bone marrow.

Myelodysplastic/myeloproliferative diseases - category of neoplasms in the WHO classification but not found in the FAB classification system. It includes clonal hematopoietic neoplasms that have some clinical, laboratory, or morphologic findings of both a myelodysplastic syndrome (MDS) and a chronic myeloproliferative disease (MPD).

Myeloid-to-erythroid ratio (M:E ratio) - ratio of granulocytes and their precursors to nucleated erythroid precursors derived from performing a differential count on bone marrow nucleated hematopoietic cells. Monocytes and lymphocytes are not included. The normal ratio is usually between 1.5:1 and 3.5:1, reflecting a predominance of myeloid elements.

Myeloid/NK cell acute leukemia - acute leukemia in which the neoplastic cells coexpress myeloid antigens (CD33, CD13, and/or CD15) and NK cell-associated antigens (CD56, CD16, CD11b), while they lack HLA-DR and T lymphocyte associated antigens CD3 and CD8.

Myeloperoxidase - enzyme present in the primary granules of myeloid cells including neutrophils, eosinophils, and monocytes.

Myelophthisis - replacement of normal hematopoietic tissue in bone marrow by fibrosis, leukemia, or metastatic cancer cells.

Myeloproliferative disorders (MPD) - group of neoplastic clonal disorders characterized by excess proliferation of one or more cell types in the bone marrow.

► N

Natural killer cell - type of lymphoid cell that has the capacity for spontaneous cytotoxicity for various target cells. Its cytotoxicity is non-MHC restricted. It possesses CD16 (the Fc γ III receptor for IgG) and CD56. NK cells constitute about 15% of the circulating lymphocytes in the peripheral blood.

Necrosis - pathologic cell death resulting from irreversible damage; "cell murder."

Neonatal alloimmune thrombocytopenia (NAIT) - thrombocytopenia due to immune destruction of platelets that occurs in newborns due to the transfer of maternal alloantibodies.

Neoplasm - abnormal formation of new tissue (such as a tumor) that serves no useful purpose; may be benign or malignant.

Neutropenia - decrease in neutrophils below $1.8 \times 10^9/\text{L}$.

Neutrophil - mature white blood cell with a segmented nucleus and granular cytoplasm. This cell constitutes the majority of circulating leukocytes. The absolute number varies between 1.8 and $7.0 \times 10^9/\text{L}$. Also called *granulocytes* or *segs*.

Neutrophilia - increase in neutrophils over $7.0 \times 10^9/\text{L}$. It is seen in bacterial infections, inflammation, metabolic intoxication, drug intoxication, and tissue necrosis.

Nondisjunction - error in segregation that occurs in mitosis or meiosis so that sister chromatids do not disjoin. A spindle fiber malfunction results in one daughter cell with an extra chromosome (trisomy) and one daughter cell with a missing chromosome (monosomy).

Nonspecific granules - large, blue-black granules found in promyelocytes. The granules have a phospholipid membrane and stain positive for peroxidase.

Nonthrombocytopenic purpura - condition in which platelets are normal in number but purpura are present; purpura is considered to be caused by damage to the blood vessels.

Normal pooled plasma - platelet-poor plasma collected from at least 20 individuals for coagulation testing. Plasmas should give PT and APTT results within the laboratory's reference interval. The plasma is pooled and used in mixing studies to differentiate a circulating inhibitor from a factor deficiency.

Normoblast - nucleated erythrocyte precursor in the bone marrow. Also known as *erythroblast*.

Normogram - chart that displays the relationship between numerical variables.

Nuclear-cytoplasmic asynchrony - condition in which the cellular nucleus matures more slowly than the cytoplasm, suggesting a disturbance in coordination. As a result, the nucleus takes on the appearance of a nucleus associated with a younger cell than its cytoplasmic development indicates. This is a characteristic of megaloblastic anemias.

Nuclear-to-cytoplasmic ratio (N:C ratio) - ratio of the volume of the cell nucleus to the volume of the cell's cytoplasm. This is usually estimated as the ratio of the diameter of the nucleus to the diameter of the cytoplasm. In immature hematopoietic cells, the N:C ratio is usually higher than in more mature cells. As the cell matures, the nucleus condenses and the cytoplasm expands.

Nucleolus (pl: nucleoli) - spherical body within the nucleus in which ribosomes are produced. It is not visible in cells that are not synthesizing proteins or that are not in mitosis or meiosis. It stains a lighter blue than the nucleus with Romanowsky stains.

Nucleotide - basic building block of DNA composed of nitrogen base (A = adenine, T = thymine, G = guanine, or C = cytosine) attached to a sugar (deoxyribose) and a phosphate molecule.

Nucleus (pl: nuclei) - characteristic structure in the eukaryotic cell that contains chromosomes and nucleoli. It is separated from the cytoplasm by a nuclear envelope. The structure stains deep bluish-purple with Romanowsky stain. In young, immature hematopoietic cells, the nuclear material is open and dispersed in a lacy pattern. As the cell becomes mature, the nuclear material condenses and appears structureless.

Null cell - See Large granular lymphocytes.

Oncogene - altered gene that contributes to the development of cancer. Most oncogenes are altered forms of normal genes that function to regulate cell growth and differentiation. The normal gene counterpart is known as a proto-oncogene.

Open canalicular system (OCS) - membrane system in the platelet forming twisted channels that lead from the platelet surface to the interior of the platelet. It is a remnant of the demarcation membrane system of the megakaryocyte. Also called *surface connected canalicular system (SCCS)*.

Opportunistic organisms - organisms that are usually part of the normal flora but can cause disease if there is a significant change in host resistance or within the organism itself.

Opsonin - antibody or complement that coats microorganisms or other particulate matter found within the blood stream so that the foreign material may be more readily recognized and phagocytized by leukocytes.

Optimal counting area - area of the blood smear where erythrocytes are just touching but not overlapping; used for morphologic evaluation and identification of cells.

Oral anticoagulant - group of drugs (e.g., coumadin, warfarin) that prevent coagulation by inhibiting the activity of vitamin K, which is required for the synthesis of functional prothrombin group coagulation factors.

Orthochromatic normoblast - nucleated precursor of the erythrocyte that develops from the polychromatophilic normoblast. It is the last nucleated stage of erythrocyte development. The cell normally is found in the bone marrow.

Osmotic fragility - laboratory procedure employed to evaluate the ability of erythrocytes to withstand different salt concentrations; this depends on the erythrocyte's membrane, volume, surface area, and functional state.

Osteoblast - cell involved in formation of calcified bone.

Osteoclast - cell involved in resorption and remodeling of calcified bone.

Outlier - data point that falls outside the expected range for all data. An outlier is not considered to be part of the population that was sampled.

Oxygen affinity - ability of hemoglobin to bind and release oxygen. An increase in CO₂, acid, and heat decreases oxygen affinity, while an increase in pO₂ increases oxygen affinity.

Oxyhemoglobin - compound formed when hemoglobin combines with oxygen.

P₅₀ value - partial pressure of oxygen at which 50% of hemoglobin is saturated with oxygen.

P53 gene - normally functions as an antioncogene by preventing proliferation of DNA-damaged cells, promoting apoptosis of these damaged cells, and preventing unwanted DNA amplification. When mutated, this gene may lose its tumor suppressive effect.

Paired t-test - statistical tool used to compare the difference between two paired data sets. Paired t-test determines whether a statistically significant difference exists between the two paired data sets.

Pancytopenia - marked decrease of all blood cells in the peripheral blood.

Panhypercellular - increase in all blood cells in the peripheral blood.

Panmyelosis - panhypercellularity in the bone marrow.

Pappenheimer bodies - iron-containing particles in mature erythrocyte. On Romanowsky stain, they are visible near the periphery of the cell and often occur in clusters.

Paroxysmal cold hemoglobinuria (PCH) - autoimmune hemolytic anemia characterized by hemolysis and hematuria upon exposure to cold.

Paroxysmal nocturnal hemoglobinuria (PNH) - stem cell disease in which the erythrocyte membrane is abnormal, making the cell more susceptible to hemolysis by complement. There is a lack of decay accelerating factor (DAF) and C8 binding protein (C8bp) on the membrane, which are normally responsible for preventing amplification of complement activation. The deficiency of DAF and C8bp is due to the lack of glycosyl phosphatidyl inositol (GPI), a membrane glycolipid that serves to attach (anchor) proteins to the cell membrane. Intravascular hemolysis is intermittent.

Passenger lymphocyte syndrome - immune hemolytic following solid organ, bone marrow, or stem cell transplant. The donor B lymphocytes that are transplanted with the organ or the bone marrow produce antibodies against recipient's blood group antigens. Hemolysis is primarily due to ABO incompatibility between donor and recipient (Group O donor and Group A or B recipient). Although ABO is the most frequent antigen system involved, Rh, Kell, Kidd, or other blood group systems may be involved.

Pelger-Huët anomaly - inherited benign condition characterized by the presence of functionally normal neutrophils with a bilobed or round nucleus. Cells with the bilobed appearance are called *pince-nez cells*.

Percent saturation - portion of transferrin that is complexed with iron.

Pericardial cavity - body cavity that contains the heart.

Pericardium - membrane that lines the pericardial cavity.

Peripheral membrane protein - protein that is attached to the cell membrane by ionic or hydrogen bonds but is outside the lipid framework of the membrane.

Peritoneal cavity - space between the inside abdominal wall and outside of the stomach, small and large intestines, liver, superior aspect of the bladder, and uterus.

Peritoneum - lining of the peritoneal cavity.

Pernicious anemia - megaloblastic anemia resulting from a lack of intrinsic factor. The intrinsic factor is needed to absorb cobalamin (vitamin B₁₂) from the gut.

Petechiae - small, pinhead-size purple spots caused by blood escaping from capillaries into intact skin. These are associated with platelet and vascular disorders.

Phagocytosis - cellular process of cells engulfing and destroying a foreign particle through active cell membrane invagination.

Phagolysosome - digestive vacuole (secondary lysosome) formed by the fusion of lysosomes and a phagosome. The hydrolytic enzymes of the lysosome digest the phagocytosed material.

Phagosome - formation of an isolated vacuole within the process of opsonization.

Pharmacokinetics - quantitative study of a drug's disposition in the body over time.

Phase microscopy - type of light microscopy in which an annular diaphragm is placed below or in the substage condenser, and a phase-shifting element is placed in the rear focal plane of the objective. This causes alterations in the phases of light rays and increases the contrast between the cell and its surroundings. This methodology is used to count platelets.

Phenotype - physical manifestation of an individual's genotype, often referring to a particular genetic locus.

Phi body - smaller version of the Auer rod.

Photomultiplier tube - light detector used in flow cytometers and other analytical instruments.

Pia mater - thin membrane directly covering the central nervous system; middle layer of the meninges.

Pica - perversion of appetite that leads to bizarre eating practices; a clinical finding in some individuals with iron deficiency anemia.

Pitting - removal of abnormal inclusions from erythrocytes by the spleen.

PIVKA (protein-induced by vitamin-K absence or antagonist) - these factors are the nonfunctional forms of the prothrombin group coagulation factors. They are synthesized in the liver in the absence of vitamin K and lack the carboxyl (COOH) group necessary for binding the factor to a phospholipid surface.

Plasma cell - transformed, fully differentiated B lymphocyte normally found in the bone marrow and medullary cords of lymph nodes. It may be seen in the circulation in certain infections and disorders associated with increased serum γ -globulins. The cell is characterized by the presence of an eccentric nucleus containing condensed, deeply staining chromatin and deep basophilic cytoplasm. The large Golgi apparatus next to the nucleus does not stain,

leaving an obvious clear paranuclear area. The cell has the PC-1 membrane antigen and cytoplasmic immunoglobulin.

Plasma cell neoplasm - monoclonal neoplasm of immunoglobulin secreting cells.

Plasma exchange - removal of patient plasma and replacement with donor plasma.

Plasmacytoid lymphocyte - an intermediate cell in immunoblast development between the B lymphocyte and the plasma cell. It has morphologic similarity to the lymphocyte but has marked cytoplasmic basophilia similar to that of plasma cells. It is occasionally seen in the peripheral blood of patients with viral infection.

Plasmacytosis - presence of plasma cells in the peripheral blood or an excess of plasma cells in the bone marrow.

Plasmin - proteolytic enzyme with trypsinlike specificity that digests fibrin or fibrinogen as well as other coagulation factors. Plasmin is formed from plasminogen.

Plasminogen - β -globulin, single-chain glycoprotein that circulates in the blood as a zymogen. Large amounts of plasminogen are absorbed with the fibrin mass during clot formation. Plasminogen is activated by intrinsic and extrinsic activators to form plasmin.

Plasminogen activator inhibitor-1 (PAI-1) - primary inhibitor of tissue plasminogen activator (t-PA) and urokinaselike plasminogen activator (tcu-PA) released from platelet α granules during platelet activation.

Plasminogen activator inhibitor-2 (PAI-2) - inhibitor of tissue plasminogen activator and urokinaselike plasminogen activator. Secretion of PAI-2 is stimulated by endotoxin and phorbol esters. Increased levels impair fibrinolysis and are associated with thrombosis.

Platelet - round or oval disc-shaped structure in the peripheral blood formed from the cytoplasm of megakaryocytes in the bone marrow. Platelets play an important role in primary hemostasis by adhering to the ruptured blood vessel wall and aggregating to form a platelet plug over the injured area. Platelets are also important in secondary hemostasis by providing platelet phospholipids important for the activation of coagulation proteins. The normal reference range for platelets is $150\text{--}450 \times 10^9/\text{L}$.

Platelet activation - stimulation of a platelet that occurs when agonists bind to the platelet's surface and transmit signals to the cell's interior. Activated platelets form aggregates known as the *primary platelet plug*.

Platelet adhesion - platelet attachment to collagen fibers or other nonplatelet surfaces.

Platelet aggregation - platelet-to-platelet interaction that results in a clumped mass; may occur in vitro or in vivo.

Platelet clump - aggregation of platelets; may occur when blood is collected by capillary puncture (due to platelet activation) and when blood is collected in EDTA anticoagulant (due to unmasking of platelet antigens that can react with antibodies in the serum).

Platelet distribution width (PDW) - coefficient of variation of platelet volume distribution; analogous to RDW.

Platelet factor 4 - protein present in platelet's alpha granules that is capable of neutralizing heparin.

Plateletpheresis - procedure in which platelets are removed from the circulation.

Platelet-poor plasma (PPP) - citrated plasma containing less than $15 \times 10^9/L$ platelets. It is prepared by centrifugation of citrated whole blood at a minimum RCF of $1000 \times g$ for 15 minutes. PPP is used for the majority of coagulation tests.

Platelet procoagulant activity - property of platelets that enables activated coagulation factors and cofactors to adhere to the platelet surface during the formation of fibrin.

Platelet-rich plasma (PRP) - citrated plasma containing approximately $200\text{--}300 \times 10^9/L$ platelets. It is prepared by centrifugation of citrated whole blood at an RCF of $150 \times g$ for 10 minutes. PRP is used in platelet aggregation studies.

Platelet satellitism - adherence of platelets to neutrophil membranes in vitro; this can occur when blood is collected in EDTA anti-coagulant.

Platelet secretion - release of the contents of the platelet alpha granules and dense bodies during platelet activation.

Platelet-type pseudo-VWD - platelet disorder characterized by an increased affinity of the platelet GPIb/IX receptor for VWF, resulting in spontaneous binding of the large VWF multimers to the platelet. It resembles VWD clinically and often presents with similar laboratory test results but is not associated with genetic mutations involving the VWF gene and thus is not considered "true" VWD.

Pleura - lining of the pleural cavities.

Pleural cavity - space between the chest wall and the lungs.

Plethora - excess of blood.

Plumbism - lead poisoning.

Pluripotential cell - cell that differentiates into many different cell lines. It has the potential to self-renew, proliferate, and differentiate into erythrocytic, myelocytic, monocytic, lymphocytic, and megakaryocytic blood cell lineages.

Poikilocytosis - term used to describe the presence of variations in the shape of erythrocytes.

Point of care (POC) instrument - instrument that allows for analytical testing of patient specimens outside the laboratory setting (e.g., home testing or physician's office testing).

Polychromatophilia - quality of being stainable with more than one portion of the stain; the term is commonly used to describe erythrocytes that stain with a grayish or bluish tinge with Romanowsky stains due to residual RNA, which takes up the blue portion of the dye.

Polychromatophilic erythrocyte - erythrocyte with a bluish tinge when stained with Romanowsky stain; contains residual RNA. If stained with new methylene blue, these cells show reticulum and are identified as reticulocytes.

Polyclonal - arising from different cell clones.

Polyclonal gammopathy - alteration in immunoglobulin production that is characterized by an increase in immunoglobulins of more than one class.

Polycythemia - condition associated with increased erythrocyte count.

Polycythemia vera - myeloproliferative disorder associated with an increased proliferation of erythroid cells.

Polymerase chain reaction - procedure for copying a specific DNA sequence many times.

Polymorphic variants - variant morphology of a portion of a chromosome that has no clinical consequence.

Polymorphonuclear neutrophil (PMN) - mature granulocyte found in bone marrow and peripheral blood. The nucleus is segmented into 2 or more lobes. The cytoplasm stains pinkish and there is abundant specific granules. This is the most numerous leukocyte in the peripheral blood ($1.8\text{--}7.0 \times 10^9/L$). Its primary function is defense against foreign antigens. It is active in phagocytosis and killing microorganisms. Also called *segmented neutrophil* or *seg*.

Polyploid/polyploidy - number of chromosomes per cell that is a multiple of n (23) other than 1 or 2 (e.g., $3n[69]$, $4n[92]$).

Popcorn cell (L&H cell) - neoplastic cell variant found in LP Hodgkin lymphoma characterized by a delicate multilobated nucleus and multiple, small nucleoli. The L&H cell has a B cell phenotype: LCA+ (leukocyte common antigen), CD20+, CD 15.

Porphyryns - highly unsaturated tetrapyrrole ring bonded by four methane ($-\text{CH}=\text{}$) bridges. Substituents occupy each of the eight peripheral positions on the four pyrrole rings. The kind and order of these substituents determine the type of porphyrin. Porphyrins are metabolically active only when they are chelated.

Portland hemoglobin - embryonic hemoglobin found in the yolk sac and detectable up to 8 weeks gestation. It is composed of two zeta (ζ) and two gamma (γ) chains.

Postmitotic pool - neutrophils in the bone marrow that are not capable of mitosis. These cells include metamyelocytes, bands, and segmented neutrophils. Cells spend about 5–7 days in this compartment before being released to the peripheral blood. Also called *maturation-storage pool*.

Post translational modification - process occurring in eukaryotic cells that modify the protein product produced by ribosomal translation; it may involve the addition of sugar groups (glycosylation) and phosphate groups (phosphorylation) or other modifications to amino acids (e.g., gamma carboxylation of coagulation proteins).

Primary aggregation - earliest association of platelets in an aggregate that is reversible.

Primary fibrinogenolysis - clinical situation that occurs when there is a release of excessive quantities of plasminogen activators into the blood in the absence of fibrin clot formation. Excess plasmin degrades fibrinogen and the clotting factors, leading to a potentially dangerous hemorrhagic condition.

Primary hemostasis - initial arrest of bleeding that occurs with blood vessel/platelet interaction.

Primary hemostatic plug - aggregate of platelets that initially halts blood flow from an injured vessel.

Primary thrombocytosis - increase in platelets that is not secondary to another condition. It usually refers to the thrombocytosis that occurs in neoplastic disorders.

Probe - tool for identifying a particular nucleotide sequence of interest. A probe is composed of a nucleotide sequence that is complementary to the sequence of interest and is therefore capable of hybridizing to that sequence. Probes are labeled in a way that is detectable, such as by radioactivity.

Procoagulant - inert precursor of a natural substance that is necessary for blood clotting or a property of anything that favors formation of a blood clot.

Proficiency testing - utilizing unknown samples from an external source (e.g., College of American Pathologists) to monitor the quality of a given laboratory's test results.

Progenitor cell - parent or ancestor cells that differentiate into mature, functional cells.

Prolymphocyte - immediate precursor cell of the lymphocyte; normally found in bone marrow. It is slightly smaller than the lymphoblast and has a lower nuclear to cytoplasmic ratio. The nuclear chromatin is somewhat clumped, and nucleoli are usually present. The cytoplasm stains light blue and is agranular.

Promonocyte - monocytic precursor cell found in the bone marrow. The cell is 14–18 μm in diameter with abundant blue-gray cytoplasm. Fine azurophilic granules may be present. The nucleus is often irregular and deeply indented. The chromatin is finely dispersed and stains a light purple blue. Nucleoli may be present. Cytochemically, the cells stain positive for nonspecific esterase, peroxidase, acid phosphatase, and arylsulfatase. The cell matures to a monocyte.

Promyelocyte - granulocytic precursor cell normally found in the bone marrow. The cell is 15–21 μm in diameter. The cytoplasm is basophilic, and the nucleus is quite large. The nuclear chromatin is lacy, staining a light purple blue. Several nucleoli are visible. The distinguishing feature is the presence of large blue-black primary (azurophilic) granules. The granules have a phospholipid membrane that stains with Sudan black B. The granules contain acid phosphatase, myeloperoxidase, acid hydrolases, lysozyme, sulfated mucopolysaccharides, and other basic proteins. The promyelocyte matures to a myelocyte. Also called *progranulocyte*.

Pronormoblast - precursor cell of the erythrocyte. The cell is derived from the pluripotential stem cell and is found in the bone marrow. The cell is 12–20 μm in diameter and has a high nuclear-cytoplasmic ratio. The cytoplasm is deeply basophilic with Romanowsky stains. The nuclear chromatin is fine, and there is one or more nucleoli. The cell matures to a basophilic normoblast. Also called *rubriblast*.

Proteomics - study of the structure and function of proteins in a cell or tissue at a specific time under certain predefined conditions; includes information on the way the proteins function and interact with each other inside cells.

Proteasome - eukaryotic assembly of proteins that degrades other proteins.

Prothrombinase complex - complex formed by coagulation factors Xa and V, calcium, and phospholipid. This complex activates prothrombin to thrombin.

Prothrombin group - group of coagulation factors that are vitamin K dependent for synthesis of their functional forms and that require calcium for binding to a phospholipid surface. Includes factors II, VII, IX, and X. Also known as *vitamin K-dependent factors*.

Prothrombin time (PT) - screening test used to detect deficiencies in the extrinsic and common pathway of the coagulation cascade and to monitor the effectiveness of oral anticoagulant therapy.

Prothrombin time ratio - proportion calculation derived by dividing the patient's prothrombin time result by midpoint of the laboratory's normal range and used to calculate the International Normalized Ratio (INR).

Prourokinase - immature, single-chain form of urokinase that is prepared from urine and by recombinant DNA techniques and can be activated to a two-chain form by plasmin.

Pseudochylous - fluid that appears chylous due to the presence of many inflammatory cells; does not contain lymph fluid or chylomicrons.

Pseudodiploid - cell that has a chromosome count of $2n$ (46) but with a combination of numerical and/or structural aberrations (e.g., 46, XY, -5, -7, 2D8, 2D21).

Pseudoneutrophilia - increase in the concentration of neutrophils in the peripheral blood ($>7.0 \times 10^9/\text{L}$) occurring as a result of cells from the marginating pool entering the circulating pool. The response is immediate but transient. This redistribution of cells accompanies vigorous exercise, epinephrine administration, anesthesia, convulsion, and anxiety states. Also called *immediate* or *shift neutrophilia*.

Pseudo-Pelger-Huët cells - acquired condition in which neutrophils display a hyposegmented nucleus. Unlike the real Pelger-Huët anomaly, the nucleus of this cell contains a significant amount of euchromatin and stains more lightly. A critical differentiation point is that all neutrophils are equally affected in the genetic form of Pelger-Huët anomaly, but only a fraction of neutrophils are hyposegmented cells in the acquired state. It is associated with MDS and MPD and may also be found after treatment for leukemias.

Pulmonary embolism - obstruction of the pulmonary artery or one of its branches by a clot or foreign material that has been dislodged from another area by the blood current.

Pure red cell aplasia (PRCA) - anemia with selective decrease in erythrocyte precursors in the marrow.

Purging - technique by which undesirable cells that are present in the blood or bone marrow products are removed.

Purpura - (1) purple discoloration of the skin caused by petechiae and/or ecchymoses; (2) a diverse group of disorders that are characterized by the presence of petechiae and ecchymoses.

Pyknotic - pertaining to degeneration of the nucleus of the cell in which the chromatin condenses to a solid, structureless mass and shrinks.

► Q

Quality control limit - expected range of results. These limits are used to determine whether a test method is in control and to minimize the chance of inaccurate patient results. If the test method is out of control, an intervention is required to reconcile the problem.

Quebec platelet disorder - storage pool disorder of platelets due to abnormal proteolysis of alpha granule proteins due to increased levels of urinary-type plasminogen activator.

Quiescence (G_0) - phase in a cell that has exited the cell cycle and is in a nonproliferative state.

► R

R (relaxed) structure - conformational change in hemoglobin that occurs as the molecule takes up oxygen.

Radar chart - graphical representation of eight CBC parameters: WBC, RBC, Hb, Hct, MCV, MCH, MCHC, and PLT. Lines are drawn to connect the parameters; the chart resembles a radar oscilloscope. Changes in the shape of the radar chart indicate different hematologic disorders.

Radial immunodiffusion - diffusion technique in which antibody is incorporated into agarose gel and antigen is placed into wells in the gel. The antigen is quantitated by the size of a precipitin ring that forms as antigen diffuses from a sample well into the gel.

Random access - capability of an automated hematology instrument to process specimens independently of one another; may be programmed to run individual tests (e.g., Hb or platelet counts) or a panel of tests (e.g., CBC with reticulocyte count) without operator intervention.

Random variation - variation within an instrument or test method that is due to chance. This type of variation can be either positive or negative in direction and affects precision.

Rapoport-Leubering shunt - metabolic pathway in which 2,3-bisphosphoglycerate (2,3-BPG) is synthesized from 1,3-bisphosphoglycerate. 2,3-BPG facilitates the release of oxygen from hemoglobin in the erythrocyte. Also referred to as *2,3-DPG (diphosphoglycerate)*.

Raynaud's phenomenon - secondary disorder resulting from vasoarterial spasms in the extremities of the body when exposed to the cold. It is characterized by blanching of the skin, followed by cyanosis, and finally redness when the affected area is warmed. Also referred to as *acrocyanosis*.

RBC indices - indices that help classify the erythrocytes as to their size and hemoglobin content. The values for hemoglobin, hematocrit, and erythrocyte are used to calculate the three indices: mean corpuscular volume (MCV), mean corpuscular hemoglobin concentration (MCHC), and mean corpuscular hemoglobin (MCH). The indices give a clue as to what the erythrocytes should look like on a stained blood film.

Reactive lymphocyte - antigen-stimulated lymphocyte that exhibits a variety of morphologic features. The cell is usually larger than the resting lymphocyte and has an irregular shape. The cytoplasm is more basophilic. The nucleus is often elongated and irregular with a finer chromatin pattern than that of the resting lymphocyte. Often this cell is increased in viral infections. Also called *virocyte*, or *stimulated*, *transformed*, *atypical*, *activated*, or *leukocytoid lymphocyte*.

Reactive neutrophilia - increase in the concentration of peripheral blood neutrophils ($>7.0 \times 10^9/L$) as a result of reaction to a physiologic or pathologic process.

Reagent blank - measurement of absorbance due to reagent alone; eliminates false increase in sample absorbance due to reagent color.

Red thrombus - thrombus composed mostly of red blood cells; so named because of its red coloration.

Reed-Sternberg cell - cell found in the classic form of Hodgkin lymphoma. It is characterized by a multilobated nucleus and large inclusion-like nucleoli.

Reference interval - test value range that is considered normal. Generally the range is determined to include 95% of the normal population.

Reflex testing - follow-up testing that is performed based on results of screening tests.

Refractive Index - degree to which a transparent object will deflect a light ray from a straight path.

Refractory - pertains to disorders or diseases that do not respond readily to therapy.

Refractory anemia - subgroup of the myelodysplastic syndromes. Anemia refractory to all conventional therapy is the primary clinical finding. Blasts constitute $<1\%$ of nucleated peripheral blood cells. The bone marrow shows signs of dyserythropoiesis.

Refractory anemia with excess blasts (RAEB) - subgroup of the myelodysplastic syndromes. There are usually cytopenias and signs of dyspoiesis in the peripheral blood with $<5\%$ blasts. The bone marrow is usually hypercellular with dyspoiesis in all hematopoietic cell lineages. Bone marrow blasts vary from 5% to 20%.

Refractory anemia with excess blasts in transformation (RAEB-T) - subgroup of the myelodysplastic syndromes. There is(are) cytopenia(s) in the peripheral blood with more than 5% blasts. The bone marrow is usually hypercellular with dyspoiesis and 20–30% blasts. In the WHO classification, this would be considered acute leukemia ($>20\%$ blasts).

Refractory anemia with ringed sideroblasts (RARS) - subgroup of the myelodysplastic syndromes characterized by $<1\%$ blasts in the peripheral blood, anemia, and/or thrombocytopenia and/or leukopenia. There are more than 15% ringed sideroblasts and $<5\%$ blasts in the bone marrow.

Refractory cytopenia with multilineage dysplasia (RCMD) - category in the WHO classification system for patients with dysplastic features in at least 10% of the cells in two or more cell lines, less than 5% blasts in the bone marrow, and less than 1% blasts in the peripheral blood.

Remission - diminution of the symptoms of a disease.

Replication - process by which DNA is copied during cell division. Replication is carried out by the enzyme DNA polymerase, which recognizes single-stranded DNA and fills in the appropriate complementary nucleotides to produce double-stranded DNA. Synthesis is initiated at a free 5' end where double-stranded DNA lies adjacent to single-stranded DNA, and replication proceeds in the 5' direction. In the laboratory, DNA replication can be induced as a means of copying DNA sequences as exploited in the polymerase chain reaction.

Reportable range - range that is defined by a minimum value and a maximum value of calibration material.

Reticulated platelet - platelet newly released from the bone marrow and that possesses residual RNA.

Restriction endonuclease - enzyme that cleaves double-stranded DNA at specific nucleotide sequences. For example, HindIII cleaves DNA only where the sequence 5'-AAGCTT-3' is present. Various other enzymes are known to cut various specific target sequences. Examples of common restriction endonucleases are BamH1, EcoR1, Mnl1, MstII, Pst1, and Xba1.

Restriction point - point that occurs in late G1; point when cell cycle progression becomes autonomous.

Reticular cell - one of the three major types of cell in the bone marrow stroma. It is also found in the spleen and lymph nodes. These cells branch to form reticular fibers. Also called *fibroblasts*.

Reticulocyte - first nonnucleated stage of erythrocyte development in the bone marrow. It contains RNA that is visualized as granules or filaments within the cell when stained supravitaly with new methylene blue. Normally, reticulocytes constitute approximately 1% of the circulating erythrocyte population.

Reticulocyte production index (RPI) - indicator of the bone marrow response in anemia. The calculation corrects the reticulocyte

count for the presence of marrow reticulocytes in the peripheral blood. It is calculated as follows:

$$(\text{Patient hematocrit [L/L]} \div 0.45 [\text{L/L}]) \times \text{reticulocyte count (\%)} \times (1 \div \text{maturation time of shift reticulocytes}) = \text{RPI}$$

Reticulocytosis - presence of excess reticulocytes in the peripheral blood.

Rh null disease - disorder associated with the lack of the Rh antigen on erythrocytes.

Rhophocytosis - energy- and temperature-dependent process by which iron enters cells.

Ribosomes - cellular particle composed of ribonucleic acid (RNA) and protein whose function is to synthesize polypeptide chains from amino acids. The sequence of amino acids in the chains is specified by the genetic code of messenger RNA. Ribosomes appear singly or in reversibly dissociable units and may be free in the cytoplasm or attached to endoplasmic reticulum. The cytoplasm of blood cells that contain a high concentration of ribosomes stains bluish purple with Romanowsky stains.

Richter's transformation - transformation from CLL to another disease, usually large B cell lymphoma.

Ringed sideroblasts - erythroblasts with abnormal deposition of excess iron within mitochondria resulting in a ring formation around the nucleus.

Ristocetin - aggregating reagent that specifically evaluates VWF interaction with glycoprotein Ib on platelets.

Ristocetin induced platelet aggregation (RIPA) - measures ability of patient's VWF to bind to normal platelets, inducing platelet aggregation in a platelet aggregation assay.

RNA (ribonucleic acid) - single-stranded molecule composed of ribonucleotides (A, C, G, and U). RNA is produced by transcription of genes from a DNA template; RNA in turn serves as a template for protein translation.

Romanowsky-type stain - any stain consisting of methylene blue and its oxidation products and eosin Y or eosin B.

Rouleaux - erythrocyte distribution characterized by erythrocytes stacked like a roll of coins. This is due to abnormal coating of the cell's surface with increased plasma proteins, which decreases the zeta potential between cells.

Russell bodies - globule filled with immunoglobulin found in pathologic plasma cells called Mott cells. *See* Mott cell.

Russell's viper venom - venom that possesses thromboplastin-like activity and activates factor X.

▶ S

Satellite DNA - DNA containing many tandem repeats. Morphologically, it appears as a small ball-like structure making up the short arm of acrocentric chromosomes. This is the locus of the nucleolar organizing region.

Scatterplot - dot-plot histogram of two cellular characteristics. Together, the two characteristics allow definition of the leukocyte subpopulations.

Schilling test - definitive test useful in distinguishing vitamin B₁₂ deficiency due to malabsorption, dietary deficiency, or absence of IF. It measures the amount of an oral dose of radioactively labeled crystalline B₁₂ that is absorbed in the gut and excreted in the urine.

Schistocyte - fragment of an erythrocyte. A schistocyte may have a variety of shapes including triangle, helmet, and comma.

Scott syndrome - rare platelet disorder characterized by abnormal Ca⁺⁺ induced phospholipids scrambling in which platelet membranes fail to support plasma procoagulant protein activation.

Secondary aggregation - irreversible aggregation of platelets that occurs over time.

Secondary fibrinolysis - clinical condition characterized by excessive fibrinolytic activity in response to disseminated intravascular clotting.

Secondary hemostasis - formation of fibrin that stabilizes a primary platelet plug.

Secondary hemostatic plug - primary platelet aggregate that has been stabilized by fibrin formation during secondary hemostasis.

Secondary thrombocytosis - increase in platelet concentration in the blood. The increase is in response to stimulation by another condition.

Secretion - energy-dependent discharge or release of products usually from glands in the body but also pertaining to the contents of platelet granules that are released after stimulation of the platelets by agonists; also product that is discharged or released.

Self-renewal - property of regenerating the same cells.

Sequestration crisis - sudden splenic pooling of sickled erythrocytes that may cause a massive decrease in erythrocyte mass within a few hours

Serine protease - family of serine proteases includes thrombin, factors VIIa, IXa, Xa, XIa, XIIa, and the digestive enzymes chymotrypsin and trypsin. They selectively hydrolyze arginine- or lysine-containing peptide bonds of other zymogens converting them to serine proteases. Each serine protease involved in the coagulation cascade is highly specific for its substrate.

Serpin - family of serine protease inhibitors that inhibit target molecules by formation of a 1:1 stoichiometric complex.

Severe combined immunodeficiency syndrome (SCIDS) - heterogeneous group of disorders based on diverse genetic origins, different inheritance patterns, and severity of clinical manifestations. The disease may be inherited either as a sex-linked trait or as an autosomal-recessive trait. This is the most severe immune deficiency disease.

Sézary's cell - circulating neoplastic cell found in Sézary's syndrome characterized by a very convoluted (cerebriform) nuclear outline.

Shelf life - time period for which a reagent or control is stable given appropriate storage conditions. Shelf life changes once the reagent or control is reconstituted if lyophilized or opened if liquid.

Shift neutrophilia - *See* Pseudoneutrophilia.

Shift to the left - appearance of increased numbers of immature leukocytes in the peripheral blood.

Sickle cell (drepanocyte) - elongated crescent shaped erythrocyte with pointed ends. Sickle cell formation may be observed in wet preparations or in stained blood smears from patients with sickle cell anemia.

Sickle-cell anemia - genetically determined disorder in which hemoglobin S is inherited in the homozygous state. No hemoglobin A is present. Hemoglobins S, F, A₂ are present.

Sickle cell trait - genetically determined disorder in which hemoglobin S is inherited in the heterozygous state. The patient has one normal β -globin gene and one β^S -globin gene. Both hemoglobin A and hemoglobin S are present.

Side light scatter - laser light scattered at a 90° angle due to internal complexity and granularity of the particle (e.g., neutrophils produce much side scatter because of their numerous cytoplasmic granules).

Sideroacrestic - defect in iron utilization.

Siderocyte - erythrocyte that contains stainable iron granules.

Sideropenic - lack of iron.

Single nucleotide polymorphism (SNP) - change in which a single base in the DNA differs from the usual base at that position

Slope - angle or direction of the regression line with respect to the x and y axes. The slope is used to identify the presence of proportional systematic error.

Small lymphocytic lymphoma (SLL) - condition identical to CLL but primarily involves the lymph nodes. The two disorders appear to belong to one disease entity with differing clinical manifestations.

Smooth endoplasmic reticulum (SER) - *See* Endoplasmic reticulum.

Smudge cell - cell whose cytoplasmic membrane has ruptured, leaving a bare nucleus. Increased numbers of smudge cells are observed in lymphoproliferative disorders such as chronic lymphocytic leukemia. It can also be seen in reactive lymphocytosis and in other neoplasms.

Southern blot - procedure first described by Ed Southern for determining DNA structure. In this procedure, DNA is cleaved with restriction endonucleases that cut DNA at specific nucleotide sequences. The resulting DNA fragments are electrophoresed in an agarose gel to separate them by size and then treated with a solution of high pH that separates double-stranded DNA into two single-stranded parts. The single-stranded fragments are then transferred to a membrane where they can be hybridized to a complementary labeled probe. Probe hybridization permits identification of the DNA fragments containing the sequence of interest. The size and number of those fragments reflects the structure of the DNA.

Specificity - ability of a test method to determine only the analyte meant to be detected or measured.

Specimen run - interval, period of time, or number of specimens for which the accuracy and precision of the laboratory procedure is expected to remain stable.

Spectrin - predominant peripheral membrane protein found in the erythrocyte membrane. It is composed of dimeric chains, α and β , that associate to form tetramers.

Spent phase - stage in polycythemia vera in which after a period of 2–10 years, the patient may develop bone marrow failure accompanied by an increase in splenomegaly. Anemia and bleeding may be the primary clinical findings, secondary to a decreased platelet count and decreasing hematocrit. This phase is often a transition to AML.

Spherocyte - abnormally round erythrocyte with dense hemoglobin content (increased MCHC). The cell has no central area of pallor because it has lost its biconcave shape.

Splenectomy - removal of the spleen.

Splenomegaly - abnormal enlargement of the spleen.

Split sample - division of a single sample into two or more aliquots for the purpose of testing on two or more instruments within the same time period or retesting the sample at another time.

Spur cell anemia - acquired hemolytic condition associated with severe hepatocellular disease such as cirrhosis, in which there is an increase in serum lipoproteins, leading to excess of erythrocyte membrane cholesterol. The total phospholipid content of the membrane, however, is normal. The predominant poikilocyte is an erythrocyte with irregular points and no area of central pallor (acanthocytes).

Stab - *See* Band.

Stage - stage of a neoplasm indicates the extent and distribution of disease. Determining the stage of disease usually involves radiologic studies, peripheral blood examination, bone marrow aspiration, and biopsy.

Standard deviation - distribution of a set of data about the mean.

Standard error of the estimate ($S_{y/x}$) - measure of the variation in the regression line. The $S_{y/x}$ is used to identify random error.

Starry sky - morphologic appearance characteristic of high-grade lymphoma produced by numerous tingible body macrophages (stars) and a diffuse sheet of neoplastic cells (sky).

Stomatocyte - abnormal erythrocyte shape characterized by a slit-like area of central pallor. This cell has a uniconcave, cup shape.

Streptokinase - bacterial enzyme derived from group C-beta hemolytic streptococci that activates plasminogen to plasmin and is used as a thrombolytic agent in the treatment of thrombosis.

Stroma - extracellular matrix or microenvironment that supports hematopoietic cell proliferation in the bone marrow.

Stromal cells - cellular elements of the hematopoietic microenvironment in the red portion of bone marrow.

Submetacentric - chromosome that has the centromere positioned off center so that the short arm is shorter than the long arm.

Sucrose hemolysis test - screening test to identify erythrocytes that are abnormally sensitive to complement lysis. In this test, erythrocytes, serum, and sucrose are incubated together. Cells abnormally sensitive to complement will lyse. The test is used to screen for paroxysmal nocturnal hemoglobinuria. Also called *sugar-water test*.

Sulfhemoglobin - stable compound formed when a sulfur atom combines with each of the four heme groups of hemoglobin; it is incapable of carrying oxygen.

Supernatant - clear liquid remaining on top of a solution after centrifugation of the particulate matter.

Supravital stain - stain used to stain cells or tissues while they are still living.

Syngeneic stem cell transplantation - transplantation of stem cells between genetically identical twins.

Synovium - continuous membrane that lines the bony, cartilaginous, and connective tissue surfaces of a joint.

Systematic variation - variation within an instrument or test method that occurs in one direction and can be predicted. This type of variation affects accuracy.

▶ T

Target cell - abnormally shaped erythrocyte. The cell appears as a target with a bull's-eye center mass of hemoglobin surrounded by an achromic ring and an outer ring of hemoglobin. The osmotic fragility of this cell is decreased. Also called *Mexican hat cell* and *codocyte*.

Tartrate resistant acid phosphatase (TRAP) - acid phosphatase staining following tartrate incubation.

T cell ALL - immunologic subgroup of ALL. There are two types: early precursor T-ALL and T-ALL. T-ALL is differentiated using two CD markers, CD7 (gp40 protein) and CD2 (E-receptor), and TdT.

T cell receptor (TCR) - antigen receptor on immunocompetent T lymphocytes

Teardrop (dacryocytes) - erythrocyte that is elongated at one end to form a teardrop or pear-shaped cell. Teardrop may form after erythrocytes with cellular inclusions have transversed the spleen. A teardrop cell cannot return to its original shape because it has either been stretched beyond the limits of deformability of the membrane or has been in the abnormal shape for too long a time.

Telangiectasia - persistent dilation of superficially located veins.

Thalassemia - group of genetically determined microcytic, hypochromic anemias resulting from a decrease in synthesis of one or more globin chains in the hemoglobin molecule. The disorder may occur in the homozygous or heterozygous state. Heterozygotes may be asymptomatic but homozygotes typically have a severe, often fatal, disease. Thalassemia occurs most frequently in populations from the Mediterranean area and Southeast Asia.

Therapeutic range - level of a drug that is beneficial but not toxic to the individual.

Transcription error - error made in reporting test results when copying results manually from the instrument to a paper or typing them into a computer.

Threshold limit - level above which voltage pulses of particles are counted. Adjusting the threshold limit allows different types of cells to be counted.

Thrombin activatable fibrinolysis inhibitor (TAFI) - inhibitor of fibrinolysis activated by the thrombin-thrombomodulin complex, which inhibits fibrinolysis by cleaving free lysine groups on fibrin

Thrombocyte - See Platelet.

Thrombocytopenia - decrease in the number of platelets in the peripheral blood below the reference range for an individual laboratory (usually below $150 \times 10^9/L$).

Thrombocytopenia with absent radii (TAR) - inherited condition characterized by isolated hypoplasia of the megakaryocytic lineage, thrombocytopenia, and bilateral radial aplasia.

Thrombocytosis - increase in the number of platelets in the peripheral blood above the reference range for an individual laboratory (usually over $450 \times 10^9/L$).

Thromboembolism - blockage of a small blood vessel by a blood clot that was formed in the heart, arteries, or veins, dislodged and moved through blood vessels until reaching a smaller vessel and blocking further blood flow.

Thrombogenic - tendency to thrombose.

Thrombolytic therapy - therapy designed to dissolve or break down a thrombus.

Thrombomodulin - intrinsic membrane glycoprotein present on endothelial cells that serves as a cofactor with thrombin to activate protein C. It forms a 1:1 complex with thrombin inhibiting thrombin's ability to cleave fibrinogen to fibrin but enhances thrombin's ability to activate protein C.

Thrombophilia - tendency to form blood clots abnormally. Also referred to as *hypercoagulability*.

Thrombophlebitis - thrombosis within a vein that is accompanied by an inflammatory response, pain, and redness of the area.

Thrombopoietin - cytokine that regulates the maturation of megakaryocytes and the production of platelets.

Thrombosis - formation of a blood clot or thrombus, usually considered to be under abnormal conditions within a blood vessel.

Thrombotic thrombocytopenia purpura (TTP) - acute disorder characterized by microangiopathic anemia, decreased number of platelets, and renal failure as well as neurological symptoms. TTP is due to decreased activity of ADAMTS-13, resulting in the presence of ultralarge molecules of VWF in the circulation and platelet agglutination.

Thrombus - blood clot within the vascular system.

TIBC - total iron binding capacity; refers to the total amount of iron that transferrin can carry, about 250–450 $\mu g/dL$.

Tingible body macrophage - macrophage phagocytosing fragments of dying cells. It is found in areas of extensive apoptosis (reactive germinal centers and high-grade lymphoma).

Tissue factor - coagulation factor present on subvascular cells that forms a complex with factor VII when the vessel is ruptured. This complex activates factor X. Tissue factor is an integral protein of the cell membrane.

Tissue factor pathway inhibitor (TFPI) - intrinsic pathway inhibitor that inhibits both F-VIIIa and F-Xa by forming a quarternary complex of TFPI-FXa-TF-FVIIa.

Tissue homeostasis - maintenance of an adequate number of cells to carry out the functions of the organism. Homeostasis is controlled by cell proliferation, cell differentiation, and cell death (apoptosis).

Tissue plasminogen activator (t-PA) - serine protease that activates plasminogen to plasmin. It forms a bimolecular complex with fibrin increasing the catalytic efficiency of t-PA for plasminogen activation.

Toxic granules - large, dark blue-black primary granules in the cytoplasm of neutrophils that are present in certain infectious states. They are usually seen in conjunction with Döhle bodies.

Toxoplasmosis - condition that results from infection with *Toxoplasma gondii*. Acquired infection may be asymptomatic, or symptoms may resemble infectious mononucleosis. There is a leukocytosis with relative lymphocytosis or rarely an absolute lymphocytosis and the presence of reactive lymphocytes.

Trabecula - projection of calcified bone extending from cortical bone into the marrow space; provides support for marrow cells.

Transcription - synthesis of RNA from a DNA template.

Transcription factor - protein that controls when genes are switched on or off (i.e., whether genes are transcribed or not).

Transcription factors bind to regulatory regions in the genome and help control gene expression.

Transferrin - plasma β_1 -globulin responsible for binding iron and its transport in the bloodstream. Each gram of transferrin can bind 1.25 mg of iron. The capacity of transferrin to bind iron is functionally measured as the total iron-binding capacity (TIBC).

Transglutaminase - F-XIIIa is the only coagulation protein with transglutaminase activity. It catalyzes the formation of isopeptide bonds between glutamine and lysine residues on fibrin, forming stable covalent crosslinks.

Transient erythroblastemia of childhood (TEC) - temporary suppression of erythropoiesis that frequently occurs after a viral infection in infants and children. Therapy is supportive, and patients usually recover within 2 months.

Translation - synthesis of protein from an RNA template.

Translocation - abnormal chromosomal rearrangement whereby part of one chromosome breaks off and becomes attached to another chromosome. The site of juxtaposition between the two chromosomes is referred to as the breakpoint.

Transplacental idiopathic thrombocytopenic purpura - form of ITP that is present in newborns because of maternal transfer of platelet-destroying antibodies.

Transudate - effusion that is formed due to increased hydrostatic pressure or decreased osmotic pressure; does not indicate a true pathologic state in the anatomic region.

Trisomy - one daughter cell with an extra chromosome (three copies instead of two).

T-structure (tense) - conformational change in a hemoglobin molecule that occurs when oxygen is released from hemoglobin.

Turnaround time - time between specimen collection and reporting of a test result.

Type 1 VWD (classic VWD) - quantitative decrease of structurally normal VWF.

Type 2 VWD - qualitative disorder of VWF; has four possible subtypes: 2A, 2B, 2M, and 2N.

Type 3 VWD - severe, rare quantitative deficiency of VWF.

Type I myeloblasts - classic description of myeloblasts. These cells contain no granules and have a highly immature nucleus.

Type II myeloblasts - more mature than the type I myeloblasts; cells that can contain Auer rods, phi bodies, and/or primary granules.

Type III myeloblasts - similar to type II myeloblasts but have >20 granules in the cytoplasm.

Tyrosine kinase protein - protein that regulates metabolic pathways and serves as receptor for growth factors.

▶ U

Ubiquitin - protein found in all eukaryotic cells that becomes covalently attached to certain residues of other proteins, tagging a protein for intracellular proteolytic destruction.

UIBC (unsaturated iron binding capacity) - portion of transferrin that is not complexed with iron. (TIBC-serum iron = UIBC).

Unfractionated heparin - heterogeneous mixture of sulfated glycosaminoglycans (range 5000–30,000 daltons) obtained from extraction of porcine intestinal mucosa or bovine lung.

Unique identification number - number assigned to a patient admitted to the hospital that can be used to identify them. It is printed on the patient's arm band.

Universal precautions - preventative guidelines to minimize the potential exposure of health care workers to blood-borne pathogens. These guidelines include the use of gloves whenever handling any body fluid.

Untranslated region (UTR) - portion of DNA on a chromosome whose bases are not involved in protein synthesis.

Urokinase (urokinase-type plasminogen activator–uPA) - enzyme found in urine and plasma that activates plasminogen to plasmin and is used as a thrombolytic agent in the treatment of thrombosis.

Urokinase-type plasminogen activator receptor (uPAR) - endothelial cell membrane receptor that binds uPA and facilitated plasminogen activation.

▶ V

Variable number tandem repeats - DNA sequences that are tandemly repeated in a genome and that can vary among different individuals.

Vascular permeability - property of endothelial cells of blood vessels that selectively allows for exchange of gases, nutrients, and waste products.

Vasculitis - inflammation of a blood vessel.

Vasoconstriction - narrowing of the lumen of blood vessels that occurs immediately following an injury.

Vaso-occlusive crisis - acute event caused by spontaneous blockage of microvasculature by rigid sickle cells. The crisis may be triggered by infection, dehydration, decreased oxygen pressure, or slow blood flow. Often the crisis occurs without a known cause.

Vertical interactions - up-and-down interactions involving the skeletal lattice and proteins of the erythrocyte membrane. These interactions stabilize the lipid bilayer membrane.

Viral load - measuring the number of copies of HIV-1 RNA indicates a patient's viral load.

Viscosity - resistance to flow; physical property dependent on the friction of component molecules in a substance as they pass one another.

Vitamin K-dependent factors - *See* Prothrombin group.

Vitronectin - serum or extracellular-matrix glycoprotein capable of binding heparin.

von Willebrand disease - autosomal dominant hereditary bleeding disorder in which there is a lack of von Willebrand factor (VWF). This factor is needed for platelets to adhere to collagen. Platelet aggregation is abnormal with ristocetin. The bleeding time is also abnormal. The APTT may be prolonged due to a decrease in the F-VIII molecule secondary to a decrease in VWF.

von Willebrand factor (VWF) - plasma factor needed for platelets to adhere to collagen. It binds to the platelet glycoprotein Ib. It is

synthesized in megakaryocytes and endothelial cells. The VWF is a molecule of multimers. It is noncovalently linked to F-VIII in plasma.

von Willebrand factor (VWF) activity (VWF:RCo; VWF:A) - test that determines the ability of VWF to function in platelet adhesion. VWF:RCo measures the ability of the patient's VWF to support agglutination of normal platelets by ristocetin in a platelet aggregometer.

von Willebrand factor (VWF):Ag assay - immunologic test that determines the quantity of VWF protein.

von Willebrand factor (VWF) multimer - VWF molecule consisting of multiple copies of identical subunits linked together.

▶ W

Warm autoimmune hemolytic anemia - anemia resulting from the presence of IgG autoantibodies that are reactive at 37°C with antigens on subject's erythrocytes. The antibody-antigen complex on the cell membrane sensitizes the erythrocyte, which is removed in the spleen or liver.

Wedge smear - blood smear prepared on a glass microscope slide by placing a drop of blood at one end and with a second slide pulling the blood the length of the slide.

White thrombus - thrombus composed mostly of platelets and fibrin that appears light gray.

Wiskott-Aldrich Syndrome/X-linked Thrombocytopenia (WAS/XLT) - WAS is a disorder of small platelets, thrombocytopenia, and severe immune dysregulation. XLT is a disorder involving mutations of the WAS gene, which manifests as isolated thrombocytopenia without immune dysfunction.

World Health Organization (WHO) classification - classification system for the neoplastic blood disorders. It uses newer diagnostic techniques to categorize neoplasms including genetics and flow cytometry.

▶ Y

y-intercept - point where the regression line intersects the y-axis. The y-intercept is used to identify the presence of constant systematic error.

▶ Z

Zymogen - inactive precursor that can be converted to the active form by an enzyme, alkali, or acid. The inert coagulation factors are zymogens. Also called *proenzyme*.

Introduction

Shirlyn B. McKenzie, Ph.D.

■ OBJECTIVES—LEVELS I AND II

At the end of this unit of study, the student should be able to:

1. Compare the reference intervals for hemoglobin, hematocrit, erythrocytes, and leukocytes in infants, children, and adults.
2. Identify the function of erythrocytes, leukocytes, and platelets.
3. Describe the composition of blood.
4. Explain the causes of change in the steady state of blood components.
5. Describe clinical pathway, critical pathway, reflex testing, and disease management and identify the laboratory's role in developing these models.
6. Compare capitated payment, prospective payment, and fee-for-service and describe the impact of capitation on the laboratory.

CHAPTER OUTLINE

- ▶ Objectives—Levels I and II
- ▶ Key terms
- ▶ Background basics
- ▶ Case study
- ▶ Overview
- ▶ Introduction
- ▶ Composition of blood
- ▶ Reference intervals for blood cell concentration
- ▶ Hemostasis
- ▶ Blood component therapy
- ▶ The laboratory's role in disease management
- ▶ Laboratory testing in the investigation of a hematologic problem
- ▶ Summary
- ▶ Review questions
- ▶ References

KEY TERMS

Activated partial thromboplastin time (APTT)
 Capitated payment
 Complete blood count (CBC)
 Diapedese
 Erythrocytes
 Fee-for-service
 Hematocrit
 Hematology
 Hemoglobin
 Hemostasis
 Leukocytes
 Platelets
 Prothrombin time (PT)
 RBC indices
 Reflex testing
 Thrombocytes

BACKGROUND BASICS

Students should complete courses in biology and physiology before beginning this study of hematology.

CASE STUDY

We will address this case study throughout the chapter.

Aaron, a two-year-old male, was seen by his pediatrician because he had a fever of 102 to 104°F over the past 24 hours. Aaron was lethargic. Prior to this, he had been in good health except for two episodes of otitis. Consider why the pediatrician may order laboratory tests and how this child's condition might affect the composition of his blood.

OVERVIEW

The hematology laboratory is one of the busiest areas of the clinical laboratory. Even small, limited-service laboratories usually offer hematology tests. This chapter is an introduction to the composition of blood and the testing performed to identify the presence of disease. It also includes a discussion on the laboratory's role in ensuring cost-effective and diagnostically efficient testing.

INTRODUCTION

Blood has been considered the essence of life for centuries. One of the Hippocratic writings from about 400 B.C. describes the body as being a composite of four humors: black

bile, blood, phlegm, and yellow bile. Fahraeus, a twentieth-century Swedish physician, suggested that the theory of the four humors came from the observation of four distinct layers in clotted blood. In the process of clotting, blood separates into a dark-red, almost black, jellylike clot (black bile); a thin layer of oxygenated red cells (blood); a layer of white cells and platelets (phlegm); and a layer of yellowish serum (yellow bile).¹ Health and disease were thought to occur as a result of an upset in the equilibrium of these humors. This may help explain why bloodletting to purge the body of its contaminated fluids was practiced from the time of Hippocrates until the nineteenth century.

The cellular composition of blood was not recognized until the invention of the microscope. With the help of a crude magnifying device that consisted of a biconvex lens, Leeuwenhoek (1632–1723) accurately described and measured the red cells (erythrocytes). The discovery of white blood cells (leukocytes) and platelets (thrombocytes) followed after microscope lenses were improved.

As a supplement to these categorical observations of blood cells, Karl Vierordt in 1852 published the first quantitative results of blood cell analysis.² His procedures for quantification were tedious and time consuming. After several years, attempts were made to correlate blood cell counts with various disease states.

Improved methods of blood examination in the 1920s and the increased knowledge of blood physiology and blood-forming organs in the 1930s allowed the study of anemias and other blood disorders to be studied on a rational basis. In some cases, the pathophysiology of hematopoietic disorders was realized only after the patient responded to experimental therapy.

Contrary to early hematologists, modern hematologists recognize that alterations in the components of blood are the *result* of disease, not a *primary* cause of it. Under normal conditions, the production of blood cells in the bone marrow, their release to the peripheral blood, and their survival are highly regulated to maintain a steady state of morphologically normal cells. Quantitative and qualitative hematologic abnormalities may result when an imbalance occurs in this steady state.

COMPOSITION OF BLOOD

Blood is composed of a liquid called *plasma* and of cellular elements, including **leukocytes**, **platelets**, and **erythrocytes**. The normal adult has about 6 liters of this vital fluid, which composes from 7% to 8% of the total body weight. Plasma makes up about 55% of the blood volume, whereas about 45% of the volume is composed of erythrocytes and 1% of the volume is composed of leukocytes and platelets (**thrombocytes**). Variations in the quantity of these blood elements are often the first sign of disease occurring in body tissue. Changes in diseased tissue often can be detected by

laboratory tests that measure deviations from normal in blood constituents. **Hematology** is primarily the study of the formed cellular blood elements.

The principal component of plasma is water, which contains dissolved ions, proteins, carbohydrates, fats, hormones, vitamins, and enzymes. The principal ions necessary for normal cell function include calcium, sodium, potassium, chloride, magnesium, and hydrogen. The main protein constituent of plasma is albumin, which is the most important component in maintaining osmotic pressure. Albumin also acts as a carrier molecule, transporting compounds such as bilirubin and heme. Other blood proteins carry vitamins, minerals, and lipids. Immunoglobulins and complement are specialized blood proteins involved in immune defense. The coagulation proteins responsible for **hemostasis** (arrest of bleeding) circulate in the blood as inactive enzymes until they are needed for the coagulation process. An upset in the balance of these dissolved plasma constituents may indicate a disease in other body tissues.

Blood plasma also acts as a transport medium for cell nutrients and metabolites; for example, hormones manufactured in one tissue are transported by the blood to target tissue in other parts of the body. Bilirubin, the main catabolic residue of hemoglobin, is transported by albumin from the spleen to the liver for excretion. Blood urea nitrogen, a nitrogenous waste product, is carried to the kidneys for filtration and excretion. Increased concentration of these normal catabolites may indicate either increased cellular metabolism or a defect in the organ responsible for their excretion. For example, in liver disease, the bilirubin level in blood increases, indicating the end organ disease. In hemolytic anemia, however, the bilirubin concentration may rise not because of liver disease but because of the increased metabolism of hemoglobin.

When body cells die, they release their cellular constituents into surrounding tissue. Eventually, some of these constituents reach the blood. Many constituents of body cells are specific for the cell's particular function; thus, increased concentration of these constituents in the blood, especially enzymes, may indicate abnormal cell destruction in a specific organ.

Each of the three cellular constituents of blood has specific functions. Erythrocytes contain the vital protein **hemoglobin**, which is responsible for transport of oxygen and carbon dioxide between the lungs and body tissues. There are five major types of leukocytes: neutrophils, eosinophils, basophils, lymphocytes, and monocytes. They are responsible for defending the body against foreign antigens such as bacteria and viruses. Platelets are necessary for maintaining hemostasis. Blood cells circulate through blood vessels, which are distributed throughout every body tissue. Erythrocytes and platelets carry out their functions without leaving the vessels, but leukocytes **diapedese** (pass through vessel walls) to tissues where they defend against invading foreign antigens.

CASE STUDY (continued from previous page)

1. If Aaron was diagnosed with otitis media, what cellular component(s) in his blood would be playing a central role in fighting this infection?

▶ REFERENCE INTERVALS FOR BLOOD CELL CONCENTRATION

Physiologic differences in the concentration of cellular elements may occur according to race, age, sex, and geographic location; pathologic changes in specific blood cell concentrations may occur as the result of disease or injury. Whites have slightly higher cell counts than blacks: Their leukocyte counts are higher by $0.5 \times 10^9/L$, hemoglobin levels by 0.7 g/dL, **hematocrit** by 0.17 L/L, and erythrocyte counts by $0.05 \times 10^{12}/L$.³

The greatest differences in reference intervals occur between newborns and adults. Generally, newborns have a higher erythrocyte concentration than any other age group. The erythrocytes are also larger than those of adults. For six months after birth, erythrocytes decrease and then slowly increase. Hemoglobin and erythrocyte counts increase in children between the ages of 5 and 17.³ The leukocyte concentration is also increased at birth but decreases after the first year of life. A common finding in young children is an absolute and relative lymphocytosis. After 12 years of age, males have higher hemoglobin, hematocrit, and erythrocyte levels than females. Tables A through K on the inside covers of this text give hematologic reference intervals for various age groups.

Each individual laboratory must determine reference intervals of hematologic values to account for the physiologic differences of a population in a specific geographical area. Reference values are determined by calculating the mean for a group of healthy individuals and reporting the reference interval as the mean ± 2 standard deviations. This interval represents the reference interval for 95% of normal individuals. A value just below or just above this interval is not necessarily abnormal; normal and abnormal overlap. Statistical probability indicates that about 5% of normal individuals will fall outside the ± 2 standard deviation range. The farther a value falls from the reference interval, however, the more likely the value is to be abnormal.

CASE STUDY (continued)

2. Aaron's physician ordered a complete blood count (CBC). The results are Hb 115 g/L; Hct 0.34 L/L; RBC $4.0 \times 10^{12}/L$; WBC $18 \times 10^9/L$. What parameters, if any, are outside the reference intervals? Why do you have to take Aaron's age into account when evaluating these results?

▶ **HEMOSTASIS**

Hemostasis is the process of forming a barrier (blood clot) to blood loss when the vessel is traumatized and limiting the barrier to the site of injury. Hemostasis occurs in stages called primary and secondary hemostasis and fibrinolysis. These stages are the result of interaction of platelets, blood vessels, and proteins circulating in the blood. An upset in any of the stages can result in bleeding or abnormal blood clotting (thrombosis). Laboratory testing for abnormalities in hemostasis is usually performed in the hematology section of the laboratory. Alternatively, hemostasis testing may be performed in a separate section of the laboratory.

✓ Checkpoint! 1

What cellular component of blood may be involved in disorders of hemostasis?

▶ **BLOOD COMPONENT THERAPY**

Blood components may be used in therapy for various hematologic and nonhematologic disorders. Whole blood collected from donors can be separated into various cellular and fluid components. Only the specific blood component (i.e., platelets for thrombocytopenia or erythrocytes for anemia) needed by the patient will be administered. In addition, the components can be specially prepared for the patient's specific needs (i.e., washed erythrocytes for patients with IgA deficiency to reduce the risk of anaphylactic reactions). Table 1 ★ lists the various components that can be prepared for specific uses. The reader may want to refer back to this table when reading about therapies that use these components in subsequent chapters.

★ **TABLE 1**

Blood Components and Their Uses		
Component Name	Composition	Primary Use
Whole blood	Red blood cells and plasma	Not used routinely. May be used in selected trauma, autologous transfusions, and neonatal situations; increases oxygen-carrying capacity and volume
Packed red blood cells (PRBC)	PRBC	Symptomatic anemia to increase oxygen-carrying capability
PRBC, washed	PRBC; plasma and most leukocytes and platelets removed	For individuals with repeated allergic reactions to components containing plasma; for IgA-deficient individuals with anaphylactic reactions to products containing plasma
PRBC, leukoreduced	PRBC; WBC removed	Decrease the risk of febrile nonhemolytic transfusion reaction, HLA sensitization, and cytomegalovirus (CMV) transmission
PRBC, frozen, deglycerolized	PRBC frozen in cryoprotective agent, thawed, washed	For individuals with rare blood groups (autologous donation)
PRBC, irradiated	PRBC with lymphocytes inactivated	Reduce risk of graft-vs-host disease
Platelets, pooled*	4–6 units of random donor platelets	Increase platelet count and decrease bleeding when there is a deficiency or abnormal function of platelets
Platelets, single* donor (pheresis)	Equivalent of 4–6 donor platelets collected from single donor	Patients refractory to random platelet transfusion or to increase platelet count due to a deficiency or abnormal function of platelets
Fresh frozen plasma (FFP)	Plasma with all stable and labile coagulation factors; frozen within 8 hours of collection of unit of blood	Patients with multiple coagulation factor deficiencies; DIC; used with packed RBC in multiple transfusions
Cryoprecipitated AHF**	Concentrated F-VIII, fibrinogen, F-XIII, VWF***	Hypofibrinogenemia, hemophilia A, von Willebrand's disease, F-XIII deficiency
Plasma, cryo-poor	Plasma remaining after cryo removed	Thrombotic thrombocytopenic purpura (TTP)
Liquid plasma	Plasma not frozen within 8 hours of collection	Stable coagulation factor deficiency; volume replacement
Granulocytes	Granulocytes	Neutropenic patient who is septic and unresponsive to antimicrobials and who has chance of marrow recovery

*Platelets may also be leukoreduced or irradiated. See PRBC for reasons.

**Cryoprecipitated antihemophilic factor, or cryo.

***von Willebrand factor.

▶ THE LABORATORY'S ROLE IN DISEASE MANAGEMENT

In the United States, personal health care spending accounts for about 14% of the gross domestic product (GDP).⁴ Yet only 3.5% of the amount spent on personal health care is for laboratory tests. In 2005, 16.6% of hospital outpatient charges under Medicare were for laboratory services.⁴

The rising cost of health care associated with diagnosis and treatment of disease has caused increased scrutiny of the health care system. In an attempt to gain an understanding of these costs and to identify whether medical resources are used inappropriately, researchers studied medical practice patterns. Results revealed overutilization of services and significant variations in diagnosis and treatment of common disorders.^{5,6,7} Study of Medicare records reveals variations in the quality of health care across geographical regions as well as disparities in types of procedures performed.⁸ Concerns over these rising costs and variations in practice resulted in the implementation of cost-containment strategies by insurers and health care organizations. Many insurers went from a fee-for-service reimbursement to a capitated payment system. **Fee-for-service** plans allow consumers to choose their own health care providers who determine the fees. Under **capitated payment** plans, the insurer contracts with certain health care providers who agree to provide services for a defined population on a per-member fee schedule. The insurer determines who the providers will be.

Under Medicare (the federal health care program for older Americans), payment for inpatient services is based on the prospective payment system (PPS). This payment system reimburses the hospital a fixed amount for services provided to a patient based on medical diagnosis (cost per case). In the capitated payment plan and the PPS plan, every test or service performed is a cost to the provider who will be reimbursed only a fixed amount regardless of the amount of service provided. Laboratory testing on outpatients is based on a fee schedule (Section 1833(h) of the Social Security Act). Payment is the lesser of the amount billed, the fee for a given geographical area, or the national limit. The laboratory uses laboratory test codes—current procedural terminology (CPT)—when billing Medicare.

These managed cost plans are an attempt by third-party payers (insurers) to ensure that services provided are necessary and reasonably priced. The new reimbursement systems place the provider at risk to provide necessary services while controlling overall costs. Thus, laboratory services must be considered a resource to be managed rather than a source of revenue.

The health care system is now interested in managing not only costs but also care. The goal of managed care is to provide quality care while maximizing efficiency and effectiveness. The use of disease management (DM) models is an attempt to meet this goal. Under these models, a protocol is

designed to identify patients with a specific disease, and a therapy is developed to maximize clinical outcomes at an acceptable cost. The DM model for a particular disease is based on evidence in the literature and other sources.⁹ Thus, DM is a population-level approach to improving health status rather than a patient-focused approach as has dominated the U.S. health care system. DM is designed to improve the value of health care delivery from the perspectives of providers, patients, and insurers. This value concept is broad based and includes the maximization of clinical, economic, quality-of-life, and satisfaction outcomes for the lowest expenditure of time and resources.¹⁰

Many organizations are creating and adopting new strategies to provide cost-effective and diagnostically efficient health care. These strategies include clinical pathways, also known as *practice guidelines*, and critical pathways (care plans). Sometimes clinical pathways and critical pathways are considered the same and the terms are used interchangeably. Here *clinical pathways* refer to plans and procedures developed by physicians using a foundation of scientific outcomes for diagnosing and treating a particular disease.^{7,10} The guidelines indicate tests, procedures, and treatments. *Critical pathways* refer to the care and services provided by an interdisciplinary health care team after treatment decisions have been made. Teams of practitioners who have the knowledge and perspectives to view the total care process develop these pathways.¹¹ Clinical and critical pathways are usually designed for common and/or high-cost diagnoses. They are not appropriate in complicated cases.

These evolving health care practices require a partnership among physicians, nurses, allied health practitioners, patients, and health care administrators. As the complexity of laboratory testing increases, communication between the physician and clinical laboratory provider must increase. The laboratory provider must be able to correlate laboratory test results with clinical disease states, pathophysiology, and treatment; effectively communicate these results to the physician; and suggest cost-effective follow-up testing when appropriate.¹² The focus should be on changing structure and processes to improve patient outcomes. The goal is optimal utilization of laboratory testing, not necessarily less testing. The laboratory can take proactive approaches to control test utilization. These include:

- Assisting in the development of critical pathways
- Managing the test ordering system
- Instituting sequential testing protocols
- Eliminating incorrect use of tests
- Designing wellness panels

As more outcome studies are performed to determine which processes and treatments are most effective and as information on the value of laboratory testing is documented, the role of laboratory tests in clinical and critical pathways will become more important. Physicians will want to order the appropriate tests under the guidelines.

▶ LABORATORY TESTING IN THE INVESTIGATION OF A HEMATOLOGIC PROBLEM

A physician's investigation of a hematologic problem includes taking a medical history and performing a physical examination. Clues provided by this preliminary investigation will help guide the physician's choice of laboratory tests to help confirm the diagnosis. The challenge is to select appropriate tests that contribute to a cost-efficient and effective diagnosis. Laboratory testing usually begins with screening tests; based on results of these tests, more specific tests, are ordered. Repeat tests may be ordered to track disease progression, evaluate treatment, identify side effects and complications, or assist in prognosis.

Hematology screening tests include the **complete blood count (CBC)**, which quantifies the white blood cells (WBC), red blood cells (RBC), hemoglobin, hematocrit, and platelets and calculates the **RBC indices**. The indices are calculated from the results of the hemoglobin, RBC count, and hematocrit to define the size and hemoglobin content of RBCs. The indices are important parameters in differentiating causes of anemia and help direct further testing. The CBC may also include a WBC differential. This procedure enumerates the five types of WBCs and reports each as a percentage of the total WBC count. A differential is especially helpful if the WBC count is abnormal. When it is, the differential identifies which cell type is abnormally increased or decreased and determines whether immature and/or abnormal forms are present, thus, providing a clue to diagnosis. The morphology of RBCs and platelets is also studied as a routine part of the differential. If a hemostasis problem is suspected, the screening tests include the platelet count, **prothrombin time (PT)**, and **activated partial thromboplastin time (APTT)**. These tests provide clues that guide the choice of follow-up tests to help identify the problem. Follow-up tests may include not only hematologic tests but also chemical, immunologic, and/or molecular analysis.

Follow-up testing that is done based on results of screening tests is referred to as **reflex testing**. As scientists learn more about the pathophysiology and treatment of hematopoietic disease, the number of tests designed to assist in diagnosis expands. To help physicians select the most cost-effective testing strategies, the laboratory must collaborate with physicians to design reflex testing protocols for

common diseases.¹³ These protocols are sometimes referred to as *algorithms*.

Throughout this text, readers are urged to use the reflex testing concept in their thought processes when studying the laboratory investigation of a disease. Each hematopoietic disorder is discussed in the following order: pathophysiology, clinical findings, laboratory findings, and treatment. The reader should consider which laboratory tests provide the information necessary to identify the cause of the disorder based on the suspected disorder's pathophysiology. Although it is unusual for the physician to provide a patient history or diagnosis to the laboratory when ordering tests, this information is often crucial to direct investigation and assist in interpretation of the test results. Perhaps with the medical necessity guidelines enforced by Medicare, the laboratory will be provided this information in the future. *Medical necessity* refers to the need for a test to be done given the patient's diagnosis. Medicare carriers determine medical necessity and require that the diagnostic related group (DRG) code accompany the request for reimbursement of tests the laboratory performs. In any case, if laboratory professionals need more patient information in order to perform testing appropriately, they should obtain the patient's chart or call the physician.

Checkpoint! 2

A 13-year-old female was seen by her physician for complaints of a sore throat, lethargy, and swollen lymph nodes. A CBC was performed with the following results: Hb 90 g/L; Hct 0.30 L/L; RBC $3.8 \times 10^{12}/L$; WBC $15 \times 10^9/L$. Is reflex testing suggested by these results?

SUMMARY

Hematology is the study of the cellular components of blood: erythrocytes, leukocytes, and platelets. Changes in the concentrations of these cells occur from infancy until adulthood. Diseases can upset the steady state concentration of these parameters. A CBC is usually performed as a screening test to determine whether there are quantitative abnormalities in blood cells. The physician may order reflex tests if one or more of the CBC parameters are outside the reference interval.

Changes in the health care system focus on containing costs while maintaining quality of care. The laboratory's role in this system is to work with physicians to optimize utilization of laboratory testing.

REVIEW QUESTIONS

LEVELS I AND II

1. In which group of individuals would you expect to find the highest reference intervals for hemoglobin, hematocrit, and erythrocyte count? (Objective 1)
 - a. newborns
 - b. males older than 12 years of age
 - c. females older than 17 years of age
 - d. children between 1 and 5 years of age
2. Which cells are important in transporting oxygen and carbon dioxide between the lungs and body tissues? (Objective 2)
 - a. platelets
 - b. leukocytes
 - c. thrombocytes
 - d. erythrocytes
3. Forty-five percent of the volume of blood is composed of: (Objective 3)
 - a. erythrocytes
 - b. leukocytes
 - c. platelets
 - d. plasma
4. Alterations in the concentration of blood cells generally are the result of: (Objective 4)
 - a. laboratory error
 - b. amount of exercise before blood draw
 - c. a disease process
 - d. variations in analytical equipment
5. Leukocytes are necessary for: (Objective 2)
 - a. hemostasis
 - b. defense against foreign antigens
 - c. oxygen transport
 - d. excretions of cellular metabolites
6. Laboratories can use which type of testing to help direct the physician's selection of appropriate testing after screening tests are performed? (Objective 5)
 - a. reflexive based on results of screening tests
 - b. manual repeat of abnormal results
 - c. second test by a different instrument
 - d. standing orders for all inpatients
7. Managed care plans use which type of payment system to help contain costs of medical care? (Objective 6)
 - a. fee-for-service
 - b. cost-per-case
 - c. capitation
 - d. disease containment
8. A model used to help diagnose and manage the care of the diabetic patient in a cost-effective and diagnostically efficient manner while providing quality care is an example of: (Objective 5)
 - a. reflex testing
 - b. disease management
 - c. capitated payment
 - d. critical pathway
9. The payment system that Medicare uses to contain costs is: (Objective 6)
 - a. capitated payment
 - b. disease management
 - c. fee-for-service
 - d. PPS
10. Under the capitation payment system, the laboratory is viewed as a: (Objective 6)
 - a. revenue center
 - b. profit center
 - c. loss center
 - d. cost center

ANSWERS TO CASE STUDY QUESTIONS

Case Summary: Aaron had clinical signs of infection and a past history of ear infections. The CBC results revealed a high WBC count consistent with an infectious process. The diagnosis of otitis media usually can be made by history and physical examination. Laboratory tests are not required.

Question:

1. If Aaron was diagnosed with otitis media, what cellular component(s) in his blood would be playing a central role in fighting this infection?

Explanation:

The leukocytes, or white blood cells, are the cells that are central in fighting infection.

Question:

2. Aaron's physician ordered a CBC. The results are Hb 11.5 g/dL; Hct 0.34L/L; RBC $4.0 \times 10^{12}/L$; WBC $18 \times 10^9/L$. What parameters, if any, are outside the reference range? Why do you have to take Aaron's age into account when evaluating these results?

Explanation:

The WBC count is increased. The upper reference range for WBC in a 2-year-old is $17 \times 10^9/L$. It is important to consider Aaron's age because the reference ranges for blood cell concentrations are different in children of various ages and are different from those in adults.

ANSWERS TO CHECKPOINTS

Checkpoint! 1

What cellular component of blood may be involved in disorders of hemostasis?

Answer

The platelets are involved in hemostasis.

Checkpoint! 2

Is reflex testing suggested by these results?

Answer

The girl has a decreased hemoglobin and increased WBC count. Reflex testing is suggested to help identify the cause of these abnormal results. A differential will identify the types of leukocytes that are present in increased concentrations and give clues to the diagnosis. Further laboratory testing can also help identify the cause of the anemia.

Cellular Homeostasis

J. Lynne Williams, Ph.D.

■ OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. Describe the location, morphology, and function of subcellular organelles of a cell.
2. Describe the lipid asymmetry found in the plasma membrane of most hematopoietic cells.
3. Differentiate the parts of the mammalian cell cycle.
4. Define R (restriction point) and its role in cell cycle regulation.
5. Define *apoptosis* and explain its role in normal human physiology.
6. Classify and give examples of the major categories of initiators and inhibitors of apoptosis.
7. List the major events regulated by apoptosis in hematopoiesis.

■ OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. Explain the significance of SNPs, introns, exons, UTRs, post-translational protein modifications.
2. List the components and explain the function of the Ubiquitin-Proteasome system.
3. Define *cyclins* and *Cdks* and their role in cell cycle regulation; describe the associated Cdk partners and function of cyclins D, E, A, and B.
4. Define *CAK* (Cdk-activating kinase) and the two major classes of CKIs (cyclin-dependent kinase inhibitors) and describe their function.
5. Compare the function of cell-cycle checkpoints in cell-cycle regulation.
6. Describe/illustrate the roles of p53 and pRb in cell-cycle regulation.
7. Propose how abnormalities of cell-cycle regulatory mechanisms can lead to malignancy.
8. Define *caspases* and explain their role in apoptosis.
9. Differentiate the extrinsic and intrinsic pathways of cellular apoptosis.
10. Define and contrast the roles of proapoptotic and antiapoptotic members of the Bcl-2 family of proteins.
11. Describe apoptotic regulatory mechanisms.
12. Give examples of diseases associated with increased apoptosis and inhibited (decreased) apoptosis.
13. Define, and give examples of, epigenetics, oncogenes and tumor suppressor genes and their roles in cell biology.
14. Differentiate using morphologic observations, the processes of necrotic cell death and apoptotic cell death.

 Ubiquitin
 Untranslated regions (UTRs)

BACKGROUND BASICS

Level I and Level II

Students should have a solid foundation in basic cell biology principles, including the component parts of a cell and the structure and function of cytoplasmic organelles. They should have an understanding of the segments composing a cell cycle (interphase and mitosis) and the processes that take place during each stage.

OVERVIEW

Not all hematology courses include the material in this chapter. However, it is a review of basic principles of cellular metabolism and homeostasis, which provide the foundation for understanding many of the pathologic abnormalities underlying the hematologic disorders in subsequent chapters. The chapter begins with a review of the basic components and cellular processes of a normal cell and presents the concept of tissue homeostasis. Cellular processes that maintain tissue homeostasis—cell proliferation and cell death—are discussed at the functional and molecular level. The chapter concludes with a discussion of what happens when genes controlling cell proliferation, differentiation, and/or cell death mutate.

INTRODUCTION

The maintenance of an adequate number of cells to carry out the functions of the organism is referred to as **tissue homeostasis**. Tissue homeostasis depends on the careful regulation of several cellular processes, including cellular proliferation, cellular differentiation, and cell death (apoptosis). A thorough understanding of cell structural components as well as the processes of cell division and cell death allows us to understand not only the normal (physiologic) regulation of the cells of the blood but also disease processes in which these events become dysregulated (e.g., cancer).

CELL MORPHOLOGY REVIEW

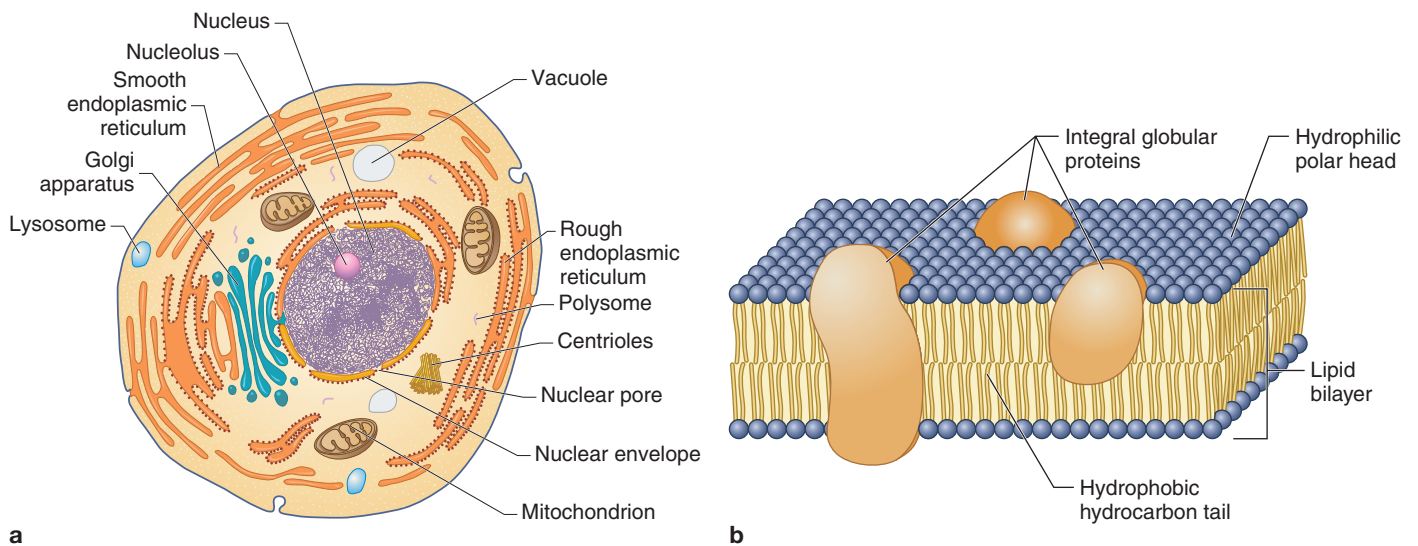

A basic understanding of cell morphology is essential to the study of hematology because many hematologic disorders are accompanied by abnormalities or changes in morphology of cellular or subcellular components and by changes in cell concentrations.

A cell is an intricate, complex structure consisting of a membrane-bound aqueous solution of proteins, carbohydrates, fats, inorganic materials, and nucleic acids. The nucleus, bound by a double layer of membrane, controls and directs the development, function, and division of the cell. The cytoplasm, where most of the cell's metabolic reactions take place, surrounds the nucleus and is bound by the cell membrane. The cytoplasm contains highly ordered organelles, which are membrane-bound components with specific cellular functions (Figure 1a■). The different kinds of organelles and the quantity of each depend on the function of the cell and the state of maturation.

CELL MEMBRANE

The outer boundary of the cell, the plasma (cell) membrane, is often considered a barrier between the cell and its environment. In fact, it functions to allow the regulated passage of ions, nutrients, and information between the cytoplasm and its extracellular milieu and thus determines the interrelationships of the cell with its surroundings.

The plasma membrane consists of a complex, ordered array of lipids and proteins that serves as the interface between the cell and its environment (Figure 1b■). The plasma membrane is in the form of a phospholipid bilayer punctuated by proteins. The lipids have their polar (hydrophilic) head groups directed toward the outside and inside of the cell and their long-chain (hydrophobic) hydrocarbon tails directed inward. While the plasma membrane has traditionally been described as a “fluid mosaic” structure,¹ it is in fact highly ordered with asymmetric distribution of both membrane lipids and proteins. The lipid and protein compositions of the outside and inside of the membrane differ from

■ **FIGURE 1** a. Drawing of a cell depicting the various organelles. b. The fluid mosaic membrane model proposed by Singer and Nicholson.

one another in ways that reflect the different functions performed at the two surfaces of the membrane.

Four major phospholipids are found in the plasma membrane: phosphatidylethanolamine (PE), phosphatidylserine (PS), phosphatidylcholine (PC), and sphingomyelin (SM). (Web Figure 1 ■). Most blood cells have an asymmetric distribution of these phospholipids with PE and PS occurring in the inner layer of the lipid bilayer and PC and SM occurring predominantly in the outer layer. The membrane lipids can freely diffuse laterally throughout their own half of the bilayer, or they may flip-flop from one side of the bilayer to the other in response to certain stimuli as occurs in platelets when activated. Membrane lipids including phospholipids, cholesterol, lipoproteins, and lipopolysaccharides contribute to the basic framework of cell membranes and account for the cell's high permeability to lipid-soluble substances. Different mixtures of lipids are found in the membranes of different types of cells.

Although lipids are responsible for the basic structure of the plasma membrane, most of the specific functions of the membrane are carried out by proteins. The proteins of the membrane provide selective permeability and transport of specific substances, structural stability, enzymatic catalysis, and cell-to-cell recognition functions. The membrane proteins are divided into two general groups: integral (transmembrane) proteins and peripheral proteins. The peripheral proteins are located on either the cytoplasmic or on the extracellular half of the lipid bilayer. Some of the integral proteins span the entire lipid bilayer while other integral proteins only partially penetrate the membrane. Some membrane-spanning proteins traverse the membrane once (e.g., erythrocyte glycophorin A) while others criss-cross the membrane multiple times (e.g. erythrocyte Band 3, the cation transporter). In some cells, such as

erythrocytes, peripheral proteins on the cytoplasmic side of the membrane form a lattice network that functions as a cellular cytoskeleton, imparting order on the membrane.

Carbohydrates linked to membrane lipids (glycolipids) or proteins (glycoproteins) may extend from the outer surface of the membrane. Functions of the carbohydrate moieties include specific binding, cell-to-cell recognition, and cell adhesion. The sugar groups are added to the lipid or protein molecules in the lumen of the Golgi apparatus after synthesis by the endoplasmic reticulum. Many of the glycoprotein transmembrane proteins serve as receptors for extracellular molecules such as growth factors. Binding of the specific ligand to a receptor may result in transduction of a signal to the cell's interior without passage of the extracellular molecule through the membrane.

CYTOPLASM

The cytoplasm, or cytosol, is where the metabolic activities of the cell including protein synthesis, growth, motility, and phagocytosis take place. The structural components, called *organelles*, include the mitochondria, lysosomes, endoplasmic reticulum (ER), Golgi apparatus, ribosomes, granules, microtubules, and microfilaments (Table 1 🌱). Organelles and other cellular inclusions lie within the cytoplasmic matrix. The composition of the cytoplasm depends on cell lineage and degree of cell maturity. The appearance of cytoplasm in fixed, stained blood cells is important in evaluating the morphology, classifying the cell, and determining the stage of differentiation. Immature or synthetically active blood cells stained with Romanowsky stains have very basophilic (blue) cytoplasm due to the large quantity of ribonucleic acid (RNA) they contain.

★ TABLE 1

Cellular Organelles

Structure	Composition	Function
Ribosomes	RNA + proteins	Assemble amino acids into protein
“Free”	Scattered in the cytoplasm	Synthesis of protein destined to remain in cytosol
“Fixed”	Linked by mRNA-forming polyribosomes	
“Fixed”	Ribosomes bound to outer surface of RER	Synthesis of protein destined for export from the cell
Endoplasmic reticulum (ER)	Interconnecting membrane-bound tubules and vesicles	Synthesis and transport of lipid and protein
Rough ER (RER)	Studded on outer surface with ribosomes	Abundant in cells synthesizing secretory protein; protein transported to Golgi
Smooth ER (SER)	Lacks attached ribosomes	Lipid synthesis, detoxification, synthesis of steroid hormones
Golgi apparatus	Stacks of flattened membranes located in juxtannuclear region	Protein from RER is sorted, modified (e.g., glycosylated), and packaged; forms lysosomes
Lysosomes	Membrane-bound sacs containing hydrolytic enzymes	Destruction of carbohydrates, lipids, and proteins (phagocytosed material or metabolites)
Mitochondria	Double-membrane organelle; inner folds (cristae) house enzymes of aerobic metabolism	Oxidative phosphorylation (ATP production) abundant in metabolically active cells
Cytoskeleton	Microfilaments, intermediate filaments, and microtubules	Gives the cell shape, provides strength, and enables movement of cellular structures
Microfilaments	Fine filaments (5–9 nm); polymers of actin	Control shape and surface movement of most cells
Intermediate filaments	Rope-like fibers (~10 nm); composed of number of fibrous proteins	Provide cells with mechanical strength
Microtubules	Hollow cylinders (~25 nm); composed of protein tubulin	Important in maintaining cell shape and organization of organelles; form spindle apparatus during mitosis
Centrosome	“Cell center”; includes centrioles	Microtubule-organizing center; forms poles of mitotic spindle during anaphase
Centrioles	Two cylindrical structures arranged at right angles to each other; consist of nine groups of three microtubules	Enable movement of chromosomes during cell division; self-replicate prior to cell division

✓ Checkpoint! 1

What is meant by the phrase “lipid asymmetry” when describing cell membranes?

NUCLEUS

The nucleus contains the genetic material, deoxyribonucleic acid (DNA), responsible for the regulation of all cellular functions. The nuclear material, chromatin, consists of DNA and associated structural proteins (histones) packaged into chromosomes. The total genetic information stored in the chromosomes of an organism constitutes its **genome**. The fundamental subunit of chromatin is the nucleosome, a beadlike segment of chromosome composed of about 180 base pairs of DNA wrapped around a histone protein. The linear array of successive nucleosomes gives chromatin a “beads-on-a-string” appearance in electron micrographs. The

appearance of chromatin varies, presumably depending on activity. It is generally considered that the dispersed, lightly stained portions of chromatin (euchromatin) represent unwound or loosely twisted regions of chromatin that are transcriptionally active. The condensed, more deeply staining chromatin (heterochromatin) is believed to represent tightly twisted or folded regions of chromatin strands that are transcriptionally inactive. In addition to being less tightly associated with the histones, active chromatin characteristically has “unmethylated” promoter regions and highly acetylated histones (see the later section on “Epigenetics”). The ratio of euchromatin to heterochromatin depends on the cell activity with the younger or more active cells having more euchromatin and a finer chromatin structure. The nuclei of most active cells contain from one to four pale staining nucleoli. The nucleolus (singular) consists of RNA and proteins and is believed to be important in RNA synthesis. The nucleolus of very young blood cells is easily seen with brightfield microscopy on stained smears.

The nuclear contents are surrounded by a double membrane, the nuclear envelope. The outer membrane (cytoplasmic side) is continuous with the ER and has a polypeptide composition distinct from that of the inner membrane. The gap between the two membranes (~50 nm) is called the *perinuclear space*. The nuclear envelope is interrupted at irregular intervals by openings consisting of nuclear pore complexes (NPCs), which provide a means of communication between nucleus and cytoplasm. They constitute envelope-piercing channels that function as selective gates allowing bidirectional movement of molecules. The nucleus exports newly assembled ribosomal subunits while importing proteins such as transcription factors and DNA repair enzymes.

Checkpoint! 2

Explain the difference between densely staining chromatin and lighter staining chromatin when viewing blood cells under a microscope.

▶ CELLULAR METABOLISM: DNA DUPLICATION, TRANSCRIPTION, TRANSLATION

Genomics is the study of the entire genome of an organism. *Functional genomics* is the study of the actual gene expression “profile” of a particular cell at a particular stage of differentiation or functional activity (i.e., which genes are actively producing mRNA). Microarray or expression array technology can be used to determine the mRNA profile being produced by a cell or tissue of interest, which would reflect which genes are actively being transcribed. The field of **proteomics** is the study of the composition, structure, function, and interaction of the proteins being produced by a cell. [Genetic nomenclature has specific rules for gene and protein font styles. To differentiate between the gene and its protein, genes are written as italicized capital letters (i.e., *RB*) while the gene’s protein product is written with only the first letter capitalized and it is not italicized. This style is used in this text.]

Genes, which contain the genetic information of an individual, constitute regions (loci) of the chromosome on which they are located. Most genes are not composed of continuous stretches of nucleotides. Rather, they are organized into segments called **exons**, which are separated by intervening sequences called **introns**. The nucleotide base pairs of the introns do not code for protein. When a gene is transcribed into RNA, the entire sequence of exons and introns is copied as *pre-messenger RNA* (sometimes called *heteronuclear RNA/hnRNA*). Subsequently, the nucleotides corresponding to the intron sequences are spliced out, resulting in the shorter, mature mRNA. However, not all of the mature mRNA will be translated into protein. Both the 5’ and the 3’ ends of the mature mRNA encoding the protein to be produced contain **untranslated regions (UTRs)**. The UTRs influence the stability of the mRNA and the efficiency of translation to pro-

tein. These regions have been shown to play an important role in regulating the proteins involved in iron metabolism in developing erythrocytes.

Sometimes large genes with multiple exons can be “read” in a variety of ways, resulting in different proteins based on alternative transcriptions of the gene. The human genome is estimated to contain ~35,000 genes; however, alternate splicing allows for greater genetic complexity than the number of genes would suggest.

Different individuals do not have identical DNA sequences. When a cell replicates its DNA during S phase of the cell cycle (discussed later), the process does not occur without error. It has been estimated that ~0.01% of the 6 billion base pairs are copied incorrectly during each S-phase.² The process of DNA replication is coupled with DNA repair systems to make sure that errors in copying are corrected. If these errors cannot be corrected, the cell may activate its internal apoptotic mechanism (discussed later), resulting in cell death. Errors in DNA replication that cannot be corrected and that subsequently result in activation of apoptosis are believed to be the underlying basis for the large degree of ineffective erythropoiesis in megaloblastic anemias. In addition to correcting copying errors, DNA repair mechanisms correct other damage to DNA that could have occurred. Failure of these DNA repair mechanisms often contribute to the development of a malignancy.

If the miscopied base pair is not corrected, a mutation (or new polymorphism) may occur. Variations of the genetic sequence of a gene that may be seen in different individuals are called *alleles*. **Polymorphism** is the term used to describe the presence of alternate copies (alleles) of a gene. Not every alteration in DNA produces an abnormality. For instance, many of the alternate alleles identified for human globin chains do not result in any abnormality of function. Generally, if the change in DNA sequence does not result in an abnormality of function, the change is called a *polymorphism*. Often the word **mutation** is used only to describe a deleterious change in a gene (e.g., the β^S globin mutation in sickle cell anemia).

A region of DNA that differs in only a single DNA nucleotide is called a **single nucleotide polymorphism (SNP)**. SNPs are found at approximately 1 in every 1000 base pairs in the human genome (resulting in ~2.5 million SNPs in the entire genome). To be considered a true polymorphism, an SNP must occur with a frequency of >1% in the population. If the alteration is known to be the cause of a disease, the nucleotide change is considered a mutation rather than an SNP.

CONTROL OF GENE EXPRESSION

Control of gene expression is a complex process. It must be regulated in both time (i.e., developmentally) and location (i.e., tissue-specific gene expression). Most genes have a promoter region upstream of the coding region of the gene. **Transcription factors (TFs)** are proteins that bind to the

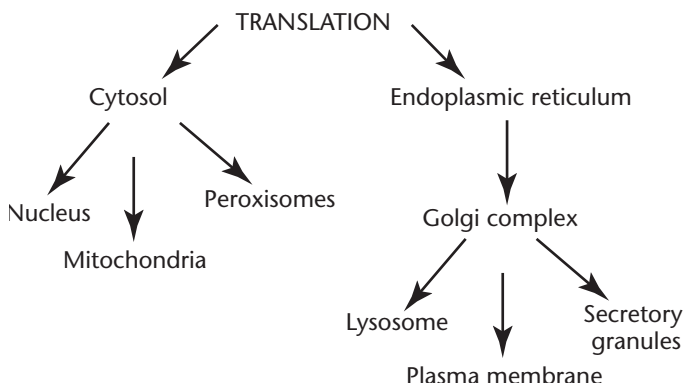

DNA of the promoter region of a target gene and regulate expression of that gene. TFs may function to either activate or repress the target gene (some TFs do both, depending on the specific targeted gene). Often TFs are tissue specific, such as GATA-1, a known erythroid specific TF that regulates expression of glycoporphin and globin chains in developing cells of the erythroid lineage.³

In addition to the basic on/off function of the promoter region, there are additional layers of control of gene expression. Some genes have enhancer elements or silencer elements, which are nucleotide sequences that can amplify or suppress gene expression, respectively.² These response elements influence gene expression by binding specific regulatory proteins (activators, repressors).

Many signals that regulate genes come from outside the cell (e.g., cytokine control of hematopoiesis). The external molecule (cytokine) or ligand binds to its specific receptor on the surface of the cell. The binding of ligand to receptor activates the receptor and initiates a cell-signaling pathway that conveys the activation signal from the receptor to the nucleus. The end result is an interaction with DNA (e.g., TF binding to one or more gene promoter regions) that either activates or represses the target gene(s).

PROTEIN SYNTHESIS AND PROCESSING

Synthesis of proteins (polypeptides) occurs on ribosomes. The newly formed polypeptides are transported to their eventual destination through a sorting mechanism within the cytoplasm.⁴ If the polypeptide lacks a “signal sequence,” translation is completed in the cytosol, and the protein either stays in the cytosol or is incorporated into the nucleus, mitochondria, or peroxisomes. If the polypeptide contains a signal sequence, the polypeptide is extruded into the lumen of the endoplasmic reticulum (which ultimately gives rise to the more distal structures of the secretory apparatus—the Golgi, endosomes, lysosomes, and plasma membrane).

Following import into the ER, proteins undergo appropriate folding and may undergo **post-translational modifications**. These are modifications in protein structure that occur after the protein is produced by translation on the ribosome. These changes include the addition of nonprotein groups (such as sugars or lipids), modification of existing amino acids (such as the γ -carboxylation of certain coagulation proteins), or cleavage of the initial polypeptide product resulting in a multi-chain molecule. As the proteins exit the ER, they may be accompanied by molecules that facilitate their transfer from the ER to the Golgi apparatus. A mutation in one of these transfer molecules, ERGIC-53, is the cause of the hemostatic disorder combined F-V-VIII deficiency. During transport through the Golgi, additional processing of the proteins occurs.

The primary structure of a protein is defined by its amino acid sequence (see Web Table 1 for review of the amino acids and their shorthand notations). A protein emerges from the ribosome in an extended, linear conformation. Subsequently, local regions are folded into specific conformations, the protein's secondary structure, determined by the primary amino acid sequence. The two major secondary protein structures are α -helices and β -pleated sheets. Most proteins are made up of combinations of α -helices and β -sheets connected by regions of a less regular structure termed *loops*. *Molecular chaperones* are cytoplasmic proteins that assist the polypeptide in this folding process. The tertiary structure of a protein refers to its unique three-dimensional shape determined by the folding of secondary structures. Sometimes appropriately folded protein monomers are assembled with other proteins to form multisubunit complexes (also facilitated by chaperones). The *quaternary structure of a protein* refers to the assembly of independently synthesized polypeptide chains into a multimeric protein (e.g., the $\alpha_2\beta_2$ tetramer, which constitutes hemoglobin A).

Proteins are often described as being made up of *domains*. Frequently, a domain is encoded in a single exon and represents a region of the polypeptide chain that can fold into a stable tertiary structure. The domains of a protein are often used to designate the location of a particular functional or structural attribute.

A mutation that alters a protein's amino acid sequence can result in failure to function. Failure to function can result from a mutation of a critical functional residue or from the amino acid alteration preventing the protein from folding into its proper three-dimensional structure. Improperly folded proteins are marked for destruction and degraded (via the ubiquitin system).

Checkpoint! 3

What is the difference between a polymorphism and a mutation?

THE UBIQUITIN SYSTEM

The ubiquitin system is responsible for disposing of damaged or misfolded proteins.⁴ In addition, it regulates numerous cellular processes (e.g., cell-cycle progression, cellular differentiation) by the timed destruction of key regulatory proteins (e.g., cyclins, membrane receptors, transcription factors). It is a nonlysosomal, proteolytic mechanism in the cytoplasm of most cells.

Molecules destined for destruction are tagged with a small (76 amino acid) polypeptide called **ubiquitin** (Figure 2 ■). Appropriately labeled molecules are then transferred to an ATP-dependent protease complex (the proteasome) for destruction. Generally, proteins bearing a single ubiquitin molecule are marked for endocytosis and degradation in lysosomes. Multi-ubiquitinated proteins are marked for destruction by the proteasome, which is assembled into a cylinder through which proteins are channeled for destruction.

■ **FIGURE 2** Ubiquitin-Proteasome system. E1 = ubiquitin activating enzyme; E2 = ubiquitin conjugating enzyme; E3 = ubiquitin ligase; Ub = ubiquitin; E1 activates Ub, which is then transferred to the E2 enzyme; E3 functions in target substrate recognition; it brings together the target and E2-Ub and then catalyzes the transfer of Ub from E2-Ub to the target. Once a target has become multi-ubiquitinated, it is directed to the 26S proteasome for degradation.

▶ TISSUE HOMEOSTASIS: PROLIFERATION, DIFFERENTIATION, AND APOPTOSIS

Tissue homeostasis refers to the maintenance of an adequate number of cells to carry out the functions of the organism. In the human body, somatic cells (including blood cells) generally undergo one of three possible fates: They (1) proliferate by mitotic cell division, (2) differentiate and acquire specialized functions, or (3) die and are eliminated from the body. Cell proliferation is required for the replacement of cells lost to terminal differentiation, cell death, or cell loss. Differentiation provides a variety of cells, each of which is capable of executing specific and specialized functions. Recently, it has become apparent that cell death is also an active process (**apoptosis**) that the cell itself can initiate. Apoptosis is physiologically as important as cell proliferation and differentiation in controlling the overall homeostasis of various tissues. When the regulation of any of these three cellular processes malfunctions or the processes become unbalanced, the consequence may be tissue atrophy, functional insufficiency, or neoplasia (cancer). The following sections present an overview of the physiologic processes first followed by a discussion of the molecular regulation of each. Not all readers may be interested in the molecular aspects of regulation, but it is included in this book for those who want to gain a foundation for understanding the development of hematologic malignancies.

THE CELL CYCLE

Cell division is a fundamental process that is required throughout the life of all eukaryotes. Although it has been known for many years that cells have the ability to grow and replicate, the actual mechanisms involved were discovered relatively recently.⁵ When a cell is stimulated to divide, it goes through a series of well-defined (biochemical and morphological) stages called the **cell cycle**, which is divided into four phases: G₁ (Gap-1), S (DNA synthesis), G₂ (Gap-2), and M (mitosis) (Figure 3 ■).

Stages of the Cell Cycle

The physical process of cell division is preceded by a series of morphologically recognizable stages referred to as *mitosis* (*M phase*) (Web Figure 2 ■). During mitosis, chromosomes condense (*prophase*), align on a microtubular spindle (*metaphase*), and sister chromatids segregate to opposite poles of the cell (*anaphase* and *telophase*). The interval between successive mitoses (known as *interphase*) shows little morphologic variation except that cells grow in volume. During interphase, the cell synthesizes molecules and duplicates its components in preparation for the next mitosis. However, DNA synthesis occurs only during a narrow window of time of interphase. In *S phase*, DNA synthesis takes place and is separated from M phase (mitosis) by two gap periods: G₁,

■ **FIGURE 3** The four phases of the cell cycle: G₁, S, G₂, and M. G₀ represents the state of quiescence when a cell is withdrawn from the cell cycle. R represents the restriction point—the point in the cell cycle after which the cell no longer depends on extracellular signals but can complete the cycle in the absence of mitogenic stimuli. (Reprinted with permission from *Recombinant DNA*, 2nd ed., New York: W. H. Freeman; 1992.)

the time between the end of mitosis and the onset of the next round of DNA replication, and G₂, the time between the completion of S and the onset of mitosis.

Not all of the cells in the body are actively dividing (i.e., actively engaged in the cell cycle). Cells may exit the cell cycle at G₁ and enter a nonproliferative phase called G₀, or **quiescence** (Figure 3). To proliferate, a cell must re-enter the cell cycle. In response to specific mitogenic stimuli, quiescent cells can exit G₀ and re-enter the cell cycle at the level of early G₁. In unicellular organisms such as bacteria, cell division depends only on an adequate supply of nutrients. In mammalian cells, all cell division cycles are initiated by specific growth factors, or mitogens, that drive the cell from G₀ to G₁ (G₀ → G₁). Some cells, such as terminally differentiated neutrophils, have irreversibly exited the cell cycle during differentiation and are in G₀. Other cells, such as hematopoietic stem cells or antigen-specific memory lymphocytes, primarily reside in G₀ but can be induced to return to G₁ and begin cycling with appropriate cytokine or antigen stimulation.

G₁ is characterized by a period of cell growth and synthesis of components necessary for replication. If conditions are unsuitable for proliferation (insufficient nutrients or mitogens), cells will arrest in G₁. As cells transit through the G₁ phase of the cell cycle, they pass through what has been called the **restriction point (R)** in late G₁. R defines a point in the cell cycle after which the cell no longer depends on extracellular signals but is committed to completing that cell cycle *independent* of further mitogenic stimuli (i.e., cell-cycle completion becomes autonomous).⁶ Cells then transit across the G₁/S boundary into the S phase of the cycle where DNA synthesis occurs followed by the G₂ phase and finally mitosis (where nuclear division [*karyokinesis*] and cytoplasmic separation [*cytokinesis*] occur).

Molecular Regulation of the Cell Cycle

The fundamental task of the cell cycle is to faithfully replicate DNA once during S phase and to distribute identical chromosome copies equally to both daughter cells during M

phase. Organized progression through the cell cycle normally ensures that this takes place, so most cells never initiate mitosis before DNA duplication is completed, never attempt to segregate sister chromatids until all pairs are aligned on the mitotic spindle at metaphase, and never reduplicate their chromosomes (reinitiate S phase) before the paired chromatids have been separated at the previous mitosis. Cells must ensure that chromosome duplication and segregation occur in the correct order (i.e., S → M → S → M). They must also see that the next event in the cycle begins *only* when the previous events have been successfully completed (i.e., chromosome duplication is complete before the chromosomes are segregated into the two daughter cells). Entry into and exit from each phase of the cell cycle are tightly regulated. Failure to regulate this process results in aneuploidy (abnormal chromosome number) seen in many malignancies. Research over the past 20 years has begun to reveal how cells guarantee the orderliness of this process.⁵

Cyclins and Cyclin-Dependent Kinases

Enzymatic activities of specific kinases (phosphorylating enzymes) regulate the transition between the various phases of the cell cycle. These kinase proteins (**Cdks**, or cyclin-dependent kinases) phosphorylate target molecules important for cell cycle control. To be active, the kinase (Cdk) must be complexed with a regulatory protein named **cyclin** (hence, the name, **cyclin-dependent kinase**). Numerous cyclins and Cdks exist in the cell. Different complexes with differing cyclin and Cdk components drive the cell from one cell cycle stage to the next. The sequential activation of successive cyclin/kinase complexes, each of which in turn phosphorylates key substrates, facilitates or regulates the movement of the cell through the cycle (Figure 4a ■). Cdk inhibitors that function to inhibit the active kinase activity by binding to the Cdks or the Cdk/cyclin complexes also exist.

At least 14 cyclins and at least 9 different Cdks have been discovered so far, although not all of them have been shown to play an essential role in regulating the cell cycle. The concentration of the different cyclin proteins rises and falls at specific times during the cell cycle (hence, they are *cycling* proteins). Different cyclin/Cdk complexes are functional at different phases of the cell cycle as summarized in Table 2 🌱.

A mammalian cell must receive external signals (growth factors and/or hormones) that trigger the cell to proliferate.⁷ These external signals result in an increase of one (or more) of the D cyclins (of which there are three: D1, D2, and D3). Cyclin D complexes with Cdk4 or Cdk6 and phosphorylates target molecules required for G₁ → S progression. The D cyclins are unique in that they are synthesized in response to growth factor stimulation and remain active in the cell as long as the mitotic stimulus is present. Toward mid to late G₁, levels of cyclin E increase and bind with Cdk2. The cyclin E/Cdk2 complex is required for the

FIGURE 4 **a.** The phases of the cell cycle with the major regulatory cyclin/Cdk complexes depicted for each. **b.** The levels of the various cyclin proteins during the cell cycle. The cyclins rise and fall in a periodic fashion, thus controlling the cyclin-dependent kinases and their activities.

G₁ to S transition. Once the cell enters S phase, cyclin E degrades rapidly, and cyclin A takes over the activation of Cdk2. Cyclin A/Cdk2 is required for the onset of DNA synthesis, progression through S phase, and entry into mitosis. Toward the end of S phase, cyclin A starts to activate another kinase, Cdk1 (previously called *cdc2*), which signals the completion of S phase and the onset of G₂. Cyclin B takes over from cyclin A as the activating partner of Cdk1, and Cyclin B/Cdk1 controls the onset, sequence of events, and the completion of mitosis. Cyclin B must be destroyed for the cell to exit mitosis and for cytokinesis to take place (Figure 4b).

TABLE 2

Cell Cycle Regulatory Proteins

Cell Cycle Phase	Cyclin	Partner Cdk
G ₁	D1, D2, D3	Cdk4, Cdk6
G ₁ /S	E	Cdk2
S	A	Cdk2
M	A	Cdk1 (Cdc2)
	B	Cdk1 (Cdc2)

Regulation of Cell-Cycle Kinase Activity

Control of cell-cycle kinase activity is somewhat unique in that protein levels of the enzyme (kinase) subunit remain constant throughout the cell cycle and do not require activation from a proenzyme precursor form (unlike the activation of the serine proteases of the blood coagulation cascade). Regulation is achieved by varying the availability of the regulatory cofactor (the cyclins) through periodic (and cell-cycle phase-specific) synthesis and degradation (by the ubiquitin system) of the appropriate cyclin partners (Figure 4b).⁸ The periodic accumulation of different cyclins determines the sequential rise and fall of kinase activities, which in turn regulates the events of the cell cycle.

Multiple mechanisms regulate cell-cycle kinase activity. In addition to the requirement for the appropriate cyclin partner (controlled by cell-cycle specific synthesis and degradation of the different cyclins), the kinase subunit (Cdk) must be phosphorylated and/or dephosphorylated at specific amino acid residues.⁹ Full kinase activity requires the phosphorylation of threonine (Thr) 161 (using the amino acid numbering of Cdk1). The kinase responsible for this activating phosphorylation is called **CAK** (**C**dk-**a**ctivating **k**inase) and is itself a Cdk (Cdk7 complexed with cyclin H). CAK is responsible for the activating phosphorylation of *all* the kinases important for mammalian cell cycle control including Cdk1, 2, 4, and 6. On the other hand, phosphorylation of Thr 14 and tyrosine (Tyr) 15 suppresses kinase activity, and these phosphates must be removed by the phosphatase called *CDC25* in order to have a fully active cyclin/Cdk complex (Web Figure 3).

The final level of regulation involves two groups of proteins that function as inhibitors of Cdks and cyclin/Cdk complexes (Figure 5).¹⁰ The first Cdk inhibitor identified was p21; other Cdk inhibitors with structural and functional similarities to p21 include p27 and p57. (This nomenclature indicates they are **p**roteins of the indicated molecular mass in kilodaltons, e.g., p21 is a protein of molecular weight of 21,000.) These three inhibitors bind multiple cyclin/Cdk complexes of various phases of the cell cycle (cyclin D/Cdk4/6, cyclin E/Cdk2, and cyclin A/Cdk2). The second group of inhibitors is a family of structurally related proteins that include p15, p16, p18, and p19. These inhibitors are more restricted in their inhibitory activity, inhibit only Cdk4 and Cdk6, and can induce cell cycle arrest in G₁.

Cell-Cycle Checkpoints

Cell proliferation and differentiation depend on the accurate duplication and transfer of genetic information, which requires the precise ordering of cell-cycle events. Cells achieve this coordination by using **cell-cycle checkpoints** to monitor events at critical points in the cycle and, if necessary, halt progression of the cycle.^{11,12,13} The main functions of checkpoints are to detect malfunctions within the system and to assess whether certain events are properly completed before the cell is allowed to proceed through the cycle.

FIGURE 5 Cdk inhibitors. There are two families of Cyclin-dependent kinase inhibitors. The first group, including p15, p16, p18, and p19, inhibits only D-type cyclin/Cdk4 or Cdk6 complexes. The second group of inhibitors, including p21, p27, and p57, possesses a greater spectrum of inhibitory activity, inhibiting the G₁ as well as S-phase cyclin/Cdk complexes (Cyclin D/Cdk4/6, Cyclin E/Cdk2 and Cyclin A/Cdk2). ⊥ indicates inhibition of the pathway.

When problems are detected, check point mechanisms interrupt cell cycling to allow correction of the problem or elimination of the defective cell.

Several major cell-cycle checkpoints have been described. The *G₁ checkpoint* checks for DNA damage and prevents progression into S-phase if the integrity of the genome is compromised. The *S-phase checkpoint* monitors the accuracy of DNA replication. The *G₂/M checkpoint* also monitors the accuracy of DNA replication during S-phase. It checks for damaged or unreplicated DNA and can block mitosis if any is found. The *metaphase checkpoint* (also called the *mitotic-spindle checkpoint*) functions to ensure that all chromosomes are properly aligned on the spindle apparatus prior to initiating chromosomal separation and segregation at anaphase. If defects are detected at any of these checkpoints, the cell cycle is stopped by inhibiting the cyclin/Cdk kinase complexes. Activation of repair pathways may be initiated, or if the damage is severe, apoptosis may be triggered (discussed later).

Two proteins critical for effective function of the G₁ checkpoint are p53 and Rb. Rb is the protein product of the retinoblastoma susceptibility gene, which predisposes individuals to retinoblastomas and other tumors when only one functional copy is present. Rb is present throughout the cell cycle, although its phosphorylation state changes markedly in different phases of the cell cycle (Figure 6 ■).^{14,15} In its hypophosphorylated (active) state, Rb has antiproliferative

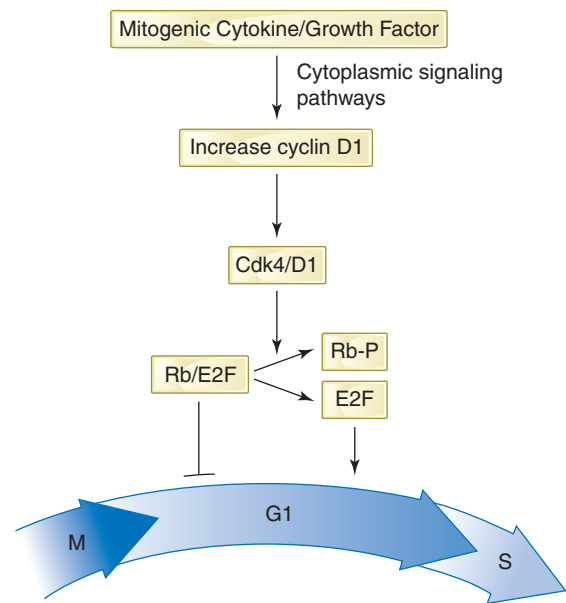

FIGURE 6 Role of the retinoblastoma susceptibility gene product (Rb) in regulation of the cell cycle. Stimulation of a cell with mitogens or growth factors induces synthesis of the D-type cyclins. Activation of G₁ phase kinase activity (Cyclin D/Cdk4/6) phosphorylates a number of intracellular substrates including the Rb protein. In the hypophosphorylated (active) state, Rb binds and sequesters transcription factors known as E2F, rendering them inactive. When Cyclin D/Cdk4 or Cdk6 phosphorylates Rb, it releases the E2F transcription factors, which then move to the nucleus, and initiate transcription of genes required for cell-cycle progression (including the genes for Cyclin E and Cyclin A). ↓ indicates stimulation of the pathway; ⊥ indicates inhibition of the pathway.

effects, inhibiting cell cycling. It does so by binding transcription factors (the E2F proteins) required for the transcription of genes needed for cell proliferation, rendering them nonfunctional. When growth factors induce activation of cyclin D/Cdk4/6, the Rb protein is one of the targets of this kinase activity. As cells progress through G₁, hyperphosphorylation of Rb by cyclin D/Cdk4/6 kinase results in inactivation of Rb and release of the active E2F transcription factors, resulting in the activation and expression of genes required for cell-cycle progression. Rb hyperphosphorylation is subsequently maintained through the cell cycle by cyclin E/Cdk2 and cyclin A/Cdk2. *RB* functions as a tumor suppressor gene. Cells lacking functional Rb protein show deregulated cell-cycle genes and cell proliferation, sometimes resulting in malignancy.

Although p53 is not required for normal cell function (i.e., it is not required for cell-cycle progression), it serves an important function as a molecular policeman, monitoring the integrity of the genome;¹⁶ p53 is a transcription factor that can both activate and inhibit gene expression (depending on the target gene). It is induced in response to DNA

damage and puts the brakes on cell growth and division, allowing time for DNA repair, or triggering apoptosis if repair is not possible.

Elevated levels of p53 result in upregulation of the Cdk inhibitor p21 and inhibition of the CDC25 phosphatase (blocking kinase function), induction of proapoptotic Bax and inhibition of anti-apoptotic Bcl-2. p53 is an important component of both the G₁ and the G₂/M checkpoints. Like Rb, p53 functions as a tumor suppressor gene and is the most commonly mutated gene in human tumors.

■ **FIGURE 7** Alternative fates for a cell induced to enter the cell cycle.

✓ **Checkpoint! 4**

A cell undergoing mitosis fails to attach one of its duplicated chromosomes to the microtubules of the spindle apparatus during metaphase. The cell's metaphase checkpoint malfunctions and does not detect the error. What is the effect (if any) on the daughter cells produced?

APOPTOSIS

Cells stimulated to enter the cell cycle may experience outcomes other than proliferation (Figure 7 ■). Cells can undergo senescence in which they are permanently growth arrested and no longer respond to mitogenic stimuli. Cells entering the cell cycle can also become terminally differentiated (committed) into specialized cell types. Uncontrolled cell cycling is a characteristic feature of malignant cells. Finally, cells can exit at any phase of the cell cycle by undergoing programmed cell death (apoptosis).

Cells can die by either of two major mechanisms: **necrosis** or **apoptosis**. The criteria for determining whether a cell is undergoing apoptosis or necrosis originally relied on distinct morphologic changes in the appearance of the cell (Table 3 ☆).¹⁷ Necrotic death is induced by lethal chemical,

biological, or physical events (extracellular assault). Such a death is analogous to “cell murder.” In contrast, apoptosis, or “programmed cell death,” is a self-induced death program regulated by the genetic material of the cell (“cell suicide”).

Apoptosis is now recognized to play an essential role in the development and homeostasis of all multicellular organisms.¹⁸ Apoptosis is essential to maintain a constant organ size in tissues that undergo continuous renewal by balancing cell proliferation and cell death. It also occurs at defined times and locations during development.

Apoptosis plays a major role in sculpting the developing organism (embryogenesis/organogenesis): It is responsible for the morphogenesis of the hands and feet (removal of interdigital webs), the formation of hollow tubes in the body (including the blood vessels, gastrointestinal tract, and heart), and the development of the immune system (the selection of appropriate T and B lymphocyte clones).

In adults, apoptosis is important in tissue homeostasis; homeostasis generally balances generation of new cells with the loss of terminally differentiated cells. Apoptosis is responsible for the elimination of excess cells (such as expanded clones of T or B lymphocytes following immune stimulation or excess PMNs following a bacterial challenge).

☆ **TABLE 3**

Cardinal Features of Apoptosis and Necrosis

Feature	Necrosis	Apoptosis
Stimuli	Toxins, severe hypoxia, massive insult, conditions of ATP depletion	Physiologic and pathologic conditions without ATP depletion
Energy requirement	None	ATP dependent
Histology	Cellular swelling; disruption of organelles; death of patches of tissue	Cellular shrinkage; chromatin condensation; fragmentation into apoptotic bodies; death of single isolated cells
DNA breakdown pattern	Randomly sized fragments	Ladder of fragments in internucleosomal multiples of 185 base pairs
Plasma membrane	Lysed	Intact, blebbed with molecular alterations (loss of phospholipid asymmetry)
Phagocytosis of dead cells	Immigrant phagocytes	Neighboring cells
Tissue reaction	Inflammation	No inflammation

★ TABLE 4

Diseases Associated with Increased and Decreased Apoptosis

Increased Apoptosis	Decreased Apoptosis
AIDS	Cancer
Neurodegenerative disorders	<ul style="list-style-type: none"> • Follicular lymphomas • Other leukemias/lymphomas • Carcinomas with p53 mutations • Hormone-dependent tumors (breast, prostate, ovarian)

Toxin-induced liver disease	

As a defense mechanism, apoptosis is used to remove unwanted and potentially dangerous cells such as self-reactive lymphocytes, cells infected by viruses, and tumor cells. Diverse forms of cellular damage can trigger apoptotic death including DNA damage or errors of DNA replication, which prevents the cell with abnormal DNA from proliferating. Similarly, intracellular protein aggregates or misfolded proteins can stimulate apoptosis (e.g., the ineffective erythropoiesis and intramedullary apoptotic death of erythroblasts in β -thalassemia major triggered by aggregates of α globin chains). In addition to the beneficial effects of programmed

cell death, the inappropriate activation of apoptosis may cause or contribute to a variety of diseases (Table 4 ★).^{19,20}

Apoptosis is initiated by three major types of stimuli (see Table 5 ★):

1. Deprivation of survival factors (growth factor withdrawal or loss of attachment to extracellular matrix)
2. Signals by “death” cytokines through apoptotic “death” receptors (tumor necrosis factor-TNF, Fas Ligand)
3. Cell-damaging stress

★ TABLE 5

Inhibitors and Initiators/Inducers of Apoptosis

Inhibitors	Initiators/Inducers
Presence of survival factors	Deprivation of survival factors
<ul style="list-style-type: none"> • Growth factors • Extracellular matrix • Interleukins • Estrogens, androgens 	<ul style="list-style-type: none"> • Growth factor withdrawal • Loss of matrix attachment
Viral products that block apoptosis	Death cytokines

Oncogene and tumor suppressor gene products (Bcl-2, Bcl-x _L , Mcl-1, Rb, c-Abl)	<ul style="list-style-type: none"> • Bacterial toxins • Viral infections • Oxidants • Glucocorticoids • Cytotoxic drugs • Radiation therapy
	Oncogene and tumor suppressor gene products (c-myc, p53, Bax, Bad, Bcl-x _S , c-Fos, c-Jun)

Conversely, apoptosis is inhibited by growth-promoting cytokines and interaction with appropriate extracellular environmental stimuli. The disruption of cell physiology as a result of viral infections can cause an infected cell to undergo apoptosis. The suicide of an infected cell may be viewed as a cellular defense mechanism to prevent viral propagation. To circumvent these host defenses, a number of viruses have developed mechanisms to disrupt the normal regulation of apoptosis within the infected cell. Finally, a number of oncogenes and tumor suppressor genes have been described that may either stimulate or inhibit apoptosis.

Necrosis vs Apoptosis

When a cell is damaged, the plasma membrane loses its ability to regulate cation fluxes, resulting in the accumulation of Na^+ , Ca^{++} , and water (Table 3, and Figure 8■). Consequently, the necrotic cell exhibits a swollen morphology. The organelles also accumulate cations and water, swell, and ultimately lyse. The rupture of the cytoplasmic membrane and organelles releases cytoplasmic components (including proteases and lysozymes) into the surrounding tissue, triggering an inflammatory response. In contrast, apoptosis is characterized by cellular shrinking rather than swelling with condensation of both the cytoplasm and the nucleus. Apoptotic cells do not lyse, but portions of the cell pinch off as apoptotic bodies that are phagocytosed by neighboring cells or macrophages. Thus, apoptosis is a very efficient process by which the body can remove a population of cells at a given time or in response to a given stimulus *without* the activation of an inflammatory response. Necrosis is a passive event elicited by the external injurious agent and generally leads to the destruction of a large group of cells in the same area. In contrast, apoptosis is an energy-dependent process orchestrated by the cell itself and generally affects only single, individual cells. In addition, apoptosis is characterized by a particular type of DNA fragmentation. DNA in an apoptotic cell is enzymatically cleaved by a specific endonuclease into oligonucleotides whose sizes are multiples of ~ 185 base pairs (corresponding to nucleosomal fragments). When electrophoresed on agarose gel, these nucleotide fragments make a discrete “ladder pattern” that is considered the hallmark of apoptosis. This is in contrast to the “smudge” pattern seen in cells undergoing necrosis, which indicates the presence of randomly and fully degraded DNA.

Molecular Regulation of Apoptosis

Caspases and the Initiation of Apoptosis The cellular events responsible for apoptotic cell death are directed by a group of proteins called **caspases**.^{21,22} Caspases are a family of cysteine proteases that cleave after **asp**artic acid amino acids in a peptide substrate and are responsible for the orderly dismantling of the cell undergoing apoptosis. A number of similarities exist between the configuration and function of the apoptotic system (caspases) and the blood coagulation system (serine proteases).

■ **FIGURE 8** Diagram illustrating the sequential ultrastructural changes in apoptosis (clockwise arrows) and necrosis (counterclockwise arrows). A normal cell is shown (1). The onset of apoptosis (2) is heralded by compaction and segregation of chromatin into sharply delineated masses that lie against the nuclear envelope, condensation of the cytoplasm, and mild convolution of the nuclear and cellular outlines. Rapid progression of the process over the next few minutes (3) is associated with nuclear fragmentation and marked convolution of the cellular surface with the development of protuberances. The latter then separate to produce membrane-bound apoptotic bodies, which are phagocytosed and digested by adjacent cells (4). Signs of early necrosis in an irreversibly injured cell (5) include clumping of chromatin into ill-defined masses, gross swelling of organelles, and the appearance of flocculent densities in the matrix of mitochondria. At a later stage (6), membranes break down and the cell disintegrates. (With permission from Definition and incidence of apoptosis: An historical perspective. In: *Apoptosis: The molecular basis of cell death*. Eds: Kerr, JRF, Harmon, BV. New York: Cold Spring Harbor Laboratory Press; 1991.)

At least 14 caspase enzymes (caspase 1–14) have been identified in humans, although not all play a significant role in apoptosis. Those that are involved in apoptosis form the effector arm of the apoptotic machinery that, once activated, carries out the proteolysis necessary for apoptosis to occur. Caspases are found in healthy cells as zymogens (inactive form) and express their protease activity following either proteolytic cleavage or autocatalytic activation at high concentrations. A hierarchical relationship similar to that described for the blood coagulation proteins exists among the various apoptotic caspases. Early acting, initiator caspases (caspase-2, -8, -9, -10) are recruited in response to apoptotic stimuli and are activated. They then

initiate the apoptotic cascade by proteolytically activating downstream, effector caspases (caspase-3, -6, -7), which in turn orchestrate the ordered dismantling of the cell resulting in cell death (Figure 9 ■).^{22,23} Activation of caspases in apoptosis does not lead to indiscriminate proteolytic degradation but to specific cleavage of key substrates including proteins involved in cell structure, cell cycle regulation, DNA repair, RNA splicing, and the activation of a key endonuclease (CAD/caspase activated DNase) responsible for the characteristic DNA fragmentation (Web Table 2 🌱).

Two major cell death pathways (Web Figure 4 ■) are initiated by a variety of events. Similar to the coagulation cascade are an “extrinsic pathway” and an “intrinsic pathway.” The extrinsic pathway is triggered by extracellular signals (“death cytokines”) and transmitted through “death receptors” on the surface of the cell. The intrinsic pathway is a mitochondria-dependent pathway, initiated by intracellular signals in response to stress, exposure to cytotoxic agents, or radiation.

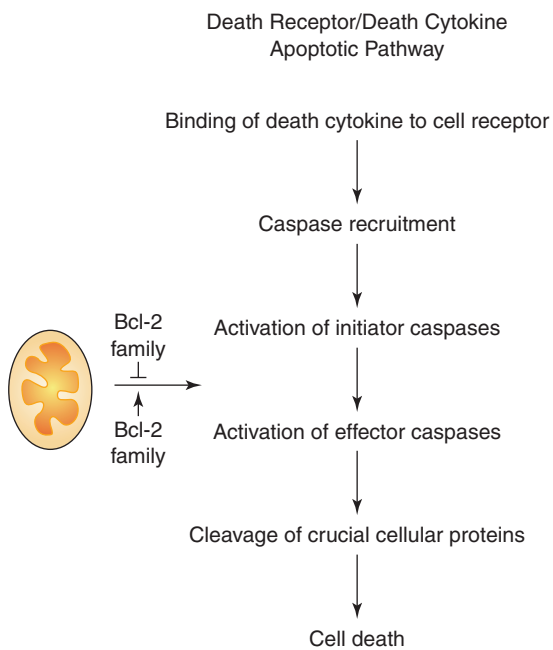

Eight death receptors have been described in mammalian cells to date.^{24,25,26} The two best-known death cytokines and death receptors (DR) are tumor necrosis factor (TNF) and the

TNF receptor, and Fas Ligand and CD95 (Fas receptor). DRs and initiator caspases do not bind each other directly but interact through adapter molecules containing “docking sites” for each protein (Web Figure 5 ■). Once the death cytokine, death receptor, adapter molecules, and initiator caspases are assembled in a complex, the caspase is activated by the process of autocatalysis.

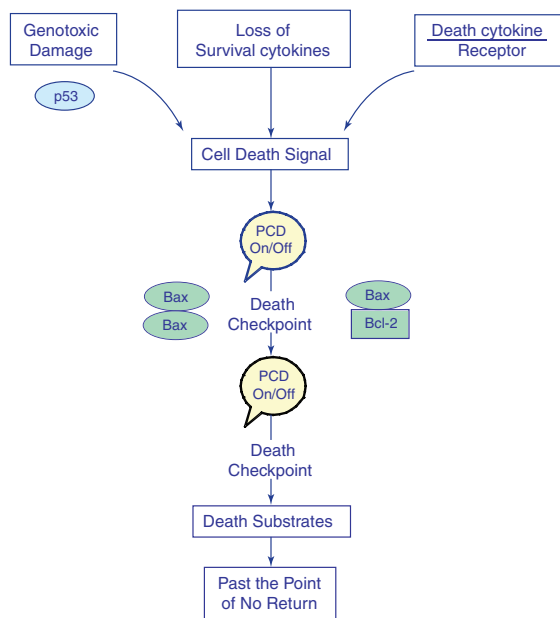

The sequence of events triggering apoptosis via the internal pathway is less understood. It involves the assembly of a second caspase-activating complex called the *apoptosome* (Web Figure 5). DNA damage, cell-cycle checkpoint defects, or loss of survival factors increase expression of pro-apoptotic Bcl family members (discussed later) and trigger mitochondrial release of cytochrome-c which serves as a cofactor for caspase activation. Cytochrome-c assembles with a different adapter protein and initiator caspase, again triggering autocatalysis. The activated initiator caspase from both pathways converge on the proteolytic activation of the effector caspase, caspase-3, and the activation of apoptosis.

Role of Bcl-2 Protein Apoptosis is a closely regulated physiologic process in which the Bcl-2 family of proteins plays an important role. The Bcl-2 family of proteins includes both pro-apoptotic and anti-apoptotic members and constitutes a critical intracellular checkpoint of apoptosis.^{27,28} The founding member, Bcl-2, was a protein originally cloned from B-cell lymphomas with the characteristic t(14;18) chromosomal translocation. Since that initial discovery, several additional related proteins have been identified, some of which promote and others oppose apoptosis. At present, there are at least six known apoptosis-inhibitory proteins (survival factors) including the originally described Bcl-2 and at least 12 proapoptotic family members.²⁶ The Bcl-2 family of proteins is localized at or near the mitochondrial membranes and constitutes a critical intracellular checkpoint of apoptosis, determining whether early activation of initiator caspases will proceed to full activation of effector caspases (see Figure 9).^{29,30}

The relative levels of anti-apoptotic and pro-apoptotic Bcl-2 members constitute a *rheostat* for apoptosis. This rheostat is regulated by different associations between survival and pro-death Bcl proteins. They all share similar structural regions that allow them to form dimers or higher oligomers (either homo- or hetero-oligomers). Bax (the first proapoptotic member discovered) can associate with itself (Figure 10 ■), and Bax:Bax homo-oligomers promote apoptosis. They induce permeabilization of the mitochondrial membrane, release of proteins including cytochrome-c, and activate the caspase cascade. With elevated levels of Bcl-2, Bax:Bcl-2 hetero-oligomers that repress apoptosis are formed. Actually, it is the overall ratio of death agonists (Bax and related proteins) to death antagonists (Bcl-2 and related proteins) and their interactions with each other that determine the susceptibility of a cell to a death stimulus (Figure 11 ■). Thus, the

■ **FIGURE 9** The apoptotic pathway triggered by death cytokine binding to death receptors. Activation of a death receptor by binding of death cytokine results in the recruitment of specific adapter proteins and activation of initiator caspases. Activated initiator caspases can then proceed to activate downstream effector caspases that mediate the cleavage of various cellular proteins during apoptosis. The contribution of the Bcl-2 family of proapoptotic and antiapoptotic proteins in determining whether activation of initiator caspases will proceed through to activation of effector caspases is depicted. ↓ indicates stimulation of the pathway; ⊥ indicates inhibition of the pathway.

■ **FIGURE 10** Model of cell death checkpoints. Following delivery of a cell death signal (genotoxic damage, loss of survival cytokines, or presence of death cytokines), the ratio of proapoptotic components (Bax and related molecules) vs. antiapoptotic components (Bcl-2 and related molecules) determines whether or not the death program will continue to completion. A preponderance of Bax:Bax homodimers promotes continuation of the process while Bax–Bcl-2 heterodimers will shut it down. PCD = programmed cell death (apoptosis). (Adapted, with permission, from: Chao DT, Korsmeyer SJ: Bcl-2 family: Regulators of cell death. *Ann Rev Immunol.* 1998; 16:395.)

cell receives and processes *death signals* from a variety of sources. They converge on this rheostat, which determines whether the cell will activate effector caspases and subsequently whether there will be cleavage of the *death substrates* necessary for apoptosis.²⁸

Cells utilize a variety of safeguards to prevent inappropriate apoptosis. Cells possess a number of proteins that modulate cell death by binding to activated caspases and interfering with their activity, the so-called **inhibitors of apoptosis proteins** (IAPs).^{21,22} Some viruses contain viral proteins that perform the same function (e.g., cowpox viral protein CrmA, Adenovirus E1B, and Baculovirus p35). These viral proteins block the apoptosis-activating defense of the host cell against viral replication (i.e., block apoptosis).

Apoptosis and the Hematopoietic System

Apoptosis is important in the hematopoietic system (Table 6). The default cellular status of hematopoietic precursor cells is *cell death*. Cytokines and components of the extracellular matrix function to suppress apoptosis, allowing survival of hematopoietic cells when appropriate cytokines are present. Apoptosis plays an essential role in the selection of appropriate recognition repertoires of T and B lymphocytes, eliminating those with nonfunctional or autoreactive antigen receptors. Apoptosis helps regulate the overall number of mature cells by inducing elimination (cell death) of excess cells when expanded numbers of mature cells are no longer needed (i.e., expanded T and B cell clones, following elimination of foreign antigen; elimination of PMNs,

■ **FIGURE 11** Bcl-2-related proteins and control of apoptosis. Pro-apoptotic (blue ovals) and anti-apoptotic (pink rectangles) Bcl-2 related proteins interact in response to an apoptotic signal. If the pro-apoptotic signals prevail, cytochrome-c (yellow circle) is released from the mitochondria, binds to an adapter protein (Apaf-1) and recruits an initiator caspase (procaspase-9); the resulting caspase-activating assembly, the apoptosome, is associated with the intrinsic pathway of apoptosis.

★ TABLE 6

The Role of Apoptosis in the Hematopoietic and Lymphoid Systems

I. Default cellular status for hematopoietic stem cells and progenitor cells
Apoptosis regulated by cytokines and extracellular matrix
II. Lymphoid homeostasis
Selection of recognition repertoires of T and B cells
Elimination of autoreactive lymphocytes
Down regulation of immune response following antigen stimulation
Cytotoxic killing by CTL* and NK* cells
III. Elimination of eosinophils, monocytes, and neutrophils following infection/inflammatory response
IV. Developmental pathways for erythropoiesis and thrombopoiesis

*CTL = cytotoxic T lymphocytes; NK = natural killer cells

eosinophils, and monocytes following an infection/inflammatory response). Apoptosis is the mechanism employed in cytotoxic killing by cytotoxic T lymphocytes (CTL) and natural killer (NK) cells. Finally, activation of apoptotic caspases is involved in platelet production and release from mature megakaryocytes and in the final stages of erythrocyte maturation (chromatin condensation and organelle removal).^{31,32}

Dysregulation of apoptosis also contributes to hematologic disorders. Apoptosis is increased in the myelodysplastic syndromes and tends to be decreased in the acute leukemias, perhaps partly explaining the pancytopenias and leukocytosis, respectively, seen in those disorders.

✓ Checkpoint! 5

What would be the effect on the hematopoietic system homeostasis if the expanded clone of antigen-activated B lymphocytes failed to undergo apoptosis after the antigenic challenge was removed?

▶ ABNORMAL TISSUE HOMEOSTASIS AND CANCER

In recent years, there has been an explosive growth in our knowledge of cancer cell biology. Of significance is the recognition that scattered throughout our own genome are genes that have the potential to cause cancer (**proto-oncogenes**)^{33,34} and other genes that have the power to block it (**anti-oncogenes** or **tumor suppressor genes**).³⁵ As researchers have worked to understand the function of these oncogenes and tumor suppressor genes, they have found that many of them are molecules that regulate normal cell growth and differentiation and/or apoptosis.^{36,37}

Cancer is a genetic disease: Most tumors are clonally derived from a single cancer “stem cell” that divides incessantly to generate a tumor of “identical” sibling cells. The cancer cell genotype is generally maintained (stably inherited) during cell division. This implies that the tumor cell DNA determines the disease phenotype. Researchers have found that certain viruses, when inoculated into animals, are capable of causing tumors. In an effort to discover the particular viral genes capable of inducing malignant transformation, it has been shown that tumor viruses carry discrete genetic elements, **oncogenes**, responsible for their ability to transform cells. The proteins encoded by these oncogenes play important roles in the cell cycle, such as initiation of DNA replication and transcriptional control of genes. Importantly, many viral oncogenes have normal counterparts in the human genome, now called *cellular proto-oncogenes*. The identification of cellular proto-oncogenes verified that the human genome carries genes with the potential to dramatically alter cell growth and to cause malignancy.

santly to generate a tumor of “identical” sibling cells. The cancer cell genotype is generally maintained (stably inherited) during cell division. This implies that the tumor cell DNA determines the disease phenotype. Researchers have found that certain viruses, when inoculated into animals, are capable of causing tumors. In an effort to discover the particular viral genes capable of inducing malignant transformation, it has been shown that tumor viruses carry discrete genetic elements, **oncogenes**, responsible for their ability to transform cells. The proteins encoded by these oncogenes play important roles in the cell cycle, such as initiation of DNA replication and transcriptional control of genes. Importantly, many viral oncogenes have normal counterparts in the human genome, now called *cellular proto-oncogenes*. The identification of cellular proto-oncogenes verified that the human genome carries genes with the potential to dramatically alter cell growth and to cause malignancy.

ONCOGENES

One of the defining features of cancer cells is their ability to proliferate under conditions in which normal cells do not.³⁸ The proteins encoded by proto-oncogenes function in the signaling pathways by which cells receive and execute growth instructions. The mutations that convert these proto-oncogenes to active oncogenes are usually either structural mutations resulting in the constitutive (formed continuously) activity of a protein without an incoming signal or regulatory mutations that lead to the production of the protein at the wrong place or time. The result in either case is a persistent internal growth signal uncoupled from environmental controls. It is possible that any gene playing a key role in cellular growth can become an oncogene if mutated in an appropriate way.

Generally, the proto-oncogenes that have been identified serve one of the following functions in normal growth control:

- Some encode growth factors (the molecules that are themselves the signals to grow) that when activated to an “oncogene” result in an autocrine growth stimulation.
- Other proto-oncogenes encode growth factor receptors; when activated to an oncogene, the mutated receptors are capable of triggering growth-promoting signals even in the absence of ligand (cytokine) binding.
- The largest class of proto-oncogenes encodes proteins that associate with growth factor receptors within the cytoplasm and function to pass receptor signals to downstream targets. Many of these proto-oncogenes encode protein-tyrosine kinases found on the inner surface of the membrane. Often the oncogenic form of these genes produces signaling molecules that exist in a constantly activated state in the absence of growth factor/receptor interaction and signaling.
- Some proto-oncogenes are transcription factors, proteins that bind DNA and function to control the expression of cellular genes required for proliferation.

Thus, proto-oncogenes are genes that regulate the initiation of DNA replication, cell division, and/or the commitment to cellular differentiation. As such, they are obvious targets for processes that damage the growth-control apparatus of the cell. Damage to these regulatory genes, referred to as *activation of the proto-oncogene* (resulting in the creation of an oncogene), occurs by one of three mechanisms: genetic mutation, genetic rearrangement, or genetic amplification. The result is either (1) a *qualitative* change in function of the protein product of the gene, resulting in enhanced activity, (2) a protein that is no longer subject to the control of regulatory factors, or (3) a *quantitative* change (increased production) of an otherwise normal oncogene protein.

TUMOR SUPPRESSOR GENES

It is now widely accepted that cancer is a multihit phenomenon, resulting from several independent genetic alterations occurring sequentially within a single cell. Specific tumor suppressor genes, or anti-oncogenes, in normal cells function to inhibit cell growth. Thus, in addition to mutations of oncogenes resulting in a growth-promoting activity, tumor cells often have inactivating mutations of growth-suppressing genes that may also contribute to tumor development. Mutations in tumor suppressor genes behave differently from oncogene mutations (Table 7). Oncogene mutations tend to be activating mutations, which functionally are dominant to wild-type (nonmutated) gene products; they produce proliferation signals even when a single copy of the oncogene is present. Tumor suppressor mutations, on the other hand, are recessive, loss-of-function mutations. Mutation in one gene copy usually has no effect, as long as a reasonable amount of normally functioning wild-type protein remains.

Understanding the function of tumor suppressor genes has been greatly aided by studies of rare cancers that run in families. Members of affected families appear to inherit susceptibility to cancer and develop certain kinds of tumors at rates much higher than the normal population. The first of these to be explained at the molecular level was the inherited susceptibility to retinoblastoma (a tumor of the eye) seen in certain families.^{39,40} Although retinoblastoma can occur sporadically, about one-third of the cases occurs in related siblings, suggesting an inherited susceptibility to the

disease. The development of retinoblastoma requires two mutations resulting in the inactivation of both of the *RB* loci on each of the chromosomes #13. In the familial form of the disease, the affected children inherit one mutant *RB* allele and one normal allele. Retinoblastoma (or other malignancies) develops when acquired mutations eliminate the function of the remaining normal (wild-type) allele (Web Figure 6). Thus, the *RB* gene acts as a tumor suppressor gene (anti-oncogene) that normally functions to arrest excessive growth of cells. As is typically true of tumor suppressor genes, even one copy is sufficient to keep growth in check. However, loss of both copies of *RB* eliminates the block and a tumor develops. As discussed above, the protein product of the *RB* gene (Rb protein) is not specific to retinal tissue but serves as a universal cell-cycle brake in most cells. Acquired mutations of *RB* (i.e., nonfamilial) are found in about 25% of sporadic cancers.

Inactivation of the *p53* gene, also a tumor suppressor anti-oncogene, is seen in more than half of all human cancers, making it the most common genetic defect detectable in human tumors.^{41,42} Interestingly, a damaged *p53* gene, the Li-Fraumeini syndrome, can also be inherited resulting (like familial retinoblastoma) in an inherited susceptibility to a variety of cancers.^{43,44} In affected individuals, 50% develop cancer by age 30 and 90% by age 70. The function of *p53* in cell-cycle regulation is to block cell-cycle progression in the event of damaged DNA or to trigger apoptosis if the damaged DNA cannot be repaired. The *p53* protein is a major component of the body's antitumor army, serving as a "molecular policeman" monitoring the integrity of the genome. Loss of function of the *p53* gene facilitates tumor formation by allowing damaged cells to proceed through the cell cycle and continue to replicate.

Although all of the Cdk inhibitors could potentially act as tumor suppressors,⁴⁵ the one that seems to have the strongest link to malignancy is *p16*.⁴⁶ Loss-of-function mutations of *p16* have been described in a wide variety of human cancers. To date, there is much less information on the involvement of other Cdk inhibitors, although it is likely that they also function as tumor suppressors and thus play a role in tumorigenesis. In addition, there are tumor suppressor genes that tend to show tissue preference in terms of site of malignancy. These include the *WT-1* gene, mutated in Wilms' tumor; the *APC* gene, mutated in adenomatous

★ TABLE 7

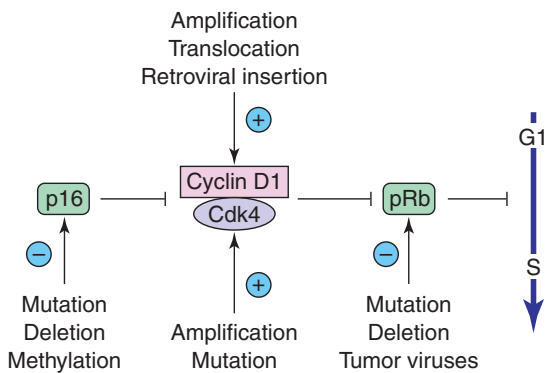

Properties of Oncogenes and Tumor Suppressor Genes

Property	Oncogenes	Tumor suppressor gene
Nature of mutation	Dominant	Recessive
	Gain of function	Loss of function
Inherited mutant allele	Never observed	Common—basis for inherited predisposition in cancers
Somatic mutations in cancers	Yes	Yes

polyposis; the *DCC* gene, deleted in colon carcinomas; and *BRCA-1* and *BRCA-2*, mutated in breast cancers.

CELL-CYCLE CHECKPOINTS AND CANCER

A common feature of many cancer cells is the loss of regulation of cell-cycle checkpoints, either by overexpression of positive regulators (for example, cyclins and Cdks) or the loss of function of negative regulators (the Cdk inhibitors, p53, or Rb).^{47,48} Cyclin D, cyclin E, and cyclin A are overexpressed in a variety of human cancers and function as oncogenes in their mutated configuration. Often specific chromosomal translocations activate the expression of the cyclin gene by placing it under the influence of other transcriptional control elements. For example, the t[11;14] translocation seen in some B-lymphocyte malignancies places the cyclin D gene under the control of the immunoglobulin heavy chain locus, resulting in activation of cyclin D expression. Thus, the Bcl-1 oncogene defined by the t(11;14) translocation is now known to represent a translocated cyclin D locus. Mutations (overexpression) of *Cdk4* also have been reported in a number of human tumors, contributing to the excessive growth characteristics of those diseases. The p16-cyclin D-Rb pathway, which controls the G₁ checkpoint in cell-cycle regulation, is believed to play a pivotal role in tumorigenesis (Figure 12 ■). Some investigators have proposed

■ **FIGURE 12** Alterations of the G₁ checkpoint that can lead to malignancy. Loss-of-function alterations of negative regulators of the cell cycle (i.e., Cdk inhibitor p16 or cell-cycle inhibitor Rb protein) may contribute to uncontrolled proliferation. Similarly, gain-of-function mutations of positive regulators of proliferation (i.e., Cyclin D, Cdk4) may contribute to uncontrolled proliferation. Inhibitory regulatory proteins with the potential to influence malignant transformation are called *tumor suppressor genes*, and positive regulatory proteins are called *proto-oncogenes*. ↓ indicates stimulation of the pathway; ⊥ indicates inhibition of the pathway. (+) indicates a mutation that increases activity of the indicated proteins; (-) indicates a mutation that decreases activity of the indicated proteins.

that a mutation involving at least one member of this checkpoint must occur in order for a malignant phenotype to be established.⁴⁹

APOPTOSIS AND CANCER

The accumulation of excess numbers of cells characteristic of malignancies may be due to increased cell proliferation (see previous discussion of cell cycle checkpoints and cancer) and/or to decreased cell death (apoptosis).⁵⁰ Thus, mutations of genes important in regulating apoptosis have also been identified as oncogenes and tumor suppressor genes. These include loss-of-function mutations of initiators of apoptosis such as p53, Bax, and other proapoptotic Bcl-2 family members, as well as overexpression of Bcl-2 and other Bcl-2 family members that function to inhibit apoptosis. Bcl-2 is overexpressed in most cases of B-cell follicular lymphoma, many cases of B-cell chronic lymphocytic leukemia (CLL), and some cases of acute myelocytic leukemia (AML). Mutations of Bax (resulting in loss of proapoptotic function) have been reported in about 20% of leukemic cell lines. The result is production of cells with an extended life span, increased proliferation capacity, and diminished cell death.

EPIGENETICS

In addition to mutations (changes in the nucleotide sequence of the gene) of various oncogenes or tumor suppressor genes that have been described in association with malignancy, there is a second group of alterations, the so-called *epigenetic alterations*. **Epigenetics** (meaning literally “on top of genetics”) refers to stable changes in gene function that are transferred through mitosis and passed from one cell to its progeny. Epigenetic changes play an important role in normal development and differentiation and are associated with “silencing” genes and chromatin condensation into heterochromatin.

One of the most common epigenetic changes found in the human genome involves the methylation of certain cytosine nucleotides (C^M) within genes and/or their promoter regions. Cytosine nucleotides particularly susceptible to methylation are those found adjacent to a guanine nucleotide, the so-called CpG dinucleotide.

These methylations or epigenetic changes become incorporated into the heritable genetic/epigenetic regulatory mechanisms of the cell and play a significant role in differentiation and development. The methylation of CpG dinucleotides is a potentially reversible process, and approximately 70–75% of CpG dinucleotides in the human genome are methylated. In addition, CpG dinucleotides are often clustered in *CpG islands*, many of which are in and around the promoter regions of genes. The unmethylated state of the promoter region of a gene favors a *transcription-ready status* or accompanies active transcription. Typically, methyla-

tion of the promoter regions is associated with gene silencing and is part of the normal terminal differentiation process seen in many diverse tissue types.

Cancer is a complex disorder that may involve DNA methylation. One may see demethylation of the genome in regions where it should be methylated, or methylation of regions of the genome that are typically unmethylated. There is a growing list of genes that acquire hypermethylation of CpGs in their promoter regions and contribute to tumorigenesis. This change is associated with transcriptional silencing of these genes and is the explanation for one of the most common causes of loss of function of key tumor suppressor genes.

Extensive information also can be encoded in the protein component of the chromatin in what is now being called the *histone code*. Modifications of the histone proteins include lysine acetylation, serine phosphorylation, lysine, and arginine methylation. These modifications can be stably passed from one cell generation to the next as well. These modifications of histones also play an important role in the complex system responsible for regulating euchromatin to heterochromatin transitions. Hypo-acetylated histones bind tightly to the phosphate backbone of DNA and help maintain chromatin in an inactive, silent state. Various types of malignant cells utilize enzymes called *histone deacetylases (HDACs)* to deacetylate key lysine aminoacids, resulting in silencing of key genes, which favors cell growth over differentiation.

Many of the newer approaches to treating cancer patients involve *demethylating agents* or *HDAC inhibitors* with the goal of reversing epigenetic changes associated with certain types of cancer.

Checkpoint! 6

Mutations of proto-oncogenes predisposing to malignancy are said to be dominant mutations while mutations of antioncogenes are said to behave as recessive mutations, requiring loss of both alleles. Explain this difference in behavior of the gene products.

SUMMARY

The cell is an intricate, complex structure bound by a membrane. The membrane is a phospholipid bilayer with integral proteins throughout and containing receptors that bind extracellular mole-

cules and transmit messages to the cell's nucleus. Within the cell is the cytoplasm with numerous organelles and the nucleus. The cellular organelles include ribosomes, endoplasmic reticulum, the Golgi apparatus, lysosomes, mitochondria, microfilaments, and microtubules. The nucleus contains the genetic material, DNA, which regulates all cell functions.

The cell cycle is a highly ordered process that results in the accurate duplication and transmission of genetic information from one cell generation to the next. The cell cycle is divided into four stages: M phase (in which cell division or mitosis takes place), S phase (during which DNA synthesis occurs), and two gap phases, G₁ and G₂. G₀ refers to quiescent cells that are temporarily or permanently out of cycle. The normal cell depends on external stimuli (growth factors) to move it out of G₀ and through G₁. The cell cycle is regulated by a series of protein kinases (Cdks), whose activity is controlled by complexing with a regulatory partner (cyclin). Different cyclins with their associated (and activated) Cdks function at specific stages of the cell cycle. Kinase activity is further modulated by both activating and inactivating phosphorylation of kinase subunits and by specific cell-cycle kinase (Cdk) inhibitors. A series of checkpoint controls or surveillance systems functions to ensure the integrity of the process.

To maintain tissue homeostasis, cells utilize the process of programmed cell death, or apoptosis, as well as proliferation. Apoptosis is a unique form of cell death that can be morphologically and biochemically distinguished from necrosis. Apoptosis plays important roles in the development of the organism, in controlling the number of various types of cells, and as a defense mechanism to eliminate unwanted and potentially dangerous cells. Apoptosis is an active process initiated by the cell and resulting in the orderly dismantling of cellular constituents. It is directed by cysteine proteases called *caspases*. Proapoptotic and antiapoptotic proteins (Bcl-2 family members) and specific protein inhibitors (IAPs, or inhibitors of apoptosis) regulate this process. Apoptosis is triggered by loss of survival factors (survival cytokines or extracellular matrix components), presence of death cytokines, or cell-damaging stress.

The various processes that govern tissue homeostasis—proliferation, differentiation, cytokine regulation, and apoptosis—are highly ordered and tightly regulated. When the regulation of these processes malfunctions, the result can be deregulated cell production and malignant transformation. Oncogenes and tumor suppressor genes are genes whose normal transcription products regulate the processes that govern tissue homeostasis. Mutations or epigenetic changes that alter the structure or function of these genes may result in uncontrolled cell growth and malignancy.

REVIEW QUESTIONS

LEVEL I

- Selective cellular permeability and structural stability are provided by: (Objective 1)
 - membrane lipids
 - membrane proteins
 - ribosomes
 - the nucleus
- Rough endoplasmic reticulum is important in: (Objective 1)
 - synthesizing lipid
 - synthesizing hormones
 - synthesizing and assembling proteins
 - phagocytosis
- The fundamental subunit of chromatin composed of ~180 base pairs of DNA wrapped around a histone protein is called: (Objective 1)
 - nucleolus
 - genome
 - heterochromatin
 - nucleosome
- Condensation of chromosomes occurs during which phase of mitosis? (Objective 3)
 - anaphase
 - telophase
 - prophase
 - metaphase
- Cells that have exited the cell cycle and entered a nonproliferative phase are said to be in: (Objective 3)
 - quiescence
 - interphase
 - G₁
 - G₂
- The regulatory subunit of the active enzyme complex responsible for regulating passage through the various phases of the cell cycle is: (Objective 3)
 - cyclin
 - Cdk
 - Cdk inhibitor
 - p21
- The point in the cell cycle at which cell proliferation (cycling) no longer depends on extracellular signals is: (Objective 4)
 - G₁
 - R
 - G₂
 - M
- Programmed cell death (cell suicide) is also known as: (Objective 5)
 - necrosis
 - senescence
 - apoptosis
 - terminal differentiation

LEVEL II

- UTRs are regions of mRNA: (Objective 1)
 - representing the introns of the gene
 - representing the exons of the gene
 - representing the splice sites for mRNA processing
 - representing regions at either end of the mRNA that are not part of the coding sequence
- The main function of the ubiquitin-proteasome system is to: (Objective 2)
 - assist in the three-dimensional folding of polypeptides into their tertiary structure
 - degrade unwanted or damaged polypeptides
 - facilitate transfer of polypeptides from the endoplasmic reticulum to the Golgi
 - direct post-translational modifications of proteins
- The kinase complex responsible for passage through and exit from mitosis is composed of: (Objective 3)
 - cyclin A/Cdk2
 - cyclin D/Cdk4
 - cyclin B/Cdk1
 - cyclin E/Cdk2
- CAK, the kinase activity responsible for the activating phosphorylations of Cdks, consists of: (Objective 4)
 - cyclin A/Cdk1
 - cyclin H/Cdk7
 - cyclin F/Cdk6
 - cyclin C/Cdk2
- Overexpression of the p21 protein would have what effect on the cell cycle of proliferating cells? (Objective 4)
 - decrease cell cycle progression
 - increase cell cycle progression
 - trigger apoptosis
 - have no effect
- The protein responsible for binding the transcription factors E2F blocking cell cycle progression beyond the restriction point (R) is: (Objective 6)
 - p53
 - p15
 - p21
 - Rb
- Apoptotic cell death is characterized by all of the following *except*: (Objective 14)
 - triggering an inflammatory response
 - condensation of the nucleus
 - cleavage of chromatin into discrete fragments (multiples of 185 base pairs)
 - condensation of the cytoplasm and cell shrinkage

REVIEW QUESTIONS (continued)

LEVEL I

9. All of the following are considered initiators of apoptosis *except*: (Objective 6)
 - a. estrogens
 - b. death cytokines
 - c. loss of matrix attachment
 - d. cell-damaging stress
10. Which of the following events in hematopoiesis is regulated by apoptosis? (Objective 7)
 - a. removal of excess neutrophils following cessation of bacterial challenge
 - b. removal of excess B lymphocytes following immune stimulation
 - c. removal of excess platelets following hemostatic challenge
 - d. a and b

LEVEL II

8. The components of apoptosis directly responsible for dismantling the cell during the programmed cell death process are: (Objective 8)
 - a. Bcl-2 family members
 - b. IAPs
 - c. initiator caspases
 - d. effector caspases
9. A predominance of Bax-Bax homodimers has what effect on apoptosis? (Objective 11)
 - a. inhibits initiator caspases
 - b. promotes activation of effector caspases
 - c. activates death receptors on the cell surface
 - d. neutralizes IAPs
10. All of the following are considered characteristics of tumor suppressor genes *except*: (Objective 13)
 - a. function normally as negative regulators of the cell cycle
 - b. undergo gain-of-function mutations resulting in malignant transformation
 - c. have mutated forms of the genes often found in inherited predispositions to malignancy
 - d. have characteristic mutations that are recessive in expression patterns.

ANSWERS TO CHECKPOINTS

Checkpoint! 1

What is meant by the phrase “lipid asymmetry” when describing cell membranes?

Answer

The phospholipid’s content of the inner (cytoplasmic) half of the lipid bilayer differs from the phospholipid’s content of the outer (external) half of the lipid bilayer. Phosphatidylethanolamine (PE) and phosphatidylserine (PS) occur in the inner layer while phosphatidylcholine (PC) and sphingomyelin (SM) occur predominantly in the outer layer.

Checkpoint! 2

Explain the difference between densely staining chromatin and lighter staining chromatin when viewing blood cells under a microscope.

Answer

Densely staining chromatin represents tightly twisted or folded regions of chromatin that are transcriptionally inactive. Lighter staining chromatin represents unwound or loosely twisted regions of chromatin that are transcriptionally active.

Checkpoint! 3

What is the difference between a “polymorphism” and a “mutation”?

Answer

Polymorphism describes a change in the nucleotide sequence of a gene that occurs with a frequency of >1% of the population. Mutation describes a change in the nucleotide sequence of a gene that results in an abnormality of function of that gene or gene product.

Checkpoint! 4

A cell undergoing mitosis fails to attach one of its duplicated chromosomes to the microtubules of the spindle apparatus during metaphase. The cell's metaphase checkpoint malfunctions and does not detect the error. What is the effect (if any) on the daughter cells produced?

Answer

If one of the paired (duplicated) sister chromatids fails to attach to the mitotic spindle during metaphase, the duplicated chromosomes will not separate during anaphase and telophase. If the cell does not catch this mistake, and cytokinesis still completes, one daughter cell will have two copies of that chromosome and the other daughter cell will have none. Both cells are said to be *aneuploid* (i.e., have an abnormal number of chromosomes).

Checkpoint! 5

What would be the effect on the hematopoietic system homeostasis if the expanded clone of antigen-activated B lymphocytes failed to undergo apoptosis after the antigenic challenge was removed?

Answer

The result would be an accumulation of excess lymphocytes and a progressive lymphocytosis.

Checkpoint! 6

Mutations of proto-oncogenes predisposing to malignancy are said to be dominant mutations while mutations of antioncogenes are said to behave as recessive mutations, requiring the loss of both alleles. Explain this difference in behavior of the gene products.

Answer

The products of proto-oncogenes are usually proteins that are important in regulating cell growth, differentiation, or apoptosis in their wild-type state. Mutations resulting in enhanced cell growth or in defective or deficient differentiation or apoptosis generally are capable of exerting an effect on the indicated process whenever the aberrant protein is produced (i.e., a single allele resulting in the production of some quantity of the indicated protein). In contrast, antioncogenes or tumor suppressor genes produce protein products that inhibit cell growth or promote apoptosis. Because the human genome carries two copies of all genes carried on the autosomes, a mutation of one tumor-suppressor allele resulting in a loss of function will still leave the other allele producing a wild-type protein product. Both alleles must be knocked out before the cell experiences complete loss of that protein effect.

Hematopoiesis

J. Lynne Williams, Ph.D.

■ OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. Describe the basic concepts of cell differentiation and maturation.
2. Compare and contrast the categories of hematopoietic precursor cells: hematopoietic stem cells, hematopoietic progenitor cells, and maturing cells, including proliferation and differentiation potential, morphology, and population size.
3. Describe the hierarchy of hematopoietic precursor cells and the relationships of the various blood cell lineages to each other (including the concept of colony-forming units/CFUs).
4. Discuss the general characteristics of growth factors and identify the major examples of early acting (multilineage), later acting (lineage restricted), and indirect acting growth factors.
5. Differentiate between paracrine, autocrine, and juxtacrine regulation.
6. List examples of negative regulators of hematopoiesis.
7. Define *hematopoietic microenvironment*.

■ OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. Identify the phenotypic characteristics differentiating the hematopoietic stem cells and progenitor cells.
2. Identify the key cytokines required for lineage-specific regulation.
3. Describe the structure and role of growth factor receptors.
4. Summarize the concept of signal transduction pathways.
5. Discuss the roles of transcription factors in the regulation of hematopoiesis and differentiation.
6. Outline current clinical uses of cytokines.
7. Describe the cellular and extracellular components of the hematopoietic microenvironment.
8. Discuss the proposed mechanisms used to regulate hematopoietic stem/progenitor cell proliferation/differentiation.

CHAPTER OUTLINE

 Progenitor cell
 Stromal cells
 Transcription factors (TF)

BACKGROUND BASICS

The information in this chapter will build on the concepts learned in previous chapters. To maximize your learning experience you should review these concepts before starting this unit of study.

Level I and Level II

- ▶ Identify the component parts of a cell, including the structure and function of cellular organelles.
- ▶ Describe the *cell cycle* and the molecules that regulate it.
- ▶ Describe *apoptosis*, the two activation pathways, and the roles of caspases and the Bcl-2 family of proteins in the process.

▶ OVERVIEW

This chapter begins with an introduction to the concepts of commitment and differentiation in the hematopoietic system. It discusses the defining characteristics of the hematopoietic precursor cells and then the cytokines that regulate the development of these precursor cells. The structure and function of the cytokine receptors are presented with a summary of the signaling pathways and transcription factors activated by receptor-cytokine binding. Finally, the hematopoietic microenvironment is described and its role in hematopoiesis summarized.

▶ INTRODUCTION

The maintenance of an adequate number of cells to carry out the functions of the organism is referred to as *tissue homeostasis*, and depends on a careful balance between

cellular proliferation, cellular differentiation, and cell death (apoptosis). The hematopoietic system presents a challenge when considering the homeostasis of the circulating blood because the majority of circulating cells are postmitotic cells that are relatively short lived. Thus, circulating blood cells are intrinsically incapable of providing their replacements when they reach the end of their life spans. **Hematopoiesis** is the process responsible for the replacement of circulating blood cells and depends on the proliferation of precursor cells that still retain mitotic capability. This process is governed by a multitude of cytokines (both stimulating and inhibitory growth factors) and takes place in a specialized microenvironment uniquely suited to regulate the process.

▶ HEMATOPOIESIS

Whereas cell proliferation and programmed cell death (apoptosis) work together to provide an adequate number of cells, **differentiation** is the process responsible for generating the diverse cell populations that provide the specialized functions needed by the organism. Differentiation has been defined as the appearance of different properties in cells that were initially equivalent. Because all cells of an organism have the same genetic information, differentiation (or the appearance of specific characteristics) occurs by the progressive restriction of other potentialities of the cell.¹ **Commitment** is the term used to define the instance when two cells derived from the same precursor take a separate route of development.¹ Commitment “assigns the program,” and the maturation process executes it (**maturation** encompasses the totality of phenomena that begins with commitment and ends when the cell has all its characteristics).¹

Hematopoiesis (the development of all the different cell lineages of the blood) has two striking characteristics: the variety of distinct blood cell types produced and the relatively brief life span of the individual cells. The cells circulating in the peripheral blood are mature blood cells and, with the exception of lymphocytes, are generally incapable of mitosis. Also they have a limited life span from days for granulocytes and platelets to ~4 months for erythrocytes. As a result, they are described as *terminally differentiated*. This constant death of mature, functional blood cells (by apoptosis) means that new cells must be produced to replace those that are removed either as a consequence of performing their biologic functions (e.g., platelets, granulocytes) or through cellular senescence or “old age” (erythrocytes). The replacement of circulating, terminally differentiated cells depends on the function of less differentiated hematopoietic precursor cells that still retain significant proliferative capabilities. These hematopoietic precursor cells, located primarily in the bone marrow in adults, consist of a hierarchy of cells with enormous proliferation potential. They maintain a daily production of approximately 2×10^{11} red blood cells (RBC) and 1×10^{11} (each) white blood cells (WBC) and platelets for the lifetime of the individual.² In addition, acute stress (blood

loss or infection) can result in a rapid, efficient, and specific increase in production over baseline of the particular cell lineage needed. For example, acute blood loss results in a specific increased production of erythrocytes while a bacterial infection results in an increased production of phagocytic cells (granulocytes and monocytes).

HEMATOPOIETIC PRECURSOR CELLS

The pioneering work of Till and McCulloch began to define the hierarchical organization of hematopoietic precursor cells using *in vivo* clonal assays.³ However, it was not until the development of clonal *in vitro* assays that the current model of blood cell production began to evolve.^{3,4,5,6,7} Hematopoietic precursor cells can be divided into three cellular compartments defined by relative maturity: **hematopoietic stem cells**, **progenitor cells**, and **maturing cells** (Table 1). The nomenclature used to define these various compartments over the past 20 years has lacked uniformity. Although there is now general agreement on the designations *stem cells* and *progenitor cells*, various authors have called the third category precursor cells,⁸ maturing cells,⁹ or morphologically recognizable precursor cells.¹⁰ In this textbook, we use the term *precursor* to include all cells antecedent to the mature cells in each lineage and the term *maturing cells* to include those precursor cells within each lineage that are morphologically identifiable under the microscope.

Stem Cells

All hematopoiesis derives from a pool of undifferentiated cells, hematopoietic stem cells (HSC), which give rise to all of the bone marrow cells by the processes of proliferation and differentiation.¹¹ The stem cell compartment is the smallest of the hematopoietic precursor compartments, constituting of only ~0.5% of the total marrow nucleated cells. However, these rare cells are capable of regenerating the entire hematopoietic system. Thus, they are defined as multipotential precursors (i.e., they maintain the capacity to give rise to *all* lineages of blood cells). The other defining charac-

teristic of stem cells is their high self-renewal capacity (i.e., they give rise to daughter stem cells that are exact replicas of the parent cell). Despite their responsibility for generating the entire hematopoietic system, the majority of stem cells are not dividing at any one time (< 5%) with the majority being withdrawn from the cell cycle or quiescent (G₀ phase of the cell cycle).

Stem cells are not morphologically distinguishable. Primitive stem cells, isolated by fluorescent-activated cell sorting, appear morphologically very similar to small lymphocytes. Because stem cells are not morphologically identifiable, they have been defined functionally by their ability to reconstitute both lymphoid and myeloid hematopoiesis when transplanted into a recipient. In mice, the existence of the true HSC has been unequivocally demonstrated by occasional successful transplants with single purified stem cells, providing direct proof that single cells capable of sustaining life-long hematopoiesis do exist.¹² There are no practical and quantitative assays for human HSC. Despite the difficulties (both practical and ethical) surrounding an effective assay for human stem cells, a number of characteristics have been used to define their phenotype, and these can be used in cell-separation protocols resulting in a high degree of purity. The currently proposed phenotype of a human HSC is:

$$CD34^{+}Thy-1^{lo}CD38^{-}Lin^{-}HLA-DR^{-}Rh123^{Dull}$$

In addition, HSCs are positive for the receptor for stem cell factor (SCF-R or c-kit, CD-117) and the thrombopoietin receptor (TPO-R, CD-110). CD-34, SCF-R, and TPO-R are not found exclusively on HSCs but also on cells that have begun to differentiate.

CD34 is a 110 kDa glycoprotein expressed by human hematopoietic stem cells and early progenitor cells.¹³ Expression of CD34 is lost as cells mature beyond the progenitor cell compartment. Thy-1 is a membrane glycoprotein that participates in T-lymphocyte adhesion to stromal cells. CD38 is a 45 kDa glycoprotein considered to be an early myeloid differentiation antigen. *Lin*⁻ refers to the absence of known differentiation markers or antigens present on more

TABLE 1

Comparison of Hematopoietic Precursor Cells

Stem Cells	Progenitor Cells	Maturing Cells
~0.5% of total hematopoietic precursor cells	3 percent of total hematopoietic precursor cells	>95% of total hematopoietic precursor cells
Multilineage differentiation potential	Restricted developmental potential (multipotential → unipotential)	Committed (unipotential) transit population
Quiescent cell population—population size stable	Population amplified by proliferation	Population amplified by proliferation
Population maintained by self-renewal	Transit population without true self-renewal	Proliferative sequence complete before full maturation
Not morphologically recognizable	Not morphologically recognizable	Morphologically recognizable
Measured by functional clonal assays <i>in vivo</i> and <i>in vitro</i>	Measured by clonal assays <i>in vitro</i>	Measured by morphologic analysis; cell counting differentials

★ TABLE 2

Lineage-Specific Markers Used in Purification of HSC

Erythrocytes	Glycophorin A
Megakaryocytes	Glycoprotein (GP) IIb/IIIa
Neutrophils	CD13, CD15, CD33
Monocytes and macrophages	CD11b, CD14
B lymphocytes	CD10, CD19, CD20
T lymphocytes	CD3, CD4, CD5, CD8, CD38, HLA-DR

lineage-restricted progenitors (Table 2★). The HLA-DR antigens are a component of the human major histocompatibility complex antigens. Rhodamine¹²³ is a fluorescent supravital dye that is taken up by cells.¹⁴ HSCs have high levels of pumps capable of effluxing dyes (and drugs). They transport the dye out of the cells and are functionally Rho123^{Dull}. Thus, the long-term reconstituting multipotential stem cells are found in the population of cells that contain no lineage-specific antigens, CD38, or HLA-DR antigens but express CD34, SCF-R, and TPO-R and are largely quiescent.

The process of self-renewal, which is a *nondifferentiating cell division*, ensures that the stem cell population is sustained throughout the individual's the lifespan. It is estimated that humans have only $\sim 2 \times 10^4$ HSCs.¹⁵ This small group of cells is able to maintain tremendous hematopoietic cell supplies through the division of only a tiny fraction of its members, keeping the remainder of the stem cells in reserve. The size of the stem cell compartment is relatively stable under homeostatic conditions. In a stem cell compartment that remains stable in size but supplies differentiating cells, a cell must be added to the compartment by proliferation within the compartment (self-renewal) for each cell that leaves by the process of differentiation. Thus, the stem cell pool must carefully balance the simultaneous processes of expansion (self-renewal) and differentiation. For an individual stem cell undergoing mitosis, these two processes are mutually exclusive.

The regulation of cell-fate decisions of the HSC—whether to remain quiescent, self-renew, or initiate differentiation—is complex and not fully understood. It is thought to involve the interplay of cytokine-receptor interactions and transcription factor activation (see discussion that follows). Quiescence is maintained through interaction with stromal cells and molecules in the hematopoietic microenvironment and interaction with cytokines that have an inhibitory effect on hematopoiesis (see discussion that follows). As an example, TGF- β , a negative regulator of hematopoiesis, upregulates the cell cycle inhibitor p21 to help maintain the quiescent status of HSC.¹⁶

It has been suggested that HSCs reside in unique “stem cell niches” in the bone marrow, which regulate and balance the processes of self-renewal and differentiation. Actually, HSC have a third option available: apoptosis or programmed cell death (which may be triggered if the appropriate cytokines or

■ **FIGURE 1** Derivation and fates of hematopoietic stem cells (HSC). Hemangioblasts are precursor cells giving rise to both HSC and vascular endothelium during embryonic development. LT (long-term) HSC and ST (short-term) HSC refer to the length of time these subpopulations of HSC take to repopulate depleted hematopoietic tissue with LT cells being developmentally more primitive than ST cells. HSCs have three possible fates: self-renewal, commitment to differentiation (becoming common lymphoid progenitors [CLP] or common myeloid progenitors [CMP]), or apoptosis. This cell-fate decision is highly regulated and involves specific transcription factors. (Adapted from Zhu J, Emerson SG. Hematopoietic cytokines, transcription factors and lineage commitment. *Oncogene*. 2002;21:3295–3313.)

microenvironment are not available to sustain the HSC) (Figure 1■). Figure 1 also depicts the hemangioblast, which is a multipotential precursor capable of producing both HSC and vascular endothelium.¹⁶ Not all HSCs are identical; there is an “age” hierarchy that has been described based on the time it takes for transplanted marrow cells to repopulate a lethally irradiated animal. Thus, the terms *long-term repopulating cells* and *short-term repopulating cells* are used, the short-term repopulating cells are further along the hematopoietic developmental pathway² (Figure 1).

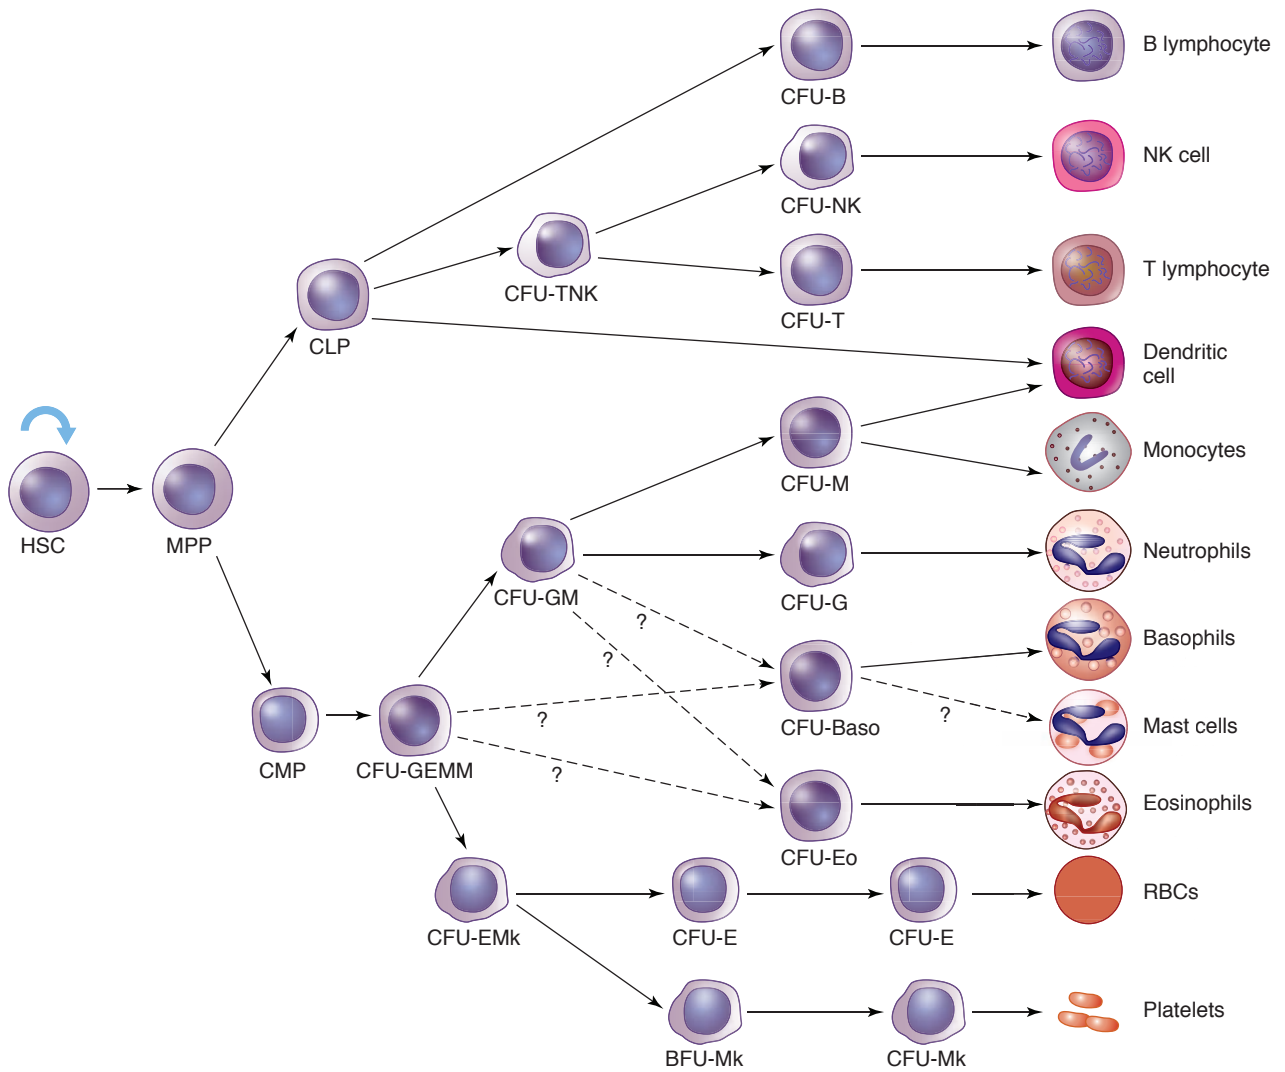

Progenitor Cells

To meet the cell demands imposed on the hematopoietic system, some stem cells ultimately undergo differentiation. The molecular mechanisms that HSCs utilize to control whether they will self-renew or differentiate upon mitosis remain a mystery. The transition from an HSC to a committed

progenitor correlates with the down-regulation of HSC-associated genes via gene silencing and the up-regulation or activation of lineage-specific genes.¹⁷ Evidence suggests that pluripotential stem and progenitor cells simultaneously express low levels of many different genes characteristic of multiple different, discrete lineages (e.g., transcription factors, cytokine receptors).¹⁸ This so-called “promiscuous” gene expression is actually characteristic of most multipotent cells. The process of down-regulating HSC-associated genes reduces the promiscuous gene expression so that genes of

the lineage to which the cell has committed are upregulated while the expression of genes associated with alternate lineages are silenced. Lineage-specific transcription factors are thought to play essential roles in this process (see below).

Upon commitment to development, the stem cell enters the next compartment, the progenitor cell (PC) compartment. Initially, the daughter cells arising from undifferentiated stem cells retain the potential to generate cells of all hematopoietic lineages (multipotential progenitor cells/MPP, see Figure 2 ■). After additional divisions, however, the

■ **FIGURE 2** The differentiation of blood cells from a pluripotent stem cell. The pluripotent hematopoietic stem cell (HSC), multipotential progenitor cell (MPP), common myeloid progenitor (CMP), and the colony-forming unit (CFU)-granulocyte, erythrocyte, macrophage, and megakaryocyte (CFU-GEMM) have the potential to differentiate into one of several cell lines and are therefore multilineage precursor cells. The CFU-GM (granulocyte, monocyte) CFU-EMk (erythrocyte, megakaryocyte) and CFU-TNK (T-lymphocyte, natural killer cell) are bipotential progenitors. The committed (unilineage) progenitors—CFU-G (granulocyte), CFU-M (monocyte), CFU-Eo (eosinophil), CFU-Baso (basophil), BFU (burst-forming unit)-E and CFU-E (erythrocyte), and BFU-Mk and CFU-Mk (megakaryocyte)—differentiate into only one cell line. The BFUs are more immature than the CFUs. The mature blood cells are those found in the peripheral blood. The common lymphoid progenitor cell (CLP) may differentiate into T- or B-lymphocytes, natural killer cells, or lymphoid dendritic cells.

progeny of daughter cells lose their ability to generate cells of progressively more lineages and gradually become restricted in differentiation potential to a single cell lineage (unilineage or committed progenitor cells). The progenitor cell compartment thus includes all precursor cells developmentally located between stem cells and the morphologically recognizable precursor cells.

The PC compartment is larger than the HSC compartment, constituting ~3% of the total nucleated hematopoietic cells. PCs do not possess self-renewal ability; in general, their process of cell division is obligatorily linked to differentiation. They are, in essence, transit cells said to be on a suicide maturation pathway (because full maturation and differentiation result in a *terminally differentiated* cell with a finite life span). Like the HSC, PCs are not morphologically identifiable but are functionally defined based on the mature progeny that they produce. Both multipotential and unipotential PCs can be assayed by their ability to form colonies of cells in semisolid media *in vitro* and are described as *colony-forming units* (CFU) with the appropriate lineage(s) appended. For example, a CFU-GEMM would be a progenitor cell capable of giving rise to a mixture of all myeloid lineages: **g**ranulocytic, **e**rythrocytic, **m**onocytic, and **m**egakaryocytic while a CFU-GM would be a bipotential PC with both granulocytic and monocytic differentiation potential, and a CFU-Mk would be a unilineage progenitor giving rise exclusively to cells of the megakaryocytic series. PCs are mitotically more active than stem cells and are capable of expanding the size of the PC compartment by proliferation in response to increased needs of the body. Thus, the PC compartment consists of a potentially *amplifying* population of cells as opposed to the stable size of the stem cell compartment.

Lineage commitment is a fundamental but poorly understood step in normal hematopoiesis. The factors that regulate this process remain unknown. It is clear, however, that differentiation is accompanied by the increased expression of certain lineage-specific genes and the silencing of genes associated with differentiation along alternate lineages by epigenetic alterations of the chromatin structure. A number of growth-regulatory glycoproteins, or cytokines (see cytokine section), influence the survival and differentiation of hematopoietic precursor cells.

Maturing Cells

After a series of amplifying cell divisions, the committed precursor undergoes a further change when the cell takes on the morphologic characteristics of its lineage. Maturing cells constitute the majority of hematopoietic precursor cells; proliferation and amplification boost these cells to more than 95% of the total precursor cell pool. In general, the capacity to proliferate is lost before full maturation of these cells is complete. They exhibit recognizable nuclear and cytoplasmic morphologic characteristics that can be used to classify

their lineage and stage of development. Because these cells can be morphologically categorized, different nomenclature is used. Generally, the earliest morphologically recognizable cell of each lineage is identified by the suffix *-blast*, with the lineage indicated (i.e., lymphoblast [lymphocytes], myeloblast [granulocytes], or megakaryoblast [megakaryocytes/platelets]). In some lineages, additional differentiation stages are indicated by prefixes or qualifying adjectives (i.e., proerythroblast, basophilic erythroblast).

✓ Checkpoint! 1

Hematopoietic stem cells that have initiated a differentiation program are sometimes described as undergoing death by differentiation. Explain.

Hematopoietic Precursor Cell Model

The head of the hierarchy of hematopoietic cells is the *pluripotent hematopoietic stem cell (HSC)*. These are the cells that have full self-renewal abilities and that give rise to all other hematopoietic elements (Figure 2). The progeny of HSCs gradually loses one or more developmental potentials and eventually becomes committed to a single lineage.

The earliest differentiating daughters of the HSC are slightly more restricted in differentiation potential. One group of daughter cells is a precursor capable of giving rise to all cells of the lymphoid system: the *common lymphoid progenitor cell (CLP)*.¹⁹ The other group is composed of daughter cells restricted to producing cells of the myeloid system (the cell lineages of the bone marrow): the *common myeloid progenitor cell (CMP)*.²⁰ These cells, although multipotential, have no self-renewal ability and are ultimately destined to differentiate. The phenotypes for the various levels of PC can be seen in Table 3 🌟.

CMP	CD34 ⁺ , Lin ⁻ , IL7R ⁻ , SCFR ⁺
CFU-GM	CD34 ⁺ , SCFR ⁺ , FcR γ ^{Hl} , CD33 ⁺ , CD13 ⁺
CFU-EMk	CD34 ⁻ , SCFR ⁺ , FcR γ ^{Lo} , CD33 ⁻ , CD13 ⁻

HSC = hematopoietic stem cell; Lin⁻ = lineage markers negative; Rh123^{Dull} = negative for supravital dye Rhodamine123; SCF-R = receptor for stem cell factor; TPO-R = receptor for thrombopoietin; CLP = common lymphoid progenitor; IL7R = receptor for IL7; CMP = common myeloid progenitor; CFU-GM = granulocyte, monocyte colony forming unit; CFU-EMk = erythroid, megakaryocytic colony forming unit; FcR γ = receptor for Fc component of IgG γ chain

Following additional differentiation steps (Figure 2), the CLP gives rise to T and B lymphocytes, NK (natural killer) cells and lymphoid dendritic cells, while the CMP gives rise to at least six different lines of cellular differentiation, ultimately producing mature neutrophils, monocytes, eosinophils, basophils, erythrocytes, and megakaryocytes/platelets. One of the first precursor cells defined as arising from the CMP was the CFU-GEMM, a cell capable of producing colonies in culture consisting of granulocytic, eosinophilic, erythrocytic, and megakaryocytic elements. However, it soon was shown that there are layers of functionally defined cells between the true CMP and the CFU-GEMM. Various authors have assigned names to these intermediate cells, including CFU-Blast,²¹ HPP-CFC²² (high proliferative potential, colony-forming cell), CFU-D12²³ (colony-forming unit, day 12), and LT-CIC²⁴ (long-term culture initiating cell). Whether these represent distinct subpopulations of early progenitor cells or overlapping subpopulations is unclear. In general, they require two to seven growth factors for optimal growth, are characterized by their capacity to produce large colonies of cells (>50,000 cells per colony) after prolonged growth periods in culture, and represent cell populations more primitive than the CFU-GEMM.²⁵

The sequence of events during the differentiation of a myeloid or lymphoid multipotential progenitor cell to a unilineage, committed progenitor cell is still being resolved. Neutrophils and monocytes are derived from a common committed bipotential progenitor cell, the CFU-GM, which ultimately gives rise to lineage restricted and morphologically recognizable precursor cells (myeloblasts and monoblasts).²⁰ Similarly, erythrocytes and megakaryocytes appear to be derived from a common bipotential progenitor cell, the CFU-EMk,^{20,26} and T lymphocytes and natural killer cells share a common precursor, the CFU-TNK.²⁷ The developmental pathway for eosinophils and basophils/mast cells remains uncertain. Some authors describe the CFU-Eo and CFU-B developing from the CFU-GM² while others depict them deriving from the CFU-GEMM.²⁸

Each of the unilineage or committed progenitor cells is named for the cell lineage to which it is committed (e.g., CFU-Mk for megakaryocytes, CFU-E for erythrocytes, CFU-M for monocytes, CFU-G for neutrophils, CFU-Eo for eosinophils, and CFU-B for basophils). Within some lineages are designated subpopulations of committed progenitor cells. Committed erythroid progenitors are designated as erythroid burst-forming units (BFU-E) and erythroid colony forming units (CFU-E) with the BFU-E being the more primitive precursor cell antecedent to the CFU-E. A similar BFU-Mk/CFU-Mk hierarchy has been described for the megakaryocyte lineage.²⁹ Each committed progenitor cell differentiates into morphologically identifiable precursors of their respective lineage (e.g., CFU-E → Proerythroblast; CFU-G → myeloblast).

Under normal steady-state physiological conditions, the majority of hematopoietic precursor cells (SC and PC) are retained in the bone marrow. A small population of SC and PC can, however, be found circulating in the peripheral blood.

The number of circulating SC/PC can be further increased by the infusion of various cytokines, enabling the collection of “mobilized” peripheral blood SC/PC for transplantation purposes rather than from a direct bone marrow harvest.

✓ Checkpoint! 2

Explain the difference in the nomenclature used to label progenitor cells from that used to label maturing cells within the hematopoietic hierarchy of cells.

▶ CYTOKINES AND THE CONTROL OF HEMATOPOIESIS

The regulation of hematopoietic stem/progenitor cell differentiation and expansion is critical because it determines the concentration of various lineages in the marrow and eventually in the peripheral blood. Hematopoietic precursor cell survival, self-renewal, proliferation, and differentiation are governed by specific glycoproteins called *hematopoietic growth factors*, or **cytokines** (Figure 3■). Growth factor control of hematopoiesis is an extraordinarily complex and highly efficient intercellular molecular communication system that allows the coordinated increases in the production and functional activity of appropriate hematopoietic cell types without expansion of the irrelevant ones. The first identified growth factors (GF) were described as *colony-stimulating factors* (CSFs) because they sustained the growth of hematopoietic colonies in in vitro cultures. Subsequently, as additional cytokines were discovered, the system of nomenclature was changed to that of *interleukins*. When a new cytokine is discovered, the initial description is based on its biologic properties; when the amino acid sequence has been defined, an interleukin number is assigned. The system has some exceptions and inconsistencies, however. For historic reasons, some cytokines retain their original names (e.g., GM-CSF, G-CSF, M-CSF, EPO, and TPO). The initial research into the biologic activities of other cytokines focused on activities outside hematopoietic regulation, and their original names have been retained (e.g., kit-ligand/SCF, Flt3 ligand/FL). More than 30 interleukins have been isolated and characterized to date.

The growth of hematopoietic precursor cells requires the continuous presence of GFs. If the relevant GFs are withdrawn, the cells die within hours by the active process of self-destruction or apoptosis. Thus, the first effect of GFs is to promote cell survival by suppressing apoptosis (programmed cell death). Second, GFs promote proliferation. Hematopoietic cells are intrinsically incapable of unstimulated cell division. All cell division or proliferation depends on stimulation by appropriate regulatory cytokines. Additionally, GFs control and regulate the process of differentiation, which ultimately produces the mature functional cells from their multipotential progenitor cell precursors (Figure 3). Finally, GFs that induce proliferation of precursor cells

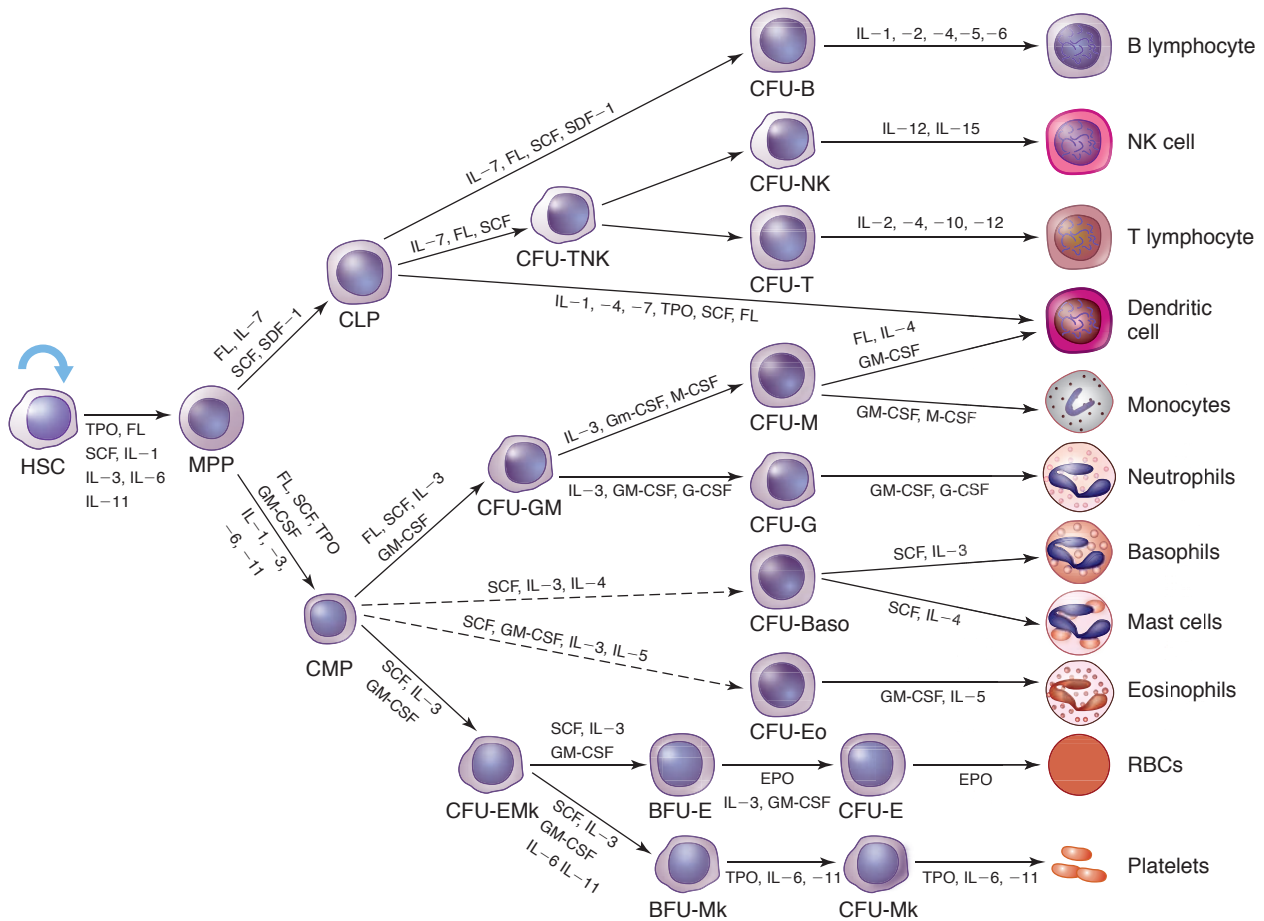

FIGURE 3 The pluripotential hematopoietic stem cell (HSC) gives rise to erythrocytes, platelets, monocytes, macrophages, granulocytes, and lymphoid cells. Under stimulation from selective growth factors, stem cell factor (SCF), Fit ligand (FL), and interleukins (IL), the HSC in quiescence (G_0) enters the cell cycle (G_1) and differentiates to the common myeloid progenitor cell (CMP) and, subsequently, to the colony-forming unit-granulocyte, erythroid, macrophage, and megakaryocyte (CFU-GEMM). The CFU-GEMM then differentiates into granulocytes, erythrocytes, monocytes, and megakaryocytes under the influence of specific growth factors, erythropoietin (EPO), thrombopoietin (TPO), granulocyte-monocyte colony-stimulating factor (GM-CSF), granulocyte colony stimulating factor (G-CSF), macrophage colony-stimulating factor (M-CSF), and interleukin-5 (IL-5). Different combinations of hematopoietic cytokines regulate the differentiation of HSC into the common lymphoid progenitor cell (CLP) and subsequently into B and T lymphocytes, natural killer (NK) cells, and lymphoid dendritic cells. (SDF-1 = stromal cell derived factor-1.)

sometimes have the capacity to enhance the functional activity of the terminally differentiated progeny of these precursor cells.

CHARACTERISTICS OF GROWTH FACTORS

Although many different cytokines have been identified as hematopoietic growth factors, many of them share a number of characteristics (Table 4). Most GFs are produced by a number of different cells, including monocytes, macrophages, activated T lymphocytes, fibroblasts, endothelial cells, osteoblasts, and adipocytes (bone marrow stromal cells). With the notable exception of erythropoietin (EPO), most GFs are produced by stromal cells in the hematopoietic microenviron-

TABLE 4

Characteristics of Hematopoietic Growth Factors

- GFs are produced by stromal cells in the hematopoietic microenvironment.
- Individual GFs have multiple biologic activities (pleiotropy).
- Many different GFs have similar or identical activities (redundancy).
- By themselves individual GFs are poor stimulators of colony growth; control of hematopoiesis generally involves the interplay of at least several GFs.
- GFs interact with membrane receptors restricted to cells of appropriate lineage.
- GF requirements change during the differentiation process.
- GFs can affect hematopoiesis directly or indirectly.
- Regulatory cytokines are organized in a complex, interdependent network and exhibit many signal amplification circuits.
- GFs commonly act synergistically with other cytokines.

ment. EPO production is atypical of the lymphohematopoietic GFs in that it is produced mainly in the kidney, released into the peripheral blood, and carried to the bone marrow where it regulates red blood cell production. As such, it is the only true hormone (endocrine cytokine), whereas the majority of the other cytokines exert their effects on cells in the local environment where they are produced. Often a single stromal cell source may produce multiple cytokines.

The majority of GFs are not lineage specific; each GF has multiple functions, and most of the GFs act on more than one cell type (i.e., they are *pleiotrophic*) (Table 5). Cytokines must be bound to surface receptors on their target cells to express their activity. They interact with membrane receptors restricted to cells of the appropriate lineage. Be-

cause many precursor cells respond to more than one GF, they obviously express receptors for multiple GFs. Some GFs influence hematopoiesis directly by binding to receptors on precursor cells and inducing the appropriate response (survival, proliferation, differentiation). Other GFs influence the process indirectly by binding to receptors on accessory cells, which in turn respond by releasing other direct-acting cytokines. Some GFs trigger cell division while others support survival without inducing proliferation.

Hematopoietic regulatory cytokines interact in a highly ordered, interdependent network creating a complex cell-to-cell communication system. Individual GFs by themselves are poor stimulators of colony growth; the control of hematopoiesis generally involves the interplay of at least several GFs. Some

TABLE 5

Hematopoietic Growth Factors (GFs)

GF	Mol. Wt.	Chromosome	Source	Major Target Cells
EPO	34–39,000	7	Kidney (liver)	Erythroid
GM-CSF	18–30,000	5	T cells, EC, fibroblasts, mast cells	Granulocytes, monos, eos, erythroid, megs, progenitor cells
IL-3	14–28,000	5	Activ T cells, mast cells	Granulocytes, monos, eos, erythroid, megs basos, progenitor cells
G-CSF	18,888	17	Monos, macros, fibroblasts, EC	Granulocytes, early progenitor cells
M-CSF	70–90,000	1	Monos, macros, fibroblasts, EC	Monos, macros, osteoclasts
IL-1	17,000	2	Monos, macros, dendritic cells	Monos, EC, fibroblasts, lymphs, PMN, early progenitor cells
IL-2	23,000	4	Activ T _H 1 cells	Prolif and activ of T, B, and NK cells
IL-4	18,000	5	Activ T _H 2 cells	Stim T _H 2, suppress T _H 1; B cells, mast cells basos, fibroblasts
IL-5	50–60,000	5	Activ T _H 2 cells	Eos, B cells, cytotoxic T cells
IL-6	21–26,000	7	Fibroblasts, EC, macros, T _H 2 cells	Early progenitor cells, B and T cells; megs; myeloid; myeloma cells
IL-7	17,000	8	Stromal cells (BM and thymus)	Pre-T, pre-B cells, NK cells, T _S differentiation
IL-8	8,000	4	Monos, macros, EC, fibroblasts	Chemotaxis of granulocytes (chemokine)
IL-9	40,000	5	Activ T _H cells	T cells, early erythroid cells, mast cells
IL-10	18,000	1	T _H 2 cells, monos, macros, activated B cells	B cells, mast cells, T _H 2 cells, inhib T _H 1 cells
IL-11	24,000	19	Stromal cells, fibroblasts	B cells, megs, early progenitor cells
IL-12	75,000	3,5	Monos, macros, B cells	T _H 1 cells, NK cells
IL-13	18,000	5	T cells, basos	Isotype switching of B cells; inhib cytotoxic and inflamm functions of monos and macros
IL-14	53–65,000	16	T cells	Activ B cells
IL-15	14–18,000	4	Monos, macros, E.C., fibroblasts	T cells (CTL), NK cells (LAK), co-stim for B cells
IL-16	16–18,000	15	T cells, Eos, mast cells	Chemotactic for CD4 ⁺ T cells, monos, eos
IL-17	22,000	2	Activ T cells	Induces cytokine production by stromal cells
IL-18	18,000	7	Macros, keratinocytes	Induces IFN production by lymphocytes
SCF/KL	28–36,000	12	Fibroblasts, EC, stromal cells	Stem cells, progenitor cells, mast cells
FL	18,000	19	Stromal cells, monos, macros, T cells	Stem cells, progenitor cells, B cells, dendritic cells
TPO	65–85,000	3	Stromal cells, hepatocytes, kidney	Megs, early progenitor and stem cells

Abbreviations used: T cell, B cell = T or B lymphocytes; NK = natural killer cells; EC = endothelial cells; monos = monocytes; macros = macrophages; basos = basophils; eos = eosinophils; megs = megakaryocytes; PMN = neutrophils; activ = activates; inhib = inhibits; inflamm = inflammation; activ T cells = T lymphocytes activated by antigens, mitogens, or cytokines; CTL = cytotoxic T lymphocytes; LAK = lymphokine activated killer cells; prolif = proliferation; stim = stimulation

GFs act synergistically with other cytokines (synergism occurs when the net effect of two or more events is greater than the sum of the individual effects). Many cytokines have overlapping activities (redundancy). The cytokine network often exhibits signal amplification circuits including autocrine, paracrine, and juxtacrine mechanisms of stimulation/amplification (Figure 4■). **Autocrine** signals are produced by and act on the same cell. **Paracrine** signals are produced by one cell and act on an adjacent cell, typically over short distances. **Juxtacrine** signals represent a specialized type of paracrine signaling in which the cytokine is not secreted by the cell that produced it but remains membrane bound, necessitating direct producer cell-target cell contact to achieve the desired effect. In contrast, endocrine signals (classic hormones) typically act over fairly long distances. The majority of cytokines regulating hematopoiesis exert their effects via paracrine or juxtacrine interactions.

GF requirements change during the differentiation process so that the cytokines/GFs needed by the HSC and early multipotential PC differ from the GF requirements of the later, lineage-restricted progenitors and the maturing precursor cells. These are described as early-acting (multilineage) GFs and later-acting (lineage-restricted) GFs, respectively. GFs and their receptors share a number of structural features, perhaps explaining some of observed functional redundancies. Most of the GFs have been cloned and characterized, and recombinant proteins are available; certain of these GFs have been shown to have important clinical applications.

Early-Acting (Multilineage) Growth Factors

Several GFs have direct effects on multipotential precursor cells and thus are capable of inducing cell production within

■ **FIGURE 4** Mechanisms of cytokine regulation. Autocrine signals are produced by and act on the same cell. Paracrine signals are produced by one cell and act on an adjacent cell, typically over short distances. A juxtacrine signal is a specialized type of paracrine signaling in which the cytokine is not secreted by the producing cell but remains membrane bound, necessitating direct cell-cell contact to achieve the desired effect. In contrast, endocrine signals (classic hormones) typically act over fairly long distances.

several lineages. Early-acting cytokines primarily affect proliferation of these noncommitted progenitor cells. These include SCF, FL, IL-3, GM-CSF, IL-6, and IL-11. Although these factors can initiate proliferation in several cell lineages, in many instances additional factors are necessary for the production of mature cells in these lineages (Figure 3).

Stem Cell Factor and Flt3 Ligand (FL) Stem cell factor (SCF) [also known as steel factor (SF), kit ligand (KL), or mast cell growth factor (MCGF)] promotes the proliferation and differentiation of stem cells and primitive multilineage progenitor cells as well as committed progenitor cells (CFU-GEMM, CFU-GM, CFU-Mk, BFU-E). SCF also promotes the survival, proliferation, and differentiation of mast cell precursors and has functional activity outside the hematopoietic system; it plays a role in normal melanocyte development and gametogenesis. Hematopoietic cells responsive to FL appear to be more primitive than SCF-responsive cells. FL increases recruitment of primitive SC/PC into cell cycle and inhibits apoptosis.³⁰ In contrast to SCF, FL has little effect on unilineage BFU-E/CFU-E, CFU-mast cell, or CFU-Eo but is a potent stimulator of granulo/monocytic, B cell, and dendritic cell proliferation and differentiation. FL and SCF have similar protein structures and share some common characteristics. Both cytokines may be found as either membrane-bound or soluble forms, although the membrane-bound form appears more important physiologically; thus, the cytokines operate primarily through juxtacrine interactions.³¹ Neither cytokine has independent in vitro colony-stimulating activity, but both act synergistically with IL-3, GM-CSF, G-CSF, and other cytokines to promote early progenitor cell proliferation.

Interleukin 3 and GM-CSF Interleukin 3 (IL-3) is one of the earliest recognized multipotential growth factors that directly affects multilineage progenitor cells and early committed progenitors such as BFU-E. IL-3 also has indirect actions and can induce the expression of other cytokines. GM-CSF is also a multipotential GF that stimulates clonal growth of all lineages except basophils. GM-CSF also activates the functional activity of most mature phagocytes including neutrophils, macrophages, and eosinophils.

Interleukin 6 and Interleukin 11 Interleukin 6 (IL-6) and Interleukin 11 (IL-11) are pleiotropic cytokines with overlapping growth stimulatory effects on myeloid and lymphoid cells as well as on primitive multilineage cells.^{32,33} Each cytokine rarely acts alone but functions synergistically with IL-3, SCF, and other cytokines in supporting hematopoiesis. Both cytokines have significant effects on megakaryocytopoiesis and platelet production.³⁴ Both mediate the acute phase response of hepatocytes and are major pyrogens in vivo.

Later-Acting (Lineage-Restricted) Growth Factors

The growth factors included here tend to have a narrower spectrum of influence and function primarily to induce mat-

uration along a specific lineage. However, most are *not* lineage specific but instead demonstrate a predominant effect on the committed progenitor cell of a single lineage, inducing differentiation of these more mature cells. These growth factors (cytokines) include granulocyte colony-stimulating factor/G-CSF (granulocytes), monocyte colony-stimulating factor/M-CSF (monocytes), erythropoietin/EPO (erythrocytes), thrombopoietin/TPO (megakaryocytes and platelets), interleukin-5/IL-5 (eosinophils), and the interleukins important in lymphopoiesis (ILs-2, -4, -7, -10, -12, -13, -14, -15).

EPO is the only cytokine to function as a true hormone as it is produced at a distant site and travels via the circulation to the bone marrow to influence erythrocyte production. It is expressed largely by cells in the liver in embryonic life and by cells of the kidney (and to a lesser extent, liver) in adult life. Its release is regulated by the body's oxygen needs and is induced by hypoxia. EPO stimulates survival, growth, and differentiation of erythroid progenitor cells (with its major effect on CFU-E). It also stimulates proliferation, and RNA and protein synthesis in erythroid-maturing cells. Reticulocytes and mature erythrocytes do not have receptors for EPO and thus are not influenced by this cytokine.

G-CSF, M-CSF, and IL-5 stimulate the proliferation of granulocyte, monocyte/macrophage, and eosinophil progenitor cells, respectively. All three also influence the function of mature cells of their respective lineages, increasing migration, phagocytosis, metabolic activities and augmenting prolongation of their life spans. M-CSF also regulates the genesis of osteoclasts, and IL-5 stimulates lymphocyte development.

TPO, also known as *mpl-ligand* or *megakaryocyte growth and development factor* (MGDF), is the major physiologic regulator of megakaryocyte proliferation and platelet production. In vitro, TPO primes mature platelets to respond to aggregation-inducing stimuli and increases the platelet release reaction.³⁵ TPO also synergizes with a variety of other GFs (SCF, IL-3, FL) to stimulate the maintenance and growth of primitive progenitor cells.

Indirect-Acting Growth Factors

Some cytokines that regulate hematopoiesis do so indirectly by inducing accessory cells to release direct-acting factors. An example is IL-1, which has no colony-stimulating activity itself. However, when administered in vivo, it induces neutrophilic leukocytosis by promoting the release of other direct-acting cytokines from accessory cells.

LINEAGE-SPECIFIC CYTOKINE REGULATION

Erythropoiesis

In the erythroid lineage, progenitor cells give rise to two distinct types of erythroid colonies in culture. A primitive progenitor cell, the BFU-E, is relatively insensitive to EPO and forms large colonies after 14 days in the form of bursts. Production of BFU-E colonies was originally described as being

supported by *burst-promoting activity*, or BPA, now known to be IL-3 or GM-CSF. CFU-E colonies grow to maximal size in 7 to 8 days and depend primarily on EPO. The CFU-E are the descendants of BFU-E and subsequently give rise to the first recognizable erythrocyte precursor, the pronormoblast. Other cytokines reported to influence production of red cells include IL-9, IL-11, and SCF. However, EPO is the pivotal humoral factor that functions to prevent apoptosis and induce proliferation/differentiation of the most committed erythroid progenitor cells and their progeny.

Granulopoiesis and Monopoiesis

Granulocytes and monocytes are derived from a common bipotential progenitor cell, the CFU-GM, derived from CFU-GEMM. Specific GFs for granulocytes and monocytes, acting synergistically with GM-CSF and/or IL-3, support the differentiation pathway of each lineage. M-CSF supports monocyte differentiation while G-CSF induces neutrophilic granulocyte differentiation. Eosinophils and basophils also are derived from the CFU-GEMM under the influence of growth factors IL-5 and IL-3/IL-4, respectively.

Megakaryocytopoiesis/Thrombopoiesis

Platelets are derived from megakaryocytes, which are progeny of the CFU-EMk. CFU-Mk are induced to proliferate and differentiate into megakaryocytes by several cytokines. However, the cytokines that induce the greatest increase in platelet production are IL-11 and TPO.

Lymphopoiesis

The growth and development of lymphoid cells from the common lymphoid progenitor cell occurs in multiple anatomic locations including the bone marrow, thymus, lymph nodes, and spleen. Multiple GFs play a role in T and B lymphocyte growth and development, most of which act synergistically (Figure 3).

✓ Checkpoint! 3

Cytokine control of hematopoiesis is said to be characterized by redundancy and pleiotropy. What does this mean?

NEGATIVE REGULATORS OF HEMATOPOIESIS

In addition to the well-studied cytokines that function as positive regulators of hematopoiesis, there exists a second group of polypeptides that inhibit cellular proliferation (Table 6 🌱). The proliferation of hematopoietic precursor cells can be limited by either decreasing production of stimulating factors or increasing factors that inhibit cell growth. There appears to be a homeostatic network of counteracting growth inhibitors secreted in response to GFs, which normally limit cell proliferation after growth stimuli. These negative regulators of hematopoiesis (e.g., TGF β) may be

★ TABLE 6

Negative Regulators of Hematopoiesis

responsible for the quiescent state with respect to DNA synthesis of stem cells and early progenitor cells.¹⁸ Several negative regulators have been shown to upregulate some cell cycle inhibitors such as p16 and p21. Alternatively, they may oppose the actions of positive regulators that act on these same cells. Whether or not precursor cells synthesize DNA and proliferate depends on a balance between these opposing influences.

The interferons and transforming growth factor- β (TGF- β) suppress hematopoietic progenitor cells, largely by inhibiting proliferation or inducing programmed cell death. Tumor necrosis factor (TNF- α) directly suppresses colony growth of CFU-GEMM, CFU-GM, and BFU-E while prostaglandins of the E series (PGEs) suppress granulopoiesis and monoipoiesis by inhibiting CFU-GM, CFU-G, and CFU-M. Acidic ferritins and lactoferrin are products of mature neutrophils that inhibit hematopoiesis via feedback regulation. Di-hydroxyvitamin D₃ (Di-OH Vitamin D3), classically associated with the stimulation of bone formation, also functions to inhibit myelopoiesis. Additionally, there are cellular components of the immune system, including T-suppressor (Ts) cells and NK cells, which function as negative regulators of hematopoiesis.

Stem cell inhibitor (SCI), also known as *macrophage inflammatory protein-1 α* (MIP-1 α), is believed to be a primary negative regulator of stem cell proliferation.³⁶ It is believed to be a local-acting regulatory cytokine present in the stromal microenvironment, that controls the steady-state quiescence of stem cells. SCI functions largely via juxtacrine interactions between stromal cells and stem cells (see below) to maintain stem cells in the G₀ phase of the cell cycle.

▶ CYTOKINE RECEPTORS, SIGNALING PATHWAYS, AND TRANSCRIPTION FACTORS

Cytokines must bind to surface receptors on their target cells to express their activity. They interact with membrane receptors restricted to cells of the appropriate lineage. Cells also need a mechanism to transfer signals from extracellular stimuli (cytokines) into appropriate cellular responses intracellularly. Binding of a cytokine (ligand) to its specific receptor transduces an intracellular signal through which the par-

ticular survival, proliferation, or differentiation responses are initiated. The intracellular portion of the receptor binds to associated intracellular molecules that activate signaling pathways. These signaling molecules translocate to the nucleus, recruit appropriate transcription factors, and activate or silence gene transcription (Figure 5 ■). Ultimately, changes in protein synthesis lead to alterations in cell proliferation or other modifications of cellular response induced by the cytokine involved. Many of these receptors have been characterized, and they can be grouped according to certain structural characteristics.³⁷ Some cytokine receptors including the receptors for Epo, G-CSF, and TPO are homodimers (i.e., they consist of two identical subunits). Other receptors are heterodimers or heterotrimers, consisting of different polypeptide subunits (the receptors for most of the other hematopoietic cytokines).

RECEPTORS WITH CYTOPLASMIC TYROSINE KINASE DOMAINS

These receptors are transmembrane proteins with cytoplasmic “tails” that contain a tyrosine kinase catalytic site or domain. When GF binds to the receptor, the receptor chains dimerize enhancing the catalytic activity of the kinase do-

■ FIGURE 5 A model for the transfer of signals from extracellular stimuli (cytokines) into appropriate intracellular responses. The binding of a cytokine or ligand (L) to its cognate receptor generally induces receptor dimerization, the activation of a cascade of downstream signaling molecules (A, B, C—signal transduction pathways), converging on the nucleus to induce or repress cytokine-specific genes. The result is an alteration of transcription, RNA processing, translation, or the cellular metabolic machinery.

main and activating intracellular signaling pathways directly. Included in this group are the receptors for M-CSF, SCF, and FL.

HEMATOPOIETIC GROWTH FACTOR RECEPTOR SUPERFAMILY

The receptors for the majority of hematopoietic GFs do not possess intrinsic kinase activity. However, ligand binding and receptor activation leads to phosphorylation of cellular substrates by the activated receptor, which serves as a docking site for adaptor molecules that do have kinase activity. All of these receptors are multichain transmembrane proteins that demonstrate enhanced binding and/or signal transduction (phosphorylation of cellular proteins) when configured as a heterodimer or homodimer. The receptors for many of the GF receptors in this large group share peptide subunits with other receptors³⁷ (Web Figure 1 ■). There are three major subgroups:

1. IL-3, IL-5, and GM-CSF receptors have unique ligand-specific α chains but share a common signal-transducing β chain (the βc family).
2. IL-6 and IL-11 similarly have ligand-specific α chains and share a common signal-transducing β chain called GP 130.
3. The receptors for IL-2, IL-4, IL-7, IL-9, and IL-15 have unique, ligand-specific α chains and share a common signaling γ chain. IL-2 and IL-15 are actually trimeric structures and share a common β subunit as well. Inherited abnormalities of the γ chain gene are responsible for the X-linked form of severe combined immunodeficiency (SCID).

It has been suggested that the functional *redundancy* seen in the cytokine regulation of hematopoiesis (i.e., the fact that multiple GFs often have overlapping activities) may be at least partly explained by the sharing of common receptor signaling subunits. For example, IL-3 and GM-CSF have very similar spectra of biologic activities and share a common β subunit.

RECEPTOR FUNCTIONAL DOMAINS

Most receptors have discrete functional domains in the cytoplasmic region of one or more of the receptor chains. Thus, mutations disrupting a discrete domain of the receptor may disrupt part, but not all, of the functions of that receptor. Kostmann's syndrome (congenital agranulocytosis) is a rare disorder characterized by a profound absolute neutropenia with a maturation arrest of precursor cells at the promyelocyte/myelocyte stage. Erythropoiesis and thrombopoiesis are normal. In some patients, molecular studies have revealed a mutation of the G-CSF receptor that disrupts a terminal *maturation-inducing* domain but leaves intact a subterminal *proliferation-inducing* domain.³⁸ These patients sustain prolif-

eration of neutrophilic progenitor and early maturing cells but fail to complete final maturation of cells in this lineage. Similarly, some individuals with previously unexplained primary erythrocytosis (i.e., *not* secondary to smoking, high altitude, or increased EPO levels) have been shown to have a mutation affecting their EPO-receptors.³⁹ The EPO-R has been shown to have two separate domains in the cytoplasmic region of the receptor: The domain closest to the membrane constitutes a positive control domain promoting proliferation, and the terminal, negative control domain slows down the intracellular signaling from the receptor. In some patients with familial erythrocytosis, a mutation results in the generation of a truncated protein receptor that lacks the terminal negative control domain. The loss of this negative control region results in enhanced responsiveness of target cells (BFU-E and CFU-E) to the growth stimulatory effects of EPO, resulting in a (benign) erythrocytosis.

✓ Checkpoint! 4

Individuals with congenital defects of the γ chain of the IL-2 receptor suffer from profound defects of lymphopoiesis for greater than individuals with congenital defects of the α chain of the IL-2 receptor. Why?

SIGNALING PATHWAYS

To transfer signals from the receptor into an appropriate response, cells use a variety of "signal transduction pathways" that are initiated by a ligand binding to its specific receptor followed by the activation of "downstream signaling molecules." The downstream signals often result in a cascade of activation steps, ultimately converging on the nucleus to modulate transcription, RNA processing, the protein synthetic machinery (translation), the cellular metabolic machinery, or cytoskeletal-dependent functions⁴⁰ (Figure 5). Protein phosphorylation is often an important part of the signaling response from cell surface receptors involved in hematopoiesis. These receptors either contain a kinase domain as an integral component of the receptor itself or activate a cytoplasmic kinase as part of the signaling pathway. The signaling cascades that are activated can involve the formation of multiprotein complexes, proteolytic cascades, and phosphorylation/dephosphorylation reactions.

Receptors that contain intrinsic kinase (or phosphatase) activity are identified by the target amino acid to be modified as receptor tyrosine kinases (RTKs), receptor serine kinases (RSKs), or receptor protein tyrosine phosphatases (PTPs).⁴⁰ Ligands generally activate these receptors by promoting receptor oligomerization resulting in juxtaposition and activation of their cytoplasmic kinase domains. The result is cross-phosphorylation of the associated subunit kinases.

Receptors that do not have intrinsic enzymatic activity recruit cytoplasmic proteins to their intracellular "tails" and induce the association and assembly of multisubunit protein

complexes that generate the enzymatic activity. The recruited proteins are termed *protein tyrosine kinases (PTKs)*. Most hematopoietic receptors signal through the Janus family of PTKs, called *JAKs*. Once activated, the JAK kinases recruit signal relay molecules, often including members of the STAT family of transcription factors (**S**ignal **T**ransducers and **A**ctivators of **T**ranscription), referred to as the **JAK-STAT signaling pathway**. Four different JAK kinases and ~10 different STAT proteins have been identified. Once STAT proteins are phosphorylated by activated JAK kinases, they dimerize, translocate to the nucleus, bind to cytokine-specific DNA sequences, and activate (or inhibit) specific gene expression^{40,41} (Figure 6■). Abnormalities of the erythrocyte JAK-STAT signaling pathway are the major cause of polycythemia vera.

TRANSCRIPTION FACTORS

The growth factors that maintain hematopoiesis are *not* thought to be “instructive” for the pathway of differentiation but to be “permissive” for cell viability and proliferation.⁴² The components that actually establish the patterns

■ **FIGURE 6** Cytokine receptor-JAK-STAT model of signal transduction. Cytokine (e.g., EPO) interaction with its specific receptor leads to receptor dimerization and activation of JAK kinases associated with the activated receptor. Activated JAK kinases mediate autophosphorylation as well as phosphorylation of the receptor, which then serves as a docking site for STATs (signal transducers and activators of transcription). These STATs are phosphorylated, dissociate from the receptor, dimerize, and translocate to the nucleus where they activate gene transcription.

of gene expression associated with lineage differentiation are the nuclear **transcription factors (TF)**. Cell-fate decisions are regulated by the integrated effects of internal transcription factors and signaling pathways initiated by external regulatory cytokines.¹⁶

Different transcription factors are restricted in their expression to particular lineages and to particular differentiation stages within one or more lineages (Web Table 1✪, Web Figures 2■, 3a■, 3b■). The effect of a particular TF may be either gene expression or gene suppression, depending on the additional molecules (co-activators or co-repressors) recruited to the gene promoter region upon TF binding. TFs associated with activation of lineage-specific differentiation programs often simultaneously inhibit alternate lineage-specific transcription factors.⁴³ Interestingly, more than half of the hematopoietic transcription factors identified have been shown to be involved in chromosomal translocations associated with leukemias. Thus, the impaired differentiation seen in leukemias is likely due to the perturbation of critical, discrete pathways of transcriptional control.

Although certain TFs are often associated with lineage-specific differentiation pathways, most are also expressed, usually at much lower levels, in hematopoietic progenitor cells that are not yet committed to a specific differentiation pathway. It is thought that this simultaneous expression of TFs for different lineages is associated with the progenitor cell's potential for multilineage development.¹⁶ Once a differentiation decision has been reached (commitment), there is upregulation of TFs for one lineage and down-regulation or antagonism of the others.

CLINICAL USE OF HEMATOPOIETIC GROWTH FACTORS

The cloning and characterization of genes encoding the hematopoietic GFs have allowed scientists to produce these cytokines in large quantity using recombinant DNA technology. As a result, GFs can be used in therapeutic regimens for hematopoietic disorders (Table 7✪). Some cytokines approved by the Food and Drug Administration (FDA) for clinical

✪ **TABLE 7**

Clinical Applications of Hematopoietic Growth Factors

- Stimulation of erythropoiesis in renal disease (EPO)
- Recovery from treatment-induced myelosuppression (G-CSF and GM-CSF)
- Therapy of myelodysplastic syndromes (IL-3, GM-CSF, EPO)
- Enhanced killing of malignant cells (IL-2, etc.)
- Priming of bone marrow for donation (IL-3, G-CSF, GM-CSF, FL)
- Stimulation of malignant cells to differentiate (various)
- Enhancement of the acute phase response (IL-1, IL-6)
- Enhancement of the immune system (IL-2, IL-15, etc.)
- Stimulation of marrow recovery in BM transplantation (G-CSF, GM-CSF, EPO, IL-11)
- Treatment in bone marrow failure (IL-3, G-CSF, GM-CSF)

cal use include G-CSF and GM-CSF (used primarily to accelerate recovery from granulocytopenia), EPO (for treatment of anemia of various etiologies), IL-11 (for treatment of thrombocytopenia), the interferons (IFN α , IFN β , and IFN γ used to treat a number of malignant and nonmalignant disorders), and IL-2 (for treatment of metastatic renal cell cancer and melanoma). In vitro studies show that cytokines used in combination often show synergy in terms of their biologic effects. Consequently, the use of combinations of growth factors is being evaluated clinically as well, often with dramatic results. For a more thorough discussion of the biologic therapies currently in clinical use or undergoing clinical evaluations, see Gordon and Sosman.⁴⁴

► **HEMATOPOIETIC MICROENVIRONMENT**

Hematopoiesis is normally confined to certain organs and tissues. The proliferation and maturation of hematopoietic precursor cells take place within a microenvironment that provides the appropriate milieu for these events.⁴⁵ Patients undergoing bone marrow transplants receive donor cells by intravenous infusion; the cells “home” to and initiate significant hematopoiesis only in the recipient’s bone marrow. No biologically significant hematopoietic activity occurs in non-hematopoietic organs. For successful engraftment, the HSCs require an appropriate microenvironment, which presumably has specific properties that make it a unique site for stem cell renewal, growth, and differentiation.

The term **hematopoietic microenvironment (HM)** refers to this localized environment in the hematopoietic organs that is crucial for the development of hematopoietic cells and maintaining the hematopoietic system throughout the individuals lifetime. The HM includes cellular elements and extracellular components including matrix proteins and regulatory cytokines (Table 8). The HM provides homing and adhesive interactions important for the co-localization of stem cells, progenitor cells, and growth regulatory proteins within the marrow cavity.

Stromal Cells

The cellular elements of the HM are referred to as hematopoietic **stromal cells**. They include adipocytes (fat cells), endothelial cells, fibroblasts (referred to by some authors as reticular cells), T lymphocytes, and macrophages. Although the last two cell types are actually hematopoietic cells, they are included in the discussion of stromal cells because they are important sources of cytokine production. The stromal cells’ capacity to support hematopoiesis derives from a number of characteristics: They are thought to express homing receptors although the exact mechanisms involved in mediating homing of hematopoietic cells are unclear; they produce and secrete a number of soluble growth and differentiation factors as well as a number of membrane-bound cytokines that function as juxtacrine regulators of hematopoiesis (such as SCF and FL); and finally, they produce the various components constituting the extracellular matrix of the HM.

Extracellular Matrix

The **extracellular matrix (ECM)** produced and secreted by the stromal cells provides the adhesive interactions important for the co-localization of stem cells (SC), progenitor cells (PC), and the growth regulatory proteins. The ECM is composed of collagens, glycoproteins, and glycosaminoglycans. Variations in the type and relative amounts of these components produce the characteristic properties of ECMs in different tissues. Collagen provides the structural support for the other components. Glycosaminoglycans (heparan-sulfate, chondroitin-sulfate, dermatan-sulfate) play a role in cell-cell interactions, helping to mediate progenitor-cell binding to the stroma. They also serve to bind and localize cytokines in the vicinity of the hematopoietic cells.

Within the hematopoietic bone marrow, precursor cells of different lineages and at different stages of differentiation can be found in distinct areas throughout the marrow space. Precursor cells at different stages of differentiation can interact with certain, but not all, ECM components and can be induced to proliferate or differentiate by some but not all cytokines. It has been proposed that at specific stages of

TABLE 8

Hematopoietic Microenvironment

Cellular (Stroma)		Extracellular	
Components	Function	Components	Function
Adipocytes, endothelial cells, fibroblasts, T-cells, macrophages	Expression of homing receptors Production of soluble growth and differentiation factors Production of integral membrane proteins that function as juxtacrine regulators (SCF, FL) Production of ECM components	Soluble factors (cytokines and growth factors) Extracellular matrix (ECM) Collagen Glycosaminoglycans (heparan, chondroitin, dermatan-sulfate) Cytoadhesion molecules	Regulation of hematopoietic stem/progenitor cell differentiation and expansion Structural support Cell-to-cell interactions; localization of growth factors Adhesion of hematopoietic precursors to ECM proteins

■ **FIGURE 7** A model for regulation of hematopoietic precursor cells in the bone marrow microenvironment. The hematopoietic stem cell (HSC) attaches to bone marrow stromal cells via specific receptors and ligands. The HSC is then influenced by both positive and negative regulatory growth factors. (CAM: cell adhesion molecule; SCF: stem cell factor; FL: Flt3-ligand; IFN: interferon; TNF: tumor necrosis factor; TGF β transforming growth factor β ; MIP-1 α : macrophage inflammatory protein-1 α [stem cell inhibitor]; G-CSF: granulocyte-colony stimulating factor; GM-CSF: granulocyte-monocyte CSF; IL-: interleukin-).

differentiation, specialized stromal cells produce extracellular matrix components and hematopoietic supportive cytokines that are conducive for the commitment and/or differentiation of precursor cells of a specific hematopoietic lineage. These interactions could explain the observed tight regulation of precursor cell differentiation and proliferation.⁴⁶

One of the important molecular determinants of the geographic localization of hematopoiesis appears to be the presence of membrane receptors on hematopoietic precursors for ECM proteins. Fibronectin (Fn) is a large, adhesive glycoprotein that can bind cells, growth factors, and ECM components. SC/PC and developing erythroblasts have Fn receptors on their surface membrane. As developing erythroblasts mature to the reticulocyte stage, they lose their Fn receptor; loss of attachment via Fn facilitates the egress of reticulocytes and erythrocytes from the erythroblastic islands in the bone marrow. Likewise, hemonection (Hn) is an adhesive glycoprotein found in the HM that interacts with Hn receptors on SC, PC, and granulocytes and is important for the attachment of these cells to the marrow. Loss of Hn receptors by developing granulocytes and loss of adhesion to ECM mediates release of mature granulocytes to the circulation. Adhesive interactions between the SC, PC, and the ECM function to help hold the hematopoietic precursor cells in microenvironmental niches, bringing cells into close proximity with

growth regulatory cytokines that are also bound and held by the ECM.⁴⁶

It has been suggested that the quiescent state of stem cells is controlled by their localization in niches that block their responsiveness to differentiation-inducing signals (Figure 7■). Stromal cells produce cell-surface-associated (juxtacrine) factors that restrain SC differentiation (TGF- β , MIP-1 α). Any manipulation that removed SC from their niche would result in a cascade of differentiation events. A major role of stromal tissue in the regulation of hematopoiesis may be to safeguard and ensure stem cell maintenance. This may explain the observation that bone marrow cells removed from their marrow environment do not retain their “stemness” for more than a few weeks when cultured in the absence of stromal cells. Inevitably, they differentiate into progenitor cells and mature cells of the various lineages and thus undergo death by differentiation.

SUMMARY

Hematopoiesis is the production of the various types or lineages of blood cells. Mature, terminally differentiated blood cells are derived from mitotically active precursor cells found primarily in the bone marrow in adults. Hematopoietic precursor cells include pluripotent hematopoietic stem cells, hematopoietic progenitor cells (multi-

lineage and unilineage), and maturing (morphologically recognizable) cells.

Hematopoietic precursor cells are stimulated to proliferate and differentiate by hematopoietic growth factors or cytokines (colony-stimulating factors and interleukins). Cytokine control of hematopoiesis is characterized by redundancy (more than one cytokine is capable of exerting the same effect on the system) and

pleiotrophy (a given cytokine usually exerts more than one biologic effect). These cytokines interact with their target cell by means of unique transmembrane receptors responsible for generating the intracellular signals that govern proliferation and differentiation. Hematopoiesis takes place in a unique microenvironment in the marrow consisting of stromal cells and extracellular matrix, which plays a vital role in controlling hematopoiesis.

REVIEW QUESTIONS

LEVEL I

- Self-renewal and pluripotential differentiation potential are characteristics of: (Objective 2)
 - mature cells
 - stem cells
 - progenitor cells
 - maturing cells
- Precursor cells that are morphologically recognizable are found in the: (Objective 2)
 - stem cell compartment
 - progenitor cell compartment
 - maturing cell compartment
 - differentiating cell compartment
- The CFU-EMk gives rise to: (Objective 3)
 - eosinophils and megakaryocytes
 - erythrocytes and monocytes
 - eosinophils and megakaryocytes
 - erythrocytes and megakaryocytes
- All hematopoietic cells are derived from the CFU-GEMM *except*: (Objective 3)
 - lymphocytes
 - platelets
 - eosinophils
 - erythrocytes
- The following cell is most sensitive to erythropoietin: (Objective 4)
 - reticulocyte
 - CFU-GEMM
 - BFU-E
 - CFU-E
- All of the following are considered “early acting, multilineage” cytokines *except*: (Objective 4)
 - IL-5
 - GM-CSF
 - SCF
 - IL-3
- Pleiotrophy refers to: (Objective 4)
 - multiple different cells that can produce the same cytokine
 - a cytokine with multiple biologic activities
 - multiple cytokines that can induce the same cellular effect
 - a cytokine that can be produced by multiple different tissues

LEVEL II

- Hematopoietic stem cells are characterized by all of the following markers *except*: (Objective 1)
 - CD34⁺
 - Lin⁻
 - HLA-DR⁺
 - Rhodamine^{Dull}
- The major molecular marker that differentiates CLP from CMP is: (Objective 1)
 - IL7-R
 - FcR γ
 - CD33
 - CD13
- All of the following are important regulators of granulopoiesis *except*: (Objective 2)
 - GM-CSF
 - FL
 - IL-2
 - IL-3
- The major cytokine important for eosinophil differentiation is: (Objective 2)
 - IL-3
 - IL-5
 - IL-7
 - IL-11
- Which of the following growth factor receptors share a common β chain? (Objective 3)
 - IL-3 and GM-CSF
 - TPO and EPO
 - IL-2 and IL-3
 - G-CSF and GM-CSF
- Cytokine receptors that lack an intrinsic kinase domain generally signal through: (Objective 4)
 - an intrinsic phosphatase domain
 - recruiting membrane-embedded kinases
 - an intrinsic protease domain
 - recruiting cytoplasmic kinases

REVIEW QUESTIONS (continued)

LEVEL I

8. Cytokine regulation in which the cytokine is not secreted by the producing cell but remains membrane bound, necessitating direct cell-cell contact to achieve the desired effect is: (Objective 5)
 - a. paracrine
 - b. endocrine
 - c. juxtacrine
 - d. autocrine
9. All of the following are thought to be negative regulators of hematopoiesis *except*: (Objective 6)
 - a. $TGF\beta$
 - b. SCF
 - c. TNF
 - d. MIP-1 α
10. The hematopoietic microenvironment is composed of: (Objective 7)
 - a. hepatocytes and extrahepatic matrix
 - b. osteoblasts and osteoclasts
 - c. marrow stromal cells and extracellular matrix
 - d. hepatocytes and splenic macrophages

LEVEL II

7. The function of the JAK-STAT pathway in hematopoiesis is to: (Objective 4)
 - a. localize cytokines in the hematopoietic microenvironment
 - b. generate homing receptors for stem and progenitor cells
 - c. produce cytoadhesion molecules to retain precursor cells in the marrow
 - d. function as a signal transduction pathway for cytokine-activated receptors
8. The stromal elements of the hematopoietic microenvironment include all of the following *except*: (Objective 7)
 - a. B-lymphocytes
 - b. adipocytes
 - c. fibroblasts
 - d. macrophages
9. Which of the following cytoadhesion molecules plays an important role in retaining erythroid-developing cells in the bone marrow microenvironment? (Objective 7)
 - a. hemonectin
 - b. fibronectin
 - c. thrombospondin
 - d. glycosaminoglycans
10. The role of stem cell "niche" in the bone marrow is thought to be to: (Objective 7)
 - a. protect hematopoietic precursor cells from the lytic action of osteoclasts
 - b. provide nourishment (oxygen, nutrients) to developing precursor cells
 - c. regulate the quiescent state of stem cells blocking differentiation-inducing signals
 - d. produce cytoadhesion molecules important for homing to the marrow

ANSWERS TO CHECKPOINTS

Checkpoint! 1

Hematopoietic stem cells that have initiated a differentiation program are sometimes described as undergoing death by differentiation. Explain.

Answer

When a hematopoietic stem cell makes the commitment to differentiate, it begins a maturation process that will culminate in what we call *terminally differentiated cells* (i.e., cells that have lost the capacity to divide and have a finite [limited] life span). Thus, the process of differentiation “dooms” the cell to eventual death.

Checkpoint! 2

Explain the difference in the nomenclature used to label progenitor cells from that used to label maturing cells within the hematopoietic hierarchy of cells.

Answer

Because progenitor cells are not morphologically recognizable, they are identified by the progeny they produce when grown in *in vitro* cultures. Thus, they are identified as colony-forming units (CFU) or burst-forming units (BFU) with the types of cells in the colony indicated by the corresponding appended letter (e.g., CFU-E = produce a colony of erythroid cells). The maturing cells, which are morphologically recognizable, are described using the root of the lineage (e.g., erythro) with appropriate prefix and suffix to indicate stage of development (e.g., proerythroblast).

Checkpoint! 3

Cytokine control of hematopoiesis is said to be characterized by redundancy and pleiotrophy. What does this mean?

Answer

Redundancy refers to the fact that many different cytokines do the same thing (i.e., GM-CSF and IL-3 have overlapping [nearly identical] activities. IL-11 and TPO both stimulate platelet production [although TPO is the more important cytokine, physiologically]). Redundancy is a good thing because it assures the organism that if a mutation knocks out a regulatory gene, there are additional cytokines that can take over and substitute for the lost activity. At least part of the explanation for redundancy may be the “shared receptor chains” that have been identified for certain groups of cytokines.

Pleiotrophy refers to the fact that a single cytokine often has multiple activities, often on multiple target cells.

Checkpoint! 4

Individuals with congenital defects of the γ -chain of the IL-2 receptor suffer from profound defects of lymphopoiesis far greater than individuals with congenital defects of the α -chain of the IL-2 receptor. Why?

Answer

The γ -chain of the IL-2 receptor is shared with five other cytokines, all important in regulating lymphopoiesis—IL-4, IL-7, IL-9, IL-11, and IL-15. Thus, a disabling mutation of the γ -chain results in loss of physiologic activity of all six cytokines, whereas mutations affecting the α -chain compromise only the physiologic activity of a single cytokine, IL-2.

Structure and Function of Hematopoietic Organs

CHAPTER OUTLINE

- ▶ Objectives—Levels I and II
- ▶ Key terms
- ▶ Background basics
- ▶ Case study
- ▶ Overview
- ▶ Introduction
- ▶ Development of hematopoiesis
- ▶ Hematopoietic tissue
- ▶ Lymph nodes
- ▶ Summary
- ▶ Review questions
- ▶ References

Structure and Function of Hematopoietic Organs

Annette J. Schlueter, M.D., Ph.D.

■ OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. Identify the sites of hematopoiesis during embryonic and fetal development as well as in childhood and adulthood.
2. Identify organ/tissue sites in which each hematopoietic cell type differentiates.
3. Explain the difference between primary and secondary lymphoid tissue.
4. Describe the function of bone marrow, spleen, lymph nodes, and thymus.

■ OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. Associate physical findings (hypersplenism, lymphadenopathy) with the presence of hematologic disease.
2. Describe the pathophysiologic changes that lead to bone marrow hyperplasia or extramedullary hematopoiesis.
3. Identify sites of extramedullary hematopoiesis.
4. Describe the structure of bone marrow, spleen, lymph nodes, and thymus.

KEY TERMS

Adipocyte
 Culling
 Endosteum
 Erythroblastic island
 Extramedullary hematopoiesis
 Germinal center
 Hyperplasia
 Lymphoid follicle
 Medullary hematopoiesis
 Osteoblast
 Osteoclast
 Pitting
 Reticular cell
 Stroma
 Trabecula

BACKGROUND BASICS

The information in this chapter builds on the concepts learned in the first three chapters. A basic anatomy and physiology course could also be helpful. To maximize your learning experience, you should review these concepts before starting this unit of study:

Level I

- ▶ Define *microenvironment* as related to hematopoietic cell development.
- ▶ Summarize the process of cell maturation in the bone marrow.

Level II

- ▶ Summarize the mechanisms of positive and negative regulators of hematopoietic cell development.
- ▶ Describe the details of hematopoiesis and the role of cytokines/growth factors in blood cell development.

**CASE STUDY**

We will refer to this case throughout this chapter.

Francine, a 40-year-old female, saw her physician for complaints of fatigue and shortness of breath. Physical examination revealed splenomegaly and lymphadenopathy. A complete blood count was ordered with the following results: Hb 8g/dL; WBC $6.5 \times 10^9/L$; Platelets $21 \times 10^9/L$.

1. Refer to the tables on the front inside cover of the book and determine which blood cell parameters if any, are abnormal.

OVERVIEW

This chapter includes a description of the tissues involved in the production and maturation of blood cells. It begins with a sequential look at blood cell production from the embryo to the adult. The histologic structure of each tissue and its function in hematopoiesis are discussed. Abnormalities in hematopoiesis that are associated with histologic and functional changes in these tissues are briefly described.

INTRODUCTION

Cellular proliferation, differentiation, and maturation of blood cells take place in the hematopoietic tissue, which in the adult consists primarily of bone marrow although some lymphocyte development also takes place in spleen and thymus. Mature cells are released to the peripheral blood and can live out their lifespan in the blood or take up residence primarily in the spleen or a lymph node. In pathologic conditions, mature cells can also reside in other tissues of the body. The link between the bone marrow and blood cell production was not established until it was recognized that blood formation was a continuous process. Before 1850, it was believed that blood cells formed in the fetus were viable until the host's death and that there was no need for a continuous source of new elements.

DEVELOPMENT OF HEMATOPOIESIS

Hematopoiesis begins as early as the eighteenth day after fertilization in an extraembryonic location, the yolk sac of the human embryo.¹ The cells made in the yolk sac include erythrocytes and a few macrophages.² The ability to make erythrocytes is important because the embryo must be able to transport oxygen to developing tissue early in gestation. Shortly thereafter, intraembryonic hematopoiesis begins in the aorta-gonads-mesonephros (AGM) region located along the developing aorta. This region has the ability to make a wider range of hematopoietic cells including lymphocytes.³ Cell production at this time is called *primitive erythropoiesis* because the hemoglobin is not typical of that seen in later developing erythroblasts. The primitive embryonic erythroblasts in the yolk sac arise from clusters of cells in the mesenchyme called *blood islands* and are closely related to development of endothelium, the cells lining blood vessels.⁴ Embryonic red cells have a megaloblastic appearance with coarse clumped chromatin. The hemoglobin in these cells consists of the embryonic varieties, Gower 1, Gower 2, and Portland.⁵

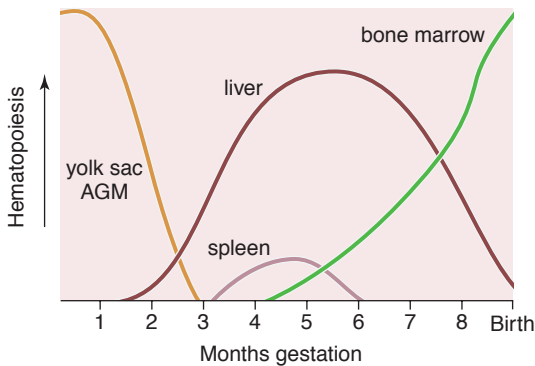

At about the third month of fetal life, the liver becomes the chief site of blood cell production, and the yolk sac and

AGM discontinue their role in hematopoiesis. The liver continues to produce a high proportion of erythroid cells, but myeloid and lymphoid cells begin to appear in greater numbers.⁶ This is the beginning of a transition to adult patterns of hematopoiesis in which myeloid differentiation predominates over erythroid differentiation.

As fetal development progresses, hematopoiesis also begins to a lesser degree in the spleen, kidney, thymus, and lymph nodes. Erythroid and myeloid cell production as well as early B cell (lymphocyte) development gradually shifts from these sites to bone marrow during late fetal and neonatal life as the hollow cavities within the bones begin to form. The bone marrow becomes the primary site of hematopoiesis at about the sixth month of gestation and continues as the primary source of blood production after birth and throughout adult life (Figure 1 ■). Granulocytic and megakaryocytic production shifts to the bone marrow before erythropoiesis, which does not transition until the end of gestation. The thymus becomes the major site of T cell (lymphocyte) production during fetal development and continues to be active throughout the neonatal period and childhood. As is true for erythrocytes in the yolk sac, the first T cells to develop are different than their adult counterparts. They use a different set of genes to make the T cell receptor, which the T cell uses to recognize and react to foreign substances.⁷ Lymph nodes and spleen continue as an important site of late B cell differentiation throughout life.

► **HEMATOPOIETIC TISSUE**

The adult hematopoietic system includes tissues and organs involved in the proliferation, maturation, and destruction of blood cells. These organs and tissues include the bone marrow, thymus, spleen, and lymph nodes. Bone marrow is the site of myeloid, erythroid, and megakaryocytic as well as lymphoid cell development. Thymus, spleen, and lymph

■ **FIGURE 1** Location of hematopoiesis during fetal development. At birth most blood cell production is limited to the marrow.

nodes are primarily sites of lymphoid cell development. Tissues in which lymphoid cell development occurs are divided into primary and secondary lymphoid tissue. Primary lymphoid tissues (bone marrow and thymus) are those in which T and B cells develop from nonfunctional precursors into cells that are capable of responding to foreign antigens (immunocompetent cells). Secondary lymphoid tissues (spleen and lymph nodes) are those in which immunocompetent T and B cells further differentiate and divide in response to antigens.

BONE MARROW

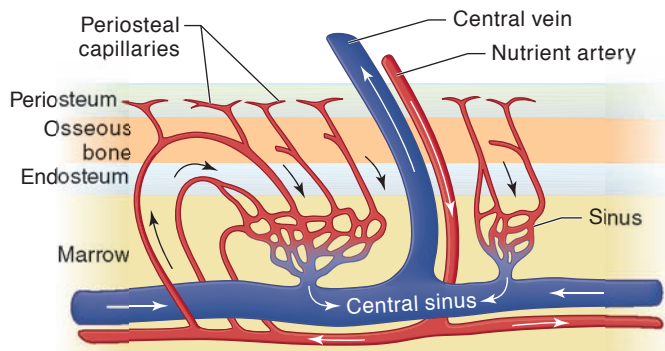

Blood-forming tissue located between the **trabeculae** of spongy bone is known as *bone marrow*. (*Trabecula* refers to a projection of calcified bone extending from cortical bone into the marrow space; it provides support for marrow cells.) This major hematopoietic organ is a cellular, highly vascularized, loose connective tissue. It is composed of two major compartments: the vascular compartment and the hematopoietic compartment. The vascular compartment is composed of the nutrient artery, periosteal arteries, central longitudinal vein, arterioles, and sinuses. The hematopoietic compartment is the site of formation and maturation of blood cells (Figure 2 ■). This compartment includes both hematopoietic cells and stromal cells.

Vasculature

The vascular supply of bone marrow is served by two arterial sources, a nutrient artery and a periosteal artery that enter the bone through small holes, the bone foramina. Blood is drained from the marrow via the central vein (Figure 3 ■). The nutrient artery branches around the central sinus that spans the marrow cavity. Arterioles radiate outward from the nutrient artery to the **endosteum** (the inner lining of the cortical bone), giving rise to capillaries that merge with capillaries from periosteal arteries to form venous sinuses within the marrow. The sinuses, lined by single endothelial cells

■ **FIGURE 2** Schematic drawing of a section of bone marrow.

■ **FIGURE 3** Diagram of the microcirculation of bone marrow. The major arterial supply to the marrow is from periosteal capillaries and from capillary branches of the nutrient artery, which have traversed the bony enclosure of the marrow through the bone foramina. The capillaries join with the venous sinuses as they reenter the marrow. The sinuses gather into wider collecting sinuses that then open into the central longitudinal vein (central sinus). (Adapted with permission from: DeBruyn PPH: Structural substrates of bone marrow function. *Semin Hematol*. 1981;18:179.)

and supported on the abluminal side by adventitial **reticular cells**, ultimately gather into wider collecting sinuses, which open into the central longitudinal vein.⁸ The central longitudinal vein continues through the length of the marrow and exits through the foramina where the nutrient artery entered.

Stroma

The bone marrow **stroma** (supporting tissue) forms a favorable microenvironment for sustained proliferation of hematopoietic cells.⁹ It forms a meshwork that provides a three-dimensional scaffolding for hematopoietic cells. Stromal components also provide cytokines that regulate hematopoiesis. The stroma is composed of three major cell types: macrophages, reticular cells (fibroblasts), and **adipocytes**.

Macrophages serve two major functions in the bone marrow: phagocytosis and secretion of hematopoietic cytokines. Macrophages phagocytose the extruded nuclei of maturing erythrocytes and abnormal cells such as B cells that have not differentiated properly. Some macrophages serve as the center of the erythroblastic islands as discussed below. It has been believed that these cells supply the developing erythroblasts with iron and cytokines; more recent studies suggest, however, that the majority of the iron is supplied by transferrin delivery from the plasma. Macrophages also provide many colony-stimulating factors needed for the development of myeloid lineage cells. Macrophages stain acid phosphatase positive.

Reticular cells are located on the abluminal surface of the vascular sinuses and send long cytoplasmic processes into the stroma. These cells also produce reticular fibers, which contribute to the three-dimensional supporting network that holds the vascular sinuses and hematopoietic elements.

The fibers can be visualized with light microscopy and after silver staining. Reticular cells are alkaline phosphatase positive.

Adipocytes are cells whose cytoplasm is largely replaced with a single fat vacuole. They most likely develop from reticular cells that synthesize fat. These cells mechanically control the volume of bone marrow in which active hematopoiesis takes place. They also provide steroids that influence erythropoiesis and maintain osseous bone integrity.^{10,11}

The proportion of bone marrow composed of adipocytes changes with age. For the first four years of life, nearly all marrow cavities are composed of hematopoietic cells, or red marrow. After four years of age, the red marrow in the shafts of long bones is gradually replaced by adipocytes, or yellow marrow. By the age of 25 years, hematopoiesis is limited to the marrow of the skull, ribs, sternum, scapulae, clavicles, vertebrae, pelvis, upper half of the sacrum, and proximal ends of the long bones. The distribution of red:yellow marrow in these bones is about 1:1. The fraction of red marrow in these areas may decrease after age 70.

Osteoblasts and osteoclasts are found in the endosteum (internal surface of calcified bone). These cells can be dislodged during bone marrow biopsy and can be found in the specimen with hematopoietic cells. Osteoblasts differentiate from a common precursor with hematopoietic cells.¹² They are involved in the formation of calcified bone and provide a niche for resting hematopoietic stem cells.¹³ They are large cells (up to 30 μm in diameter) that resemble plasma cells except that the perinuclear halo (Golgi apparatus) is detached from the nuclear membrane and, in Wright-stained specimens, appears as a light area away from the nucleus (Figure 4■). In addition, the cytoplasm may be less basophilic, and the nucleus has a finer chromatin pattern than plasma cells. Osteoblasts are normally found in groups. These cells are more commonly seen in children and in metabolic bone diseases. The cells are alkaline phosphatase positive.

Osteoclasts are cells related to macrophages that are involved in resorption and remodeling of calcified bone. They are even larger than osteoblasts and can reach up to 100 μm in diameter. The cells are multinucleated and have granular cytoplasm that can be either acidophilic or basophilic. They resemble megakaryocytes except that the nuclei are usually discrete (whereas the megakaryocyte has a single, large multilobulated nucleus) and often contain nucleoli (Figure 4).

Hematopoietic Compartment

Hematopoietic cells are arranged in distinct niches within the marrow cavity. Erythroblasts constitute 25–30% of the marrow cells and are produced near the sinuses. They develop in **erythroblastic islands** composed of a single macrophage surrounded by erythroblasts in varying states of maturation. The macrophage cytoplasm extends out to surround the erythroblasts. During this close association, the macrophages regulate erythropoiesis by secreting various

a

b

cytokines.¹⁴ The least mature cells are closest to the center of the island, and the more mature cells are at the periphery.

The location of leukocyte development differs depending on its type. Granulocytes are produced in nests close to the trabeculae and arterioles and are relatively distant from the venous sinuses. These nests are not quite as apparent morphologically as are erythroblastic islands. Megakaryocytes are very large, polyploid cells that produce platelets from their cytoplasm. They are located adjacent to the vascular sinus.¹⁵ Cytoplasmic processes of the megakaryocyte form long proplatelet processes that pinch off to form platelets (Figure 5 ■). Lymphocytes are normally produced in lymphoid aggregates located near arterioles. Lymphoid progenitor cells can leave the bone marrow and travel to the thymus where they mature into T lymphocytes. Some remain in the bone marrow where they mature into B lymphocytes. Some B cells return to the bone marrow after being activated in the spleen or lymph node. Activated B cells transform into plasma cells, which can reside in the bone marrow and produce antibody.

✓ Checkpoint! 1

Describe the bone marrow stromal location of erythrocyte, granulocyte, platelet, and lymphocyte differentiation.

Bone forms a rigid compartment for the marrow. Thus, any change in volume of the hematopoietic elements as occurs in many anemias and leukemias must be compensated for by a change in the space-occupying adipocytes. Normal red marrow can respond to stimuli and increase its activity to several times the normal rate. As a result, the red marrow becomes hyperplastic and replaces portions of the fatty marrow. Bone marrow **hyperplasia** (an excessive proliferation

■ **FIGURE 5** Scanning electron micrograph of the luminal face of the myeloid sinus wall with an intraluminal segment of a proplatelet process (PP) showing periodic constriction along its length. PI: platelet displaying tear-drop shape. (Reprinted with permission from: DeBruyn PPH: Structural substrates of bone marrow function. *Semin Hematol.* 1981;18:179.)

of normal cells) accompanies all conditions with increased or ineffective hematopoiesis. The degree of hyperplasia is related to the severity and duration of the pathologic state. Acute blood loss can cause erythropoietic tissue to temporarily replace fatty tissue whereas severe chronic anemia can cause erythropoiesis to be so intense that it not only replaces fatty marrow but also erodes the bone's internal surface. In malignant diseases that invade or originate in the bone marrow such as leukemia, proliferating abnormal cells can replace both normal hematopoietic tissue and fat.

In contrast, the hematopoietic tissue can become inactive or hypoplastic. Fat cells then increase, providing a cushion for the marrow. Environmental factors such as chemicals and toxins can suppress hematopoiesis whereas other types of hypoplasia can be genetically determined. Myeloproliferative disease, which begins as a hypercellular disease, frequently terminates in a state of aplasia in which hematopoietic tissue is replaced by fibrous tissue.

CASE STUDY (continued from earlier in this chapter)

Microscopic examination of a stained blood smear from Francine revealed a predominance of very young blood cells (blasts) in the peripheral blood. These cells are normally found only in the bone marrow. Subsequently, she had a bone marrow aspirated for examination. This revealed 100% cellularity (red marrow) with a predominance of the same type of blasts as those found in the peripheral blood.

2. Describe Francine's bone marrow as normal, hyperplastic, or hypoplastic.
3. What conditions can cause this bone marrow finding?

Blood Cell Egress

Special properties of the maturing hematopoietic cell as well as of the venous sinus wall are important in migration of blood cells from the bone marrow.¹⁶ These cells must migrate between reticular cells but through endothelial cells to reach the circulation. As cell traffic across the sinus increases, the reticular cells contract creating a less continuous layer over the abluminal sinus wall. This provides the mature hematopoietic cells more interaction sites on the sinus endothelial surface. In areas in which the reticular cell layer contracts, it creates compartments between the reticular cell layer and the endothelial layer where mature cells accumulate.

The new blood cell interacts with the abluminal endothelial membrane by a receptor-mediated process, forcing the abluminal membrane into contact with the luminal endothelial membrane. The two membranes fuse, and then under pressure from the passing cell, they separate, creating a pore through which the remainder of the hematopoietic cell enters the lumen of the sinus. These pores are only

2–3 μm in diameter. Because of the small size of the endothelial cell pores, blood cells must have the ability to deform so that they can pass through the sinusoidal lining. Progressive increases in deformability and motility have been noted as granulocytes mature from the myeloblast to the segmented granulocyte stage. This facilitates the movement of cells into the sinus lumen.

Many soluble factors are important in facilitating the release of blood cells from bone marrow. Among these are G-CSF, GM-CSF, and a large number of chemokines.^{17,18} Some of these molecules are used clinically to increase circulating granulocytes or hematopoietic stem cells into the circulation to obtain granulocytes for transfusion or stem cells for transplantation.

Checkpoint! 2

Describe the process by which a blood cell moves from the marrow to the vascular space.

Extramedullary Hematopoiesis

Hematopoiesis in the bone marrow is called **medullary hematopoiesis**. **Extramedullary hematopoiesis** denotes blood cell production in hematopoietic tissue other than bone marrow. In certain hematologic disorders when hyperplasia of the marrow cannot meet the physiologic blood needs of the tissues, extramedullary hematopoiesis can occur in the hematopoietic organs that were active in the fetus, principally the liver and spleen. Organomegaly frequently accompanies significant hematopoietic activity at these sites. This extramedullary hematopoiesis in postnatal life reflects the ability of inert hematopoietic cells to become active, functional cells if the need arises.

THYMUS

The thymus is a lymphopoietic organ located in the upper part of the anterior mediastinum. It is a bilobular organ demarcated into an outer cortex and central medulla. The cortex is densely packed with small lymphocytes (thymocytes), cortical epithelial cells, and a few macrophages. The medulla is less cellular and contains more mature thymocytes mixed with medullary epithelial cells, dendritic cells, and macrophages (Figure 6 ■).

The primary purpose of the thymus is to serve as a compartment for maturation of T lymphocytes.¹⁹ Precursor T cells leave the bone marrow and enter the thymus through arterioles in the cortex. As they travel through the cortex and the medulla, they interact with epithelial cells and dendritic cells, which provide signals to ensure that T cells can recognize foreign antigen but not self-antigen. They also undergo rapid proliferation. Only about 3% of the cells generated in the thymus exit the medulla as mature T cells. The rest die by apoptosis and are removed by thymic macrophages. The thymus is responsible for supplying the T-dependent areas of lymph nodes, spleen, and other peripheral lymphoid tissue with immunocompetent T lymphocytes.

■ **FIGURE 6** A schematic drawing of the thymus. See text for the role of the various cell types. Hassall's corpuscles are collections of epithelial cells that may be involved in the development of certain (regulatory) T cell subsets in the thymus.

The thymus is a well-developed organ at birth and continues to increase in size until puberty. After puberty, however, it begins to atrophy until in old age it becomes barely recognizable. This atrophy could be driven by increased steroid levels beginning in puberty and decreased growth factor levels in adults.^{20,21} The atrophied thymus is still capable of producing new T cells if the peripheral pool becomes depleted as occurs after the lymphoid irradiation that accompanies bone marrow transplantation.²²

SPLEEN

The spleen is located in the upper left quadrant of the abdomen beneath the diaphragm and to the left of the stomach. After several emergency splenectomies were performed without causing permanent harm to the patients, it was recognized that the spleen was not essential to life. However, it does play a role in filtration of foreign substances and old erythrocytes from the circulation, storage of platelets, and immune defense.

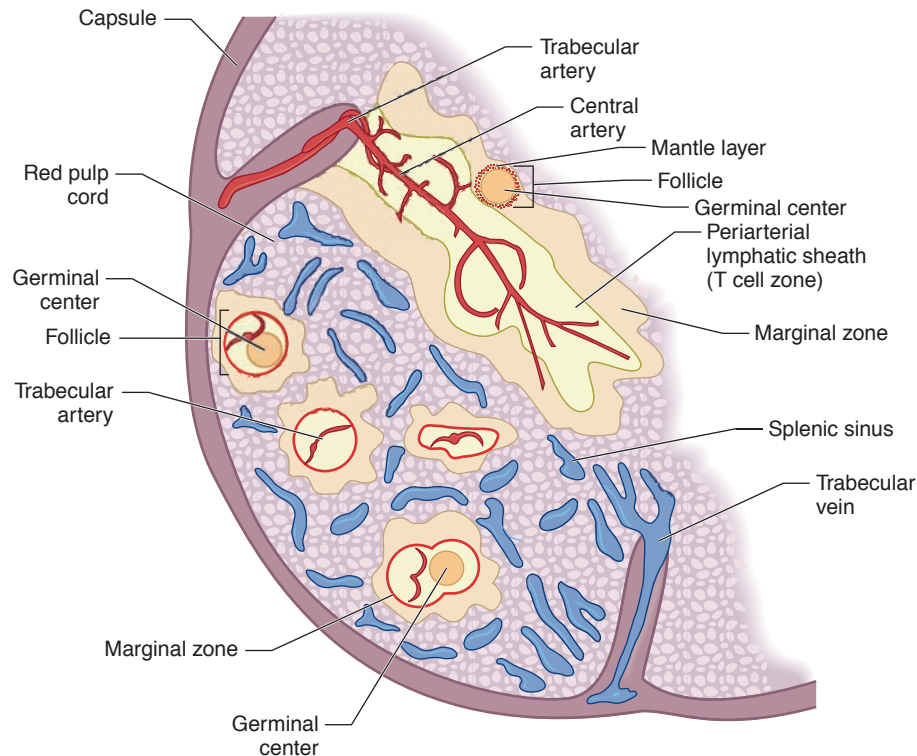

Architecture

The spleen, enclosed by a capsule of connective tissue, contains the largest collection of lymphocytes and macrophages in the body (Figure 7 ■). These cells together with a reticular meshwork are concentrated in different areas of the spleen and contribute to the formation of three zones of tissue: white pulp, red pulp, and the marginal zone.

The white pulp, a visible grayish white zone, is composed of lymphocytes and located around a central artery. The area closest to the artery, which contains many T cells as well as macrophages and dendritic cells, is termed the *periarterial lymphatic sheath*. Peripheral to this area are B cells arranged into follicles (a sphere of B cells within lymphatic tissue). Activated B cells are found in specialized follicular areas called **germinal centers**. Germinal centers appear as lightly stained areas in the center of a **lymphoid follicle**. They consist of a mixture of B lymphocytes, follicular dendritic cells, and phagocytic macrophages. The immune response is initiated in the white pulp. In some cases of heightened immunologic activity, the white pulp can increase to occupy half the volume of the spleen (it is normally 20% or less).

White pulp is surrounded by the marginal zone, a reticular meshwork containing blood vessels, macrophages, and specialized B cells. This zone lies at the junction of the white pulp and red pulp and is important in initiating certain types of immune responses as well as performing functions similar to that of the red pulp (see below).

The red pulp contains sinuses and cords. The sinuses are dilated vascular spaces for venous blood. The red color of the pulp is caused by the presence of erythrocytes in the sinuses. The cords are composed of masses of reticular tissue and macrophages that lie between the sinuses. The cords of the red pulp provide zones for platelet storage and destruction of damaged blood cells.

■ **FIGURE 7** A schematic drawing of splenic tissue. See text for an explanation of the splenic tissue architecture. The periaarterial lymphatic sheath contains many T cells, macrophages and dendritic cells. B cells are arranged into follicles. Activated B cells are in the germinal centers. (Adapted from *Seminars in Hematology*, V7(4), Weiss L et al: Anatomical hazards to the passage of erythrocytes through the spleen, p. 373, 1970, with permission from Elsevier.)

Blood Flow

The spleen is richly supplied with blood. It receives 5% of the total cardiac output, a blood volume of 300 mL/minute. Blood enters the spleen through the splenic artery, which branches into many vessels in the trabeculae. Vessel branches can terminate in the white pulp, red pulp, or marginal zone. Blood entering the spleen can follow either the rapid transit pathway (closed circulation) or the slow transit pathway (open circulation). The rapid transit pathway is a relatively unobstructed route by which blood enters the sinuses in red pulp from arteries and passes directly to the venous collecting system. In contrast, blood entering the slow transit pathway moves sluggishly through a circuitous route of macrophage-lined cords before it gains access to the sinuses. Plasma in the cords freely enters the sinuses, but erythrocytes meet resistance at the sinus wall where they squeeze through the tiny openings. This skimming of the plasma from blood cells in the cords to the sinuses sharply increases the hematocrit in the cords. Sluggish blood flow and continued erythrocyte metabolic activity in cords results in a splenic environment that is hypoxic, acidic, and hypoglycemic. Hypoxia and hypoglycemia occur as erythrocytes utilize available oxygen and glucose. Metabolic byproducts create the acidic environment.

Functions

Blood that empties into the cords of the red pulp and of the white pulp and marginal zone takes the slow transit pathway, which is very important to splenic function including culling, pitting, immune defense, and storage. The discriminatory filtering and destruction of senescent or damaged red cells by the spleen is termed **culling**. Cells entering the spleen through the slow transit pathway become concentrated in the hypoglycemic, hypoxic cords of the red pulp, a hazardous environment for aged or damaged erythrocytes. Slow passage through a macrophage-rich route allows the phagocytic cells to remove these old or damaged, less deformable erythrocytes before or during their squeeze through the $3\ \mu\text{m}$ pores to cords and sinuses. Normal erythrocytes withstand this adverse environment and eventually reenter the circulation.

Pitting refers to the spleen's ability to "pluck out" particles from intact erythrocytes without destroying them. Blood cells coated with antibody are susceptible to pitting by macrophages. The macrophage removes the antigen-antibody complex and the attached membrane. The pinched off cell membrane can reseal itself, but the cell cannot synthesize lipids and proteins for new membrane due to its lack of cellular organelles. Therefore, extensive pitting causes a reduced

surface-area-to-volume ratio, resulting in the formation of spherocytes (erythrocytes that have no central area of pallor on stained blood smears). The presence of spherocytes on a blood film is evidence that the erythrocyte has undergone membrane assault in the spleen.

✓ Checkpoint! 3

Describe how old or damaged erythrocytes are removed from the circulation by the spleen.

The white pulp and marginal zones of the spleen are important lines of defense in blood-borne infections because of their rich supply of lymphocytes and phagocytic cells as well as the slow transit circulation through these areas. Blood-borne antigens are forced into close contact with phagocytes (antigen-presenting cells) and lymphocytes allowing for recognition of the antigen as foreign and leading to phagocytosis and antibody formation.

The immunologic function of the spleen is probably less important in the well-developed immune system of the adult than in the less-developed immune system of the child. Young children who undergo splenectomy may develop overwhelming, often fatal, infections with encapsulated organisms such as *S. pneumoniae* and *H. influenzae*. This can also be a rare complication of splenectomy in adults. The loss of the marginal zone can be especially important in this regard.²³

Sequestering approximately one-third of the platelet mass, the red pulp cords of the spleen act as a reservoir for platelets. Massive splenomegaly can result in a pooling of 80–90% of the platelets, producing peripheral blood thrombocytopenia. Removal of the spleen results in a transient thrombocytosis with a return to normal platelet concentrations in about 10 days.

Hypersplenism

In a number of conditions, the spleen may become enlarged and, through exaggeration of its normal activities of filtering and phagocytosing, cause anemia, leukopenia, thrombocytopenia, or combinations of cytopenias. A diagnosis of hypersplenism is made when three conditions are met: (1) the presence of anemia, leukopenia, or thrombocytopenia in the peripheral blood, (2) the existence of a cellular or hyperplastic bone marrow corresponding to the peripheral blood cytopenias, and (3) the occurrence of splenomegaly. The correction of cytopenias following splenectomy confirms the diagnosis.

Hypersplenism has been categorized into two types: primary and secondary. The primary type is said to occur when no underlying disease can be identified. The spleen functions abnormally and causes the disease. This type of hypersplenism is very rare.

Secondary hypersplenism occurs in those cases in which an underlying disorder causes the splenic abnormalities. The causes of secondary hypersplenism are many and varied. Hypersplenism can occur secondary to compensatory (or work-

load) hypertrophy of this organ. Inflammatory and infectious diseases are thought to cause splenomegaly by an increase in the defensive functions of the spleen. For example, an increase in the clearing of particulate matter can lead to an increase in the number of macrophages, or hyperplasia of lymphoid cells can result from prolonged infection. Several blood disorders can cause splenomegaly. In these disorders, the blood cells can be intrinsically abnormal or coated with antibody and are removed from circulation in large numbers (e.g., hereditary spherocytosis, immune thrombocytopenic purpura).

Infiltration of the spleen with additional cells or metabolic byproducts can also cause hypersplenism. Such conditions include disorders in which the macrophages accumulate large quantities of undigestible substances; some of these disorders, such as Gaucher's disease, will be discussed later. Neoplasms in which the malignant cells occupy much of the splenic volume can cause splenomegaly. If the tumor cells incapacitate the spleen, the peripheral blood shows the evidence of hyposplenism (similar to the findings after splenectomy). An outstanding feature of myelofibrosis, a disorder in which the bone marrow is progressively replaced with fibrous tissue, is splenomegaly. In these cases, the spleen contains foci of extramedullary hematopoiesis. Congestive splenomegaly can occur following liver cirrhosis with portal hypertension or congestive heart failure when blood that does not flow easily through the liver is rerouted through the spleen.

✓ Checkpoint! 4

List three causes each of workload and infiltrative splenic hypertrophy.

Splenectomy

The effects of hypersplenism can be relieved by splenectomy; however, this procedure is not always advisable, especially when the spleen is performing a constructive role such as antibody production or filtering protozoa or bacteria. Splenectomy appears to be most beneficial in patients with hereditary or acquired conditions in which erythrocytes or platelets undergo increased destruction, such as hemolytic disorders or idiopathic thrombocytopenic purpura. The blood cells are still abnormal after splenectomy, but the major site of their destruction is removed. Consequently, the cells have a more normal life span. Splenectomy results in characteristic erythrocyte abnormalities easily noted on blood smears by experienced clinical laboratory professionals. After splenectomy, the erythrocytes often contain inclusions (e.g., Howell Jolly bodies, Pappenheimer bodies). Abnormal shapes may also be seen.

The lifespan of healthy erythrocytes is not increased after splenectomy. Other organs, primarily the liver assume the culling function. Blood flow through the liver also is slowed by passage through sinusoids, which are lined with specialized macrophages called *Kupffer cells*. These macrophages

can perform functions similar to the phagocytes in the splenic cords and marginal zone. Even when a spleen is present, the liver, because of its larger blood flow, is responsible for removing most of the particulate matter of the blood. The liver, however, is not as effective as the spleen in filtering abnormal erythrocytes. This is probably because of the relatively rapid flow of blood past hepatic macrophages.

Acquired hyposplenism is a complication of sickle cell anemia. The acidic, hypoxic, hypoglycemic environment of the spleen leads to sickling of the erythrocytes in the spleen. This leads to blockage of the blood vessels and infarcts of the surrounding tissue. The tissue damage is progressive and leads to functional splenectomy (also referred to as *autosplenectomy*).

CASE STUDY (continued from earlier in this chapter)

Francine was diagnosed as having leukemia.

4. What do you think is the cause of the splenomegaly?
5. Why might the peripheral blood reveal changes associated with hyposplenism when the spleen is enlarged?

spaces throughout the body, carry lymph toward the ducts near the neck where lymph enters the blood. Lymph is formed from blood fluid that escapes into connective tissue. The bean-shaped lymph nodes occur in groups or chains along the larger lymphatic vessels. Lymph nodes contain an outer area called the *cortex* and an inner area called the *medulla* (Figure 8 ■). Fibrous trabeculae extend inward from the capsule to form irregular communicating compartments within the parenchyma. The cortex contains B cell follicles surrounded by T lymphocytes and macrophages. Similar to the spleen, follicles contain areas of activated B cells known as *germinal centers*. A stimulated node can have many germinal centers whereas a resting node contains follicles with small resting lymphocytes and macrophages. The medulla, which surrounds the efferent lymphatics, consists of cords of plasma cells that lie between sinusoids.

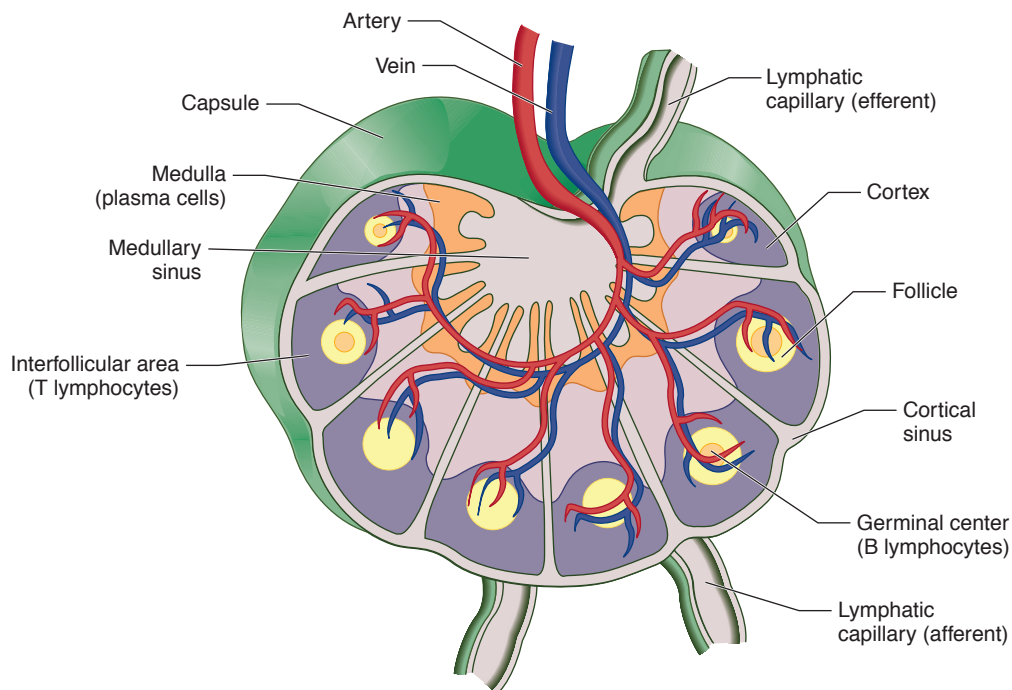

Lymph nodes act as filters removing foreign particles from lymph by dendritic cells and macrophages. Dendritic cells in turn stimulate T and B cells. Stimulated B cells move from the germinal centers to the medulla where they reside as plasma cells and secrete antibody. Thus, lymph nodes provide immune defense against pathogens in virtually all tissues.

► **LYMPH NODES**

The lymphatic system is composed of lymph nodes and lymphatic vessels that drain into the left and right lymphatic ducts. The vessels, which originate in connective tissue

MUCOSA-ASSOCIATED LYMPHOID TISSUE (MALT)

MALT is a collection of loosely organized aggregates of lymphocytes found throughout the body in association with mucosal surfaces.²⁴ Its basic organization is similar to that of

■ **FIGURE 8** A schematic drawing of a lymph node. Note the location of T and B lymphocyte populations.

lymph nodes in that T- and B-cell-rich areas can be identified, but they are not as clearly demarcated as in lymph nodes. The medulla is not present as a separate structure, and no fibrous capsule can be identified. In the intestine, some of these aggregates are known as *Peyer's patches*. Tonsils and the appendix also are part of MALT. The function of MALT is to trap antigens that are crossing mucosal surfaces and initiate immune responses rapidly.

LYMPHADENOPATHY

Lymph nodes can become enlarged by expansion of the tissue within the node due to inflammation, prolonged immune response to infectious agents, or malignant transformation of lymphocytes or macrophages. Alternatively, lymph node enlargement can occur because of metastatic tumors that originate in extranodal sites.

CASE STUDY (continued from the previous page)

Francine had lymphadenopathy. The leukemia was diagnosed as a leukemia of the lymphocytic cells.

6. What might explain the lymphadenopathy?

SUMMARY

Hematopoiesis occurs in several different locations during human development. The major locations include the yolk sac, aorta-gonads-mesonephros (AGM) region, liver, bone marrow, and thymus. Further differentiation of lymphocytes also occurs in the spleen and lymph nodes. In the adult, the bone marrow is the location of the most primitive stem cells and thus is ultimately responsible for initiating all hematopoiesis. Myeloid cells, platelets, and erythrocytes essentially complete their differentiation in the bone marrow. T cells finish most of their differentiation in the thymus. B cells are able to respond to antigens by the time they leave the bone marrow but differentiate further into antibody-secreting plasma cells in the spleen and lymph nodes. The spleen removes senescent or abnormal erythrocytes and removes particulate matter from erythrocytes. Hypersplenism may occur and is most commonly secondary to another disorder. This leads to exaggeration of its normal activity. Lymph nodes are important in immune defense, initiating immune responses to foreign particles found in lymph.

REVIEW QUESTIONS

LEVEL I

1. B cells develop or differentiate in all of the following tissues *except*: (Objective 2)
 - a. thymus
 - b. bone marrow
 - c. spleen
 - d. lymph nodes
2. Lack of a spleen results in: (Objective 4)
 - a. younger circulating erythrocytes
 - b. granular inclusions in erythrocytes
 - c. pitting of erythrocytes
 - d. spherocytes
3. Peyer's patches are most closely related to the: (Objective 3)
 - a. lymph node
 - b. spleen
 - c. thymus
 - d. liver
4. All of the following are functions of bone marrow stroma *except* that it: (Objective 4)
 - a. controls the volume of marrow available for hematopoiesis
 - b. provides structural support for marrow elements
 - c. secretes growth factors for hematopoiesis
 - d. provides an exit route from marrow for mature blood cells

LEVEL II

1. A common site of adult extramedullary hematopoiesis is the: (Objective 3)
 - a. liver
 - b. thymus
 - c. lymph node
 - d. yolk sac
2. Which of the following is a criterion for a diagnosis of hypersplenism? (Objective 1)
 - a. presence of a low WBC count in the blood
 - b. low cell counts in the bone marrow
 - c. circulating antibody-coated platelets
 - d. splenic macrophages containing undigestible substances
3. Hypersplenism can result from increased: (Objective 1)
 - a. splenic macrophages
 - b. B cell proliferation
 - c. abnormal erythrocytes
 - d. all of the above
4. Extramedullary hematopoiesis in the adult is often accompanied by: (Objectives 1, 2, 3)
 - a. splenomegaly
 - b. liver atrophy
 - c. leukocytosis
 - d. hyposplenism

REVIEW QUESTIONS (continued)

LEVEL I

5. Which site of early hematopoiesis is extraembryonic? (Objective 1)
 - a. yolk sac
 - b. liver
 - c. AGM
 - d. spleen

LEVEL II

5. Hypersplenism associated with compensatory hypertrophy of the spleen can be found: (Objectives 1, 4)
 - a. in neoplasms when malignant cells occupy much of the splenic space
 - b. when there are intrinsically abnormal erythrocytes
 - c. in liver cirrhosis with portal hypertension
 - d. when splenic macrophages accumulate large amounts of undigestible substances

ANSWERS TO CASE STUDY QUESTIONS

Case Summary: Francine had an acute lymphocytic leukemia. This is a type of leukemia that is characterized by a malignant proliferation of immature lymphocytic cells.

Question:

1. Refer to the tables on the inside cover of the book and determine which blood cell parameters, if any, are abnormal.

Explanation:

The hemoglobin is decreased. The WBC is normal, but the platelets are markedly decreased.

Question:

2. Describe Francine's bone marrow as normal, hyperplastic, or hypoplastic.

Explanation:

The bone marrow is hyperplastic. Normal bone marrow cellularity varies with age. A rule of thumb is that cellularity is 100% minus the age of the individual. This applies to marrow cellularity in the range of 30–90%.

Question:

3. What conditions can cause this bone marrow finding?

Explanation:

Conditions associated with an increased cellularity of bone marrow may include anemia and leukemia.

Question:

4. What do you think is the cause of the splenomegaly?

Explanation:

The splenomegaly could be due to extramedullary hematopoiesis. Malignant cells may be proliferating in the spleen.

Question:

5. Why might the peripheral blood reveal changes associated with hyposplenism when the spleen is enlarged?

Explanation:

Tumor cells can incapacitate the spleen, causing functional hyposplenism.

Question:

6. What might explain the lymphadenopathy?

Explanation:

The malignant lymphocytic cells may be proliferating in the lymph nodes causing enlargement.

ANSWERS TO CHECKPOINTS

Checkpoint! 1

Describe the bone marrow stromal location of erythrocyte, granulocyte, platelet, and lymphocyte differentiation.

Answer

Erythrocytes develop in erythroblastic islands located near the sinuses. The more mature cells are at the periphery of the island, and the more immature are closer to the center. Granulocytes are produced in nests that are close to trabeculae and arterioles but distant from venous sinuses. Platelets are produced from the cytoplasm of megakaryocytes, which are located next to the vascular sinus.

Checkpoint! 2

Describe the process by which a blood cell moves from the marrow to the vascular space.

Answer

New blood cells move along adventitial cells to the abluminal surface of venous sinuses. Spaces between reticular cells allow hematopoietic cells to contact the abluminal side of vascular endothelium, and a receptor-mediated process forces the abluminal and luminal sides of the endothelial cell to touch where the new blood cell is located. These two portions of the endothelial membrane fuse and create a pore through which the blood cell enters the vascular space.

Checkpoint! 3

Describe how old or damaged erythrocytes are removed from circulation by the spleen.

Answer

Old or damaged erythrocytes circulating through the slow transit compartment of the red pulp encounter a toxic (hypoxic, hypoglycemic, acidic) environment and become identifiable to macrophages in the red pulp cords as cells that need to be removed from the circulation. The macrophages phagocytose these undesirable cells before they exit the spleen.

Checkpoint! 4

List 3 causes each of workload and infiltrative splenic hypertrophy.

Answer

Workload splenic hypertrophy is a form of secondary hypersplenism. It is associated with inflammatory and infectious diseases that increase the defensive function of the spleen. This is thought to be caused by an increase in the number of macrophages or an increase in lymphoid cells. Blood disorders in which cells are intrinsically abnormal or are coated with antibody lead to removal of these cells by the splenic macrophages.

Additional cells or metabolic by-products in the spleen can cause infiltrative hypertrophy. This includes disorders in which macrophages accumulate large amounts of undigestible substances,

neoplasms in which tumor cells infiltrate the spleen, myelofibrosis in which the spleen contains foci of extramedullary hematopoiesis and in congestive splenomegaly following liver cirrhosis.

The Erythrocyte

Joel Hubbard, Ph.D.

■ OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. List and describe the stages of erythrocyte maturation in the marrow from youngest to most mature cells.
2. Explain the maturation process of reticulocytes and the cellular changes that take place.
3. Identify the normal range for reticulocytes.
4. Explain the function of erythropoietin; include the origin of production, bone marrow effects, and normal values.
5. Describe the function of the erythrocyte membrane.
6. Name the energy substrate of the erythrocyte.
7. Diagram the mechanism of extravascular erythrocyte destruction and hemoglobin catabolism.
8. Diagram the mechanism of intravascular erythrocyte destruction and hemoglobin catabolism.
9. State the average dimensions and life span of the normal erythrocyte.
10. Describe the function of 2,3-BPG and its relationship to the erythrocyte.

■ OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. Summarize the mechanisms involved in the regulation of erythrocyte production.
2. Describe the structure of the erythrocyte membrane, including general dimensions and features; assess the function of the major membrane components.
3. Explain the mechanisms used by the erythrocyte to regulate permeability to cations, anions, glucose, and water.
4. Compare and contrast three pathways of erythrocyte metabolism and identify key intermediates as well as the relationship of each to erythrocyte survival and longevity.
5. Generalize the metabolic and catabolic changes within the erythrocyte that occur with time that “label” the erythrocyte for removal by the spleen.
6. Compare and contrast erythrocyte extravascular destruction with intravascular destruction and identify which process is dominant given laboratory results.
7. Predict the effects of increased and decreased erythropoietin levels in the blood.

KEY TERMS

BACKGROUND BASICS

The information in this chapter builds on the concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study.

Level I

- ▶ Describe the process of cell differentiation and maturation, regulation, and the function of growth factors; describe cell organelles and their function.
- ▶ Give the functional description of the erythroid marrow.

Level II

- ▶ List and describe the function of specific growth factors important in erythrocyte development.
- ▶ Describe the structure and function of the spleen and bone marrow.

CASE STUDY

We will address this case study throughout the chapter.

Stephen, a 28-year-old Caucasian male of Italian descent, became progressively ill following a safari vacation to West Africa. The patient arrived at the ER for evaluation following several days of fever, chills, and malaise. The advent of hemoglobinuria prompted the patient to seek emergency aid. A clinical history and physical examination supported a diagnosis of anemia. Because Stephen had recently returned from a malarial endemic area, the physician first suspected malaria although the patient had been on primaquine preventive drug therapy while traveling abroad. Blood smears examined for malaria, however, resulted in a negative diagnosis. Consider additional laboratory tests that could help identify the cause of Stephen's anemia.

▶ OVERVIEW

This chapter is a study of the erythrocyte. It begins with a description of erythrocyte production and maturation. This is followed by an account of the erythrocyte membrane composition and function, cell metabolism, and kinetics of cell production. The chapter concludes with a description of the destruction of the senescent cell.

▶ INTRODUCTION

The erythrocyte (red blood cell, RBC) was one of the first microscopic elements recognized and described after the discovery of the microscope. For centuries, these corpuscles were considered inert particles with no function. In 1817, Francois Magendie diluted blood with water, found no microscopic corpuscles, and erroneously surmised that the red blood cells seen by others were probably air bubbles.¹ We now know that erythrocytes suspended in water will burst, which explains Magendie's negative findings. Magendie eventually recognized his mistake and later provided a morphologic description of the erythrocyte. Not until 1865, however, when Felix Hoppe-Seyler discovered the oxygen-carrying capacity of the red pigment (hemoglobin) within the red blood cells, did the function of these "globules" begin to be understood. Today, we recognize the erythrocyte as being one of the most highly specialized cells in the body.

▶ ERYTHROPOIESIS AND RED BLOOD CELL MATURATION

Erythron refers to the totality of all stages of erythrocytes, including precursor cells in the marrow and mature cells in the peripheral blood and within vascular areas of specific organs such as the spleen. **Erythropoiesis**, or the production of erythrocytes, is normally an orderly process through which the peripheral concentration of erythrocytes is maintained at a steady state. The life cycle of erythrocytes includes stimulation of lineage commitment and maturation of precursor cells in the marrow by **erythropoietin**; a circulating life span for mature cells of approximately 120 days \pm 10 days, and the destruction of senescent cells by mononuclear cells in the liver, spleen, and bone marrow.

ERYTHROID PROGENITOR CELLS

Red cell production begins with the hematopoietic stem cell (HSC). Stem cell differentiation is induced by certain microenvironmental influences to produce a committed erythroid progenitor cell. The committed (unipotential) erythroid progenitor cell compartment consists of two populations of cells, neither identifiable microscopically but defined by their behavior in cell culture systems: the burst-forming unit-erythroid (**BFU-E**) and colony-forming unit-erythroid (**CFU-E**).² The BFU-E progenitor

cells proliferate under the influence of what was originally called “burst-promoting activity” (BPA), now known to be IL-3 or GM-CSF, released by local microenvironmental stromal cells. BFU-Es have a low concentration of erythropoietin (EPO) receptors and thus are relatively insensitive to EPO except in high concentrations. The BFU-Es are defined as progenitor cells that give rise to a “burst” or multifocal colony of cells in an in vitro colony assay in 10 to 14 days. The colony consists of several hundred to several thousand cells recognizable as hemoglobin-containing RBC precursors. Maturation of the BFU-E gives rise to the CFU-E progenitor cell. An individual CFU-E, which undergoes only a few cell divisions, gives rise to a single, discrete colony of 8 to 60 identifiable cells after 2–5 days of culture.² CFU-Es have a high concentration of EPO membrane receptors; hence, they respond to lower EPO concentrations than do BFU-Es. The CFU-E is the immediate precursor of the earliest morphologically recognizable erythroid precursor, the pronormoblast. The graph below shows the relationship of the various hematopoietic progenitor cells to the cytokines that affect their maturation.

BFU-Es are CD34⁺ and have a high proliferative potential but a low rate of cycling. As they mature to the CFU-E stage, they lose CD34⁺ expression but begin to express surface proteins characteristic of the erythroid lineage including gly-

■ **FIGURE 1** Pronormoblast in the center. Note the large N:C ratio, presence of nucleoli, and lacy chromatin. The cytoplasm is deep blue with a lighter pinkish area next to the nucleus. Also note above at about one o'clock the polychromatophilic normoblast (arrow). (Bone marrow; Wright-Giemsa stain, 1000× magnification)

cophorin A, Rh antigens, and in a subset of CFU-E, the ABH and Ii antigens.²

Additional cytokines shown to have a positive effect on erythrocyte precursor proliferation include stem cell factor (SCF), thrombopoietin, and IL-11 while tumor necrosis factor- α , transforming growth factor- β , and interferon- γ have a negative effect on erythropoiesis.

ERYTHROID-MATURING CELLS

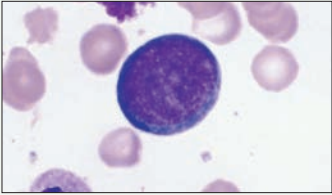

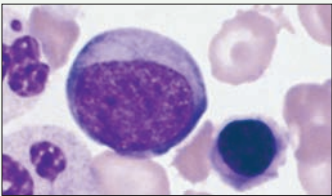

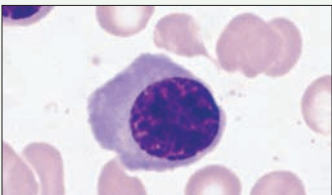

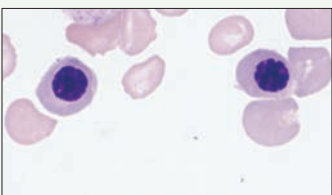

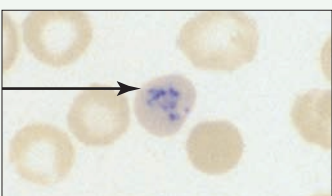

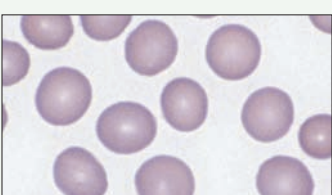

Erythroid-maturing cells include those precursor cells in the bone marrow that are morphologically identifiable. Nucleated erythrocyte precursors in the bone marrow are collectively called **erythroblasts**. If the maturation sequence is “normal,” the cells are often called **normoblasts**. Young erythrocytes with residual RNA but without a nucleus are referred to as **reticulocytes** (polychromatophilic erythrocytes). Bone marrow normoblast maturation occurs in an orderly and well-defined sequence under normal conditions encompassing six morphologically defined stages. The process involves a gradual decrease in cell size together with progressive condensation of the nuclear chromatin and eventual expulsion of the pyknotic nucleus. The cytoplasm in the younger normoblasts stains deeply basophilic due to the predominance of RNA (Figure 1 ■). As the cell matures, there is an increase in hemoglobin production, which is acidophilic, and the cytoplasm takes on a gray to pink or salmon color (Figures 1 and 2 ■). Two terminology systems are used to describe erythrocyte precursors. One uses the word *normoblast* and the other *rubriblast*. This text uses the normoblast terminology. The stages in order from most immature to mature cell are pronormoblast (rubriblast), basophilic normoblast (prorubricyte), polychromatophilic normoblast (rubricyte), orthochromatic normoblast (metarubricyte), reticulocyte, and erythrocyte (Table 1 🌟).

■ **FIGURE 2** Developing normoblasts. At nine o'clock there is an early polychromatophilic normoblast; in the center from left to right are an early orthochromatic normoblast, late orthochromatic normoblast, band neutrophil, and a basophilic normoblast. (Bone marrow; Wright-Giemsa stain, 1000× magnification)

TABLE 1

Morphologic Characteristics of Erythroid Precursors

Cell Type (% of nucleated cells in BM)	Image (Wright stain)	Size	N/C Ratio	Cytoplasmic Characteristics	Nuclear Characteristics
Pronormoblast (rubriblast) (1%)		20–25 μm	High (8:1)	Small to moderate amount of deep blue cytoplasm; pale area next to nucleus might be seen	1–3 faint nucleoli; reddish purple color; homo- geneous, lacy chromatin
Basophilic normoblast (prorubricyte) (1–3%)		16–18 μm	Moderate (6:1)	Deep blue-purple color; occasionally small patches of pink; irregular cell borders may be present; perinuclear halo might be apparent	Indistinct nucleoli; coars- ening chromatin; deep purplish-blue color
Polychromatophilic normoblast (rubricyte) (13–30%)		12–15 μm	Low (4:1)	Abundant; gray-blue color	Chromatin irregular and coarsely clumped, eccentric
Orthochromic normoblast (metarubricyte) (1–4%)		10–15 μm	Low (1:2)	Pink-salmon color; may have varying degrees of basophilia	Small; dense; pyknotic; round or bizarre shape; eccentric
Reticulocyte (new methylene blue stain)		7–10 μm	—	Punctuate purplish-blue inclusions	No nucleus
(Wright's stain)				Polychromatophilic (diffusely basophilic)	
Mature RBC		7–8 μm	—	Salmon color	No nucleus

The normoblasts generally spend from 5 to 7 days in the proliferating and maturing compartment of the bone marrow. After reaching the reticulocyte stage, there is an additional 2–3 days of maturation, the first 1–2 days of which are spent in the marrow before the cell is released to the peripheral blood. The mature circulating erythrocyte has a life span of 100–120 days. This lengthy life span accounts for the relatively small number of erythroid precursors in the marrow in comparison to the large circulating erythrocyte mass.

Erythropoietin (EPO) is the only cytokine important in regulating the final stages of erythroid maturation (the maturing cells). A number of hormones are known to have some erythropoietic effect, however. The most notable is the erythropoietic effect of androgens, which was exploited for the treatment of various anemias before the development of recombinant EPO. Androgens appear to both stimulate EPO secretion and directly affect the erythropoietic marrow, which partially explains the difference in hemoglobin concentrations according to sex and age. Other hormones, which have varying (although minor) effects on erythropoiesis, include thyroid hormones, adrenal cortical hormones, and growth hormone.³ Anemic patients with hypopituitarism, hypothyroidism, and adrenocortical insufficiency show an increase in erythrocyte concentration when the appropriate deficient hormone is administered. The reduction of EPO in hypothyroidism may partially be the result of the reduced demand for cellular oxygen by metabolically hypoactive tissue.

✓ Checkpoint! 1

What is meant by the term erythron?

CHARACTERISTICS OF CELL MATURATION

Although the stages of erythrocyte maturation are usually described in steplike fashion, the actual maturation is a gradual and continuous process (Table 1). Some normoblasts may not conform to all criteria for a particular stage, and a judgment must be made when identifying those cells. The more experience one has in examining the blood and bone marrow, the easier it becomes to make these judgments.

Pronormoblast

This is the earliest morphologically recognizable erythrocyte precursor. Each pronormoblast produces between 8 and 32 mature erythrocytes (a total of 3 to 5 cell divisions during the maturation sequence). The cell is the largest of the normoblast series, from 20–25 μm in diameter with a high nuclear:cytoplasmic (N:C) ratio. The nucleus occupies 80% or more of the cell. This cell is rather rare in the bone marrow.

Cytoplasm The cytoplasm contains a large number of ribosomes and stains deeply basophilic. A pale area next to the nucleus is sometimes apparent. This represents the Golgi apparatus, which does not take up the dyes of the Romanowsky stain. Small amounts of hemoglobin are present but are not visible by light microscopy.

Nucleus The nucleus is large, taking up most of the cell volume, and stains bluish-purple. The chromatin is in a fine linear network often described as lacy. The pronormoblast chromatin has a coarser appearance and stains darker than the chromatin of a white cell blast. The nucleus contains from 1 to 3 faint nucleoli.

Basophilic Normoblast

This cell is similar to the pronormoblast except that it is usually smaller (16–18 μm in diameter) and has a slightly decreased N:C ratio. The nucleus occupies approximately three-fourths of the cell volume. Because these cells are actively dividing, it is possible to find a basophilic normoblast (in G₂, prior to mitosis) that is larger than the pronormoblast (in G₁).

Cytoplasm The cytoplasm is still deeply basophilic, often more so than that of the previous stage due to the increased number of ribosomes. However, in late basophilic normoblasts, the presence of varying amounts of hemoglobin can cause the cell to take on a lighter blue hue or show scattered pink areas. A pale area surrounding the nucleus, the perinuclear halo, is sometimes seen. This halo corresponds to the mitochondria, which also do not stain with Romanowsky stains.

Nucleus The chromatin is coarser than that of the pronormoblast. The dark violet heterochromatin interspersed with the lighter-staining euchromatin can give the chromatin a wheel-spoke appearance. A few small masses of clumped chromatin may be seen along the rim of the nuclear membrane. Nucleoli usually are not apparent.

Polychromatophilic Normoblast

The cell is about 12–15 μm in diameter with a decreased N:C ratio due to continued condensation of the nuclear chromatin. This is the last stage capable of mitosis.

Cytoplasm The most characteristic change in the cell at this stage is the presence of abundant gray-blue cytoplasm. The staining properties of the cytoplasm are due to the synthesis of large amounts of hemoglobin and decreasing numbers of ribosomes. The cell derives its name, polychromatophilic, from this characteristic cytoplasmic feature.

Nucleus The nuclear chromatin is irregular and coarsely clumped due to increased aggregation of nuclear heterochromatin.

Orthochromic Normoblast

This cell is about 10–15 μm in diameter with a low N:C ratio.

Cytoplasm After the final mitotic division of the erythropoietic precursors, the concentration of hemoglobin increases within the erythroblast. The cytoplasm is predominantly pink or salmon color but retains a tinge of blue due to residual ribosomes.

Nucleus The nuclear chromatin is heavily condensed. In late stages, the nucleus is structureless (pyknotic) or fragmented. The nucleus is often eccentric or even partially extruded. Using phase-contrast microscopy, these cells demonstrate motility with protraction and retraction of cytoplasmic projections.⁴ These movements are in preparation for ejection of the nucleus, which usually occurs while the erythroblast is still part of the erythroblastic island (see below). Alternatively, the nucleus may be lost as the cell passes through the wall of a marrow sinus. The expelled nucleus is engulfed by a marrow macrophage.

Reticulocyte

After the nucleus is extruded, the cell is known as a *reticulocyte*. When the nucleus is first extruded, the cell has an irregular lobulated or puckered shape. The cell is remodeled, eliminating excess membrane and gradually acquiring its final biconcave shape while it completes its maturation program. The reticulocyte matures over a span of 2–3 days, the first half of which is spent in the bone marrow and the latter half in the circulating blood.

The reticulocyte has residual RNA and mitochondria in the cytoplasm, which give the young cell a bluish tinge with Romanowsky stains; thus, the cell is appropriately described as a diffusely basophilic erythrocyte or **polychromatophilic erythrocyte**. About 80% of the cell's hemoglobin is made during the normoblast stages with the remaining 20% made during the reticulocyte stage. The reticulocyte is slightly larger, 7–10 μm , than a mature erythrocyte. After 1 1/2 to 2 days in the bone marrow, the reticulocyte is released into the vascular sinuses of the marrow. From there, it gains access to the peripheral blood. Reticulocyte maturation continues in the peripheral blood for another day or two. These cells can be identified in vitro by reaction with supravital stains, new methylene blue N, or brilliant cresyl blue, which cause precipitation of the RNA and mitochondria. This supravital staining method identifies the reticulocytes by the presence of punctate purplish blue inclusions. Normally, reticulocytes compose 0.5–2.5% (absolute concentration 18–158 $\times 10^9/\text{L}$) of peripheral blood erythrocytes in a nonanemic adult. The actual reference interval varies among laboratories. The absolute concentration of reticulocytes is calculated by multiplying the percent of reticulocytes by the RBC count. When reticulocytes are increased, an increased number of polychromatophilic erythrocytes (polychromasia) may be seen on the Romanowsky-stained peripheral blood smear.

Reticulocytes may contain small amounts of iron dispersed throughout the cytoplasm, which can be identified with Perl's Prussian blue stain. Erythrocytes with identified iron are called *siderocytes*. Nucleated RBC precursors that stain with Prussian blue are called *sideroblasts*. The spleen is responsible for removal of these iron-containing granules and the normal mature circulating cell is devoid of granular inclusions.

✓ Checkpoint! 2

What is the first stage of red cell maturation that has visible cytoplasmic evidence of hemoglobin production on a Romanowsky-stained smear?

🔍 CASE STUDY (continued from earlier in this chapter)

In addition to malaria screening, the ER physician also ordered a CBC with the following results:

WBC	14 $\times 10^9/\text{L}$	Differential	
RBC	3.10 $\times 10^{12}/\text{L}$	Segs	70%
HGB	9.2 gm/dL	Bands	11%
HCT	28%	Metas	2%
MCV	93 fL	Lymphs	13%
MCH	30.6 pg/dL	Monos	2%
MCHC	32.5 gm/dL	Eos	2%
PLT	230 $\times 10^9/\text{L}$	NRBCs/100 WBCs	18
		RBC Morphology	
		Anisocytosis	3+
		Poikilocytosis	2+
		Spherocytosis	1+
		Schistocytes	1+
		Polychromasia	2+

1. Predict Stephen's reticulocyte count: low, normal, or increased.

Erythrocyte

The mature erythrocyte is a biconcave disc about 7–8 μm in diameter and 80–100 fL in volume. It stains pink to orange because of its content of the intracellular acidophilic protein, hemoglobin (28–34 pg/cell). The cell has lost its residual RNA and mitochondria as well as important enzymes; therefore, it is incapable of synthesizing new protein or lipid.

ERYTHROBLASTIC ISLANDS

Erythropoiesis occurs in distinctive histologic configurations called *erythroblastic islands* (EI) that consist of concentric circles of developing erythroblasts clustered around a central macrophage. The central macrophage sends out slender cytoplasmic processes that maintain direct contact with each

erythroblast. Erythroblasts adhere to the central macrophage by a variety of cytoadhesion molecules including fibronectin (Fn) and thrombospondin (Tsp). As the erythroblast matures, it moves along a cytoplasmic extension of the macrophage. As the cell becomes sufficiently mature for nuclear expulsion, cytoadhesion molecule receptors (FnR, Tsp-R, and others) are no longer expressed on the cell membrane. As a result, the cell detaches from the EI, passes through a pore in the cytoplasm of endothelial cells lining the marrow sinuses, and enters the circulation.⁴ The central macrophage phagocytizes the nucleus, which is extruded from the orthochromatic erythroblasts before the cell leaves the bone marrow. Any defective erythroblasts produced during the process of erythropoiesis (“ineffective erythropoiesis”) also are phagocytized by the macrophage.

Surrounding the EI are fibroblasts, macrophages, and endothelial cells, which provide the optimal microenvironment for terminal erythroid maturation. The EI is a fragile structure and is usually disrupted by the process of marrow aspiration. However, maturing erythroblasts with adherent macrophage cytoplasmic fragments may be seen on marrow aspirate smears. Intact erythroblastic islands can occasionally be seen in marrow core biopsies.⁴

► ERYTHROCYTE MEMBRANE

Around the beginning of the twentieth century, investigations began that established the complexity of the erythrocyte membrane. Steven Hedin performed experiments that demonstrated the osmotic properties and selective permeability of the erythrocyte.⁵ He found that erythrocyte volume increased in hypotonic solutions (these having a lower osmotic pressure than the erythrocyte) and solutions such as urea or glycerol. Other solutions, however, caused the cell to shrink. Antigenic properties of the membrane were recognized several years later by Karl Landsteiner, who observed that human sera caused clumping of the erythrocytes in different individuals. He originally divided these individuals into three groups, A, B, and C, according to their erythrocyte agglutination patterns with human sera.⁶ Today we identify these blood types as groups A, B, and O. Hundreds of other erythrocyte antigens have since been identified.

The red cell membrane is essential for erythrocyte development and function. Developing erythroblasts have membrane receptors for EPO and transferrin (iron), which are required during erythropoiesis. The erythrocyte membrane selectively sequesters vital components (e.g., organic phosphates such as 2,3-BPG) and lets metabolic waste products (lactate, pyruvate) escape. The membrane helps regulate metabolism by reversibly binding and inactivating many glycolytic enzymes. It carefully balances exchange of bicarbonate and chloride ions, which aid in the transfer of carbon dioxide from tissues to lungs and balance cation and water concentrations to maintain erythrocyte ionic composition.

Finally, in association with the “membrane skeleton,” the erythrocyte membrane provides the red cell with the dual characteristics of strength and flexibility needed to survive its 120-day life span in the circulation.

MEMBRANE COMPOSITION

The erythrocyte membrane is a phospholipid bilayer-protein complex composed of ~52% protein, 40% lipid, and 8% carbohydrate (Table 2).⁷ The chemical structure and composition control the membrane functions (e.g., transport, durability/strength, flexibility) and determine the membrane’s antigenic properties. Any defect in structure or alteration in chemical composition can alter erythrocyte membrane functions and lead to the cell’s premature death. Mature erythrocytes lack the cellular organelles (nucleus, ribosomes, and mitochondria) and enzymes necessary to synthesize new lipid and protein. Thus, extensive damage to the membrane cannot be repaired, and the damaged cell will be culled from the circulation by the spleen.

Checkpoint! 3

How would an increase in RBC membrane permeability affect intracellular sodium balance?

TABLE 2

Erythrocyte Membrane Composition

Lipids and glycolipids (~45%)	Unesterified cholesterol
	Phospholipids
	Phosphatidylinositol/PI
	Phosphatidylethanolamine/PE
	Phosphatidylserine/PS
	Phosphatidylcholine/PC (lecithin)

Tropomodulin (band 5)	

Lipid Composition

Approximately 95% of the lipid content of the membrane consists of equal amounts of unesterified cholesterol and phospholipids. The remaining lipids are free fatty acids (FA) and glycolipids (e.g., globoside). Mature erythrocytes are unable to synthesize fatty acids, phospholipids, or cholesterol. Consequently, they depend on lipid exchange with the plasma and fatty acid acylation for phospholipid repair and renewal during their 120-day lifespan.

The overall structure of the membrane is that of a phospholipid bilayer with the phospholipid molecules arranged with polar heads exposed at each membrane surface and their hydrophobic fatty acid sidechains directed to the interior of the bilayer. The major phospholipids are phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylserine (PS), and sphingomyelin (SM). Small amounts of phosphatidylinositol (PI), phosphatidic acid (PA), and lysophospholipids are also present.⁸ The phospholipids are asymmetrically distributed within the membrane bilayer. The choline phospholipids (PC, SM) are concentrated in the outer half of the bilayer, and the amino phospholipids (PE, PS, PI) are largely confined to the inner half. Although there is transmembrane diffusion of the phospholipids from areas of higher concentration to the bilayer leaflet of lower concentration, the asymmetry is maintained by an ATP-dependent transport system, the aminophospholipid translocase (also nicknamed “flippase”).⁹ Considerable evidence that the mobility of phospholipids within the membrane contributes to membrane fluidity exists. Exchange between phospholipids of the membrane and plasma can occur, especially with the phospholipids of the outer bilayer leaflet.

Cholesterol and glycolipids are intercalated between the phospholipids in the membrane bilayer.⁸ Cholesterol is present in approximately equal proportions on both sides of the lipid bilayer. Cholesterol affects the surface area of the cell and membrane permeability. Membrane cholesterol exists in free equilibrium with unesterified cholesterol of plasma lipoproteins. Once in the plasma, cholesterol is partially converted to esterified cholesterol by the action of lecithin-cholesterol acyl transferase (LCAT). Once esterified, cholesterol cannot return to the red cell membrane; thus, LCAT catalyzes a unidirectional pathway of cholesterol transfer that tends to deplete the red cell membrane of cholesterol. It is not surprising that when LCAT is absent (congenital LCAT deficiency or hepatocellular disease), free plasma cholesterol increases, resulting in accumulation of cholesterol within erythrocyte membranes, and RBC membrane surface area expands. An excess of cell membrane due to proportional increases in cholesterol and phospholipids, maintaining the normal ratio, results in the formation of macrocytocytes (large target cells). An increase in the cholesterol-to-phospholipid ratio, however, increases the membrane’s microviscosity (decreased fluidity). An increase in membrane lipids due to a disproportionate increase in cholesterol results in

the formation of **acanthocytes**, which have reduced survival as compared to normal RBCs.

The shape of the red cell can also be altered by expansions of the separate lipid bilayers relative to each other. Processes that expand the bilayer’s outer leaflet (or contract the inner) result in the formation of membrane spicules, producing echinocytes (see Figure 3■). Conversely, expansion of the inner leaflet of the bilayer leads to invagination of the membrane and the formation of stomatocytes (cup-shaped cells) (Figure 3).

Reticulocytes normally contain more membrane lipid and cholesterol than do older erythrocytes. This excess lipid material is removed from the reticulocytes during the final stages of maturation in the circulation by the splenic macrophages. Splenectomized patients can have cells with an abnormal accumulation of cholesterol and/or other lipids in the membrane, which will present as target cells, acanthocytes, and/or echinocytes on the blood smear.

A small portion of membrane lipids consists of glycolipids in the form of glycosphingolipid. Red cell glycolipids are located entirely in the external half of the lipid bilayer with their carbohydrate portions extending into the plasma. Glycolipids are responsible for some important antigenic properties of the red cell membrane; they carry the ABH, Lewis, and P blood group antigens.

■ **FIGURE 3** Model of discocyte-echinocyte and discocyte-stomatocyte transformation. RBC shape is determined by the ratio of the surface areas of the two hemileaflets of the lipid bilayer. Preferential accumulation of compounds in the outer leaflet of the lipid bilayer cause expansion and results in RBC crenation and echinocytosis; expansion of the inner leaflet of the bilayer results in stomatocytosis. ✓ Checkpoint! 4

Compare and contrast the placement of lipids in the erythrocyte membrane and their functions.

Protein Composition

Erythrocyte membrane proteins are of two types: integral and peripheral (Figure 4■). Integral proteins penetrate or traverse the lipid bilayer and interact with the hydrophobic lipid core of the membrane. In contrast, peripheral proteins do not penetrate into the lipid bilayer but interact with integral proteins or lipids at the membrane surface. In the red cell, the major peripheral proteins are on the cytoplasmic side of the membrane attached to membrane lipids or inte-

gral proteins by ionic and hydrogen bonds. Both types of membrane proteins are synthesized during erythroblast development. The proteins of the red cell have been studied by first lysing the cell by hypotonic hemolysis, extracting the proteins, and analyzing them by polyacrylamide gel electrophoresis in sodium dodecyl sulfate (SDS-PAGE). The proteins, separated according to molecular weight, were initially identified by number according to their migration during electrophoresis with the larger proteins (which migrated the shortest distance) beginning the numbering sequence.

Integral proteins include transport proteins and the glycoporphins. The three major glycoporphins—A, B, and C (GPA, GPB, GPC)—are made up of three domains: the cytoplasmic domain, the hydrophobic domain, which spans the bilayer,

■ **FIGURE 4** Model of the organization of the erythrocyte membrane showing the peripheral and integral proteins and lipids. Spectrin is the predominant protein of the skeletal protein lattice. Spectrin dimers join head to head to form spectrin tetramers. At the tail end, spectrin tetramers come together at the junctional complex. This complex is composed of actin oligomer and stabilized by tropomyosin, which sits in the groove of the actin filaments. The actin oligomer is capped on one end by tropomodulin and on the other by adducin. Band 4.9 protein (dematin) binds to actin and bundles actin filaments. Spectrin is attached to actin by protein 4.1, which also attaches the skeletal lattice to the lipid membrane via its interaction with glycophorin C (minor attachment site). Ankyrin links the skeletal protein network to the inner side of the lipid bilayer via band 3. Protein 4.2 interacts with ankyrin and band 3 (major attachment site).

and the extracellular domain on the exterior surface of the membrane.⁷ The extracellular domain is heavily glycosylated and is responsible for most of the negative surface charge (zeta potential) that keeps red cells from sticking to each other and to the vessel wall. They also carry various red cell antigens. Genetic polymorphisms at the GPA locus are responsible for the MN blood group antigens; GPB carries the S, s, and U antigens, and GPC carries the Gerbich antigens.⁸ Glycophorin C also plays a role in attaching the skeletal protein network located on the cytoplasmic side of the membrane to the bilipid layer. The glycophorins are synthesized early in erythroid differentiation (GPC is found in BFU-E) and thus serve as lineage-specific markers for erythrocytic differentiation.

Band 3, also known as the *anion exchange protein 1* (AE1), is the major integral protein of the red cell with more than 1 million copies per cell. Band 3/AE1 is the transport channel for the chloride-bicarbonate exchange, which occurs during the transport of CO₂ from the tissues back to the lungs. Like most transport channels, Band 3 spans the membrane multiple times (12–14). Anion exchange is thought to occur by a “ping-pong” mechanism. An intracellular anion enters the transport channel and is translocated outward and released. The channel remains in the outward conformation until an extracellular anion enters and triggers the reverse cycle.⁸

In addition to its role as an anion exchanger, band 3 is a major binding site for a variety of enzymes and cytoplasmic membrane components.⁸ The N-terminal, cytoplasmic domain of band 3, binds glycolytic enzymes, regulating their activity and serving as a regulator of red cell glycolysis. Band 3 also binds hemoglobin at its cytoplasmic domain with intact hemoglobin binding weakly but partially denatured hemoglobin (Heinz bodies) binding more avidly. Binding of hemoglobin to band 3 is thought to play a role in erythrocyte senescence. Band 3 is also important in attaching the skeletal protein network to the lipid bilayer by binding to the skeletal proteins ankyrin and band 4.2. The Ii blood group antigens are carried on the carbohydrate component of the red cell band 3 protein.^{10,11}

The red cell membrane contains more than 100 additional integral proteins.⁸ These include all of the various transporter proteins (glucose transporter, urea transporter, Na⁺/K⁺-ATPase, Ca²⁺-ATPase, Mg²⁺-ATPase), the Rh protein, the Kell antigen protein, various receptors (transferrin, insulin, insulinlike growth factor, etc.) and decay-accelerating factor (DAF).

Peripheral proteins are found primarily on the cytoplasmic face of the erythrocyte membrane and include enzymes and structural proteins. The structural proteins are organized into a two-dimensional lattice network directly laminating the inner side of the membrane lipid bilayer called the *red cell membrane skeleton*.¹² The horizontal interactions of this lattice are parallel to the plane of the membrane and serve as a skeletal support for the membrane lipid layer. The vertical interactions of the lattice are perpendicular to the

plane of the membrane and serve to attach the skeletal lattice network to the lipid layer of the membrane. The skeletal proteins give red cell membranes their viscoelastic properties and contribute to cell shape, deformability, and membrane stability. The red cell skeleton proteins include spectrin, actin, ankyrin (band 2.1), band 4.2, band 4.1, adducin, band 4.9 (de-matin), tropomyosin, and tropomodulin. Defects in this erythrocyte cytoskeleton are associated with abnormal cell shape, decreased stability, and hemolytic anemia.

Spectrin, the predominant skeletal protein, exists as a heterodimer of two large chains (α and β). The two chains associate in a side-by-side, antiparallel arrangement (N-terminal of α chain associated with C-terminal of β chain). The $\alpha\beta$ heterodimers form a slender, twisted, highly flexible molecule ~100 nm in length. Spectrin heterodimers in turn self-associate head to head to form tetramers and some larger oligomers.⁸ Spectrin is described as functioning as a kind of spring. In the red cell, spectrin tetramers (which would have an extended length of ~200 nm) are tightly coiled in vivo with an end-to-end distance of only ~76 nm.¹³ These coiled tetramers can extend reversibly when the membrane is stretched but cannot exceed their maximum extended length (200 nm) without rupturing.

Ankyrin is a large protein that serves as the high-affinity binding site for the attachment of spectrin to the inner membrane surface. It binds spectrin near the region involved in dimer-tetramer associations. In turn, ankyrin is bound with high affinity to the cytoplasmic portion of band 3 (the actual anchor for the membrane skeleton).¹⁴ *Band 4.2* binds to ankyrin and band 3, strengthening their interaction and helping to bind the skeleton to the lipid bilayer at its major attachment point.¹⁵

Red cell *actin* is functionally similar to actin in other cells. However, unlike its organization in muscle cells, red cell actin is organized into short, double-helical protofilaments of 12–14 actin monomers. These short filaments are stabilized by their interactions with other proteins of the red cell skeleton including *tropomodulin*, *adducin*, *tropomyosin*, and *band 4.9*. Spectrin dimers bind to actin filaments near the tail end of the spectrin dimer. *Protein 4.1* interacts with spectrin and actin and with GPC in the overlying lipid bilayer. It serves to stabilize the otherwise weak interaction between spectrin and actin and is necessary for normal membrane stability.⁸ This complex of spectrin, actin, tropomodulin, tropomyosin, adducin, band 4.9, and band 4.1 serves as the secondary attachment point for the red cell skeleton, binding to GPC of the membrane.

The skeletal proteins are not static but are in a continuous disassociation–association equilibrium with each other (e.g., spectrin dimer-tetramer interconversions) and with their attachment sites. This equilibrium occurs in response to various physical and chemical stimuli that affect the erythrocytes as they journey throughout the body. Calcium also influences the red cell cytoskeleton. Most intracellular calcium (80%) is

found in association with the erythrocyte membrane. Calcium is normally maintained at a low intracellular concentration by the activity of an ATP-fueled Ca^{2+} pump (Ca^{2+} -ATPase). Elevated Ca^{2+} levels induce membrane protein cross-linking.¹⁶ This cross-linking essentially acts as a fixative, stabilizing red cell shape and reducing the cell's deformability. The abnormal erythrocyte shape of irreversibly sickled cells can be produced by calcium-induced irreversible cross-linking and alteration of the cytoskeletal proteins.

The erythrocyte membrane together with the membrane skeleton is responsible for the dual cellular characteristics of structural integrity as well as deformability. The 7 μm erythrocyte must be sufficiently flexible to squeeze through the tiny capillary openings, particularly in the splenic vasculature ($\sim 3 \mu\text{m}$); this requires significant deformations of the cell. At the same time, cells must be able to withstand the rigors of the turbulent circulation as they travel throughout the body for 120 days. Deformability of the red cell is due to three unique cellular characteristics¹⁷:

- its biconcave shape (large surface area-to-volume ratio)
- the viscosity of its internal contents (the “solution” of hemoglobin)
- the unique viscoelastic properties of the erythrocyte membrane

Red cells have an “elastic extension” capability (primarily due to the elasticity of coiled spectrin tetramers and association-dissociation of skeletal proteins) whereby the cells can resume a normal shape after being distorted by an external applied force. However, application of large or prolonged forces can be associated with reorganization of the cytoskeletal proteins, producing a permanent deformation or, if the force is excessive, fragmentation.¹⁷ In addition to being a major component of erythrocyte deformability, the membrane skeleton is the principal determinant of erythrocyte stability. The proportion of spectrin dimers versus tetramers (or higher oligomers) is a key factor influencing membrane stability.¹⁸ Higher proportions of dimers result in increased fragility while higher proportions of tetramers and oligomers result in stabilization. Also, interaction of the cytoskeleton with the lipid bilayer and integral membrane proteins stabilizes the cell membrane. If the bilayer uncouples from the skeleton, portions of lipid-rich membrane will be released in the form of microvesicles, resulting in a decrease in the surface area-to-volume ratio and the formation of spherocytes.¹⁹

✓ Checkpoint! 5

Compare placement in the membrane and function of peripheral and integral erythrocyte membrane proteins.

MEMBRANE PERMEABILITY

The red cell membrane is freely permeable to water (exchanged by a water channel protein²⁰) and to anions (ex-

★ TABLE 3

Concentration of Cations in the Erythrocyte versus Plasma

Cation	Erythrocyte (mmoles/L)	Plasma (mmoles/L)
Sodium (Na^+)	5.4–7.0	135–145
Potassium (K^+)	98–106	3.6–5.0
Calcium (Ca^{2+})	0.0059–0.019	2.1–2.6
Magnesium (Mg^{2+})	3.06	0.65–1.05

changed by the anion transport protein, band 3). In contrast, the red cell membrane is nearly impermeable to monovalent and divalent cations. Glucose is taken up by a glucose transporter in a process that does not require ATP.²¹

The cations, Na^+ , K^+ , Ca^{2+} , and Mg^{2+} are maintained in the erythrocyte at levels much different than those in plasma (Table 3 ★). Erythrocyte osmotic equilibrium is normally maintained by both the selective (low) permeability of the membrane to cations and cation pumps located in the cell membrane. To maintain low intracellular Na^+ and Ca^{2+} and high K^+ concentrations (relative to plasma concentrations), the red cell utilizes two cation pumps, both of which use intracellular ATP as an energy source.

The Na^+/K^+ cation pump hydrolyzes one mole of ATP in the expulsion of 3Na^+ and the uptake of 2K^+ . This normally balances exactly the passive “leaks” of each cation along its respective concentration gradient between plasma and cytoplasm. This Na^+/K^+ -ATPase is activated by intracellular Na^+ and extracellular K^+ , although physiologic regulation of Na^+ and K^+ transport is primarily due to increased intracellular Na^+ .⁸ Calcium plays a role in maintaining low membrane permeability to Na^+ and K^+ . An increase in intracellular Ca^{2+} allows Na^+ and K^+ to move in the direction of their concentration gradients.⁸ Additionally, increased intracellular Ca^{2+} activates the Gárdos channel, which causes selective loss of K^+ and, consequently, water, resulting in dehydration. Low intracellular Ca^{2+} is maintained by a Ca^{2+} -ATPase pump. The Ca^{2+} pump depends on magnesium to maintain its transport function. Although Mg^{2+} is necessary for active extrusion of Ca^{2+} from the cell, Mg^{2+} is not moved out of the cell in the process.

If erythrocyte membrane permeability to cations increases or the cation pumps fail (either due to decreased glucose for generation of ATP via glycolysis or decreased ATP), Na^+ accumulates in the cells in excess of K^+ loss. The result is an increase in intracellular monovalent cations and water, cell swelling, and, ultimately, osmotic hemolysis.

► ERYTHROCYTE METABOLISM

The metabolism of the erythrocyte is limited because of the absence of a nucleus, mitochondria, and other subcellular organelles. Although the binding, transport, and release of

O₂ and CO₂ are passive processes not requiring energy, various energy-dependent metabolic processes that are essential to cell viability occur. Energy is required by the erythrocyte to:

1. maintain the cation pumps, moving cations against electrochemical gradients
2. maintain hemoglobin iron in the reduced state
3. maintain reduced sulfhydryl groups in hemoglobin and other proteins
4. maintain red cell membrane integrity and deformability

The most important metabolic pathways in the mature erythrocyte are linked to glucose metabolism. These pathways include: (Table 4) (★)

1. glycolysis (glycolytic pathway, formerly known as Embden-Meyerhof pathway)
2. hexose-monophosphate shunt
3. methemoglobin reductase pathway
4. Rapoport-Luebering shunt

Because the red cell lacks a citric acid cycle (due to the lack of mitochondria), it is limited to obtaining energy (ATP) solely by anaerobic glycolysis. Glucose enters the red cell through a membrane-associated glucose carrier, which transports glucose into the cell in a process that does not require ATP. Transport of glucose into the RBC is independent of insulin.

GLYCOLYTIC PATHWAY

The erythrocyte obtains its energy in the form of ATP from glucose breakdown in the glycolytic pathway, formerly known as the Embden-Meyerhof pathway (Figure 5). About 90–95% of the cell’s glucose consumption is metabolized by this pathway. Normal erythrocytes have no glycogen deposits and depend entirely on environmental glucose

for **glycolysis**. Glucose is metabolized by this pathway to lactate or pyruvate, producing a net gain of 2 moles of ATP per mole of glucose. If NADH is available in the cell, pyruvate is reduced to lactate. The lactate or pyruvate formed is transported from the cell to the plasma and metabolized elsewhere in the body.

Adequate amounts of ATP are necessary to maintain erythrocyte shape, flexibility, and membrane integrity by regulating intracellular cation concentration (see previous discussion of membrane permeability). ATP is needed to maintain normal levels of intracellular cations against their concentration gradients. Increased osmotic fragility is noted in cells with abnormally permeable membranes and/or decreased ATP production. Upon the exhaustion of glucose, ATP for the cation pumps is no longer available, and cells cannot maintain normal intracellular cation concentrations. The cells become sodium and calcium logged and potassium depleted. The cell accumulates water and changes from a biconcave disc to a sphere and is removed from the circulation.

HEXOSE MONOPHOSPHATE (HMP) SHUNT

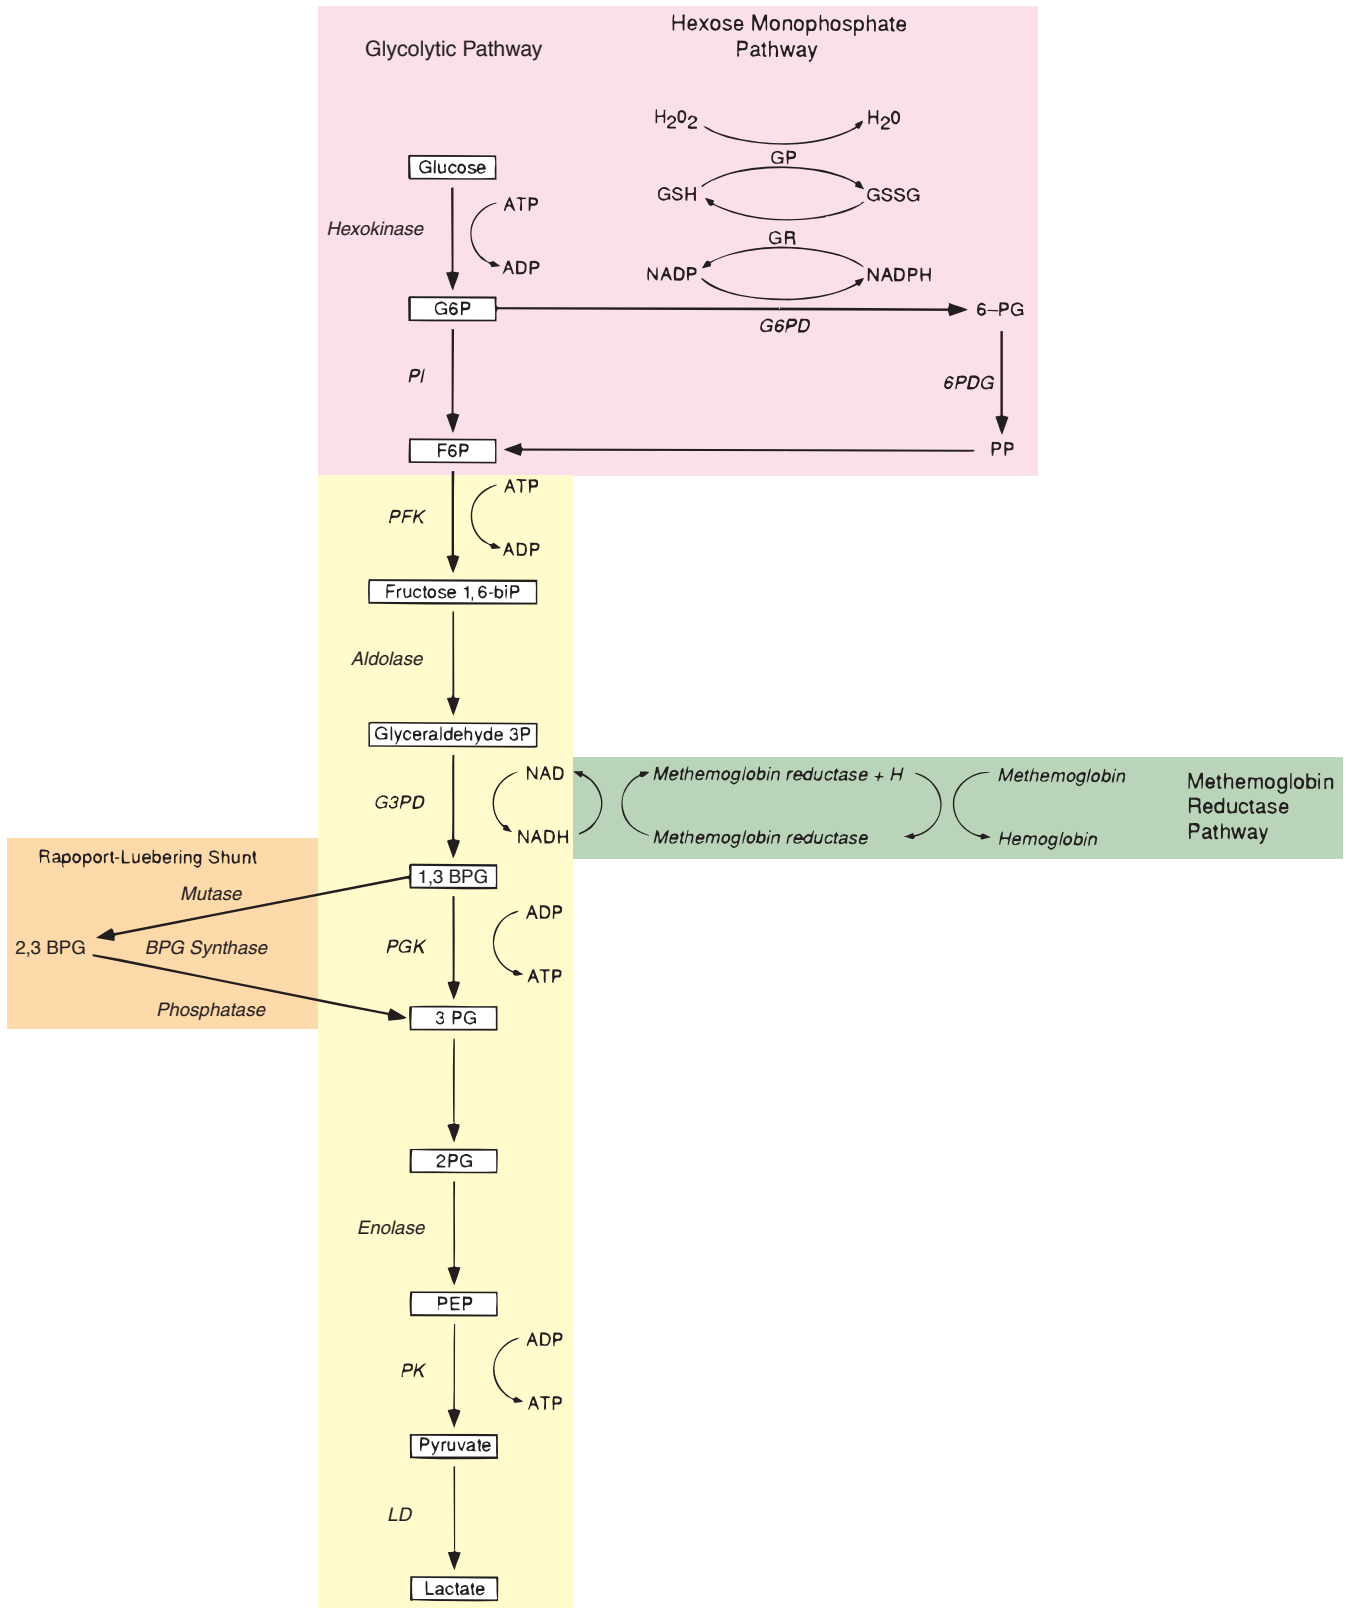

Not all of the glucose metabolized by the red cell goes through the direct glycolytic pathway. Five to 10% of cellular glucose enters the oxidative HMP shunt, an ancillary system for producing reducing substances (Figure 5). Glucose-6-phosphate is oxidized by the enzyme glucose-6-phosphate dehydrogenase (G6PD) in the first step of the HMP. In the process, NADP⁺ is reduced to NADPH.

Glutathione is highly concentrated in the erythrocyte and is important in protecting the cell from oxidant damage by reactive oxygen species (ROS), which are produced during oxygen transport and by other oxidants such as chemicals

★ TABLE 4

Role of Metabolic Pathways in the Erythrocyte

Metabolic Pathway	Key Enzymes	Function	Hemopathology
Glycolytic pathway	Phosphofructokinase Pyruvate kinase (PK)	Produces ATP accounting for 90% of glucose consumption in RBC	Hemolytic anemia Hereditary PK deficiency
Hexose-monophosphate shunt	Glutathione reductase Glucose-6-phosphate dehydrogenase (G6PD)	Provides NADPH and glutathione to reduce oxidants that would shift the balance of oxyhemoglobin to methemoglobin	Hemolytic anemia Hereditary G6PD deficiency Glutathione reductase deficiency Hemoglobinopathies
Rapoport-Leubering	BPG-Synthetase	Controls the amount of 2,3-BPG produced, which in turn affects the oxygen affinity of hemoglobin	Hypoxia
Methemoglobin reductase	Methemoglobin reductase	Protects hemoglobin from oxidation via NADH (from glycolytic pathway) and methemoglobin reductase	Hemolytic anemia Hypoxia

■ **FIGURE 5** Erythrocyte metabolic pathways. The glycolytic pathway is the major source of energy for the erythrocyte through production of ATP. The hexose-monophosphate pathway is important for reducing oxidants by coupling oxidative metabolism with pyridine nucleotide (NADP) and glutathione (GSSG) reduction. The methemoglobin reductase pathway supports methemoglobin reduction. The Rapoport-Luebering shunt produces 2,3-BPG, which alters hemoglobin-oxygen affinity.

and drugs. In the process of reducing oxidants, glutathione itself is oxidized. (The reduced glutathione is referred to as GSH while the oxidized form is referred to as GSSG.) NADPH produced by the HMP converts GSSG back to GSH, the form necessary to maintain hemoglobin in the reduced functional state. The erythrocyte normally maintains a large ratio of NADPH to NADP^+ . When the HMP is defective, hemoglobin sulfhydryl groups (-SH) are oxidized, which leads to denaturation and precipitation of hemoglobin in the form of **Heinz bodies**. Heinz bodies attach to the inner surface of the cell membrane, decreasing cell flexibility. Heinz bodies are removed from the cell with a portion of the membrane by macrophages in the spleen. These bodies can be visualized with supravital stains. If large portions of the membrane are damaged in this manner, the whole cell may be removed. This commonly occurs in patients with G6PD deficiency.

Reduced GSH also is responsible for maintaining reduced -SH groups of membrane proteins. Decreased GSH leads to oxidative injury of membrane protein -SH groups, compromising protein function and resulting in “leaky” cell membranes. Cellular depletion of ATP can then occur due to increased consumption of energy by the cation pumps.

Ascorbic acid, or vitamin C, is also an important antioxidant in the erythrocyte where it consumes oxygen free radicals and helps preserve alpha-tocopherol (vitamin E, another important antioxidant) in membrane lipoproteins.²²

METHEMOGLOBIN REDUCTASE PATHWAY

The methemoglobin reductase pathway, an offshoot of the glycolytic pathway, is essential to maintain heme iron in the reduced (ferrous) state, Fe^{++} (Figure 5). Methemoglobin (hemoglobin with iron in the oxidized ferric state, Fe^{+++}) is generated simultaneously with the oxidative compounds discussed above as O_2 dissociates from the heme iron. Methemoglobin cannot bind oxygen. The enzyme methemoglobin reductase (also known as NADH diaphorase, or cytochrome ϵ_5) with NADH produced by the glycolytic pathway functions to reduce the ferric iron in methemoglobin, converting it back to ferrous hemoglobin. In the absence of this system, the 2% of methemoglobin formed daily eventually builds up to 20–40%, severely limiting the blood's oxygen-carrying capacity. Challenges by oxidant drugs can interfere with methemoglobin reductase and cause even higher levels of methemoglobin. This results in **cyanosis** (a bluish discoloration of the skin due to an increased concentration of deoxyhemoglobin in the blood).

✓ Checkpoint! 6

Uncontrolled oxidation of hemoglobin results in what RBC intracellular inclusion?

RAPOPORT-LEUBERING SHUNT

The Rapoport-Leubering shunt is a part of the glycolytic pathway (Figure 5). This pathway bypasses the formation of 3-phosphoglycerate and ATP from 1,3-bisphosphoglycerate (1,3 BPG). Instead, 1,3-BPG forms 2,3-BPG (also known as *2,3-diphosphoglycerate*, *2,3-DPG*) catalyzed by BPG mutase. Therefore, the erythrocyte sacrifices one of its two ATP-producing steps in order to form 2,3-BPG. When hemoglobin binds 2,3-BPG, oxygen release is facilitated (i.e., binding 2,3-BPG causes a decrease in hemoglobin affinity for oxygen). Thus, 2,3-BPG plays an important role in regulating oxygen delivery to the tissues.

🔍 CASE STUDY (continued from earlier in this chapter)

Stephen was admitted for identification and treatment of the anemia. More lab tests were ordered with the following results:

	Patient	Reference Interval
Total bilirubin	4.8 mg/dL	0.1–1.2
Direct bilirubin	1.6 mg/dL	0.1–1.0
Haptoglobin	25 mg/dL	35–165
Hemoglobin electrophoresis		
HbA	98%	>95%
Hb-F	1%	<2%
Hb-A2	1%	1.5–3.7%
Heinz body stain	Positive	Negative
Fluorescent spot test for G6PD deficiency	Positive	

2. What cellular mechanism results in hemolysis due to a deficiency in G6PD?

✓ Checkpoint! 7

Which erythrocyte metabolic pathway is responsible for providing the majority of cellular energy? For regulating oxygen affinity? For maintaining hemoglobin iron in the reduced state?

▶ ERYTHROCYTE KINETICS

In the middle of the nineteenth century, Dr. Dennis Jourdanet, a French physician practicing in the highlands of Mexico, noted that patients with altitude sickness exhibited

symptoms similar to those of patients with anemia at sea level.²³ Those with altitude sickness, however, had no decrease in red corpuscles as was typical of anemic patients at sea level. He also noted that his “healthy” patients in the highlands had more than the normal number of red corpuscles and that their blood flowed more slowly than normal. He believed that the increased number of red corpuscles in an individual at high altitude compensated for the reduced atmospheric pressure of oxygen. Not until 1890, however was the increase in erythrocytes accepted as an acquired adjustment to high altitude.²³

Over the following decades, it was discovered that the stimulation of erythropoiesis in the bone marrow in response to decreased oxygen pressure was the result of a hormone, erythropoietin (EPO) that is released into the peripheral blood by renal tissue in response to hypoxia. Hormonal control of red blood cell mass is closely regulated and is normally maintained in a steady state within narrow limits.

ERYTHROCYTE CONCENTRATION

The normal erythrocyte concentration varies with sex, age, and geographic location. A high erythrocyte count ($5.2 \times 10^{12}/L$) and hemoglobin concentration (19 g/dL) at birth are followed by a gradual decrease that continues until about the second or third month of extrauterine life. At this time, red blood cell and hemoglobin values fall to $\sim 3.5 \times 10^{12}/L$ and 10–11 g/dL, respectively.²⁴ This erythrocyte decrease in infancy is sometimes called *physiologic anemia* of the newborn; its most likely cause is a temporary cessation of bone marrow erythropoiesis after birth due to a low concentration of erythropoietin. EPO levels are high in the fetus due to the relatively **hypoxic** environment in utero and the high oxygen affinity of hemoglobin F (fetal hemoglobin). After birth, however, when the lungs replace the placenta as a means of providing oxygen, the arterial blood oxygen saturation rises from 45% to 95%. EPO cannot be detected in the infant’s plasma from about the first week of extrauterine life until the second or third month. Reticulocytes reflect the bone marrow activity during this time. At birth and for the next few days, the mean reticulocyte count is high (4–7%). Within a week, the count drops and remains low (<1%) until about the second month of life, at which time EPO levels rise again (when the hemoglobin levels fall to ~ 12 g/dL). This corresponds to the recovery from “physiologic anemia of the newborn.”

Males have a higher erythrocyte concentration than females after the age of puberty due to the presence of testosterone. Before puberty, and after “male menopause,” males and females have comparable erythrocyte levels.^{25,26} Testosterone stimulates renal and extrarenal EPO production and directly enhances differentiation of marrow stem and progenitor cells.²⁷

Individuals living at high altitudes have a higher mean erythrocyte concentration than those living at sea level. De-

creases in the partial pressure of atmospheric oxygen at high altitudes result in a physiologic increase in erythrocytes in the body’s attempt to provide adequate tissue oxygenation.

Checkpoint! 8

Why are there different reference ranges for hemoglobin concentration in male and female adults but not in male and female children?

REGULATION OF ERYTHROCYTE PRODUCTION

The body can regulate the number of circulating erythrocytes by changing the rate of cell production in the marrow and/or the rate of cell release from the marrow. Delivery of erythrocytes to the circulation is normally well balanced to match the rate of erythrocyte destruction, which does not vary significantly under steady-state conditions. Impaired oxygen delivery to the tissues and low intracellular oxygen tension (PO_2) trigger increased EPO release and increased erythrocyte production by the marrow. Conditions that stimulate erythropoiesis include anemia, cardiac or pulmonary disorders, abnormal hemoglobins, and high altitude. Erythropoiesis is influenced by a number of cytokines including SCF, IL-3, GM-CSF, and EPO. However, EPO is the principal cytokine essential for terminal erythrocyte maturation.

Erythropoietin (EPO) is a thermostable renal glycoprotein hormone with a MW of about 34,000 daltons. Renal cortical interstitial cells²⁸ secrete EPO in response to cellular hypoxia. This feedback control of erythropoiesis is the mechanism by which the body maintains optimal erythrocyte mass for tissue oxygenation. Plasma levels of EPO are constant when the hemoglobin concentration is within the normal range but increase steeply when the hemoglobin decreases below 12 g/dL.²⁹ EPO is also produced by extrarenal sources, including marrow macrophages and stromal cells, which likely contributes to steady-state erythropoiesis.² However, under conditions of tissue hypoxia, oxygen sensors in the kidneys trigger the release of renal EPO, resulting in an increased stimulus for erythropoiesis.

EPO has been defined in biologic terms to have an activity of $\sim 130,000$ IU/mg of protein.³⁰ Normal plasma contains from 5 to 25 U of EPO per L of plasma. EPO can also be found in the urine at concentrations proportional to that found in the plasma (Table 5).³¹ In anemia, plasma levels of EPO are related to both hemoglobin concentration and the pathophysiology of the anemia. For example, patients with pure erythrocyte aplasia have plasma EPO levels significantly higher than patients with iron deficiency anemia or megaloblastic anemia even though hemoglobin concentration in all three types of anemia can be similar. Plasma EPO levels are significant because they reflect not only EPO pro-

TABLE 5

Characteristics of Erythropoietin

General Characteristics

Composition	Glycoprotein
Stimulus for synthesis	Cellular hypoxia
Origin	Kidneys 80–90%
	Liver <15%
Normal range	Plasma 2–25 IU/L

Functions

Stimulates BFU-E and CFU-E to divide and mature
 Increases rate of mRNA and protein (hemoglobin) synthesis
 Decreases normoblast maturation time
 Increases rate of enucleation (extrusion of nucleus)
 Stimulates early release of bone marrow reticulocytes (shift)

Response to Anemia

Generally increased except in anemia of renal disease

duction but also its disappearance from the blood or utilization by the bone marrow.

Patients with renal disease and nephrectomized patients are usually severely anemic, but they continue to make some erythrocytes and produce limited amounts of EPO in response to hypoxia. Anephric individuals have detectable but low plasma EPO concentrations. In addition to the production of EPO by marrow macrophages and stromal cells, hepatocytes act as an extrarenal source of EPO, accounting for <15% of the total EPO production in humans.³² In addition, the adult liver appears to require a more severe hypoxic stimulus for EPO production than the kidney. The liver is the major site of EPO production during fetal development. At birth, a gradual and irreversible switch from hepatic to renal production of EPO occurs.³³

Increased EPO production is due to synthesis of EPO rather than release of preformed stores. The hypoxia-induced increase of EPO is due to both increased gene transcription and stabilization of EPO mRNA.³⁴ Regulation of EPO production is mediated by the transcription factor hypoxia-inducible factor-1 (HIF-1).³⁵ Under hypoxic conditions, HIF-1 binds to DNA regulatory sequences (hypoxia-responsive element/HRE) in the EPO gene, activating transcription of EPO. Under conditions of normal oxygen concentration, HIF-1 is degraded by a hydroxylase enzyme that requires oxygen for activity; as levels of HIF-1 decrease, HIF-1 cannot bind DNA or activate transcription of EPO.³²

EPO exerts its action by binding to specific receptors (EPO-R) on erythropoietin-responsive cells. EPOs major action is stimulation of committed progenitor cells, primarily the CFU-E to survive, proliferate, and differentiate (see discussion of erythropoiesis earlier in this chapter). A small subset of BFU-E has EPO-R but in low number, and BFU-E are largely unresponsive to the effects of EPO. Thus, under conditions of EPO stimulation, the primary elements of the

erythroid precursor cells to respond are the CFU-Es and early normoblasts. However, acute demands for erythropoiesis with extremely high EPO levels can induce influx from the pre-CFU-E pool (the BFU-E). When this occurs, the characteristics of the resulting erythrocytes include an increase in mean corpuscular volume (MCV) and an increase in i antigen and HbF concentration.² EPO-Rs on the cell membrane increase as the BFU-E matures to the CFU-E and gradually decrease as the normoblasts mature. The EPO-R is absent on reticulocytes. Other effects of EPO include decreasing normoblast maturation time, increasing rate of mRNA and protein (hemoglobin) synthesis, increasing rate of enucleation (extrusion of the nucleus), and stimulating early release of bone marrow reticulocytes (stress or shift reticulocytes).

The primary way by which EPO stimulates erythropoiesis is by preventing apoptosis. Erythropoiesis is maintained by a finely tuned balance between the positive signals generated by EPO and negative signals from death receptor ligands and inhibitory cytokines. Erythroid progenitors differ in their sensitivity to EPO; some progenitors require much less EPO than others to survive and mature to reticulocytes.³⁶ Progenitors with increased sensitivity to EPO are thought to provide RBC production when EPO levels are normal or decreased. Progenitors that require high concentrations of EPO die of apoptosis under these conditions. Progenitors requiring high concentrations of EPO, however, could be rescued from apoptosis when EPO concentrations are elevated as occurs in anemia, thus providing increased erythrocytes under these conditions.

The EPO-R exists in the membrane as a homodimer and lacks intrinsic kinase activity. However, the cytoplasmic tail of the receptor recruits and binds cytoplasmic kinases, Janus kinases 2 (JAK-2), which are activated when EPO binds to the EPO-R (see Figure 6). At least four different signaling pathways are activated by this EPO/EPO-R/JAK-2 interaction. Abnormal interactions and/or function of these components have been linked to familial forms of erythrocytosis and certain myeloproliferative disorders.

The normal bone marrow can increase erythropoiesis 5- to 10-fold in response to increased EPO stimulation if sufficient iron is available. Erythropoiesis is affected (and limited) by serum iron levels and by transferrin saturation.³⁷ In hemolytic anemia, there is a readily available supply of iron recycled from erythrocytes destroyed *in vivo* that results in a sustained ~6-fold increase in erythropoiesis. The rate of erythropoiesis in blood loss anemia during which iron is lost from the body, however may be dependent on preexisting iron stores. In this case, the rate of erythropoiesis usually does not exceed 2.5 times normal unless large parenteral or oral doses of iron are administered.

A number of tumors have been reported to cause an increase in erythropoietin production. Stimulation of the hypothalamus can cause an increase in release of EPO from the kidneys, explaining the association of polycythemia and

cerebellar tumors. The serum EPO level increases dramatically in patients undergoing chemotherapy for leukemia as well as other cancers in response to marrow suppression by chemotherapeutic agents.³⁷

The production of synthetic hematopoietic growth factors using recombinant DNA technology has revolutionized the management of patients with some anemias. Several recombinant forms of human EPO (rHuEPO) are available and are commonly used for treatment of the anemia associated with end-stage renal disease and chemotherapy as well as HIV-related anemia.^{30,38}

CASE STUDY (continued from earlier in this chapter)

4. Would you predict Stephen's serum erythropoietin levels to be low, normal, or increased? Why?

Checkpoint! 9

What would the predicted serum EPO levels be in a patient with an anemia due to end-stage kidney disease?

▶ ERYTHROCYTE DESTRUCTION

Red blood cell destruction is normally the result of senescence. Erythrocyte aging is characterized by a decline in certain cellular enzyme systems. It has been suggested that declines in enzymes in the glycolytic pathway, which in turn would lead to decreased ATP production and loss of adequate reducing systems, would result in a loss of the ability to maintain cell shape and deformability as well as membrane integrity. Although many of these enzymes are higher in reticulocytes than in mature erythrocytes, it is unclear whether the activities of these enzymes continue to decline during the aging of the erythrocyte.^{39,40,41}

The exposure of phosphatidylserine (PS) on the outer leaflet of the erythrocyte membrane is one of the signals that allows macrophages to recognize senescent erythrocytes.⁴² This is the only major difference between senescent and nonsenescent erythrocytes that has been clearly documented.⁴³ The chromatin condensation and mitochondrial destruction that play a role in erythrocyte production parallel changes seen in apoptotic cells as does the PS externalization seen in erythrocyte senescence. The parallels with apoptosis has led some researchers to speculate that erythrocyte maturation and senescence represent “apoptosis in slow motion.”⁴⁴

About 90% of aged erythrocyte destruction is extravascular, taking place in the mononuclear phagocytic cells of the spleen, liver, and bone marrow. The remaining 10% is catabolized intravascularly, whereby the erythrocytes lyse and release hemoglobin directly into the bloodstream.

EXTRAVASCULAR DESTRUCTION

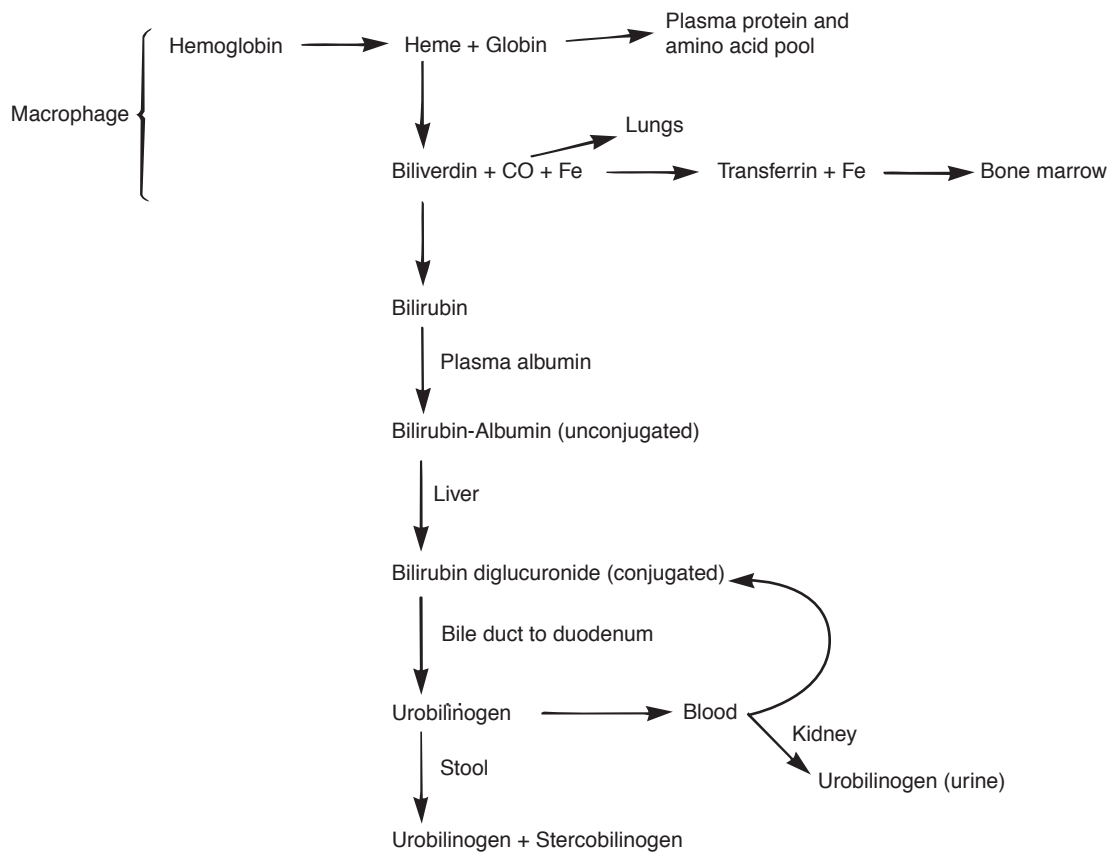

Erythrocyte removal by the spleen, bone marrow, and liver is referred to as extravascular destruction. This pathway, which is the most efficient method of cell removal, conserves and recycles essential erythrocyte components such as amino acids and iron (Figure 6■). Most extravascular destruction of erythrocytes takes place in the macrophages of the spleen. The exact signal(s) that marks erythrocytes for destruction remains unknown. However, the architecture of the spleen with its torturous circulation, sluggish blood flow, and relative hypoxic and hypoglycemic environment, makes it well suited for culling aged erythrocytes.

Several theories have been proposed to explain the underlying pathology of senescent red cells. Erythrocytes accumulate surface membrane damage during their 120-day lifespan in the circulation at least in part from oxidative damage as well as circulatory “wear and tear.”⁴¹ These damaged regions of the membranes are removed by macrophages in the spleen. The biconcave disk shape of the RBC, essential for its deformability, requires a high surface area to volume ratio. Progressive loss of membrane should cause the erythrocyte to assume a more rigid spherical shape with less deformability and reduced ability to pass through the spleen's small apertures. To whatever extent RBCs progressively lose some of the critical enzymes needed for ATP production and antioxidant protection, they can suffer oxidation of critical membrane proteins, lipids, and hemoglobin. This may cause protein denaturation, distortion, and rigidity of the membrane and contribute to the cell's removal. Oxidative damage also causes clustering of band 3 molecules, which can be a “senescence”-identifying feature. The glucose supply in the spleen is low, limiting the energy-producing process of glycolysis within the erythrocyte. Aged erythrocytes can quickly deplete their cellular level of ATP, resulting in limited ability to maintain osmotic equilibrium via the energy-dependent cation pumps. Any combination of these events could contribute to the trapping of erythrocytes in the vasculature of the spleen and their removal by splenic macrophages.

Hemoglobin is composed of a porphyrin ring (heme) complexed with iron and bound to protein chains called *globin*. Within the macrophage, the hemoglobin molecule is broken down into heme, iron, and globin. Iron and globin (a polypeptide) are conserved and reused for new hemoglobin or other protein synthesis. Heme iron can be stored as ferritin or hemosiderin within the macrophage or released to the transport protein, transferrin, for delivery to developing normoblasts in the bone marrow. This endogenous iron exchange is responsible for about 80% of the iron passing through the transferrin pool. Thus, iron from the normal erythrocyte aging process is conserved and reutilized. The globin portion of the hemoglobin molecule is broken down and recycled into the amino acid pool.

Heme is further catabolized by the macrophage and eventually excreted in the feces. The α -methane bridge of the

EXTRAVASCULAR HEMOGLOBIN DEGRADATION

■ **FIGURE 6** Most hemoglobin degradation occurs within the macrophages of the spleen. The globin and iron portions are conserved and reutilized. Heme is reduced to bilirubin, eventually degraded to urobilinogen, and excreted in the feces. Thus, indirect indicators of erythrocyte destruction include the blood bilirubin level and urobilinogen concentration in the urine.

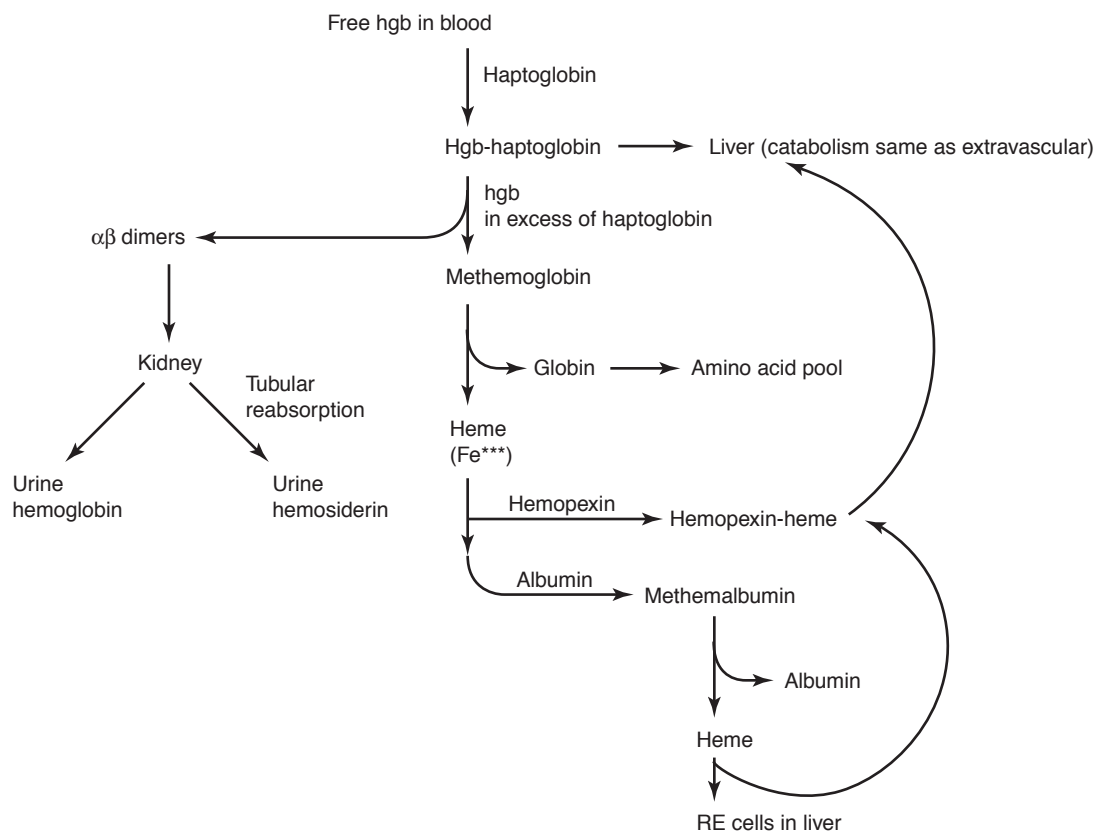

porphyrin ring is cleaved, producing a molecule of carbon monoxide and the linear tetrapyrrole biliverdin. Carbon monoxide is released to the blood stream, carried to the lungs, and expired. The biliverdin is rapidly reduced within the cell to bilirubin. **Bilirubin**, released from the macrophage, is bound by plasma albumin and carried to the liver (unconjugated or “indirect” bilirubin). Upon uptake by the liver, bilirubin is conjugated with two molecules of bilirubin glucuronide by the enzyme bilirubin UDP-glucuronyltransferase present in the endoplasmic reticulum of the hepatocyte. Once conjugated, bilirubin becomes polar and lipid insoluble. Bilirubin diglucuronide (conjugated or “direct” bilirubin) is excreted into the bile, eventually reaching the intestinal tract where it is converted into urobilinogen by intestinal bacterial flora. Most urobilinogen is excreted in the feces where it is quickly oxidized to urobilin or stercobilin. Ten to 20% of urobilinogen is reabsorbed from the gut back to the plasma. The reabsorbed urobilinogen is either excreted in urine or returned to the gut via an entero-

hepatic cycle. In liver disease, the enterohepatic cycle is impaired and an increased amount of urobilinogen is excreted in the urine.

INTRAVASCULAR DESTRUCTION

The small amount of hemoglobin released into the peripheral blood circulation through intravascular erythrocyte breakdown undergoes dissociation into α - β dimers, which are quickly bound to the plasma glycoprotein **haptoglobin** (Hp) in a 1:1 ratio (Figure 7■). Haptoglobin is an α 2-globulin present in plasma at a concentration of 35-164 mg/d (males) or 40-175 mg/dl (females). The haptoglobin-hemoglobin (HpHb) complex is too large to be filtered by the kidney, so haptoglobin carries hemoglobin dimers to the liver. Hepatocytes, which have haptoglobin receptors, take up the HpHb and process it in a manner similar to that of hemoglobin released by extravascular destruction.

INTRAVASCULAR HEMOGLOBIN DEGRADATION

■ **FIGURE 7** When the erythrocyte is destroyed within the vascular system, hemoglobin is released directly into the blood. Normally, the free hemoglobin quickly complexes with haptoglobin, and the complex is degraded in the liver. In severe hemolytic states, haptoglobin can become depleted, and free hemoglobin dimers are filtered by the kidney. Additionally, with haptoglobin depletion, some hemoglobin is quickly oxidized to methemoglobin and bound to either hemopexin or albumin for eventual degradation in the liver.

The HpHb complex is cleared very rapidly from the bloodstream with a $T_{1/2}$ disappearance rate of 10–30 minutes. The haptoglobin concentration can be depleted very rapidly in acute hemolytic states because the liver is unable to maintain plasma haptoglobin levels. Haptoglobin, however, is an acute-phase reactant, and increased concentrations can be found in inflammatory, infectious, or neoplastic conditions. Therefore, patients with hemolytic anemia accompanied by an underlying infectious or inflammatory process may have normal haptoglobin levels.

When haptoglobin is depleted, as in severe hemolysis, free α - β dimers can be filtered by the kidney and reabsorbed by the proximal tubular cells. α - β dimers passing through the kidney in excess of the reabsorption capabilities of the tubular cells appear in the urine as free hemoglobin. Dimers reabsorbed by the tubular cells are catabolized to bilirubin and iron, both of which may reenter the plasma pool. However, some iron remains in the tubular cell and is complexed to storage proteins forming ferritin and **hemosiderin**.

Eventually, tubular cells loaded with iron are sloughed off and excreted in the urine (**hemosiderinuria**). The iron inclusions can be visualized with the Prussian blue stain. Thus, the presence of hemosiderinuria is a sign of recent increased intravascular hemolysis.

Hemoglobin not excreted by the kidney or bound to haptoglobin is either cleared directly by hepatic uptake or oxidized to methemoglobin. Heme dissociates from methemoglobin and avidly binds to a β -globulin glycoprotein, **hemopexin**. Hemopexin is synthesized in the liver and combines with heme in a 1:1 ratio. The hemopexin-heme complex is cleared from the plasma slowly with a $T_{1/2}$ disappearance of 7–8 hours. When hemopexin becomes depleted, the dissociated oxidized heme combines with plasma albumin in a 1:1 ratio to form methemalbumin. Methemalbumin clearance by the liver is also very slow. In fact, methemalbumin could only be a temporary carrier for heme until more hemopexin or haptoglobin becomes available. Heme is transferred from methemalbumin to hemopexin for clear-

ance by the liver as it becomes available. When present in large quantity, methemalbumin and hemopexin-heme complexes impart a brownish color to the plasma. Schumm's test is designed to detect these abnormal compounds spectrophotometrically.

✓ Checkpoint! 10

What lab tests would diagnose an increase in RBC destruction (i.e., hemolysis), and what would be the expected results?

🌀 CASE STUDY (continued from earlier in this chapter)

5. Stephen's haptoglobin level is 25 mg/dL. Explain why he has a low haptoglobin value.

SUMMARY

Erythrocytes are derived from the unipotent committed progenitor cells BFU-E and CFU-E. Morphologic developmental stages of the erythroid cell include (in order of increasing maturity) the pronormoblast, basophilic normoblast, polychromatophilic normoblast, orthochromatic normoblast, reticulocyte, and erythrocyte. Erythropoietin, a hormone produced in renal tissues, stimulates erythropoiesis and is responsible for maintaining a steady-state erythrocyte mass. Erythropoietin stimulates survival and differentiation of erythroid progenitor cells, increases the rate of erythropoiesis, and effects an early release of reticulocytes from the marrow.

The erythrocyte concentration varies with sex, age, and geographic location. Higher concentrations are found in males (post-

puberty) and newborns and at high altitudes. Decreases below the reference range result in a condition called *anemia*.

The erythrocyte membrane is a lipid-protein bilayer complex that is important for maintaining cellular deformability and selective permeability. As the cell ages, the membrane is reduced in surface area relative to cell volume and becomes more rigid, and the cell is culled in the spleen. The normal erythrocyte life span is 100–120 days.

The erythrocyte derives its energy and reducing power from glycolysis and ancillary pathways. The glycolytic pathway provides ATP to help the cell maintain erythrocyte shape, flexibility, and membrane integrity through regulation of intracellular cation permeability. The HMP shunt provides reducing power to protect the cell from permanent oxidative injury. The methemoglobin reductase pathway helps reduce heme from the ferric (Fe^{3+}) back to the ferrous (Fe^{2+}) state. The Rapoport-Leubering shunt facilitates oxygen delivery to the tissue by producing 2,3-BPG.

Destruction of aged erythrocytes occurs primarily in the macrophages of the spleen and liver through processes known as *extravascular* and *intravascular destruction*. Extravascular destruction of the erythrocyte is the physiologically preferred pathway for aged or abnormal erythrocyte removal (splenic and hepatic macrophages). Hemoglobin is broken down into heme, globin and iron. Iron and globin are conserved and reused. Heme is catabolized to bilirubin and excreted. Intravascular destruction of erythrocytes results in release of hemoglobin into the peripheral blood circulation. Hemoglobin or its derivatives combine with albumin, haptoglobin, and/or hemopexin and are transported to the liver where it is catabolized. Free hemoglobin can be filtered by the kidney and some reabsorbed by renal tubular cells. Free hemoglobin in the urine is a sign of acute intravascular hemolysis.

REVIEW QUESTIONS

LEVEL I

- The earliest recognizable erythroid precursor on a Wright-stained smear of the bone marrow is: (Objective 1)
 - pronormoblast
 - basophilic normoblast
 - CFU-E
 - BFU-E
- This renal hormone stimulates erythropoiesis in the bone marrow: (Objective 4)
 - IL-1
 - erythropoietin
 - granulopoietin
 - thrombopoietin
- Haptoglobin can become depleted in: (Objective 8)
 - inflammatory conditions
 - intravascular hemolysis
 - infectious diseases
 - kidney disease

LEVEL II

- The last stage of erythrocyte maturation that can undergo mitosis is: (Objective 1)
 - basophilic normoblast
 - orthochromic normoblast
 - pronormoblast
 - polychromatophilic normoblast
- Spherocytes are erythrocytes with an increase in cell hemoglobin concentration. This could result in: (Objective 3)
 - increased membrane permeability
 - increased cell elasticity
 - absence of the MN antigens
 - decreased cell deformability
- As a person ascends to high altitudes, the increased activity of the Rapoport-Leubering pathway: (Objective 4)
 - causes precipitation of hemoglobin as Heinz bodies
 - has no effect on oxygen delivery to tissues
 - causes increased release of oxygen to tissues
 - causes decreased release of oxygen to tissues

REVIEW QUESTIONS (continued)

LEVEL I

4. The erythrocyte life span is most directly determined by: (Objective 5)
 - a. spleen size
 - b. serum haptoglobin level
 - c. membrane deformability
 - d. cell size and shape
5. Which of the following depicts the normal sequence of erythroid maturation? (Objective 1)
 - a. pronormoblast → basophilic normoblast → polychromatic normoblast → orthochromic normoblast → reticulocyte
 - b. pronormoblast → polychromatic normoblast → orthochromic normoblast → basophilic normoblast → reticulocyte
 - c. basophilic normoblast → polychromatic normoblast → reticulocyte → orthochromic normoblast → pronormoblast
 - d. orthochromic normoblast → basophilic normoblast → reticulocyte → polychromatic normoblast → pronormoblast
6. The primary effector (cause) of increased erythrocyte production, or erythropoiesis, is: (Objective 4)
 - a. supply of iron
 - b. rate of bilirubin production
 - c. tissue hypoxia
 - d. rate of EPO secretion
7. An increase in the reticulocyte count should be accompanied by: (Objective 2)
 - a. a shift to the left in the Hb-O₂ dissociation curve
 - b. abnormal maturation of normoblasts in the bone marrow
 - c. an increase in total and direct serum bilirubin
 - d. polychromasia on the Wright's stained blood smear
8. What property of the normal erythrocyte membrane allows the 7- μ m cell to squeeze through 3- μ m fenestrations in the spleen? (Objective 5)
 - a. fluidity
 - b. elasticity
 - c. permeability
 - d. deformability
9. An increase of erythrocyte membrane rigidity would be predicted to have what effect? (Objective 5)
 - a. increase in erythropoietin production
 - b. increase in cell volume
 - c. decrease in cell life span
 - d. decrease in reticulocytosis
10. A patient with an anemia due to increased intravascular hemolysis would likely present with which of the following lab results? (Objective 8)
 - a. increased haptoglobin
 - b. hemoglobinuria
 - c. normal hemoglobin and hematocrit
 - d. decreased serum bilirubin

LEVEL II

4. A newborn has a hemoglobin level of 16.0 g/dL at birth. Two months later a CBC indicates a hemoglobin concentration of 11.0 g/dL. The difference in hemoglobin concentration is most likely due to: (Objective 1)
 - a. chronic blood loss
 - b. inherited anemia
 - c. increased intravascular hemolysis
 - d. physiologic anemia of the newborn
5. Compared to sea level, at high altitudes an individual's erythrocytes are: (Objective 1)
 - a. produced at a lower rate
 - b. larger than normal
 - c. destroyed at an increased rate
 - d. at a higher concentration
6. Which of the following is necessary to maintain reduced levels of methemoglobin in the erythrocyte? (Objective 4)
 - a. vitamin B₆
 - b. NADH
 - c. 2,3-BPG
 - d. lactate
7. A patient lost about 1500 mL of blood during surgery but was not given blood transfusions. His hemoglobin before surgery was in the reference range. What would be the most likely finding 3 days later. (Objective 1, 6)
 - a. increase in total bilirubin
 - b. increase in indirect bilirubin
 - c. increase in erythropoietin
 - d. increased haptoglobin
8. An anemic patient has hemosiderinuria, increased serum bilirubin, and decreased haptoglobin. This is an indication that there is: (Objective 6)
 - a. increased intravascular hemolysis
 - b. decreased extravascular hemolysis
 - c. hemolysis accompanied by renal disease
 - d. a defect in the Rapoport-Leubering pathway
9. A laboratory professional finds evidence of Heinz bodies in the erythrocytes of a 30-year-old male. This is evidence of: (Objective 4)
 - a. increased oxidant concentration in the cell
 - b. decreased hemoglobin-oxygen affinity
 - c. decreased production of ATP
 - d. decreased stability of the cell membrane
10. A 65-year-old female presents with an anemia of 3 weeks' duration. In addition to a decrease in her hemoglobin and hematocrit, she has an increased serum bilirubin, a decrease in serum haptoglobin, and 3⁺ polychromasia on her blood smear. Based on these preliminary findings, what serum erythropoietin result is expected? (Objective 6, 7)
 - a. decreased
 - b. normal
 - c. increased
 - d. no correlation

ANSWERS TO CASE STUDY QUESTIONS

Case Summary: This is a case of Stephen, a 28-year-old Caucasian male of Italian descent with an acute hemolytic anemia. An initial diagnosis of malaria was presumptively made. The patient, however, was negative for malaria. He was eventually diagnosed as having G6PD deficiency and a hemolytic anemia induced by the antimalarial drug primaquine.

Question:

1. Predict Stephen's reticulocyte count: low, normal, or increased.

Explanation:

From the erythrocyte count, HGB, and HCT, we know the patient is moderately anemic. The increase of polychromatic erythrocytes on a blood smear suggests an increased number of reticulocytes.

Question:

2. What is the cellular mechanism that results in hemolysis due to a deficiency in G6PD?

Explanation:

In the hexose monophosphate shunt, the reduction of NADPH and glutathione depends on the enzyme glucose-6-phosphate dehydrogenase (G6PD). When this enzyme is deficient, hemoglobin denatures under oxidant stress, and intracellular hemoglobin precipitates form.

Question:

3. Explain how Heinz body inclusions cause damage to the erythrocyte membrane.

Explanation:

Hemoglobin precipitates known as Heinz bodies form along the inner surface of the erythrocyte membrane. This results in a loss of membrane flexibility, cell lysis, and splenic trapping.

Question:

4. Would you predict Stephen's serum erythropoietin levels to be low, normal, or increased? Why?

Explanation:

Hemolytic anemias result from factors outside the marrow. Erythroid production and maturation are normal. The loss of erythrocytes results in a systemic decrease in cellular oxygen tension. This stimulates EPO production from the kidneys, which in turn stimulates erythropoiesis in the marrow.

Question:

5. Stephen's haptoglobin level is 25 mg/dL. Explain why Stephen has a low haptoglobin value.

Explanation:

The oxidant stress caused by the malarial drug primaquine was out of balance due to the patient's erythrocyte deficiency of G6PD. This resulted in hemoglobin precipitation (Heinz bodies) and cell destruction. Some of the hemoglobin is released into the peripheral blood and is bound by haptoglobin. The haptoglobin reserves become depleted quickly.

ANSWERS TO CHECKPOINTS

Checkpoint! 1

What is meant by the term "erythron"?

Answer

Erythron refers to the summation of stages of erythrocytes in the marrow, peripheral blood, and within vascular areas of specific organs such as the spleen. Erythropoiesis involves the entire erythron.

Checkpoint! 2

What is the first stage of red cell maturation that has visible cytoplasmic evidence of hemoglobin production on a Romanowsky-stained smear?

Answer

The basophilic normoblast stage may have patches of newly synthesized hemoglobin. The RNA in the young cell stains dark blue, but

the hemoglobin stains pink. In the next stage, polychromatophilic normoblast, a mix of the blue and pink stains give the cytoplasm a bluish gray, or polychromatic, staining appearance.

Checkpoint! 3

How would an increase in RBC membrane permeability affect intracellular sodium balance?

Answer

A cation pump within the membrane controls the intracellular balance of sodium (Na^+) and potassium (K^+). Sodium is maintained at a low intracellular concentration while potassium is kept concentrated inside the cell at 25 times more than the concentration of sodium. The biconcave disc shape of an RBC is vital to the cell's function and longevity of the cell. Maintaining this shape depends on the mem-

brane structure providing an exact permeability to ions on either side of the membrane. Even a slight increase in membrane permeability can cause an inflow of sodium resulting in a defective membrane and an alteration of shape.

Checkpoint! 4

Compare and contrast the placement of lipids in the erythrocyte membrane and their function.

Answer

Approximately 95% of the lipid content of the membrane consists of equal amounts of unesterified cholesterol and phospholipids. The remaining lipids are free fatty acids and glycolipids. Membrane cholesterol exists in free equilibrium with plasma cholesterol. The phospholipids' molecules are arranged with polar heads directed to the inside and outside of the cell and the hydrophobic tails directed to the interior of the bilayer. The mobility of phospholipids within the membrane contributes to membrane fluidity. A small portion of membrane lipids are glycolipids in the form of glycosphingolipid. Glycolipids are responsible for some antigenic properties of the membrane.

Checkpoint! 5

Compare placement in the membrane and function of peripheral and integral membrane erythrocyte proteins.

Answer

Integral proteins span the entire thickness of the cell membrane whereas peripheral proteins are on the inner side (cytoplasmic) of the membrane. The integral proteins carry the erythrocyte antigens and attach the skeletal lattice to the bilipid layer of the membrane. The peripheral proteins form a skeletal support for the membrane lipid layer.

Checkpoint! 6

Uncontrolled oxidation of hemoglobin results in what RBC intracellular inclusion?

Answer

The erythrocyte normally maintains a large ratio of NADPH to NADP⁺. When the RBC metabolic pathways fail to reduce oxidized hemoglobin, hemoglobin sulfhydryl groups (-SH) are oxidized, which leads to denaturation and precipitation of hemoglobin in the form of Heinz bodies. Heinz bodies attach to the inner surface of the cell membrane, decreasing cell flexibility.

Checkpoint! 7

Which erythrocyte metabolic pathway is responsible for providing the majority of cellular energy? For regulating oxygen affinity? For maintaining hemoglobin iron in the reduced state?

Answer

About 90–95% of the cell's glucose breakdown occurs in the Embden-Meyerhof pathway. Two moles of ATP are generated from each mole of glucose metabolized. ATP is the primary energy source of the erythrocyte. The Rapoport-Leubering shunt produces 2,3-DPG, which affects oxygen affinity. The hexose-monophosphate shunt and methemoglobin reductase pathways help maintain hemoglobin iron in the reduced state.

Checkpoint! 8

Why are there different reference intervals for hemoglobin concentration in male and female adults but not in male and female children?

Answer

The male hormone, testosterone, stimulates erythropoiesis indirectly by stimulating EPO production in the kidney. This results in about a 1–2 gm increase in hemoglobin in males. Testosterone production increases significantly in adolescence.

Checkpoint! 9

What would the predicted serum EPO levels be in a patient with an anemia due to end-stage kidney disease?

Answer

End-stage renal disease results in a primary decrease in EPO production and, therefore, decreased serum EPO levels. Because EPO is the primary stimulator of erythropoiesis, low levels result in marrow erythroid hypoplasia and a moderate to severe anemia.

Checkpoint! 10

What are the laboratory tests that would diagnose an increase in RBC destruction (i.e., hemolysis) and what would be the expected results?

Answer

The lab tests that should be done include the total bilirubin, haptoglobin, and the hemoglobin/hematocrit (H&H). If hemolysis is significant, the indirect bilirubin would increase and the hematocrit and hemoglobin would decrease. The haptoglobin would be decreased because it removes extracellular hemoglobin dimers. Respiratory carbon monoxide could also be measured as an indicator of heme catabolism, but this is rarely done. When present in large quantity, methemalbumin and hemopexin-heme complexes impart a brownish color to the plasma. So, in addition, a Schumm's test could be performed to detect these abnormal compounds spectrophotometrically.

Hemoglobin

Shirlyn B. McKenzie, Ph.D.

■ OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. Diagram the quaternary structure of a molecule of hemoglobin identifying the heme ring, globin chains, and iron.
2. Assemble fetal and adult hemoglobin molecules with appropriate globin chains.
3. Explain how pH, temperature, 2,3-BPG, and PO₂ affect the oxygen dissociation curve (ODC).
4. List the types of hemoglobin normally found in adults and newborns and give their approximate concentration.
5. Summarize hemoglobin's function in gaseous transport.
6. Define *normal hemoglobin values*.
7. Explain how the fine balance of hemoglobin concentration is maintained.
8. Compare HbA with HbA1c and explain what an increased concentration of HbA1c means.

■ OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. Construct a diagram to show the synthesis of a hemoglobin molecule.
2. Describe the ontogeny of hemoglobin types; contrast differences in oxygen affinity of HbF and HbA, and relate them to the structure of the molecule.
3. Explain the molecular control of heme synthesis.
4. Given information on pH, 2,3-BPG, CO₂, temperature, and HbF concentration, interpret the ODC and translate it into the physiologic effect on oxygen delivery.
5. Contrast the structures and functions of relaxed and tense hemoglobin and propose how these structures affect gaseous transport.
6. Describe how abnormal hemoglobins are acquired, and select a method by which they can be detected in the laboratory.
7. Assess the oxygen affinity of abnormal, acquired hemoglobins and reason as to how this affects oxygen transport.
8. Compare and contrast the exchange of O₂, CO₂, H⁺, and Cl⁻ at the level of capillaries and the lungs.

CHAPTER OUTLINE

 (T) structure

BACKGROUND BASICS

The information in this chapter builds on the concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study.

Level I

- ▶ List and describe the stages of erythrocyte maturation.
- ▶ Summarize the role of erythropoietin in erythropoiesis.
- ▶ Describe the site of erythropoiesis.

Level II

- ▶ Describe the metabolic pathways present in the mature erythrocyte, and explain their role in maintaining viability of the erythrocyte.
- ▶ Describe the appearance of the bone marrow when erythropoiesis is decreased or increased.
- ▶ Summarize the development of hematopoiesis from the embryonic stage to the adult.

CASE STUDY

We will address this case study throughout the chapter.

Jerry, a 44-year-old male, arrived in the emergency room by ambulance after a bicycle accident. Examination revealed multiple fractures of the femur. He was otherwise healthy. The next day, he was taken to surgery to repair the fractures. After surgery, his hemoglobin was 7 gm/dL. He refused blood transfusions and was discharged 6 days later. Jerry called his doctor within days of being discharged and told him that he had difficulty walking around the house on crutches because of shortness of breath and lack of stamina. Consider why Jerry's hemoglobin was decreased after surgery and how this could be related to his current symptoms.

OVERVIEW

This chapter describes the synthesis and structure of hemoglobin and factors that regulate its production. The different types of hemoglobin produced according to developmental stage are compared. The function of hemoglobin in gaseous exchange is considered, and factors that affect this function are analyzed. Structure, formation, and laboratory detection of abnormal hemoglobins are also discussed.

INTRODUCTION

Hemoglobin is a highly specialized intracellular erythrocyte protein responsible for transporting oxygen from the lungs to tissue and facilitating carbon dioxide transport from the tissue to the lungs. Each gram of hemoglobin can carry 1.34 mL of oxygen.

Hemoglobin occupies approximately 33% of the volume of the erythrocyte and accounts for 90% of the cell's dry weight. Each cell contains between 28 and 34 pg of hemoglobin. This concentration is measured by cell analyzers and reported as mean corpuscular hemoglobin (MCH). In anemic states, the erythrocyte may contain less hemoglobin (decreased MCH) and/or have fewer erythrocytes present, which results in a decrease of the blood's oxygen-carrying capacity.

The erythrocyte's membrane and its metabolic pathways are responsible for protecting and maintaining the hemoglobin molecule in its functional state. Abnormalities in the membrane that alter its permeability or alterations of the cell's enzyme systems can lead to changes in the structure and/or function of the hemoglobin molecule and affect the capacity of this protein to deliver oxygen.

Although a small amount of hemoglobin is synthesized early as the pronormoblast stage, most hemoglobin synthesized in the developing normoblasts occurs at the polychromatophilic normoblast stage. All together, 75–80% of the cell's hemoglobin is made before the extrusion of the nucleus. Because the reticulocyte does not have a nucleus, it cannot make new RNA for protein synthesis. However, residual RNA and mitochondria in the reticulocyte enable the cell to make the remaining 20–25% of the cell's hemoglobin. The mature erythrocyte contains no nucleus, ribosomes, or mitochondria and is unable to synthesize new protein.

Hemoglobin concentration in the body is the result of a fine balance between production and destruction of erythrocytes. The normal hemoglobin concentration in an adult male is about 15 g/dL with a total blood volume of about 5000 mL. Therefore, the total body mass of hemoglobin is approximately 750 g:

$$15 \text{ g/dL} \times 5000 \text{ mL} \times 1 \text{ dL}/100 \text{ mL} = 750 \text{ g}$$

Because the normal erythrocyte life span is ~120 days, $1/120$ of the total amount of hemoglobin is lost each day through removal of senescent erythrocytes. Thus, an equivalent

lent amount must be synthesized each day to maintain a steady-state concentration. This amounts to approximately 6 g of new hemoglobin per day:

$$\frac{750 \text{ g}}{120 \text{ days}} = 6.25 \text{ g/day (amount of hemoglobin lost and synthesized each day)}$$

If we divide the total amount of hemoglobin synthesized each day (6.25 g) by the mean amount of hemoglobin in a red cell (MCH, ~30 pg), we can determine the daily production of new red blood cells:

$$\frac{6.25 \text{ g/day}}{30 \text{ pg/cell}} \times 10^{12} \text{ pg/g} = 2 \times 10^{11} \text{ cells/day}$$

▶ HEMOGLOBIN STRUCTURE

Hemoglobin is a large tetrameric molecule, molecular weight 66,700 daltons, composed of four globular protein subunits (Figure 1 ■). Each of the four subunits contains a heme group and a globin chain. Heme, the prosthetic group of hemoglobin, is a tetrapyrrole ring with a ferrous iron located in the center of the ring. Hemoglobin structure is described in Table 1 ⚡ (Figure 2 ■). Each heme subunit can carry one molecule of oxygen bound to the central ferrous iron; thus, each hemoglobin molecule can carry four molecules of oxygen.

■ **FIGURE 1** Hemoglobin is a molecule composed of four polypeptide subunits. Each subunit has a globin chain with a heme nestled in a hydrophobic crevice that protects the iron from being oxidized. Four different types of globin chains— α , β , δ , γ —occur in pairs. The types of globin chains present determine the type of hemoglobin. Depicted here is hemoglobin A, consisting of 2 α and 2 β chains. The contacts between the α , β -chains in a dimer (i.e., $\alpha_1\beta_1$) are extensive and allow little movement. The contacts between the dimer pairs (i.e., $\alpha_1\beta_2$ and $\alpha_2\beta_1$), however, are smaller and allow conformational change of the molecule as it goes from oxyhemoglobin to deoxyhemoglobin.

⚡ **TABLE 1**

The Structure of Hemoglobin

Structure	Conformational Description
Primary	Sequence of individual amino acids held together by peptide bonds in the globin chains; is critical to stability and function of molecule; determines the overall structure
Secondary	Arrangement of the amino acids resulting from hydrogen bonding between the peptide bonds of the amino acids next to or near each other (75% α -helix; consists of 8 α -helical segments, labeled A \rightarrow H, separated by nonhelical segments)
Tertiary	Folding superimposed on the helical and pleated domains; forms the heme hydrophobic pocket within globin chains; this tertiary structure changes upon ligand binding
Quaternary	Relationship of the four protein subunits to one another; quaternary structural changes seen upon ligand binding result from the tertiary changes

The composition of the globin chains is responsible for the different functional and physical properties of hemoglobin. Two types of globin chains are produced: alpha-like (alpha [α], zeta [ζ]), and nonalpha (epsilon [ϵ], beta [β], delta [δ], and gamma [γ]). The tetrameric hemoglobin molecule consists of two pairs of unlike chains: two identical α -like and two identical non- α -chains. A pair of α -like chains (α or ζ) combines with a pair of non- α -chains (ϵ , β , δ , or γ) to form the various types of hemoglobin (Table 2 ⚡). The arrangement of each globin chain is similar. Each α - and ζ -chain has 141 amino acids while each ϵ , β -, δ -, and γ -chain has 146 amino acids. Each chain is wound up into eight spiral or α -helical segments separated by seven short, nonhelical segments. The helical segments are lettered A–H, starting at the amino end of the chain. The amino acids of the globin chains are identified by their helix location and amino acid number (i.e., F8 is the eighth amino acid in the F helix). Amino acids between helices are identified by amino acid number and the letters of the two helices (i.e., EF3). The nonhelical segments allow the chains to fold upon themselves.

The four subunits of hemoglobin, each consisting of a heme group surrounded by a globin chain, are held together by salt bonds, hydrophobic contacts, and hydrogen bonds in a tetrahedral formation giving the hemoglobin molecule a nearly spherical shape. When ligands, such as oxygen, bind to hemoglobin, the number and stridency of intersubunit contacts change. Mutations in the globin chains can affect subunit or dimer pair interactions and thus alter hemoglobin-oxygen affinity or the molecule's stability.

✓ Checkpoint! 1

Describe the quaternary structure of a molecule of hemoglobin. How can a mutation in one of the globin chains at the subunit interaction site, $\alpha_1\beta_2$, affect hemoglobin function?

■ **FIGURE 2** The structure of hemoglobin: Primary structure is the sequence of amino acids; secondary structure is the coiled α helix and β -pleated sheet formed by hydrogen bonding between the peptide bonds in the chain; tertiary structure is the folding of the molecule into a three-dimensional structure; quaternary structure is the combination of the four polypeptide subunits, each of which contains a heme group, into a larger protein. (Timberlake, Karen C.; Timberlake, William. *Basic Chemistry*, 2nd, © N/A. 2008. Electronically reproduced by permission of Pearson Education, Inc., Upper Saddle River, New Jersey.)

▶ HEMOGLOBIN SYNTHESIS

HEME

Heme is an iron-chelated porphyrin ring that functions as a prosthetic group (nonamino acid component) of a protein. The porphyrin ring, protoporphyrin IX, is composed of a flat tetrapyrrole ring with ferrous iron (Fe^{2+}) inserted into the center. (Porphyrins are metabolically active only when chelated.) Ferrous ions have six electron pairs per atom. In heme, four of these electron pairs are coordinately bound to the N atoms of each of the four pyrrole rings. In hemoglobin, one (fifth) of the two remaining electron pairs is coordinately bound with the N of the proximal histidine (F8) of the globin chain, and the other pair (sixth) is the binding site for molecular oxygen. In the deoxygenated state, the sixth electron pair is occupied by a water molecule.¹ Iron must be in the ferrous (Fe^{2+}) state for oxygen binding to occur. Ferric iron (Fe^{3+}), which has lost an electron, cannot serve as an oxygen carrier because the sixth potential binding site (electron pair) for oxygen is no longer available.

Heme synthesis begins in the mitochondria with the condensation of glycine and succinyl coenzyme A (CoA) to form 5-aminolevulinic acid (ALA). This reaction occurs in the presence of the cofactor pyridoxal phosphate, succinyl CoA synthase, and the enzyme 5-aminolevulinic synthase (ALAS). This first reaction is the rate-limiting step in the synthesis of

★ TABLE 2

Normal Types of Hemoglobin According to Developmental Stage

Developmental Stage	Type	Globin Chains	Reference Interval
Embryonic	Gower I	$\zeta_2\varepsilon_2$	—
	Gower II	$\alpha_2\varepsilon_2$	—
	Portland	$\zeta_2\gamma_2$	—
Fetal	HbF	$\alpha_2\gamma_2$	90–95% before birth 50–85% at birth
	HbA	$\alpha_2\beta_2$	10–40% at birth
	HbA ₂	$\alpha_2\delta_2$	<1% at birth
>1 year old	HbF	$\alpha_2\gamma_2$	<2%
	HbA	$\alpha_2\beta_2$	>95%
	HbA ₂	$\alpha_2\delta_2$	<3.5%
Adult	HbA	$\alpha_2\beta_2$	>95%
	HbA ₂	$\alpha_2\delta_2$	1.5–3.7%
	HbF	$\alpha_2\gamma_2$	<2%

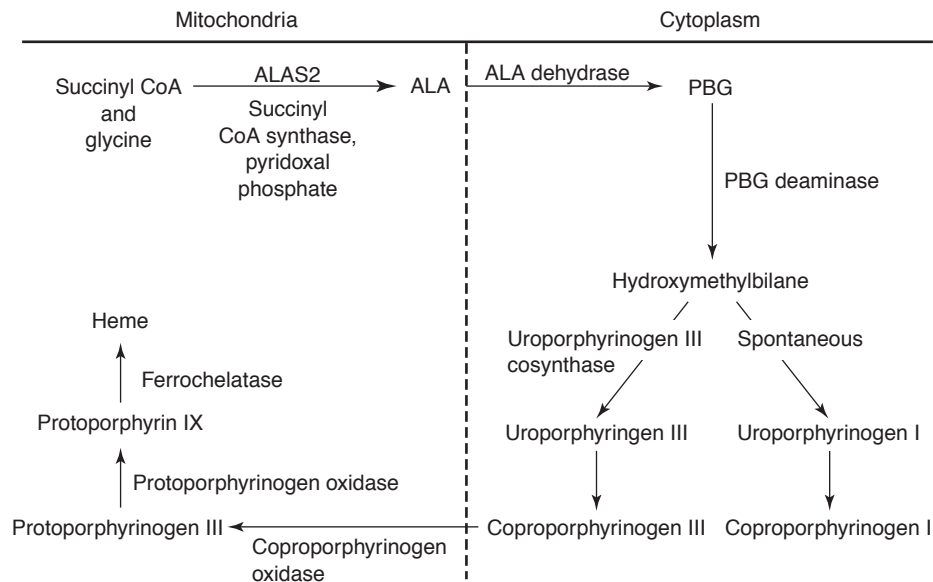

heme and occurs only when the cell has an adequate supply of iron. Synthesis continues through a series of steps in the cytoplasm, eventually forming coproporphyrinogen. Coproporphyrinogen then reenters the mitochondria and is further modified to form the protoporphyrin IX ring (Figure 3 ■). The final step, also occurring in the mitochondria, is the chelation of iron with protoporphyrin IX catalyzed by ferrochelatase to form heme (Figure 4 ■). Heme then leaves the mitochondria to combine with a globin chain in the cytoplasm. See Web Figure 1 ■ for detailed molecular structures of intermediates in heme synthesis.

GLOBIN

Globin chain synthesis is directed by eight genetic loci (Figure 5 ■). These genes produce the seven different types of globin chains: zeta, alpha, epsilon, gamma-A, gamma-G, delta, and beta (α , ζ , ϵ , γ^A , γ^G , δ , β). Two are found only in embryonic hemoglobins (ζ , ϵ). The genes for the ζ -chain (the fetal equivalent of the α -chain) and α -chain are located on chromosome 16 (the α gene cluster). The ζ -chain is synthesized very early in embryonic development. After 8–12 weeks, ζ -chain synthesis is replaced by α -chain synthesis. There are two α -loci (α -1 and α -2), both of which transcribe mRNA for α -chain synthesis. The protein product from each locus is identical. The non- α -globin genes are arranged in linear fashion in order of activation on chromosome 11 (the non- α -gene cluster). The non- α -globin chains show a high degree of homology.

The ϵ -gene is located toward the 5' end of chromosome 11; during embryonic development, ϵ -chain synthesis is switched off, and the two γ -genes are activated. One γ -gene directs the production of a γ -chain with glycine at amino acid position 136, γ^G while the other directs the production of a γ -chain with alanine at position 136, γ^A . The γ^G -chain synthesis predominates before birth (3:1), but γ^G - and γ^A -chain syntheses are equal (1:1) in adults. The next two genes on chromosome 11, δ and β , are switched on to a small degree when the γ -genes are activated, but they are not fully activated until γ -chain synthesis diminishes at about 35 weeks of gestation. The rate of synthesis of the δ -chain is only $1/140$ that of the β -chain. After birth, most cells produce predominantly α and β chains for the formation of HbA, the major adult hemoglobin.

The synthesis of globin peptide chains occurs on polyribosomes in the cytoplasm of developing erythroblasts (Figure 6 ■). Globin chains are released from the polyribosomes and combine with heme molecules released from the mitochondria. The globin chains are folded to create a hydrophobic pocket near the exterior surface of the chain between the E and F helices. Heme is inserted into this hydrophobic pocket where it is readily accessible to oxygen. A newly formed α -chain-heme subunit and a non- α -chain-heme subunit combine spontaneously, facilitated by electrostatic attraction, to form a dimer (e.g., $\alpha\beta$). Two dimers then combine to form the tetrameric hemoglobin molecule (e.g., $\alpha_2\beta_2$). The heme is positioned between two

■ **FIGURE 3** Synthesis of heme: It begins in the mitochondria with the condensation of glycine and succinyl CoA. The product, 5-aminolevulinic acid (ALA), leaves the mitochondria to form the pyrrole ring, porphobilinogen (PBG). The combination of four pyrroles to form a linear tetrapyrrole (hydroxymethylbilane), the cyclizing of the linear form to uroporphyrinogen, and the decarboxylation of the side chains to form coproporphyrinogen occur in the cytoplasm. The final reactions, the formation of protoporphyrin IX, and the insertion of iron into the protoporphyrin ring occur in the mitochondria.

■ **FIGURE 4** The hemoglobin molecule on the left reveals the quaternary structure of hemoglobin with four protein chains folded around a heme molecule. On the right is a heme molecule. Heme is composed of a flat tetrapyrrole ligand (porphyrin) and iron. The iron has six coordinate sites. Nitrogen atoms of porphyrin occupy four coordination sites in a square planar arrangement around the iron. Iron, which is in the ferrous state, has two other coordinate sites, one of which is occupied by the N of the proximal histidine (F8) of globin and one with molecular oxygen or H_2O . (Tro, Nivaldo Jose. *Chemistry: A Molecular Approach* 1st, © 2008. Electronically reproduced by permission of Pearson Education, Inc., Upper Saddle River, New Jersey.)

histidines of the globin chain called the *proximal* (F8) and *distal* (E7) *histidines*. The proximal histidine (F8) is bonded with the heme iron. The iron is protected in the reduced ferrous state in this hydrophobic pocket. The exterior of the chain is hydrophilic, which makes the molecule soluble.

✓ Checkpoint! 2

What globin chains are synthesized in the adult?

▶ REGULATION OF HEMOGLOBIN SYNTHESIS

Normally, the production of α subunits, non- α subunits, and heme are nearly equal. This indicates that tight regulatory mechanisms exist, controlling the production of hemoglobin. Hemoglobin synthesis is regulated by several mechanisms including:

- Activity of the erythroid enzyme 5-aminolevulinate synthase (ALAS2)
- Activity of porphobilinogen deaminase (PBGD)

■ **FIGURE 5** The genes for the globin chains are located on chromosomes 11 and 16. The ζ -chain appears to be the embryonic equivalent of the α -chain, both of which are located on chromosome 16. Note that the α -gene is duplicated. The other globin genes are located on chromosome 11.

■ **FIGURE 6** Assembly of hemoglobin. The α and β globin polypeptides are translated on their respective mRNAs. On binding of heme, the protein folds into its native three-dimensional structure. The binding of α and β hemoglobin subunits to each other is facilitated by electrostatic attraction. An unstable intermediate encounter complex can rearrange to form the stable $\alpha\beta$ dimer. Two dimers combine to form the functional $\alpha_2\beta_2$ tetramer. (Adapted, with permission, from Bunn HF: Subunit assembly of hemoglobin: An important determinant of hematologic phenotype. *Blood*. 1987; 69:1.)

- Concentration of iron
- Regulation of globin chain synthesis

The first enzyme in the heme synthetic pathway, ALAS, catalyzes the initial reaction of condensation of glycine and succinyl-CoA to form 5-ALA, the rate-limiting step in heme synthesis. As mentioned previously, this reaction takes place in the mitochondria. Because ALAS is synthesized on ribosomes in the cytosol, it must be imported into the mitochondria to catalyze the reaction. This mitochondrial import can be inhibited by high concentrations of heme.² When iron is scarce, the synthesis of ALAS is decreased.

Iron entering the developing erythroblast can be in either the pool available for metabolic processes (heme synthesis) or the storage pool (ferritin and hemosiderin). An **iron regulatory protein (IRP)**, previously referred to as **iron respon-**

sive element-binding protein (IRE-BP), is the primary physiologic iron sensor.³ It plays an important role in regulating the available iron in each of these pools by affecting heme synthesis, synthesis of proteins involved in iron metabolism and the formation of ferritin and transferrin receptors.^{2,3,4,5,6} When iron is scarce, translation of ALAS is prevented, the synthesis of ferritin and hemosiderin decreases, and the synthesis of transferrin receptors increases.

The rate of globin synthesis is governed primarily by the rate at which the DNA code is transcribed to mRNA, but it is also modified by the processing of globin pre-mRNA to mRNA, the translation of mRNA to protein, and the stability of globin mRNA. The individual globin genes have separate promoter regions that are available for activation at variable times during embryonic and fetal development. In addition, the β -gene cluster has a locus control region (LCR), located upstream (5') of the genes, which plays an important role in regulating the entire gene cluster. The α -gene cluster has a similar control region, the HS40, which is thought to have a similar function. Heme plays an important role in controlling the synthesis of globin chains. It stimulates globin synthesis by inactivating an inhibitor of translation.

CASE STUDY (continued from earlier in this chapter)

Jerry's doctor gave him iron supplements to take every day.

1. If Jerry is iron deficient, what is the effect of this deficient state on the synthesis of ALAS, transferrin receptor, and ferritin?
2. What was the rationale for giving Jerry the iron?

▶ **ONTOGENY OF HEMOGLOBIN**

The type of hemoglobin is determined by its composition of globin chains (Table 2). Individual globin chains are expressed at different levels in developing erythroblasts of the human embryo, fetus, and adult. Some hemoglobins (Gower I, Gower II, and Portland) occur only in the embryonic stage of development. HbF is the predominant hemoglobin in the fetus and newborn, and hemoglobin A is the predominant hemoglobin after 1 year of age.

Studies have suggested that the synthesis of different globin chains occurs in sequence depending on the developmental stage. This is due to the sequential activation and then inactivation (i.e., "switching") among the α - and non- α -globin gene clusters. In vitro cultures of burst forming unit—Erythrocyte (BFU-E) from fetal liver, neonatal (umbilical cord) blood, and adult blood show HbF production from these three sources to decrease in concentration from fetal to neonatal to adult. The switch from fetal to adult hemoglobin synthesis is closely related to gestational age and is unaffected by the time of birth: Premature infants do not switch over to adult hemoglobin synthesis any earlier than they

would if they had been carried full term. The perinatal switch from HbF to HbA synthesis is probably time controlled by a developmental clock.^{7,8} The stem cells are gradually reprogrammed during the perinatal period leading to a switching from γ -chain production to predominantly β -chain production.

EMBRYONIC HEMOGLOBINS

Intrauterine erythropoiesis is associated with the production of the embryonic hemoglobins Gower 1, Gower 2, and Portland in the first trimester of gestation. The embryonic hemoglobins are made from the combination of pairs of embryonic globin chains, ζ and ϵ in pairs ($\zeta_2\epsilon_2$) or embryonic chains in combination with α - and γ -chains ($\alpha_2\epsilon_2$; $\zeta_2\gamma_2$). These primitive hemoglobins are detectable during early hematopoiesis in the yolk sac and liver and are not usually detectable after the third month of gestation.

FETAL HEMOGLOBIN

Hemoglobin F (HbF; $\alpha_2\gamma_2$) is the predominant hemoglobin formed during liver and bone marrow erythropoiesis in the fetus. HbF composes 90–95% of the total hemoglobin production in the fetus until ~34–36 weeks of gestation. At birth, the infant has 50–85% HbF.

ADULT HEMOGLOBINS

In adults, hemoglobin A (HbA; $\alpha_2\beta_2$) is the major hemoglobin. It is formed during erythropoiesis in the bone marrow. Although HbA is found as early as 9 weeks gestation, β -chain synthesis continues at a low level and does not exceed γ -chain synthesis until after birth. At ~36 weeks gestation, β -chain synthesis significantly increases while γ -chain synthesis declines so that at birth, approximately equal amounts of γ - and β -chains are being produced. After birth, the percentage of HbA continues to increase with the infant's age until normal adult levels (>95%) are reached by the end of the first year of life.

HbF production constitutes less than 2% of the total hemoglobin of adults. In normal adults, most if not all HbF is restricted to a few erythrocytes, referred to as *F cells*. F cells constitute less than 8% of adult RBC, and from 13% to 25% of the hemoglobin in each F cell is HbF. The switch from HbF to HbA after birth is incomplete and in part reversible. For example, patients with hemoglobinopathies or severe anemia can have increased levels of HbF, often proportionate to the decrease in HbA. In bone marrow recovering from suppression and in some neoplastic hematologic diseases, HbF levels often rise.

HbA₂($\alpha_2\delta_2$) appears late in fetal life, composes less than 1% of the total hemoglobin at birth, and reaches normal adult values (1.5–3.7%) after one year. The δ -gene locus is transcribed very inefficiently compared to the β -locus. This low level of transcription is thought to be due to changes in the region of the gene that recognizes erythroid-specific

transcription factors (e.g., GATA-1). HbA₂ has a slightly higher oxygen affinity than HbA; otherwise, the two hemoglobins have similar or identical ligand binding curves, Bohr effect, and response to 2,3-BPG.

✓ Checkpoint! 3

What are the names and globin composition of the embryonic, fetal, and adult hemoglobins?

GLYCOSYLATED HEMOGLOBIN

HbA_{1c} on chromatography is a minor component of normal adult hemoglobin (HbA) that has been modified posttranslationally (HbA₃ on starch block electrophoresis). A component usually has been added to the N terminus of the β -chain. The most important subgroup of HbA_{1c} is HbA_{1c}, which has glucose irreversibly attached. This hemoglobin is referred to as **glycosylated hemoglobin**. HbA_{1c} is produced throughout the erythrocyte's life, its synthesis dependent on the concentration of blood glucose. Older erythrocytes typically contain more HbA_{1c} than younger erythrocytes having been exposed to plasma glucose for a longer period of time. However, if young cells are exposed to extremely high concentrations of glucose (>400 mg/dL) for several hours, the concentration of HbA_{1c} increases with both concentration and time of exposure.

Measurement of HbA_{1c} is routinely used as an indicator of control of blood glucose levels in diabetics because it is proportional to the average blood glucose level over the previous two to three months. Average levels of HbA_{1c} are 7.5% in diabetics and 3.5% in normal individuals.

✓ Checkpoint! 4

A patient has an anemia caused by a shortened RBC life span (hemolysis); how would this affect the HbA_{1c} measurement?

▶ HEMOGLOBIN FUNCTION

The function of hemoglobin is to transport and exchange respiratory gases. The air we breathe is a mixture of nitrogen (78.6%), oxygen (20.8%), water, and carbon dioxide (CO₂). The sea level atmospheric pressure is 760 torr. Each of the gases in the air contributes to this pressure in proportion to its concentration. The partial pressure each gas exerts is referred to as *P*. Thus, the partial pressure of oxygen in the atmosphere is $20.8\% \times 760 = 159$ torr.

The partial pressure gradient of a gas (in this case, oxygen) determines the rate of diffusion of that gas across the alveolar-capillary membrane. When air is inspired, water vapor is added to the incoming gas to bring its relative humidity up to 100% at body temperature. This amounts to a relatively constant water vapor pressure of 47 torr. Therefore, the PO₂ of inspired air is $(760-47) \times 20.8\% = 148$ torr. As

the inspired air mixes with alveolar gas, the PO_2 is diluted further by the presence of carbon dioxide given off at the lungs as a byproduct of metabolism. The now arterialized blood leaves the lungs with a PO_2 of 100 torr and a PCO_2 of 40 torr. In comparison, the PO_2 of interstitial fluid in tissues is about 40 torr and the PCO_2 is about 45 torr. Thus, when blood reaches the tissues, oxygen diffuses out of the blood (because the PO_2 in blood is higher than in tissues), and CO_2 diffuses into the blood (because the PCO_2 is higher in tissues than in blood). The amount of dissolved O_2 and CO_2 the plasma can carry is limited. Most O_2 and CO_2 diffuse into the erythrocyte to be transported to tissue or lungs.

OXYGEN TRANSPORT

Hemoglobin with bound oxygen is called **oxyhemoglobin**; hemoglobin without oxygen is called **deoxyhemoglobin**. The amount of oxygen bound to hemoglobin and released to tissues depends not only on the PO_2 and PCO_2 but also on the affinity of Hb for O_2 . The ease with which hemoglobin binds and releases oxygen is known as **oxygen affinity**. Hemoglobin affinity for oxygen determines the proportion of oxygen released to the tissues or loaded onto the cell at a given oxygen pressure (PO_2). Increased oxygen affinity

means that the hemoglobin has a high affinity for oxygen, will bind oxygen more avidly, and does not readily give it up whereas decreased oxygen affinity means the hemoglobin has a low affinity for oxygen and releases its oxygen more readily.

Oxyhemoglobin and deoxyhemoglobin have different three-dimensional configurations. In the unliganded or deoxy state, the tetramer is stabilized by intersubunit salt bridges and is described as being in the tense (**T**) structure or state. In oxyhemoglobin, the salt bridges are broken, and the molecule is described as being in the relaxed (**R**) structure state. The change in conformation of hemoglobin (from T to R) occurs as a result of a coordinated series of changes in the quaternary structure of the tetramer as the subunits bind oxygen (see below). The T configuration is a low oxygen-affinity conformation, and the R state is a high oxygen-affinity conformation.

Oxygen affinity of hemoglobin is usually expressed as the PO_2 at which 50% of the hemoglobin is saturated with oxygen (P_{50}). The P_{50} in humans is normally about 26 torr. If hemoglobin-oxygen saturation is plotted versus the partial pressure of oxygen (PO_2), a sigmoid-shaped (S-shaped) curve results. This is referred to as the *oxygen dissociation curve* (ODC) (Figure 7 ■). The shape of the curve reflects subunit

■ **FIGURE 7** The oxygen affinity of hemoglobin is depicted by the oxygen dissociation curve (ODC). The fractional saturation of hemoglobin (Y axis) is plotted against the concentration of oxygen measured as the PO_2 (X axis). At a pH of 7.4 and an oxygen tension (PO_2) of 26 torr hemoglobin is 50% saturated with oxygen (red line). The curve shifts in response to temperature, CO_2 , O_2 , 2,3-BPG concentration and pH. When the curve shifts left (blue line), there is increased affinity of Hb for O_2 . When the curve shifts right (black line), there is decreased affinity of Hb for O_2 . (McMurry, John; Castellion, Mary E.; Ballantine, David S., *Fundamentals of General, Organic, and Biological Chemistry*, 5th ed., © 2007. Electronically reproduced by permission of Pearson Education, Inc., Upper Saddle River, New Jersey.)

interactions between the four subunits of hemoglobin (heme-heme interaction or cooperativity). Monomeric molecules such as myoglobin have a hyperbolic ODC. The sigmoid-shaped curve indicates that more than one molecule of O_2 is binding to a molecule of hemoglobin and that binding of one molecule of O_2 to hemoglobin facilitates the binding of additional O_2 .

The shape of the curve has certain physiologic advantages. The “flattened” top of the *S* reflects the fact that >90% saturation of hemoglobin still occurs over a fairly broad range of pO_2 . This enables us to survive and function in conditions of lower oxygen availability, such as living (or skiing) at high altitudes. Note that the steepest part of the curve occurs at oxygen tensions found in tissues. This allows the release of large amounts of oxygen from hemoglobin during the small physiologic changes in PO_2 encountered in the capillary beds of tissues. This is physiologically of great importance, for it allows the overall transfer of oxygen from the lungs to the tissues with relatively small changes in PO_2 . The ODC shows that the oxygen saturation of hemoglobin drops from ~100% in the arteries where the PO_2 is about 100 torr to ~75% in the veins where the PO_2 is about 40 torr. This indicates that hemoglobin gives up about 25% of

its oxygen to the tissues. When the curve is shifted to the right, the P_{50} is increased, indicating that the oxygen affinity has decreased. This results in the release of more oxygen to the tissues. When the curve is shifted to the left, the P_{50} is decreased, indicating that oxygen affinity has increased. In this case, less oxygen is released to the tissues.

CASE STUDY (continued from earlier in this chapter)

Jerry was lethargic and pale. He was having problems with activities of daily living.

3. Explain why Jerry could have these symptoms.

The Allosteric Property of Hemoglobin

The sigmoid shape of the ODC is primarily due to heme-heme interactions described below. While the sigmoid shape of the ODC is due to heme-heme subunit interactions, the relative position of the curve (shifted right or left) is due to other variables.

Hemoglobin is an allosteric protein. This means that hemoglobin’s structure (conformation) and function are affected by other molecules, primarily 2,3-bisphosphoglycer-

■ **FIGURE 8** 2,3 BPG binds in the central cavity of deoxyhemoglobin. This cavity is lined with positively charged groups on the beta chains that interact electrostatically with the negative charges on 2,3-BPG. The α -globin chains are in pink, the β -chains are in blue and the heme prosthetic groups in red. (Horton, Robert; Moran, Laurence A.; Scrimgeour, Gary; Perry, Mark; Rawn, David, *Principles of Biochemistry*, 4th ed., © 2006. Electronically reproduced by permission of Pearson Education, Inc., Upper Saddle River, New Jersey.)

ate (2,3-BPG; also referred to as diphosphoglycerate [2,3-DPG]) known as the *allosteric regulator*. A byproduct of the glycolytic pathway, 2,3-BPG, is present at almost equimolar quantities with hemoglobin in erythrocytes. In the presence of physiologic concentrations of 2,3-BPG, the P_{50} of hemoglobin is about 26 torr. In the absence of 2,3-BPG, the P_{50} of hemoglobin is 10 torr, a very high oxygen affinity. Thus, in the absence of 2,3-BPG, little oxygen is released to the tissues.

Protons (H^+), CO_2 , and organic phosphates (2,3-BPG) are all allosteric effectors of hemoglobin, which preferentially bind to deoxyhemoglobin, forming salt bridges within and between chains and stabilizing the deoxyhemoglobin (T) structure. 2,3-BPG binds to deoxyhemoglobin in a 1:1 ratio. The binding site for 2,3-BPG is in a central cavity of the hemoglobin tetramer structure between the β -globin chains. It binds to the positive charges on both β -chains, thereby crosslinking the chains and stabilizing the quaternary structure of T/deoxyhemoglobin. (Figure 8 ■)

Hemoglobin also binds oxygen allosterically. Oxygen binds to hemoglobin in a 4:1 ratio because one molecule of O_2 binds to each of the 4 heme portions of the tetramer. The binding of oxygen by a hemoglobin molecule depends on

the interaction of the four heme groups, referred to as *heme-heme interaction*. The interaction of the heme groups is the result of movements within the tetramer triggered by the uptake of a molecule of oxygen by one of the heme groups.

In the deoxygenated state, the heme iron is 0.4–0.6 Å out of the plane of the porphyrin ring because the iron atom is too large to align within the plane. The iron is displaced toward the proximal histidine of the globin chain to which it is linked by a coordinate bond. Fully deoxygenated hemoglobin (T state) has a low oxygen affinity, and loading of the first oxygen onto the tetramer does not occur easily. On binding of oxygen, the atomic diameter of iron becomes smaller due to changes in the distribution of electrons, and the iron moves into the plane of the porphyrin ring, pulling the histidine of the globin chain with it (Figure 9 ■). These small changes in the tertiary structure of the molecule near the heme group result in a large shift in the quaternary structure, altering the bonds and contacts between chains and weakening the intersubunit salt bridges. Likewise, loading of a second O_2 onto the tetramer while it is still in the T conformation does not occur easily. However, the iron atom of the second heme is likewise shifted, further destabilizing the salt bridges. During the course of loading the third O_2 onto

■ **FIGURE 9** Changes in the conformation of hemoglobin occur when the molecule takes up O_2 . In the deoxyhemoglobin state, the heme iron of a hemoglobin subunit is below the porphyrin plane (blue). On uptake of an O_2 molecule, the iron decreases in diameter and moves into the plane of the porphyrin ring, pulling the proximal histidine with it (red). The helix containing the histidine also shifts disrupting ion pairs that link the subunits. 2,3-BPG is expelled, and the remaining subunits are able to combine with O_2 more readily. (Horton, Robert; Moran, Laurence A.; Scrimgeour, Gary; Perry, Marc; Rawn, David. *Principles of Biochemistry*, 4th ed., © 2006. Electronically reproduced by permission of Pearson Education, Inc., Upper Saddle River, New Jersey.)

hemoglobin, the salt bridges are broken, and the hemoglobin molecule shifts from the T to the R configuration, pulling the β -chains together. Consequently, the size of the central cavity between the β -chains decreases, and 2,3-BPG is expelled. In the high oxygen-affinity R configuration, the third and fourth O_2 are added easily. The structural changes within successive heme subunits facilitate the binding of oxygen by the remaining heme subunits because fewer subunit crosslinks need to be broken to bind subsequent oxygen molecules.

Oxygen interacts weakly with heme iron, and the two can dissociate easily. As O_2 is released by hemoglobin in the tissues, the heme pockets narrow and restrict entry of O_2 while the space between the β -chains widens and 2,3-BPG binds again in the central cavity. Thus, as 2,3-BPG concentration increases, the T configuration of hemoglobin is favored and the oxygen affinity decreases.

This cooperative binding of oxygen makes hemoglobin a very efficient oxygen transporter. Cooperativity ensures that once a hemoglobin tetramer begins to accept oxygen, it promptly is fully oxygenated. In the process of oxygen release to the tissues, the same general principle is followed. Individual hemoglobin molecules are either fully deoxygenated or fully oxygenated. Only a small portion of the molecules exists in a partially oxygenated state.

Adjustments in Hemoglobin-Oxygen Affinity

Variations in environmental conditions or physiological demand for oxygen result in changes in erythrocyte and plasma parameters that directly affect hemoglobin-oxygen affinity. In particular, PO_2 , pH (H^+), PCO_2 , 2,3-BPG, and temperature affect hemoglobin-oxygen affinity (Table 3 ) .

Several physiologic mechanisms of oxygen delivery can be explained by the hemoglobin–2,3-BPG interaction. When a person goes from sea level to high altitudes, the body adapts to the decreased atmospheric pressure of oxygen by releasing more oxygen to the tissues. This adaptation is mediated by increases of 2,3-BPG in the erythrocyte, usually noted within 36 hours of ascent. EPO and erythrocyte mass also increase as a part of the adaptive mechanism to decreased PO_2 , but this adaptation can take several days to improve tissue oxygenation.⁹

Fetal hemoglobin (HbF) has a higher oxygen affinity compared to adult hemoglobin, HbA. Fetal blood's higher oxy-

gen affinity is primarily due to the fact that hemoglobin F does not readily bind 2,3-BPG. The more efficient binding of 2,3-BPG to HbA facilitates the transfer of oxygen from the maternal (HbA) to the fetal (HbF) circulation.

Rapidly metabolizing tissue as occurs during exercise produces CO_2 and acid (H^+) as well as heat. These factors decrease oxygen affinity and promote the release of oxygen from hemoglobin to the tissue. However, in the alveolar capillaries of the lungs, the high PO_2 and low PCO_2 drives off the CO_2 in the blood and reduces H^+ concentration, promoting the uptake of O_2 by hemoglobin (increasing oxygen affinity). Thus, PO_2 , PCO_2 , and H^+ facilitate the transport and exchange of respiratory gases.

The effect of pH on hemoglobin-oxygen affinity is known as the **Bohr effect**, an example of the acid-base equilibrium of hemoglobin that is one of the most important buffer systems of the body. A molecule of hemoglobin can accept H^+ when it releases a molecule of oxygen. Deoxyhemoglobin accepts and holds the H^+ better than oxyhemoglobin. In the tissues, the H^+ concentration is higher because of the presence of lactic acid and CO_2 . When blood reaches the tissues, the affinity of hemoglobin for oxygen is decreased by the high H^+ concentration, thereby permitting the more efficient unloading of oxygen at these sites.

Thus, proton binding facilitates O_2 release and helps minimize changes in the hydrogen ion concentration of the blood when tissue metabolism is releasing CO_2 and lactic acid. Up to 75% of the hemoglobin oxygen can be released if needed (as in strenuous exercise) as the erythrocytes pass through the capillaries.

Checkpoint! 5

What factors influence an increase in the amount of oxygen delivered to tissue during an aerobic workout?

CARBON DIOXIDE TRANSPORT

After diffusing into the blood from the tissues, carbon dioxide is carried to the lungs by three separate mechanisms: dissolution in the plasma, formation of bicarbonic acid, and binding to the N-terminus groups of hemoglobin (carbaminohemoglobin) (Table 4 ; Figure 10 ).

Plasma Transport

A small amount of carbon dioxide is dissolved in the plasma and carried to the lungs. There it diffuses out of the plasma and is expired.

Bicarbonic Acid

Most of the carbon dioxide transported by the blood is in the form of bicarbonic acid, which is produced when carbon dioxide diffuses from the plasma into the erythrocyte. In the

 TABLE 3

Factors That Affect Oxygen-Hemoglobin Affinity

Increase Affinity	Decrease Affinity

$\downarrow H^+$	\uparrow Temperature
\downarrow Temperature	\uparrow 2,3-BPG
\downarrow 2,3-BPG	

Key: \uparrow = increased

TABLE 4

Carbon Dioxide Transport in Blood

Mechanism	Percent of Transportation
Dissolved in plasma	7
Formation of carbonic acid, H_2CO_3	70
Bound to Hb	23

■ **FIGURE 10** Transport of oxygen and carbon dioxide in the erythrocyte is depicted. Lower figure: CO_2 diffuses from the tissue into the venous blood and then into the erythrocyte. Within the erythrocyte, CO_2 reacts with water to form bicarbonic acid, H_2CO_3 . The bicarbonic acid dissociates into bicarbonate (HCO_3^-) and a proton (H^+). The HCO_3^- leaves the cell and enters the blood. In exchange, chloride (Cl^-) from the blood enters the erythrocyte (chloride shift). The proton is accepted by oxyhemoglobin (HbO_2), which facilitates through the Bohr effect the dissociation of oxygen into the tissues. Upper figure: In the lungs, O_2 and HCO_3^- enter the red cell. O_2 combines with Hb, releasing H^+ . HCO_3^- combines with H^+ to form H_2CO_3 , which dissociates into H_2O and CO_2 , and are expired. To maintain electrolyte balance, at the same time that the HCO_3^- flows into the RBCs, the Cl^- flows out (the reverse chloride shift). The cell membrane anion-exchange protein controls this ion exchange. (Sackheim, George I.; Lehman, Dennis D. *Chemistry for the Health Sciences*, 8th ed., © 1998. Electronically reproduced by permission of Pearson Education, Inc., Upper Saddle River, New Jersey.)

presence of the erythrocyte enzyme, carbonic anhydrase (CA), CO_2 reacts with water to form bicarbonic acid:

Subsequently, hydrogen ion and bicarbonate are liberated from carbonic acid and the H^+ is accepted by deoxyhemoglobin:

These bicarbonate ions do not remain in the RBC because the cell can hold only a small amount of bicarbonate. Thus, the free bicarbonate diffuses out of the erythrocyte into the plasma. The cell cannot tolerate a loss in negative ions, so in exchange for the loss of bicarbonate, Cl^- diffuses into the cell from the plasma, a phenomenon called the **chloride shift**. This occurs via the anion exchange channel (band 3). The bicarbonate combines with Na^+ (NaHCO_3) in the plasma and is carried to the lungs where the PCO_2 is low. There the bicarbonate diffuses back into the erythrocyte, is rapidly converted back into CO_2 and H_2O , and expired.

Hemoglobin Binding

Approximately 23% of the total CO_2 exchanged by the erythrocyte in respiration is through carbaminohemoglobin. Deoxyhemoglobin directly binds 0.4 moles of CO_2 per mole of hemoglobin. Carbon dioxide reacts with uncharged N-terminal amino groups of the four globin chains to form carbaminohemoglobin. At the lungs, the plasma PCO_2 decreases, and the CO_2 bound to hemoglobin is released and diffuses out of the erythrocyte to the plasma. It then is expired as it enters the alveolar air space.

CASE STUDY (continued from earlier in this chapter)

After a week at home, Jerry called his doctor, who sent him back to the hospital where he was given 2 units of packed red cells. Within a day, he had more energy.

4. Explain why Jerry could have had more energy after the transfusions.

NITRIC OXIDE AND HEMOGLOBIN

Nitric oxide (NO) is produced in the endothelium by the action of NO synthase. NO derives its name as the endothelium-derived relaxing factor (EDRF) due to its ability to relax smooth muscle and dilate blood vessels.¹⁰ It is important in other aspects of normal vessel physiology as well as inhibition of platelet activation. Some NO diffuses into the blood from the endothelium where it reacts with hemoglobin and other plasma molecules. Reaction of oxyhemoglobin with NO destroys the NO and forms methemoglobin and nitrate. This is referred to as *dioxigenation*.

This reaction is responsible for complications such as vasoconstriction and increase of blood pressure due to loss of NO that are encountered when using artificial hemoglobin-based oxygen carriers in solution.

NO also reacts with deoxyhemoglobin to form iron-nitrosyl hemoglobin (HbNO) and with the cysteine at position 93 of the β -chain to form S-nitroso hemoglobin. It has been proposed that these later two reactions could serve to preserve NO by acting as a carrier of NO in the circulation and later reversing the reaction, releasing NO.^{10,11} The rate of reaction of NO with hemoglobin within the erythrocyte is decreased by a factor of at least 1000 from the rate of reaction with free hemoglobin because of the slow diffusion of NO through the RBC membrane and the laminar blood flow that pushes the erythrocytes inward away from the vessel endothelium where the NO is concentrated.¹¹

ARTIFICIAL OXYGEN CARRIERS

Efforts to reduce allogeneic blood transfusions and improve oxygen delivery to tissues have resulted in development of **artificial oxygen carriers (AOCs)**. Two groups of AOCs include hemoglobin-based oxygen carriers (HBOCs) in solution and perfluorocarbons (PFCs). The HBOCs consist of purified human or bovine hemoglobin and recombinant hemoglobin. The hemoglobin is altered chemically or genetically or is microencapsulated to decrease oxygen affinity and to prevent its breakdown into dimers that have significant nephrotic toxicity.¹² The oxygen dissociation curve of HBOCs is similar to that of native human blood. Side effects of these AOCs are Hb-induced vasoconstriction and resulting hypertension. These side effects are related to NO scavenging by the free hemoglobin as well as endothelin release and sensitization of peripheral adrenergic receptors.¹³ Because hemoglobin in solution imparts color to plasma, it might not be possible to perform laboratory tests based on colorimetric analysis of patients receiving this product because measurements could give erroneous results.

PFCs are fluorinated hydrocarbons with high gas-dissolving capacity. They do not mix in aqueous solution and must be emulsified. In contrast to HBOCs, a linear relationship between pO_2 and oxygen content in PFCs exists. This means

that relatively high O_2 partial pressure is required to maximize delivery of O_2 by PFCs. The PFC droplets are taken up by the mononuclear-phagocyte (MNP) system, broken down, bound to blood lipids, transported to the lungs, and exhaled.¹³

AOCs are not approved for use in the United States although HBOCs are approved for compassionate use.¹³ Phase III trials are complete or in progress for HBOCs, but no trials are in place for PFCs.

► ACQUIRED NONFUNCTIONAL HEMOGLOBINS

The acquired, nonfunctional hemoglobins are hemoglobins that have been altered posttranslationally to produce molecules with compromised oxygen transport, thereby causing *hypoxia* and/or *cyanosis* (Table 5 ★). **Hypoxia** is a condition in which there is an inadequate amount of oxygen at the tissue level. (Hypoxemia is an inadequate amount of oxygen in the blood, arterial $PO_2 < 80$ torr.) **Cyanosis** refers to a bluish color of the skin due to the presence of more than 5 g/dL of deoxyhemoglobin in the blood.

METHEMOGLOBIN

Methemoglobin is hemoglobin with iron in the ferric (Fe^{+++}) state. It is incapable of combining with oxygen. Methemoglobin not only decreases the oxygen-carrying capacity of blood but also results in an increase in oxygen affinity of the remaining normal hemoglobin. This results in an even higher deficit of O_2 delivery. Normally less than 1.5% methemoglobin is formed by auto-oxidation of hemoglobin per day. At this concentration, the abnormal pigment is not harmful because the reduction in oxygen-carrying capacity of the blood is insignificant. Several reducing systems hold the accumulation of higher concentrations in control (Table 6 ★). Of these reducing systems, the most important, accounting for more than 60% of the reduction of methemoglobin, is NADH methemoglobin reductase.

Increased levels of methemoglobin are formed when an individual is exposed to certain oxidizing chemicals or drugs. Even small amounts of these chemicals and drugs can

★ TABLE 5

Abnormal Acquired Hemoglobins

Methemoglobin	Hb iron in ferric state	Cannot combine with oxygen	Demonstration of maximal absorption band at wavelength of 630 nm; chocolate color blood
Sulfhemoglobin	Sulfur combined with hemoglobin	$1/100$ oxygen affinity of HbA	Absorption band at 620 nm
Carboxyhemoglobin	Carbon monoxide combined with hemoglobin	Affinity for carbon monoxide is 200 times higher than for oxygen	Absorption band at 541 nm

TABLE 6

Erythrocyte Systems Responsible for Methemoglobin Reduction

Rank in Order of Decreasing Methemoglobin Reduction	System
First	NADH methemoglobin reductase (also known as <i>cytochrome b5 methemoglobin reductase, diaphorase I, DPNH-diaphorase, DPNH dehydrogenase I, NADH dehydrogenase, NADH methemoglobin-ferrocyanide reductase</i>)
Second	Ascorbic acid
Third	Glutathione
Fourth	NADPH methemoglobin reductase

cause oxidation of large amounts of hemoglobin. If the offending agent is removed, methemoglobinemia disappears within 24–48 hours.

Infants are more susceptible to methemoglobin production than adults because HbF is more readily converted to methemoglobin and because infants' erythrocytes are deficient in reducing enzymes. Exposure to certain drugs or chemicals that increase oxidation of hemoglobin or water high in nitrates can cause methemoglobinemia in the infant segment of the population. Color crayons containing aniline can cause methemoglobinemia if ingested.

Cyanosis develops when methemoglobin levels exceed 10% (more than 1.5 g/dL) while hypoxia is produced at levels exceeding 30–40%. Methemoglobin can be reduced by medical treatment with methylene blue or ascorbic acid, which speeds up reduction by NADPH-reducing enzymes. In some cases of severe methemoglobinemia, exchange transfusions are helpful.

Methemoglobinemia can also result from congenital defects in the reducing systems mentioned above or from an inherited hemoglobin variant, HbM (Table 7). A deficiency or abnormality of NADH methemoglobin reductase causes the most severe methemoglobinemia. In this condition, cyanosis is observed from birth, and methemoglobin levels reach 10–20%. The oxygen affinity of normal hemo-

globin is increased in these children, resulting in increased erythropoiesis and subsequently higher than normal hemoglobin levels. The hereditary structural hemoglobin variant, HbM, also results in methemoglobinemia. HbM is characterized by amino acid substitutions in the globin chains near the heme pocket that stabilize the iron in the oxidized, Fe⁺⁺⁺, state. Methemoglobinemia caused by these hereditary defects cannot be reduced by treatment with methylene blue or ascorbic acid. However, even in the homozygous state, individuals with HbM or defects in the reducing systems rarely have methemoglobin levels of more than 30% and are usually asymptomatic.

Laboratory diagnosis of methemoglobinemia involves demonstration of a maximum absorbance band at a wavelength of 630 nm at pH 7.0–7.4. The blood sample can be chocolate brown in color when compared to a normal blood specimen. Differentiation of acquired types from hereditary types of methemoglobin requires assay of NADH methemoglobin reductase and hemoglobin electrophoresis (Table 7). Enzyme activity is reduced only in hereditary NADH-methemoglobin reductase deficiency, and hemoglobin electrophoresis is abnormal only in HbM disease. The acquired types of methemoglobinemia show normal enzyme activity and a normal electrophoresis pattern.

In the presence of methemoglobinemia, oxygen saturation obtained by a cutaneous pulse oximeter (fractional oxyhemoglobin, FhbO₂) can be lower than the oxygen saturation reported from a blood-gas analysis. This is so because FhbO₂ is calculated as the amount of oxyhemoglobin compared to the total hemoglobin (oxyhemoglobin, deoxyhemoglobin, methemoglobin, and other inactive hemoglobin forms) whereas oxygen saturation in a blood-gas analysis is the amount of oxyhemoglobin compared to the total amount of hemoglobin able to combine with oxygen (oxyhemoglobin plus deoxyhemoglobin). FhbO₂ and oxygen saturation are the same if no abnormal hemoglobin is present.¹⁴

Sulfhemoglobin

Sulfhemoglobin is a stable compound formed when a sulfur atom combines with the heme group of hemoglobin. The sulfur atom binds to a pyrrole carbon at the periphery of the porphyrin ring. Sulfuration of heme groups results in a drastically right-shifted oxygenation dissociation curve,

TABLE 7

Differentiation of Types of Methemoglobinemia

Cause of Methemoglobinemia	Inherited/Acquired	Enzyme Activity	Hb Electrophoresis
Exposure to oxidants	Acquired	Normal	Normal
Decreased enzyme activity	Inherited	Decreased	Normal
Presence of hemoglobin M	Inherited	Normal	Abnormal

which renders the heme groups ineffective for oxygen transport. This effect appears to be due to the fact that even half-sulfurated, half-oxygen-liganded tetramers exist in the T configuration (the low oxygen-affinity form) of hemoglobin. Although the heme iron is in the ferrous state, sulfhemoglobin binds to oxygen with an affinity only one-hundredth that of normal hemoglobin. Thus, oxygen delivery to the tissues can be compromised if there is an increase in this abnormal hemoglobin. The bright green sulfhemoglobin compound is so stable that the erythrocyte carries it until the cell is removed from circulation. Ascorbic acid or methylene blue cannot reduce it; however, sulfhemoglobin can combine with carbon monoxide to form carboxysulfhemoglobin. Normal levels of sulfhemoglobin do not exceed 2.2%. Cyanosis is produced at levels exceeding 3–4%.

Sulfhemoglobin has been associated with occupational exposure to sulfur compounds, environmental exposure to polluted air, and exposure to certain drugs. Sulfhemoglobinemia is formed during the oxidative denaturation of hemoglobin and can accompany methemoglobinemia, especially in certain drug- or chemical-induced hemoglobinopathies. Sulfhemoglobin is formed on exposure of blood to trinitrofluorene, acetanilid, phenacetin, and sulfonamides. It also is found to be elevated in severe constipation and in bacteremia with *Clostridium welchii*. Diagnosis of sulfhemoglobinemia is made spectrophotometrically by demonstrating an absorption band at 620 nm. Confirmation testing is done by isoelectric focusing. This is the only abnormal hemoglobin pigment not measured by the cyanmethemoglobin method, which is used to measure hemoglobin concentration.

Carboxyhemoglobin

Carboxyhemoglobin is formed when hemoglobin is exposed to carbon monoxide. Hemoglobin's affinity for carbon monoxide is more than 200 times higher than its affinity for oxygen. Carboxyhemoglobin is incapable of transporting oxygen because CO occupies the same ligand-binding position as O_2 . As is the case with methemoglobinemia, carboxyhemoglobin has a great impact on oxygen delivery because it destroys the molecule's cooperativity. CO also has a pronounced effect on the oxygen dissociation curve, shifting it to the left, resulting in increased affinity and a decreased release of O_2 by remaining normal hemoglobin molecules. High levels of carboxyhemoglobin impart a cherry red color to the blood and skin. However, high levels of carboxyhemoglobin with high levels of deoxyhemoglobin can give blood a purple pink color.

Blood normally carries small amounts of carboxyhemoglobin formed from the carbon monoxide produced during heme catabolism. The normal level of carboxyhemoglobin varies depending on individuals' smoking habits and their environment. City dwellers have higher levels than country

dwellers due to the carbon monoxide produced from automobiles and industrial pollutants in cities.

Acute carboxyhemoglobinemia causes irreversible tissue damage and death from anoxia. Chronic carboxyhemoglobinemia is accompanied by increased oxygen affinity and polycythemia. In severe cases of carbon monoxide poisoning, patients can be treated in hyperbaric oxygen chambers.

Carboxyhemoglobin is commonly measured in whole blood by a spectrophotometric method. Sodium hydrosulfite reduces hemoglobin to deoxyhemoglobin, and the absorbances of the hemolysate are measured at 555 nm and 541 nm. Carboxyhemoglobin has a greater absorbance at 541 nm.

Checkpoint! 6

A 2-year-old child was found to have 15% methemoglobin by spectral absorbance at 630 nm. What tests would you suggest to help differentiate whether this is an inherited or acquired methemoglobinemia, and what results would you expect with each diagnosis?

SUMMARY

Hemoglobin is the intracellular protein of erythrocytes responsible for transport of oxygen from the lungs to the tissues. A fine balance between production and destruction of erythrocytes serves to maintain a steady-state concentration.

Hemoglobin is a globular protein composed of four subunits. Each subunit contains a porphyrin ring with an iron molecule (heme) and a globin chain. The four globin chains are arranged in identical pairs, each composed of two different globin chains. Hemoglobin synthesis is controlled by iron concentration within the cell, activity and synthesis of the first enzyme in the heme synthetic pathway, ALAS, activity of PBGD and globin chain synthesis.

The oxygen affinity of hemoglobin depends on PO_2 , pH, PCO_2 , 2,3-BPG, and temperature. Hemoglobin-oxygen affinity can be graphically depicted by the ODC. When the curve shifts to the right, oxygen affinity decreases; when it shifts to the left, oxygen affinity increases. Increased CO_2 , heat, and acid decrease oxygen affinity; high O_2 concentrations increase oxygen affinity.

Hemoglobin is an allosteric protein, which means that hemoglobin structure and function are affected by other molecules. In particular, the uptake of 2,3-BPG or oxygen can cause conformational changes in the molecule. The structure of deoxyhemoglobin is known as the T structure and that of oxyhemoglobin is known as the R structure.

When hemoglobin is exposed to oxidants or other compounds, the molecule can be altered, which compromises its ability to carry oxygen. High concentrations of these abnormal hemoglobins can cause hypoxia and cyanosis, which can be detected by spectrophotometric methods.

REVIEW QUESTIONS

LEVEL I

- Which of the following types of hemoglobin is the major component of adult hemoglobin? (Objective 4)
 - HbA
 - HbF
 - HbA₂
 - Hb Portland
- One of the most important buffer systems of the body is the: (Objective 5)
 - chloride shift
 - Bohr effect
 - heme-heme interaction
 - ODC
- When iron is depleted from the developing erythrocyte, the: (Objective 7)
 - synthesis of heme is increased
 - activity of ALAS is decreased
 - formation of globin chains stops
 - heme synthesis is not affected
- When the H⁺ concentration in blood increases, the oxygen affinity of hemoglobin: (Objective 3)
 - increases
 - is unaffected
 - decreases
 - cannot be measured
- Which of the following is the correct molecular structure of hemoglobin? (Objective 1)
 - four heme groups, two iron, two globin chains
 - two heme groups, two iron, four globin chains
 - two heme groups, four iron, four globin chains
 - four heme groups, four iron, four globin chains
- 2,3-BPG combines with which type of hemoglobin? (Objectives 3, 5)
 - oxyhemoglobin
 - relaxed structure of hemoglobin
 - deoxyhemoglobin
 - $\alpha\beta$ dimer
- During exercise, the oxygen affinity of hemoglobin is: (Objective 3)
 - increased in males but not females
 - decreased due to production of heat and lactic acid
 - unaffected in those who are physically fit
 - affected only if the duration is more than 1 hour
- Which of the following hemoglobins is *not* normally found in adults? (Objective 4)
 - hemoglobin A
 - hemoglobin A₂
 - hemoglobin F
 - hemoglobin Portland

LEVEL II

- Which of the following hemoglobins is *not* found in the normal adult? (Objective 2)
 - $\alpha_2\beta_2$
 - $\alpha_2\gamma_2$
 - $\alpha_2\delta_2$
 - $\alpha_2\varepsilon_2$
- Which of the following is the major hemoglobin in the newborn? (Objective 2)
 - $\alpha_2\beta_2$
 - $\alpha_2\gamma_2$
 - $\alpha_2\delta_2$
 - $\alpha_2\varepsilon_2$
- A 2-year-old child was found to have 15% methemoglobin by spectral absorbance at 630 nm. What test would you suggest to help differentiate whether this is an inherited or acquired state? (Objective 6)
 - hemoglobin electrophoresis and NADPH reductase determination
 - bone marrow aspiration and examination
 - haptoglobin and sulfhemoglobin determination
 - glycosylated hemoglobin measurement by column chromatography
- A 25-year-old male was found unconscious in a car with the motor running. Blood was drawn and sent to the chemistry lab for spectral analysis. The blood was cherry red in color. What hemoglobin should be tested for? (Objective 6)
 - sulfhemoglobin
 - methemoglobin
 - carboxyhemoglobin
 - oxyhemoglobin
- The oxygen dissociation curve in a case of chronic carboxyhemoglobin poisoning would show: (Objective 7)
 - a shift to the right
 - a shift to the left
 - a normal curve
 - decreased oxygen affinity
- A college student from Louisiana vacationed in Colorado for spring break. He arrived at Keystone Resort area on the first day. The second day he was nauseated and had a headache. He went to the medical clinic at the resort and was told he had altitude sickness. The doctor told him to rest for another 24 hours before participating in any activities. What is the most likely reason he will overcome this condition in the next 24 hours? (Objective 4)
 - His level of HbF will increase to help release more oxygen to the tissues.
 - The amount of carboxyhemoglobin will decrease to normal levels.
 - The levels of ATP in his blood will reach maximal levels.
 - The level of 2,3-BPG will increase and, in turn, decrease oxygen affinity.

REVIEW QUESTIONS (continued)

LEVEL I

9. Which of the following is considered a normal hemoglobin concentration in an adult male? (Objective 6)
 - a. 11.0 g/dL
 - b. 21.0 g/dL
 - c. 15.0 g/dL
 - d. 9.0 g/dL
10. Which of the following plays an important role in hemoglobin-oxygen affinity? (Objective 3)
 - a. 2,3-BPG
 - b. NADPH reductase
 - c. NaHCO_3
 - d. Cl^-

LEVEL II

7. When iron in the cell is replete, the translation of ferritin mRNA is: (Objective 3)
 - a. decreased
 - b. increased
 - c. unaffected
 - d. variable
8. An aerobics instructor just finished an hour of instruction. Blood is drawn from her for a research study and the oxygen dissociation is measured. What would you expect to find? (Objective 4)
 - a. a shift to the left
 - b. a shift to the right
 - c. no shift
 - d. an increased oxygen affinity
9. In the lungs, a hemoglobin molecule takes up two oxygen molecules. What effect will this have on the hemoglobin molecule? (Objectives 5, 8)
 - a. It will increase oxygen affinity.
 - b. It will narrow the heme pockets blocking entry of additional oxygen.
 - c. The hemoglobin molecule will take on the tense structure.
 - d. The center cavity will expand, and 2,3-BPG will enter.
10. A patient with emphysema would be expected to have (Objective 4):
 - a. increased blood pH
 - b. decreased blood pH
 - c. increased oxygen affinity
 - d. decreased 2,3-BPG level

ANSWERS TO CASE STUDY QUESTIONS

Case Summary: Jerry lost a substantial amount of blood from the fractures and surgery. If his hemoglobin had been normal before the accident (14–16 g/dL), he lost about one-half of the volume of his blood. With the loss of this much blood, he also lost a substantial amount of iron. Although he was given iron supplements, it will take time for his hemoglobin to reach normal again. He had symptoms of anemia with lethargy and pallor. They result from a loss of hemoglobin and, hence, a decrease in the amount of oxygen delivered to the tissue. The blood transfusions will bring his hemoglobin concentration up more rapidly and give his body the energy it needs to repair itself.

Question:

1. If Jerry is iron deficient, what is the effect on synthesis of ALAS, transferrin receptor, and ferritin?

Explanation:

The iron regulatory protein (IRP) is the primary physiologic iron sensor and plays a role in regulating the synthesis of molecules involved in hemoglobin synthesis. Lack of iron results in decreased synthesis of ALAS, increased synthesis of transferrin receptor, and decreased synthesis of ferritin.

Question:

2. What was the rationale for giving Jerry the iron?

Explanation:

Because Jerry had lost the blood through bleeding, he also lost a substantial amount of iron. Even if body storage of iron is normal, iron supplements are often given, in this case to provide the iron needed for rapid and increased hemoglobin synthesis.

Question:

3. Explain why Jerry may have these symptoms.

Explanation:

Jerry's hemoglobin was very low, which means that his tissues were not getting the oxygen they needed. This leads to a decrease in metabolic activity and, consequently, a decrease in energy. Pallor is a classic sign of anemia because blood is preferentially circulated to critical areas of the body including the brain, heart, and so on. The skin's blood supply decreases, causing a loss of the pinkish color of the skin, especially apparent in Caucasians.

Question:

4. Explain why Jerry may have had more energy after the transfusions.

Explanation:

The transfusions boosted Jerry's hemoglobin level and, thus, increased the amount of oxygen that could be transported to the tissues for critical metabolic processes.

ANSWERS TO CHECKPOINTS

Checkpoint! 1

Describe the quaternary structure of a molecule of hemoglobin. How may a mutation in one of the globin chains at the subunit interaction site affect hemoglobin function?

Answer

Hemoglobin is composed of four subunits, each of which is composed of a heme group nestled in a globin chain. There are two pairs of globin chains. The four subunits are held together by salt bonds, hydrophobic contacts, and hydrogen bonds in a tetrahedral formation giving the hemoglobin molecule a nearly spherical shape. An oxygen molecule can attach to each of the four subunits. In the deoxyhemoglobin form, 2,3-DPG combines in the central cavity of the molecule.

Because there is considerable movement between chains when ligands such as oxygen bind to a hemoglobin molecule, mutations in

globin genes may affect subunit or dimer pair interactions. These could result in altered oxygen affinity or hemoglobin instability.

Checkpoint! 2

What globin chains are produced in the adult?

Answer

The chains, produced are α , β , δ , γ . The chains pair up to form HbA, HbA₂ and HbF.

Checkpoint! 3

What are the names and globin composition of the embryonic, fetal, and adult hemoglobins?

Answer

Embryonic	$\xi_2\gamma_2$	Hb Portland
	$\xi_2\varepsilon_2$	Hb Gower I
	$\alpha_2\varepsilon_2$	Hb Gower II

Fetal	$\alpha_2\gamma_2$	HbF (also found in adult)
Adult	$\alpha_2\beta_2$	HbA
	$\alpha_2\delta_2$	HbA ₂

Checkpoint! 4

A patient has an anemia caused by a shortened RBC life span (hemolysis). How would this affect the HbA_{1c} measurement?

Answer

The red cells are being destroyed at an increased rate and are being replaced with new cells that have no HbA_{1c}. The red cell lifespan decreases and the amount of HbA_{1c} depends on a time-averaged concentration of glucose with older cells having more HbA_{1c} than younger cells. The HbA_{1c} is not a good indication of glucose control in this case. This same phenomenon also could occur in patients treated with erythropoietin. Additionally, if abnormal forms of hemoglobin are present such as in sickle cell anemia (HbS), there is no HbA and therefore there is no HbA_{1c}.

Checkpoint! 5

What factors influence an increase in the amount of oxygen delivered to tissue during an aerobic workout?

Answer

During an aerobic workout, a buildup of lactic acid and CO₂ occurs in the tissues. This leads to a shift to the right in affinity of hemoglobin for oxygen, resulting in an increase of oxygen delivered to the tissues.

Checkpoint! 6

A 2-year-old child was found to have 15% methemoglobin by spectral absorbance at 630 nm. What tests would you suggest to help differentiate whether this is an inherited or acquired methemoglobinemia, and what results would you expect with each diagnosis?

Answer

Tests that should be done include NADPH-reductase activity and hemoglobin electrophoresis.

The Leukocyte

CHAPTER OUTLINE

- ▶ Objectives—Level I and Level II
- ▶ Key terms
- ▶ Background basics
- ▶ Case study
- ▶ Overview
- ▶ Introduction
- ▶ Leukocyte concentration in the peripheral blood

- ▶ Leukocyte surface markers
- ▶ Leukocyte function

Part I: Granulocytes and Monocytes

- ▶ Neutrophils
- ▶ Eosinophils
- ▶ Basophils
- ▶ Monocytes

Part II: Lymphocytes

- ▶ Lymphocytes
- ▶ Summary
- ▶ Review questions
- ▶ References

The Leukocyte

Rebecca J. Laudicina, Ph.D.
Yasmen Simonian, Ph.D.

■ OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. Identify terms associated with increases and decreases in leukocytes.
2. Differentiate morphologically the leukocyte precursors found in the proliferative compartment of the bone marrow.
3. Compare and contrast the development including distinguishing maturation and cell features of the granulocytic, monocytic-macrophage, and lymphocytic cell lineages.
4. Compare and contrast the morphologic and other distinguishing cell features of each of the leukocytes found in the peripheral blood.
5. Compare and contrast the function of each of the leukocytes found in the peripheral blood.
6. Summarize the process of neutrophil migration and phagocytosis.
7. List the adult reference ranges for the leukocytes found in the peripheral blood.
8. Calculate absolute cell counts from data provided.
9. Differentiate absolute values and relative values of cell count data.
10. List causes/conditions that increase or decrease absolute numbers of individual leukocytes found in the peripheral blood.
11. Compare and contrast pediatric and newborn reference ranges and adult reference ranges.
12. Explain immunoglobulin diversity.

■ OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. Summarize the kinetics of the granulocytic, monocytic-macrophage, and lymphocytic cell lineages.
2. Describe the processes that permit neutrophils to leave the peripheral blood circulation and move to a site of infection and propose how defects in these processes affect the body's defense mechanism.
3. Compare and contrast the immunologic features and functions of each of the leukocytes found in the peripheral blood.
4. Summarize lymphocyte membrane characteristics and molecular changes used to differentiate subtypes.
5. Differentiate between polyclonal and monoclonal antibodies and discuss each type in relationship to a patient's clinical condition.

OBJECTIVES—LEVEL II (continued)

6. Compare and discriminate morphological features of Russell bodies, Mott cells, and flame cells.
7. Design systems to evaluate laboratory data of leukocytes for error detection.
8. Formulate pathways to correlate laboratory data of leukocytes with clinical knowledge of the patient.

KEY TERMS

Adaptive immune response
 Agranulocytosis
 Antigen-presenting cells (APC)
 Azurophilic granules
 Barr body (drumstick)
 B cell receptor (BCR)
 Charcot-Leyden crystals
 Cell-mediated immunity
 Chemokines
 Chemotaxis
 Degranulation
 Diapedesis
 Drumstick (Barr body)
 Dutcher bodies
 Erythrophagocytosis
 Flame cell
 Granulocytosis
 Humoral immunity
 Immune response (IR)
 Immunoblast
 Immunoglobulin
 Innate immune response
 Large granular lymphocyte (LGL)
 Leukocytosis
 Leukopenia
 Memory cell
 Monoclonal gammopathies
 Monocyte-macrophage system
 Mononuclear phagocyte (MNP) system
 Mott cell
 Natural killer (NK) cell
 Neutrophilia
 Neutropenia
 Pathogen-associated molecular pattern (PAMP)
 Pattern recognition receptors (PRR)
 Phagocytosis
 Plasma cell
 Plasmacytoid lymphocyte
 Reactive lymphocyte
 Russell bodies
 T cell receptor (TCR)

BACKGROUND BASICS

In addition to the basics from previous chapters, it is helpful to have a basic understanding of immunology (immune system and function), biochemistry (proteins, carbohydrates, and lipids), algebra, the use of percentages, ratios and proportions, and the metric system.

To maximize your learning experience, you should review these concepts from previous chapters before starting this unit of study:

Level I

- ▶ Identify components of the cell and describe their function.
- ▶ Summarize the function of growth factors and the hierarchy of hematopoiesis.
- ▶ Describe the structure and function of the hematopoietic organs.

Level II

- ▶ List the growth factors and identify their function in leukocyte differentiation and maturation.

CASE STUDY

We will refer to this case study throughout the chapter.

Harry, a 30-year-old male in good physical condition, had a routine physical examination as a requirement for purchasing a life insurance policy. A CBC was ordered with the following results: Hb 15.5 g/dL (155 g/L); hct 47% (0.47 L/L); RBC count $5.2 \times 10^{12}/L$; platelet count $175 \times 10^9/L$; and WBC count $12 \times 10^9/L$. Consider how you could explain these results in a healthy male.

► OVERVIEW

Leukocytes develop from the pluripotential hematopoietic stem cell in the bone marrow. They are involved in the defense against foreign pathogens or antigens. In the presence of infection or inflammation, the number of these cells can increase and can show morphologic changes. Thus, an important screening test for a wide variety of conditions is the leukocyte (WBC) count. This chapter is a study of the normal differentiation and maturation of leukocytes. Each type of leukocyte is discussed including cell morphology, concentration, and function. Because of the length of the chapter, it is divided into two parts: Part I includes the granulocytes and monocytes, and Part II covers lymphocytes. The lymphocyte section is divided into T, B, and NK cell development and function. The synthesis and structure of immunoglobulins, lymphocyte receptors, and cell antigens are described with attention to the use of these markers in identifying lymphocyte types.

► INTRODUCTION

Leukocytes (white blood cells, WBC) are essential cellular components of the peripheral blood. With the exception of T lymphocytes, leukocyte precursors differentiate, proliferate, and mature in the bone marrow. Mature leukocytes are released into the peripheral blood where they circulate briefly until they move into the tissues in response to stimulation. They perform their function of host defense primarily in the tissues. The neutrophil, band neutrophil, eosinophil, basophil, monocyte, and lymphocyte are the leukocytes normally found in the peripheral blood of children and adults.

The era of morphologic hematology began in 1877 with Paul Ehrlich's discovery of a triacidic stain.¹ The stain allowed differentiation of leukocytes on fixed blood smears by different staining properties of the components of the cells. Wright stain, a Romanowsky-type stain, is used to stain the cellular components of blood and bone marrow that are smeared on glass slides. Methylene blue and eosin are the major components of the Wright stain. Basic cellular elements react with the acidic dye, eosin, and acidic cellular elements react with the basic dye, methylene blue. The eosinophil contains large amounts of basic protein in its granules, which react with the eosin dye, hence, the name *eosinophil*. The basophil has granules that are acidic and react with the basic dye, methylene blue, hence, the name *basophil*. The neutrophil granules react with both acid and basic components of the stain, giving the cell cytoplasm a neutral to pinkish appearance. The nuclear DNA and cytoplasmic RNA of cells are acidic and pick up the basic stain, methylene blue. Hemoglobin is a basic cellular component of red blood cells and reacts with the acid dye, eosin, and stains orange red to salmon pink. The eosinophil, basophil, and neutrophil are polymorphonuclear and contain many granules and thus are classified as granulocytes. Monocytes

and lymphocytes are mononuclear cells and contain small numbers of fine granules or no granules. The monocyte cytoplasm is a bluish gray, and the lymphocyte cytoplasm is sky blue.

Leukocytes were first observed by William Hewson, the father of hematology, in the eighteenth century. In the nineteenth century, the studies of inflammation and bacterial infection intensified interest in leukocytes.² Many researchers studied the similarity of pus cells in areas of inflammation and the leukocytes of the blood. Ilya Metchnikov observed the presence of nucleated blood cells surrounding a thorn introduced beneath the skin of a larval starfish.¹

Many of Ehrlich's observations and Metchnikov's experiments provided the groundwork for understanding the leukocytes as defenders against infection. Ehrlich recognized that variations in numbers of leukocytes accompanied specific pathologic conditions, such as eosinophilia in allergies, parasitic infections, and dermatitis as well as neutrophilia in bacterial infections.

It is now recognized that the leukocyte function of fighting infection includes two separate but interrelated events: phagocytosis (innate immune response) and the development of the adaptive immune response. Granulocytes and monocytes are responsible for phagocytosis while monocytes and lymphocytes interact to produce an effective adaptive immune response. Eosinophils and basophils interact in mediating allergic and hypersensitivity reactions.

► LEUKOCYTE CONCENTRATION IN THE PERIPHERAL BLOOD

Leukocytes develop from pluripotential hematopoietic stem cells (HSC) in the bone marrow. On specific hematopoietic growth factor stimulation, the stem cell proliferates and differentiates into the various types of leukocytes: granulocytes (neutrophils, eosinophils, basophils), monocytes, and lymphocytes. On maturation, these cells can be released into the peripheral blood or remain in the bone marrow storage pool until needed.

The total peripheral blood leukocyte count is high at birth, $9\text{--}30 \times 10^9/\text{L}$. A few immature granulocytic cells (myelocytes, metamyelocytes) can be seen in the circulation the first few days of life; however, immature leukocytes are not present in the peripheral blood after this age except in certain diseases. Within the first week, the leukocyte count drops to $5\text{--}21 \times 10^9/\text{L}$. A gradual decline continues until the age of 8 years at which time the leukocyte concentration averages $8 \times 10^9/\text{L}$. The Bogalusa Heart Study found that in children between the ages of 5 and 17, females had, on the average, leukocyte counts $0.5 \times 10^9/\text{L}$ higher than males.³ Adult values average from 4.5 to $11.0 \times 10^9/\text{L}$. Although reports on the reference interval for older adults have been conflicting, it is now generally accepted that total leukocyte counts in adults do not decline with age. The concentration of neutrophils and lymphocytes remains constant in the adult years.⁴

Various physiologic and pathological events affect the concentrations of leukocytes. Pregnancy, time of day, and activity level affect the WBC concentration. Infections and immune-regulated responses cause significant changes in leukocytes. Many other pathologic disorders also can cause quantitative and/or qualitative changes in white cells. Considerable heterogeneity in leukocyte concentration has been found among racial, ethnic, and sex subgroups, suggesting the need for unique reference intervals for specific populations.⁵

Thus, when evaluating cell count data, knowing the patient's age, sex, and possibly race/ethnicity as well as previous cell counts on the same patient is helpful. It also is helpful to assess the accuracy of cell counts by correlating them with the patient's clinical history. Additional testing can be done as a result of abnormalities in the WBC count. Changes associated with diseases and disorders will be discussed in subsequent chapters on leukocytes.

CASE STUDY (continued from earlier in this chapter)

The CBC results on Harry were Hb 15.5 g/dL; Hct 0.47 L/L; RBC count $5.2 \times 10^{12}/L$; platelet count $175 \times 10^9/L$; and WBC count $12 \times 10^9/L$.

1. Are any of these results outside the reference range? If so, which one(s)?
2. If this were a newborn, would you change your evaluation? Why?

An increase or decrease in the total number of leukocytes can be caused by an altered concentration of all leukocyte types or, more commonly, by an alteration in one specific type of leukocyte. For this reason, an abnormal total WBC count should be followed by a leukocyte differential count. A manual leukocyte differential count enumerates each leukocyte type within a total of 100 leukocytes. The differential results are reported as the percentage of each type counted. To accurately interpret whether an increase or decrease in cell types exists, however, it is necessary to calculate the absolute concentration using the results of the WBC count and the differential (relative concentration) in the following manner:

$$\text{Differential count (in decimal form)} \times \text{WBC count} \\ \times (10^9/L) = \text{Absolute cell count} \times (10^9/L)$$

The usefulness of this calculation is emphasized in the following example. Each of two different blood specimens had a relative lymphocyte concentration of 60%. The total leukocyte count of one was $3 \times 10^9/L$ and of the other was $9 \times 10^9/L$. The relative lymphocyte concentration on both specimens appears elevated (reference range is 25–35%); however, calculation of the absolute concentration (reference range 1.0 to $4.8 \times 10^9/L$) shows that only one specimen has an absolute increase in lymphocytes; the other is within the reference range:

$$0.6 \times (3 \times 10^9/L) = 1.8 \times 10^9/L \text{ (within reference range)} \\ 0.6 \times (9 \times 10^9/L) = 5.4 \times 10^9/L \text{ (increased)}$$

The neutrophil is the most numerous leukocyte in the adult peripheral blood, composing 40–80% of total leukocytes ($1.8\text{--}7 \times 10^9/L$). At birth, the neutrophil concentration is about 50–60%; this level drops to ~30% by 4–6 months of age. After 4 years of life, the concentration of neutrophils gradually increases until adult values are reached at ~6 years of age. Most peripheral blood neutrophils are mature segmented forms; however, a few non-segmented forms (bands) (up to 5%) can be seen in normal specimens. Most variations in the total leukocyte count are due to an increase or decrease in neutrophils.

Peripheral blood eosinophil concentrations are maintained at 0–5% (up to $0.4 \times 10^9/L$) throughout life. It is possible that no eosinophils are seen on a 100-cell differential; however, careful scanning of the entire smear should reveal an occasional eosinophil.

Basophils are the least plentiful cells in the peripheral blood, 0–1% (up to $0.2 \times 10^9/L$). It is common to find no basophils on a 100-cell differential; the finding of an absolute basophilia, however, is very important because it can indicate the presence of a hematologic malignancy.

Monocytes usually compose 2–10% ($0.1\text{--}0.8 \times 10^9/L$) of circulating leukocytes. Occasionally, reactive lymphocytes resemble monocytes, possibly giving even the experienced clinical laboratory scientist difficulty in performing the differential.

The lymphocyte concentration varies with the age of the individual. About 30% of the leukocytes at birth are lymphocytes. This increases to ~60% at about 4–6 months of age and remains at this level until ~4 years of age. Then a gradual decline occurs until a mean level of ~34% at age 21 is reached. The concentration in adults ranges from 25% to 35% ($1.0\text{--}4.8 \times 10^9/L$).

▶ LEUKOCYTE SURFACE MARKERS

Leukocytes as well as other cells express a variety of molecules on their surface. These surface molecules can be used as markers to help identify the lineage of a cell as well as subsets within the lineage. These markers can be identified by reactions with specific monoclonal antibodies. A nomenclature system was developed to identify antibodies with similar characteristics using cluster of differentiation (CD) and a number. The CD designation is now used to identify the molecule recognized by the monoclonal antibody. In addition to using CD markers to identify cell lineage, some surface markers are used to identify stages of maturation as they are transiently expressed at a specific stage of development. Other markers are expressed only after the cell has been stimulated and thus can be used as a marker of cell activation. Cell markers are very helpful in differentiating neoplastic hematologic disorders. Surface markers can be identified by flow cytometry or cytochemical stains.

**CASE STUDY** (continued from earlier in this chapter)

A leukocyte differential was performed with the following results:

Neutrophils	58%
Lymphocytes	32%
Monocytes	6%
Eosinophils	3%
Basophils	1%

3. Are any of the WBC concentrations outside the reference interval (relative or absolute)?

▶ LEUKOCYTE FUNCTION

The leukocytes' primary function is to protect the host from infectious agents or pathogens. The innate system (natural) with the acquired (adaptive) or specific immune system is the body's major defense system. The **innate immune response** (innate IR) is the body's first response to common classes of invading pathogens. When a pathogen enters the body, it must be recognized as foreign (nonself) by soluble proteins (e.g., antibody or complement) and leukocyte cell-surface receptors (Fc γ R, CR1, CR3) before specific effector mechanisms can eliminate it. The leukocyte receptors that participate in the innate IR are always available and do not require cell activation to be expressed. Other leukocyte receptors recognize structures that are shared by different pathogens or common alterations that the pathogen makes to the body's cells (known as **pathogen-associated molecular patterns [PAMP]**). Examples of PAMP include bacterial lipopolysaccharide, viral RNA and bacterial DNA. Receptors for PAMP are sometimes referred to as **pattern recognition receptors (PRR)**.⁶ Once a pathogen has been recognized, effector cells can attack, engulf, and kill it. Neutrophils, monocytes, and macrophages play a major role in the innate immune system. The innate IR is rapid but limited.

The **adaptive immune response** (adaptive IR) is initiated in lymphoid tissue where pathogens encounter lymphocytes, the major cells involved in this response. The lymphocytes recognize antigens on the pathogens (or antigens presented by antigen-presenting cells [APC]) and become activated. During lymphopoiesis, lymphocyte precursor cells are capable of rearranging their antigen receptor genes (immunoglobulin light and heavy chain loci in B cells and T cell receptor polypeptides [$\alpha\beta$ - or $\delta\gamma$ -loci] in T cells). This results in a subset of mature T and B lymphocytes (effector cells) that express receptors for the specific antigens of various pathogens. Thus, the effector cells mount a highly specialized defense. The successful adaptive IR eliminates the pathogen. This IR is slower to develop than the innate IR, but it provides long-lasting immunity (memory) against the pathogen with which it interacts.

PART I

GRANULOCYTES AND MONOCYTES

▶ NEUTROPHILS

Neutrophils are the most numerous leukocyte in the peripheral blood. They are easily identified on Romanowsky-stained peripheral blood smears as cells with a segmented nucleus and fine pinkish granules.

DIFFERENTIATION, MATURATION, AND MORPHOLOGY

Leukocytes develop from HSC in the bone marrow. The common myeloid progenitor (CMP) cell gives rise to the committed precursor cells for the neutrophilic, eosinophilic, basophilic, and monocytic lineages. The common lymphoid progenitor (CLP) cell gives rise to committed precursor cells for T, B, and natural killer (NK) lymphocytes⁷. When lineage commitment has occurred, maturation begins. Myeloid, monocytic, and lymphoid elements go through unique maturation processes. The myeloid elements include the granulocytes and their precursors' colony-forming unit—granulocyte monocyte (CFU-GM), colony-forming unit-granulocyte (CFU-G), the monocytic elements including monocytes and their precursors (CFU-GM, colony-forming unit-monocyte [CFU-M]), and the lymphoid elements including the lymphocytes and their precursors (CFU-T/NK, CFU-T, and CFU-B).

Normally, the life span of the neutrophil is spent in three compartments: the bone marrow (site of differentiation, proliferation, and maturation), the peripheral blood (where they circulate for a few hours), and the tissues (where they perform their function of host defense). Neutrophilic production is primarily regulated by three cytokines, interleukin-3, granulocyte monocyte-colony-stimulating factor, and granulocyte-colony-stimulating factor (IL-3, GM-CSF, G-CSF). GM-CSF and G-CSF also regulate survival and functional activity of mature neutrophils. The neutrophil undergoes six morphologically identifiable stages in the process of maturation. The stages from the first morphologically identifiable cell to the mature segmented neutrophil include (1) myeloblast, (2) promyelocyte, (3) myelocyte, (4) metamyelocyte, (5) band or unsegmented neutrophil, and (6) segmented neutrophil or polymorphonuclear neutrophil (PMN).

During the maturation process, obvious progressive changes occur in the nucleus. The nucleoli disappear, the chromatin condenses, and the once round nuclear mass indents and eventually segments. These nuclear changes are accompanied by distinct cytoplasmic changes. The scanty, agranular, basophilic cytoplasm of the earliest stage is gradually replaced by pink-to-neutral-staining granular cytoplasm in the mature differentiated stage (Figures 1 ■ and 2 ■, Table 1 ⚙). There are four

FIGURE 1 Stages of neutrophil development. Compare the chromatin pattern of the nucleus and the cytoplasmic changes in the various stages. **a.** myeloblast: nucleus has fine chromatin and nucleoli; cytoplasm is agranular; **b.** promyelocyte: nucleus has coarser chromatin, nucleoli are still visible, and there are primary granules in the cytoplasm; **c.** myelocyte: nuclear chromatin is condensed and nucleoli are not visible; secondary granules give the cytoplasm a pinkish color; **d.** metamyelocyte: nucleus is kidney shaped and cytoplasm is pinkish; **e.** band (arrow) and segmented neutrophil: the nuclear chromatin is condensed and the cytoplasm is pinkish; **f.** compare the nuclear and cytoplasmic features of these maturing neutrophilic cells. From left are a very early band, myelocyte, promyelocyte, myeloblast, and very early band; above the myeloblast are 2 segmented neutrophils. (Bone marrow; Wright-Giemsa stain; 1000× magnification)

■ **FIGURE 2** In the center are a myelocyte (top) and a promyelocyte (bottom). Note the changes in the nucleus and cytoplasm. The myelocyte has a clear area next to the nucleus, which represents the Golgi apparatus. Note the azurophilic granules in the promyelocyte. Also present are two bands and in the top right corner a metamyelocyte. Orthochromatic normoblasts are present. (Bone marrow, Wright-Giemsa stain, 1000× magnification)

subsets of granules/organelles (primary, secondary, secretory, and tertiary) containing different constituents produced at various times during neutrophil development. The diversity of granule content is due to differences in the timing of biosynthesis of the granule constituents and is regulated by different transcription factors. Leukopoiesis is an amazing process generating $1-5 \times 10^9$ cells per hour or 10^{11} cells per day.⁷ However, the marrow has the capacity to significantly increase the neutrophil production over this baseline level in response to inflammatory stimuli. The morphology of the stages of maturation is discussed below.

Myeloblast

The myeloblast (Table 1, Figures 1a and 3■) is the earliest morphologically recognizable neutrophil precursor. The myeloblast size varies from 14 to 20 μm in diameter, and it has a high nuclear to cytoplasmic (N:C) ratio. The nucleus is usually round or oval and contains a delicate, lacy, evenly stained chromatin. One to five nucleoli are visible. The small amount of cytoplasm is agranular, staining from deep blue to a lighter blue. A distinct unstained area adjacent to the nucleus representing the Golgi apparatus can be seen. These cells can stain faintly positive for peroxidase and esterase enzymes and for lipids (Sudan black B) although granules are not evident by light microscopy. Staining reactions with peroxidase and esterase help differentiate myeloblasts from monoblasts and lymphoblasts. CD markers also aid in identifying the lineage of blasts. Myeloblast CD markers include CD34, CD33, CD13, CD38, and CD45RA.⁸

Promyelocyte

The promyelocyte/progranulocyte (Table 1, Figures 1b and 2) varies in size from 15 to 21 μm . The nucleus is still quite large, and the N:C ratio is high. The nuclear chromatin

structure, although coarser than that of the myeloblast, is still open and rather lacy, staining purple to dark blue. The color of the nucleus varies somewhat depending on the stain used, and several nucleoli can still be visible. The basophilic cytoplasm is similar to that of the myeloblast but is differentiated by the presence of prominent, reddish-purple primary granules, also called nonspecific or **azurophilic granules**, which are synthesized during this stage. The granules can be shown by cytochemical techniques to contain peroxidase and a number of antimicrobial compounds. Contents of primary granules are listed in Table 2♣.

Myelocyte

The myelocyte (Table 1, Figures 1c, 2, and 3) varies in size from 12 to 18 μm . The nucleus is reduced in size due to nuclear chromatin condensation and appears more darkly stained than the chromatin of the promyelocyte. Nucleoli can be seen in the early myelocyte but are usually indistinct. The myelocyte nucleus can be round, oval, slightly flattened on one side, or slightly indented.⁹ The clear light area next to the nucleus, representing the Golgi apparatus, can still be seen. The myelocyte goes through two to three cell divisions; this is the last stage capable of mitosis. The early myelocyte has a more basophilic cytoplasm; the later more mature myelocyte has a more neutral to pink cytoplasm, and the N:C ratio is decreased.

The hallmark for the myelocyte stage is the appearance of specific or secondary granules. Synthesis of peroxidase-positive primary granules is halted, and the cell switches to synthesis of peroxidase-negative secondary granules. Secondary granules are detected first near the nucleus in the Golgi apparatus. This has sometimes been referred to as the *dawn of neutrophilia*. These neutrophilic granules are small, sandlike

■ **FIGURE 3** At about nine o'clock in the central group of cells is a pronormoblast. At about five o'clock is a myeloblast. Note that the myeloblast has a more lacy, lighter-staining chromatin with distinct nucleoli and bluish cytoplasm. The normoblast chromatin is more smudged with indistinct nucleoli and very deep blue-purple cytoplasm. Also pictured are bands, metamyelocyte, myelocytes, basophilic normoblast, polychromatophilic normoblast, and orthochromatic normoblast. (Bone marrow, Wright-Giemsa stain, 1000× magnification)

★ TABLE 1

Characteristics of Cells in the Maturation Stages of the Neutrophil

Cell Stage (% in bone marrow)	Size (μm)	Nucleus	Cytoplasm	N:C ratio	Granules	CD Markers	Maturation Transit Time
Myeloblast (0.2–1.5) (see Fig. 1a)	14–20	Round or oval; delicate, lacy chromatin; nucleoli	Deep blue	High	Absent	CD13, CD33, CD34, CD38	~1 day
Promyelocyte (2–4) (see Fig. 1b)	15–21	Round or oval, chromatin lacy but more condensed than blast; nucleoli present	Deep blue	High but less than myeloblast	Large, reddish-purple (azurophilic) primary or nonspecific granules	CD33, CD38	1–3 days
Myelocyte (8–16) (see Fig. 1c)	12–18	Round to oval; chromatin more condensed; nucleoli usually absent	Light pink; can have patches of blue	Decreased from promyelocyte	Small pinkish-red specific granules; azurophilic granules; secretory vesicles		1–5 days
Metamyelocyte (9–25) (see Fig. 1d)	10–18	Chromatin condensed; stains dark purple; kidney bean shape to oval	Pink	Decreased	Predominance of small pinkish red specific granules; some azurophilic granules present; secretory vesicles		0.5–4 days
Band (nonsegmented) (9–15) (see Fig. 1e)	9–15	Chromatin condensed at ends of horseshoe shaped nucleus; stains dark purple	Pink	Decreased	Abundant small, pinkish-red specific granules; some azurophilic granules present; secretory vesicles; tertiary granules		0.5–4 days
Polymorphonuclear (segmented) (6–12) (see Fig. 1f)	9–15	Nucleus segmented into 2–4 lobes; chromatin condensed; stains dark purple	Pink	Decreased	As in band	CD15, CD16, CD11b/CD18	1–5 days

granules with a pink-red to pink-violet tint. Like the primary granules, the secondary granules are surrounded by a phospholipid membrane that stains with Sudan black B. Large primary azurophilic granules can still be apparent, but their concentration decreases with each successive cell division

because their synthesis has ceased. Their ability to pick up stain also decreases with successive mitotic divisions. A partial list of secondary granule contents is found in Table 2.⁹

Secretory vesicles are scattered throughout the cytoplasm of myelocytes, metamyelocytes, band neutrophils, and

segmented neutrophils (Table 2).¹⁰ Secretory vesicles are specialized vesicles formed by endocytosis in the later stages of neutrophil maturation; they contain plasma proteins including albumin. The secretory vesicles fuse with the plasma membrane on neutrophil stimulation, increasing the neutrophil surface membrane and expression of adhesion and chemotactic receptors. Tertiary or gelatinase-containing granules are synthesized mainly during the metamyelocyte and band neutrophil stages.⁹

Metamyelocyte

The metamyelocyte (Table 1, Figures 1d and 3) varies in size from 10 to 18 μm in diameter. Traditionally, the characteristic most apparently differentiating it from the myelocyte was nuclear indentation, giving the nucleus a kidney bean shape. More recent research suggests that nuclear shape is variable and is not the most reliable identifying feature. Care should be taken to review other cellular features such as the degree of the chromatin clumping, color of the cytoplasm, predominant granules present, and the cell size. The nuclear chromatin is coarse and clumped and stains dark purple. Nucleoli are not visible. The cytoplasm is a neutral pink color with a predominance of secondary and secretory granules. The ratio of secondary to primary granules is $\sim 2:1$. The metamyelocyte's cytoplasm resembles the color of the cytoplasm of a fully mature neutrophil.⁹

Band Neutrophil

The band neutrophil, also called *nonsegmented neutrophil*, is slightly smaller in diameter, 9–15 μm , than the metamyelocyte. The metamyelocyte becomes a band when the indentation of the nucleus is more than half the diameter of the hypothetical round nucleus (Table 1, Figure 1e). The indentation gives the nucleus a horseshoe shape. The chromatin displays increased condensation at either end of the nucleus. The cytoplasm appears pinkish, resembling both the previous stage and the fully mature segmented forms. The band neutrophil is the first stage that normally is found in the peripheral blood. All four types of granules (primary, secondary, secretory, and tertiary) can be found at this stage,

but primary granules are not usually differentiated with Wright's stain in bands

Segmented Neutrophil

Although similar in size to the band form, 9–15 μm , the PMN is recognized, as its name implies, by a segmented nucleus with two or more lobes connected by a thin nuclear filament (Table 1, Figures 1e, f). The chromatin is condensed and stains a deep purple black. Most neutrophils have three or four nuclear lobes, but a range of two to five lobes is possible. Fewer than three lobes are considered hyposegmented. A cell with more than five lobes is considered abnormal and referred to as a *hypersegmented neutrophil*. Observing three or more five-lobed neutrophils in a 100-cell differential is also considered hypersegmentation. Nuclear lobes are often touching or superimposed on one another, sometimes making it difficult to differentiate the cell as a band or PMN.

Individual laboratories and agencies such as the Clinical and Laboratory Standards Institute (CLSI) have outlined criteria for differentiating bands from PMNs in manual differentials.¹¹ A *band* is defined as having a nucleus with a connecting strip or isthmus with parallel sides and having width enough to reveal two distinct margins with nuclear chromatin material visible between the margins. If a margin of a given lobe can be traced as a definite and continuing line from one side across the isthmus to the other side, a filament is assumed to be present although it is not visible. If a clinical laboratory scientist is not sure whether a neutrophil is a band form or a segmented form, it is arbitrarily classified as a segmented neutrophil. From a traditional clinical viewpoint, determining whether young forms of neutrophils (band forms and younger) are increased has been useful.⁹ However, differentials performed by automated hematology instruments do not differentiate between band and segmented neutrophils. Band neutrophils are fully functional phagocytes and often are included with the total neutrophil count.¹¹

The cytoplasm of the mature PMN stains a pinkish to clear color. It contains many secondary granules, tertiary granules, and secretory vesicles. Primary granules are pres-

★ TABLE 2

Neutrophil Granule Contents

Primary Granules	Secondary Granules	Secretory Vesicles	Tertiary Granules
Myeloperoxidase	Lactoferrin	Alkaline phosphatase	Gelatinase
Lysozyme	Lysozyme	Complement receptor 1	Lysozyme
Cathepsin G, B, and D	Histaminase	Cytochrome b ₅₅₈	
Defensins (group of cationic proteins)	Collagenase		
Bactericidal permeability increasing protein (BPI)	Gelatinase		
Esterase N	Heparinase		
Elastase			

ent, but because of their loss of staining quality, might not be readily evident. The ratio of secondary to primary granules remains ~2:1.

In addition to protein material found in neutrophilic granules, lipids and carbohydrates also can be found. About one-third of the lipids in neutrophils consists of phospholipids. Much of the phospholipid is present in the plasma membrane or membranes of the various granules. Cholesterol and triglycerides constitute most of the nonphospholipid neutrophil lipid. Cytoplasmic nonmembrane lipid bodies can also be found in neutrophils; their role in cell function is unclear. Lipid material is likewise found in neutrophilic precursors. A cytochemical stain for lipids, Sudan black B, is used to differentiate myeloid precursors from lymphoid precursors. Glycogen is also found in both neutrophils and some myeloid precursors. Neutrophils sometimes function in hypoxic conditions as at an abscess site and obtain energy by glycolysis, utilizing glycogen. The periodic acid-Schiff (PAS) stain is used to detect glycogen in cells. CD markers on the neutrophil include CD15, CD16, and CD11b/CD18.⁸

In females with two X chromosomes or males with XXY chromosomes (Klinefelter syndrome), one X chromosome is randomly inactivated in each somatic cell of the embryo and remains inactive in all daughter cells produced from that cell. The inactive X chromosome appears as an appendage of the neutrophil nucleus and is called a **drumstick** or an *X chromatin body* (**Barr body**) (Figure 4■). The number of chromatin bodies detected in the neutrophil is one less than the number of X chromosomes present; however, chromatin bodies are not visible in every neutrophil. The X chromatin bodies can be identified in 2–3% of the circulating PMNs of 46, XX females, and Klinefelter males.⁹

✓ Checkpoint! 1

An adult patient's peripheral blood smear revealed many myelocytes, metamyelocytes, and band forms of neutrophils. Is this a normal finding?

■ **FIGURE 4** The segmented neutrophil on the right has an X chromatin body (arrow). (Peripheral blood, Wright-Giemsa stain, 1000× magnification)

DISTRIBUTION, CONCENTRATION, AND KINETICS

The kinetics of a group of cells—their production, distribution, and destruction—also is described as the *cell turnover rate*. For the neutrophil, kinetics follows the movement of the cell through a series of interconnected compartments (the marrow, blood, and tissues).

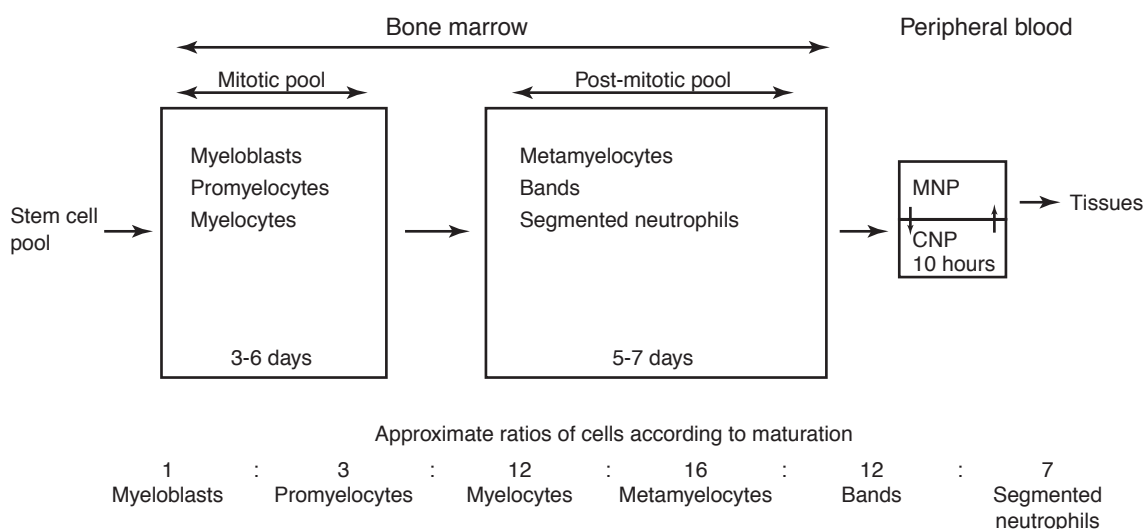

Bone Marrow

Neutrophils in the bone marrow can be divided into two pools: the mitotic pool and the postmitotic pool (Figure 5■). The *mitotic pool*, also called the *proliferating pool*, includes cells capable of DNA synthesis: myeloblasts, promyelocytes, and myelocytes. Cells spend about 3–6 days in this proliferating pool undergoing four to five cell divisions. Two to three of these divisions occur in the myelocyte stage, but the number of cell divisions at each stage is variable. The postmitotic pool, also known as the *maturation and storage pool*, includes metamyelocytes, bands, and segmented neutrophils. Cells spend about 5–7 days in this compartment before they are released to the peripheral blood. However, during infections, the myelocyte-to-blood transit time can be as short as 2 days. The postmitotic storage pool is almost three times the size of the mitotic pool.¹⁰

The largest compartment of PMNs is found within the bone marrow and is referred to as the *mature neutrophil reserve*. The blood compartment is about one-third the size of the bone marrow compartment, and only one-half of the blood compartment PMNs are circulating. The other half are attached to the vascular endothelium.¹⁰

Once precursor cells have matured in the bone marrow, they are released into the peripheral blood. Normally, input of neutrophils from the bone marrow to the peripheral blood equals output of neutrophils from the blood to the tissues, maintaining a relative steady-state blood concentration. However, when the demand for neutrophils is increased as in infectious states, the neutrophil concentration in the peripheral blood can increase quickly as neutrophils from the bone marrow storage (reserve) pool are released. Depending on the strength and duration of the stimulus, the marrow myeloid precursor cells (CFU-GM, CFU-G) also can be induced to proliferate and differentiate to form additional neutrophils. The transit time between development in the bone marrow and release to the peripheral blood can be decreased as a result of several mechanisms: (1) acceleration of maturation, (2) skipped cellular divisions, and (3) early release of cells from the marrow.

The mechanism regulating the production and release of neutrophils from the bone marrow to the peripheral blood is not completely understood but likely includes a feedback loop between the circulating neutrophils and the bone marrow. G-CSF is probably the primary humoral feedback mediator in normal steady-state conditions. The major sources of G-CSF are marrow stromal cells and macrophages. Inflammatory cytokines such as IL-1 and tumor necrosis factor

■ **FIGURE 5** Neutrophils are produced from stem cells in the bone marrow and spend about 1–2 weeks in this maturation compartment. Most neutrophils are released to the peripheral blood as segmented forms. When the demand for these cells is increased, more immature forms can be released. One-half of the neutrophils in the peripheral blood is in the marginating pool (MNP); the other half is in the circulating pool (CNP). Neutrophils spend <10 hours in the blood before marginating and exiting randomly to tissue. (Adapted from Boggs DR, Winkelstein A. *White Cell Manual*, 4th ed. Philadelphia: FA Davis Co.; 1983.)

(TNF) are important in causing an increase in the neutrophil concentration in pathologic conditions. These cytokines induce the macrophage to release G-CSF and GM-CSF. The vascular endothelial cell that forms the inner lining of blood vessels also generates cytokines that govern activation and recruitment of leukocytes. Endothelial cells can be important in recruiting neutrophils in the earliest phases of inflammation and injury.

The release mechanism of the bone marrow storage pool is selective in normal, steady-state kinetics, releasing only segmented neutrophils and a few band neutrophils. The mechanisms controlling this regulated release are not fully understood. The release is partially regulated by the small pore size in the vascular endothelium of bone marrow sinusoids and by the mature segmented neutrophil's ability to deform enough to squeeze through the narrow opening. Immature cells are larger and less deformable and cannot penetrate the small pores; however, when an increased demand for neutrophils exists, a higher proportion of less mature neutrophils is released into the peripheral blood. Glucocorticoids, endotoxin (bacterial lipopolysaccharide), and G-CSF can increase neutrophil release from the marrow.

Peripheral Blood

Neutrophils are released from the bone marrow to the peripheral blood, but not all neutrophils are circulating freely at the same time. About half the *total blood neutrophil pool* (TBNP) is temporarily marginated along the vessel walls (*marginating pool/MNP*) while the other half is freely circulating (*circulating pool/CNP*). Thus, if all marginated neutrophils were to circulate freely, the total neutrophil count would

double. Marginating neutrophils roll on the endothelial surface at a slow rate caused by a loose binding interaction between selectin adhesion proteins on neutrophils (L-selectin) and the L-selectin ligand on endothelial cells. The two pools are in equilibrium and rapidly and freely exchange neutrophils. Stimulants such as strenuous exercise, epinephrine, or stress can induce a shift from the MNP to the CNP, temporarily increasing the neutrophil count.

The average neutrophil circulates ~7.5 hours in the blood before diapedesing (transendothelial migration) to the tissues, although a few die of senescence (apoptosis) while in the circulation. These are occasionally seen as “necrobiotic neutrophils” on the peripheral blood smear.

Tissues

Most neutrophils move into the tissues from the marginated pool in response to chemotactic stimulation (see below). In the tissues, the neutrophil is either destroyed by trauma (cell necrosis) or lives until programmed cell death, apoptosis, occurs. PMNs that do not receive activation signals generally die within 1–2 days. However, elevated levels of GM-CSF or G-CSF associated with an infection or inflammatory process can prolong the neutrophil life span to 3–5 days by blocking apoptosis. Senescent (apoptotic) neutrophils are phagocytosed by macrophages.⁹

Neutrophil Kinetics

Neutrophils constitute the majority of circulating leukocytes. The absolute concentration varies between 1.8 and $7.0 \times 10^9/L$. A number of physiologic and pathologic variations affect the concentration of circulating leukocytes.

Pathologic causes of changes in leukocyte numbers are discussed in subsequent chapters on white cell disorders.

Alteration in the concentration of peripheral blood leukocytes is often the first sign of an underlying pathology. A normal leukocyte count does not rule out the presence of disease, but **leukocytosis** (an increase in leukocytes) or **leukopenia** (a decrease in leukocytes) is an important clue to disease processes and deserves further investigation including a leukocyte differential count to identify the concentration of the different types of leukocytes. Granulocytopenia (granulocytes $<2 \times 10^9/L$) defines a decrease in all types of granulocytes (i.e., eosinophils, basophils, and neutrophils). **Neutropenia** is a more specific term denoting a decrease in only neutrophils. Neutropenia in adults exists if the absolute neutrophil count falls below $1.8 \times 10^9/L$. The condition of absence of granulocytes is called **agranulocytosis**, and the patient is at high risk of developing an infection. **Granulocytosis** is a term used to denote an increase in all granulocytes. **Neutrophilia** is a more specific term indicating an increase in neutrophils. Neutrophilia in adults occurs when the absolute concentration of neutrophils exceeds $7 \times 10^9/L$. This condition is most often the result of the body's reactive response to bacterial infection, metabolic intoxication, drug intoxication, or tissue necrosis.

Although the WBC count and absolute neutrophil count are used to evaluate neutrophil production, they reflect a transient moment in overall neutrophil kinetics and do not provide accurate, quantitative information on the rate of production or destruction, status of marrow reserves, or abnormalities in cell distribution in the tissues.

✓ Checkpoint! 2

An adult patient's WBC count is $10 \times 10^9/L$, and there are 90% neutrophils. What is the absolute number of neutrophils? Is this in the reference range for neutrophils? If not, what term would be used to describe it?

FUNCTION

To be effective in its role in host defense, the neutrophil must move to the site of the foreign agent, engulf it, and destroy it. Thus, neutrophils function primarily in the tissues where microbial invasion typically occurs. Monocytes-macrophages help in this process but are slower to arrive at the site. The four steps in the innate immune response can be described as adherence, migration (chemotaxis), phagocytosis, and bacterial killing.

Adherence

Neutrophils flow freely along the vascular endothelium when neither the neutrophil nor vascular endothelial cell (VEC) is activated. Neutrophil adherence and migration to

the site of infection begin with a series of interactions between the neutrophils and VEC when these cells are activated by a variety of inflammatory mediators (cytokines).

Several different families of cytoadhesion molecules (CAM) and their ligands play a major role in the adherence process. Adhesion molecules include: (Table 3 ★)

- Selectins and their ligands
- Intercellular adhesion molecules (ICAMs)
- β_2 (CD18) family of leukocyte integrins and their ligands (Immunoglobulin-like CAM)

Adhesion molecules and their ligands located on the leukocytes and VEC act together to induce activation-dependent adhesion events. They are critical for every step of cell recruitment to sites of tissue injury including margination along vessel walls, **diapedesis**, and **chemotaxis**. Adhesion molecules are transmembrane proteins with three domain types: extracellular, transmembrane, and intracellular. A ligand's binding to the extracellular domain sends a signal across the membrane to the cell's interior, which activates secondary messengers within the cell. These secondary messengers affect calcium flux, NADPH oxidase activity, cytoskeleton assembly, and phagocytosis.

Neutrophils and endothelial cells are transformed from a basal state to an activated state by inflammatory mediators (cytokines and chemokines). The initial result is activation of all three classes of CAMs. Springer has proposed a model of the neutrophil-endothelial cell adhesion process¹² that can be divided into four stages: (1) activation of VEC, (2) activation of neutrophils, (3) binding of neutrophils to inner vessel linings, and (4) transendothelial migration (Figure 6 ■).

Stage one involves the activation of VEC, which mediates a loose association of VECs with neutrophils. Inflammatory cytokines (IL-1, tumor necrosis factor- α [TNF- α], or interferon- γ [IFN- γ]) activate VEC to express E- and P-selectins as well as L-selectin ligands. E-selectin is newly synthesized by the activated VEC; P-selectin is mobilized and translocated from storage sites in the Weibel-Palade bodies to the surface of the VEC. E- and P-selectin molecules on the VEC surface interact with their ligands on the neutrophil. Additionally L-selectin, which is constitutively present in the neutrophil membrane, interacts with its ligands that are upregulated on the activated VEC. These interactions induce the neutrophil to transiently associate and dissociate with the VEC, causing the neutrophil to "roll" on the VEC surface. The rolling neutrophils are thus situated to respond to additional signals from chemoattractants (chemotactic substances—chemical messengers that cause directional migration of cells along a concentration gradient) generated by infectious agents or an inflammatory response.¹⁰

Stage two is the activation of neutrophils. **Chemokines** (cytokines with chemotactic activity) or other chemoattractants released by tissue cells, microorganisms, and activated VEC bind to the endothelial cell surface. There they interact with the loosely bound leukocytes, resulting in activation of leukocyte integrins. Chemoattractants include specific and

★ TABLE 3

Adhesion Molecules Important in Leukocyte-Endothelial Cell Interactions

Molecules	CD Designation	Expressed By	Counter-Receptor/Ligand
1. β_2 -integrins/Neutrophils $\alpha_L\beta_2$ (LFA-1)	CD11a-CD18	Activated leukocytes	ICAM-1 on VEC (CD54) ICAM-2 on VEC (CD102) ICAM-3 (CD50)
$\alpha_M\beta_2$ (Mac-1)	CD11b-CD18	Activated leukocytes	ICAM-1 on EC iC3b, fibrinogen, factor X

LFA = leukocyte function-related antigen, CD = cluster of differentiation, EC = endothelial cell, ICAM = intercellular adhesion molecules, PSGL-1 = P selectin glycoprotein ligand-1.

nonspecific proinflammatory mediators such as C5a (complement activation peptide), bacterial products, lipid mediators (e.g., platelet-activating factor [PAF]), and chemokines. The neutrophil activation-dependent adhesion receptors include the β_2 integrin molecules. Leukocyte plasma membranes have at least three β_2 -integrins: CD11a/CD18 (LFA-1/leukocyte function associated antigen-1), CD11b/CD18 (Mac-1, also known as the *CR3 complement receptor*), and CD11c/CD18. Each has an α subunit (CD11a, CD11b, and CD11c) noncovalently linked to a β subunit (CD18).¹⁰ The neutrophil L-selectin molecule is downregulated at this time.

An autosomal recessive disorder, leukocyte adhesion deficiency type-I (LAD-I), has partial or total absence of expression of the β_2 integrins on leukocyte membranes, often due to a mutation of the CD18 gene. This results in absence of leukocyte adhesion to the VEC as well as lack of mobility or migration and can result in life-threatening bacterial infections. An inability to synthesize the E- and L-selectin ligand SLe^x is seen in leukocyte adhesion deficiency type 2 (LAD-2) and results in reoccurring infections.¹³

Stage three involves arrest of neutrophil rolling because activated neutrophils are more tightly bound to inner vessel linings. Expression of the neutrophils' activation-dependent β_2 integrin adhesion receptors mediates firm adherence of neutrophils to ICAMs expressed by activated VEC near the site of infection or inflammation. The integrin receptors' intracellular domains react with the neutrophil's cytoskeleton, triggering a rapid cytoskeletal rearrangement in the neutrophil on ligand interaction. This induces a cytoskeletal and morphologic change in the leukocyte required for cellular migration. Stage three ends with a strong, sustained attachment of the leukocyte to the VEC. At this time, leukocyte NADPH oxidase membrane complexes are assembled and activated (discussed later).

Stage four involves the transendothelial migration phase that occurs when neutrophils move through the vessel wall by the process of diapedesis, occurring predominantly at the borders of VECs. Passing out of the vessel to the tissue requires modification of the VEC cell-to-cell adherent junctions. The neutrophils use pseudopods to squeeze between endothelial cells, leaving the vascular space and passing through the subendothelial basement membranes and peri-

■ **FIGURE 6** Adhesion of neutrophils to the vascular endothelium and eventual migration of neutrophils into the tissue occur as a result of activation of endothelial cells (EC) and neutrophils by exposure to chemoattractants. When the cells are activated, they are induced to express adhesion molecules. These transmembrane molecules send a signal across the membrane to the interior of the cell when they attach to their receptor. The process occurs in 4 stages: In stage 1, E,P-selectin and L-selectin (VEC) receptor are expressed on activated EC. The neutrophil's L-selectin and receptors for E,P-selectin cause the neutrophil to attach loosely to the EC and roll along the endothelium. Neutrophils in stage 2 are activated by the presence of chemoattractants in the local environment and express the β_2 -integrins. These chemoattractants also activate the ECs. The neutrophils in stage 3 attach to the activated ECs via the attachment of their β_2 -integrins to ICAMs of the EC, resulting in a firmer attachment than in stage 1 and halting the rolling of the neutrophil. The neutrophil in stage 4 migrates through the endothelium and basement membrane (diapedesis) to the area of inflammation. They move in the direction of the chemoattractants (chemotaxis).

endothelial cells. Subendothelial basement membranes are eroded, presumably by secretion of neutrophil gelatinase B and elastase from neutrophil granules. Migration is enhanced when the VEC is activated by IL-1 and/or TNF.¹⁰

Migration

Once in the tissues, neutrophil migration (*chemotaxis*) is guided by chemoattractant gradients. Neutrophils continue their migration through the extravascular tissue, moving by directed ameboid motion toward the infected site. Locomotion of neutrophils (and other leukocytes) is a process of "crawling," not "swimming." During locomotion along a chemotactic gradient, the neutrophils acquire a characteristic asymmetric shape, a process made possible by the alterations of the cytoskeleton triggered by neutrophil activation. There is an extension of a broad pseudopodium (protopod) at the anterior of the cell (containing the nucleus and organelles) and a narrow knoblike tail (uropod) at the rear of the cell. Neutrophil migration through the tissues requires β_1 and β_2 integrins with the continuous formation of new adhesive contacts at the cell front and detachment from the adhesive substrate at the rear of the cell. Chemotaxis is induced by a variety of chemoattractant molecules including bacterial formyl

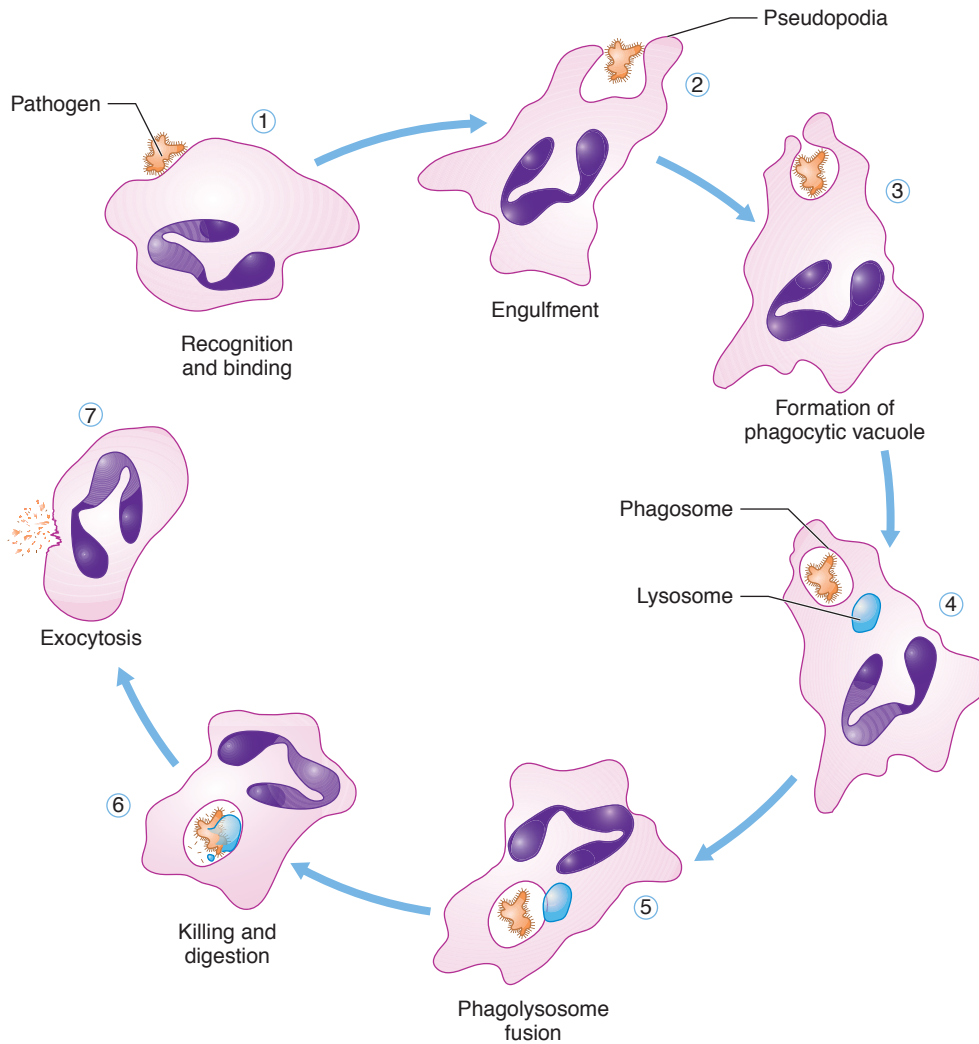

peptides (fMLP), C5_a, LTB₄, IL-8, and PAF, many of the same molecules which activated the PMN during stage two.¹²

✓ Checkpoint! 3

A patient with life-threatening recurrent infections is found to have a chromosomal mutation that results in a loss of active integrin molecules on the neutrophil surface. Why would this result in life-threatening infections?

Phagocytosis

After arriving at the site of infection, phagocytosis by neutrophils can begin. Monocytes and macrophages also arrive at the site of injury and continue to accumulate and contribute to the inflammatory process. Phagocytes must recognize the pathogen as foreign before attachment occurs and phagocytosis begins (Figure 7 ■). Recognition is followed by ingestion of the particle, fusion of the neutrophil granules with the phagosome (degranulation), and finally the process of bacterial killing and digestion. **Phagocytosis** is an active process that requires a large expenditure of energy by the cells. The required energy can be provided by anaerobic glycolysis or aerobic processes.

■ **FIGURE 7** Phagocytosis begins with recognition and attachment of the pathogen to the neutrophil (or macrophage). The pathogen is then internalized, forming a phagocytic vacuole. Next the granule fuses with the vacuole, forming a phagolysosome, and releases its contents into the vacuole to help kill and digest the microbe (degranulation). This is followed by extrusion of undigested vacuole contents from the neutrophil (exocytosis).

The principal factor in determining whether or not phagocytosis can occur is the physical nature of the surfaces of both the foreign particle and the phagocytic cell. Phagocytes recognize unique molecular characteristics of the pathogen's surface (PAMP) and bind to the invading organism via specific PRR (see leukocyte function, discussed previously). Some pathogens can be recognized by the process of opsonization (the coating of a particle with a soluble factor). Enhancement of phagocytosis through the process of opsonization speeds the ingestion of particles. Two well-characterized opsonins are immunoglobulin G (IgG) and complement component C3b (see lymphocyte section for description of structure of IgG). The antibody, IgG, binds to the microorganism/particle by means of its Fab region while the Fc region of the antibody attaches to Fc receptors on the neutrophil membrane

(Fc γ RI/CD64, Fc γ RII/CD32, Fc γ RIII/CD16). Thus, the antibody forms a connecting link between the microorganism/particle and the neutrophil. The neutrophil also has receptors for activated complement component C3b (CR1/CD35, CR3/CD11b/CD18, CR4/CD11c/CD18). Some bacteria with polysaccharide capsules avoid recognition, thus reducing the effectiveness of phagocytosis.

Following recognition and attachment, the particle is surrounded by neutrophil cytoplasmic extensions or pseudopods (Figure 7). As the pseudopods touch, they fuse, encompassing the particle within a phagosome that is bound by the cytoplasmic membrane turned "inside out." A plasma membrane-bound oxidase is activated during ingestion, which plays an important role in microbactericidal activities.

Bacterial Killing and/or Digestion

Bacterial killing and/or digestion follows ingestion of particles. After formation of the phagosome, neutrophil granules migrate toward and fuse with the phagosome membrane, discharging their granule contents into the phagocytic vesicle, forming a phagolysosome (**degranulation**). The bactericidal and digestive proteins contained within both primary and secondary granules are thus normally sequestered from the cytoplasm of the neutrophil, selectively released, and activated within a membrane-enclosed system.

Microbicidal mechanisms that follow ingestion can be divided into oxygen-dependent/oxidative or oxygen-independent/nonoxidative activities (Table 4). Oxygen-dependent microbicidal activity is most important physiologically. Phagocytosis is accompanied by an energy-dependent “respiratory burst” that generates oxidizing compounds produced from partial oxygen reduction. The respiratory burst is described as including a significant increase in glycolysis, a 2–3-fold increase in oxygen consumption, a 2–10-fold increase in hexose monophosphate shunt (HMS) activity and generation of NADPH, and the production of a series of reactive oxygen species (ROS).¹⁴ The oxidizing compounds—ROS—are important agents in killing ingested organisms. The enzyme activity needed to generate ROS is provided by NADPH oxidase, also known as *respiratory burst oxidase (RBO)*. In resting cells, NADPH oxidase is found as separate components of the plasma membrane (gp^{91phox} , p^{22phox} , and Rap^1) and intracellular stores (p^{47phox} and p^{67phox}). When phagocytosis takes place, the plasma membrane is internalized as the wall of the phagocytic vesicle with the outer plasma membrane surface now facing the interior of the phagosome. When the resting cell is exposed to any of a wide variety of activating stimuli, activated NADPH oxidase is assembled from the cytoplasmic and membrane-associated subunits at the phagosome membrane. From this location, the NADPH oxidase generates and pours ROS into the phagosome.

Once assembled, the oxidase produces superoxide anion, (O_2^-) and $NADP^+$. The $NADP^+$ activates the hexose monophosphate (HMP) shunt, generating more NADPH. O_2^- is further metabolized to produce additional ROS (H_2O_2 , OH^- , 1O_2) with increasing bactericidal potency.

NADPH oxidase

Superoxide oxidase

The activated oxidase can be detected in the laboratory by a nitroblue tetrazolium (NBT) test, cytochrome reduction, or chemiluminescence test.

The second oxygen-dependent microbicidal system involves the primary granule enzyme myeloperoxidase (MPO). Myeloperoxidase catalyzes the interaction of hydrogen peroxide produced during the respiratory burst with halide ions (e.g., chloride/ Cl^-) giving rise to oxidized halogens (e.g., hypochlorous acid/HOCl), which increase bacterial killing.¹⁴

The oxidants generated by the respiratory burst have potent microbicidal activity against a wide variety of microorganisms such as bacteria, fungi, and multicellular and unicellular parasites. However, the phagocyte and surrounding tissues are also susceptible to damage. Phagocytes use a variety of mechanisms to detoxify the oxidant radicals, such as the superoxide dismutase, catalase, and a variety of other antioxidants.

Oxygen-independent granular proteins present in primary, gelatinase, and specific granules of neutrophils can successfully kill and degrade many strains of both gram-negative and gram-positive bacteria. The most important nonoxygen-dependent antimicrobial proteins of PMNs are listed in Table 4. Initially, the pH within the phagolysosome decreases, which inhibits bacterial growth, but this alone is insufficient to kill most microbes. Acidic conditions, however, can enhance the activity of some granular proteins such as hydrolases and lactoferrin, which perform optimally at low pH. In the extracellular environment, microorganisms that escape phagocytosis are also subject to killing by reactive oxygen metabolites such as H_2O_2 that forms from the O_2^- secreted by active plasma membrane NADPH complexes into the tissue matrices. Neutrophils themselves are not resistant to the toxic effects of the oxidants they secrete and

TABLE 4

Neutrophil Antimicrobial Systems

Oxygen Dependent	Oxygen Independent
Myeloperoxidase independent	Acid pH of phagosome: antibacterial; enhances some oxygen-dependent antimicrobial mechanisms and other enzymes
Hydrogen peroxide (H_2O_2)	Lysozyme (primary and secondary granules): hydrolyzes cell wall of some bacteria; digests killed microbes
Superoxide anion (O_2^-)	Lactoferrin (secondary granules): binds iron necessary for bacterial growth; also directly bactericidal
Hydroxyl radicals (OH^-)	BPI—Bactericidal permeability inducing protein (primary granules); coat microbes; alters cell permeability
Singlet oxygen (1O_2)	Defensins—small cationic peptides; broad spectrum of bactericidal activity
Myeloperoxidase dependent (forms oxidized halogens)	Collagenase (secondary granules): degrades microbe macromolecules
	Hydrolases (primary granules): digests microbe

thus have high mortality during any sustained inflammatory response.¹⁵

In patients with chronic granulomatous disease, neutrophils are missing one of the components of the NADPH oxidase complex and therefore fail to produce the respiratory burst. They are still capable of eliminating infection caused by strains of bacteria susceptible to killing by oxygen-independent mechanisms, but this antimicrobial system is not very effective alone. Often these patients eventually die of multiple infections with bacteria resistant to the killing actions of these granular proteins.

In addition to their primary functions of phagocytosis and killing of microorganisms, neutrophils interact in other physiologic processes. Neutrophils stimulate coagulation by releasing a substance that activates prekallikrein to kallikrein, which then cleaves kinins from high-molecular-weight kininogen. Kinins are responsible for vascular dilation and increased vessel permeability. Kinins, which are also chemotactic for neutrophils, attract them to sites of inflammation. Neutrophils initially activate kinin production, but as the cells accumulate, they break down kinins. Neutrophils also secrete pyrogen, a substance that acts on the hypothalamus to produce fever. This endogenous pyrogen is now known to be interleukin-1 (IL-1).

✓ Checkpoint! 4

A patient has a compromised ability to utilize the oxygen-dependent pathway in neutrophils. What two important microbial killing mechanisms could be affected?

▶ EOSINOPHILS

The eosinophil originates from the IL-5–responsive CD34⁺ myeloid progenitor cells. Cytokines that influence the proliferation and the differentiation of the eosinophil lineage include GM-CSF, IL-3, and IL-5. However, it is now recognized that IL-5, released by T_{H2} lymphocytes, has relative lineage specificity for eosinophils and is the major cytokine required for eosinophil production and terminal differentiation.¹⁶

DIFFERENTIATION, MATURATION, AND MORPHOLOGY

The eosinophil undergoes a morphologic maturation similar to the neutrophil with the same six stages of maturation identified. It is not possible to morphologically differentiate eosinophilic precursors from neutrophilic precursors with the light microscope until the myelocyte stage, however, when the typical acidophilic crystalloid granules of the eosinophil appear. Granule formation begins in the promyelocyte with small coreless granules. The first two stages (eosinophilic myeloblast and promyelocyte) will not be described because they are morphologically identical to the neutrophilic myeloblast and promyelocyte.

Eosinophilic Myelocyte to Mature Eosinophil

The eosinophilic myelocyte contains large, eosin-staining, crystalloid granules. Maturation from the myelocyte to the metamyelocyte, band, and segmented eosinophil stage is similar to that described for the neutrophils with gradual nuclear indentation and segmentation. No appreciable change occurs in the cytoplasm in these latter stages of development. The reddish orange spherical granules are larger than neutrophilic granules, are uniform in size, and are evenly distributed throughout the cell. Because of the low percentage of eosinophils in the bone marrow, differentiating the eosinophil into its maturational stages (e.g., eosinophilic myelocyte) serves no useful purpose when the count is normal. Bone marrow maturation and storage time are about 9 days.

The mature eosinophil (Figure 8■) is 12 to 15 μm in diameter. The nucleus usually has no more than two or three lobes, and the cytoplasm is completely filled with granules. The eosinophil contains three types of granules: primary granules, granules called *small granules* (which contain the enzymes acid phosphatase and aryl-sulphatase), and the eosinophil-specific, or crystalloid, granules that are bound by a phospholipid membrane and have a central crystalloid core surrounded by a matrix. The eosinophil-specific granules contain four major proteins: major basic protein (MBP), eosinophil cationic protein (ECP), eosinophil peroxidase (EPO), and eosinophil-derived neurotoxin (EDN), also known as *protein x (EPX)* (Table 5♣). The MBP is located in the crystalloid core; the other three proteins are found in the granule matrix. The crystalloid core also appears to store a number of proinflammatory cytokines such as IL-2, IL-4, and GM-CSF, and the matrix contains IL-5 and TNF- α . The eosinophil has the capacity to synthesize and elaborate a number of other cytokines as well. The eosinophil's capacity

■ FIGURE 8 Eosinophil (Peripheral blood, Wright-Giemsa stain, 1000 \times magnification)

TABLE 5

Major Constituents of Eosinophil Granules

Protein (Abbreviation)	Characteristics
Major basic protein (MBP)	Is cytotoxic for protozoans and helminth parasites Stimulates release of histamine from mast cells and basophils Neutralizes mast cell and basophil heparin
Eosinophil cationic protein (ECP)	Is capable of killing mammalian and nonmammalian cells Stimulates release of histamine from mast cells and basophils Inhibits T lymphocyte proliferation Activates plasminogen Enhances mucus production in the bronchi Stimulates glycosaminoglycan production by fibroblasts
Eosinophil-derived neurotoxin (EDN)	Can provoke cerebral and cerebellar dysfunction in animals Inhibits T cell responses
Eosinophil peroxidase (EPO)	Combines with H ₂ O ₂ and halide ions to produce a potent bactericidal and helminthocidal action Is cytotoxic for tumor and host cells Stimulates histamine release and degranulation of mast cells Diminishes roles of other inflammatory cells by inactivating leukotrienes
Lysophospholipase	Forms Charcot-Leyden crystals
Miscellaneous enzymes	Phospholipase D: inactivates mast cell PAF (platelet activating factor) Arylsulphatase: inactivates mast cell LT-D ₄ (leukotriene D ₄) Histaminase: neutralizes mast cell histamine Acid phosphatase, catalase, nonspecific esterases
Lipid-derived mediators	LT-C ₄ : promotes smooth muscle contraction and mucus secretion PG-E ₁ and E ₂ : inhibits mast cell degranulation PAF TXB ₂ (thromboxand B ₂)

to produce cytokines has led to increased interest and research into the eosinophil's role as an effector cell in allergic inflammation. The eosinophil, like the neutrophil, contains a number of lipid bodies that increase during eosinophil activation *in vitro*.^{16,17} Eosinophils express the CD9, CD11a, and CD13 molecules.

Tissue Eosinophils

Smears of bone marrow can contain large cells with a well-defined reticular chromatin pattern in the nucleus, nucleoli, an irregular cytoplasmic outline, and cytoplasmic granules similar to the reddish orange granules of blood eosinophils. It is thought that these cells are tissue variants of the more motile eosinophils of the peripheral blood. Tissue eosinophils can be found in tissue other than bone marrow (see section below). Some evidence indicates that tissue eosinophils can develop and mature in extramedullary sites in response to locally produced cytokines.¹⁶

DISTRIBUTION, CONCENTRATION, AND KINETICS

Eosinophils in adults have a concentration in the peripheral blood $\leq 0.40 \times 10^9/L$. The cell shows a diurnal variation with highest concentration in the morning and the lowest concentration in the evening.¹⁶

Eosinophilia in adults is defined as $>0.40 \times 10^9/L$; it is associated with allergic diseases, parasitic infections, toxic reactions, gastrointestinal diseases, respiratory tract disorders, neoplastic disorders, and other conditions. Eosinophilia is T cell dependent; T cells are the predominant source of IL-5. Persistent eosinophilia is seen in hypereosinophilic syndrome, a myeloproliferative disorder.

Very little is known about the kinetics of eosinophils. Most of the body's eosinophil population lies in connective tissue below the epithelial layer in tissues that are exposed to the external environment such as the nasal passages, lung, skin, gastrointestinal tract, and urinary tract. These cells spend ~ 18 hours in the peripheral blood before migrating to the tissues where they can live for several weeks. Once in the tissues, eosinophils do not reenter the circulation.¹⁶

FUNCTION

Eosinophils have multiple biologic functions and contribute to a variety of immune defense mechanisms. Eosinophil production and function are influenced by the cellular arm of the immune system (T cells). Eosinophils are associated with allergic diseases, parasitic infections, and chronic inflammation. Their major role is host defense against helminth parasites via a complex interaction of the eosinophils, adaptive immune system, and parasite. The eosinophil adheres to the organism and releases its granule contents onto the surface

of the parasite via exocytosis. A number of eosinophil proteins are highly toxic for larval parasites, including MBP, ECP, and EPO. Eosinophils also are capable of phagocytosing bacteria (although less efficiently than neutrophils and macrophages) and have been shown to function as antigen-presenting cells.¹⁸

The eosinophils are proinflammatory cells that are capable of either protecting or damaging the host depending on the situation. Eosinophils respond weakly to IL-3, IL-5, and GM-CSF as chemotaxins, but IL-5 synthesized by T lymphocytes has been shown to prime eosinophils for a better chemotactic response to PAF, LTB₄, or IL-8. Products released from basophils and mast cells (eosinophil chemotactic factor/ECF), lymphokines from sensitized lymphocytes, and allergy-related antigen/antibody complexes are strongly chemotactic for eosinophils. Eosinophils express Fc receptors for IgE, which is prevalent in the response to parasitic infections and mediates activation of eosinophil killing mechanisms. The cytokines IL-3, IL-5, and GM-CSF promote the adherence of eosinophils; transendothelial migration is 10 times higher in the presence of these cytokines. These cytokines also prolong the survival of eosinophils in culture.

Eosinophils have a β_2 integrin-independent mechanism for recruitment into the tissues. This was first suggested when eosinophils and mononuclear leukocytes—but not neutrophils—were found at sites of infection in children with congenital β_2 -integrin deficiency (LAD-1). Eosinophil recruitment appears to be modulated by the eosinophil adhesion receptor, VLA-4, and its ligand on VEC and VCAM-1. VCAM-1 has been shown to be expressed on VEC when the vascular endothelium is activated by IL-1, TNF, or IL-4. Changes in eosinophil adhesion molecule expression occur during eosinophil migration. This implies that dynamic changes in cell adhesion molecules are involved in cell recruitment to areas of inflammation.

The eosinophil liberates substances that can neutralize mast cell and basophil products, thereby down modulating the allergic response (Table 5). Increasing evidence suggests a direct correlation between the degree of eosinophilia and

severity of inflammatory diseases such as asthma. In these conditions, the cytotoxic potential of eosinophils is turned against the host's own tissue.¹⁹

Charcot-Leyden crystals are bipyramidal crystals commonly found in fluids or tissues in association with eosinophilic inflammatory reactions. They are composed primarily of lysophospholipase, an eosinophil component found in eosinophil primary granules as opposed to the crystal-containing secondary or specific granules.

▶ BASOPHILS

Basophils (Figure 9 ■) originate from the CD34⁺ myeloid progenitors in the bone marrow. IL-3 is the main cytokine involved in human basophil growth and differentiation, but it is believed that GM-CSF, SCF, IL-4, and IL-5 also have a role.^{20,21}

DIFFERENTIATION, MATURATION, AND MORPHOLOGY

Basophils undergo a maturation process similar to that described for the neutrophil. The first recognizable stage is the promyelocyte, although this stage is very difficult to differentiate from the promyelocyte of the neutrophil or eosinophil. As with eosinophils and neutrophils, the various stages of the maturing basophil are characterized by a gradual indentation and segmentation of the nucleus.

Basophilic Myelocyte to Mature Basophil

The basophilic myelocyte, metamyelocyte, band, and segmented form are easily differentiated from other granulocytes by the presence of the large purple-black granules unevenly distributed throughout the cytoplasm. The granules are described as metachromatic and contain histamine, heparin, cathepsin G, major basic protein, and lysophospholipase.²⁰ The mature basophil ranges in size from 10 to 15 μ m and has a segmented nucleus and many purple granules obscuring both the background of the cytoplasm and the nu-

■ **FIGURE 9** a. Basophil. (Peripheral blood, Wright-Giemsa stain, 1000 \times magnification). b. Basophil with washed out granules (staining artifact).

cleus. Basophil granules contain peroxidase and are positive with the PAS reaction. Basophil granules are water soluble and can dissolve on a well-rinsed Wright-stained smear, resulting in clear areas within the cytoplasm. Usually a few deep-purple-staining granules remain to aid in the identification of the cell. Basophils express the CD9, CD11a, and CD13 molecules.

Mast Cell (Tissue Basophil)

The relationship between basophils and mast cells continues to be investigated. Research shows that mast cells and basophils represent distinct, terminally differentiated cells derived from the CD34⁺ common myeloid progenitor cell. Distinct committed progenitor cells (CFU-B and CFU-MC) have been identified for each lineage.²² Mast cells are found in the bone marrow and tissues but are not found in peripheral blood. Mast cells have proliferative potential and live for several weeks to months. At times, differentiating the mast cell and the basophil precursors in the bone marrow is difficult although some differences exist (Table 6). The mast cell nucleus is round and surrounded by a dense population of granules. The mast cell granules contain acid phosphatase, protease, and alkaline phosphatase. Mast cells have an antigen profile similar to that of macrophages.

CONCENTRATION, DISTRIBUTION, AND DESTRUCTION

Basophils’ maturation in the bone marrow requires 2.5–7 days before they are released into circulation. In the peripheral blood, they number less than $0.2 \times 10^9/L$ (<1% of the total leukocytes). Basophilia in adults is defined as $>0.2 \times 10^9/L$ in the peripheral blood. Basophils are end-stage cells incapable of proliferation and spend only hours in the peripheral blood.

FUNCTION

The basophil and mast cell function as mediators of inflammatory responses, especially those of immediate hypersensitivity reactions such as asthma, urticaria, allergic rhinitis, and anaphylaxis. These cells have membrane receptors for IgE (FcεR). When IgE attaches to the receptor, the cell is activated and degranulation is initiated. Degranulation releases enzymes that are vasoactive, bronchoconstrictive, and chemotactic (especially for eosinophils). This release of mediators initiates the classic clinical signs of immediate hypersensitivity. These cells can synthesize more granules after degranulation occurs. Basophils and mast cells express CD40L, the ligand for CD40, an antigen on B lymphocytes. The interaction of B lymphocyte CD40 and basophil CD40L, in conjunction with IL-4, can induce IgE synthesis by B lymphocytes. Thus, basophils can play an important role in inducing and maintaining allergic reactions.²¹

✓ Checkpoint! 5

Indicate which of the granulocytes will be increased in the following conditions: a bacterial infection, an immediate hypersensitivity reaction, and an asthmatic reaction.

▶ MONOCYTES

The monocyte is produced in the bone marrow from a bipotential progenitor cell (CFU-GM) that is capable of maturing into either a monocyte or a granulocyte. The differentiation and proliferation of CFU-GM into monocytes depend on the action of GM-CSF, IL-3, and M-CSF (monocyte-stimulating factor). Monocytes continue to differentiate, transforming to macrophages in the tissues. Monocytes and macrophages can be stimulated by T lymphocytes and endotoxin to liberate

TABLE 6

Comparison of the Characteristics of Basophils and Mast Cells

Characteristics	Basophils	Mast Cells
Origin	Hematopoietic stem cell	Hematopoietic stem cell
Site of maturation	Bone marrow	Connective or mucosal tissue
Proliferative potential	No	Yes
Life span	Days	Weeks to months
Size	Small	Large
Nucleus	Segmented	Round
Granules	Few, small (peroxidase positive)	Many, large (acid phosphatase, alkaline phosphatase positive)
Key cytokine regulating development	IL-3	Stem cell factor (SCF)
Surface receptors		
IL-3-R	Present	Absent
c-kit (SCF-R)	Absent	Present
IgE receptor (FcεR)	Present	Present

M-CSF, which can be one mechanism for the monocytosis associated with some infections. M-CSF also activates the secretory and phagocytic activity of monocytes and macrophages.²³ Monocytes and macrophages make up the **monocyte-macrophage system**. More recently, it has been proposed to call this continuum of cells the **mononuclear phagocyte system (MNP)**.

DIFFERENTIATION, MATURATION, AND MORPHOLOGY

The morphologically recognizable monocyte precursors in the bone marrow are the monoblast and the promonocyte. These cells are present in very low concentration in the normal bone marrow and are found in abundance only in leukemic processes involving the MNP system. The monoblast of the marrow cannot be morphologically distinguished from the myeloblast by light microscopy unless proliferation of the monocytic series is marked as occurs in monocytic leukemia. Cytochemical stains and immunophenotyping frequently are used to help differentiate myeloblasts and monoblasts in suspected cases of leukemia.

The promonocyte is usually the first stage to develop morphologic characteristics that allow it to be clearly differentiated as a monocyte precursor by light microscopy. The identification of early monocyte precursors is aided by observing folds or indentations in the nucleus and by their association with mature monocytes.

Monoblast

The monoblast's (Figure 10a ■) nucleus is most often ovoid or round but can be folded or indented. Monoblasts are large, from 12–20 μm in diameter. The pale blue-purple nuclear chromatin is finely dispersed (lacy), and several nucleoli are easily identified. The monoblast has abundant agranular blue-gray cytoplasm. Differentiation of the monoblast from the myeloblast may be possible with special cytochemical stains. The monoblast has nonspecific esterase activity demonstrated by reaction with the substrates α -naphthyl butyrate or naphthol AS-D acetate (NASDA). Sodium fluoride inhibits NASDA activity. The myeloblast has both specific esterase activity (demonstrated by reaction with the substrate naphthol AS-D chloroacetate) and nonspecific esterase activity, but the nonspecific esterases are

■ **FIGURE 10** Stages of monocyte maturation: **a.** monoblast: Note lacy chromatin, nucleoli, and high N:C ratio; **b.** promonocyte: The chromatin is somewhat more coarse and the amount of cytoplasm is increased; **c.** monocyte: The nucleus is more lacy than that of a neutrophil or lymphocyte and is irregular in shape. (a, b: Bone marrow, Wright-Giemsa stain, 1000 \times magnification; c: Peripheral blood, Wright-Giemsa stain, 1000 \times magnification)

not inhibited by sodium fluoride. Immunophenotyping is also used to differentiate myeloblasts and monoblasts.

Promonocyte

The promonocyte (Figure 10b ■) is an intermediate form between the monoblast and the monocyte. The cell is large, 12–20 μm in diameter. The nucleus is most often irregular and indented with a fine chromatin network. Nuclear chromatin is coarser than the monoblast, and nucleoli can be present. The promonocyte's cytoplasm is abundant with a blue-gray color; azurophilic granules can be present. Cytochemical stains for nonspecific esterase, peroxidase, acid phosphatase, and arylsulfatase are positive.

Monocyte

Mature monocytes (Figure 10c ■) range in size from 12 to 20 μm with an average size of 18 μm , making them the largest mature cells in peripheral blood. The nucleus is frequently horseshoe- or bean-shaped and possesses numerous folds, giving it the appearance of brainlike convolutions. The chromatin is loose and linear, forming a lacy pattern in comparison to the clumped dense chromatin of mature lymphocytes or granulocytes. Monocytes, however, are sometimes difficult to distinguish from large lymphocytes, especially in reactive states when there are many reactive lymphocytes. The monocyte cytoplasm has variable morphologic characteristics depending on its activity. The cell adheres to glass and “spreads” or sends out numerous pseudopods resulting in a wide variation of size and shape on blood smears. The blue-gray cytoplasm is evenly dispersed with fine, dustlike membrane-bound granules, which give the cell cytoplasm the appearance of ground glass. Vacuoles are frequently observed in the cytoplasm.

Electron-microscopic cytochemistry reveals two types of granules present in monocytes. One type contains peroxidase, acid phosphatase, and arylsulfatase, suggesting that these granules are similar to the lysosomes (azurophilic granules) of neutrophils. Less is known about the content of the other type of granule except that it does not contain alkaline phosphatase. The lipid membrane of the granules stains faintly with Sudan black B. Many CD markers including CD11b/CD18, CD13, CD14, and CD15 are found on monocytes.

Macrophage

The monocyte leaves the blood and enters the tissues where it matures into a macrophage (Figure 11 ■). The transition from monocyte to macrophage is characterized by progressive cellular enlargement, reaching a 15–80 μm size. The nucleus becomes round with a reticular (netlike) appearance, nucleoli appear, and the cytoplasm appears blue-gray with ragged edges and many vacuoles present. As it matures, the macrophage loses peroxidase, but increases are seen in the amount of endoplasmic reticulum (ER), lysosomes, and mitochondria. Also, distinct granules are noted in the maturing macrophage. Macrophages acquire the expression of CD68, a glycoprotein that can be important in lipid metabolism. These cells can live for months in the tissues. Macrophages do not normally reen-

■ **FIGURE 11** A macrophage. Note the numerous vacuoles and cellular debris. (Bone marrow, Wright-Giemsa stain, 1000 \times magnification)

ter the blood, but in areas of inflammation, some can gain access to the lymph, eventually entering the circulating blood.

Tissue macrophages, also known as *histiocytes*, develop different cytochemical and morphologic characteristics that depend on the site of maturation and habitation in tissue. These cells are widely distributed in the body and have been given specific names depending on their anatomic location. For example, macrophages in the liver are known as *Kupffer cells*, those in the lung as *alveolar macrophages*, those in the skin as *Langerhans cells*, and those in the brain as *microglial cells*.

Macrophages can proliferate in the tissue, especially in areas of inflammation, thereby increasing the number of cells at these sites. Occasionally, two or more macrophages fuse to produce giant multinucleated cells. This occurs in chronic inflammatory states and granulomatous lesions where many macrophages are tightly packed together. Fusion also occurs when particulate matter is too large for one cell to ingest or when two cells simultaneously ingest a particle.

DISTRIBUTION, CONCENTRATION, AND KINETICS

Before maturing into monocytes, the promonocyte undergoes two or three divisions. Bone marrow transit time is about 54 hours. In contrast to the large neutrophil storage pool, there is no significant reserve pool of monocytes in the bone marrow; most are released within a day after their derivation from promonocytes. Monocytes diapedese into the tissue from the peripheral blood in a random manner after an average transit time in the vascular system of ~ 8 hours.²³

The total vascular monocyte pool consists of a marginated pool and a circulating pool; the marginating pool is about three times the size of the circulating pool. Monocytes in the circulating peripheral blood number about $0.1\text{--}0.8 \times 10^9/\text{L}$ in the normal adult, or $\sim 2\%\text{--}10\%$ of the total leukocytes. Children have a slightly higher concentration. Monocytosis (increase in monocytes) in adults occurs when the absolute monocyte count is $>0.8 \times 10^9/\text{L}$.

FUNCTION

Monocytes and macrophages are active in both the innate and adaptive IR. In addition to their phagocytic function, they secrete a variety of substances that affect the function of other cells, especially lymphocytes. Lymphocytes in turn secrete soluble products—lymphokines—that modulate monocytic functions.

Monocytes and macrophages ingest and kill microorganisms. They are particularly important in inhibiting the growth of intracellular microorganisms. This inhibition requires cellular activation (enhancement of function) of monocytes by soluble products of T lymphocytes. Killing by activated monocytes is nonspecific (i.e., the secretions from *Listeria*-sensitized T cells activate a killing mechanism in monocytes not only to *Listeria* but also to other microorganisms). Activation also can occur as the result of the actions of other substances on monocytes such as endotoxins and naturally occurring opsonins. Activation results in the production of many large granules, enhanced phagocytosis, and an increase in the activity of the HMP shunt.

Monocytes/macrophages have some ability to bind directly to microorganisms via PAMP and PRR (see leukocyte function), but binding is enhanced if the microorganism has been opsonized by complement or immunoglobulin (Web Figure 1 ■). Macrophages possess receptors for the Fc component of IgG and for the complement component C3b. Following attachment, the opsonized organism is ingested in a manner similar to that of neutrophils (see Figure 7). Primary lysosomes fuse with the phagosome, releasing hydrolytic enzymes and other microbicidal substances. The most powerful microbicidal substances of monocytes and macrophages are products of oxygen metabolism—superoxide (O_2^-), hydroxy radical (OH^-), singlet oxygen (1O_2), and hydrogen peroxide (H_2O_2)—generated in a reaction analogous to the neutrophil respiratory burst.

Activated macrophages attach to tumor cells and kill them by a direct cytotoxic effect. If the tumor cell has immunoglobulin attached, the macrophage Fc receptor attaches to the Fc portion of the immunoglobulin and exerts a lytic effect on the tumor cell.

Macrophages are important scavengers, phagocytosing cellular debris, effete cells, and other particulate matter. Monocytes in the blood ingest activated clotting factors, thus limiting the coagulation process. They also ingest denatured protein and antigen–antibody complexes. Macrophages lining the blood vessels remove toxic substances from the blood, preventing their escape into tissues. The macrophages of the spleen are important in removing aged erythrocytes from the blood; they conserve the iron of hemoglobin by either storing it for future use or releasing it to transferrin for use by developing normoblasts in the marrow. By virtue of their Fc receptor, the splenic macrophages also remove cells sensitized with antibody. In autoimmune hemolytic anemias or in autoimmune thrombocytopenia, the spleen is sometimes removed to prevent premature destruction of these

antibody-coated cells in an attempt to alleviate the resulting cytopenias.

For unknown reasons, erythrocytes in some pathologic conditions are randomly phagocytosed and destroyed by monocytes and macrophages in the blood and bone marrow (erythrophagocytosis) (Figure 12 ■). **Erythrophagocytosis** is readily identified when the ingested erythrocytes still contain hemoglobin. At times, erythrocyte digestion can be inferred by finding ghost spheres within the macrophage.

In addition to its role in pathogen control and tissue homeostasis, the MNP plays a major role in initiating and regulating the adaptive IR.²³ Macrophages phagocytize and degrade both soluble and particulate substances that are foreign to the host. Through unknown mechanisms, they spare critical portions of these antigens known as *antigenic determinants* or *epitopes*. These antigenic determinants are bound by MHC molecules on the macrophage membrane and are presented to antigen-dependent T lymphocytes. Thus, monocytes and macrophages can function as **antigen-presenting cells (APC)**. In addition to antigen presentation, the macrophage produces a number of cytokines that regulate the adaptive IR as well as the inflammatory response. Antigen-specific T lymphocyte proliferation requires antigen presentation in context with cell surface MHC antigens and stimulation with soluble mediators such as IL-1 and IL-2. T lymphocytes respond to foreign antigens only when the antigens are displayed on APCs that have the same MHC phenotype as the lymphocyte itself.

Macrophages stimulate the proliferation and differentiation of lymphocytes through secretion of cytokines. They secrete IL-1, which stimulates T lymphocytes to secrete interleukin-2 (IL-2), a growth factor that stimulates the proliferation of other T lymphocytes. In addition, IL-2 acts in synergy with interferon (IFN) to activate macrophages. When released from macrophages, arachidonic metabolites (e.g., leukotrienes, prostaglandins) inhibit the function of activated lymphocytes. Activated lymphocytes in turn secrete lymphokines that regulate the function of macrophages. For these interdependent reactions to occur between the macrophage and lymphocyte, the two cell populations must express compatible MHC antigens.

In addition to IL-1, macrophages release a variety of substances that are involved in host defense or that can affect

■ **FIGURE 12** Erythrophagocytosis by a monocyte. (Peripheral blood, Wright-Giemsa stain, 1000× magnification)

the function of other cells. Other secretory products involved in host defense include lysozymes, complement components, and IFN (an antiviral compound). Secreted substances that modulate other cells include hematopoietic growth factors (e.g., G-CSF, M-CSF, GM-CSF), substances which stimulate the growth of new capillaries (angiogenic cytokines), factors that stimulate and suppress the activity of lymphocytes, chemotactic substances for neutrophils, and a substance that stimulates the hepatocyte to secrete fibrinogen. After death, activated macrophages also release enzymes such as collagenase, elastase, and neutral proteinase that hydrolyze tissue components.

An adult patient's neutrophil count and monocyte count are extremely low ($<0.50 \times 10^9/L$ and $<0.050 \times 10^9/L$, respectively). What body defense mechanism is at risk?

PART II

LYMPHOCYTES

For many years after its discovery, the lymphocyte was considered an insignificant component of blood and lymph. Since 1960, major advances in immunology have targeted lymphocytes as the effector cells of the adaptive immune response. The lymphocyte's primary functions are to: recognize and react with antigens; work with monocytes to eliminate pathogens; and provide long-lasting immunity to previously encountered pathogens.

► LYMPHOCYTES

COMMITMENT AND DIFFERENTIATION

The lymphoid lineage arises from the pluripotential HSC found in the bone marrow. This stem cell gives rise to committed progenitor cells: the CLP and the CMP. The lymphoid progenitor cell differentiates and matures under the inductive influence of selective microenvironments into three types of morphologically identical but immunologically and functionally diverse lymphocytes. T lymphocytes and B lymphocytes are the major cells of the adaptive immune response. A third type of lymphocyte, the natural killer (NK) cell, has characteristics distinctly different from those of T and B lymphocytes and is an effector cell of innate immunity against infectious agents and transformed cells that have altered expression of histocompatibility antigens (see section on NK cells).

T and B lymphopoiesis can be divided into two distinct phases: antigen-independent lymphopoiesis and antigen-dependent lymphopoiesis (Figure 13■). Antigen-independent lymphopoiesis takes place within the primary lymphoid tissue

(bone marrow, thymus, fetal liver). Antigen-independent lymphopoiesis begins with the committed lymphoid progenitor cell and results in the formation of immunocompetent T and B lymphocytes (referred to as *virgin* or *naïve lymphocytes* because they have not yet reacted with antigens). These cells exit the primary lymphoid tissue and migrate to secondary lymphoid tissue (spleen, lymph nodes, gut-associated lymphoid tissue) where the secondary phase of lymphopoiesis continues. Antigen-dependent lymphopoiesis begins with recognition of and interaction with antigens by specific antigen receptors on the surface of the immunocompetent T and B lymphocytes (T cell receptors [TCR] and B cell receptors [BCR]). Interaction with antigen results in the formation of effector T and B lymphocytes. These effector cells mediate the adaptive immune response.

Effector T cells are responsible for cell-mediated cytotoxic reactions (T_C), suppressor functions (T_S), and delayed hypersensitivity responses (T_{DHS}). They also produce cytokines that regulate immune responses (T regulatory cells, T_{Reg}) and provide helper activity for B cells (T_H). B lymphocytes can concentrate and present antigens to T cells and are the precursors of immunoglobulin-secreting plasma cells. Each B lymphocyte can be programmed to make a specific antibody targeted against a specific triggering antigen by rearrangement of its immunoglobulin genes. The NK cells are a form of cytotoxic lymphocyte that composes a major component of the innate immune system. NK cells play a key role in the cytolysis of both tumor- and pathogen-infected cells. They do not rearrange or express T-cell receptor genes or B-cell immunoglobulin genes and thus do not express antigen-specific receptors.

Morphologic criteria cannot be used to differentiate between T, B, and NK lymphocytes. When there is a need to distinguish between them, monoclonal antibodies and flow cytometry for subset-specific CD molecules are most often used.

DIFFERENTIATION: MORPHOLOGY OF IMMATURE LYMPHOCYTES

Three morphologic stages of lymphoid maturation are recognized: lymphoblast, prolymphocyte, and lymphocyte. The morphologic changes that occur during differentiation or activation are shared by the major lymphocyte subgroups. T, B, and NK lymphocytes and their precursors are indistinguishable by morphologic criteria.

Lymphoblast

The lymphoblast (Figure 14a■) is about 10–18 μm in diameter with a high N:C ratio. The nuclear chromatin is lacy and fine, but it appears more smudged or heavy than that of myeloblasts. One or two well-defined pale blue nucleoli are visible. The nuclear membrane is dense, and a perinuclear clear zone can be seen; it has less basophilic agranular cytoplasm than other white cell blasts. Subtle morphologic differences exist, but lymphoblasts are usually indistinguishable from myeloblasts. Cytochemical stains can be used to help identify their lymphoid origin. Unlike myeloblasts, lymphoblasts stain negative for peroxidase, lipid, and esterase but

■ **FIGURE 13** Lymphocytes originate from the common lymphoid progenitor cell/CLP (derived from the pluripotential hematopoietic stem cell/HSC) in the bone marrow. Lymphocyte progenitors that mature in the thymus become T lymphocytes, and those that mature in the bone marrow become B lymphocytes, natural killer cells (NK), or lymphoid-derived dendritic cells (LD). Three *morphologic* stages can be identified in this development to T- and B-cells: lymphoblast, prolymphocyte, and lymphocyte. On encounter with antigen, these immunocompetent T and B lymphocytes undergo blast transformation, usually in the lymph nodes, to form effector lymphocytes. The B lymphocytes eventually emerge as plasma cells. Effector T lymphocytes, however, are often morphologically indistinguishable from the original T lymphocytes. The recognizable morphologic stages of blast transformation include reactive lymphocytes, immunoblasts, plasmacytoid lymphocytes (B-cells), and plasma cells (B-cells). Flow cytometry indicates that some morphologic stages could represent several stages of immunologic maturation.

contain acid phosphatase and sometimes deposits of glycogen (PAS+). Both T and B lymphoblasts contain a DNA polymerase, terminal deoxynucleotidyl transferase (TdT), present in immature lymphoid cells intermediate between the CLP and differentiated T and B cells.

Prolymphocyte

The prolymphocyte is difficult to distinguish in normal bone marrow specimens (Figure 14b ■). The prolymphocyte is slightly smaller than the lymphoblast with a lower N:C ratio. The nuclear chromatin is clumped but more finely dispersed than that of the lymphocyte. Nucleoli are usually present, and the cytoplasm is light blue and agranular.

Lymphocyte

The mature lymphocyte has extreme size variability, 7–16 μm when flattened on a glass slide, which is primarily dependent on the amount of cytoplasm present (Figure 14c ■). Small lymphocytes range in size from 7–10 μm . In these cells, the nucleus is about the size of an erythrocyte and occupies about 90% of the cell area. The chromatin is deeply con-

densed, staining a dark purple. Nucleoli, although always present, are rarely visible with the light microscope as small, light areas within the nucleus. The nucleus is surrounded by a narrow rim of sky blue cytoplasm. A few azurophilic granules and vacuoles can be present. Lymphocytes are motile and can show a peculiar hand-mirror shape on stained blood smears with the nucleus in the rounded anterior portion (protopod) trailed by an elongated section of cytoplasm known as the *uropod*. Small lymphocytes include a diversity of functional subsets including resting, immunocompetent, differentiated effector, and memory T and B lymphocytes.

Large lymphocytes are heterogeneous and range in size from 11 to 16 μm in diameter. The nucleus can be slightly larger than in the small lymphocyte, but the difference in cell size is mainly attributable to a larger amount of cytoplasm. The cytoplasm can be lighter blue with peripheral basophilia or darker than the cytoplasm of small lymphocytes. Azurophilic granules can be present; if prominent, the cell is described as a large granular lymphocyte. These granules differ from those of the myelocytic cells in that they are peroxidase negative. The nuclear chromatin can appear similar to that of the small lym-

■ **FIGURE 14** Morphologic stages of lymphocyte maturation. **a.** lymphoblast: Note the lacy chromatin and high N:C ratio; **b.** prolymphocyte: Note the increased amount of cytoplasm; **c.** lymphocyte: The nuclear chromatin is coarse and smudged. (a, b: Bone marrow, Wright-Giemsa stain, 1000× magnification; c: Peripheral blood, Wright-Giemsa stain, 1000× magnification)

phocyte or more dispersed, and the nucleus can be slightly indented. These large cells, like small lymphocytes, probably represent a diversity of functional subsets.

Normally ~3% of blood lymphocytes are described as **large granular lymphocytes (LGL)**, so named because of the presence of large granules in their cytoplasm. These cells consist of a mixed population of both NK cells and some mature CD8⁺ (cytotoxic) T cells (T_C). These cells have a round or indented nucleus and abundant pale blue cytoplasm containing coarse pink granules (Figure 15 ■). The granules, thought to be related to the cells' cytolytic capacity, contain the pore-forming proteolytic enzyme perforin and granzymes (serine proteases with pro-apoptotic activity).

ACTIVATION: MORPHOLOGY OF ACTIVATED LYMPHOCYTES

During development into immunocompetent T and B lymphocytes (cells with the ability to respond to stimulation by an antigen), the cells acquire specific receptors for a particular antigen, which commits them to an antigen specificity. During the antigen-dependent phase of lymphocyte development, contact and binding of this specific antigen to receptors on immunocompetent T and B lymphocytes begin a

complex sequence of cellular events known as *blast transformation (blastogenesis)*. The end result is a clonal amplification of cells responsible for the overt expression of immunity to the specific antigen. Usually occurring within the lymph node, this series of events includes cell enlargement, an increase in the rough endoplasmic reticulum (RER), enlargement of the nucleolus, dispersal of chromatin and an increase in DNA synthesis, and mitosis. These transformed cells, called *immunoblasts*, have the option to differentiate into terminally differentiated effector cells capable of mediating the immune response or long-lived memory cells. The morphologically identifiable forms of antigen-stimulated lymphocytes include the reactive lymphocyte, reactive immunoblast, plasmacytoid lymphocyte, and plasma cell.

Reactive lymphocytes and immunoblasts can be either T or B lymphocytes, which can be determined only by cell marker studies (flow cytometry). In the past, reactive lymphocytes and immunoblasts were referred to as *Downey cells* (a term usually used to describe the cells seen in infectious mononucleosis) and were classified as Types I, II, or III, depending on various morphologic criteria. This classification is obsolete because the various types of Downey cells are simply morphologic variations accompanying the process of blast transformation.

■ **FIGURE 15** Large granular lymphocyte. (Peripheral blood, Wright-Giemsa stain, 1000 \times magnification)

Reactive Lymphocyte

The **reactive lymphocyte** (Figure 16a■) exhibits a variety of morphologic features, including one or more of the following. It can increase in size (16–30 μm) and have a decreased N:C ratio. The nucleus can be round but is more frequently elongated, stretched, or irregular. The chromatin becomes more dispersed, staining lighter than the chromatin of a resting lymphocyte, and nucleoli can be seen. There usually is an increase in diffuse or localized basophilia of the cytoplasm, and azurophilic granules and/or vacuoles can be present. The cytoplasmic membrane can be indented by surrounded erythrocytes, which sometimes gives the cell a scalloped edge.

The reactive lymphocyte is also referred to as a *stimulated*, *transformed*, *atypical*, *activated*, or *variant lymphocyte*. However, the word *atypical* carries the connotation of abnormal or malignant, and some hematologists therefore prefer not to use the term to describe normal lymphocytes in various stages of reaction to antigenic stimulation.

A few reactive lymphocytes can be seen in the blood of healthy individuals, but they are found in increased numbers in viral infections. For this reason, the reactive lymphocyte has also been called a *virocyte*.

Immunoblast

The **immunoblast** (Figure 16b■) is the next stage in blast transformation. The cell is large, 12–25 μm in size. The cell is characterized by prominent nucleoli and a fine nuclear chromatin pattern (but coarser than that of other leukocyte blasts). The large nucleus is usually central and stains a purple-blue color. The abundant cytoplasm stains an intense blue color due to the high density of polyribosomes. These are cells preparing for or engaged in mitosis. The immunoblast proliferates, increasing the pool of cells programmed to respond to the initial stimulating antigen.

These programmed daughter cells (effector lymphocytes) mature into cells that mediate the effector arm of the immune response.

The daughter cells of B immunoblasts, which mediate **humoral immunity**, are plasmacytoid lymphocytes (Figure 16c■) and plasma cells (Figure 16d■). Humoral immunity is the production of antibodies by activated B lymphocytes stimulated by antigen. The plasmacytoid lymphocyte (also referred to as lymphocytoid plasma cell) is believed to be an intermediate cell between the B lymphocyte and the plasma cell. It gains its descriptive name from its morphologic similarity to the lymphocyte but has marked cytoplasmic basophilia similar to that of plasma cells.

In contrast to the progeny of the B immunoblast, effector cells produced from the T immunoblast, T cytotoxic cells (T_C), T suppressor cells (T_S), or T helper cells (T_H) are morphologically indistinguishable from the original unsensitized lymphocytes or appear as LGL.

Plasmacytoid Lymphocyte

The **plasmacytoid lymphocyte** ranges in size from 15 to 20 μm . The nuclear chromatin is less clumped (more immature) than that of a plasma cell, and it can have a single visible nucleolus. The nucleus is central or slightly eccentric, and the cytoplasm is deeply basophilic. The cell has some cytoplasmic immunoglobulin (cIg) as well as surface membrane immunoglobulin (sIg). This cell is occasionally seen in the peripheral blood of patients with viral infections.

Plasma Cells

Plasma cells are round or slightly oval with a 9–20 μm diameter. The nucleus is eccentrically placed and contains coarse blocklike radial masses of chromatin, often referred to as the *cartwheel* or *spoke wheel arrangement*. Nucleoli are not present. The paranuclear Golgi complex is obvious and surrounded by deeply basophilic cytoplasm. The cytoplasm stains red with pyronine (pyroninophilic) because of the high RNA content. The RER is well developed, and the cytoplasm enlarges because of the production of large amounts of immunoglobulin. As cytoplasmic immunoglobulin increases, the cell's secretory capacity increases. Membrane sIg is usually absent, but azurophilic granules and rodlike crystal inclusions can be present.

Memory Cells

A number of the T and B immunoblast daughter cells alternatively form T and B memory cells. **Memory cells** are morphologically similar to the resting small lymphocytes, retain the ability to react with the stimulating antigen, and are capable of eliciting a rapid secondary immune response when challenged again by the same antigen.

The reactive lymphocyte is commonly found in the blood during viral infection; the immunoblast, plasmacytoid lymphocyte, and plasma cell usually are found only in lymph nodes and other secondary lymphoid tissue. During intense stimulation of the immune system, however, these trans-

■ **FIGURE 16** Stages of lymphocyte activation. **a.** Reactive lymphocyte: The cell is large with an increased amount of basophilic cytoplasm. Note the normal lymphocyte below the reactive lymphocyte; **b.** Immunoblast: The N:C ratio is high. The nucleus has a lacy chromatin pattern, and the cytoplasm is deep blue; a small lymphocyte is above the immunoblast **c.** Plasmacytoid lymphocyte: The nuclear chromatin is coarse, and there is a moderate amount of deep blue cytoplasm; there is a reactive lymphocyte to the lower right. **d.** Plasma cell: The fully differentiated B cell has an eccentric nucleus and there is a large amount of basophilic cytoplasm. (Peripheral blood, Wright-Giemsa stain, 1000× magnification)

formed cells can be found in the peripheral blood due to lymphocyte recirculation.

✓ Checkpoint! 7

How would you morphologically differentiate a reactive lymphocyte from a plasma cell on a peripheral blood smear?

LYMPHOID LINEAGE DIFFERENTIATION

The phenotypic features of lymphocytes that allow them to be identified as T lymphocytes or B lymphocytes include cytochemical staining properties, CD surface markers, and membrane antigens. This differentiation is possible throughout antigen-independent and antigen-dependent lympho-

poiesis. Examples of markers for B cell precursors include CD10, CD19, CD21, CD22, and CD24. Markers for T cell precursors include CD1, CD2, CD3, CD5, and CD7. T lymphoblasts contain nonspecific esterase, β -glucuronidase, and N-acetyl β -glucosamidase, as well as a punctuate pattern of acid phosphatase positivity. The esterase and acid phosphatase stains for B lymphoblasts are either negative or have a scattered granular pattern of positivity. B lymphoblasts can contain small amounts of immunoglobulin or the μ immunoglobulin heavy chain, which can be detected by using immunofluorescent techniques.

T Lymphocytes

Bone marrow lymphoid precursor cells migrate to the thymus (primary lymphoid organ) where they proliferate and

differentiate to acquire cellular characteristics of T lymphocytes. It is unclear which specific precursor cell migrates, the HSC, CLP, CFU-T/NK, or CFU-T. Lymphopoiesis at this stage correlates to the antigen-independent stage of lymphoid development.

The hormone thymosin, synthesized and secreted by epithelial cells in the thymus, is believed to influence T lymphocyte maturation. Intrathymic proliferation and death for potential T lymphocytes is high with about 95% of the cells produced undergoing apoptosis. Consequently, only a small portion of T-precursor cells leave the thymus as immunocompetent, naïve T lymphocytes.

The historic viewpoint has been that the thymus functions in T lymphopoiesis primarily during fetal life and the first few years after birth, and the T lymphoid system was considered to be nearly fully developed at birth. Surgical removal of the thymus after birth does not severely impair immunologic defense; however, lack of thymus development in the fetus (DiGeorge syndrome) results in the absence of T lymphocytes and severe impairment of cell mediated immunity. However, more recent studies utilizing polymerase chain reaction-based assays to detect excised products of the TCR gene rearrangement (described below) have demonstrated that while thymic function declines significantly (by 5-fold at age 35 years), the T cell pool continues to be replenished by a functioning thymus throughout life.²⁴

Cell-mediated immunity is the basis of the immune response mediated by T lymphocytes and requires interaction between histocompatible T lymphocytes, macrophages, and antigens. Several important T lymphocyte subsets are involved. T cells diversify late in thymic maturation into either T helper/effector (T_H , T_{Reg} $CD4^+$, or T_4) lymphocytes or T cytotoxic/suppressor (T_C/T_S , $CD8^+$, or T_8) lymphocytes. When activated, these cells proliferate, produce lymphokines, and mount a diverse set of effector functions. These subsets are phenotypically and functionally distinct but morphologically indistinguishable.

T lymphocytes confer protection against antigens that have the ability to avoid contact with antibodies by residing and replicating within the cells of the host. Thus, serious infection with intracellular parasites (bacteria, fungi, and viruses) can occur if T lymphocytes are deficient.

T Lymphocyte Membrane Markers Lymphocyte subpopulations were first identified by virtue of unique surface receptors, which have a binding affinity for certain ligands. Binding of sheep red blood cells (SRBC) by T lymphocytes via the E (erythrocyte) receptor traditionally has been a marker for identifying T cells. The E receptor, now known as *CD2* or *lymphocyte function antigen-3 (LFA-3)*, binds SRBC, forming a rosette. The T lymphocyte is the center of the rosette, and the SRBCs form the petals.

T lymphocytes also possess receptors for the Fc portion of IgM and IgG (*CD16*). T lymphocytes can change the specificity of their Fc receptor upon antigenic stimulation. Additionally, CD surface markers (including *CD4* and *CD8*, discussed above)

and/or other antigens are used to differentiate developmental stages of T precursor cells. *CD4* and *CD8* are members of the immunoglobulin supergene family of adhesion molecules.

T Lymphocyte Antigen Receptor The T lymphocyte has an antigen receptor on its surface (**T cell receptor**, [TCR]), responsible for initiating the cellular immune response. The TCR is a heterodimer of two peptide chains linked by a disulfide bond (Figure 17 ■). This receptor is a member of the immunoglobulin supergene family of adhesion molecules. Two subsets of T cells are defined by expression of distinct TCR polypeptides: TCR with gamma and delta chains ($\gamma\delta$ T cells) and TCR with alpha and beta chains ($\alpha\beta$ T cells). More than 90% of T lymphocytes are $\alpha\beta$ T cells.^{25,26} The organization of the TCR chains is similar to

■ **FIGURE 17** The T lymphocyte has an antigen receptor (TCR) on its surface that is composed of two peptide chains linked by a disulfide bond. This receptor is expressed in a complex with *CD3* (γ , δ , ϵ polypeptides) and a ζ -polypeptide dimer. This TCR is in close proximity to an MHC-restricted receptor (*CD4* or *CD8*) that recognizes the appropriate molecule on antigen presenting cells (APCs). The helper T lymphocyte receptor (*CD4*), shown here, recognizes Class II MHC molecules, and the suppressor T lymphocytes receptor (*CD8*) recognizes Class I MHC molecules.

that of the immunoglobulin chains. Each TCR chain is composed of a variable region that binds an antigen and a constant region that anchors the TCR to the cell membrane. The variable (V) region is made from three DNA segments—variable (V), diversity (D), and joining (J)—in the beta and delta chains but only two segments, V and J, in the alpha and gamma chains. A complete V region (i.e., VDJ) is translocated to a constant (C) segment to form the individual TCR chains. Random rearrangement and recombination of various V, D, and J segments and subsequent joining with a C segment provide the antigenic diversity of T cell receptors. This diversity allows the T lymphocyte to recognize many different antigens.

The $\alpha\beta$ and $\gamma\delta$ TCR are expressed as a molecular complex with several other transmembrane polypeptide chains (CD3 γ , CD3 δ , and CD3 ϵ) in the cell membrane. These chains form $\delta:\epsilon$ and $\gamma:\epsilon$ heterodimers in the cell membrane producing the CD3 complex. Also included in the TCR is a ζ -chain homodimer (CD247). These auxiliary molecules (CD3 and CD247) with the $\gamma\delta$ TCR or $\alpha\beta$ TCR mediate intracellular signal transduction when antigen binds to the TCR antigen-receptor.²⁷ Antigenic stimulation of T lymphocytes requires presentation of antigen bound to major histocompatibility (MHC) molecules of antigen-presenting cells (APC). T cell response is “MHC restricted,” that is, T lymphocytes respond only to foreign antigens displayed by APCs having the same MHC phenotype as the T cell. APCs include dendritic cells, macrophages, and B lymphocytes.

Dendritic cells are derived from the HSC and are present in all tissues. There are two pathways of development for dendritic cells: one group originates from the CMP (myeloid-derived) and the other group originates from the CLP (lymphoid-derived). Their function is to process the antigen and present it in a recognizable form to T lymphocytes.

The different subsets of T lymphocytes recognize different classes of MHC molecules with the CD4 and CD8 molecules of the T cell serving as “coreceptors” in the interaction. In cytotoxic or suppressor T cells, the CD8 molecule recognizes and interacts with Class I MHC molecules, but in T helper cells, the CD4 molecule recognizes and interacts with Class II MHC molecules.

T Lymphocyte Developmental Stages Differentiation of the various developmental stages for both T and B lymphocytes is based on the appearance of specific molecular changes as well as membrane molecules. It is possible to define distinct stages of intrathymic differentiation of T lymphocytes using monoclonal probes to identify the presence of CD antigens on the cell surface as well as molecular evidence of TCR gene rearrangement. Some antigenic determinants appear at a very early developmental stage of the cell and disappear with maturity; other unique determinants appear on more mature cells (Figure 18 ■).²⁸

Commitment to the T cell lineage depends on cytokines produced by the thymic stroma including IL-1 α and tumor necrosis factor- α (TNF- α). The exact lymphoid progenitor

cell that migrates to the thymus is unclear; however, acquisition of cell surface CD1 identifies a precursor cell committed to T lineage differentiation.^{29,30} The stages of T cell development are most reliably defined based on changes in rearrangement of the gene loci for the TCR polypeptides and the presence of the TCR coreceptors, CD4 and CD8. The major developmental stages are termed pro-T cell, pre-T cell, double positive (DP) and single positive (SP) thymocyte, and T cell (Figure 18).

The earliest committed T-cell precursor, a *pro-T cell*, is CD34+ and contains germline configuration of the TCR α -, β -, γ -, and δ -loci. These cells are also CD25+ (IL-2 receptor) and CD44+ (thymic homing receptor) but CD4-CD8- (“double negative” cells). They contain TdT (terminal deoxynucleotidyl transferase). During transition from pro-T to pre-T cell, rearrangement of the β -chain locus occurs. If the rearrangement is successful, the β -chain is expressed in the cytoplasm (c β) toward the end of the pro-T stage.

At the next developmental stage, pre-T cell, the TCR β -chain appears on the cell surface complexed with a surrogate α -chain (preT α) and the CD3 polypeptides as a pre-TCR (pre-T α /TCR β). Expression of the pre-TCR signals expression of both CD4 and CD8, forming *double positive (DP) thymocytes* (late pre-T cell). During the pre-T cell stage, the α -chain undergoes rearrangement.

When a functional α -chain has been produced, it pairs with the β -chain to form the $\alpha\beta$ TCR. This appears on the surface of the cell with the CD3 complex (DP, $\alpha\beta$ TCR:CD3). In the next step, the DP thymocyte undergoes selection and differentiation into either SP CD4+CD8- (T_H) or CD4-CD8+ (T_{S/C})T cells. At this point, the cells are immunocompetent but naïve T cells. SP T_H or T_{S/C} cells leave the thymus and enter the circulation to complete final maturation. In the periphery, encounters with the antigen specifically recognized by the unique variable region of the TCR result in activation and generation of appropriate effector cells and memory T cells (antigen-dependent phase of lymphopoiesis).

Thus, early thymocytes have markers of both helper (CD4+) and suppressor (CD8+) cells (DP thymocytes); later mature (though naïve) T cells express one or the other (CD4+ T_H cells or CD8+ T_{S/C} cells). About 60–80% of peripheral blood T lymphocytes are CD4 cells (T₄). They are also the predominant T lymphocytes of the lymph nodes. CD8 cells (T₈) make up only 35% of peripheral blood T lymphocytes but are the predominant T lymphocyte found in the bone marrow. The normal T₄:T₈ ratio in circulating blood is thus ~2:1. The balance between T₄ and T₈ must be maintained for normal activity of the immune system. This ratio can be depressed in viral infections, immune deficiency states, and acquired immune deficiency syndrome (AIDS) and can be increased in disorders such as acute graft versus host disease, scleroderma, and multiple sclerosis.

There are two subtypes of CD4+ cells: T_{H1} and T_{H2}. They differ as to the cytokines they produce, the cells they affect, and the pathogens with which they react. T_{H1} cells participate in cell-mediated immunity against intracellular

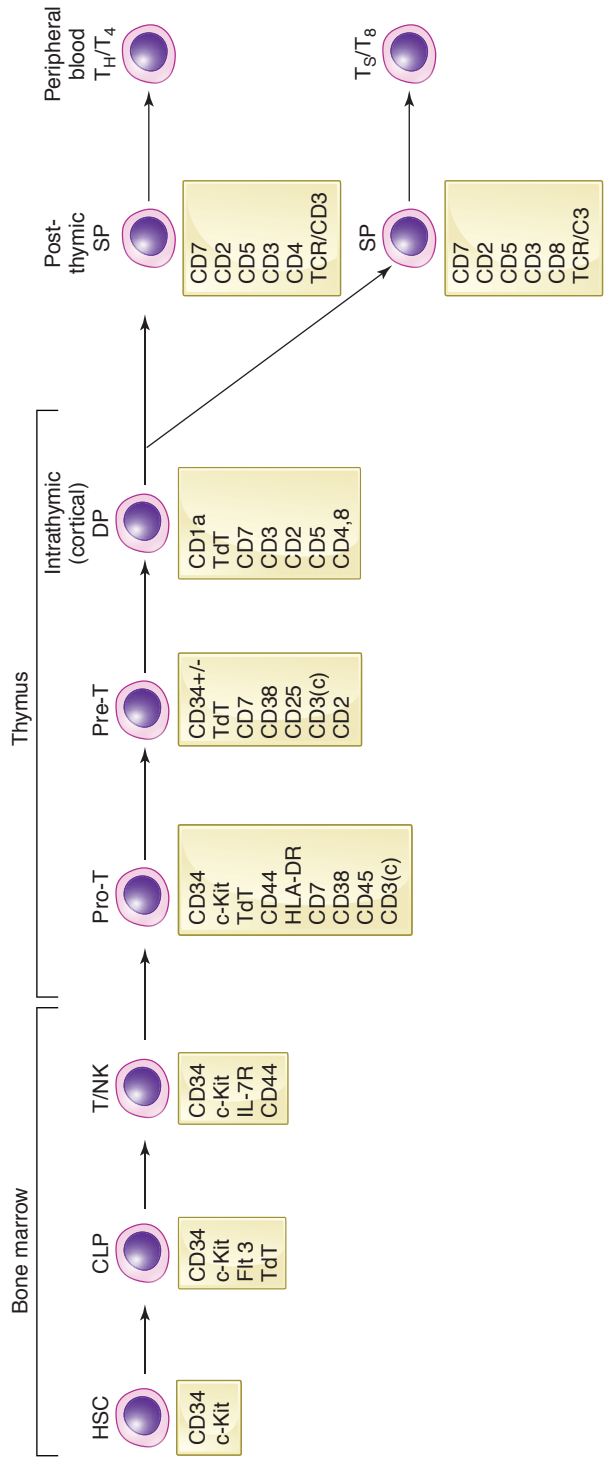

FIGURE 18 Immunologic maturation of the T lymphocyte from the common lymphoid progenitor cell (CLP) to the peripheral blood T helper (T_H) and T suppressor/cytotoxic (T_S/T_C) lymphocytes. Monoclonal antibodies and molecular studies for TCR gene rearrangements have identified at least four intrathymic stages of maturation before the cells are released to the peripheral blood as mature T lymphocytes. These include pro-T cell, pre-T cell, double positive (DP), and single positive (SP). Differentiation into either helper or suppressor lymphocytes occurs at the last intrathymic stage of maturation. (CD = cluster of differentiation; TCR = T cell receptor; TdT = thymidine deoxynucleotidyl transferase; IL-7R = interleukin 7 receptor; c-Kit = stem cell factor receptor, also called CD117)

pathogens and activate macrophages. T_{H2} cells provide help to the B cells and are essential for antibody-mediated immunity. Table 7 🌟 summarizes the T helper cell functions.

B Lymphocytes

B lymphocyte precursors derived from the CLP undergo the antigen-independent phase of B cell maturation in the bone marrow. The immunocompetent (naïve) mature B lymphocytes then enter the blood and migrate to the germinal centers (follicles) and medullary cords of lymph nodes, the germinal centers of the spleen, and other secondary lymphoid tissue. If B cells fail either to enter a lymphoid follicle or to encounter and be stimulated by specific antigens, the cells die (by apoptosis) within several days to several weeks. Upon encounter with specific antigen, the B cells finish their differentiation program. Antigenic stimulation causes the B lymphocytes to undergo proliferation and differentiation into plasmacytoid lymphocytes and finally into immunoglobulin antibody-secreting plasma cells. The immunoglobulin recognizes and binds to foreign antigen. B lymphocytes compose 15–30% of peripheral blood lymphocytes.

B Lymphocyte Membrane Markers B lymphocytes can be identified and differentiated from T lymphocytes by virtue of complement receptors and surface membrane immunoglobulin as well as CD antigens/markers. B lymphocytes form rosettes with mice erythrocytes as well as sheep erythrocytes that are coated with antibody and complement (EAC). EACs attach to B lymphocytes by means of B lymphocyte complement receptors. Surface membrane immunoglobulin can be detected by fluorescein-conjugated antisera to the different classes of immunoglobulins.

Membrane markers are present at various stages in B lymphocyte development. B lymphocytes are identified using flow cytometry and a panel of antibodies to surface antigens that corresponds to the stage of the cell’s differentiation (Figure 19 ■). CD markers expressed by B lymphocytes and their precursors include CD10, CD19, CD20, CD21, CD22, CD24, and CD38. The CD19 antigen is considered a “pan-B” antigen because it is found on the earliest B lymphocyte and is retained until the latest stages of activation. The CD10 antigen, the common acute lymphoblastic leukemia antigen (CALLA), was originally believed to be a specific marker of leukemia cells in acute lymphoblastic leukemia. It is now known that CALLA is present on a small percentage (<3%)

of normal bone marrow cells and is found on only early B lymphocyte precursors, disappearing as cell maturation occurs. B cells also express Fc receptors capable of binding the Fc portion of IgG, IgM, IgA and IgE on their membranes.^{31,32}

B Lymphocyte Antigen Receptor

Like T cells, B cells recognize and interact with specific antigens via an antigen-specific **B cell receptor (BCR)**. The antigen-binding component of the BCR consists of an immunoglobulin (Ig) molecule identical to that produced by the mature B lymphocyte/plasma cell. The complete BCR consists of the immunoglobulin molecule with two accessory molecules, Igα and Igβ, which function as signaling molecules in B cell activation.

Immunoglobulin A unique molecule produced by B lymphocytes and plasma cells, **immunoglobulin** (antibody) consists of two pairs of polypeptide chains: two heavy and two light chains linked together by disulfide bonds (Figure 20 ■). The number and arrangement of these bonds are specific for the various immunoglobulin classes and subclasses. The five types of heavy chains (HC) are α, δ, ε, γ, and μ, which determine the class of the antibody (IgA, IgD, IgE, IgG, and IgM, respectively). Although each B cell precursor has two sets of HC genes (one on each chromosome 14), only one encodes the HC protein in any given cell. Thus, within a given immunoglobulin molecule, the two heavy chains are always identical. The two classes of light chains, κ and λ, have many subclasses. As with the heavy chains, the two light chains within an immunoglobulin molecule are always identical. Either -κ or λ-chain can be found in association with any of the various heavy chains. Each of the classes and subclasses of immunoglobulin has distinct physical and biologic properties (Web Table 1 🌟).

Each heavy and light immunoglobulin chain consists of a variable region and a constant region. The constant region is the same for all antibodies within a given class or subclass, but the variable region in each immunoglobulin molecule is different. The constant region mediates effector functions such as complement fixation. Together, the variable regions of the light (V_L) and heavy (V_H) chains determine the antibody-combining site. Rearrangement of gene segments of the heavy chain variable regions (see below) allows a diverse repertoire of immunoglobulin specificity for foreign antigens.

🌟 TABLE 7

Helper T Cell Functions

Type	Stimulating Cytokine	Effector Cytokines	Functions	Detrimental Effects
T _{H1}	IL-12	INF-γ, IL-2, TNF _α , TGF _β	Targets intracellular pathogens, mediates DTH and cytotoxicity, promotes secretion of IgG ₂	Arthritis, autoimmunity, organ transplant rejection
T _{H2}	IL-4	IL-4, IL-5, IL-6, IL-10, IL-13, TGF-β	Targets extracellular pathogens, activates eosinophils and mast cells, promotes IgG, activates B lymphocytes by secreting lymphokines	IgE mediated allergies and asthma

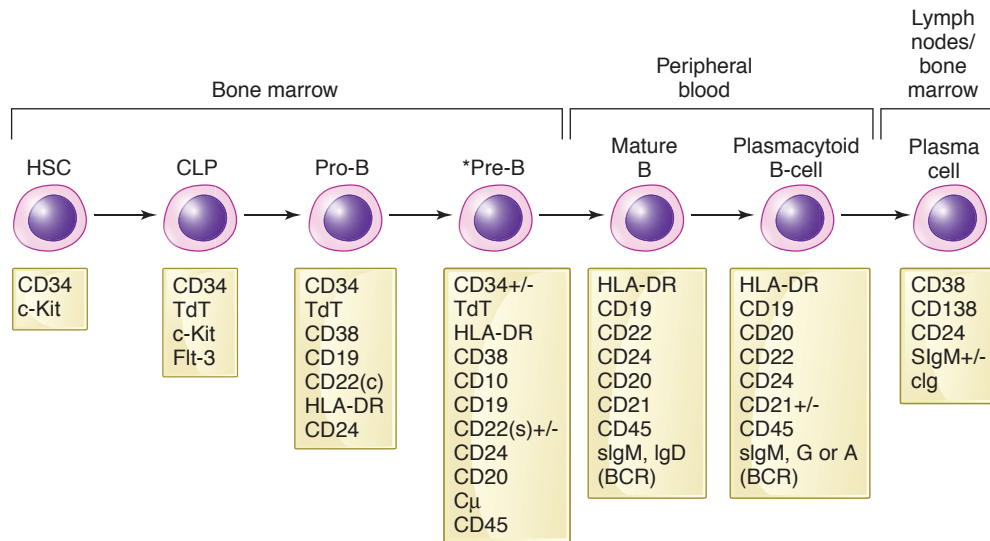

FIGURE 19 Immunologic maturation of the B lymphocyte from the pluripotent hematopoietic stem cell (HSC) to the plasma cell. Each stage of maturation can be defined by specific antigens (CD) that appear sequentially on the developing cell. Stem cells, pro-B lymphocytes, and pre-B lymphocytes are normally found in the bone marrow. The mature B lymphocyte is found in the peripheral blood. When stimulated by antigens, the B lymphocytes undergo maturation to plasma cells in the lymph nodes or bone marrow. In this figure, the pre-B cell stage includes the pre-pre-B cell, also referred to as the intermediate pre-B cell. (C μ = cytoplasmic μ chains; sIg = surface membrane immunoglobulin; clg = cytoplasmic immunoglobulin; CD = cluster of differentiation; BCR = B-cell receptor; c-Kit = stem cell factor receptor, also called CD117.)

The rate-limiting step in antibody production is the synthesis of heavy chain. A balance between production of heavy and light chains normally ensures no excess of one or the other. Neoplastic diseases of plasma cells, however, upset the balance; excesses of light chains or heavy chains can then be found in both serum and urine.

Immunoglobulin Gene Rearrangement During B lymphocyte development, a rearrangement of the gene loci coding for immunoglobulin heavy and light chains in the B progenitor cells similar to that for the TCR components occurs. This is one of the earliest features allowing the cell to be recognized as a B cell precursor. HC and LC gene rearrangement occurs at different stages of B cell development (see below). The gene rearrangement of the HC locus involves random selection of coding sequences from menus of three serially arranged DNA segments (V, D, and J) and recombination to form a variety of unique coding sequences and antibody specificities. The κ and λ LC also rearrange gene segments to provide additional immunoglobulin diversity. Light chain-variable gene segments include the V and J regions but no D region.

B Lymphocyte Developmental Stages Early antigen-independent stages of B lymphopoiesis occur in the bone marrow. The earliest committed B cell precursor is the pro-B cell (Figure 19).³¹ The *pro-B cell* is characterized by the pres-

ence of CD34 (an early hematopoietic cell antigen) and CD19 (pan-B antigen) and TdT. During the pro-B stage, HC rearrangement (DJ and VDJ) of the μ heavy chain of IgM takes place.

When a successful μ HC rearrangement has been completed, free cytoplasmic μ chains (C μ) can be seen and the cell becomes an early (large) pre-B cell. *Pre-B cells* are characterized by the loss of CD34, persistence of CD19, and the appearance of CD10 (CALLA), CD20, and CD24. Similar to the parallel stage in T cell development, pre-B cells produce a “pre-BCR” complex on the cell surface consisting of the μ HC complexed with a surrogate light chain (ψ LC). The μ/ψ LC associates with the accessory molecules Ig α and Ig β to form the pre-BCR. Toward the end of the pre-B cell stage, LC gene rearrangement occurs; it is characterized by loss of TdT and persistence of CD-19, -20, and -24.

When successful rearrangement of the LC locus is complete and the cell expresses either a $\mu\kappa$ or a $\mu\lambda$ IgM, the molecule is transported to the cell surface to form a functional BCR (sIgM). The cell is now a *mature B cell*; it is positive for CD-19, -20, -21, -22, and -24. The immunocompetent but naïve mature B cell is characterized by the dual expression of both μ (IgM) and δ (IgD) BCR on the cell surface.

As with T cells, during antigen-independent lymphopoiesis in the marrow, proliferation and apoptotic cell death are significant. This eliminates those cells with non-functional immunoglobulin gene rearrangement as well as those that produce autoreactive antigen receptors.

■ **FIGURE 20** Schematic drawing of an IgG molecule. The four peptide chains include two light and two heavy chains. Disulfide bonds between the chains are indicated by —s-s—. The variable domains are indicated by V, and the constant regions by C. The variable regions have variable amino acid sequences depending on the antibody specificity, and the constant regions have a constant sequence among immunoglobulins of the same class. The two heavy chains (H) determine the class of immunoglobulin, in this case for IgG. The two light chains can be either kappa or lambda.

B lymphocytes are not capable of reacting with antigens until they develop both IgM and IgD on their surface (i.e., mature B cell stage). At this stage, the immunocompetent but naïve cells leave the marrow and travel to the secondary lymphoid tissue (primarily lymph nodes) where the antigen-dependent phase of B cell development continues.

These naïve B cells recirculate through the blood and enter the peripheral lymph nodes and spleen. In these tissues, the B cells can undergo further differentiation into effector cells in response to antigenic challenge. After encountering the antigen recognized by the specific BCR, some activated B cells undergo isotype switching of the constant region of the HC gene, converting to IgG, IgA, or IgE BCR. Most mature B lymphocytes possess only one class of immunoglobulin on their membrane, although a small percentage can express IgG or IgA with IgM and IgD. Surface-

bound immunoglobulin serves as the receptor for a particular antigen.

There are two subclasses of mature B lymphocytes. B-1 lymphocytes are also known as CD5⁺ B cells because they express CD5 (normally considered a T cell marker). These cells are produced early in embryonic development and are found primarily in pleural and peritoneal cavities where they are thought to provide defense against environmental flora. B-2 lymphocytes are produced primarily after birth, are CD5⁻, and are found primarily in the circulation and secondary lymphoid tissues. CD5⁺ B-1 lymphocytes are the cells most commonly associated with autoimmune diseases and chronic lymphocytic leukemia (CLL).

Plasma Cell Development When stimulated by antigens, mature B lymphocytes undergo proliferation and transformation into plasma cells (the antigen-dependent phase of B-lymphopoiesis). Antigen activation of B lymphocytes results in the transformation from reactive lymphocytes to immunoblasts, to plasmacytoid lymphocytes, and finally to plasma cells in the lymph nodes. Plasma cells are the fully activated terminal form of the B lymphocyte lineage. Their primary function is formation and secretion of immunoglobulin that recognizes a particular antigen. Each plasma cell is committed to secreting large amounts of specific immunoglobulin of the same isotype (Ig class) and idiotype (antigen specificity) as the BCR of its precursor B cell. Plasma cells have large quantities of cytoplasmic immunoglobulin (cIg⁺) but contain little or no surface immunoglobulin (sIg). On the other hand, B cells from which plasma cells are derived are sIg⁺, but cIg⁻.

Plasma cells are not normally present in the peripheral blood or lymph and constitute less than 4% of the cells in the bone marrow. Most plasma cells are found in the medullary cores of lymph nodes although intense stimulation of the immune system can cause them to be found in the peripheral blood. Plasma cells are sometimes found in the blood in rubeola, infectious mononucleosis, toxoplasmosis, syphilis, tuberculosis, and multiple myeloma.

Normal plasma cell morphology was included with the discussion of lymphocyte morphology. Morphologic variations of plasma cells include *flame cells* and *Mott cells*. **Flame cells** are named for their reddish-purple cytoplasm (Figure 21 ■). The red tinge is caused by a glycoprotein produced in the RER, and the purple tinge is caused by the presence of ribosomes. These cells contain more immunoglobulin than do normal plasma cells. At one time, flame cells were believed to be associated with IgA multiple myeloma, but it is now recognized that these cells can be seen in a variety of pathologies and occasionally in normal bone marrow.

Mott cells, also called *grape cells*, are plasma cells filled with globules containing immunoglobulin (Russell bodies) (Figure 22 ■). **Russell bodies** normally stain blue-violet or pink, but in the staining process, the globulin can dissolve and the cell then appears to be filled with colorless vacuoles. The globules form as a result of the accumulation of material in the RER, smooth endoplasmic reticulum (SER), and the

■ **FIGURE 21** Flame cells. Note the reddish tinge of cytoplasm. The color is especially apparent at the periphery of the cytoplasm. These are variants of plasma cells. (Bone marrow, Wright-Giemsa stain, 1000 \times magnification).

Golgi complex caused by an obstruction of secretion. This pathologic plasma cell is associated with chronic plasmacyte hyperplasia, parasitic infection, and malignant tumors.

Intranuclear membrane-bound inclusion bodies known as **Dutcher bodies**, have been described in plasma cells from patients with dysproteinemias. These inclusions stain with PAS, indicating that they contain glycogen or glycoprotein. Dutcher bodies are most often found in neoplastic plasma cells.

Alterations in immunoglobulin production can be classified as hypogammaglobulinemia, polyclonal gammopathy, and monoclonal gammopathy. These conditions are most commonly detected by serum protein electrophoresis be-

■ **FIGURE 22** Mott cell (grape cell). Note the large globules in the cytoplasm. This is a variant of a plasma cell. (Bone marrow, Wright-Giemsa stain, 1000 \times magnification)

cause each class of immunoglobulin has a specific electrical charge that permits migration in an electrical field. Hypogammaglobulinemia is a decrease in the total concentration of immunoglobulins. Polyclonal gammopathies result in an increase in immunoglobulin in more than one class (polyclonal antibodies) and are frequently seen in viral or bacterial infections. **Monoclonal gammopathies** arising from one clone of cells (a monoclonal antibody) are characterized by an increase in one specific class of immunoglobulin with identical heavy and light chains. This type of alteration is usually the result of unregulated proliferation (neoplastic) of one clone of plasma cells.

Natural Killer Cells

The third population of lymphoid cells, **natural killer cells (NK)**, have the capacity for spontaneous cytotoxicity for various target cells. Unlike T_c cells whose cytotoxic activity is "MHC restricted," NK cells are effector cells whose cytotoxicity is non-MHC restricted (they do not require interaction with appropriate MHC molecules on the target cell).³³ Their CD markers are not characteristic of either T or B cells. NK cells do not rearrange either the BCR (immunoglobulin) or TCR (α -, β -, γ -, δ -) gene loci. NK cells possess CD16 (the Fc γ III receptor for IgG) and CD56. The CD16 marker is shared with neutrophils and some macrophages. NK cells have some T cell antigens on their cell membranes (up to 50% of NK cells can have weak expression of CD8 and CD2) but not CD3.³⁴

NK cells originate in the bone marrow from the CLP (Figure 23 ■). NK cells and T cells have a close developmental relationship with evidence that the immediate precursor of an NK-committed progenitor is a bipotential CFU-T/NK.²⁹ IL-15 is the major cytokine regulating NK cell differentiation and development (Figure 23). NK cells constitute about 15% of the circulating lymphocytes in the peripheral blood. Most NK cells are short lived with life spans from a few days to a few weeks.³⁴

Most (but not all) NK cells have an LGL morphology, but not all LGLs are NK cells. Under normal circumstances, most LGLs are CD3⁻. CD3⁺ LGLs are thought to be activated cytotoxic T cells that recognize specific epitopes of foreign protein such as those of viruses and are non-MHC restricted.³⁵ The separation between the two cell types is not absolute. There may be an intermediate cell population whose relationship with these two cell populations has not been determined.^{25,36}

NK cells mediate two cytolytic activities. They recognize and kill tumor cells and those infected with a virus (natural killing). They also can recognize and attack antigens with attached IgG via their IgG receptor (CD16) referred to as *antibody-dependent cellular cytotoxicity* (ADCC). NK cells are activated by IL-2 to express nonspecific cytotoxic functions. Together with a small population of T_c cells (that have the LGL morphology and are activated by IL-2), they are called *lymphokine-activated killer (LAK)* cells. NK cells also can be activated by IL-12, a cytokine produced by macrophages. The

■ **FIGURE 23** Natural killer (NK) cell maturation pathway. Immunologic maturation of NK cells from the pluripotential hematopoietic stem cell (HSC) and common lymphoid progenitor cell (CLP) to the mature NK cell. Each stage of maturation can be defined by specific antigens (CD) and/or presence of cytokine receptors that appear on the developing cell. NK progenitors and immature cells are found in the bone marrow, and mature NK cells are found in the peripheral blood. (CD = cluster of differentiation; IL-7R = IL-7 receptor; c-Kit = stem cell factor receptor, also referred to as CD117)

activated Tc and NK cells rely primarily on the perforin/granzyme system to kill their targets.³³ On contact with their target, perforin released from the granules introduces a hole in the target cell membrane, allowing activated granzymes and other granule contents to enter. Granzymes activate the target cell apoptotic pathway, inducing target cell death. Fas Ligand or other apoptosis-inducing cytokines on NK cell membranes can also contribute to cytotoxicity through death-receptors on target cells. In addition, NK cells appear to be involved in regulation of hematopoiesis with a suppressive effect on hematopoietic cell proliferation.³⁴

NK cells have a “fail-safe” mechanism to guard against an inappropriate response against self.³⁵ The NK cells have killer-cell immunoglobulin-like receptors (KIR) that include both activating and inhibiting subgroups of receptors. Ligands for these receptors include both cell surface proteins that are altered when a cell is infected and MHC class I molecules. The inhibiting receptors bind to the MHC class I molecules of autologous cells and allogeneic cells of similar HLA-C type. This interaction between the “target” cell MHC molecules and the inhibitory KIR receptors blocks NK cell activation and protects healthy self-cells and allogeneic cells with similar HLA-C phenotypes from NK attack. The NK cell is said to be tolerant of these cells. Allogeneic cells that lack similar MHC class I molecules, or autologous cells that are infected and lose expression or alter conformation of the MHC class I molecules, fail to bind to the NK cell’s inhibitory KIR receptors. These uninhibited NK cells become activated via their activating receptors and can mount an attack on the altered or allogeneic cell and kill it. Thus, the NK cell attacks cells when a self-MHC Class I determinant is missing. The alloreactive NK cell is said to recognize “missing-self.”³⁷ KIR-mediated inhibition can block activation

that is triggered by engaging a single activating receptor.³⁷ On the other hand, if several activating receptors are activated at once, KIR inhibition can be overcome and the resting NK cell is activated. This suggests that for a potential target cell to activate the NK cell, it must be able to upregulate an array of activating NK receptors; activating just one would not necessarily trigger an NK response.

The activity of NK cells is firmly regulated and is activated by signals from a variety of sources, which are listed in Table 8 🌟.

LYMPHOCYTE FUNCTION

The T lymphocyte, B lymphocyte, and macrophage interact in a series of events that allows the body to attack and eliminate foreign antigens. This series is known collectively as the adaptive immune response (IR). The body’s ability to mount an IR against a particular foreign antigen is controlled by IR genes located in the major histocompatibility complex (MHC) loci on chromosome 6. These genes code for histocompatible antigens found on the surface of essentially all nucleated cells.

The MHC gene cluster in humans is called the *human leukocyte antigen (HLA) region* (Table 9 🌟). The HLA genes are located in specific regions within the complex known as HLA-A, HLA-B, HLA-C, and HLA-D (HLA-DP, HLA-DQ, and HLA-DR). The regions are classified according to their structure and specific role in the IR. Class I MHC include HLA-A, HLA-B, and HLA-C genes, which code for cell surface recognition proteins found on essentially all nucleated cells. These proteins are utilized by T_C and NK cells to distinguish self from non-self. HLA-D genes code for MHC Class II antigens on B lymphocytes, dendritic cells, a subpopulation of macrophages,

★ TABLE 8

Regulation of NK Activity		
Source of Activating Signal	Activating Signal	Mode of Action
Cytokines	IFN α/β IL-12	Stress molecules serve to signal NK cells in the presence of viral pathogens Produced by macrophages for NK cell stimulation
Fc Receptor	Activating molecule that binds Fc portion of antibody	Allows NK cells to target cells against which a humoral response has been mounted and lyse the cells by antibody-dependant cellular cytotoxicity (ADCC)
Activating and Inhibitory Receptors	Variety of receptors that bind ligands on both endogenous and exogenous target cells <i>Activating</i> NKG2D, NKp46, CD2 or DNAM <i>Inhibiting</i> KIR, Ly49, CD94/NKG2A	Either activate or suppress NK cell cytolytic activity

and activated T lymphocytes. The Class II antigens, also known as *Ia antigens*, determine the ability of immune cells to cooperate and interact in the IR. The D region is arranged into at least three subregions: DP, DQ, and DR. The Class III genes code for components of the complement system.

The B lymphocytes are responsible for the part of the IR known as *humoral immunity* (i.e., the production of antibodies). To accomplish effective humoral immunity, the peripheral B lymphocyte must be activated and must differentiate to a plasma cell. The antibodies circulate in body fluids and can bind directly to the pathogen, which makes it a target for phagocytosis by cells that have receptors for the antibody (Fc γ R-I, -II, -III).

The T lymphocytes are responsible for part of the IR known as *cell-mediated immunity (CMI)*, which requires interaction among histocompatible macrophages, T lymphocytes, and antigens. CMI is independent of antibody production by B lymphocytes. At least three important functional subsets of T lymphocytes are involved in the IR: helper T lymphocytes (T_H), suppressor T lymphocytes (T_S), and cytotoxic T lymphocytes (T_C). When these cells become activated in the IR, they proliferate, produce lymphokines, and perform a variety of other effector functions.

Lymphokines are cytokines released primarily from T lymphocytes that influence the function of other lymphocytes, macrophages, and other body cells (Table 10★). B lympho-

★ TABLE 9

Major Histocompatibility Complex Antigens		
Class I	Class II (Ia antigens)	Class III
HLA-A	HLA-DP	Complement components
HLA-B	HLA-DQ	
HLA-C	HLA-DR	

★ TABLE 10

Some Soluble Mediators Released from T Lymphocytes and Their Effects on Other Cells	
Lymphokine	Action
Macrophage inhibition factor (MIF)	Prevents migration of macrophages from site of inflammation
IFN γ	Inhibits intracellular viral multiplication, inhibits proliferation of T _{H2} cells, activates macrophages
IL-2	Induces proliferation and activation of other lymphocytes
IL-3	Is multilineage colony-stimulating factor; acts in synergy with other cytokines to stimulate growth of hematopoietic colonies, has a negative effect on lymphoid progenitors
IL-4	Stimulates proliferation of B lymphocytes
IL-5	Stimulates proliferation/differentiation of B lymphocytes and eosinophils
IL-6	Stimulates proliferation/differentiation of B lymphocytes
IL-9	Enhances T cell survival, activates mast cells
IL-10	Inhibits production of IFN γ by T _{H1} cells, suppresses macrophage function
IL-13	B cell growth and differentiation, inhibits production of proinflammatory cytokines
IL-14	Stimulates proliferation of activated B-cells
IL-16	Serves as a chemoattractant of CD4 ⁺ lymphocytes
IL-17	Has an indirect effect on hematopoiesis by inducing other cytokines, releases IL-6, G-CSF, PGE2; enhances ICAM-1
IFN α and IFN β	Activates macrophages, granulocytes, T _C lymphocytes
MIP-1 α	Is responsible for chemotaxis, respiratory burst

cytes and NK cells also can secrete lymphokines. Under the influence of lymphokines, monocytes can produce monocyte-derived cytokines. Most cytokines work synergistically in inducing their physiologic response.

T cells do not react directly with the pathogen but with short peptides derived from the breakdown of pathogens or their protein products by antigen-presenting cells (e.g., macrophages or dendritic cells). The processed peptide is bound by an MHC molecule on the APC, forming a peptide:MHC complex. The T cell receptor (TCR) binds to the complex on the infected cell and “kills” it or activates the APC. Recognition of and binding to a target cell requires the TCR to bind with the antigen/MHC complex and the T cell co-receptor (CD4 or CD8) to bind to appropriate MHC molecules (class I or II). MHC class I molecules form a complex with antigens that are derived from intracellular pathogens. MHC class I molecules in the infected cell bind processed viral proteins and transport the complex to the cell surface. These MHC:protein complexes bind and activate CD8⁺ T cells. Class II MHC molecules complex with peptides derived from extracellular pathogens; this complex binds to CD4⁺ T cells.

Macrophages phagocytize and degrade extracellular pathogens. The peptide fragments complex with MHC class II molecules, and the complex is transported to the cell surface where it is recognized by lymphocytes with the CD4 receptor (T-helper cells, T_H). The T_H cell activates the macrophage through direct cell contact and secretion of cytokines. B lymphocytes can bind pathogens by their surface immunoglobulin. The pathogen is engulfed and degraded, and its peptides are complexed with class II MHC molecules. As in the macrophage, the complex is transported to the cell

surface where T_H cells recognize it. B cells are activated by contact with the T_H cell and secretion of cytokines.

Adhesion Molecules of the Adaptive Immune Response

Adhesion receptors are important in the congregation of lymphoid cells at sites of infection (Table 11). The TCR/CD3 complex recognizes antigens bound to monocytes/macrophages. LFA-1 (leukocyte function-related antigen) on activated leukocytes and LFA-3 on VEC are important in the antigen-independent adhesion of activated T lymphocytes, localizing these cells in sites of antigen accumulation. LFA-1 on T lymphocytes is required for the lymphocytes’ interaction with other cells, most likely by promoting adherence. The ligand for LFA-1 is the intercellular adhesion molecule on VEC, ICAM-1, which modulates inflammatory responses by up-regulation (promoting lymphocyte adherence) or down-regulation of expression. Inflammatory mediators such as lipopolysaccharide (LPS, endotoxin), IL-1, and TNF cause strong expression of ICAM-1 in tissues, increasing adherence of lymphocytes and monocytes expressing LFA-1 in areas of inflammation. LFA-3 is expressed on endothelial cells and is the ligand for CD2 on T lymphocytes. Reaction of CD2 with its VEC ligand generates an activation signal in the T lymphocyte.

The B₁ integrin subfamily of very late activation (VLA) molecules appears on lymphocytes several weeks after antigen stimulation. The six VLA molecules—VLA-1–VLA-6—are recognized as CD49a through CD49f, respectively. VLA-4 binds to the VCAM-1 receptor on VEC, a member of the immunoglobulin superfamily. The VCAM-1 receptor is induced on the endothelium by inflammatory mediators. Other B₁

TABLE 11

Adhesion Molecules Involved in the Interaction of Lymphocytes with Other Cells in the Immune Response

Adhesion Molecule	CD Designation	Expressed By	Ligand	Function
LFA-1	CD11a/CD18	Activated leukocytes	ICAM-1, ICAM-2 on endothelial cells	Mediates interaction of lymphocytes with other cells, possibly by promoting adherence to target cells at site of antigen
CD2	CD2	T lymphocytes Monocytes	LFA-3 (CD58) on EC	Promotes adherence of the monocytes and T lymphocytes to EC, mediates activation of T lymphocytes
CD4	CD4	T _H lymphocytes	Class II MHC	Enhances adhesion of T _H lymphocytes to other cells, mediates activation of T _H lymphocytes
CD8	CD8	T _S lymphocytes	Class I MHC	Enhances adhesion and activation of T _S lymphocytes, promotes avidity of cytotoxic T lymphocytes and target cells
VLA1, VLA2, VLA3 VLA4, VLA5, VLA6	CD49a, CD49b, CD49c, CD49d, CD49e, CD49f	Lymphocytes (VLA-4 also on monocytes)	VLA4 ligand VCAM-1 on EC	Increases adhesion of cells in area of inflammation

EC = endothelial cell, CD = cluster of differentiation, LFA = leukocyte function-related antigen, ICAM = intercellular cytoadhesion molecule, MHC = major histocompatibility complex antigens, VLA = very late activation

integrin molecules bind to extracellular matrix components such as collagen and are expressed on many leukocytes and other nonhematopoietic cells.

Aging and Lymphocyte Function

Although many immune functions are well conserved throughout life, some investigators believe that a derangement of some immune responses occurs in the elderly, possibly contributing to an increased risk of morbidity and mortality in this age group. Although there is a decrease in absolute numbers of lymphocytes, there is an increase in activated NK cells and T lymphocytes that mediate non-MHC-restricted spontaneous cytotoxicity.

Lymphocyte Metabolism

Lymphocytes contain all enzymes of the glycolytic and tricarboxylic acid cycle. Glucose enters the cell through facilitated diffusion and is catabolized to produce ATP through oxidative phosphorylation. The ATP is used for recirculation and locomotion as well as replacement of lipids and proteins and maintenance of ionic equilibrium. The HMP shunt provides only a fraction of the needed energy, but it is important for purine and pyrimidine synthesis required for DNA replication and mitosis as well as provision of reducing energy by production of NADPH.

DISTRIBUTION, CONCENTRATION, AND KINETICS

Lymphocytes have a peripheral blood concentration in adults ranging from 1.0 to $4.8 \times 10^9/L$. At birth, the mean lymphocyte count is $5.5 \times 10^9/L$. This value rises to a mean of $7 \times 10^9/L$ in the next 6 months and remains at that level until ~age 4. A gradual decrease in lymphocytes is noted from 4 years of age until reaching adult reference range values in the second decade of life. *Lymphocytosis*, an increase in lymphocytes, occurs in adults when the absolute number of lymphocytes exceeds $4.8 \times 10^9/L$. *Lymphocytopenia*, a decrease in lymphocytes, occurs in adults when the absolute number of lymphocytes is $<1.0 \times 10^9/L$.

Although lymphocytes are the second most numerous intravascular leukocyte in adults, peripheral blood lymphocytes comprise only ~5% of the total body lymphocyte concentration. Ninety-five percent of the lymphocytes are located in extravascular tissue of the lymph nodes and spleen. Movement of lymphocytes between the intravascular and extravascular compartments is continuous. Lymphocytes from lymph nodes enter the lymphatic channels and gain entry to the blood as the lymph drains into the right lymphatic duct and the thoracic duct. When blood lymphocytes are stimulated by an antigen, they migrate to specific areas of lymphoid tissue where they undergo proliferation and transformation into effector cells. These cells also can pass directly through the cytoplasm of postcapillary or high endothelial venule cells (emperipolesis) as they recirculate between intravascular and extravascular compartments.

Lymphocytes leave and reenter the blood (recirculate) many times during their life spans. About 80% of lymphocytes in the peripheral blood are “long lived” with a life span ranging from a few months to many years. These cells spend most of their lives in a prolonged, intermitotic, G_0 phase. The remaining 20% of the lymphocytes live from a few hours to ~5 days. The majority of these short-lived, rapidly turning over lymphocytes are immunocompetent, naïve B lymphocytes.

✓ Checkpoint! 8

A young adult patient's blood smear reveals 70% reactive lymphocytes and 10% nonreactive lymphocytes (80% total lymphocytes) in a $10 \times 10^9/L$ WBC count. What is the absolute concentration of total lymphocytes and reactive lymphocytes? What is a probable cause of these findings?

🌀 CASE STUDY (continued from earlier in this chapter)

4. Is there a need for reflex testing on Harry? Explain your answer.

SUMMARY

Leukocytes include five morphologically and functionally distinct types of nucleated blood cells: neutrophils, eosinophils, basophils, monocytes, and lymphocytes. The leukocytes develop from the pluripotential hematopoietic stem cells in the bone marrow. Under the influence of hematopoietic growth factors, the stem cell matures into terminally differentiated cells. These cells circulate only a matter of hours in the peripheral blood before diapedesing into the tissues.

The leukocytes serve as the defenders of the body against foreign invaders and noninfectious challenges by participating in phagocytosis and the immune response. The leukocytes are attracted to sites of inflammation, infection, or tissue injury by chemoattractants and leave the circulation using special adhesion molecules and ligands located on the leukocytes and endothelial cells of the vessel walls. Neutrophils and monocytes are active in phagocytosis, and eosinophils function in defending the body against parasites. Eosinophils are involved in allergic reactions and chronic inflammation. Basophils are also involved in allergic reactions by releasing histamine and heparin when activated via the binding of IgE to membrane Fc receptors.

Monocytes function as phagocytes and secrete a variety of cytokines that affect the function of other cells, especially that of lymphocytes. Monocytes, also referred to as *antigen-processing (or presenting) cells* (APC), play a major role in initiating and regulating the immune response.

The three types of lymphocytes are T, B, and NK cells. T and B lymphocytes have antigen-independent and antigen-dependent phases of maturation. In the antigen-independent maturation process, B lymphocytes mature in the bone marrow and T lymphocytes mature in the thymus. There are at least three different major types of T lymphocytes: $CD4^+$ helper T lymphocytes (T_H), $CD8^+$

suppressor T lymphocytes (T_S), and $CD8^+$ cytotoxic lymphocytes (T_C). The lymphoid precursor cell from the bone marrow matures and acquires cellular molecular characteristics of a T or B lymphocyte. In the antigen-dependent maturation process, these lymphocytes mature, and immunocompetent T and B lymphocytes undergo a series of cellular events in response to encounters with antigens known as *blast transformation*. The end result is a clonal amplification of lymphocytes responsible for immunity to the specific antigen that stimulated transformation. Reactive lymphocytes are the most common form of antigen-stimulated lymphocyte found in the peripheral blood. NK cells, also known as *large granular lymphocytes (LGL)*, are a form of cytotoxic lymphocyte. LGLs have two distinct populations categorized by the presence or absence of CD3. Natural killer cells are thought to be $CD3^-$ (NK-LGL), and activated cytotoxic T-cells are thought to be $CD3^+$ (T-LGL) with the possibility of existing intermediate forms. The cytotoxicity of NK cells is not MHC restricted.

T and B lymphocytes have separate but related functions in the immune response. Monocytes/macrophages and dendritic cells

phagocytize antigens, preserving critical immunologic determinants that are presented to the T lymphocytes. The T lymphocytes bind to the antigens and the MHC molecules on the surface of the macrophage by means of the TCR and either CD4 or CD8. Cytokines released by the macrophage and the T lymphocyte activate the lymphocyte. T_S lymphocytes also are activated by the released cytokines and serve to suppress the immune response. The B lymphocyte's functional activity includes the synthesis and secretion of antibodies. Surface immunoglobulin serves as the B lymphocyte receptor for the processed antigen that is bound to the macrophage and T_H lymphocyte. The B lymphocyte can also bind to the MHC receptors on the T_H lymphocyte. As a result of this interaction, the B lymphocyte transforms to an antibody-secreting plasma cell.

NK-LGLs function in the first line (innate) defense mechanism. They can target virus-infected cells or tumor cells for killing. T-LGLs are thought to be activated cytotoxic T-cells that recognize specific epitopes of foreign protein such as viruses.

REVIEW QUESTIONS

LEVEL I

- Leukocytosis can be defined as an increase in: (Objective 1)
 - neutrophils, monocytes, and macrophages
 - neutrophils, eosinophils, erythrocytes, and basophils
 - neutrophils, eosinophils, basophils, monocytes, lymphocytes
 - neutrophils, eosinophils, basophils, monocytes, lymphocytes, megakaryocytes
- The hallmark of differentiating myelocytes from promyelocytes morphologically is the visual identification of what in the myelocytes? (Objective 2)
 - primary granules
 - secondary granules
 - loss of nucleoli
 - pink cytoplasm
- The granulocytic maturation process differs from the lymphocytic and monocytic-macrophage maturation process in that: (Objective 3)
 - granules never develop in cells in the monocytic-macrophage cell line
 - the nucleus in the granulocytic cell line eventually segments
 - the scanty cytoplasm in the lymphocytic cell line eventually becomes abundant and very granular
 - the nucleoli disappear in only the granulocytic line
- Primary granules first appear in the: (Objective 2)
 - myeloblast
 - promyelocyte
 - myelocyte
 - band

LEVEL II

- The average cell turnover rate for granulocytes and monocytes in the peripheral blood is: (Objective 1)
 - <12 hours
 - 24 hours
 - 8–10 days
 - 10 years
- The following cells are found in the granulocytic proliferating pool (mitotic pool) of the marrow: (Objective 1)
 - pluripotential stem cells
 - unipotential progenitor cells
 - monoblasts, myeloblasts, and macrophages
 - myeloblasts, promyelocytes, and myelocytes
- The most likely explanation for a patient who has a WBC count of $16 \times 10^9/L$ with many reactive lymphocytes and a few immunoblasts present is: (Objective 3)
 - a heightened immune response
 - early leukemia or lymphoma
 - the presence of immunodeficiency
 - qualitatively abnormal lymphocytes
- A patient has lymphocytic leukemia with 60% lymphoblasts in the peripheral blood. The best way for the clinical laboratory scientist to determine whether these are T or B lymphoblasts is to: (Objective 4)
 - do a TdT stain on the blood
 - determine the CD surface markers on the blasts
 - do a molecular analysis to find oncogenes
 - send the peripheral blood specimen to cytogenetics

REVIEW QUESTIONS (continued)

LEVEL I

5. The first heavy immunoglobulin chain produced in the maturing B lymphocyte is: (Objective 12)
 - a. alpha
 - b. beta
 - c. mu
 - d. gamma
6. Lymphocytes can be differentiated from monocytes because monocytes have a: (Objective 4)
 - a. large variation in cell size
 - b. more lobular nucleus and fine granular grey cytoplasm
 - c. low N:C ratio with intense basophilia on the cytoplasmic edges
 - d. round dense chromatin nuclear pattern and sky blue cytoplasm
7. The eosinophil's primary function is to: (Objective 5)
 - a. protect the host from helminth parasites
 - b. protect the host from autoimmune destruction
 - c. secrete cytokines to attract monocytes to the site of infection
 - d. secrete cytokines to attract lymphocytes to the site of infection
8. Leukocyte migration to the tissues is regulated by leukocyte-endothelial cell recognition which requires: (Objective 6)
 - a. interaction of adhesion molecules and their receptors
 - b. activation of membrane oxidase
 - c. leukocyte degranulation
 - d. hematopoietic growth factors
9. The adult reference range for lymphocytes found in the peripheral blood is: (Objective 7)
 - a. $0.2-0.8 \times 10^9/L$
 - b. $1.0-4.8 \times 10^9/L$
 - c. $2.0-7.0 \times 10^9/L$
 - d. $3.9-10.6 \times 10^9/L$
10. An 80% lymphocyte count with a total WBC count of $4.4 \times 10^9/L$ on an adult would indicate a: (Objectives 1, 8, 9)
 - a. relative and absolute decrease in lymphocytes
 - b. relative decrease in lymphocytes but an absolute number in the reference range
 - c. relative increase in lymphocytes but an absolute number in the reference range
 - d. relative and absolute increase in lymphocytes

LEVEL II

5. The largest compartment of neutrophils is found in the: (Objective 1)
 - a. granulocyte proliferating/mitotic compartment
 - b. granulocyte maturation/postmitotic compartment
 - c. peripheral blood compartment
 - d. tissues
6. Which of the following is felt to have a controlling influence on the release of neutrophils from the bone marrow? (Objective 2)
 - a. pore diameter of histiocytes lining the vessel
 - b. morphologic age of endothelial cells
 - c. size of postmitotic storage pool
 - d. morphologic age of cells and growth factors
7. A 30-year-old healthy male needed a CBC as part of his physical examination for purchasing a life insurance policy. He decided to combine his daily 5-mile run with his appointment to get his blood drawn. He ran 3 miles to the laboratory, had his blood drawn, and returned home. His WBC count was increased to $15 \times 10^9/L$, but all other CBC parameters were normal. What is the most likely explanation for the increased WBC count? (Objectives 1, 8)
 - a. He has a bacterial or viral infection.
 - b. He has a leukemia with leukemic cells present.
 - c. Nucleated RBCs have entered the peripheral blood.
 - d. The marginating neutrophil pool entered the circulating pool.
8. The adhesion molecules that play a role in neutrophil adhesion include: (Objective 2)
 - a. selectins, superoxides, integrins
 - b. ICAMs, integrins, superoxides
 - c. NADPH, superoxides, myeloperoxidase
 - d. selectins, ICAMs, integrins
9. A patient with a strep throat would most likely produce: (Objective 5)
 - a. monoclonal antibody
 - b. paraprotein
 - c. polyclonal antibody
 - d. M protein
10. A patient who is immunosuppressed would most likely have: (Objective 3)
 - a. an increase in $CD4^+$ lymphocytes
 - b. lymphocytosis and eosinophilia
 - c. a decrease in $CD4^+$ lymphs
 - d. an increase in T_H to T_s ratio

ANSWERS TO CASE STUDY QUESTIONS

Case Summary: Harry had a physical as a prerequisite for buying a life insurance policy. His results were within the reference range for his sex and age except for the WBC count, which was above the reference range.

Question:

1. Are any of these results outside the reference range? If yes, which one(s)?

Explanation:

The WBC count is above the reference range.

Question:

2. If this were a newborn, would you change your evaluation? Why?

Explanation:

Newborns have a higher reference range for WBC; therefore, if this were a newborn, the WBC count would fall within the reference range.

Question:

3. Are any of the WBC concentrations outside the reference range (relative or absolute)?

Explanation:

All results, both percents and absolute values, are within the reference range.

Question:

4. Is there a need for reflex testing on Harry? Explain your answer.

Explanation:

Although Harry's WBC count is slightly above the reference range, his absolute individual white cell numbers are within it. Given the fact that he has no symptoms, the physical examination was normal, and no abnormal cells were noted on the blood smear, there is probably no need to do additional testing. The reference range is usually set by calculating the mean and adding and subtracting two standard deviations. This range includes 95% of normal individuals. About 5% of individuals have a result outside this range but are still normal. This may be the case with Harry.

ANSWERS TO CHECKPOINTS

Checkpoint! 1

An adult patient's peripheral blood smear revealed many myelocytes, metamyelocytes, and band forms of neutrophils. Is this a normal finding?

Answer

No, metamyelocytes and myelocytes are not normal findings in the peripheral blood. They indicate a shift to the left in granulocytes and can be seen in infection, inflammation, and other conditions.

Checkpoint! 2

An adult patient's WBC count is $10 \times 10^9/L$, and there are 90% neutrophils. What is the absolute number of neutrophils? Is this in the reference range for neutrophils, and if not, what term would be used to describe it?

Answer

The absolute count for neutrophils is $9 \times 10^9/L$. This indicates an increase in neutrophils referred to as *neutrophilia*.

Checkpoint! 3

A patient with life-threatening recurrent infections is found to have a chromosomal mutation that results in a loss of active integrin molecules on the neutrophil surface. Why would this result in life-threatening infections?

Answer

This is known as *leukocyte adhesion deficiency-1 (LAD-1)*, an inability of the neutrophils to "tightly adhere" to the vascular endothelial surface. If the neutrophils cannot do this, they have difficulty moving to the site of infection, and therefore, a patient with this condition would be at risk for infections.

Checkpoint! 4

A patient has a compromised ability to utilize the oxygen-dependent pathway in neutrophils. What two important microbial killing mechanisms could be affected?

Answer

Production of the respiratory burst and generation of cytotoxic reactive oxygen intermediates would be abnormal.

Checkpoint! 5

Indicate which of the granulocytes will be increased in the following conditions: a bacterial infection, an immediate hypersensitivity reaction, and an asthmatic reaction.

Answer

Neutrophils are increased in a bacterial infection. Basophils are increased in an immediate hypersensitivity reaction. Eosinophils are increased in an asthmatic reaction.

Checkpoint! 6

An adult patient's neutrophil count and monocyte count are extremely low ($<0.50 \times 10^9/L$ and $<0.050 \times 10^9/L$, respectively). What body defense mechanism is at risk?

Answer

Phagocytosis and/or the innate immune system is compromised when the neutrophil and monocyte concentrations are decreased.

Checkpoint! 7

How would you morphologically differentiate a reactive lymphocyte from a plasma cell on a peripheral blood smear?

Answer

A reactive lymphocyte's size is usually increased, 16 to 30 μm , and the N:C ratio is decreased. The nuclear chromatin pattern may be dispersed, and nucleoli may be visible. The cytoplasm is frequently abundant, very basophilic, and foamy. The cytoplasmic membrane may have scalloped edges due to indentations made by surrounding erythrocytes. Azurophilic granules may be present. A plasma cell ranges in size from 14 to 20 μm and has a decreased N:C ratio. The small nucleus is eccentrically placed in the cell. The nuclear chromatin may have a spoke wheel pattern. The cytoplasm is nongranular and has a deep basophilic color.

Checkpoint! 8

A young adult patient's blood smear reveals 70% reactive lymphocytes and 10% nonreactive lymphocytes in a $10 \times 10^9/\text{L}$ WBC count. What is the absolute concentration of total lymphocytes and reactive lymphocytes? What is a probable cause of these findings?

Answer

The counts indicate $8 \times 10^9/\text{L}$ total lymphocytes and $7 \times 10^9/\text{L}$ reactive lymphocytes. A viral infection is a probable cause of these results.

Introduction to Anemia

CHAPTER OUTLINE

- ▶ Objectives—Level I and Level II
- ▶ Key terms
- ▶ Background basics
- ▶ Case study
- ▶ Overview
- ▶ Introduction
- ▶ How does anemia develop?
- ▶ Interpretation of abnormal hemoglobin concentrations
- ▶ Adaptations to anemia
- ▶ Diagnosis of anemia
- ▶ Classification of anemia
- ▶ Summary
- ▶ Review questions
- ▶ References

Introduction to Anemia

Shirlyn B. McKenzie, Ph.D.
Catherine N. Otto, Ph.D., M.B.A.

■ OBJECTIVES—LEVEL I

Upon completion of this chapter, the student should be able to:

1. Describe and identify specific anisocytes and poikilocytes.
2. Classify and describe erythrocytes based on erythrocyte indices.
3. Calculate absolute reticulocyte count, corrected reticulocyte count and reticulocyte production index from reticulocyte results, hematocrit, and RBC count.
4. Describe and identify erythrocyte inclusions including staining characteristics.
5. Describe and recognize abnormal variation in erythrocyte distribution on stained smears.
6. Identify laboratory tests to evaluate erythrocyte destruction.
7. Given CBC and RPI results, categorize an anemia according to morphologic classification.
8. Correlate polychromatophilia on a blood smear with other laboratory results of erythrocyte production and destruction.

■ OBJECTIVES—LEVEL II

Upon completion of this chapter, the student should be able to:

1. Relate adaptations to anemia with patient symptoms.
2. Correlate patient history and clinical symptoms with laboratory results in anemia.
3. Interpret RDW results.
4. Assess bone marrow response to anemia given CBC and reticulocyte results.
5. Correlate poikilocytes with the mechanism of formation and assess their clinical significance.
6. Correlate CBC results with findings on a blood smear and troubleshoot discrepancies.
7. Determine the clinical significance of erythrocyte inclusions and select methods to differentiate the inclusions.
8. Evaluate the distribution of erythrocytes on stained smears and determine its clinical significance.
9. Assess and interpret bone marrow findings in the presence of anemia.
10. Compare the sensitivity and specificity of tests used to screen and confirm a differential diagnosis of anemia.
11. Compare the morphologic and functional classification of anemia.
12. Given laboratory results, classify an anemia in terms of morphology and pathophysiologic mechanism (function).
13. Choose appropriate follow-up tests to determine anemia classification and evaluate the results.

KEY TERMS

Acanthocyte
 Anisocytosis
 Basophilic stippling
 Cabot ring
 Codocyte
 Echinocyte
 Elliptocyte
 Heinz body
 Helmet cell
 Howell-Jolly body
 Immature reticulocyte fraction (IRF)
 Knizocyte
 Leptocyte
 Macrocyte
 Megaloblastic
 Microcyte
 Pancytopenia
 Pappenheimer body
 Poikilocytosis
 Reticulocyte production index (RPI)
 Schistocyte
 Sickle cell
 Spherocyte
 Stomatocyte
 Target cell
 Teardrop/dacryocyte

BACKGROUND BASICS

The information in this chapter builds on the concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study.

Level I

- ▶ Describe the production, maturation, and destruction of blood cells and explain how the balance between erythrocyte production and destruction is maintained; describe the normal concentration and appearance of an erythrocyte.
- ▶ Summarize the role of hemoglobin in gaseous transport; explain how 2,3-BPG, and H^+ affect oxygen affinity.
- ▶ Discuss the appearance of a normal bone marrow and list reasons why a bone marrow examination could be necessary.
- ▶ Discuss the principle and normal results of the following tests: hemoglobin, hematocrit, reticulocyte count, erythrocyte count, and erythrocyte indices; calculate indices.

Level II

- ▶ Identify the helpful stains in assessing bone marrow; correlate peripheral blood findings with bone marrow appearance.
- ▶ Correlate CBC results with findings on the peripheral blood smear and other laboratory test results; determine the validity and accuracy of CBC results and suggest corrective action when necessary.

**CASE STUDY**

We will address this case study throughout the chapter.

George, a 50-year-old male, visited his doctor when he noted the whites of his eyes appeared yellow and that he had dark urine. His CBC revealed a hemoglobin of 31 g/L. Given this clinical description, consider what laboratory tests should be ordered to assist in diagnosis.

OVERVIEW

This chapter is a general introduction to anemia. It begins with a description of how anemia develops and the body's adaptations to a decrease in hemoglobin. The emphasis of the chapter is on the laboratory investigation of anemia. This includes discussion of screening tests used to diagnose anemia and other more specific tests used to identify the etiology and pathophysiology of the anemia. Identification of abnormal erythrocyte morphology and its association with anemia is discussed in depth. The chapter concludes with a description of the morphologic and functional classification schemes of anemia and the use of laboratory tests to correctly classify an anemia.

INTRODUCTION

Anemia is functionally defined as a decrease in the competence of blood to carry oxygen to tissues, thereby causing tissue hypoxia. In clinical medicine, it refers to a decrease in the normal concentration of hemoglobin or erythrocytes. It is one of the most common problems encountered in clinical medicine. However, anemia is not a disease but the expression of an underlying disorder or disease; it is an important clinical marker of a disorder that could be basic or sometimes more complex. Therefore, once the diagnosis of anemia is made, the physician must determine its exact cause.

Treating anemia without identifying its cause could not only be ineffective but also could lead to more serious problems. For example, if a patient experiencing iron deficiency anemia due to chronic blood loss were given iron or a blood transfusion, the hemoglobin level might temporarily rise; however, if the cause of the deficiency is not isolated and treated, serious complications of the primary disease may develop, and the anemia would probably return after cessation of treatment. Thus, it is necessary to identify and understand the etiology and pathogenesis of an anemia to institute correct treatment.

HOW DOES ANEMIA DEVELOP?

To understand how anemia develops, it is necessary to understand normal erythrocyte kinetics. Total erythrocyte mass (M) in the steady state is equal to the number of new

erythrocytes produced per day (P) times the erythrocyte life span (S), which is normally about 100–120 days.

$$\begin{array}{ccccccc} M & = & P & \times & S \\ | & & | & & | \\ \text{Mass} & & \text{Production} & & \text{Survival} \end{array}$$

Thus, the average 70 kg man with 2 liters of erythrocytes must produce 20 mL of new erythrocytes each day to replace the 20 mL normally lost due to cell senescence.¹

$$\frac{2,000 \text{ mL (M)}}{100 \text{ days (S)}} = 20 \text{ mL/day (P)}$$

From this formula, it is clear that if the survival time of the erythrocyte is decreased by one-half as can occur in hemolysis or hemorrhage, the bone marrow must double production to maintain mass at 2,000 mL.

$$\frac{2,000 \text{ mL (M)}}{50 \text{ days (S)}} = 40 \text{ mL/day (P)}$$

New erythrocytes are released as reticulocytes. Thus, the increased production of cells is reflected by an increase in the absolute reticulocyte count in the peripheral blood. The marrow can compensate for decreased survival in this manner until production is increased to a level 5–10 times normal, which is the maximal functional capacity of the marrow. Thus, if all necessary raw products for cell synthesis are readily available, erythrocyte life span can decrease to about 18 days before marrow compensation is inadequate and anemia develops. If, however, bone marrow production of erythrocytes does not adequately increase when the erythrocyte survival is decreased, the erythrocyte mass cannot be maintained and anemia develops. There is no mechanism for increasing erythrocyte life span to help accommodate an inadequate bone marrow response.

Thus, anemia can develop if (1) erythrocyte loss or destruction exceeds the maximal capacity of bone marrow erythrocyte production or (2) the bone marrow erythrocyte production is impaired. Anemia can be classified according to these principles (functional classification) based on laboratory test results, which aid the physician in diagnosis. The functional classification includes survival defects, proliferation defects, and maturation defects (which have a high degree of ineffective erythropoiesis). A morphologic classification is also possible based on the erythrocyte indices and reticulocyte count. These classifications are discussed later in this chapter.

▶ INTERPRETATION OF ABNORMAL HEMOGLOBIN CONCENTRATIONS

Diagnosis of anemia is usually made after the discovery of a decreased hemoglobin concentration. Hemoglobin is the carrier protein of oxygen; thus, it is expected that a decrease

in its concentration is accompanied by a decrease in oxygen delivery to tissues (functional anemia).

Screening for anemia generally relies on the relative hemoglobin and hematocrit. However, the hemoglobin or hematocrit concentration can be misleading in a few instances (Table 1 .

- In *hypervolemia*, the total blood volume increases. This is primarily caused by a plasma volume increase while the erythrocyte mass remains stable. In this case, the relative hemoglobin/hematocrit concentration appears falsely decreased.
- In *hypovolemia*, such as occurs in dehydration, a relative decrease in plasma volume occurs, resulting in a falsely elevated hemoglobin/hematocrit.

Diagnosis of anemia requires an upward adjustment of hemoglobin and hematocrit values dependent on the altitude.² The hemoglobin reference interval at high altitudes is higher than the reference interval at lower altitude. Therefore, signs of anemia at high altitudes can occur at higher hemoglobin concentrations than at sea level. Cigarette smoking has a similar effect. The hemoglobin reference interval for cigarette smokers is higher than in nonsmokers.³

 TABLE 1

Conditions in which the Hemoglobin or Hematocrit Can Be Misleading and Require Further Investigation or Interpretation in Light of Other Factors

Hematocrit disproportionately low (relative increase in plasma volume):

- Hydremia of pregnancy
- Overhydration in oliguric renal failure
- Congestive heart failure
- Congestive splenomegaly
- Chronic diseases
- Hypoalbuminemia
- Recumbency

Hematocrit disproportionately high relative to red cell mass (relative decrease in plasma volume):

- Dehydration
- Protracted diarrhea (especially in infants), cholera
- Stress erythrocytosis
- Intestinal malfunction (pyloric destruction, etc.)
- Abdominal paracentesis with fluid restriction
- Peritoneal dialysis with hypertonic solution
- Diabetic acidosis
- Diabetes insipidus with restricted fluid

Higher reference interval:

- High altitudes
- Smokers

Presence of abnormal hemoglobins with altered oxygen affinity

Decrease in both plasma volume and RBC mass (hematocrit normal, RBC low):

- Acute blood loss
- Cancer
- Myxedema, Addison disease, panhypopituitarism

(Adapted, with permission from *Wintrub's Clinical Hematology*, 10th ed. Edited by GR Lee, J Foerster, J Lukens, F Paraskevas, GP Greer, GM Rodgers. Baltimore: Williams & Wilkins. 1999.)

In most cases, the physician integrates the patient's clinical findings with laboratory test results to correctly diagnose the illness. The examples mentioned serve to emphasize the fact that when making a diagnosis of anemia, the physician cannot depend solely on laboratory test results but also must consider patient history, physical examination, and symptoms.

▶ ADAPTATIONS TO ANEMIA

Signs and symptoms of anemia range from slight fatigue or barely noticeable physiologic changes to life-threatening reactions depending on:

- Rate of onset
- Severity of blood loss
- Ability of the body to adapt

With rapid loss of blood as occurs in acute hemorrhage, clinical manifestations are related to hypovolemia and vary with the amount of blood lost. A normal person may lose up to 1,000 mL or 20% of total blood volume and not exhibit clinical signs of the loss at rest, but with mild exercise, tachycardia is common.⁴ Severe blood loss of 1,500–2,000 mL or 30–40% of total blood volume leads to circulatory collapse and shock. Death is imminent if the acute loss reaches 50% of total blood volume (2,500 mL).

Slowly developing anemias can show an equally severe drop in hemoglobin as is seen in acute blood loss, but the threat of shock or death is not usually present. The reason for this apparent discrepancy is that in slowly developing anemias, the body has several adaptive mechanisms that allow organs to function at hemoglobin levels of up to 50% less than normal. The adaptive mechanisms are of two types: an increase in the oxygenated blood flow to the tissues and an increase in oxygen utilization by the tissues (Table 2 🌟).

INCREASE IN OXYGENATED BLOOD FLOW

Oxygenated blood flow to the tissues can be increased by increasing the cardiac rate, cardiac output, and circulation rate. Oxygen uptake by hemoglobin in the alveoli of the

lungs is increased by deepening the amount of inspiration and increasing the respiration rate. In anemia, decreased blood viscosity due to the decrease in erythrocytes and decrease in peripheral resistance help to increase the circulation rate, delivering oxygen to tissues at an increased rate. Blood flow to the vital organs, the heart and brain, can preferentially increase while flow to tissues with low oxygen requirements and normally high blood supply such as skin and the kidneys is decreased.

INCREASE IN OXYGEN UTILIZATION BY TISSUE

An important compensatory mechanism at the cellular level that allows the tissue to extract more oxygen from hemoglobin involves an increase in 2,3-BPG (2,3-bisphosphoglycerate—also known as 2,3-diphosphoglycerate/2,3-DPG) within the erythrocytes. An increase in erythrocyte 2,3-BPG permits the tissues to extract more oxygen from the blood even though the PO_2 remains constant and shifts the oxygen dissociation curve to the right. It is not clear exactly how anemia stimulates this increase in cellular 2,3-BPG.

Another adaptive mechanism at the cellular level involves the Bohr effect. The scarcity of oxygen causes anaerobic glycolysis by muscles and other tissue, which produces a buildup of lactic acid. Additionally, H^+ are generated from bicarbonic acid (H_2CO_3) formed during the transport of CO_2 from the tissues to the lungs. This acidosis decreases hemoglobin's affinity for oxygen in the capillaries, thus causing release of more oxygen to the tissues.

Even with these physiologic adaptations, different anemic patients respond differently to similar changes in hemoglobin levels. The extent of the physiologic adaptations is influenced by:

1. Severity of the anemia
2. Competency of the cardiovascular and respiratory systems
3. Oxygen requirements of the individual (physical and metabolic activity)
4. Duration of the anemia
5. Disease or condition that caused the anemia
6. Presence and severity of coexisting disease

🌟 TABLE 2

Adaptations to Anemia

Increase in oxygenated blood flow

- Increase in cardiac rate
- Increase in cardiac output
- Increase in circulation rate
- Preferential increase in blood flow to vital organs

Increase in oxygen utilization by tissues

- Increase in 2,3-BPG in erythrocytes
- Decreased oxygen affinity of hemoglobin in tissues due to Bohr effect

▶ DIAGNOSIS OF ANEMIA

Anemia can impair an individual's ability to carry on activities of daily living and decrease the individual's quality of life (QOL). Thus, accurate diagnosis and treatment are essential to improve patient outcomes. The diagnosis of anemia and determination of its cause are made by using a combination of information received from the patient history, the physical examination, and the laboratory investigation (Table 3 🌟).

★ TABLE 3

Important Information for Evaluating a Patient for Anemia

Diagnosis of anemia and determination of its cause requires information obtained from the patient history, physical examination, and laboratory data

- I. Patient history
 - A. Dietary habits
 - B. Medications
 - C. Exposure to chemicals and toxins
 - D. Symptoms and their duration
 1. Fatigue
 2. Muscle weakness
 3. Headache
 4. Vertigo
 5. Syncope
 6. Dyspnea
 7. Palpitations
 - E. Previous record of abnormal blood examination
 - F. Family history of abnormal blood examination
- II. Signs of anemia obtained by physical examination
 - A. Skin pallor
 - B. Pale conjunctiva
 - C. Koilonychia
 - D. Hypotension
 - E. Jaundice
 - F. Smooth tongue
 - G. Neurological dysfunction
 - H. Hepatomegaly
 - I. Splenomegaly
 - J. Bone deformities in congenital anemias
- III. Laboratory investigation
 - A. Erythrocyte count
 - B. Hemoglobin
 - C. Hematocrit
 - D. Erythrocyte indices: MCV, MCH, MCHC
 - E. Reticulocyte count and reticulocyte production index
 - F. Blood smear examination
 - G. Leukocyte and platelet quantitative and qualitative examination
 - H. Tests to measure erythrocyte destruction depending on other information available: serum bilirubin, haptoglobin, lactate dehydrogenase (LD), methemalbumin, urine hemosiderin
 - I. Bone marrow examination (depending upon results of other laboratory tests and patient clinical data)

HISTORY

The patient's history including symptoms can reveal some important clues as to the cause of the anemia. Information solicited by the physician should include dietary habits, medication taken, possible exposure to chemicals or toxins, and description and duration of the symptoms. The most common complaint is tiredness. Muscle weakness and fatigue develop when there is not enough oxygen available to burn fuel for the production of energy.

Severe drops in hemoglobin can lead to a variety of additional symptoms. When oxygen to the brain is decreased, headache, vertigo, and syncope can occur. Dyspnea and palpitations from exertion, or occasionally while at rest, are not

uncommon complaints. The patient should be questioned as to any overt signs of blood loss, such as hematuria, hematemesis, and bloody or black stools. Family history can help define the rarer hereditary types of hematologic disorders. For example, sickle cell anemia and thalassemia are frequently manifested to some degree in several members of the immediate family.

PHYSICAL EXAMINATION

Physical examination of the patient helps the physician detect the adverse effects of a long-standing anemia (Table 3).

- Changes in epithelial tissue from oxygen deprivation is noted in some patients. Skin pallor is easily noted in most Caucasian patients, but because of variability in natural skin tone, pale conjunctiva is a more reliable indicator of anemia. The presence of pallor, particularly conjunctival pallor, has been shown to be a cost effective and feasible method to screen for anemia in a variety of settings.^{5,6}
- Hypotension can accompany significant decreases in blood volume.
- Heart abnormalities can occur as a result of the increased cardiac workload associated with the physiologic adaptations to anemia. Cardiac problems usually occur only with chronic or severe anemias (hemoglobin <7 g/dL).
- Organomegaly of the spleen and liver are of primary importance in establishing the extent of involvement of the hematopoietic system in the production and destruction of erythrocytes. Massive splenomegaly is characteristic of some hereditary chronic anemias. The spleen can also become enlarged in some autoimmune hemolytic anemias when it is the primary site of destruction of antibody-sensitized erythrocytes.
- Anemia can also occur secondarily to a defect in hemostasis. The presence of bruises, ecchymoses, and petechiae indicates that the platelets can be involved in the disorder that is producing the anemia.

In addition to these general physical findings associated with anemia, there can be findings associated with a particular type of anemia. These include koilonychia in iron deficiency, a smooth tongue in megaloblastic anemia, jaundice in hemolytic anemias, bone deformities and extramedullary hematopoietic tissue masses in the hereditary hemoglobinopathies, and neurological dysfunction in pernicious anemia.

In addition to determining the extent of anemic manifestations, physical examination helps to establish the underlying disease process causing the anemia. Some disorders associated with anemia include chronic diseases such as rheumatoid arthritis as well as malignancies, gastrointestinal lesions, kidney disease, parasitic infection, and liver dysfunction.

LABORATORY INVESTIGATION

After the physical examination and patient history, a physician who suspects the patient has anemia orders laboratory tests. Initially, screening tests are performed to determine whether anemia is present and to evaluate erythrocyte production and destruction/loss. The initial screening test is the complete blood count (CBC), which includes red blood cell (RBC) count, hemoglobin, hematocrit, RBC indices, white blood cell (WBC) count, and platelet count. Depending on these test results, additional tests such as the reticulocyte count, bilirubin, and review of the blood smear can be suggested. In addition, the urine and stool can be examined for the presence of blood. When combined with the information from the history and physical examination of the patient, results of these tests can give insight to the cause of the anemia. These routine tests can be followed by a protocol of specific diagnostic tests that help establish the etiology and pathophysiology of the anemia. These specific tests will be discussed in the appropriate chapters on anemia.

Erythrocyte Count, Hematocrit, and Hemoglobin

The erythrocyte count, hematocrit, and hemoglobin are determined using routine laboratory tests used to screen for the presence of anemia. Generally, concentrations for these parameters parallel each other. A diurnal variation in hemoglobin, hematocrit, and erythrocyte values occurs with highest values in the morning and lowest values in the evening.

Erythrocyte counts are usually performed only if automated instruments are available. Thus, in a clinic or physician's office with limited resources, screening can be limited to either the hematocrit or hemoglobin. If one of the three screening tests is abnormal, it is helpful to have the results of the other two so that the red cell indices can be calculated.

A decreased concentration in one or more of these parameters based on the individual's age and sex should be followed by other laboratory tests to help establish criteria for diagnosis. The Centers for Disease Control (CDC) recommended cutoff values for a diagnosis of anemia according to age and sex are provided in Table 4. Upward adjustments for these cutoff values should be utilized for individuals living at high altitudes and for those who smoke. There is a direct dose–response relationship between the amount smoked and the hemoglobin level.³ The CDC recommended adjustments are included in Tables 5 and 6. Hemoglobin and hematocrit values also vary in pregnancy with a gradual decrease in the first two trimesters and a rise during the third trimester (Table 7).

The highest normal hemoglobin, hematocrit, and erythrocyte counts are seen at birth. In the neonate, erythrocytes are macrocytic, and the reticulocyte count is 2–6%. From 3 to 10 nucleated erythrocytes per 100 leukocytes can be observed in the peripheral blood during the first week of

life. A gradual decrease in these parameters occurs for 2 months after birth. This decline is followed by a gradual increase until normal adult values are reached at about 14 years of age. A difference in erythrocyte values between sexes is noted at puberty, females having lower values than males.

Although anemia in the elderly is prevalent, it should not be considered a normal part of aging. Hematologic values change very little in normal older adults and increase slightly after menopause.⁷ In men over 70 years of age, the hemoglobin decreases about 1 g/dL partly due to a decrease in androgens. A slight decline in the hemoglobin of about 0.2 g/dL occurs in women over 70.^{8,9} The third National Health and Nutrition Examination Survey (NHANES III, 1988–94) studied a group of noninstitutionalized older individuals and found that after age 65, the prevalence of anemia rose to 11% in men and 10.2% in women.^{10,11} The highest prevalence of anemia is in those over 85 years of age (26% of men and 20% of women). In this anemic group, one-third had a nutritional deficiency, one-third had anemia of chronic disease or inflammation, and one-third were unexplained.

Variations in hemoglobin are also reported to occur as a result of blood-drawing techniques. Hemoglobin values are about 0.7 g/dL higher if the patient's blood is obtained while the individual is in an upright position rather than supine. Prolonged vasoconstriction by the tourniquet can cause hemoconcentration of the sample and elevate the hemoglobin value.

Erythrocyte Indices

The erythrocyte indices help classify the erythrocytes as to their size and hemoglobin content. Hemoglobin, hematocrit, and erythrocyte count values are used to calculate the three indices: mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), and mean corpuscular hemoglobin concentration (MCHC). (The conversion factors in the formulas for the indices vary depending on the use of conventional units or Systeme International Units [SI] for the hemoglobin and hematocrit.) The indices give a clue as to what the erythrocytes should look like on the stained blood film. Because abnormal erythrocyte morphology is characteristic of dis-

tinct types of anemia, the indices are useful for classification of anemic states. Indices may be falsely increased or decreased depending upon a number of factors (see ∞ Table 7). The laboratory scientist should always correlate the indices with the Hb, Hct, RBC count, and other indices to ensure that technical problems are identified when they occur.

Mean Cell Volume The MCV indicates the average volume of individual erythrocytes expressed in femtoliters (fL), (10^{-15} L). It is measured directly on automated cell counters and also can be manually calculated from the hematocrit and RBC count. The reference interval is 80.0–100.0 fL. The mean MCV is slightly increased in nonanemic individuals over the age of 65 (about 90.0 fL versus 87.0 fL).⁸

$$\text{MCV (fL)} = \frac{\text{hct (L/L)} \times 1000}{\text{RBC count} (\times 10^{12}/\text{L})}$$

(Multiply by 10 if hct is expressed in %).

Example A patient has a hematocrit of 0.45 L/L and an RBC count of $5.0 \times 10^{12}/\text{L}$.

$$\text{MCV (fL)} = \frac{0.45 \text{ L/L (hct)} \times 1000}{5 \times 10^{12}/\text{L (RBC count)}} = 90.0 \text{ fL}$$

The value 90.0 fL means the cell has a normal volume and therefore is normocytic.

The MCV is used to classify cells as normocytic, microcytic, or macrocytic (Table 8★). Abnormalities in the MCV are clues to disease processes of the hematopoietic system;

★ TABLE 8

Classification of Erythrocytes Based on MCV

Normocytic	80.0–100.0 fL
Microcytic	<80.0 fL
Macrocytic	>100.0 fL

they are useful in preliminary assessment of anemia pathophysiology.

This index usually correlates with the appearance of cells on stained blood smears (i.e., cells with an increased MCV appear larger [macrocytes], and cells with a decreased MCV appear smaller [microcytes]). However, it must be remembered that MCV is a measurement of volume whereas estimation of flattened cells on a blood smear is a measurement of cell diameter. Cell diameter and cell volume are not the same. Spherocytes usually have a normal or only slightly decreased volume (MCV), but on a stained smear, they are unable to flatten as much as normal erythrocytes because of a decreased surface area and increased rigidity. Spherocytes, therefore, often appear to have a smaller diameter than normal cells. On the other hand, target cells can appear larger due to an increased diameter, but the MCV is often normal.

On instruments using hydrodynamic focusing technology, the MCV can change by up to 4.0 fL if the blood specimen is left uncapped for 4 hours or more due to oxygenation of the blood.¹² The MCV also can increase significantly if blood is stored for 24 hours at room temperature.

Mean Corpuscular Hemoglobin The MCH is a measurement of the average weight of hemoglobin in individual erythrocytes. The MCH is calculated from the hemoglobin and erythrocyte count. The reference interval of MCH for normocytic cells is 28.0–34.0 pg.

$$\text{MCH}(\text{pg}) = \frac{\text{Hb (g/dL)} \times 10}{\text{RBC count} (\times 10^{12}/\text{L})}$$

Example A patient has a hemoglobin concentration of 15 g/dL and an RBC count of $5 \times 10^{12}/\text{L}$.

$$\text{MCH}(\text{pg}) = \frac{15 \text{ g/dL (Hb)} \times 10}{5 \times 10^{12}/\text{L (RBC count)}} = 30.0 \text{ pg}$$

(If hemoglobin is expressed in g/L, do not multiply by 10.)

The value 30.0 pg means the cell contains an average weight of hemoglobin that is within the reference range (28–34 pg).

The MCH does not take into account the size of a cell; it should not be interpreted without taking into consideration the MCV. It varies in a direct linear relationship with MCV. Smaller cells normally contain less hemoglobin, and larger cells normally contain more hemoglobin. In some anemias, a decrease or increase in cell size (MCV) is associated with a proportional decrease or increase in the amount of hemoglobin within the cell (MCH), resulting in a normochromic cell (normal MCHC). In other anemias, however, the decrease in the amount of hemoglobin within the cell (MCH) is substantially more than the decrease in cell size, and the cell appears hypochromic (decreased MCHC). It is important to understand this concept because microcytic cells with an MCH <28.0 pg are not necessarily hypochromic, and macrocytes with a MCH >34.0 pg are usually normochromic.

Mean Corpuscular Hemoglobin Concentration

The MCHC is the ratio of hemoglobin mass to volume in which it is contained (i.e., average concentration of hemoglobin in a deciliter of erythrocytes expressed in g/dL). The MCHC is calculated from the hemoglobin and hematocrit. The reference interval of MCHC is 32.0–36.0 g/dL.

$$\text{MCHC}(\text{g/dL}) = \frac{\text{Hb}(\text{g/dL})}{\text{Hct (L/L)}}$$

Example A patient has a hemoglobin concentration of 15.0 g/dL and a hematocrit of 0.45 L/L.

$$\text{MCHC}(\text{g/dL}) = \frac{15 \text{ g/dL (Hb)}}{.45 \text{ L/L (hct)}} = 33.3 \text{ g/dL}$$

(If hematocrit is expressed in percent, multiply by 100.)

The value, 33.3 g/dL, reveals that the cells contain a normal concentration of hemoglobin and are therefore normochromic.

This index indicates whether the general cell population is normochromic or hypochromic (Table 9). The word *hyperchromic* should be used sparingly. The only erythrocyte that is hyperchromic with an MCHC more than 36.0 g/dL is the spherocyte. Spherocytes have a decreased surface-to-volume ratio due to a loss of membrane but have not lost an appreciable amount of their hemoglobin. The MCHC can be increased in some cases of sickle cell anemia and hemoglobin C disease when the hemoglobin concentration in the cell is close to the solubility value of hemoglobin.¹⁰ The MCHC can be falsely increased with hemolysis, cold agglutinins, and/or insufficient blood in relation to EDTA in the collection tube. The erythrocyte's deformability and its viscosity affect the MCV and MCHC measurements using different automated technologies. The MCHC rarely changes using impedance analyzers and, therefore, its usefulness in classifying anemias can be limited.¹² The MCHC from analyzers using hydrodynamic focusing can be more clinically useful.

In certain conditions, the indices MCV, MCH, and MCHC can be falsely elevated.

Developmental Changes in Erythrocyte Indices

The MCV is increased to a mean of 108 fL at birth but decreases to a mean of 77 fL between the ages of 6 months and 2 years (Figure 1).¹³ It increases to a mean of 80.0 fL by

★ TABLE 9

Classification of Erythrocytes Based on MCHC	
Normochromic	32.0–36.0 g/dL
Hypochromic	<32.0 g/dL
Hyperchromic	>36.0 g/dL

■ **FIGURE 1** Peripheral blood from a newborn; note the macrocytic erythrocytes. (Wright-Giemsa stain; 1000× magnification)

5 years of age but does not reach the adult mean of 90 fL until about 18 years of age. The MCH changes in parallel to the MCV throughout infancy and childhood. The MCHC, however, remains constant within the adult reference interval. Between the ages of 12 and 17 years, males have a higher MCHC and lower MCH and MCV than females.¹⁴

✓ Checkpoint! 1

Calculate the indices and describe the erythrocytes given the following information: Hb 7.1 g/dL, Hct 0.23L/L; RBC count $3.59 \times 10^{12}/L$.

Red Cell Distribution Width Because the MCV represents an average of erythrocyte volume, it is less reliable in describing the erythrocyte population when considerable variation in erythrocyte size (anisocytosis occurs). The RDW (red cell distribution width), the coefficient of variation of MCV, is a calculated index provided by hematology analyzers to help identify anisocytosis. It is calculated as follows:

$$\frac{\text{Standard deviation of MCV} \times 100}{\text{Mean MCV}} = \text{RDW}$$

The reference interval for RDW is 11.5–14.5%. All abnormalities found to this time have been on the high side, indicating an increase in the heterogeneity of erythrocyte size.

Caution must be used in interpreting the RDW because it reflects the ratio of the standard deviation of cell size and the mean MCV. An increased standard deviation (heterogeneous cell population) with a high MCV can give a normal RDW. Conversely, a normal standard deviation (homogeneous cell population) with a low MCV can give an increased RDW. Examination of the erythrocyte histogram/cytogram and stained blood smear gives clues as to the accuracy of the RDW in these cases. When the standard deviation is increased, indicating a true variability in cell size, the base of the erythrocyte histogram is broader than usual.

CASE STUDY (continued earlier from this chapter)

George's only complaint was dark urine and the yellow color of his eyes. His CBC results were hemoglobin 3.1 g/dL; hematocrit 0.08 L/L; RBC count $0.71 \times 10^{12}/L$; RDW 21.6; reticulocytes 22%. Calculate the erythrocyte indices.

1. Does the information given suggest acute or chronic blood loss? What is the significance of the RDW?

✓ Checkpoint! 2

A patient has an MCV of 130 fL and an RDW of 14.5. Review of the blood smear reveals anisocytosis. Explain the discrepancy between the blood smear finding and RDW.

Reticulocyte Count

Immature, anuclear erythrocytes containing organelles and residual ribosomes for hemoglobin synthesis are known as reticulocytes. Reticulocytes usually spend 2–3 days in the bone marrow and an additional day in the peripheral blood before losing their RNA and becoming mature erythrocytes. The peripheral blood reticulocyte count indicates the degree of effective bone marrow activity and is one of the most useful and cost-effective laboratory tests in monitoring anemia and response to therapy. It is also helpful in classifying the pathophysiology of anemia. Reticulocytes can sometimes be identified as *polychromatophilic* erythrocytes (erythrocytes with a bluish tinge) on Romanowsky-stained smears. The polychromatophilia is due to the presence of basophilic ribosomes (RNA) mixed with acidophilic hemoglobin (Figure 2■).

Methods for Counting Reticulocytes The reticulocyte count is one of the few remaining common hematology tests to be performed manually (Figure 3■). Although auto-

■ **FIGURE 2** The large erythrocytes with a bluish tinge are polychromatophilic erythrocytes, which are larger than the more mature erythrocytes. Note also the spherocytes. (Peripheral blood; Wright-Giemsa stain; 1000× magnification)

FIGURE 3 The erythrocytes with the particulate inclusions are reticulocytes. The inclusions represent reticulum that stains with the supravital stain brilliant cresyl blue. (Peripheral blood; 1000× magnification)

mated methods are available on hematology analyzers, more than half of the laboratories still use the manual method¹⁵. Test results are expressed as a percentage of reticulocytes in relation to total RBC count or can be expressed as the absolute number (see next section). The reference interval varies among laboratories and the procedure used, but it is about 0.5–2.5% or 18–158 × 10⁹/L. In the automated method, more than 30,000 RBCs are assessed, so the method is more precise than the manual method (which assesses 1000 RBCs) and is more accurate when the reticulocyte count is very low.

In the healthy aged, there appears to be a decrease in the lifespan of the erythrocyte.¹⁶ This is compensated for by an active bone marrow so that the hemoglobin and hematocrit remain in the reference interval of other adults. There is, however, a slight reticulocytosis, reflecting the increased production of erythrocytes.

Absolute Reticulocyte Count In anemia, a more informative index of erythropoietic activity than the relative reticulocyte count is needed. When reported in percentage, the reticulocyte count does not indicate the relationship between the peripheral blood erythrocyte mass and the number of reticulocytes being produced. The percentage can be increased due to either an increase in the number of reticulocytes in the circulation or a decrease in the number of total RBCs. Therefore, it is recommended that in addition to the percentage of reticulocytes, labs report the absolute reticulocyte count to provide a more useful estimate of reticulocyte production. The absolute count is provided by automated analyzers and can be calculated when using manual methods for reticulocytes:

$$\text{Absolute reticulocyte } (\times 10^9/\text{L}) = \frac{\text{RBC count } (\times 10^{12}/\text{L}) \times \text{Reticulocyte count } (\%)}{100}$$

For example, in a patient with an RBC count of 3.5 × 10¹²/L and a 10% reticulocyte count, the absolute

reticulocyte count is (3.5 × 10¹²/L) × 10% = 350 × 10⁹/L. The mean normal value is 90 × 10⁹/L.

The corrected reticulocyte count is another means to adjust the reticulocyte count in proportion to the severity of anemia. In this procedure, the percentage of reticulocytes is multiplied by the ratio of the patient’s hematocrit to an average age and sex appropriate normal hematocrit:

$$\text{Corrected reticulocyte count} = \frac{\text{Patient hematocrit}}{\text{Normal hematocrit}} \times \% \text{ reticulocyte}$$

Corrected reticulocyte counts less than 2% are associated with hypoproliferative anemias. For practical purposes, the corrected reticulocyte count or preferably absolute reticulocyte count is used to assess the degree of erythropoiesis in anemic patients.^{15,17}

✓ Checkpoint! 3

Is it possible to have an increased relative reticulocyte count but an absolute reticulocyte count in the normal interval? Explain.

Quantitation of Reticulocyte Immaturity Under normal physiologic conditions when there is no anemia, the reticulocytes are released into the peripheral blood where they spend another day maturing to the erythrocyte. When the need for erythrocytes in the circulation increases, the bone marrow releases reticulocytes earlier than normal. These more immature reticulocytes are called *stress reticulocytes* or *shift reticulocytes*. They appear as large polychromatophilic cells on the Romanowsky-stained blood smear. It takes longer for these reticulocytes to mature in the peripheral blood because the remainder of the bone marrow maturation time is added to the peripheral blood maturation time (Table 10★). The more severe the anemia, the earlier the reticulocyte is released. In a stimulated marrow, hematocrit levels of 0.35L/L, 0.25 L/L, and 0.15 L/L are associated with early reticulocyte release and a prolongation of the reticulocyte maturation in peripheral blood to approximately 1.5, 2.0, and 2.5 days, respectively. This is similar to the left shift in granulocytes seen in peripheral blood when the need for granulocytes is increased. To correct for the prolongation of maturation of these circulating shift reticulocytes and

★ TABLE 10

Correlation of the Hematocrit with Reticulocyte Maturation Time in the Peripheral Blood

Hematocrit (L/L)	Reticulocyte Maturation Time (Days)
.35	1.5
.25	2.0
.15	2.5

anemia, the **reticulocyte production index (RPI)** is calculated. The following formula is used:

$$\frac{\text{Patient's hematocrit}}{0.45 \text{ L/L}} \times \frac{\text{Reticulocyte count (\%)}}{\text{Reticulocyte maturation time (days)}}$$

For example, if a patient with a 0.25 L/L hematocrit had a 15% reticulocyte count, the RPI would be:

$$\frac{.25 \text{ L/L}}{.45 \text{ L/L}} \times \frac{15\%}{2.0} = 3.3 \text{ RPI}$$

The RPI is a good indicator of the adequacy of the bone marrow response in anemia. Generally speaking, an RPI > 2 indicates an appropriate bone marrow response, whereas an RPI < 2 indicates an inadequate compensatory bone marrow response (hypoproliferation) or an ineffective bone marrow response. When utilized in this way, the reticulocyte count provides a direction for the course of investigation concerning anemia etiology and pathophysiology.

Reticulocyte maturity level also can be classified based on semi quantitative assessment of RNA concentration within the maturing erythrocyte. Younger reticulocytes contain more RNA than more mature reticulocytes. Some automated hematology instruments not only provide a relative and absolute reticulocyte count but they also assess reticulocytes for maturity level based on RNA content level (assessed by intensity of staining) and report an index of maturity. The term used for this index varies by instrument manufacturer, but it is recommended that it be called the **immature reticulocyte fraction (IRF)**.

The Miles H.3/Advia 120 System by Bayer Diagnostics uses a different method to classify reticulocyte maturity. It reports a reticulocyte hemoglobin content (CHr) and mean reticulocyte cell hemoglobin concentration (CHCMr) for reticulocyte maturity level.

The IRF can be helpful in evaluating bone marrow erythropoietic response to anemia, monitoring anemia, and evaluating response to therapy. In anemia, an increased IRF generally indicates an adequate erythropoietic response while a normal or subnormal IRF reflects an inadequate or no response to the anemia.¹⁸ (The normal reference interval using the Cell-Dyn 3500 and 3700 systems with impedance technology is 0.29 +/- 0.6.)¹² When the bone marrow increases production of erythrocytes, an observable increase in the IRF occurs *before* an increase in the reticulocyte count or an increase in hemoglobin, hematocrit, or RBC count occurs. After bone marrow transplantation, it is the first sign of a successful engraftment. In patients receiving human recombinant erythropoietin (rHuEPO) or iron therapy for anemia, an increased IRF predicts a successful outcome.

The Clinical Laboratory Standards Institute (CLSI), recommends that the IRF index replace the reticulocyte production index (RPI).¹⁵ Laboratories that do not have instruments that measure this parameter may use the RPI.

CASE STUDY (continued from earlier in this chapter)

George's RBC count is $0.7 \times 10^{12}/\text{L}$ and his reticulocyte count is 22%.

2. Calculate his absolute reticulocyte count. Is this count increased, decreased, or normal?

Blood Smear Examination

The erythrocyte is sometimes called a *discocyte* because of its biconcave shape. On a Romanowsky-stained blood smear, the erythrocyte appears as a 7 μm disc with a central area of pallor surrounded by a rim of pink-staining hemoglobin. The area of pallor is caused by the closeness occurring between the two concave portions of the membrane when the cell becomes flattened on a glass slide. Normally the area of pallor occupies about one-third the diameter of the cell. The area of pallor is not seen in erythrocytes suspended in saline or plasma and viewed with the light microscope.

Although doing so is not always necessary, reviewing the stained blood smear assists in diagnosing the type of anemia in 25% of the cases.¹⁹ The normal morphology of the erythrocyte can be altered by various pathological conditions intrinsic or extrinsic to the cell. Careful examination of a stained blood smear reveals these morphologic aberrations. **Anisocytosis** denotes a nonspecific variation in the size of the cells. Some variation in size is normal because of the variation in age of the erythrocytes, younger cells being larger and older cells smaller (Figures 4a■ and 4b■). **Poikilocytosis** is the general term used to describe a nonspecific variation in the shape of erythrocytes (Figures 5a■ and 5b■). Some shapes and sizes, however, are particularly characteristic of specific underlying hematologic disorders or malignancies. These include nucleated erythrocytes (except in newborns), schistocytes, teardrop erythrocytes, spherocytes, acanthocytes, and marked erythrocyte shape abnormalities in normocytic anemia without evidence of hemolysis. It is important to keep in mind that some abnormal morphology can be artifactual because of poorly made or improperly stained smears. If artifactual morphology is suspected, the erythrocytes should be examined in a wet preparation. If the abnormal morphology is present in this preparation, the possibility of artifacts can be eliminated.

Anisocytosis Anisocytosis, variation in cell size, can be detected by examining the blood smear and/or by reviewing the MCV and RDW. Normal erythrocytes have a diameter of about 7–8 μm and an MCV of 80–100 fL. If the majority of cells are larger than normal, the cells are macrocytic; if smaller than normal, they are microcytic (Table 11🔄). If there is a significant variation in size with microcytic, normocytic, and macrocytic cells present, the MCV can be normal because it is an average of cell size. In this case, the RDW is helpful. An RDW more than 14.5 suggests that the erythrocytes are heterogeneous in size, which makes

■ **FIGURE 4** **a.** Normocytic, normochromic erythrocytes. Compare the size of the cells to the nucleus of the lymphocytes. **b.** These erythrocytes show marked anisocytosis. Note the spherocytes. (MCV 104 fL; RDW 30.2) (Peripheral blood; Wright-Giemsa stain; 1000× magnification)

■ **FIGURE 5** **a.** Erythrocytes with marked anisocytosis and poikilocytosis. (Peripheral blood; Wright-Giemsa stain; 400× magnification). **b.** Poikilocytosis with acanthocytes, helmet cell, elliptocytes, echinocytes, schistocytes, and spherocytes. There is also anisocytosis with microcytes and macrocytes. At least two of the macrocytes are polychromatophilic, indicating that they are reticulocytes. (Peripheral blood; 1000× magnification Wright-Giemsa stain)

🔄 **TABLE 11**

Abnormalities in Erythrocyte Size

Terminology	Description	Associated Disease States
Anisocytosis	Increased variation in the range of red cell sizes	See disease states associated with microcytes and macrocytes below
Microcytosis	Red cells with a reduced volume (<80 fL)	Iron deficiency anemia; thalassemia; sideroblastic anemia
Macrocytosis	Red cells with an increased volume (>100 fL)	Megaloblastic anemias; hemolytic anemia; recovery from acute hemorrhage; liver disease; asplenia; aplastic anemia; myelodysplasia; endocrinopathies

the MCV less reliable.¹⁸ Microscopic examination of the cells is especially helpful when the RDW is elevated. To evaluate erythrocyte size microscopically, the cells are compared with the nucleus of a normal small lymphocyte. Normocytic erythrocytes are about the same size as the lymphocyte nucleus (Figure 4a). Figures 4b and 5a show erythrocytes with a marked degree of anisocytosis.

Microcytes **Microcytes** are erythrocytes with a diameter less than 7.0 μm and an MCV less than 80 fL. The cell is usually hypochromic but can be normochromic (Figure 6■). Microcytes in the shape of spheres (microspherocytes) can appear hyperchromic. Microcytes are usually associated with defective hemoglobin formation (Table 11).

Macrocytes **Macrocytes** are larger than normal erythrocytes, having a diameter more than 8.0 μm and an MCV of more than 100 fL. The cell usually contains an adequate amount of hemoglobin resulting in a normal MCHC and normal to increased MCH. Macrocytes are associated with impaired DNA synthesis as occurs in Vitamin B₁₂, or folate, deficiency as well as other diseases (Table 11). Young erythrocytes are normally larger than mature erythrocytes, but within a day of entering the blood stream, they are groomed by the spleen to normal size. When the reticulocyte count is increased, the MCV can be increased.

Poikilocytosis In the past, poikilocytosis was reported as slight, moderate, or marked (or 1+ to 4+). This practice is being replaced, and many laboratories report only significant poikilocytosis. The stained smear should be reviewed keeping in mind the overall context of the laboratory results and the significance of the reported findings. Using the 40X–50X objective, review at least 10 fields to identify variations in size, shape, and hemoglobin content. To evaluate abnormalities including inclusions, review with the 100X

■ **FIGURE 6** Microcytic, hypochromic erythrocytes. Compare the size of the erythrocytes with the nucleus of the lymphocyte. Normocytic cells are about the same size as the nucleus. There is only a thin rim of hemoglobin around the periphery of the cells indicating they are hypochromic. Note the elliptocytes. (Peripheral blood; Wright-Giemsa stain; 1000 \times magnification)

objective. When determining significance and deciding whether to report poikilocytes, the following should be considered:

1. Will it assist in differential diagnosis of the anemia?
2. Will it make a difference in the management of the patient?
3. Is the dominant poikilocyte significant in this setting?
4. Is the specific constellation of findings indicative of a particular pathologic state?

Figure 4a illustrates normal erythrocytes, and Figure 5a and 5b illustrate poikilocytosis. Following is a description of specific types of poikilocytes, their physiologic significance, and disorders with which they are associated (Table 12♣).

Acanthocytes **Acanthocytes**, or spur cells, are small spherical cells with irregular thornlike projections (Figures 5b and 7e■). Often the projections have small bulblike tips. Acanthocytes do not have a central area of pallor. These cells have membranes with altered lipid content. Acanthocytes have a normal life span with a normal to slightly decreased osmotic fragility. Acanthocytes can be seen in liver disease, abetalipoproteinemia (congenital acanthocytosis), and other diseases (Table 12).

Target Cells **Target cells**, also called **codocytes**, are thin, bell-shaped cells with an increased surface-to-volume ratio (Figure 7f■). On stained blood smears, the cells have the appearance of a target with a bull's eye in the center (Figure 8■). The bull's eye is surrounded by an achromic zone and a thin outer ring of pink-staining hemoglobin. The typical appearance of these cells is discernible in the area of the slide only where the cells are well separated but not in the extreme outer feather edge where all cells are flattened. Target cells can appear as artifacts when smears are made in a high-humidity environment or when a wet smear is blown dry rather than fan dried. Target cells have decreased osmotic fragility due to the increased surface-to-volume ratio of the cell.

Target cells can be seen in disorders in which there is an increase in membrane lipids, such as liver disease. Increased surface-to-volume ratio can also occur as a result of diminution of corpuscular hemoglobin as in iron deficiency anemia and thalassemia. Target cells can occur in some hemoglobinopathies, especially hemoglobin S and hemoglobin C disease (Table 12).

Teardrops **Teardrops**, also called **dacryocytes**, are erythrocytes that are elongated at one end to form a teardrop or pear-shaped cell (Figures 7g■ and 9■). Some teardrops can form after erythrocytes containing cellular inclusions have transversed the spleen. Erythrocytes with inclusions are more rigid in the area of the inclusion, and this portion of the cell has more difficulty passing through the splenic filter than the rest of the cell. As splenic macrophages attempt to

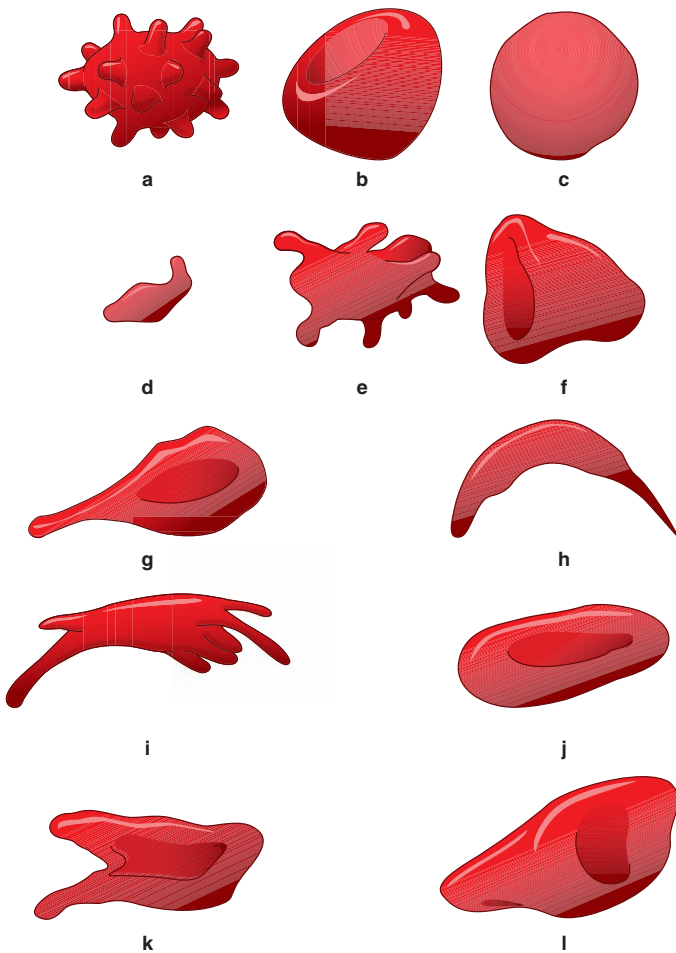

TABLE 12

Abnormalities in the Shape of Erythrocytes

Terminology	Synonyms	Description	Associated Disease States
Poikilocytosis	—	Increased variation in the shape of red cells	See disease states associated with specific poikilocytes on this table
Acanthocyte (spike)	Spur cell	Red cells with spicules of varying length irregularly distributed over the surface	Abetalipoproteinemia; alcoholic liver disease; disorders of lipid metabolism; post splenectomy; fat malabsorption; retinitis pigmentosa
Codocyte (bell)	Target cell	Thin bell-shaped cells with an increased surface-to-volume ratio; on stained blood smears, they assume the appearance of a target with a bull's eye in the center surrounded by an achromic zone and outer ring of hemoglobin; osmotic fragility is decreased	Hemoglobinopathies; thalassemias; obstructive liver disease; iron deficiency anemia; splenectomy; renal disease; LCAT deficiency
Dacryocyte (tear)	Teardrop; tennis racquet cell	Round cell with a single elongated or pointed extremity; often microcytic and/or hypochromic	Myelophthisic anemias; thalassemias
Drepanocyte (sickle)	Sickle cell	Red cells containing polymerized HbS showing various shapes: sickle, crescent, or boat shaped	Sickle cell disorders
Echinocyte (sea urchin)	Burr cells; crenated cell	Spiculated red cells with short equally spaced projections over the entire surface	Liver disease; uremia; pyruvate kinase deficiency; peptic ulcers; cancer of stomach; heparin therapy
Elliptocyte (oval)	Ovalocyte; pencil cell; cigar cell	Oval to elongated ellipsoid cell with central area of pallor and hemoglobin at both ends	Hereditary elliptocytosis; iron deficiency anemia; thalassemia; anemia associated with leukemia
Keratocyte (horn)	Helmet cells; horn-shaped cells	Red cells with one or several notches with projections that look like horns on either end	Microangiopathic hemolytic anemias; heart-valve hemolysis; Heinz-body hemolytic anemia; glomerulonephritis; cavernous hemangiomas
Knizocyte	—	Red cells with more than two concavities; on stained blood smears has a dark band of hemoglobin across the center with a pale area on either side	Conditions in which spherocytes are found
Leptocyte (thin)	Thin cell	Thin, flat cell with hemoglobin at periphery; usually cup shaped, MCV is decreased but diameter of cell is normal	Thalassemia; iron deficiency anemia; hemoglobinopathies; liver disease
Schistocyte (cut)	Schistocyte; fragmented cell	Fragments of red cells; variety of shapes including triangles, comma shaped; microcytic	Microangiopathic hemolytic anemias; heart-valve hemolysis; DIC; severe burns; uremia
Spherocyte	—	Spherocytic red cells with dense hemoglobin content (hyperchromatic); lack an area of central pallor; osmotic fragility increased	Hereditary spherocytosis; immune hemolytic anemias; severe burns; ABO incompatibility; Heinz-body hemolytic anemias
Stomatocyte (mouth)	Mouth cell; cup form; mushroom cap	Uniconcave red cells with the shape of a very thick cup; on stained blood smears cells have an oval or slitlike area of central pallor	Hereditary stomatocytosis; spherocytosis; alcoholic cirrhosis; anemia associated with Rh null disease; lead intoxication; neoplasms
Xerocytes	—	Dense, irregularly contracted cells; hemoglobin can be concentrated at periphery of the cell	Familial xerocytosis

remove this rigid inclusion, the cell is stretched into an abnormal shape. The teardrop cannot return to its original shape because the cell either has been stretched beyond the limits of deformability of the membrane or has been in the abnormal shape for too long a time. This is most likely the mechanism of formation of teardrops observed in thalassemia when Heinz bodies are present. Teardrops are also observed in myelofibrosis with myeloid metaplasia and metastatic cancer to the bone marrow. The mechanism of formation of dacryocytes in these pathologic states is unclear (Table 12).

Sickle Cells **Sickle cells**, also called *drepanocytes*, are elongated, crescent-shaped erythrocytes with pointed ends (Figure 7h■). Some forms have more rounded ends with a flat rather than concave side (Table 12). These modified forms of sickle shape can be capable of reversing to the normal discocyte. Sickle cell formation can be observed in wet preparations or in stained blood smears from patients with sickle cell anemia. The hemoglobin within the cell is abnormal and polymerizes into rods at decreased oxygen tension or decreased pH. The cell first transforms into a holly leaf shape (Figure 7i■). Then, as the hemoglobin polymerization

■ **FIGURE 9** Note the presence of teardrops. Note also the echinocytes, acanthocytes, and spherocytes. (Peripheral blood; Wright-Giemsa stain; 1000× magnification)

continues, it transforms into a sickle-shaped cell. Some holly-leaf forms may be observed on stained blood smears in addition to the typical sickle shape. The sickle cell has decreased osmotic fragility but increased mechanical fragility. The irregular shape of the cell decreases the erythrocyte sedimentation rate by inhibiting rouleaux formation.

Echinocytes **Echinocytes**, also called *burr cells*, are usually smaller than normal erythrocytes with regular, spikelike projections on their surface (Figures 5b, 7a ■, and 9). For true “in vivo” echinocytes, the characteristic appearance is not related to tonicity of the medium in which the cells are suspended. The shape change is instead thought to be the result of an increase in the area of the outer leaflet of the lipid bilayer as compared to the inner layer. Echinocyte formation is reversible (i.e., the cell can revert to a discocyte). Echinocytes can eventually assume the shape of a spherocyte, presumably because of grooming (removal) of the membrane spines by the spleen; in this circumstance, the cell cannot revert to a normal shape.

Normal discocytes can be transformed into echinocytes under certain in vitro conditions. Echinocytes are a common artifact in stained blood smears because of the “glass effect” of the slide. The glass releases certain basic substances, raising the pH of the medium surrounding the cell and inducing echinocyte formation. Plasma provides a buffering effect on the cells, and for this reason, blood films made from whole blood may show only certain areas of echinocyte transformation. To determine the in vivo or in vitro nature of echinocytes, it can be necessary to enclose a drop of blood between two plastic cover slips (wet preparation) and observe the unstained individual erythrocytes. If no echinocytes are in the wet preparation but were noted on the stained blood smears, the cell abnormality occurred as an in vitro artifact.

Echinocytes have been reported to occur *in vivo* in a variety of conditions (Table 12). Echinocytes appear within several days in blood stored at 4°C. Consequently, blood from patients receiving transfusions can show the presence of echinocytes if blood is taken from the patient immediately after transfusion; however, after a few minutes, the buffering action of patient's plasma causes the transfused echinocyte to resume a normal discoid shape.

Elliptocytes **Elliptocytes**, also called *pencil cells* and *cigar cells*, vary from elongated oval shapes (ovalocytes) to elongated rodlike cells (Figures 7j ■ and 6). Elliptocytes have a central area of biconcavity with hemoglobin concentrated at both ends. Elliptocytes are formed after the erythrocyte matures and leaves the bone marrow because reticulocytes and young erythrocytes in patients with elliptocytosis are normal in shape. The mechanism of formation is not known but is assumed to involve alterations of the erythrocyte membrane skeleton. The osmotic fragility of elliptocytes is normal except in hemolytic hereditary elliptocytosis when osmotic fragility is increased. Autohemolysis at 48 hours is increased but is corrected by the addition of both glucose and ATP, suggesting that elliptocytes have abnormal membrane permeability. Rouleaux formation is normal. Elliptocytes are the predominant shape of erythrocytes in hereditary elliptocytosis. These abnormal shapes also can occur in other diseases (Table 12). Megaloblastic anemia is associated with abnormally large oval erythrocytes called *macroovalocytes*.

Helmet Cells **Helmet cells**, also called *keratocytes*, have a concavity on one side and two hornlike protrusions on either end (Figures 7k ■ and 5b). They are produced by impalement on a fibrin strand. The two halves of the erythrocyte hang over the strand as saddlebags; the membranes of the touching sides fuse, producing a vacuole-like inclusion on one side. This cell with an eccentric vacuole is called a *blister cell*. The vacuole bursts, leaving a notch with two spicules on the ends. It has also been suggested that these cells could result from repeated collisions in abnormalities of the circulation. Helmet cells are associated with microangiopathic hemolytic anemia (Table 12).

Knizocytes **Knizocytes** are cells with more than two concavities (Figure 7l ■). The appearance of this cell on stained blood smears can vary depending upon how the cell comes to rest on the flat surface; however, most knizocytes have a dark-staining band across the center with a pale area on either side surrounded by a rim of pink-staining hemoglobin. The mechanism of formation is unknown. Knizocytes are associated with spherocytosis (Table 12).

Leptocytes **Leptocytes** are thin, flat, cells with normal or larger than normal diameter. Although the diameter of the cell is normal or increased, the MCV is usually decreased. The cells have an increased surface-to-volume ratio either as

a result of decreased hemoglobin content or increased surface area. The leptocyte is usually cup shaped like stomatocytes, but the cup has little depth. Target cells can be formed from leptocytes on dried blood smears when the depth of the cup increases. Leptocytes are seen in liver disease and in anemias characterized by hypochromic erythrocytes (Table 12).

Schistocytes **Schistocytes** are erythrocyte fragments caused by mechanical damage to the cell (Figures 5a, 5b, and 7d ■, Table 12). They appear in a variety of shapes: triangular, comma shaped, helmet shaped, and others. Because schistocytes are fragments of erythrocytes, they are usually microcytic. They maintain normal deformability, but their survival in the peripheral blood is reduced. The fragments can assume a spherical shape and hemolyze or can be removed in the spleen.

Schistocytes are found whenever blood vessel pathology is present. Erythrocyte fragmentation is particularly associated with intravascular fibrin formation. Erythrocytes become hung up on fibrin strands in the vessels (termed the *clothesline effect*). The force of blood flow can release the distressed cell intact, or the cell can be fragmented by the fibrin strand, producing schistocytes. This mechanism of erythrocyte damage predominates in microangiopathic hemolytic anemias. Schistocytes can also be seen in valvular lesions, uremia, and march hemoglobinuria. Seen in severe burn victims, spheroschistocytes are the result of heat damage to the spectrin in the membrane cytoskeleton.

Spherocytes **Spherocytes** (Figures 4b and 7c ■) are erythrocytes that have lost their biconcavity due to a decreased surface-to-volume ratio. On stained blood smears, the spherocyte appears as a densely stained sphere lacking a central area of pallor. Although the cell often appears microcytic on stained blood smears, the volume (MCV) is usually normal. The spherocyte is the only erythrocyte that can be called hyperchromic because of an increased MCHC. Spherocytes have increased osmotic fragility with hemolysis beginning in NaCl concentrations of about 0.6% and complete at about 0.4%. Autohemolysis (in vitro suspension of patients' cells and serum) is increased. Spherocytes, which are less deformable than discocytes, have a decreased life span and are removed in the spleen. Spherocytes are seen in hereditary spherocytosis and a variety of other disorders (Table 12). They represent a significant finding when associated with hemolytic anemia because it is an indication of immune hemolytic anemia.

Stomatocytes In wet preparations, **stomatocytes** appear as small cup-shaped uniconcave discs (Figures 7b ■ and 10 ■). Upon staining, these cells exhibit a slitlike (mouthlike) area of pallor. Normal discocytes can be transformed under certain conditions to stomatocytes and, eventually, to spherostomatocytes. The stomatocyte shape is reversible, but the

FIGURE 10 Stomatocytes. Note the slitlike area of pallor. (Peripheral blood; Wright-Giemsa stain; 1000× magnification)

spherostomatocyte is not. Cationic drugs and low pH cause a gradual loss of biconcavity leading to the stomatocyte and eventually formation of a sphere. Stomatocytosis is the opposite of echinocytosis; the shape change in stomatocytosis is thought to be the result of an increase in the lipid content or area of the inner leaflet of the membrane lipid bilayer.

Stomatocytes also can appear as an artifact on stained blood smears and, thus, care should be used in identifying them. Stomatocytes *in vivo* are characteristic of a rare autosomal dominant hemolytic anemia called *hereditary stomatocytosis*. Stomatocytes are also associated with a variety of other diseases (Table 12).

CASE STUDY (continued from earlier in this chapter)

George's blood smear revealed marked spherocytosis.

3. Explain the importance of this finding.
4. Explain George's abnormal indices.

Variation in Hemoglobin (Color) Normal erythrocytes have an MCH of approximately 30 pg. On stained smears, the erythrocyte has a central area of pallor approximately

one-third the diameter of the cell. In certain conditions, the cells contain less hemoglobin than normal. The only erythrocyte that contains more hemoglobin than normal in relation to its volume is the spherocyte. Spherocytes lack a central area of pallor and stain uniformly dense.

Hypochromic Cells Hypochromic cells are poorly hemoglobinized erythrocytes with an exaggerated area of pallor (>1/3 the diameter of the cell) on Romanowsky-stained blood smears. Hypochromic cells, although occasionally normocytic, are usually microcytic (Figure 6). Hypochromic cells are the result of decreased or impaired hemoglobin synthesis (Table 13).

Polychromatophilic Erythrocytes Polychromatophilic erythrocytes (reticulocytes) are usually larger than normal cells with a bluish tinge on Romanowsky-stained blood smears (Figure 2). The bluish tinge is caused by the presence of residual RNA in the cytoplasm. Large numbers of these cells are associated with decreased erythrocyte survival or hemorrhage and an erythroid hyperplastic marrow (Table 13).

Erythrocyte Inclusions Erythrocytes do not normally contain any particulate inclusions. When present, inclusions can help direct further investigation because they are associated with certain disease states. Diseases/conditions associated with these inclusions are listed in Table 14. The erythrocyte inclusions are described here as they appear on Romanowsky-stained blood smears unless otherwise stated.

Basophilic Stippling Erythrocytes with **basophilic stippling** are cells with bluish-black granular inclusions distributed across their entire cell area (Figure 11a). The granules may vary in size and distribution from small diffuse to coarse and punctate. The granules, which are composed of aggregated ribosomes, are sometimes associated with mitochondria and siderosomes. It is believed that basophilic stippling is not present in living cells; instead, stippling probably is produced during preparation of the blood smear or during the staining process. Electron microscopy has not shown an intracellular structure similar to basophilic stippling. Cells dried slowly or stained rapidly can demonstrate fine, diffuse stippling as an artifact. Pathologic basophilic stippling is more coarse and punctate.

TABLE 13

Variations in Erythrocyte Color

Terminology	Description	Associated Disease or Physiologic States
Hypochromia	Decreased concentration of hemoglobin in the red cell; red cells have an increased area of central pallor (>1/3 diameter of cell)	Iron deficiency anemia; thalassemia; other anemias associated with a defect in hemoglobin production
Polychromasia	Young red cells containing residual RNA; stain a pinkish-gray to pinkish-blue color on Wright's stained blood smears; usually appear slightly larger than mature red cells	Hemolytic anemias; newborns; recovery from acute hemorrhage

TABLE 14

Abnormal Erythrocyte Inclusions

Terminology	Description	Associated Disease States
Basophilic stippling	Round or irregularly shaped granules of variable number and size distributed throughout the red cell; composed of aggregates of ribosomes (RNA); stain bluish black with Wright's stain	Lead poisoning; anemias associated with abnormal hemoglobin synthesis; thalassemia
Cabot rings	Appear as a figure 8, ring, or incomplete ring; thought to be composed of the microtubules of the mitotic spindle; stain reddish violet with Wright's stain	Severe anemias; dyserythropoiesis
Howell-Jolly bodies	Small, round bodies composed of DNA usually located eccentrically in the red cell; usually occurs singly, rarely more than 2 per cell; stains dark purple with Wright's stain	Post-splenectomy; megaloblastic anemias; some hemolytic anemias; functional asplenia; severe anemia
Pappenheimer bodies	Clusters of granules containing iron that are usually found at the periphery of the cell; visible with Prussian blue stain and Wright's stain	Sideroblastic anemia; thalassemia; other severe anemias
Heinz bodies	Bodies composed of denatured or precipitated hemoglobin; not visible on Wright's stained blood smears; with supravital stain appear as purple, round-shaped bodies of varying size, usually close to the cell membrane; can also be observed with phase microscopy on wet preparations	G6PD deficiency; unstable hemoglobin disorders; oxidizing drugs or toxins; post-splenectomy
Reticulofilamentous substance	Artificial aggregation of ribosomes; not visible on Wright's stained smears; supravital stain must be used (new methylene blue), appears as deep blue reticular network	Normal reticulocytes

Cabot Rings **Cabot rings** are reddish-violet erythrocytic inclusions usually occurring in the formation of a figure eight or oval ring. Cabot rings are thought to be remnants of spindle fibers, which form during mitosis. They occur in severe anemias and in dyserythropoiesis (Figure 11f ■).

Howell-Jolly Bodies **Howell-Jolly bodies** are dark purple or violet spherical granules in the erythrocyte (Figure 11b ■). These inclusions are nuclear (DNA) fragments usually occurring singly in cells, rarely more than two per cell. Howell-Jolly bodies are associated with nuclear maturation abnormalities. They are thought to occur as a result of an individual chromosome failing to attach to the spindle apparatus during mitosis, and, thus, it is not included in the reformed nucleus. When the nucleus is extruded, the Howell-Jolly body is left behind (until removed by splenic macrophages).

Pappenheimer Bodies **Pappenheimer bodies** are secondary lysosomes variable in their composition of iron and protein, or mitochondria with iron micelles (Figure 11d ■). This type of inclusion appears as clusters of small granules in erythrocytes and normoblasts and stains with both Romanowsky and Perl's Prussian blue stains. Romanowsky stains visualize Pappenheimer bodies by staining the protein matrix of the granules whereas Perl's Prussian blue is responsible for staining the iron portion of the granules. Pappenheimer bodies occur only in pathologic states.

Heinz Bodies **Heinz bodies** do not stain with Romanowsky stains but can be visualized with supravital stains or with phase microscopy of the living cell. They appear as 2–3 μm round masses lying just under or attached to the cell

membrane. Heinz bodies are composed of aggregated denatured hemoglobin.

Sideroblasts *Sideroblasts* are nucleated erythrocytes that contain stainable iron granules whereas *siderocytes* are nonnucleated erythrocytes containing stainable iron granules (Figures 11c ■ and 11e ■). Sideroblasts and siderocytes can be identified with Perl's Prussian blue iron stain, which stains iron aggregates blue. Finely dispersed ferritin cannot be visualized by this technique. It is hypothesized that when ferritin is not used rapidly by cells, it aggregates and is proteolyzed within lysosomes, forming hemosiderin (a nonspecific complex of iron and partially degraded proteins and lipids). Thus, hemosiderin represents an abundant supply of iron or an abnormality in iron use by the cell. It is usually found in cells heavily loaded with iron, such as macrophages. About 50–70% of all erythroblasts in the marrow contain iron, which can be visualized with Perl's Prussian blue stain. This number decreases in some pathologic states and can be markedly increased in others. Reticulocytes and erythrocytes in the peripheral blood do not normally contain ferritin aggregates.

Variation in Erythrocyte Distribution on Stained Smears On a well-made blood smear, the erythrocytes are evenly distributed and well separated on the feather edge of the smear. Stacking or aggregating of cells is associated with certain pathologic states (Table 15 🔄).

Agglutination In the presence of IgM antibodies (cold agglutinins) directed against erythrocyte antigens, erythrocytes can agglutinate forming irregular clusters of varying sizes (Figure 12 ■). These clusters are readily differentiated

FIGURE 11 a. Erythrocyte with basophilic stippling. Note also the teardrop cells. b. Howell-Jolly bodies in erythrocytes. These bodies are the single round purple inclusions. Note echinocytes, acanthocytes, target cells, and spherocytes. c. The erythroblasts with blue inclusions (iron granules) are referred to as sideroblasts. These granules do not stain with Romanowsky stains. d. These erythrocytes contain iron granules called *Pappenheimer bodies*, which will stain with both Romanowsky and Perl's Prussian blue stains. e. Siderocytes. f. Cabot ring (a, b, d, f. Peripheral blood, Wright-Giemsa stain, 1000× magnification; c. Bone marrow, Perl's Prussian blue stain, 1000× magnification; e. TABLE 15

Abnormalities in Erythrocyte Arrangement

Terminology	Description	Associated Disease States
Agglutination	Irregular clumps of red blood cells from antigen–antibody reaction	Cold agglutinins; autoimmune hemolytic anemias
Rouleaux	Red blood cells arranged in rolls or stacks; usually associated with abnormal or increased plasma proteins; red blood cells can be dispersed by mixing cells with saline	Multiple myeloma and other gammopathies

from rouleaux by their irregular conformations (grape-like clusters). On automated cell counters, a blood count with a grossly elevated MCV and low RBC count but a normal hemoglobin suggests the presence of cold-reacting erythrocyte agglutinins. The effect of cold agglutinins is overcome by keeping the blood at 37°C. When performing blood counts, the diluting fluid must also be kept at 37°C.

Rouleaux *Rouleaux* is an alignment of erythrocytes one on top of another resembling a stack of coins (Figure 13 ■). This phenomenon occurs normally when blood is collected and allowed to stand in tubes. It can also be seen in the thick portion of blood smears. In certain pathologic states that are accompanied by an increase in fibrinogen or globulins, rouleaux become marked and are readily seen in the feather edge of blood smears. When the erythrocyte assumes abnormal shapes, such as sickled forms, rouleaux formation is inhibited. Rouleaux is also inhibited when erythrocytes are suspended in saline.

Leukocyte and Platelet Abnormalities

Some nutritional deficiencies, stem cell disorders, and bone marrow abnormalities affect the production, function, and/or morphology of all hematopoietic cells; thus, evaluation of the quantity and morphology of leukocytes and platelets can supply additional important data as to the cause of anemia.

■ **FIGURE 12** This blood smear is from a patient with cold agglutinin disease. Notice the clumping of the erythrocytes. (Peripheral blood; Wright-Giemsa stain; 1000× magnification)

Bone Marrow Examination

Bone marrow evaluation usually is not necessary to determine the cause of an anemia. However, it can provide supplemental diagnostic information in anemic patients when other laboratory tests are not conclusive. For example, in hypoproliferative anemias, bone marrow evaluation can reveal myelodysplasia or infiltration of the marrow with malignant cells or granulomas.

Microcytic, Hypochromic Anemia Serum iron studies and occasionally hemoglobin electrophoresis are usually adequate to differentiate the causes of a microcytic, hypochromic anemia. When iron studies are not definitive, a bone marrow exam can be helpful. However, measurement of serum ferritin levels have largely negated the need for bone marrow iron assessment. Low or absent bone marrow iron or serum ferritin confirms iron deficiency anemia. In patients with sideroblastic anemia, the diagnostic bone marrow finding is the presence of sideroblasts with iron deposits circling the nucleus. These ringed sideroblasts represent iron-laden mitochondria.

Macrocytic Anemias Macrocytic anemias can be due to hemolytic anemias, megaloblastic anemia, or nonmegaloblastic anemia. Diagnostic features of megaloblastic

■ **FIGURE 13** Rouleaux. The erythrocytes are stacked on one another like a stack of coins. This blood smear is from a patient with multiple myeloma, a malignant plasma cell disorder. The background of the slide has a bluish hue due to the large amount of protein in the plasma. (Peripheral blood; Wright-Giemsa stain; 1000× magnification)

anemia such as hypersegmented granulocytes can be found on peripheral blood smears and supported by low vitamin B₁₂ or folic acid levels. However, if vitamin B₁₂ and folic acid levels are normal, a bone marrow examination is suggested to rule out myelodysplastic syndrome. Hemolytic anemias with an increased MCV due to reticulocytosis can usually be diagnosed by other laboratory tests and review of the blood smear. Nonmegaloblastic anemias have various causes, but clinical symptoms, history, and other laboratory tests are usually sufficient to arrive at a diagnosis. However, if aplastic anemia (often macrocytic but not megaloblastic) is suspected, a bone marrow examination is indicated.

Normocytic, Normochromic Anemia If a diagnosis of aplastic anemia or pure red cell aplasia is suspected, a bone marrow examination is essential to demonstrate hypoplasia and an increase in fat and/or fibrosis.

Tests for Erythrocyte Destruction

Tests of erythrocyte destruction are important in evaluating erythrocyte survival. If the hemoglobin concentration is stable over at least several days in an anemic patient, then the measurements of erythrocyte production including marrow cellularity and RPI are indirect measurements of erythrocyte destruction. Serum unconjugated bilirubin is primarily derived from hemoglobin catabolism; its concentration in the absence of hepatobiliary disease can yield further information concerning erythrokinetics. Increased unconjugated bilirubin indicates increased hemoglobin catabolism, either intravascular or extravascular. Conversely, anemia due to chronic and acute blood loss as well as hypoproliferative

anemias are associated with normal or decreased serum bilirubin because the number of erythrocytes catabolized is decreased. Cytoplasmic maturation abnormalities can also be accompanied by normal to decreased serum bilirubin even though there is an increase in erythrocyte destruction. This happens because when insufficient heme is being synthesized (hypochromic cells), less heme is being catabolized. Thus, the bilirubin level should always be interpreted with the degree of anemia. It has been suggested that too many variables affect serum bilirubin levels to make it a reliable measurement of RBC destruction.

Other laboratory tests are used to evaluate erythrocyte turnover or blood loss. Hemosiderin in urine, decreased plasma haptoglobin, and increased methemalbumin are associated with increased intravascular hemolysis. Certain biochemical constituents that are concentrated in blood cells are released to the peripheral blood as the cell lyses, and these constituents are indicators of the degree of cellular destruction. In anemias associated with ineffective erythropoiesis or hemolysis, these products will be increased in the blood. The most commonly measured constituents include uric acid, the main end product of purine metabolism, and lactate dehydrogenase (LD), an enzyme that is present in the cell cytoplasm.

The choice of laboratory tests for the differential diagnosis of anemia should depend on the test's specificity and sensitivity. A highly sensitive test is one that will likely be positive when the disorder is present. A highly specific test is one that will be negative when the disorder is not present. Highly sensitive tests are good for screening for the disorder, and highly specific tests are good for confirming the diagnosis of the disorder. Table 16 shows a variety of tests used in

TABLE 16

Operating Characteristics of Discriminating Tests Used in Diagnosing Anemia			
Test	Sensitivity (%)	Specificity (%)	Disease
RDW >15	87–100	66	Iron deficiency anemia
Ferritin <12	65–97	99	Iron deficiency anemia
Transferrin saturation <16	95	70–95	Iron deficiency anemia
Reticulocyte count	62–90	99(>10%)	Hemolysis
Coombs' test	90	95	Autoimmune hemolytic anemia
MCHC >36	100	100*	Hereditary spherocytosis
Splenomegaly	100	?	Hereditary spherocytosis
MCV >105	11	95	Vitamin B ₁₂ or folic acid deficiency
MCV <100	100	40–50	Iron deficiency anemia
MCV <80	100	?	Thalassemia
Hemosiderin (urine)	100	?	Paroxysmal nocturnal hemoglobinuria

*Provided that artifacts are excluded

MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; RDW, red cell distribution width (From Djulbegovic B, Hadley T, Pasic R. A. new algorithm for diagnosis of anemia. *Postgrad Med* 85(5):119–30, 1989.)

diagnosing anemia together with their rates of sensitivity and specificity.

✓ Checkpoint! 4

What laboratory test is the least invasive and most cost efficient to evaluate erythrocyte production in the presence of anemia?

► CLASSIFICATION OF ANEMIA

The purpose of the classification of anemias is to assist the physician in identifying the cause by using laboratory test results in addition to other clinical data. The classification also is useful to laboratory professionals when correlating various test results for accuracy and when making suggestions for additional follow-up tests. Although specific diagnosis is the ultimate goal of any anemia classification system, it must be kept in mind that anemia frequently develops from more than one mechanism, complicating correlation and interpretation of laboratory test results. In addition, complicating factors can alter the typical findings of a specific anemia. For example, preexisting iron deficiency can inhibit the reticulocytosis that normally accompanies acute blood loss or mask the macrocytic features of folic acid deficiency. In these cases, laboratory test results can depend on which mechanism predominates. Anemias can be classified by either morphology or pathophysiology (function).

MORPHOLOGIC CLASSIFICATION

Anemias can be initially classified morphologically according to the average size and hemoglobin concentration of the erythrocytes as indicated by the erythrocyte indices. This morphologic classification is helpful because MCV, MCH, and MCHC are determined when anemia is diagnosed, and certain causes of anemia are characteristically associated with specific erythrocyte size (large, small, or normal) and hemoglobin content (normal or abnormal). The general categories of a morphologic classification include macrocytic, normochromic; normocytic, normochromic; and microcytic, hypochromic.

It must again be stressed that, although an anemia initially seems to belong in one of these categories, the morphologic expression can be the result of a combination of factors. For example, a combined deficiency of iron and folate can result in a normal MCV even though iron deficiency is normally microcytic and folate deficiency is normally macrocytic. These complicated cases usually can be detected by examining the blood smear for specifics of erythrocyte morphology.

A morphologic assessment of anemia, however, is not sufficient; determining the etiology of anemia through additional laboratory tests yields even more meaningful information. Patient history and physical examination are essential for a differential diagnosis within given classifications.

FUNCTIONAL CLASSIFICATION

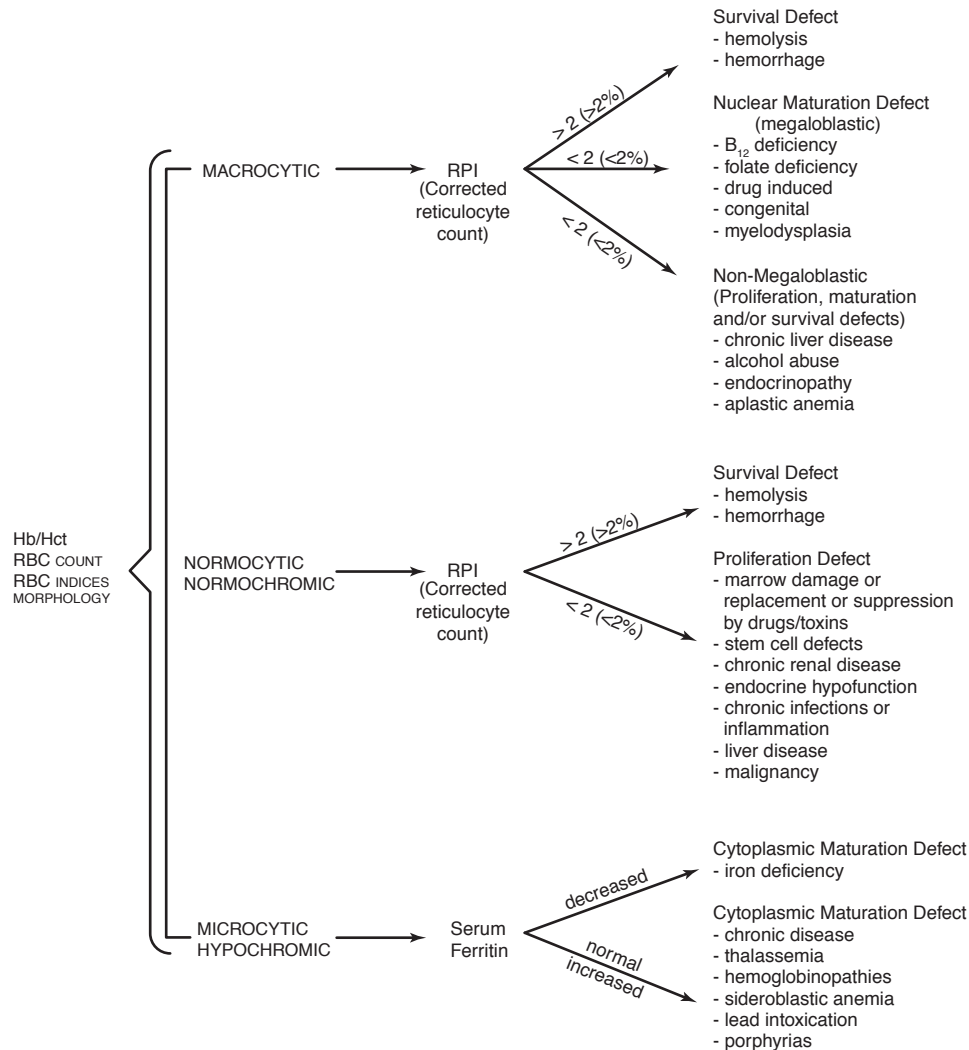

Considering that the normal bone marrow compensatory response to decreased peripheral blood hemoglobin levels is an increase in erythrocyte production, persistent anemia can be expected as the result of three pathophysiologic mechanisms: (1) a proliferation defect (decreased production), (2) a maturation defect, or (3) a survival defect (increased destruction). These are considered to be the three functional classifications of anemia. The functional classification uses the absolute reticulocyte count, corrected reticulocyte count, IRF or RPI, and/or serum iron studies to categorize an anemia. Proliferation and maturation defects usually have a normal or decreased IRF and/or $RPI < 2$ and corrected reticulocyte count $< 2\%$; survival defects are characterized by an increased IRF and/or $RPI > 2$ and corrected reticulocyte count $> 2\%$. Serum iron studies are most helpful in identifying the pathophysiology of microcytic anemias because the IRF or RPI is variable in these cases.

Although some anemias can be the result of several mechanisms, one mechanism is usually dominant. The initial step in approaching an anemic patient is the identification of this dominant mechanism. If the functional and morphologic classifications of anemia are combined, the result is a classification using the corrected reticulocyte count, IRF or RPI, iron studies, and morphology of the erythrocyte (Figure 14 ■). If an anemia does not fit into any of these categories, it is probably multifactorial.

Proliferative Defects

Proliferative defects are characterized by decreased proliferation, maturation, and release rates of erythrocytes in response to anemia (Figure 15 ■). The most characteristic laboratory findings of proliferation defects are normocytic, normochromic erythrocytes, decreased absolute reticulocyte count, corrected reticulocyte count, and IRF, and $RPI < 2$, signifying a marrow output of reticulocytes inadequate for the degree of anemia. Serum bilirubin levels are normal or decreased because of the decrease in cell production. The bone marrow is hypocellular with normal or increased iron stores. Decreased proliferation can be caused by inappropriate erythropoietin production or production of cytokines that inhibit erythropoiesis. This trophic basis is responsible for the anemias associated with malignancies, chronic renal disease, and certain endocrinopathies.

Conversely, erythropoietic stimulating mechanisms can be normal, but the bone marrow can fail to respond to the stimulus appropriately. This occurs when the bone marrow is infiltrated with fibrous, neoplastic, or granulomatous tissue or when the marrow is damaged by chemicals, drugs, or radiation. It is possible to differentiate these causes of hypoproliferation by observing whether all cell lineages are affected or only the erythrocytes are involved. If the proliferation defect is due to inappropriate erythropoietin production, decreased proliferation is limited to the erythrocytic lineage. In contrast, marrow damage or infiltration is

■ **FIGURE 14** Classification of anemias using function and morphology. (Corrected reticulocyte count is in parentheses.)

characterized by hypoplasia of all normal hematopoietic cells in the bone marrow, producing **pancytopenia** (decrease in all blood cells) in the peripheral blood. In addition, marrow infiltration is usually accompanied by poikilocytosis and a leukoerythroblastic peripheral blood picture, presumably caused by damage of the normal sinusoidal barrier.

Many proliferative defects also are associated with decreased erythrocyte lifespan; however, survival is only moderately decreased and could easily be compensated for by a normal functioning marrow or a normal cytokine stimulus. Rarely is hypoproliferation caused by an abnormality in the hematopoietic stem cells.

Maturation Defects

Maturation defects disrupt the orderly process of either nuclear or cytoplasmic development producing qualitatively abnormal cells (Figure 15). The erythrocytes are macrocytic

in nuclear defects and microcytic in cytoplasmic defects. Despite the abnormal maturation process, the marrow attempts to increase production of erythrocytes, resulting in bone marrow erythroid hyperplasia. However, because these cells are often intrinsically abnormal, many are destroyed before they can be released to the peripheral blood (ineffective erythropoiesis). Because many of the abnormal erythrocytes are not released to the peripheral blood, the corrected reticulocyte count, the absolute reticulocyte concentration and IRF are decreased, and the RPI <2. Poikilocytes indicative of abnormal erythropoiesis are frequently present in direct proportion to the severity of the anemia.

Cytoplasmic maturation defects are caused by abnormal hemoglobin production. Therefore, the defect is limited to the erythroid lineage. Hemoglobin production can be impaired due to one or more of the following: limited iron supply, defective iron utilization, decreased globin synthesis,

■ **FIGURE 15** Functional classification of anemia. Anemia may be due to proliferation, maturation, and/or survival defects. Proliferation and maturation defects are due to defective erythropoiesis in the bone marrow. Survival defects are caused by increased destruction of erythrocytes. This destruction may occur in the bone marrow if the cells are intrinsically abnormal and/or in the peripheral circulation. If cells are destroyed in the bone marrow, it is called ineffective erythropoiesis. In some cases an anemia may be due to several causes such as in megaloblastic anemia. Although this anemia is classified as a maturation defect, it also is characterized by ineffective erythropoiesis in which the abnormal cells are destroyed before they reach the peripheral blood. Thus, there also is a survival defect.

and defective porphyrin (heme) synthesis. Most erythrocytes produced in association with cytoplasmic maturation defects are microcytic and hypochromic with a variable degree of poikilocytosis. These anemias are best differentiated using iron studies.

Because all developing hematopoietic cells have nuclei, nuclear maturation defects affect all hematopoietic cell lineages and probably other body cells as well. As a result, the peripheral blood could reflect not only anemia but also pancytopenia with characteristic morphologic changes apparent in all cell lines. The distinctive morphologic changes in cells are collectively termed **megaloblastic** (delayed nuclear development in comparison to cytoplasmic development).

Survival Defects

Survival defects are the result of premature loss of circulating erythrocytes either by hemorrhage or hemolysis (Figure 15). In this type of defect, bone marrow proliferation increases and maturation is orderly. The absolute reticulocyte concentration and IRF are increased, the corrected reticulocyte count is $>2\%$ and the RPI is typically >2 . The blood

film reflects this increased erythropoietic activity by the presence of polychromatophilic macrocytes. If anemia persists despite increased erythrocyte production, the patient has persistent blood loss or active hemolytic disease.

In contrast to poikilocytes that are formed in the bone marrow as a result of dyserythropoiesis typical of proliferation and maturation defects, poikilocytes of a survival defect are formed after the cell leaves the marrow. The most common poikilocytes are schistocytes and spherocytes. The schistocyte is the result of intravascular mechanical trauma to the cell, such as a shearing by fibrin strands or damage by passage through abnormal capillaries. Spherocytes indicate extravascular erythrocyte membrane damage. Generally, the erythrocyte population is normocytic and normochromic. It is possible, however, that macrocytosis can prevail depending on the degree of reticulocytosis or that microcytosis can predominate depending on the number of schistocytes or microspherocytes.

Other indications of decreased erythrocyte survival can include increased serum bilirubin, decreased haptoglobin, and increased methemalbumin, hemosiderinuria, hemoglobinuria, hemoglobinemia, exhaled CO, and urine or fecal urobilinogen.

A knowledge of the functional and morphologic classification of anemias is necessary to design a cost-effective laboratory testing approach that aids in specific diagnosis. Only appropriate tests that help identify the cause of anemia should be performed on the laboratory workup. Guidelines for reimbursement of laboratory tests within ICD codes by third-party payers make it clear that test ordering must be rationally based. Web Figure 1 ■ shows general schemas of laboratory testing that are useful in diagnosing anemias. It should be remembered that the patient's clinical history and physical examination are always performed by the physician before beginning a laboratory workup. The information gained in these areas can eliminate the need for some tests and/or suggest additional tests. These schemas will gain more meaning as you read the following chapters on each group of anemias.

CLASSIFICATION USING THE RED CELL DISTRIBUTION WIDTH

Changes in the MCV and RDW are relatively reproducible in certain anemias. When used with the reticulocytes count, the differential diagnosis is narrowed and classification of the anemia is facilitated.²⁰ (It has been suggested that the classification of anemias use the terms *heterogeneous* (increased RDW) and *homogeneous* (decreased RDW) in conjunction with the descriptive morphologic terms *microcytic*, *normocytic*, and *macrocytic* (e.g., homogeneous macrocytic, heterogeneous macrocytic) (Table 17 🌟).

🌟 TABLE 17

Classification of Anemias by MCV and RDW		
	Normal RDW	Increased RDW
Normocytic	Acute hemorrhage Splenic pooling Chronic disease Chronic leukemia	Immune hemolytic anemia Early iron, B ₁₂ , or folate deficiency Sideroblastic anemia Myelofibrosis Sickle cell anemia/trait Chronic liver disease Myelodysplastic syndrome
Microcytic	Heterozygous thalassemia Chronic disease Hemoglobin E trait	Iron deficiency Homozygous thalassemia Hb S/B ^{thal} Hb H disease Hemolytic anemia with schistocytes
Macrocytic	Chronic liver disease Aplastic anemia Chemotherapy Alcohol ingestions Antiviral medications	Immune hemolytic anemia with marked reticulocytosis B ₁₂ or folate deficiency CLL with high lymph count Cytotoxic chemotherapy Chronic liver disease Myelodysplastic syndrome

Studies of anemic individuals provided the following information regarding the relation between categories of anemia and RDW.^{9,20}

1. Hypoproliferative anemias have a normal RDW regardless of the MCV.
2. Maturational defect anemias (excluding the rare hereditary types) have an increased RDW regardless of the MCV or the degree of anemia. The RDW is increased in these individuals before anemia develops or before abnormal cells can be identified on the smear.
3. The RDW is normal after acute hemorrhage if iron supplies are adequate.
4. Uncompensated hemolytic anemias have a high RDW while compensated hemolytic states have a normal RDW.

CASE STUDY (continued from earlier in this chapter)

5. Classify George's anemia morphologically and functionally.

SUMMARY

Anemia is a decrease in the competence of blood to carry oxygen to the tissue due to a decrease in the concentration of hemoglobin. Diagnosis of anemia is made with a combination of information from the patient history, physical examination, and laboratory investigation. Initially, routine laboratory tests are performed to determine the presence of anemia and to evaluate erythrocyte production and destruction. These tests include erythrocyte count, hemoglobin, hematocrit, erythrocyte indices, reticulocyte count, blood smear examination, and serum bilirubin. More specific tests can be performed based on the results of these routine tests.

The erythrocyte indices can be used to determine the size and hemoglobin content of erythrocytes. Because some anemias are characterized by specific erythrocyte morphology, the indices are helpful in initially classifying the anemia.

The manual reticulocyte count is routinely reported in relative terms: the number of reticulocytes per erythrocytes in percent. Automated reticulocyte counts are reported in both relative and absolute terms. More information is available from the absolute count, corrected reticulocyte count, estimate of IRF, and RPI. Generally, the reticulocyte count in an anemic patient should be increased if the bone marrow is increasing production of erythrocytes.

Examination of the blood film is helpful in assessing anisocytosis and poikilocytosis. Anisocytosis is a variation in erythrocyte size. It is also calculated and expressed as the red cell distribution width (RDW) on some automated cell counters. Macrocytes are erythrocytes with a volume of more than 100 fL while microcytes have a cell volume of less than 80 fL. It is not uncommon to find a variety of cell sizes in some anemias. Poikilocytosis is a variation in cell shape. Specific shapes give clues to the cause of anemia. When present, erythrocyte inclusions also are helpful in determining the cause of anemia. Pappenheimer bodies indicate faulty iron

metabolism, and Howell-Jolly bodies are found in megaloblastic anemia after splenectomy and in some hemolytic anemias.

Bone marrow examination is indicated if laboratory tests give inconclusive results. Bone marrow is examined for cellularity, cellular structure, M:E ratio, and iron stores.

Anemias are generally classified by a functional or morphologic scheme or by a combination of the two. The morphologic classification includes three general categories based on erythrocyte in-

dices: normocytic, normochromic; macrocytic, normochromic; and microcytic, hypochromic. The functional classification uses the IRF or RPI and serum iron studies to classify the anemias according to pathophysiology: proliferation defect, maturation defect, and survival defect. These classifications help the laboratory scientist and physician design a cost-effective approach to laboratory testing to reach a specific diagnosis.

REVIEW QUESTIONS

LEVEL I

- Which erythrocyte inclusions are composed of aggregated, denatured hemoglobin and stain with supravital stains but not with Romanowsky stains? (Objective 4)
 - Howell-Jolly bodies
 - Pappenheimer bodies
 - sideroblasts
 - Heinz bodies
- A patient with anemia has an RPI of 2.3 with an MCV of 103 fL. How would you classify this anemia? (Objective 7)
 - macrocytic
 - normocytic
 - microcytic
 - maturation defect
- A blood smear reveals uneven distribution of blood cells, and the cells appear to be stacked together like a stack of coins. How would you describe this distribution? (Objective 5)
 - agglutination
 - rouleaux
 - anisocytosis
 - poikilocytosis
- Which of the following tests will give information about rate of erythrocyte destruction? (Objective 6)
 - RPI
 - serum bilirubin
 - serum ferritin
 - MCV
- A patient has the following results: RBC count, $2.5 \times 10^{12}/L$ and hemoglobin 5.3 g/dL, hematocrit 0.17 L/L, reticulocyte count 1%. What are the absolute reticulocyte count and RPI? (Objective 3)
 - absolute count, $25 \times 10^9/L$; RPI, 0.15
 - absolute count, $250 \times 10^9/L$; RPI, 0.15
 - absolute count, $170 \times 10^9/L$; RPI, 0.38
 - absolute count, $100 \times 10^9/L$; RPI, 1.5

LEVEL II

- What follow-up test is most appropriate to determine the cause of anemia in a patient with the following results: RBC count, $2.5 \times 10^{12}/L$, and hemoglobin 5.3 g/dL, hematocrit 0.17 L/L, reticulocyte count 1% (Objective 13)
 - LDH
 - vitamin B₁₂
 - serum ferritin
 - IRF
- What is the functional classification of the anemia in the preceding question? (Objective 12)
 - proliferation defect
 - survival defect
 - nuclear maturation defect
 - cytoplasmic maturation defect
- Why might the serum bilirubin results be misleading as an indicator of erythrocyte destruction in the patient in question 1? (Objective 2)
 - The cells are not being destroyed at an increased rate, and the liver is not excreting the bilirubin due to liver failure.
 - The cells are being produced in the bone marrow and released as fast as they are being destroyed, so the bilirubin will be normal.
 - The cells could be destroyed at an increased rate, but the hypochromic cells do not release much hemoglobin, and, hence, less bilirubin is formed.
 - The cells are not destroyed as fast in anemic individuals as in normal individuals, and the bilirubin will be falsely decreased.
- Which of the following laboratory tests is most specific for an anemia due to vitamin B₁₂ or folic acid deficiency? (Objective 10)
 - low ferritin
 - high RDW
 - Coomb's test
 - MCV > 105 fL

REVIEW QUESTIONS (continued)

LEVEL I

6. How would you classify the cell population with the following indices: MCV 70 fL, MCH 25 pg, MCHC 32 g/dL? (Objective 2)
 - a. normocytic, normochromic
 - b. macrocytic, normochromic
 - c. microcytic, normochromic
 - d. microcytic, hypochromic
7. If the cell population in question 6 were homogeneous (absence of anisocytosis), what might the RDW show? (Objective 2)
 - a. false increase
 - b. false decrease
 - c. normal reference interval
 - d. true increase
8. A peripheral blood smear that has an erythrocyte mixture of macrocytes, microcytes, and normocytes present can best be described by which term? (Objective 1)
 - a. poikilocytosis
 - b. polychromatophilia
 - c. megaloblastosis
 - d. anisocytosis
9. Which of the following erythrocyte inclusions cannot be stained and visualized with Romanowsky stains? (Objective 4)
 - a. Pappenheimer bodies
 - b. Howell-Jolly bodies
 - c. Heinz bodies
 - d. basophilic stippling
10. If there is an increase in macrocytic polychromatophilic erythrocytes on the Romanowsky-stained blood smear, with what laboratory test result should you correlate this? (Objective 8)
 - a. serum bilirubin
 - b. reticulocyte count
 - c. leukocyte count
 - d. MCHC

LEVEL II

5. In anemia caused by hemorrhage, what would you expect to find in your laboratory investigation? (Objective 2)
 - a. presence of polychromatophilic macrocytes on the peripheral blood smear
 - b. hypoplastic bone marrow with nuclear maturation abnormalities
 - c. megaloblastosis in the bone marrow and pancytopenia in the peripheral blood
 - d. decreased IRF and RPI
6. Bone marrow examination in a patient with a hemoglobin of 80 g/L reveals erythrocytic hyperplasia with normal appearing erythrocytic precursors. This is an indication that the anemia is due to a: (Objective 9)
 - a. proliferation defect
 - b. nuclear maturation defect
 - c. survival defect
 - d. cytoplasmic maturation defect
7. Which of the following is an adaptation to anemia that tends to increase blood flow to tissues? (Objective 1)
 - a. decrease in 2,3-DPG
 - b. shallow inspiration
 - c. decreased respiratory rate
 - d. increased heart rate
8. A 53-year-old patient had a hemoglobin of 70 g/L. The reticulocyte count is 15%. Which of the following would you expect on the blood smear? (Objective 6)
 - a. poikilocytes
 - b. polychromatophilia
 - c. agglutination
 - d. Howell-Jolly bodies
9. In the patient in question 8, numerous schistocytes were identified on the blood smear. How could this finding affect the RDW? (Objective 3)
 - a. increase it
 - b. decrease it
 - c. have no effect
 - d. invalidate it
10. A patient has a hemoglobin of 90 g/L and a reticulocyte count of 20%. A bone marrow revealed an M:E ratio of 1:2 and 70% cellularity. How would you describe this marrow? (Objective 4)
 - a. aplasia
 - b. erythrocytic hypoplasia
 - c. dysplasia
 - d. erythrocytic hyperplasia

ANSWERS TO CASE STUDY QUESTIONS

Case Summary: George had a severe macrocytic, hyperchromic anemia as revealed by the red cell indices. The anemia developed slowly over time, which gave his body the opportunity to adapt to a low hemoglobin level. The probability of shock and death of a patient who had lost this much blood quickly would have been high. The yellowness of the eyes suggests a high bilirubin concentration, which is typical of a hemolytic anemia. This patient had a test that revealed antibodies and complement on his red blood cells. This supports the diagnosis of an immune hemolytic anemia. The presence of spherocytes supports this diagnosis because they are a sign that the spleen has removed antibody/antigen complexes from the cell membrane. Note that the MCHC is increased, which is typical of spherocytes. The high reticulocyte count and presence of polychromatophilic erythrocytes indicate the bone marrow is responding appropriately by increasing output of erythrocytes. The high reticulocyte count is probably responsible for the increased MCV.

Question:

1. Calculate the erythrocyte indices. Does the information given suggest acute or chronic blood loss? What is the significance of the RDW?

Explanation:

MCV 113 fL; MCH 43.7 pg; MCHC 38.8 g/dL. The case history suggests chronic blood loss. The hemoglobin is very low, and the patient probably would be in shock if he had lost this much blood suddenly. The RDW suggests significant anisocytosis.

Question:

2. Calculate the absolute reticulocyte count. His RBC count is $0.71 \times 10^{12}/L$, and the reticulocyte count is 22%. Is this increased, decreased, or normal?

Explanation:

The absolute reticulocyte count is

$$22\% \times 0.71 \times 10^{12}/L = 0.156 \times 10^{12}/L = 156 \times 10^9/L$$

This is at the high end of the reference range.

Question:

3. George's blood smear revealed marked spherocytosis. Explain the importance of this finding.

Explanation:

Spherocytes are cells that have lost membrane. They are significant in this case because they indicate a hemolytic anemia.

Question:

4. Explain George's abnormal indices.

Explanation:

The indices are all elevated: MCV 113 fL; MCH 43.6 pg; MCHC 38.8 g/dL. The increased MCV may be due to the high reticulocyte count. The MCH is elevated due to the presence of these large cells that are able to hold more hemoglobin than a smaller cell. The MCHC is elevated due to the marked spherocytosis.

Question:

5. Classify George's anemia morphologically and functionally.

Explanation:

George's anemia is morphologically classified as macrocytic, hyperchromic. Functionally, it is classified as a survival defect. It appears that the cells are being destroyed by an immune hemolytic process. The bone marrow has increased production of cells as the increased reticulocyte count indicates.

ANSWERS TO CHECKPOINTS

Checkpoint! 1

Calculate the indices and describe the erythrocytes given the following information: Hb = 7.1g/dL, Hct = 0.23L/L, RBC = $3.59 \times 10^{12}/L$.

Answer

MCV = 64 fL; MCH = 19.8 pg; MCHC = 30.8 g/dL. The cells are microcytic and hypochromic.

Checkpoint! 2

A patient has an MCV of 130 fL and an RDW of 14.5. Review of the blood smear reveals anisocytosis. Explain the discrepancy between the blood smear finding and the RDW.

Answer

The RDW is calculated by dividing the standard deviation of erythrocyte size by MCV. If the SD is abnormally high but the MCV is also high, an RDW in the normal range may be calculated.

Checkpoint! 3

Is it possible to have an increased relative reticulocyte count and an absolute reticulocyte count in the normal interval? Explain.

Answer

Yes. If the patient is very anemic, the ratio of reticulocytes to total number of erythrocytes is not a very accurate indicator of bone marrow production. For example, a reticulocyte count in a patient with a decreased erythrocyte count may be calculated to be an increased percentage of reticulocytes. However, calculating the absolute number of reticulocytes will reveal that the number of reticulocytes is actually in the reference interval. Of course, a reticulocyte count in the reference interval in the presence of anemia is not an adequate response.

Checkpoint! 4

What laboratory test is the least invasive and most cost efficient to evaluate erythrocyte production in the presence of anemia?

Answer

The reticulocyte count is an informative index of erythropoietic activity. It requires a peripheral blood specimen and is easy to perform. Calculation of the absolute reticulocyte count or RPI provides more information. The IRF is provided by some instruments and is very helpful in providing a reticulocyte maturity index.

Anemias of Disordered Iron Metabolism and Heme Synthesis

CHAPTER OUTLINE

- ▶ Objectives—Level I and Level II
- ▶ Key terms
- ▶ Background basics
- ▶ Case study
- ▶ Overview
- ▶ Introduction
- ▶ Iron metabolism
- ▶ Laboratory assessment of iron
- ▶ Iron-deficiency anemia
- ▶ Anemia of chronic disease
- ▶ Anemias associated with abnormal heme synthesis
- ▶ Hemochromatosis
- ▶ Porphyrias
- ▶ Summary
- ▶ Review questions
- ▶ References

Anemias of Disordered Iron Metabolism and Heme Synthesis

Shirlyn B. McKenzie, Ph. D.

■ OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. Define *sideropenic* and *sideroachrestic* as they relate to anemias.
2. Diagram the transport of iron from ingestion to incorporation into heme.
3. Define the following terms and explain their role in iron metabolism: *transferrin*, *hemosiderin*, *ferritin*, *TIBC*.
4. Describe physiologic factors that affect the amount of iron needed by the body.
5. Compare and contrast the typical blood features and iron studies associated with iron deficiency anemia (IDA), anemia of chronic disease (ACD), lead poisoning, and sideroblastic anemia.
6. Explain the etiology and pathophysiology of iron deficiency anemia, anemia of chronic disease, and sideroblastic anemia.
7. Define *hemosiderosis*.
8. Calculate transferrin saturation and UIBC.

■ OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. List the three stages of iron deficiency and define characteristic RBC morphology of each stage.
2. Compare and contrast iron stores, hemoglobin, serum iron, TIBC, saturation, serum ferritin, and RBC morphology in the three stages of iron deficiency.
3. Describe the function of the proteins involved in iron metabolism including hepcidin, HFE, transferrin receptor, hemojuvelin, divalent metal transporter 1, duodenal cytochrome-B reductase, hephaestin, and ferroportin.
4. Explain the molecular control of total body iron and cellular iron.
5. Describe how genetic defects in the iron metabolism proteins can affect the body's iron homeostasis.
6. Contrast the basic defects in iron deficiency anemia, sideroblastic anemia, and anemia of chronic disease, and describe how these defects affect hemoglobin synthesis.
7. Recognize the clinical features associated with iron deficiency.

■ OBJECTIVES—LEVEL II (*continued*)

8. Correlate the following laboratory features with iron deficiency anemia and sideroblastic anemia: erythrocyte morphology and protoporphyrin studies, iron studies, and bone marrow.
9. Select laboratory tests and discuss test results that help differentiate iron deficiency anemia, anemia of chronic disease, and sideroblastic anemia.
10. Summarize the results of bone marrow analysis in sideroblastic anemia and anemia of chronic disease, and contrast them with those found in iron deficiency anemia.
11. Outline the classification of sideroblastic anemias and describe the differentiating feature of the hereditary type.
12. Describe the relationship of the anemias associated with alcoholism and malignant disease to sideroblastic anemia.
13. Describe the role of molecular diagnostics in hereditary sideroblastic anemia.
14. Explain the significance of finding microcytic anemia in the presence of lead poisoning, and suggest reflex testing that would help define an accurate diagnosis.
15. Explain how lead poisoning and alcohol affect erythropoiesis and their relationship to sideroblastic anemia, and recognize the abnormal peripheral blood and clinical features that can be associated with these disorders.
16. Discuss the treatment for iron deficiency, sideroblastic anemia, and anemia of chronic disease and expected laboratory findings associated with successful therapy.
17. Differentiate primary (hereditary) and secondary hemochromatosis and summarize typical results of iron studies in this disease.
18. Describe the genetic abnormality associated with hereditary hemochromatosis and identify the screening and diagnostic tests for this disease.
19. Describe the basic defect in porphyria and its effect on the blood.
20. Develop a reflex-testing pathway for an effective and cost-efficient diagnosis when microcytic and/or hypochromic cells are present.
21. Evaluate laboratory test results and use them to identify the etiology and pathophysiology of the anemias that have a defective heme synthesis component.

KEY TERMS

Anemia of chronic disease (ACD)	Pappenheimer bodies
Anemia of inflammation (AI)	Pica
Apo ferritin	Plumbism
DcytB	Porphyrias
DMT1	Rhophocytosis
Ferritin	Sideroacrestic anemia
Ferroportin 1	Sideroblastic anemia
Hemochromatosis	Sideropenic anemia
Hemojuvelin (HJV)	Total iron-binding capacity (TIBC)
Hemosiderin	Transferrin
Hepcidin	Transferrin saturation
Hephaestin	Unsaturated iron-binding capacity (UIBC)
HFE	

BACKGROUND BASICS

The information in this chapter builds on the concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study.

Level I

- ▶ Diagnosis of anemia: List the laboratory tests used to diagnose and classify anemias and identify abnormal values.
- ▶ Classification of anemia: Outline the morphologic and functional classification of anemias.

Level II

- ▶ Function, structure, and synthesis of hemoglobin: Diagram the synthesis of heme and explain the role of iron in hemoglobin synthesis.
- ▶ Erythrocyte destruction: Diagram degradation of hemoglobin when the erythrocyte is destroyed and interpret laboratory tests associated with increased erythrocyte destruction.

CASE STUDY

We will address this case study throughout the chapter.

Jose, an 83-year-old anemic male, was admitted to a local hospital with recurrent urinary tract bleeding and an infection associated with prostatitis. Consider how these conditions can affect the hematopoietic system.

OVERVIEW

This chapter includes a discussion of a group of anemias associated with defective hemoglobin synthesis due to faulty iron metabolism or porphyrin biosynthesis. The discussion begins with a detailed description of iron metabolism and laboratory tests used to assess the body's iron concentration. This is followed by a description of the specific anemias included in this group—iron deficiency anemia, anemia of chronic disease, and sideroblastic anemia. Hemochromatosis

is also discussed even though it is not characterized by anemia. In this disease, iron metabolism is abnormal, and results of iron studies must be differentiated from those found in sideroblastic anemia. The rare porphyrias are briefly discussed because porphyrin is an integral component in the synthesis of heme.

INTRODUCTION

Defective hemoglobin production can be due to disturbances in either heme or globin synthesis (Table 1). The result of these disturbances is a cytoplasmic maturation defect reflected by a microcytic, hypochromic anemia. Defective heme synthesis is caused by abnormalities of iron homeostasis (deficiency and/or metabolism) or rarely by defective porphyrin metabolism (Figure 1). Defective globin synthesis is caused by a deletion or mutation of globin genes. These globin deletions and mutations are the result of a hereditary condition known as *thalassemia*.

Anemia characterized by deficient iron for hemoglobin synthesis is known as **sideropenic anemia**, commonly referred to as *iron deficiency anemia (IDA)*. Iron deficiency primarily affects the erythrocyte and developing central nervous system. Sideropenic anemia caused by inadequate iron intake or absorption or increased blood loss responds to iron therapy given either orally or less commonly, parenterally.

Defective heme synthesis also can result from defective iron metabolism. **Sideroachrestic anemias** are characterized by adequate or excess stores of iron but defective utilization in the synthesis of hemoglobin. The **anemia of chronic disease (ACD)**, also referred to as the **anemia of inflammation (AI)**, is characterized by iron retention in the macrophages, thus making iron unavailable to the erythrocyte for heme synthesis.

Defects in porphyrin synthesis involve the enzymes required for heme synthesis. The defect can affect the insertion of iron into the porphyrin ring to form heme. These conditions include primary and secondary **sideroblastic anemias**. For convenience, the **porphyrias** are included in this chapter, although the porphyrias except for the erythropoietic porphyria type are not generally characterized by the presence of anemia.

★ TABLE 1

Causes of Defective Hemoglobin Production That May Result in a Microcytic Hypochromic Anemia

Defects in heme synthesis

- Abnormal iron metabolism
 - Iron deficiency
 - Defective iron utilization
- Defective porphyrin metabolism

Defects in globin synthesis (thalassemias): deletions or mutations of globin genes

■ **FIGURE 1** Sites of defective hemoglobin synthesis that can result in anemia. Some of these anemias are hereditary or congenital and others are acquired. (ACD = anemia of chronic disease; IDA = iron deficiency anemia; SA = sideroblastic anemia; EPO = erythropoietin; $//\rightarrow$ = defective or disturbed)

▶ IRON METABOLISM

Iron is required by every cell in the body. It has vital roles in oxidative metabolism, cellular growth and proliferation, and oxygen transport and storage.¹ Iron must be bound to protein compounds to fulfill these functions. Iron in inorganic compounds or in an ionized form is potentially dangerous. If the amount of iron exceeds the body's capacity for transport and storage in the protein-bound form, iron toxicity can develop, causing damage to cells and a potentially lethal condition. Conversely, if too little iron is available, the synthesis of physiologically active iron compounds is limited and critical metabolic processes are inhibited.

Important advances in our understanding of iron metabolism are the result of the discovery of genes and proteins that participate in the regulation of iron homeostasis. As the roles of these proteins are explained, the pathophysiology of disorders involving iron metabolism is revealed. Proteins that play a role in iron metabolism include hepcidin, HFE (hemochromatosis), transferrin receptor (TfR), hemojuvelin, divalent metal transporter 1 (DMT1), duodenal cytochrome-B reductase (DcytB), and ferroportin, also known as IREG1. The role of these proteins is described in the following sections.

DISTRIBUTION

Iron-containing compounds in the body are one of two types: (1) functional compounds that serve in metabolic (hemoglobin, myoglobin, iron-responsive element-binding protein) or enzymatic (cytochromes, cytochrome oxygenase, catalase, peroxidase) functions and (2) compounds that serve as transport (transferrin, transferrin receptor) or storage forms (ferritin and hemosiderin) for iron (Table 2 \star). A poorly understood iron compartment is the intracellular "labile pool." Iron leaves the plasma and enters the intracellular fluid compartment for a brief time before it is incorporated into cellular components (heme or enzymes) or storage

compounds. This labile pool is believed to be the chelatable iron pool (see Therapy, Hemochromatosis). The total iron concentration in the body is 40–50 mg of iron/kg of body weight. Men have higher amounts than women.

Iron is found primarily in erythrocytes, macrophages, hepatocytes, and enterocytes (absorptive cells at the luminal [apical] surface of the duodenum). Hemoglobin constitutes the major fraction of body iron (functional iron) with a concentration of 1 gm iron/kg of erythrocytes, or about 1 mg iron/mL erythrocytes. Iron in hemoglobin remains in the erythrocyte until the cell is removed from the circulation. Hemoglobin released from the erythrocyte is then degraded in the macrophages of the spleen and liver, releasing iron. Approximately 85% of this iron from degraded hemoglobin is promptly recycled from the macrophage to the plasma where it is bound to the transport protein, transferrin, and delivered to developing normoblasts in the bone marrow for heme synthesis. The macrophages recycle 10 to 20 times more iron than is absorbed in the gut.² This iron recycling provides most of the marrow's daily iron requirement for erythropoiesis.

Iron in hepatocytes and intestinal enterocytes is stored and utilized as needed to maintain iron homeostasis. The hepatocytes store iron that can be released and utilized when the amount of iron in the plasma is not sufficient to support erythropoiesis. Enterocytes that absorb dietary iron can either export it to the plasma or store it. Iron stored in enterocytes is lost when the cells are sloughed into the intestine.

ABSORPTION

Total body iron homeostasis depends on balancing and linking the absorption of iron by the enterocytes of the duodenum with total body requirements. No significant mechanism regulates iron loss. Factors influencing iron absorption are listed in Table 3 \star .

Dietary iron exists in two forms: nonheme iron (ionic or ferric form) present in vegetables and whole grains and

TABLE 2

Composition and Distribution of Iron in Adults

Compound	Iron Content, Male (mg Iron/ Kg Body Weight)	Iron Content, Female (mg Iron/ Kg Body Weight)	Percent of Total Iron
Functional iron			
Hemoglobin	31	28	60–75
Myoglobin	5	4	3.5
Other tissue iron	<1	<1	0.2
Heme enzymes (cytochromes, catalases, peroxidases)			
Nonheme enzymes (iron-sulfur proteins, metalloflavoproteins, ribonucleotide reductase)			
Transport			
Transferrin	<1	<1	0.1
Storage			
Ferritin	~8	4	10–20
Hemosiderin	~4	2	5–10
Labile pool	~1	~1	2
Total iron	50	40	

heme iron (ferrous form) present primarily in red meats in the form of hemoglobin. Nonheme iron is the most common form ingested worldwide, but heme iron is more common in Western countries. The ferric complexes from nonheme sources are not easily absorbed. Gastric acid solubilizes this form of iron and provides an acidic environment around the apical brush border of the enterocytes. This low pH facilitates the transport of iron across the enterocyte membrane. The ferric iron is reduced to the ferrous state at the enterocyte brush border through the action of the enzyme, **DcytB**, a ferric reductase. The ferrous iron is then

transported across the apical enterocyte plasma membrane by **DMT1**, an integral membrane protein. DMT1 also transports the divalent forms of manganese, lead, zinc, cobalt, and copper across the enterocyte membrane³ (Figure 2■).

Heme iron is more readily absorbed than nonheme iron, but the mechanism of absorption is less well understood. Heme is split from the globin portion of hemoglobin in the intestine, and is then assimilated directly by the enterocytes. Once inside the cell, iron is released from heme by heme oxygenase. The iron then enters the same iron pool as the nonheme iron. A heme carrier protein (HCP1) found in the duodenal enterocyte was recently described, but its contribution to iron absorption has not been documented.⁴

In the enterocyte, the iron can be stored as ferritin or transported across the basolateral membrane into the plasma. The iron stored as ferritin is lost when the enterocyte is sloughed off into the intestinal tract. Iron transport across the basolateral membrane is via a basolateral transporter protein known as **ferroportin 1** (also known as IREG1). Ferroportin 1, an integral membrane protein, transports ferrous ions and is the only known cellular exporter of iron. Export is facilitated by the ferroxidase, **hephaestin** (a homologue of the plasma protein ceruloplasmin). Hephaestin oxidizes the Fe^{2+} to Fe^{3+} , the form of iron required for binding to apotransferrin in the blood. Hephaestin is a copper-containing ferroxidase that requires adequate amounts of copper for its function. Thus, it is not surprising that copper deficiency is associated with abnormal iron metabolism. Export of iron from nonintestinal cells requires

TABLE 3

Factors Affecting Iron Absorption in the GI Tract

- Bioavailability of iron: from the diet and from macrophage recycling
- Condition of mucosal cells in the GI tract
- Intraluminal factors: parasites, toxins, intestinal motility; increased motility or decreased absorptive surface area can decrease absorption
- Hematopoietic activity of bone marrow: rate of erythropoietic activity directly related to the amount absorbed
- Tissue iron stores: Amount of storage iron inversely related to the amount absorbed
- Oxygen content of the blood: hypoxia associated with increased absorption
- Systemic inflammation or infection: decreases absorption
- Blood hemoglobin concentration: anemia associated with increased absorption

■ **FIGURE 2** The absorption of nonheme iron in the intestine. Most nonheme iron in the diet is in the ferric iron form (Fe^{3+}). When the Fe^{3+} reaches the intestine and comes into contact with the cells lining the gut (enterocytes), the iron is reduced to the ferrous form (Fe^{2+}) by a reductase, DCTB, located at the apical enterocyte membrane. The Fe^{2+} then can be transported across the membrane by DMT1. Ferroportin transports the iron across the enterocyte basolateral membrane, a process thought to be facilitated by hephaestin. Hphaestin is an oxidase that oxidizes the iron to Fe^{3+} , the form that combines with transferrin. Some iron can remain in the cell as ferritin, depending on the systemic iron balance.

ceruloplasmin, which also converts Fe^{2+} to Fe^{3+} for binding to transferrin.

There appears to be a predetermined set point of iron stores that results in a negative correlation between the amount of iron absorbed and the amount of iron stored.⁵ The efficiency of intestinal absorption of iron increases in response to accelerated erythropoietic activity and depletion of body iron stores. Thus, bleeding, hypoxia, or hemolysis results in accelerated erythrocyte production and enhanced absorption of iron. However, increased iron uptake in extravascular hemolytic anemias and anemias associated with a high degree of ineffective erythropoiesis can lead to an excess of iron in various organs because the body does not lose the iron from erythrocytes hemolyzed *in vivo*. Conversely, diminished erythropoiesis as occurs in starvation decreases the absorption of iron.

IDA due to a lack of dietary iron is usually treated with daily oral doses of ferrous salts. The efficiency of absorption of this therapeutic iron is greatest during the initial

treatment period when body stores are depleted. Increased absorption occurs up to 6 months after hemoglobin values return to normal or until iron stores are replenished. Absorption also increases 10–20% in early stages of developing ID.

TRANSPORT

Transferrin is a plasma transport protein that mediates iron exchange between tissues (Table 4 ; Figure 3 ). It is not lost in delivering iron to the cells but returns to the plasma and is reused. Transferrin is a single polypeptide chain composed of two homologous lobes, each of which contains a single iron-binding site. The binding of a ferric iron to either site is random. If only one transferrin lobe binds an iron molecule, it is termed *monoferric transferrin*; if both sites are occupied, it is *diferric transferrin*. Transferrin without iron is called *apotransferrin*.

Each gram of transferrin binds 1.4 mg of iron. Enough transferrin is present in plasma to bind 253–435 μg of iron per deciliter of plasma. This is referred to as the **total iron-binding capacity (TIBC)**.

The serum iron concentration is about 70–201 $\mu\text{g}/\text{dL}$ and almost all (95%) of this iron is complexed with transferrin; thus, transferrin is about one-third saturated with iron (serum iron/TIBC $\times 100 = \%$ **transferrin saturation**). The reserve iron-binding capacity of transferrin (transferrin without bound iron) is referred to as the serum **unsaturated iron-binding capacity (UIBC)** (TIBC – Serum iron = UIBC).

The majority of transferrin-bound iron is delivered to the developing bone marrow normoblasts where the iron is released for use in hemoglobin synthesis. Iron in excess of physiologic requirements is deposited in tissues (primarily the liver) for storage.

Only a small amount of transferrin-bound iron is derived from iron absorbed by enterocytes. Most of the iron bound to transferrin is recycled iron derived from the monocyte-macrophage system. The major flow of iron in the body is from transferrin to erythroid marrow, then to erythrocytes, and finally to macrophages when the senescent erythrocyte is removed and degraded by liver, bone marrow, and splenic macrophages. Recovered iron from hemoglobin catabolism in the monocyte-macrophage system enters the plasma and is again bound to transferrin for transfer back to the bone marrow (Figure 4 ). In disorders associated with

 **TABLE 4**

Characteristics of Transferrin

- Function: responsible for transporting iron
- B_1 -globulin
- MW 79,570 D
- Half-life: 18 days
- Synthesized in the liver

■ **FIGURE 3** Iron is absorbed by the mucosal cells in the gut as ferrous iron. It can be stored in the mucosal cell as ferritin or it can leave the cell as oxidized ferric iron and be transported in the blood by transferrin. Transferrin can deliver iron to developing normoblasts in the bone marrow, other body cells or macrophages in the liver or spleen. Transferrin is reutilized after it delivers iron to the cells.

intravascular hemolysis, plasma hemoglobin combines with haptoglobin. The haptoglobin-hemoglobin complex is taken into the macrophage via the cell's hemoglobin scavenger receptor, CD163.⁶

In contrast to serum ferritin, transferrin is a negative acute phase reactant (levels decrease during the acute phase response). Increased levels are found in pregnancy and in estrogen therapy.

■ **FIGURE 4** The daily iron cycle. Most iron is recycled from the erythrocytes to the bone marrow. Only a small amount of iron is lost from the body through loss of iron containing cells. To maintain iron balance, a similar amount of iron is absorbed from the duodenum.

Lactoferrin also functions as an iron transport protein but is found primarily in tissue fluid and cells. It has antimicrobial properties and is important in protecting the body from infection.

Transferrin releases iron at specific receptor sites on the developing cell, referred to as the *transferrin receptor1* (TfR1). These receptors are expressed on virtually all cells, but the number per cell is a function of cellular iron requirements. Cells with high iron requirements have high numbers of TfR1. Erythroid precursors, especially intermediate normoblasts that are rapidly synthesizing hemoglobin, have high numbers of transferrin receptors, about 800,000 per cell. The TfR1 is a transmembrane glycoprotein dimer with two identical subunits, each of which can bind a molecule of transferrin. A homologous protein, TfR2, is more limited in expression. It is found on hepatocytes, duodenal crypt cells, and erythroid cells.

Iron enters the cell in an energy- and temperature-dependent process. After transferrin binds to its receptor, the transferrin-TfR complex clusters with other transferrin-TfR complexes on the cell membrane, and the membrane invaginates and seals, forming an endosome with the complex inside (endocytosis) (Figure 5 ■). In the acidic endosome, iron is released from transferrin and transported into the cyto-

plasm via DMT1 transport proteins present in the endosomal membrane. The endosome with the apotransferrin and TfR is transported back to the cell surface. The apotransferrin is released, making both it and the receptor available for recycling. Ferritin molecules are also endocytosed on erythroblasts in a process called **rhophocytosis** (a form of micropinocytosis). However, ferritin iron incorporated into the cell this way does not appear to be utilized for hemoglobin synthesis.

Cells release the extracellular portion of their transferrin receptors through proteolytic cleavage as they mature. These cleaved receptors referred to as *serum* or *soluble transferrin receptors* (sTfR) are found in the blood. With increased erythropoiesis, soluble transferrin receptors in the plasma increase.

STORAGE

The primary iron storage depot is the liver. The largest non-heme iron stores in the body are hemosiderin and ferritin (Table 5 🟢). Storage iron provides a readily available iron supply in the event of increased iron loss through bleeding. Depletion of these storage compounds reflects an excess iron loss over what is absorbed.

■ **FIGURE 5** Iron binds to apotransferrin in the plasma forming monoferric or diferric transferrin. Transferrin binds to transferrin receptors on the cell surface. The transferrin-receptor complex enters the cell where the iron is released. The apotransferrin-receptor complex is transported to the cell surface where the apotransferrin is released to the plasma for reutilization. (Adapted from: Hoffman R, Benz EJ, Shattil SJ, Furie B, Cohen HJ, eds. *Hematology: Basic Principles and Procedures*. New York: Churchill Livingstone; 1991.)

★ TABLE 5

Storage Forms of Iron

Iron Form	Role	Laboratory Analysis	Reference Interval
Ferritin	Primary storage form of soluble iron; readily released for heme synthesis	Serum ferritin levels Prussian blue staining	20–300 µg/L males 12–200 µg/L females
Hemosiderin	Partially degraded storage form of iron; slow release	Bone marrow estimation using Prussian blue stain	40–60% sideroblasts in bone marrow

Ferritin

Ferritin consists of a spherical protein shell that can store up to 4500 iron atoms. Ferritin is 17–33% iron by weight. Ferritin without iron in its shell is called **apoferritin**.

Ferritin is a multimer composed of 24 subunits arranged to form a hollow sphere. There are two types of subunit polypeptides, heavy (H) and light (L). The H polypeptide has ferroxidase activity, but the L form does not. Although ferritin contains 24 subunits, the proportion of H and L subunits varies by cell type. Ferritins in the heart, placenta, and erythrocytes are rich in the H subunit, and ferritins in the iron storage sites, such as the liver and spleen, are rich in the L subunits.

Ferritin acts as the primary storage compound for the body's iron needs and is readily available for erythropoiesis. It controls the amount of iron released for cellular activity and by binding the iron, protects the cellular constituents from oxidative damage catalyzed by free ferrous ions. Ferritin is found in the bone marrow, liver, and spleen, usually within membrane-bound vesicles called *siderosomes*. Normally from 30% to 60% of the normoblasts contain iron aggregates (ferritin). Mature erythrocytes usually do not contain iron aggregates because any excess iron in the cell after hemoglobin synthesis is complete is removed by splenic macrophages.

Ferritin is a water-soluble form of storage iron that cannot be visualized by unstained light microscopy but does stain with iron stains (when clustered in siderosomes). Ferritin is primarily an intracellular protein, but small amounts enter the blood through active secretion or cell lysis. The amount of circulating ferritin parallels the concentration of storage iron in the body. Therefore, serum ferritin concentration is used as an index of iron stores: 1 ng/mL of serum ferritin indicates about 8 mg of storage iron. Serum ferritin does not exhibit diurnal variations as are seen with serum iron levels.

The patient's comorbidities must be considered when interpreting serum ferritin levels. Ferritin is not a reliable indicator of iron stores in the presence of inflammation or tissue damage because it is an acute phase reactant. However, if serum ferritin is decreased, it invariably means that iron stores are low or depleted.

Hemosiderin

Hemosiderin is a heterogeneous aggregate of carbohydrate, lipid, protein, and iron; up to 50% of its weight is iron. Hemosiderin is found primarily in macrophages and is formed

by the partial degradation of ferritin. At high levels of cellular iron, ferritin forms aggregates, which are taken up by lysosomes and degraded, forming hemosiderin. The ratio of ferritin to hemosiderin varies with the total body iron concentration. At lower cellular iron concentrations, the ferritin form predominates, but at higher concentrations, the majority of storage iron exists as hemosiderin. Iron from hemosiderin is released slowly and is not readily available for cellular metabolism. Binding in the form of hemosiderin probably keeps iron from harming cellular constituents.

Storage iron in the form of hemosiderin can be estimated on bone marrow tissue sections. Bone marrow macrophages contain hemosiderin if body iron stores are normal or increased. Hemosiderin appears as yellow to brown refractile pigment on unstained marrow or liver specimens. On Prussian blue-stained specimens, the iron appears as blue intracellular particles. Stores can be graded from 0 to 4+ or as markedly reduced, normal, or increased.

PHYSIOLOGICAL REGULATION OF IRON BALANCE

Body iron is stringently conserved by reutilization so that daily absorption and loss are small. Total body iron lost through secretions of urine, sweat, bile, and desquamation of cells lining the gastrointestinal tract amounts to about 1 mg/day. Normal erythrocyte aging results in destruction of 20–25 mL of erythrocytes/day (releasing about 20–25 mg iron), but most of this hemoglobin iron is scavenged and reused by developing normoblasts. Thus, the total daily requirement for new iron is about 1 mg.

Because there is no physiological route for excretion of excess iron, the major regulation of total body iron depends on accurate sensing of systemic iron and the adjustment of iron absorption and retention according to needs. Iron deficiency can occur if dietary intake of iron is not adequate, if absorption is impaired, or if there is increased loss of iron through bleeding. Iron overload can occur if absorption abnormally increases or if the individual receives transfusions or iron injections (Table 6).

Iron Balance at the Tissue Level

Iron homeostasis is accomplished by the interaction of iron with proteins that aid in its absorption, retention, export,

TABLE 6

Causes of Iron Deficiency and Iron Overload

Causes of Iron Deficiency	Causes of Iron Overload
Increased requirement/demand due to blood loss, rapid growth, treatment with EPO	Increased absorption of iron
Inadequate diet	Multiple transfusions
Malabsorption	Iron injections

and transport. These proteins include hepcidin, DcytB, DMT1, ferroportin, HFE, TfR, and hemojuvelin (Table 7). The liver is the primary storage depot for iron and plays a central role in the regulation of total body iron homeostasis by synthesizing hepcidin in response to multiple signals.² Thus, the liver has been called the *command central* of iron homeostasis. The proteins involved in iron absorption can be upregulated or downregulated depending on total body iron status.

Hepcidin **Hepcidin** (also referred to as *HAMP*) is the master iron-regulating hormone that acts by inhibiting expression or activity of genes involved in intestinal iron transport. It decreases absorption and/or transfer of iron from enterocytes to plasma transferrin when iron stores are adequate. Hepcidin also blocks the export of iron stored in macrophages. Downregulation of hepcidin permits increased

TABLE 7

Proteins Involved in Iron Homeostasis

Protein	Metabolic Role
Hepcidin	Master iron-regulating protein; regulates iron recycling/balance via interaction with ferroportin1; is negative regulator of intestinal iron absorption
DMT1	Transports iron across the enterocyte apical plasma membrane
DCytB	Reduces Fe ³⁺ iron to Fe ²⁺ at enterocyte border
Ferroportin1	Transports iron across the basolateral membrane of enterocyte
Hephaestin	Facilitates cellular export of iron; oxidizes Fe ⁺⁺ iron to Fe ⁺⁺⁺ for binding to apotransferrin
Transferrin receptor (TfR)	Binds transferrin to cell for internalization of iron
HFE	Interacts with TfR to regulate the receptor's affinity for transferrin
Transferrin (Tf)	Transports iron found in blood
Hemojuvelin (HJV)	Regulates hepcidin expression

iron absorption when total body iron is low. Hepcidin synthesis is induced by an excess of iron and inhibited by lack of iron. Thus, it is a negative regulator of iron absorption and/or transfer. Hepcidin synthesis also is controlled by anemia and hypoxia.⁷ The body's response to insufficient oxygen delivery is an increase in erythropoiesis. An increase in erythropoietic activity results in a decrease in hepcidin secretion, which allows absorption of more iron in the intestine and increased availability of iron from iron stores. The specific mediator that conveys this signal from the bone marrow to the hepatic sites of hepcidin synthesis is not yet known.

Hepcidin synthesis is affected by not only iron status and erythropoietic activity but also infection and inflammation. Bacteria-activated macrophages and neutrophils synthesize hepcidin but at lower levels than the hepatocytes. In the presence of inflammation, the cytokine interleukin-6 (IL-6) induces synthesis of hepcidin resulting in hypoferrremia (decreased serum iron). Other cytokines can be involved in this process but have not been specifically identified. Because hepcidin induces iron retention in the macrophages (traps intracellular iron) and most iron used in erythropoiesis comes from recycled iron from the macrophage, hypoferrremia can develop rapidly in the presence of inflammation or infection even though total body iron can be normal or even increased. This appears to be the pathologic basis for the anemia of chronic disease (ACD, see below).

Hepcidin decreases iron absorption by inhibiting the expression of genes involved in the uptake or transfer of iron (e.g., DMT1, DcytB) and by binding to the iron exporter ferroportin. When there is dietary iron deficiency, hepcidin release is blocked, and DMT1, DcytB and ferroportin are upregulated.⁸ When hepcidin binds ferroportin, ferroportin is internalized within the cell and degraded. Since ferroportin determines if iron is delivered to the plasma or remains within the enterocyte and is shed, its presence or absence plays a vital role in iron homeostasis. Hepcidin's interaction with ferroportin is thought to be the major mechanism that controls systemic iron homeostasis while DMT1 and DcytB are strongly regulated by local iron concentration in the enterocytes.⁹

HFE **HFE** is a transmembrane protein that associates with beta2-microglobulin (Beta2M). HFE binds to the transferrin receptor (TfR) on cells and regulates the receptor's interaction with transferrin. When bound to TfR, HFE reduces the affinity of the receptor for iron-bound transferrin (Tf-Fe) by 5- to 10-fold. Thus, HFE is involved in regulating iron absorption and uptake. Mutations of HFE are associated with hereditary hemochromatosis (a condition of total body iron overload).

TfR2 can bind transferrin but less efficiently than TfR, and it does not complex with HFE. It appears that TfR2 influences the synthesis or release of hepcidin. In TfR2 knock-out mice (mice that do not express TfR2), hepcidin expression is decreased and hepatocytes are overloaded with iron,

resulting in hemochromatosis.¹⁰ On the other hand, the interaction of Tf-Fe with hepatocyte TfR2 results in an increase in hepcidin secretion into the circulation. Thus, it appears that TfR2 may be the iron sensor of hepatocytes. The expression of TfR2 is not controlled by the IRE/IRE-BP complex (discussed in the next section).

Hemojuvelin Hemojuvelin (HJV), a glycosylphosphatidylinositol-anchored protein, has been shown to regulate hepcidin expression in mice.¹¹ When the HJV gene is mutated, the mice fail to express hepcidin in response to dietary or injected iron, resulting in increased absorption of iron. In humans, HJV mutations are associated with severe iron overload.

Thus, it appears that although hepcidin is the major iron-regulating protein, additional proteins are involved in iron homeostasis by their influence on hepcidin synthesis or function.

Iron Balance at the Cellular Level

Control of iron balance at the cellular level occurs by regulation of transcription and translation of proteins involved in iron metabolism. Transcriptional control has not yet been explained, but regulation at the translational level has been described. Several proteins of iron metabolism have mRNA with similar RNA stem-loop-stem structures in either the 5' or 3' noncoding regions, referred to as the iron responsive element (IRE). These regions are recognized and bound by an iron-binding protein (IRE-BP; also known as *iron-regulatory protein/IRP*). The binding affinity of IRP for the IRE is determined by the amount of cellular iron. The IRP binds to the IRE region when iron is scarce and dissociates when iron is plentiful.

When bound to the IRE of mRNA, the IRP modulates the translation of the mRNA.¹² The IRP regulates translation in one of two ways, depending on the location of the IRE (stem-loop-stem structure) in the mRNA. If the IRE is in the 5' untranslated region (UTR) of the mRNA, binding of the IRP results in the disruption of translation by preventing the assembly of initiation factors at the initiator site (Figure 6■). Because binding occurs when iron is scarce, translation of these proteins is decreased in the absence of iron.¹³⁻¹⁶ The mRNAs of ferritin, ferroportin, and ALA synthase2 (ALAS2) fall into this group. If the IRE is in the 3' UTR of the mRNA, binding of the IRP stabilizes the mRNA that would otherwise be digested/degraded (Figure 7■). Thus, translation increases when iron is scarce. The mRNAs of TfR and DMT1 fall into this second group.

Thus, IRP regulates cellular iron by coordinating synthesis of ferritin and TfR in opposite directions. The level of TfR expression reflects the need of the cell for iron and is an important factor in hemoglobin synthesis. When the cell needs more iron, TfRs increase to maximize the amount of iron incorporated into the cell and formation of ferritin decreases. When cells have adequate or excess iron, the ferritin levels

■ **FIGURE 6** Regulation of iron at the cellular level. A stem-loop-stem structure in the 5' noncoding region, referred to as the *iron responsive element (IRE)*, is present in some mRNA. Binding of iron regulatory protein (IRP) to the IRE prevents initiation of translation. When the level of cellular iron is replete, the iron binds to IRP, preventing IRP binding to the IRE and allowing assembly of initiation factors at the initiation site which allows translation to take place. The translation of mRNAs of ferritin, ferroportin, and ALAS2 is regulated in this fashion.

rise and transferrin receptors decrease. Regulation of the ALAS2 gene serves to coordinate the synthesis of porphyrin (heme) with iron availability.

Iron Metabolism in the Mitochondria

Most iron entering the erythroid cells is routed to the mitochondria for hemoglobin synthesis and Fe-S cluster biogenesis. Key mitochondrial proteins thought to be involved in this iron metabolism include frataxin, ATP-binding cassette protein B7 (ABC7), and mitochondrial ferritin.

The mitochondria contain a variety of Fe-S cluster (iron-containing functional group) proteins including ferrochelatase and aconitase. The ABC7 protein is thought to function in the export of the Fe-S assembled clusters from the mitochondria to the cytosol. Mutations in this protein are characterized by anemia, neurological symptoms, and erythroid cells containing iron aggregates in the mitochondria. ABC7 also interacts with ferrochelatase in heme synthesis.⁶

Mitochondrial ferritin serves as an iron storage molecule and is highly expressed in tissue with numerous mitochondria. It is encoded by a gene on chromosome 5 (5q23). It is highly expressed also in the sideroblasts of patients with

■ **FIGURE 7** Regulation of iron at the cellular level. A stem-loop structure in the 3' noncoding region, referred to as the *iron-responsive element (IRE)*, is present in some mRNA. Binding of iron regulatory protein (IRP) to the IRE stabilizes the mRNA. When cellular iron is replete, the iron binds to the IRP and prevents its binding to the IRE. This results in degradation of the mRNA by endonuclease. The translation of the mRNAs of TfR and DMT1 is regulated in this fashion.

X-linked sideroblastic anemia, a disease in which iron accumulates in the mitochondria to form ringed sideroblasts. Frataxin is a protein in the mitochondrial matrix that is thought to play a role in mitochondrial iron export and storage.¹⁷

IRON REQUIREMENTS

Normally, humans maintain a relatively constant body concentration of iron throughout the life span. This is accomplished by maintaining a positive iron balance during growing years and establishing an equilibrium between loss and absorption in adult life. Humans are unable to excrete iron to achieve this balance. Therefore, the rate of absorption and loss of iron must be matched to avoid iron deficiency or excess.

Factors That Increase Fe Requirements

Normal physiologic factors that increase the daily requirement for iron include menstruation, pregnancy, and growth. Pathologic factors that increase the need for iron include blood loss, malabsorption, and human recombinant erythropoietin (rHuEPO) therapy in hemodialysis patients with ane-

mia. The pathologic factors are discussed in the next section on iron deficiency anemia.

Menstruation The average daily iron loss in menstruating females is twice that of their male counterparts. To maintain total body iron balance, menstruating females must absorb about 2 mg of iron daily. National statistics from the third National Health and Nutrition Examination Survey from 1988 to 1994 (NHANES III) reveal that 9–11% of adolescent and young adult females are in an iron deficient state and 2–5% have IDA.¹⁸ In women of childbearing age, ID is more prevalent in minority, low-income, and multiparous women.

Pregnancy The daily iron requirement during pregnancy is about 3.4 mg; if spread out as a daily average over the three trimesters, it would be about 1,000 mg per pregnancy. The fetus accumulates ~250 mg of iron from maternal stores via the placenta; added to this is the iron requirement for increased maternal blood volume and iron loss at delivery due to bleeding. Thus, a single pregnancy without supplemental iron could exhaust iron stores.

Infancy/Children In infancy, rapid growth of body size and hemoglobin mass requires more iron in proportion to food intake than at any other time of life. During the first six months of life, an infant synthesizes ~50 g of new hemoglobin. In addition, iron is needed for tissue growth. At birth, normal iron stores of 30 mg are adequate to see the infant through the first 4 to 5 months of life but can be depleted quickly in an infant on an iron-deficient, milk-only diet. Premature infants are at an even higher risk of rapid iron depletion because much of the placental transfer of iron occurs in the last trimester of pregnancy, and they have a faster rate of postnatal growth than full-term infants.¹⁷ It is recommended that full-term infants begin iron supplements no later than 4 months of age and that low-birth-weight infants begin no later than two months of age.¹⁹

Iron requirements are also high in childhood, especially in 1–3 year olds. Data from NHANES III revealed that in 1-year-olds, the prevalence of ID is 13%,¹⁸ yet 1–3 year olds, especially those from low income families, have the lowest daily iron intake of any age group.²⁰ A recent study of 1–3-year-old children from urban lower- and middle-class socioeconomic groups showed that 35% had evidence of iron insufficiency in various stages. Of these, 10% had overt IDA.²¹

▶ LABORATORY ASSESSMENT OF IRON

Laboratory testing to determine iron status includes measurement of serum iron, total iron-binding capacity (TIBC), calculation of percent saturation of transferrin, serum ferritin, and serum transferrin receptor (sTfR) (Table G, back cover). An indirect assessment of iron availability is provided by the zinc protoporphyrin (ZPP).

IRON STUDIES

Transferrin can be measured as a protein by immunochemical methods, but because the percent saturation (with iron) is helpful in the differential diagnosis of anemia, it is usually measured functionally as the maximum amount of iron able to be bound in the serum (TIBC). The measured serum iron and TIBC are used to calculate the percent saturation.

As a general rule, changes in the quantity of total body storage iron are accompanied by fluctuations in the serum iron and TIBC. As storage iron increases, serum iron increases and TIBC decreases; conversely, if storage iron decreases or is absent, serum iron decreases and TIBC increases. A transferrin saturation below 16% is an indicator of iron deficiency (ID) while a saturation above 55% is diagnostic for iron overload or hemochromatosis.

Ferritin can be measured in the serum where its concentration is directly proportional to the amount of storage iron in the body. Generally, serum ferritin levels less than 12 $\mu\text{g/L}$ indicate depletion of iron stores while levels $>1000 \mu\text{g/L}$ indicate iron overload. Decreased serum ferritin levels can be the first indication of developing IDA. Serum ferritin levels decrease before the exhaustion of mobilizable iron stores whereas abnormalities in the TIBC and serum iron may become detectable only when iron stores are depleted. Care should be used in interpreting serum ferritin levels, however, because ferritin is an acute phase reactant. Nonspecific increases can be seen in malignancy, infections, and liver disease as well as in inflammatory responses even though storage iron can be decreased. Thus, concomitant ID can be masked in these conditions if other tests of iron status are not considered. Table 8  shows the variations in tissue iron in various disease states.

Small concentrations of TfR can be identified in serum by sensitive immunoassay techniques. TfR in serum (sTfR) is a

truncated form of the intact protein found on the cell membrane and circulates bound to Tf. The level of circulating sTfR mirrors the amount of cellular receptor. The sTfR is thus inversely proportional to the amount of body iron because cellular receptor synthesis increases when cells lack iron. The level of sTfR is not affected by concurrent disease states (i.e., inflammation, infection) as is serum ferritin. Circulating sTfR increases in iron-deficiency anemia but not anemia of chronic disease.

When iron is not available for incorporation into the protoporphyrin ring to form heme or the heme synthesis is disturbed, zinc is an alternate protoporphyrin ligand and can be incorporated instead, forming zinc protoporphyrin (ZPP). As a result, excess protoporphyrin in the form of ZPP can accumulate in the cell. This can be detected by measuring fluorescence in the blood.

Checkpoint! 1

A patient's iron studies revealed serum iron $100 \mu\text{g/dL}$ and TIBC $360 \mu\text{g/dL}$. Calculate % saturation and UIBC. Are these values normal or abnormal?

FERROKINETICS

Quantitative measurement of internal iron exchange (ferrokinetics) is useful in understanding the pathophysiology of certain erythropoietic disorders. Ferrokinetic studies monitor the movement of radioactively labelled iron (^{59}Fe) from the plasma to the bone marrow and its subsequent uptake into circulating erythrocytes. Plasma iron is labeled by intravenous injection of a tracer amount of radioiron. The labeled iron binds to transferrin for transport. Its clearance from the plasma can be followed by counting the radioactiv-

 TABLE 8

Effects of Disease on Tissue Iron

Disease	Percent Transferrin Saturation	Ferritin	Bone Marrow Iron
Iron-deficiency anemia	Low	Low	Absent
Anemia of chronic disease	Normal/low	Normal/high	Abundant
Anemia of chronic renal disease	Normal/high	Normal/high	Abundant
Anemia of chronic liver disease	High	High	Abundant
Anemia of hypothyroidism	Normal	Normal	Normal
Sideroblastic anemias	High	High	Abundant with ringed sideroblasts
Hypoplastic/aplastic anemias	High	High	Abundant
Polycythemia vera	Low	Low	Low or absent

(Hospital Practice. 1986;21(3A):115. © 1986 The McGraw Hill Companies, Inc.)

ity that remains in the plasma at intervals up to 90 minutes. The rate at which iron leaves the plasma is called the *plasma iron turnover (PIT)* rate. Tissue need is the primary determinant of PIT. The PIT is a good indicator of total erythropoiesis and correlates well with the erythroid cellularity of bone marrow.

The amount of iron used for effective hemoglobin synthesis can also be measured by determining the amount of labeled iron incorporated into circulating erythrocytes over time. Normal erythrocyte utilization is 70–90% by day 10 to 14. This is termed the *erythrocyte iron turnover (EIT)* rate. The EIT is a good measure of effective erythropoiesis and correlates with the reticulocyte production index.

The normal discrepancy between the rate at which iron leaves the plasma (PIT = 0.7 mg/day/dL) and the rate at which it moves from marrow to circulating erythrocytes (EIT = 0.56 mg/day/dL) suggests that the red cell utilization (RCU) of iron is <100%. Some of the labeled iron can enter the liver or bone marrow macrophages. In addition, 5–10% of bone marrow iron is involved in ineffective erythropoiesis, causing a loss of the labeled iron by intramedullary destruction of abnormal erythrocytes.

A rapid or increased PIT coupled with a normal or increased RCU indicates increased erythropoiesis. A normal to increased PIT coupled with a decreased RCU indicates ineffective erythropoiesis, and a decreased PIT with corresponding decreased RCU indicates decreased erythropoiesis.

Ferrokinetic studies can be of value in locating sites of medullary and extramedullary erythropoiesis by counting surface radioactivity over the liver, spleen, and sacrum.

▶ IRON-DEFICIENCY ANEMIA

Iron deficiency (ID) is the most common nutritional deficiency in the world. It is prevalent in countries where grain is the mainstay of the diet or meat is scarce. Unfortunately, these are also countries where hookworm infestation is endemic. The combination of decreased availability of dietary iron and chronic blood loss from parasitic infection increases the risk of developing IDA. Malnutrition is associated not only with decreased iron intake but also with decreased intake of other essential nutrients including folate. Thus, causes of anemia associated with malnutrition may be multifactorial.

HISTORICAL ASPECTS

In America between 1870 and 1920, *chlorosis*, a word used to describe the condition of ID, was so common in young women it was believed that every female had some form of the disease during puberty.²² The word *chlorosis* was coined because of the greenish tinge of the skin in these patients; however, often the greenish hue was not apparent but pallor (paleness of the skin) was pronounced. Other classic clinical

signs and symptoms of anemia were present including shortness of breath on exertion, lethargy, and heart palpitations. These chlorotic girls were found to have decreased numbers of red cells and an increase in the proportion of serum to cells. Some of the chlorotic girls were also noted to have perverted appetites, craving substances such as chalk, cinders, charcoal, and bugs. As therapy for these patients, doctors prescribed iron salts even though the exact nature of the disease had not been identified. Some physicians linked chlorosis to dietary habits; others implicated menstruation as a possible cause of the disease because chlorosis affected girls in puberty but not boys.

ETIOLOGY

ID can occur due to normal or pathologic conditions that result in an increased demand for iron, malabsorption, or poor diet. In malabsorption or with an iron deficient diet, iron stores can become depleted over a period of years. With an increase in the demand for iron, iron depletion can occur more rapidly, sometimes over a period of months.

Dietary Deficiency

In most developed countries, inadequate dietary intake of iron is rarely the cause of anemia (except in infancy, pregnancy, and adolescence). Diet and socioeconomic status, however, are factors in the development of iron deficiency in children.

Blood Loss

The average adult male in the United States ingests many times more iron than is required. It would take an adult male about eight years to develop IDA if he absorbed no iron during those years. ID in adult males is almost always due to chronic blood loss from the gastrointestinal or genitourinary tracts. For each milliliter of blood lost, there is a loss of about 0.5 mg of iron. Gastrointestinal lesions leading to blood loss include peptic ulcers, hiatus hernia, malignancies, alcoholic gastritis, excessive salicylate ingestion, hookworm infestation, and hemorrhoids. The correlation of ID and GI lesions in elderly patients is high.²³ Genitourinary tract blood loss occurs less frequently; it can result from lesions within the genitourinary system.

Less often, blood loss is the result of intravascular hemolysis. If haptoglobin becomes depleted, the free circulating hemoglobin dissociates into dimers, is filtered by the kidneys, and appears in the urine (hemoglobinuria). This results in a loss of iron, the amount of which is proportional to the amount of hemoglobin in the urine. Some of the hemoglobin is reabsorbed by the renal tubules, resulting in the deposition of iron as hemosiderin in renal tubular cells and eventual sloughing of these cells into the urine (hemosiderinuria). Such is the case with paroxysmal nocturnal hemoglobinuria (PNH) or malfunctioning prosthetic heart valves.

Hemodialysis

Anemia is a common finding in patients with kidney disease. The causes are varied, but the most important factor is a loss or decrease in erythropoietin (EPO) production by the diseased kidneys. Thus, hemodialysis patients are often given recombinant human EPO (rHuEPO), also referred to as *epoetin alfa*, to increase erythropoiesis. However, sufficient iron cannot be mobilized from storage sites rapidly enough to meet the need for a 2- to 4-fold increase in the rate of erythropoiesis that can result from this therapy. The result can be a functional iron deficiency.²⁴ Lack of an adequate response to EPO therapy is primarily due to functional ID.²⁵ However, if the patient is given intravenous iron injections with rHuEPO, the hematopoietic response is enhanced.

Malabsorption

Malabsorption is an uncommon cause of ID except in malabsorption syndromes (such as sprue), after gastrectomy, in atrophic gastritis, and in achlorhydria. Gastrectomy results in impaired iron absorption due to the absence of gastric juice, which helps to solubilize and reduce dietary iron into the more easily absorbed ferrous form. In addition, with the loss of the reservoir function of the stomach, nutrients can transit rapidly through the duodenum, allowing insufficient time for iron absorption.

IDA is frequently accompanied by atrophic gastritis and achlorhydria, but it is unknown whether achlorhydria and gastritis are causes of iron malabsorption or the ID is a cause of atrophic gastritis and hence achlorhydria. In patients with gastritis and achlorhydria, therapy with oral iron can be ineffective due to poor iron absorption.

✓ Checkpoint! 2

A 30-year-old female and a 25-year-old male both had a bleeding ulcer. Assume that each acquired the ulcer at the same time, was losing about the same amount of blood, had equal amounts of storage iron to begin with, and was taking in about 15 mg of dietary iron each day. Would you expect that the woman and man would develop ID at the same time? Explain.

PATHOPHYSIOLOGY

Defined as a diminished total body iron content, ID develops in sequential stages over a period of negative iron balance (losing more iron than is absorbed in the gut). These stages are commonly referred to as:

- Iron depletion
- Iron deficient erythropoiesis
- Iron deficiency anemia (IDA)

Thus, ID can range in severity from reduced iron stores with no functional effect (Stages 1 and 2) to severe anemia with deficiencies of tissue iron-containing enzymes (Stage 3). Laboratory evaluation of iron status is helpful in defining these three stages (Table 9 🌟).

- **Stage 1** During the iron depletion stage, iron stores are exhausted as indicated by a decrease in serum ferritin. There is no anemia, and erythrocyte morphology is normal, but the red cell distribution width (RDW) is frequently elevated. The abnormal RDW can be the first hematologic indication of a developing ID in the nonanemic patient.

In hospitalized patients, the RDW is not as specific and the ferritin not as sensitive in detecting ID.²⁶ Hospitalized patients have a high incidence of other diseases that can affect these parameters.

- **Stage 2** The second stage of ID is characterized by iron-deficient erythropoiesis. There is insufficient iron to insert into the protoporphyrin ring to form heme. As a result, the protoporphyrin accumulates in the cell and complexes with zinc to form zinc protoporphyrin (ZPP). Bone marrow sideroblasts are absent.

Anemia and hypochromia are still not detectable, but the erythrocytes can become slightly microcytic. The reticulocyte index, reticulocyte hemoglobin content (CHr; Technicon H*3), however, can decrease even in the absence of anemia²⁷. The CHr measures the functional availability of iron during hemoglobin synthesis in the erythrocyte. This index is not available on all hematology analyzers.

- **Stage 3** A long-standing negative iron flow eventually leads to the last stage of iron deficiency: IDA. Blood loss can significantly shorten the time for this stage to develop. All laboratory tests for iron status become markedly abnormal. The most significant finding is the classic microcytic hypochromic anemia.

It is apparent then, that when microcytic hypochromic anemia is present, the situation represents the advanced stage of severely deficient total body iron.

CLINICAL FEATURES

The onset of IDA is insidious, usually occurring over a period of months to years. Early stages of ID usually show no clinical manifestations, but as anemia develops, clinical symptoms appear. In addition to symptoms of anemia, a variety of other abnormalities may occur due to a decrease or absence of iron-containing enzymes in various tissues. These include koilonychia (concavity of nails), glossitis, pharyngeal webs, muscle dysfunction, inability to regulate body temperature when cold or stressed, and gastritis.

A curious manifestation of ID is the *pica* syndrome. **Pica** is an unusual craving for ingesting unnatural items. The most common dysphagias described in patients with ID include ice-eating (phagophagia), dirt/clay-eating (geophagia), and starch-eating (amylophagia).^{28,29} In one study of 55 patients with IDA, 58% had pica, and of these, 88% had phagophagia.²⁸

Iron-deficient infants perform worse in tests of mental and motor development than do nonanemic infants.³⁰ There is speculation that untreated ID at this stage of human develop-

ment has long-lasting effects on the central nervous system.³¹ Symptoms reported to occur in iron deficient children include irritability, loss of memory, and difficulties in learning. Deficiencies of the immune system have been attributed to iron-related impairment of host defense mechanisms.

In the absence of iron in the gut, other metals are absorbed in increased amounts. This can be significant when an iron deficient person is exposed to toxic metals such as lead, cadmium, and plutonium.

LABORATORY FEATURES

Laboratory tests are essential for an accurate diagnosis of ID and in evaluation of therapy.

Peripheral Blood

The blood picture in well-developed ID is microcytic (MCV 55–74 fL) and hypochromic (MCHC 22–31 g/dL, MCH 14–26 pg) (Figure 8■). Because ID develops progressively,

FIGURE 8 Microcytic, hypochromic anemia of iron deficiency. Compare size of RBCs to nucleus of small lymphocyte in center. (Peripheral blood; Wright-Giemsa stain; 1000× magnification)

any gradation between the well-developed microcytic hypochromic iron-deficient blood picture and normal can occur. Microcytosis and anisocytosis, characterized by an increased RDW, are usually the first morphologic signs, developing even before anemia. The blood film demonstrates progressively abnormal poikilocytosis. The most frequent poikilocytes are target cells, elliptocytes, and dacryocytes (teardrop cells).

The typical blood picture can be masked if the iron-deficient patient has a concurrent vitamin B₁₂ or folate deficiency (causes of macrocytic anemia). In these cases, microcytosis can become apparent only after vitamin B₁₂/folic acid replacement therapy.

Both the relative and absolute number of reticulocytes can be normal or even slightly increased, but the reticulocyte count is decreased relative to the severity of the anemia with an RPI of less than 2. A decreased CHR is an early indicator of iron-restricted erythropoiesis in nonanemic individuals and can be a promising alternative or adjunct to iron studies.²⁷ In patients on chronic hemodialysis, the CHR has been shown to be superior to the presence of hypochromic red cells in detecting iron deficiency. Using a cutoff of CHR <26 pg, the CHR has a sensitivity of 100% and a specificity of 73%.³²

The leukocyte count is usually normal but can increase due to chronic marrow stimulation in long-standing cases or after hemorrhage. With concomitant hookworm infestation, eosinophilia can be present.

Platelets can be normal, increased, or decreased. Thrombocytosis frequently accompanies ID. It has been proposed that thrombocytosis is related to ID caused by chronic blood loss. Thrombocytopenia can occur in patients with severe or long-standing anemia, especially if accompanied by folate deficiency. Numeric changes seen in platelets are corrected with treatment that replenishes iron stores.

CASE STUDY (continued from earlier in this chapter)

Jose, the 83-year-old patient, had a CBC upon admission. The results were:

RBC	$4.15 \times 10^{12}/L$
Hb	81 g/L
Hct	0.26 L/L
Platelets	$174 \times 10^9/L$
WBC	$2.8 \times 10^9/L$

1. How would you describe his anemia morphologically?

Iron Studies

Iron studies on iron-deficient patients help establish the diagnosis. The serum iron is decreased, usually less than 30 µg/dL, the TIBC is increased, and transferrin saturation is decreased to less than 15%. Serum iron concentration has a diurnal variation with highest levels in the morning, so sampling time is an important consideration.

The serum ferritin level is decreased in all stages of ID and can be the first indication of a developing ID state. Serum ferritin is generally considered the single best test to detect iron deficiency. Once serum ferritin levels fall below 12 µg/L, the levels may no longer correlate with storage iron because stores are exhausted. Serum ferritin is an important test to differentiate IDA from other microcytic hypochromic anemias. Levels are normal to increased in the anemia of chronic disease unless complicated by ID and increased in sideroblastic anemia and thalassemia.

Because serum ferritin is an acute phase reactant, the lower limit of the reference interval for this parameter may need to be adjusted to detect ID in some patient populations (Table 10). It has been suggested that to detect ID in patients with concomitant anemia of chronic disease, inflammation, infection, pregnancy, and a wide range of concomitant medical problems, the lower limit of serum ferritin should be raised from 12 g/L.^{25,33–36} It has also been suggested that the threshold level of serum ferritin for a diagnosis of ID in the aged subject be raised because serum ferritin levels rise with age.³⁷

The sTfR assay has proved useful in detecting and differentiating IDA and anemia of chronic disease. Patients with ID have a mean sTfR level over twice ($13.91 + 4.63$ mg/L) that of mean sTfR levels in normal individuals ($5.36 + 0.82$ mg/L). Conversely, patients with chronic disease and acute infection (ACD) have mean levels almost identical to those of normal individuals (Table 11). Receptor levels also parallel the reticulocyte count, suggesting that the receptor level can reflect the turnover of transferrin receptors as cells mature. Thus, the sTfR level can provide an index of erythrocyte production in the marrow.

A combination of sTfR and serum ferritin can be used to calculate the TfR-F index:

$$\text{TfR-F Index} = \text{sTfR}/\log \text{ferritin}$$

TABLE 10

Serum Ferritin Cutoff Levels for Detecting Iron Deficiency in Patients with Other Diseases and Conditions

Disease	Upper Serum Ferritin Cutoff Levels for a Diagnosis of ID
Chronic renal disease (absolute ID)	100 µg/L
Chronic renal disease on EPO therapy* (functional ID)	100–800 µg/L
Anemia of chronic disease	50 µg/L
Rheumatoid arthritis	70 µg/L
Other medical problems	100 µg/L
Pregnancy	30 µg/L
Reference interval:	
Males	20–300 µg/L
Females	12–200 µg/L

*Functional iron deficiency is present when iron saturation is 20–50%, serum ferritin 100–800 µg/L, and the patient responds to intravenous iron therapy with an increase in hemoglobin and/or a decrease in requirement for EPO.

This index can improve detection of subclinical iron-deficient states in healthy individuals.^{38,39} An index of >1.8 indicates depletion of iron stores.

Combinations of serum ferritin, MCV, TIBC, percent saturation, and sTfR can eliminate the need for costly, inconvenient, and painful bone marrow examination to assess iron stores in patients with inflammation or chronic disease and in early stages of ID.^{33,40,41}

CASE STUDY (continued from the previous page)

Reflex testing for anemia on Jose followed based on the CBC results. The following test results were obtained:

Reticulocyte count	2.6%
Serum iron	18 µg/dL
TIBC	425 µg/dL

- Calculate % saturation.
- Is this value normal, decreased, or increased?
- What disease, if any, is suggested by this value?

Erythrocyte Protoporphyrin (EP) Studies

Using ZPP measurement, the evaluation of EP is useful when attempting to identify the etiology of microcytic hypochromic anemia. The concentration of ZPP increases in iron-deficient erythropoiesis and in anemias in which heme synthesis is disturbed. Because ZPP persists throughout the cell's life span, a measure of ZPP utilizing a hematofluorimeter provides a retrospective indicator of iron availability at the time of cell maturation. The ZPP measurement correlates inversely with serum ferritin concentration but is more cost effective.⁴² It can detect iron depletion even before anemia develops and thus is a good screening tool for the early stages of ID. Because there is a significant number of nonanemic toddlers with iron depletion and ID has a detrimental effect on development in children, ZPP should be considered as a more sensitive test of ID than the hematocrit.⁴³ ZPP is also more diagnostically efficient than serum iron or serum

ferritin in screening for ID in the presence of infection or inflammation and in hospitalized patients with microcytic anemia.^{42,44} Thus, ZPP can be a valuable screening assay for these populations.

The level of ZPP is useful also as a screening test to differentiate ID and thalassemia, the two most common causes of microcytic hypochromic anemia. ZPP can be elevated in thalassemia, but the increase in ID is 3 to 4 times higher than in thalassemia.⁴⁵ When laboratory analysis reveals a high ZPP combined with a high RDW, ID is strongly suggested.⁴⁶ The RDW is typically normal or only slightly elevated in thalassemia trait. Table 12  lists other conditions associated with increased EP levels.

In patients with concurrent lead poisoning, the ZPP cannot be used to distinguish ID and thalassemia because lead inhibits ferrochelatase, the enzyme needed to incorporate iron into the protoporphyrin ring. Consequently, the free erythrocyte porphyrin complexes with zinc, and ZPP is increased in lead poisoning whether or not iron is available.

Bone Marrow

The bone marrow shows mild to moderate erythroid hyperplasia with a decreased M:E ratio. Total cellularity is often moderately increased. This increase in marrow erythropoietic activity without a corresponding increase in peripheral blood reticulocytes suggests an ineffective erythropoietic component. With appropriate iron therapy, the erythroid hyperplasia initially increases and then returns to normal. A common finding (not exclusive to IDA) is the presence of poorly hemoglobinized erythroblasts with scanty irregular (ragged) cytoplasm. This change is most evident at the polychromatophilic stage. Erythroid nuclear abnormalities are sometimes present and can resemble the changes found in dyserythropoietic anemia. These changes include budding, karyorrhexis, nuclear fragmentation, and multinuclearity. Stains for iron reveal an absence of hemosiderin in the macrophages, an invariable characteristic of ID. Sideroblasts are markedly reduced or absent.

Evaluation of iron stores using serum iron studies eliminates the need for bone marrow examination in almost all cases.

- Thalassemia

THERAPY

Once the cause of the anemia has been established, the principles of treatment are to treat the underlying disorder (e.g., bleeding ulcer), administer iron, and observe the response. The anemia is usually corrected by the oral administration of ferrous sulfate. Parenteral iron therapy, which is more dangerous and expensive than oral iron therapy, is indicated only rarely for unusual circumstances. Intravenous iron dextran is often required in patients with chronic renal disease who are receiving therapy with recombinant human EPO (rHuEPO).⁴⁷ To maintain a twofold to threefold increase in the rate of erythrocyte production in patients treated with epoetin alfa, enough iron should be given to maintain serum iron concentrations at 80–100 µg/dL.⁴⁸

Iron-deficient patients treated with iron experience a return of strength, appetite, and a feeling of well-being within 3–5 days whereas the anemia is not alleviated for weeks. The dysphagias also are corrected before the anemia is relieved.

A response to iron therapy is defined as an increase of 1 gm/hemoglobin in one month. Because reticulocytes are new red cells just released from the bone marrow, reticulocyte counts and the CHr or IRF give a snapshot of recent red cell production. Reticulocyte response to iron therapy begins at about the 3rd day after the start of therapy, peaks at about the 9th to 10th day (4–10% reticulocytes), and declines thereafter. Increases in reticulocyte hemoglobin content (CHr) or the immature reticulocyte fraction (IRF) are early indicators of a response to iron therapy and begin to increase well in advance of an increase in reticulocytes and hemoglobin.^{32,49} If therapy is successful, the hemoglobin should rise until levels within normal limits are established, usually within 6–10 weeks. To restore iron stores, extended therapy with small amounts of iron salts could be required (usually for 6 months) after the hemoglobin has returned to normal.

Due to the high prevalence of ID in toddlers, screening all 1-year-olds for iron deficiency and/or anemia is a well-accepted practice. It has been suggested that if the hemoglobin concentration is decreased, a therapeutic trial of iron be initiated in this population. If anemia persists after one month of therapy, further evaluation is necessary⁵⁰ (Web Figure 1 .

▶ ANEMIA OF CHRONIC DISEASE

The anemia of chronic disease (ACD), also called anemia of inflammation or infection (AI) is usually defined as the anemia that occurs in patients with chronic infections, chronic inflammatory disorders, trauma, organ failure, or neoplastic disorders not due to bleeding, hemolysis, or marrow involvement. ACD is characterized by low serum iron but normal iron stores (Table 13 ). The anemia appears to be a specific entity and does not relate to any nutritional deficiency. Anemias associated with renal, endocrine, or hepatic insufficiency are usually excluded from ACD.

★ TABLE 13

Conditions Associated with Anemia of Chronic Disorders

Category	Conditions
Chronic infections (after 1–2 months of sustained infection)	Pulmonary infections Subacute bacterial endocarditis Pelvic inflammatory disease Osteomyelitis Chronic urinary tract infection Chronic fungal disease Tuberculosis
Chronic, noninfectious inflammation	Rheumatoid arthritis Rheumatic fever Systemic lupus erythematosus Sterile abscess Regional enteritis Ulcerative colitis
Other	Malignant diseases Alcoholic liver disease Congestive heart failure Thrombophlebitis Ischemic heart disease Severe tissue trauma Thermal injury Fractures

Anemia of chronic disease is the most common anemia other than IDA due to blood loss. It accounts for the anemia in more than one-third of anemic hospitalized patients without blood loss. Anemia is present in up to 50% of patients with malignant solid tumors and is often the clue that leads to a diagnosis of cancer. The most common anemia in these patients is ACD.

PATHOPHYSIOLOGY

ACD is characterized by hypoferremia, decreased transferrin (decreased TIBC), increased serum ferritin, and increased iron in bone marrow macrophages. This suggests a block in the mobilization of iron from macrophages for recycling to the bone marrow normoblasts. Because macrophages recycle 10–20 times more iron than is absorbed by enterocytes, any changes in iron flux through the macrophages affect iron balance more rapidly than changes in iron absorption and transport by enterocytes. Studies reveal that this block in iron release from macrophages is mediated by hepcidin, which is produced in response to interleukin 6 (IL-6) and other inflammatory cytokines (Web Figure 2 ■). These cytokines are produced as a result of the immune response and/or inflammatory response and are increased in patients with ACD. Hepcidin plays a role in the body's innate immune system, which is designed to sequester iron from pathogens and thus restrict their growth. The severity of ACD is roughly correlated to the activity of the associated

disease. Absorption of iron in the intestine also is decreased leading to iron deficiency over time.

Other contributing factors to this anemia are decreased erythropoietin (EPO) production and direct suppression of erythropoiesis by cytokines^{51,52} (Table 14 ★). In general, the EPO levels in patients with anemia of chronic disease are lower than in anemic patients with similar hemoglobin levels but without chronic disease.^{53,54} This finding suggests a blunted EPO response to anemia in ACD. Pharmacologic doses of EPO overcome this inhibitory effect and correct the anemia in some patients.⁵⁵

ACD is also associated with shortened erythrocyte survival as a result of extracorporeal factors. The reason for the decreased erythrocyte life span is unknown, but several mechanisms have been suggested including nonspecific macrophage activation, hemolytic factors elaborated by tumors, vascular factors, and the presence of bacterial toxins capable of hemolyzing erythrocytes.

Of all mechanisms described, the block in release of iron from macrophages is the most significant.

CLINICAL FEATURES

The signs and symptoms of ACD are usually those associated with the underlying disorder. Rarely severe, the degree of the anemia roughly correlates with the activity of the underlying disease.

LABORATORY FEATURES

Many of the laboratory test results are nonspecific in ACD, but with clinical signs and primary diagnosis, they help to establish that the anemia is ACD. This is important because ACD does not usually require therapy for the anemia.

Peripheral Blood

A mild anemia with a hemoglobin of not less than 90 g/L and hematocrit of not less than 0.27 L/L is characteristic. Erythrocytes are usually normocytic (MCV > 85 fL) and normochromic but can present as normocytic, hypochromic, or, in long-standing cases, microcytic and hypochromic (Figure 9 ■). The reticulocyte production index is < 2. The white blood cell count and platelet count are normal unless they are changed due to the primary disease state.

★ TABLE 14

Mechanisms of Anemia in ACD

✓ Checkpoint! 3

How does the peripheral blood picture in ACD differ from that seen in IDA?

Iron studies show decreased serum iron (10–70 $\mu\text{g/dL}$), decreased or normal TIBC (100–300 $\mu\text{g/dL}$), normal to low transferrin saturation (10–25%), and normal or increased serum ferritin. Serum ferritin can be helpful in distinguishing this anemia from IDA. Although serum iron is low in both anemias, serum ferritin, which reflects body iron stores, is normal or increased in ACD and low in IDA. Because ACD is partially due to iron-deficient erythropoiesis, the ZPP levels are increased.

It is important to keep in mind that ferritin is an acute phase reactant and is very often increased in inflammatory conditions. Therefore, in ACD, serum ferritin can be normal even if concurrent ID exists. If serum ferritin falls in the interval of 20–100 $\mu\text{g/L}$ in ACD, another means of assessing iron should be considered, such as sTfR assay or bone marrow examination.⁵⁶ Serum TfR is high in IDA but normal in uncomplicated ACD.

CASE STUDY (continued from earlier in this chapter)

- How do the patient's iron study results help in differentiating the diagnosis of iron deficiency from ACD?
- What additional iron test that was not done would be most helpful in this case?

Bone Marrow The bone marrow usually shows an increased M:E ratio because of a decrease in erythrocyte precursors. The proportion of younger erythroblasts is increased. Poor hemoglobin production is apparent, especially in the polychromatophilic erythroblasts. The proportion of sideroblasts decreases to less than 30%; however, the macrophages appear to have increased amounts of hemosiderin in the form of coarse iron aggregates (Figure 9b). This finding helps to distinguish the anemia of chronic disease from IDA. In IDA, macrophage iron and sideroblasts are absent.

Bone marrow examination is usually not necessary for distinguishing ACD from IDA. An algorithm using the MCV, serum ferritin, and iron saturation can correctly differentiate and classify most cases of ACD and IDA⁴⁵ (Web Figure 3 ■). Additional tests, such as sTfR and calculation of the sTfR-F index, can provide additional diagnostic information in some cases.

THERAPY

Anemia can be alleviated by successful treatment of the underlying disease. Anemia is usually mild and nonprogressive; thus, transfusion is rarely warranted except in older patients with vascular disease and circulatory insufficiency.

▶ ANEMIAS ASSOCIATED WITH ABNORMAL HEME SYNTHESIS

These anemias are associated with defects in enzymes of the heme biosynthetic pathway leading to abnormal heme synthesis. Iron incorporation into the protoporphyrin ring to form heme can be blocked. In contrast to IDA, the positive

iron balance in these anemias can lead to an increase in iron stores predominantly in the spleen, liver, and bone marrow. Serum ferritin levels above 250 µg/L in the male and above 200 µg/L in the female indicate increased iron stores.

The conditions discussed in this section include sideroblastic anemia and the porphyrias. Lead poisoning also is included because of its pathophysiologic relationship to these anemias through a block in heme synthesis.

SIDEROBLASTIC ANEMIAS

Mutations that affect the first enzymatic step in heme synthesis, the formation of ALA, result in sideroblastic anemia. Mutations in the subsequent steps of heme synthesis result in metabolic disorders called *porphyrias*. Sideroblastic anemia (SA) is the result of diverse clinical and biochemical manifestations that reflect multiple underlying hereditary, congenital, or acquired pathogenic mechanisms. However, all types are characterized by (1) an increase in total body iron, (2) the presence of ringed sideroblasts in the bone marrow, and (3) hypochromic anemia.

Classification

The classification of sideroblastic anemia is arbitrary at best, and many different schemes of classification exist. The classification in Table 15 is one of the most descriptive. The two major groups are those that are inherited and those that are acquired.

Hereditary Form The most common form of hereditary sideroblastic anemia is due to a defective sex-linked recessive gene. Although carrier females often show a dimorphic population of morphologically abnormal and normal erythrocytes, they rarely have anemia. Affected males demonstrate the typical findings of sideroblastic anemia. In rare instances, both sexes are equally affected implying the presence of another hereditary form that is transmitted in an autosomal recessive manner. In the hereditary forms, anemia can become apparent in infancy but most commonly appears in young adulthood. Symptoms rarely do not occur until age 60.

Acquired Form The acquired forms of sideroblastic anemia are more common than the hereditary forms. The acquired forms are classified according to whether the basis of

the anemia is unknown (idiopathic) or is secondary to an underlying disease or toxin (secondary type). The idiopathic form, *refractory anemia with ringed sideroblasts (RARS)*, can affect either sex in adult life. It is included in a group of acquired stem cell disorders called *myelodysplastic syndromes* that have a tendency to terminate in acute leukemia.

The acquired secondary type sideroblastic anemias are associated with malignancy, drugs, or other toxic substances. In this type, once the underlying disorder is effectively treated or the toxin removed, the anemia abates.

Pathophysiology

Studies of patients with sideroblastic anemia have shown disturbances of the enzymes regulating heme synthesis. Ringed sideroblasts are specific findings for these heme enzyme abnormalities. Ringed sideroblasts are formed from an accumulation of nonferritin iron in the mitochondria that encircle the erythroblast nucleus. The mitochondria eventually rupture as they become iron laden. When stained with Prussian blue, the iron appears as blue punctate deposits circling the nucleus (ringed sideroblasts). Iron within the erythroblasts is normally deposited diffusely throughout the cytoplasm.

Hereditary Sideroblastic Anemia Defective heme synthesis appears to be involved in the pathogenesis of the hereditary form of sideroblastic anemia. The most common form of SA in this group is sex linked and due to an abnormal δ-aminolevulinate synthase enzyme (ALAS).

Two different forms of ALAS are the nonerythroid or hepatic form (ALAS1) and the erythroid form (ALAS2). The nonerythroid form, also known as the *housekeeping form*, is coded for by a gene expressed in all tissues and has been assigned to the chromosomal region 3p21. The erythroid form is coded for by a gene that has been assigned to the Xp21-q21 chromosomal region. ALAS2 is the first and rate-limiting enzyme in heme synthesis.

Sex-linked SA (XLSA) is due to an abnormal ALAS2 enzyme that is the result of heterogeneous point mutations in the catalytic domain of the ALAS2 gene.⁵⁷ More than 22 different mutations have been described in this gene.⁵⁸ The mutations are located in exons 5–11 and all but one are missense (single-base change) leading to substitution of a single amino acid in the protein.

Evidence indicates that the activity of ALAS2 depends totally on the presence of the cofactor, pyridoxal phosphate. This cofactor binds to the enzyme and is crucial for its stability, for the maintenance of a conformation optimal for substrate binding and product release, and for its catalytic activity. In 17 of the 22 ALAS2 mutations, there is a partial to complete clinical response to pharmacologic doses of pyridoxine. Excess pyridoxine possibly enhances the abnormal ALAS enzyme activity by stabilizing it after synthesis.⁵⁸ In the pyridoxine-refractory sex-linked SA, it appears that the gene mutation affects the processing of ALAS2 precursor, which terminates ALAS2 translation prematurely or abolishes its function.^{58,59}

TABLE 15

Classification of Sideroblastic Anemia

Hereditary	Acquired
Sex linked	Idiopathic refractory sideroblastic anemia (IRSA) or refractory anemia with ringed sideroblasts (RARS)
Autosomal recessive	Secondary to drugs, toxins, lead Associated with malignancy

Significant ineffective erythropoiesis is characterized by bone marrow erythroid hyperplasia. This increased erythropoietic activity results in increased iron absorption in the gut. Iron overload can be significant and can lead to complications such as cardiac failure and diabetes.

Other hereditary forms of sideroblastic anemia have been described but are less common than the sex-linked type.⁶⁰

Acquired Sideroblastic Anemia The acquired SA can be categorized as refractory anemia with ringed sideroblasts (RARS) and those secondary to drugs or toxins.

RARS. This form of SA is considered to be the result of an acquired stem cell disorder. It is discussed in the chapter on myelodysplastic syndromes.

Secondary to Drugs or Toxins. Acquired sideroblastic anemia secondary to drugs or toxins is the result of the interference of the drugs or toxins with the activity of heme enzymes. Lead and alcohol are the most common causes of this form of SA.

Lead Poisoning. Lead poisoning (**plumbism**) has been recognized for centuries. In children, it generally results from ingestion of flaked lead-based paint from painted items. Lead was removed from paint after 1978. Children from lower socioeconomic backgrounds are at increased risk; those between 1 and 3 years of age are at greatest risk. Clinically, lead toxicity in children is associated with hyperactivity, low IQ, concentration disorders, hearing loss, and impaired growth and development. In adults, lead poisoning is primarily the result of inhalation of lead or lead compounds from industrial processes. It is the most common disease of toxic environmental origin in the United States.⁶¹

Many states require laboratories and physicians to report elevated blood lead levels to the state health department, which can report to the Centers for Disease Control (CDC). Thirty-seven states reported elevated blood levels to the CDC in 2004. Although average blood lead levels have dropped by 80% since the late 1970s, about 10,000 adults had blood lead levels >25 µg/dL in 2004.⁶² Hundreds of thousands of children under age six still have increased blood lead levels.

Lead serves no physiological purpose. Although lead poisoning consistently shortens the erythrocyte life span, the anemia accompanying plumbism is not primarily the result of hemolysis but of a marked abnormality in heme synthesis. Once ingested, lead passes through the blood to the bone marrow, where it accumulates in the mitochondria of erythroblasts and inhibits cellular enzymes involved in heme synthesis. The heme enzymes most sensitive to lead inhibition are δ -aminolevulinic acid dehydrase (δ -ALA-D) and ferrochelatase (heme synthase). The effect of lead on ferrochelatase is competitive inhibition with iron. Other enzymes can be affected at higher lead concentrations. Thus, the synthesis of heme is primarily disturbed at the conversion of δ -ALA to porphobilinogen (which uses the enzyme δ -ALA-D), and at the incorporation of iron into protoporphyrin to form heme (which uses the enzyme fer-

rochelatase). As a result, urine excretion of δ -ALA increases. The erythrocyte protoporphyrin (in the form of ZPP) is also strikingly increased. Iron accumulates in the cell.

Studies have revealed that microcytic, hypochromic anemia is not characteristic of elevated lead levels in children. Evidence suggests that the presence of a microcytic anemia in plumbism is most likely due to complications of ID or to the coexistence of alpha-thalassemia trait.^{63–65} One study found that 33% of African American children with lead poisoning and microcytosis had alpha-thalassemia trait.⁶³

Coexistent ID and lead poisoning put children at a higher risk for developing even more serious lead poisoning because children absorb larger portions of lead in iron-deficient states and the competitive inhibition of ferrochelatase by lead is even greater in the absence of iron. Thus, it is critical to make a diagnosis of ID when it coexists with lead poisoning.

In 1991, the Centers for Disease Control and Prevention (CDC) set a new acceptable blood lead level at 10 µg/dL or less, down from the 30 µg/dL level set in the mid-1970s. The CDC also recommended five decision levels for evaluation and treatment depending on the lead level (Web Table 1 .

Although the zinc protoporphyrin (ZPP) measurement has been utilized to screen for lead in the past, it is no longer recommended as an appropriate screening tool because ZPP is unaffected until lead levels reach approximately 20 µg/dL.⁶⁶ It is now apparent that lead levels <20 µg/dL can impair neuropsychologic development. Thus, ZPP can be useful as a screening tool in children with very high lead levels, but screening generally should be done by direct lead measurements. ZPP cannot be used to differentiate IDA and thalassemia in the presence of lead poisoning because of the increase in erythrocyte protoporphyrin caused by lead.

Alcoholism. Anemia is a common finding (up to 62%) in hospitalized chronic alcoholics.²⁶ Megaloblastic and sideroblastic anemia occur in the majority, but anemia in this population has many other causes including ACD, IDA, acute blood loss and chronic hemolysis⁶⁷ (Table 16 ). Less than one-half have an isolated cause for the anemia (Table 17 ). Studies show that sideroblastic anemia is particularly common among alcoholics with a poor diet and can be asso-

 TABLE 16

Mechanisms of Anemia in Chronic Alcoholism

- Megaloblastosis associated with folate deficiency
- Iron-deficiency anemia from chronic or acute blood loss
- Sideroblastic anemia from toxic effects of alcohol on enzymes needed for heme synthesis
- Hemolytic anemia
 - Chronic hemolysis due to splenic sequestration
 - Spur cell anemia occurring in the setting of severe liver disease, splenomegaly, and jaundice
 - Transient hemolytic anemia associated with portal hypertension and acute congestive splenomegaly

★ TABLE 17

Incidence and Causes of Anemia in Study of 121 Hospitalized Alcoholics⁶⁷

		Percentage	
One	45%	ACD	81%
Two	37%	Megaloblastic changes in BM	34
Three	18%	Ringed sideroblasts	23
		Iron deficiency	13

ACD = Anemia of Chronic Disease

ciated with a concomitant decrease in folic acid and megaloblastosis. The presence of a dimorphic erythrocyte population and siderocytes in the peripheral blood is a clue to a diagnosis of SA. Alcohol is believed to interfere with some enzymes of hemoglobin synthesis including inhibition of the synthesis of pyridoxal phosphate and of activity of uroporphyrinogen decarboxylase and ferrochelatase but enhancement of activity of δ -aminolevulinic acid synthase. Alcoholics with a poor diet can also have an inadequate intake of pyridoxine. Alcohol is directly toxic to hematologic cells as evidenced by the frequent presence of vacuoles in bone marrow precursor cells, thrombocytopenia, and granulocytopenia.

Interpreting laboratory tests in alcoholism is difficult because the alcohol has effects on multiple parameters. Even in the absence of megaloblastosis and anemia, the cells are frequently macrocytic (MCV 100–110 fL). Alcohol has a direct effect on folate metabolism, interfering with absorption, storage, and release. Serum iron levels are increased during drinking episodes but return to normal after cessation.

Secondary to Malignancy Ringed sideroblasts can be found in diseases other than sideroblastic anemia (Table 18★). For example, ringed sideroblasts are often associated with hematologic malignancies (e.g., leukemia, malignant histiocytosis, multiple myeloma, lymphoma). Some investigators believe that the presence of ringed sideroblasts in these disorders suggests that the malignancy can result from

★ TABLE 18

Diseases Associated with the Presence of Ringed Sideroblasts

- Megaloblastic anemia
- Primary bone marrow disorders
- Chemotherapy

an abnormal clone of pluripotential stem cells that affects the erythrocyte as well as other cell lineages. Occasionally, ringed sideroblasts appear in the bone marrow following treatment of malignant disease (e.g., multiple myeloma, Hodgkin’s disease). The appearance of ringed sideroblasts after treatment is a very poor prognostic sign, as these cases almost always terminate in acute leukemia.

Clinical Features

In patients with acquired sideroblastic anemias secondary to drugs or malignancy, the manifestations of the underlying disorder dominate. Patients with hereditary sideroblastic anemia or RARS, however, generally show primary signs and symptoms of anemia. In hereditary sideroblastic anemias, most patients also exhibit signs associated with iron overload including hepatomegaly, splenomegaly, and diabetes. In the latter stages of the disease, cardiac function may be affected.

Laboratory Features

See Table 19★ for laboratory findings in sideroblastic anemia.

Peripheral Blood The anemia is usually moderate to severe. A dimorphic picture of normochromic and hypochromic cells is characteristically seen in inherited and acquired secondary forms of sideroblastic anemia (Figure 10■). Dual

★ TABLE 19

Laboratory Findings in Sideroblastic Anemia

- Dual population of hypochromic and normochromic erythrocytes
- Pappenheimer bodies in erythrocytes
- Normal or increased platelets
- Increased serum iron, serum ferritin, and percent saturation
- Ringed sideroblasts in the bone marrow

■ **FIGURE 10** Blood film from a patient with sideroblastic anemia. Two populations of erythrocytes are present: hypochromic and normochromic. This is the dimorphic blood picture typical of sideroblastic anemia. Note also the numerous inclusions (Pappenheimer bodies). (Peripheral blood; Wright-Giemsa stain; 1000× magnification)

populations of macrocytes and microcytes or normocytes can also be found. Hypochromic macrocytes are especially prevalent in RARS whereas hypochromic microcytes are common in the hereditary form of SA. Macrocytes are common in SA associated with alcoholism.

If a dimorphic erythrocyte population is present, the MCV, MCH, and MCHC can be normal because these parameters represent an average of all erythrocytes, thus emphasizing the need for careful examination of CBC parameters and the blood smear. The RDW and erythrocyte histogram/cytogram are useful in detecting these dual populations. The RDW is increased, and the RBC histogram/cytogram shows two peaks representing the dual population.

Other abnormalities of erythrocytes are often seen. Poikilocytosis and target cells can be present. Erythrocytes can contain **Pappenheimer bodies** (iron deposits). When Pappenheimer bodies are present, reticulocyte counts must be performed carefully because both RNA and Pappenheimer bodies take up supravital stains. On the other hand, Pappenheimer bodies stain with both Romanowsky stains and Prussian blue stain, whereas reticulated RNA does not stain with either. (Polychromatophilic erythrocytes, which are young red cells with RNA, do stain with Romanowsky stain. These cells stain as reticulocytes with supravital stains.) Nucleated erythrocytes are rarely present.

Basophilic stippling can be seen in any of the sideroblastic anemias. However, coarse, punctate, basophilic stippling resulting from aggregated ribosomes and degenerating mitochondria is a particularly characteristic feature of lead poisoning (Figure 11 ■). The punctate stippling occurs in the reticulocyte and is found in developing erythroblasts. It has been shown that the granules in these stippled erythroblasts contain free ionized iron and that the hemoglobin produc-

■ **FIGURE 11** Peripheral blood smear from a patient with lead poisoning. Note the heavy basophilic stippling in erythrocyte. (Peripheral blood; Wright-Giemsa stain; 1000× magnification)

tion in the cells is grossly deficient. Many stippled cells in peripheral blood in lead poisoning are actually siderocytes.

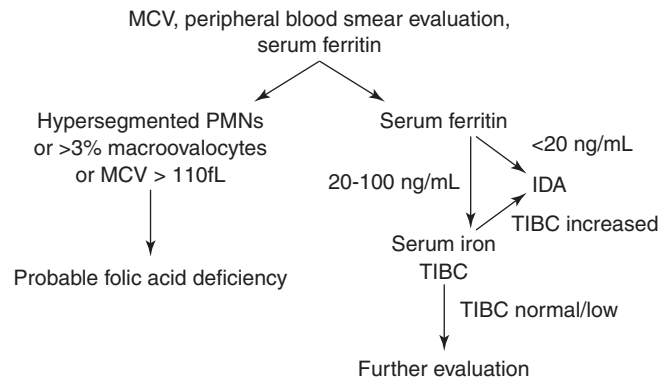

Other laboratory test results can be abnormal. Even though the bone marrow is usually hyperplastic, the reticulocyte production index is <2, indicating that the anemia has an ineffective erythropoietic component. Other indications of ineffective erythropoiesis including a slightly increased serum bilirubin (usually <2.0 mg/dL), decreased haptoglobin, and increased lactate dehydrogenase (LD) are usually present. Iron studies show increased serum iron, normal or decreased TIBC with increased saturation levels (sometimes reaching 100%), and increased serum ferritin. Leukocyte and platelet counts are usually normal but can be decreased. Thrombocytosis is found in about a one-third of patients.

In alcoholics, the direct and indirect effects of alcohol complicate the interpretation of laboratory tests used to diagnose anemia including MCV, serum iron, TIBC, serum ferritin, and red cell and serum folate (Figure 12 ■).

CASE STUDY (continued from earlier in this chapter)

7. Do the iron studies in Jose (serum iron 18 μg/dL, TIBC 425 μg/dL) suggest sideroblastic anemia?

Bone Marrow Bone marrow changes include erythroid hyperplasia often accompanied by various degrees of megaloblastosis. The megaloblastosis is sometimes responsive to folate, which indicates the presence of a complicating folate deficiency. Erythroblasts appear poorly hemoglobinized with scanty, irregular cytoplasm. Macrophages contain increased amounts of storage iron. Ringed sideroblasts constitute more than 40% of the erythroblasts (Figure 13 ■). Ringed sideroblasts are erythroblasts with iron granules that encircle one-third or more of the nucleus. The siderotic granules are

■ **FIGURE 12** An algorithm for diagnosis of anemia in alcoholics

■ **FIGURE 13** Ringed sideroblasts. (Bone marrow; Prussian blue stain; 1000× magnification)

larger than those found in normal sideroblasts. In the hereditary forms of sideroblastic anemia, the abnormal granules occur primarily in the later stages of erythroblast development and the polychromatophilic and orthochromatic erythroblast stages. In the idiopathic and secondary forms, the abnormal granules occur beginning at the earlier erythroblast stages.

The ringed sideroblasts must be present for the diagnosis of sideroblastic anemia; however, it is important to recognize that other disease entities may have ringed sideroblasts present without involving a diagnosis of sideroblastic anemia.

Molecular Studies If hereditary sex-linked sideroblastic anemia is suspected based on erythrocyte morphology and iron studies, the patient should be tested for the presence of ALAS2 gene mutations. This can be done by studying genomic DNA or cDNA (from RNA) of reticulocytes⁵⁸. If a mutation is found, other family members should be tested. Even if anemia is not present in family members, there is a risk of iron overload. Molecular studies also allow a distinction to be made between hereditary sideroblastic anemia and RARS.

CASE STUDY (continued from the previous page)

8. Do Jose's laboratory test results and clinical history indicate that a bone marrow examination is necessary?

Therapy

Pyridoxine therapy is generally tried on patients with the hereditary form of sideroblastic anemia; less than one-half experience a return to normal hemoglobin levels with this

form of therapy, although some have a partial response. In some patients, iron overload decreases responsiveness to pyridoxine, but when the iron load is reduced by phlebotomy, hemoglobin concentration increases.⁶⁸ Folic acid is administered to those with megaloblastic features. Although the anemia can be treated, iron overload is the primary complication of this anemia. Sometimes the risk of hemochromatosis is lessened by removal of excess body iron through phlebotomy or chelation therapy. Iron overload is monitored by iron studies (percent saturation of transferrin). Female carriers should also be monitored. Some patients live for many years tolerating their anemia well; others die because of complications of iron overload, infections, or bone marrow failure.

Secondary sideroblastic anemia resulting from a disease, toxin, or drug may be corrected by successful treatment of the disease or by elimination of the toxin/drug.

▶ HEMOCHROMATOSIS

Hemochromatosis is a term used to describe the clinical disorder that results in parenchymal tissue damage from progressive iron overload. Hemochromatosis typically is not associated with anemia but is included in this chapter because iron studies are markedly abnormal in patients with the disorder. Due to its prevalence, hemochromatosis should be considered when symptoms are present, when there is a family history of the disorder, or when iron studies suggest iron overload. Iron overload is said to exist when serum ferritin is higher than 200 µg/L in premenopausal women or higher than 300 µg/L in men and postmenopausal women. The danger of hemochromatosis lies in the fact that excess iron deposits are stored not only in macrophages but also in hepatocytes, cardiac cells, endocrine cells, and other parenchymal tissue. Iron interferes with the normal function of these cells. This situation has potentially fatal consequences, especially in relation to cardiac and hepatic tissue.

Hemochromatosis is classified as hereditary or secondary. The hereditary form is caused by genetic mutations. The secondary type is associated with other hematologic diseases and a variety of other conditions. (Table 20 🌟)

HEREDITARY HEMOCHROMATOSIS

Etiology and Pathophysiology

Hereditary hemochromatosis (HH) is characterized by increased iron absorption in the gut and progressive iron overload. It is a genetic disorder with a prevalence of 1 in 200–250 persons. One in 10 Caucasians in the United States is a carrier. It is the most common genetic abnormality in those with a European ancestry. At least five genes have been implicated in causing HH including hepcidin, *HFE*, *TfR2*, ferroportin, and *HJV* genes. Mutations in *HFE*, *TfR2* and *HJV* appear to cause aberrant regulation of hepcidin (Table 21 🌟).

★ TABLE 20

Causes of Iron Overload

Hereditary

- Classical hemochromatosis: HFE mutations (type 1)
- Juvenile hemochromatosis (type 2)
- Hemojuvelin (HJV) mutations
- Hepcidin mutations
- Transferrin-receptor 2 deficiency (type 3)
- Ferroportin deficiency (type 4)
- DMT1 mutations and congenital atransferrinemia

Secondary

- Anemias with ineffective erythropoiesis (i.e., Sickle cell anemia, thalassemia, refractory anemias with erythroid hypercellular bone marrow, X-linked sideroblastic anemia)
- Chronic transfusions
- Chronic liver disease
- Viral hepatitis
- Dietary iron overload
- Overload from injections or ingestion of iron supplements
- Alcoholism

The most common form of HH in populations of European origin is due to mutations in the *HFE* gene, identified in 1996.⁶⁹ Mutations result in an autosomal recessive disorder of low penetrance with adult onset. Clinical disease is more common in males than females. The *HFE* gene is mapped to chromosome 6(6q21,3). The most common mutation is cys282 → tyrosine: C282Y. Less common are the mutations his63 → asp: H63D and ser65 → cys: S65C. Clinical signs of the disease may be found in homozygous C282Y and compound heterozygosity for C282Y and H63D. The penetrance of C282Y is low with only half of homozygotes developing iron overload (increased serum Tf saturation and serum ferritin levels) and ~1% with clinical features of hemosiderosis. This suggests that modifier genes and epigenetic or environmental factors affect the severity of the HH phenotype. Genetic mutations in at least two genes have been proposed to affect the phenotypic expression of homozygous C282Y: *HJV* and hepcidin.^{70,71}

The normal HFE protein is a cell surface transmembrane protein found in the crypt cells of the duodenum as well as other cells. It associates with B₂-microglobulin and TfR. It is thought to regulate iron absorption by its interaction with the TfR in those cells.⁷² When HFE is bound to the TfR, the affinity of the TfR for the iron-transferrin complex is decreased. Thus, the ability of the mucosal cell to sense plasma iron and regulate iron absorption depends on the interaction of HFE with TfR. The mechanism of how mutations in the HFE protein may affect iron metabolism is unclear but may involve interactions of HFE with proteins in addition to TfR as it has been shown that HFE can regulate iron concentration in cells without binding to TfR. The finding of decreased hepatic expression of hepcidin in *HFE* related HH has focused attention on the role of HFE in the liver. Mutations in the *HFE* gene result in inappropriately low hepcidin expression, suggesting that the *HFE* gene is involved in the normal regulation of synthesis of hepcidin and that the effect of the mutated *HFE* gene is due to hepcidin deficiency. About 3–4 mg of iron a day is absorbed from the GI tract as compared to 1–2 mg normally. Because the body has no mechanism to excrete excess iron, it accumulates at about 0.5–1.0 gm/year. Cells' capacity to store iron by complexing with apoferritin is exceeded and "free" intracellular iron accumulates. This free iron facilitates the buildup of reactive oxygen species that cause cell injury and cell death and leads to organ failure. Most of the excess iron is deposited in the liver.

Other less common forms of HH are due to mutations in other genes involved in iron sensing and regulation but all appear to result in deregulation of hepcidin expression. Mutations of the *TfR2* gene results in a disease that is clinically indistinguishable from HFE-associated HH.

Genetic mutations in the ferroportin gene are expressed in an autosomal dominant fashion. Mutations that affect ferroportin's ability to export iron cause iron overload in reticuloendothelial cells ("ferroportin disease"), and mutations that cause hyporesponsiveness of ferroportin to hepcidin result in increased absorption of iron and iron overload in parenchymal cells of the liver and other organs.

★ TABLE 21

Role of Iron-Regulating Proteins in the Pathogenesis of Disorders of Iron Metabolism

Disorder	Defect/Mutation	Fe Absorption	Fe in Macrophages	Plasma Iron	Ferritin
ACD	IL-6 increases hepcidin, which binds ferroportin	Decreased	Increased	Decreased	Increased
Hereditary hemochromatosis (autosomal recessive)	<i>HFE</i> gene; <i>TfR2</i> gene	Increased	Decreased	Increased	Increased
Hereditary hemochromatosis (juvenile; autosomal recessive)	<i>HJV</i> gene Hepcidin gene	Increased	Decreased	Increased	Increased
Hereditary hemochromatosis (autosomal dominant)	Ferroportin gene	Increased	Increased	Normal until late in disease	Increased
Iron-loading anemias (ineffective erythropoiesis)	Erythropoietic drive-suppresses hepcidin synthesis	Increased	Increased (due to hemolysis)	Increased	Increased

Mutations in the hemojuvelin (*HJV*) gene cause a severe autosomal dominant type of HH. This type affects young men and women usually in the second decade of life. A marked decrease in hepcidin occurs, resulting in severe iron overload. A subgroup of patients with juvenile hemochromatosis have a null mutation in the hepcidin gene. The consequence is a complete absence of hepcidin-mediated control of intestinal iron absorption and severe iron overload.

Rare mutations in the transferrin gene and ceruloplasmin gene produce autosomal recessive disorders affecting iron metabolism. Congenital hypotransferrinemia is characterized by increased iron absorption but the unbound iron circulates in plasma without a mechanism for uptake into developing erythroblasts. There is severe hypochromic, microcytic anemia. The circulating nontransferrin-bound iron is deposited in the parenchymal cells of the liver, heart, and pancreas. Ceruloplasmin serves an essential role in catalyzing the oxidation of Fe^{++} to Fe^{+++} , which is the form necessary for binding to apotransferrin. Although excess iron is deposited in tissues, liver injury does not occur. A mild normochromic, normocytic anemia is characteristically found.

Clinical Findings

Clinical penetrance of the most common form of HH is incomplete and only 1 in 5,000 have clinical symptoms. About 81% of symptomatic patients have the C282Y/C282Y genotype. Asymptomatic patients who have the C282Y/C282Y genotype or the H63D/C282Y genotype should have their serum iron and ferritin levels monitored for they are at risk for developing iron storage disease. Clinical findings include chronic fatigue, arthralgia, infertility, impotence, cardiac disease, diabetes, and/or cirrhosis.⁷³ Hyperpigmentation of the skin is also found.

Laboratory Findings

Screening tests for hemochromatosis usually include percent saturation of transferrin and serum ferritin. The criterion for a diagnosis of hemochromatosis is usually >50% transferrin saturation in females and >60% saturation in males. Saturation often approaches 100%. Adding serum ferritin analysis increases specificity for HH. Iron overload is suggested when the serum ferritin is elevated. Although an increase in transferrin saturation is sensitive for hemochromatosis, DNA testing to identify the mutated gene is necessary to definitively diagnose hereditary hemochromatosis (HH). Biopsy of the liver and/or bone marrow usually are not needed. Liver enzymes are usually elevated. Anemia is not present unless complicating conditions exist.

Screening for HH is controversial. Some have recommended population screening with transferrin saturation and suggest that laboratories include transferrin saturation in their routine lab panels.⁷⁴ Genetic screening is still very costly for population screening, and unresolved ethical issues including patient privacy, counseling, and insurance concerns exist. With the recognition of the low penetrance of clinical disease (<1%), interest in large-scale screening

has largely disappeared. It is recommended, however, that both symptomatic and asymptomatic first-degree relatives of those with HH be tested because transferrin saturation will not detect carriers.⁷⁵ The goal in screening and identifying the disease early is to allow treatment with phlebotomy before the onset of clinical disease.

SECONDARY HEMOCHROMATOSIS

Secondary hemochromatosis is associated with a number of conditions including anemias that have an ineffective erythropoietic component and increased iron absorption. These include β -thalassemia, congenital dyserythropoietic anemia, X-linked sideroblastic anemia, and anemias associated with DMT1 mutations. Iron overload often develops in patients who have transfusion-dependent anemias such as sickle cell disease. Iron overload is also found in chronic liver disease and congenital atransferrinemia. Serum iron studies are also abnormal in 40–50% of patients with chronic viral hepatitis, alcoholic liver disease, and nonalcoholic steatohepatitis. Alcohol disrupts normal iron metabolism and results in excess iron deposition in the liver in about one-third of alcoholics.⁷⁶

TREATMENT

Phlebotomy is usually the treatment for HH. Each unit of blood removes about 250 mg of iron from the body. It is suggested that following initial venesection therapy to deplete iron stores, iron status be monitored annually by serum ferritin levels.⁷⁷

Treatment of secondary hemochromatosis sometimes includes the infusion of iron chelators (e.g., deferoxamine) to bind iron and enable urinary excretion. Only a very small amount of iron is available for chelation (from the labile pool) at one time; thus, continuous infusion of the chelator over a long period of time is required to remove this iron. Chelation therapy is the primary form of treatment for transfusion-induced hemochromatosis.

✓ Checkpoint! 4

What is the risk of population genetic screening for HH? What is the benefit of population genetic screening for HH?

► PORPHYRIAS

Heme is an iron-chelated porphyrin ring. Its biosynthesis occurs in most cells, but the major sites of synthesis are in the erythroid cells of the bone marrow and hepatocytes. Thus, the activity of the enzymes catalyzing porphyrin metabolism is highest in these cells.

The porphyrias represent a group of inherited disorders characterized by a block in porphyrin synthesis. Abnormal porphyrin metabolism is due to a defect in one or more of the enzymes in the heme synthesis pathway. As a result of

these enzyme deficiencies, the porphyrin heme precursors behind the bottleneck accumulate in tissues, and large amounts are excreted in the urine and/or feces. These excess porphyrin deposits cause most of the symptoms and clinical findings associated with porphyria. The most common findings include photosensitivity, abdominal pain, and neuropathy (motor dysfunction, sensory loss, and mental disturbances). However, usually adequate production of heme for hemoglobin synthesis occurs.

Although rare, the porphyrias have received wide recognition and stimulated interest because the disease affected the royal families of England and Scotland, especially those descended from Mary, Queen of Scots. Historians have described George III as suffering from a mental and physical disorder thought to have been porphyria. Princess Charlotte, the granddaughter of George III and heir to the throne, died in childbirth; her death was attributed to an acute porphyria attack at the time of delivery.

Two forms of porphyria (erythropoietic and hepatic) are expressed, depending on the primary site (bone marrow or liver) of defective porphyrin metabolism (Table 22). Only the erythropoietic porphyrias affect the erythrocytes. Therefore, these porphyrias are discussed here.

PATHOPHYSIOLOGY

The erythropoietic porphyrias result from an abnormality of the enzymes in the heme biosynthetic pathway within the erythroblasts of the bone marrow. At least two types exist: congenital erythropoietic porphyria (CEP) and erythropoietic protoporphyria (EPP). These two types are classified according to the particular enzyme defect and the excessive porphyrin intermediates produced. Although CEP is associated with hemolytic anemia, anemia in EPP is rare.

Porphyryns are functionless products produced by the irreversible oxidation of type I and type III porphyrinogens.

★ TABLE 22

Classification and Characteristics of the Porphyrias

Porphyria	Mode of Inheritance	Enzymatic Defect	Metabolites in Excess			
			Urine	Feces	Erythroid Cells	Tissue Source
Erythropoietic						
Congenital erythropoietic porphyria (CEP)	Autosomal recessive	Uroporphyrinogen III cosynthase	Uroporphyrin I, Coproporphyrin I	Coproporphyrin I, uroporphyrin I	Uroporphyrin I, coproporphyrin I	Erythropoietic
Congenital erythropoietic protoporphyria (EPP)	Autosomal dominant	Ferrochelatase (Heme synthase)	Normal	Protoporphyrin	Protoporphyrin	Erythropoietic and occasionally hepatic
Hepatic and erythropoietic						
Hepatoerythropoietic porphyria (HEP)	Recessive	Uroporphyrinogen decarboxylase	Uroporphyrin	Uroporphyrin	ZPP	Hepatic and erythropoietic
Hepatic						
Acute intermittent porphyria (AIP)	Autosomal dominant	Porphobilinogen deaminase	δ-ALA, Porphobilinogen	Sometimes coproporphyrin and protoporphyrin	Normal	Hepatic
Hereditary coproporphyrinemia (HCP)	Autosomal dominant	Coproporphyrinogen oxidase	Coproporphyrin III; Uroporphyrin (in attack)	Coproporphyrin III	Normal	Hepatic
Variete porphyria (PV)	Autosomal dominant	Protoporphyrinogen oxidase	Porphobilinogen, δ-ALA, Uroporphyrin, Coproporphyrin	Protoporphyrin Coproporphyrin	Normal	Hepatic
Porphyria cutanea tarda (PCT)	Autosomal dominant	Uroporphyrinogen decarboxylase	Uroporphyrin I Uroporphyrin III, Coproporphyrin (slight)	Protoporphyrin Coproporphyrin	Normal	Hepatic
ALA dehydratase deficiency porphyria (ADP)	Autosomal recessive	ALA dehydratase	δ-ALA, Coproporphyrin III		Normal	Hepatic

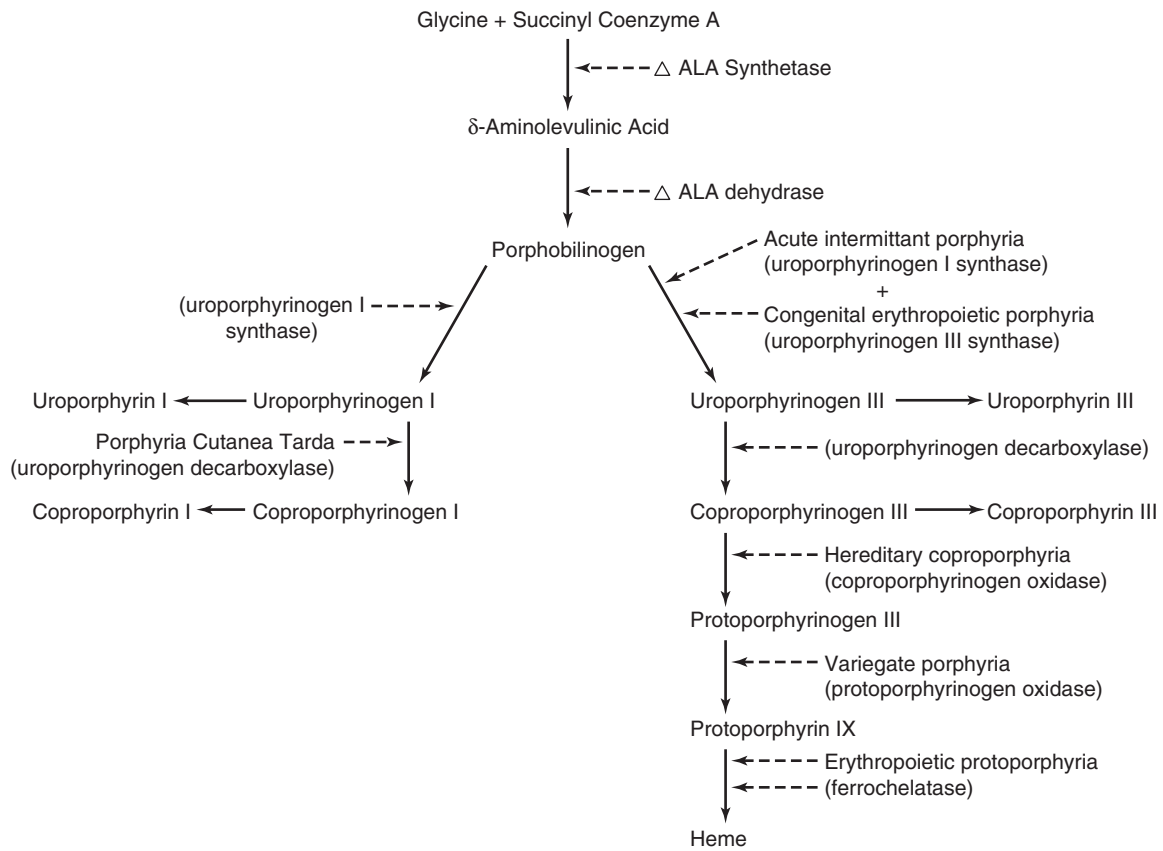

Porphyrinogens of the type III series are the precursors of heme whereas the type I isomers do not produce any useful metabolites and cannot be used in heme synthesis. In normal heme synthesis, both type I and III isomers are formed but in a 1:10,000 ratio. Normally, most porphyrinogens are readily converted during heme synthesis to heme, and very small amounts of the porphyrin intermediates are formed. If, for some reason, excessive amounts of porphyrinogen are produced, the oxidized porphyrin compounds also increase. Porphyrins are tetrapyrroles and resonating compounds (contain alternating single and double bonds); erythrocytes that contain these substances show red fluorescence with UV light.

Congenital Erythropoietic Porphyria

CEP (Gunther’s disease) is characterized by the presence of excessive amounts of type I porphyrins: uroporphyrin I (UroI) and coproporphyrin I (CoproI). A defect in uroporphyrinogen III cosynthase results from point mutations in the gene, which channels the porphobilinogen into the

functionless UroI isomer (Figure 14 ■). However, enough Uro III is produced to generate adequate amounts of heme. This suggests that a deficiency of cosynthetase is not the only abnormality. Another possibility for the excessive amounts of UroI isomer is hyperactivity of the uroporphyrin I synthetase. Validation of either of these hypotheses requires purification, characterization, and accurate measurement of these enzymes.

The excess porphyrins are deposited in body tissues and excreted in urine and feces. Intense fluorescence with ultraviolet light can verify their presence. The cause of the hemolytic anemia that accompanies CEP is unknown but is thought to be closely associated with the excessive porphyrin deposits within erythrocytes. The finding that normal erythrocytes infused into CEP patients have a normal life span supports this. The erythrocytes in CEP can be subject to photohemolysis as they pass through the dermal capillaries exposed to UV light. The erythrocytes show increased photohemolysis in vitro, but whether this is also an in vivo phenomenon is uncertain.

■ **FIGURE 14** The formation of heme from glycine and succinyl-coenzyme A involves the production of porphyrinogen intermediates. Normally, only very small amounts of the series I isomers are formed. However, in the hereditary condition erythropoietic porphyria, there is an abnormality in this pathway, and large amounts of the functionless series I isomers are formed. These isomers are oxidized to porphyrin and accumulate in the tissues. Another form of porphyria, erythropoietic protoporphyria, is characterized by excessive production of protoporphyrin.

Erythropoietic Protoporphyrin

EPP is characterized by an overproduction of protoporphyrin, the immediate precursor of heme, and is associated with a defect in ferrochelatase (Figure 10). Adequate amounts of heme are produced, however, and no anemia is present. Excess protoporphyrin IX builds up in the cell, can leak into skin dermal capillaries and can be found in the skin, liver, blood, and feces. Due to its insolubility in water, protoporphyrin is not present in the urine. This porphyria is thought to be of both erythropoietic and hepatic origin.⁷⁸

CLINICAL FEATURES

CEP is a rare autosomal recessive disease with ~130 cases reported. EPP is inherited as an autosomal dominant trait, but recessive inheritance is possible.⁷⁹ About 300 cases of EPP have been reported, but the actual rate of occurrence is probably masked due to the subtlety of the clinical signs and the absence of colored porphyrins in the urine.

The first signs of CEP occur in infancy. The urine is colored pink to reddish brown, depending on the amount of uroporphyrin excreted. This is usually first noted as a pink stain on the infant's diaper. The excess porphyrins in the skin create an extreme photosensitivity to sunlight. Vesicular or bullous eruptions appear on bared areas shortly after exposure to sunlight. The lesions heal slowly and can become infected. Repeated eruptions and skin injury cause scarring and can lead to severe mutilation of the face, ears, and hands. The excess porphyrin stains the teeth a dirty brown. Under UV light, the teeth fluoresce bright red. Hypertrichosis affects the entire body but is especially present in exposed areas. The hair can be blond and downy or dark and coarse. Splenomegaly is a consistent finding and is usually progressive with the disease. A mild to severe hemolytic anemia is present with erythrocyte life span decreased to as little as 18 days. Patients with CEP never exhibit the abdominal pain or neurologic and psychotic signs associated with hepatic porphyrias.

Clinical signs of EPP are more subtle, and its course is relatively mild in comparison to CEP. Photosensitivity is not severe, and scarring is usually absent. Sunlight exposure leads to erythema and urticaria. Protoporphyrin accumulates in the erythrocytes, which causes them to fluoresce intensely, but there is no hemolytic anemia. Occasionally hepatic damage occurs.

LABORATORY FEATURES

CEP

The peripheral blood in CEP exhibits a mild to severe normocytic anemia with anisocytosis and poikilocytosis. The blood smear reveals significant polychromatophilia and nucleated erythrocytes. Reticulocytes are increased. The erythrocytes fluoresce with UV light.

The bone marrow in CEP shows erythroid hyperplasia. A large portion of the erythroblasts demonstrate intense fluo-

rescence with UV light. The fluorescence is localized principally in the nuclei. The fact that not all erythroblasts fluoresce suggests that two populations of erythrocytes exist, and one of which is normal.

Serum iron and storage iron are usually normal. Haptoglobin is absent and unconjugated bilirubin, urinary, and fecal urobilinogen are increased.

Large amounts of uroporphyrin I and coproporphyrin I are excreted in the urine and feces. These isomers are also found in the plasma and in erythrocytes.

EPP

The blood and bone marrow in EPP usually reveal no abnormalities on routine examination; however, under UV light, the cytoplasm of erythroblasts fluoresces intensely. The erythrocytes, plasma, and feces contain large amounts of protoporphyrin. The protoporphyrins are not found in the urine. The protoporphyrin in erythrocytes is free (FEP), not bound to zinc as in IDA and lead poisoning. The FEP is higher than in other disorders associated with an increase in erythrocyte protoporphyrin levels. This block in heme synthesis, which occurs in the reaction just prior to insertion of iron into the porphyrin ring, would be expected to cause an accumulation of iron within the erythroblasts. The fact that this iron buildup does not occur cannot be explained.

PROGNOSIS AND THERAPY

Individuals with CEP do not usually survive beyond the fifth decade of life. Attempts to decrease the excess porphyrins have been unsuccessful, but the quality of life for CEP patients has improved by minimizing the scarring and mutilation with effective dermatologic treatment. Avoidance of exposure to sunlight is critical. Splenectomy has sometimes resulted in a decrease of porphyrin production and helped ameliorate the hemolytic anemia. Evidence for long-term success with splenectomy, however, is questionable. Blood transfusion in conjunction with administration of chelators to reduce iron overload suppresses erythropoiesis and decreases or eliminates symptoms. Bone marrow transplantation is suggested in severe phenotypes because the predominant site of porphyrin production is the bone marrow.

Treatment of EPP is aimed at protecting the skin from sunlight and minimizing the toxic effects of protoporphyrin on the liver. In most patients with EPP, high doses of β -carotene improves tolerance to sunlight. Blood transfusions and hematin can be utilized to suppress erythropoiesis. Splenectomy can be helpful if hemolysis and splenomegaly are prominent. Cholestyramine can promote excretion of liver protoporphyrin.⁸⁰

Genes of the heme biosynthetic pathway have been cloned, and mutations associated with porphyrias have been identified. Gene therapy will likely be an option for porphyrias in the future.⁷⁸ In this type of therapy, a functional

gene would be transferred to specific hematopoietic or hepatic stem cells of the patient, restoring normal heme synthesis pathways.

SUMMARY

Hemoglobin synthesis requires adequate production of heme and globin. Inadequate amounts of either can result in anemia—usually microcytic, hypochromic anemia. Defects in heme synthesis could be due to faulty iron or porphyrin metabolism (Table 23).

Many proteins that play a role in iron homeostasis have been identified. These include hepcidin, ferroportin1, hephaestin, DMT1, DCytB, HFE, transferrin receptor and transferrin. The anemias with a faulty iron metabolic component include IDA and ACD. IDA is due to inadequate amounts of iron for heme synthesis. This ID usually occurs because of blood loss or a nutritional deficiency of iron. ACD has several pathophysiologic mechanisms related to cytokines produced as a result of inflammation or infection. The major mechanism is a block in reutilization of macrophage iron. The erythrocytes are normocytic, normochromic, but in long-standing anemia, they can be microcytic, hypochromic.

Abnormal porphyrin metabolism results in SA and porphyrias. Defects in globin synthesis are due to genetic defects that affect production of the globin chains. These globin defects are known as thalassemias.

Sideroblastic anemia (SA) is due to defective porphyrin synthesis and a block in the insertion of iron into the porphyrin ring to form heme. The erythrocyte population in SA characteristically contains cells that are normochromic and hypochromic (dual population). The bone marrow has ringed sideroblasts. Hereditary SA is due to defective ALAS2, the enzyme in the first step of heme synthesis. SA can also occur because of the effects of drugs or toxins on enzymes involved in heme synthesis.

Iron studies are helpful in differentiating these disorders. Serum iron is decreased in IDA and ACD; it is normal to increased in SA. The serum transferrin is increased and saturation decreased if total body iron is decreased, whereas if storage iron is normal or increased, the serum transferrin is normal or decreased with normal or increased saturation. Serum ferritin is a reliable indicator of iron stores except in the presence of inflammation when it is falsely increased. It is decreased in ID and normal or increased in SA, ACD, and hemochromatosis. The serum transferrin receptor assay is

★ TABLE 23

Summary of Conditions Associated with Abnormal Heme Synthesis and/or Iron Metabolism/Utilization

Condition	Etiology	CBC	Iron Studies	Other
Iron deficiency anemia	Inadequate iron due to deficient dietary intake; decreased absorption; increased loss	Microcytic, hypochromic, anisocytosis, poikilocytosis	Decreased serum iron, serum ferritin, and percent saturation of transferrin; increased TIBC and sTfR	Increased ZPP (do not use to evaluate if possibility of concurrent lead poisoning); decreased CHR
Anemia of chronic disease	Impaired release of iron from macrophages due to increased hepcidin induced by cytokines; inhibition of EPO production and impaired erythropoiesis; shortened erythrocyte survival	Normocytic, normochromic; in long-standing cases can be microcytic, hypochromic	Decreased serum iron and low to normal TIBC; low/normal transferrin saturation; serum ferritin normal or increased; sTfR normal	Increased ZPP
Sideroblastic anemia	Defect in enzymes needed for heme synthesis; can be hereditary or acquired (secondary to drugs/toxins)	Dual population of normochromic and hypochromic erythrocytes	Increased serum iron and transferrin saturation; normal or decreased TIBC; increased serum ferritin	Bone marrow shows ringed sideroblasts; peripheral blood erythrocytes may contain Pappenheimer bodies
Hemochromatosis (no anemia)	Hereditary: genetic mutation (C282Y and/or H63D); acquired: transfusion, iron injections, chronic liver disease	No anemia or characteristic peripheral blood cell morphology	Increased serum iron, transferrin saturation, and serum ferritin	Molecular testing to identify mutated gene is suggested if transferrin saturation is >55%
Porphyrias (anemia not characteristic)	Block in porphyrin synthesis due to defect in enzymes for heme synthesis; CEP and EPP affect erythrocytes	CEP: normocytic hemolytic anemia; anisocytosis and poikilocytosis; polychromatophilia; NRBC EPP: no abnormalities	Storage iron and serum iron normal	CEP: increased uroporphyrin I and coproporphyrin I excreted in urine and feces, plasma, and erythrocytes; series III isomers also increased CEP, EPP: normoblasts demonstrate intense fluorescence with UV light

useful in differentiating ID and ACD. Levels are increased in ID and normal in ACD.

Hemochromatosis is a disorder characterized by total body iron excess. Anemia is not a characteristic of this disorder, but it is included in this chapter to help the reader compare and differentiate iron study results with those associated with defective heme synthesis. Hemochromatosis can be caused by a genetic defect or chronic transfusion. The most common hereditary form of hemochromatosis (HH) is due to a mutation of the *HFE* gene. Mutations in several other genes associated with iron metabolism can

also cause HH. These mutations are believed to affect the synthesis of hepcidin. Serum iron studies reflect the excessive iron overload with increased serum ferritin and a very high saturation of transferrin.

The porphyrias are a heterogeneous group of hereditary disorders that are due to a block in porphyrin synthesis. The defect is in a critical enzyme in the porphyrin metabolic pathway. Two forms have an erythropoietic component, CEP and EPP. Erythrocytes have very high levels of free erythrocyte protoporphyrin, and excess porphyrins are deposited in tissues and excreted in feces/urine.

REVIEW QUESTIONS

LEVEL I

- What is the iron transport protein? (Objective 3)
 - ferritin
 - transferrin
 - hemosiderin
 - albumin
- The term *sideropenic* is most closely associated with which of the following anemias? (Objective 1)
 - iron deficiency
 - sideroblastic
 - lead poisoning
 - anemia of chronic disease
- Microcytic, hypochromic erythrocytes are most characteristic of which of the following anemias? (Objective 5)
 - megaloblastic
 - lead poisoning
 - iron deficiency
 - anemia of chronic disease
- Which of the following individuals is most likely to require an increased intake of iron? (Objective 4)
 - adult male
 - menopausal female
 - mother of 3 preschool children
 - 75-year-old male
- The basic defect in sideroblastic anemia is: (Objective 6)
 - inadequate iron intake
 - inadequate absorption of iron in the gut
 - cytokine inhibition of erythropoiesis
 - faulty enzymes regulating heme synthesis
- Anemia(s) characterized by defective heme synthesis include: (Objective 6)
 - hemochromatosis
 - megaloblastic anemia
 - thalassemia
 - sideroblastic anemia
- The most common cause of ID in middle-aged men is: (Objective 6)
 - inadequate iron in the diet
 - cancer
 - prescription drugs
 - chronic bleeding

LEVEL II

Use this history for questions 1–4.

A 75-year-old male experiencing mental confusion and fatigue was seen by his physician. Laboratory tests were ordered:

RBC	$3.3 \times 10^{12}/L$
Hb	9.3 g/dL
Hct	0.29 L/L
PLT	$168 \times 10^9/L$
WBC	$4.0 \times 10^9/L$
Differential	
Segmented neutrophils	60%
Band neutrophils	9%
Lymphocytes	25%
Monocytes	3%
Eosinophils	3%

RBC morphology: Anisocytosis with microcytic, hypochromic RBCs, and normocytic, normochromic RBCs present

Laboratory data for anemia workup:

Reticulocyte count	1.0%
Serum iron	274 $\mu\text{g}/\text{dL}$
Total iron-binding capacity (TIBC)	285 $\mu\text{g}/\text{dL}$

- Which anemia of defective heme synthesis is associated with this type of red cell morphology? (Objective 8)
 - sideroblastic anemia
 - anemia of chronic disease
 - IDA
 - erythropoietic porphyria
- Which laboratory result(s) is (are) most useful in distinguishing this patient's anemia from IDA? (Objective 9)
 - bone marrow
 - MCV
 - hemoglobin
 - iron studies

REVIEW QUESTIONS (continued)

LEVEL I

8. Which of the following is most often associated with microcytic, hypochromic anemia? (Objective 5)
 - a. lead poisoning
 - b. ID
 - c. sideroblastic anemia
 - d. anemia of chronic disease
9. Which of the following best describes hemosiderosis? (Objective 7)
 - a. decrease in serum iron
 - b. increase in serum iron
 - c. increase in macrophage iron
 - d. increase in total body iron
10. A patient with anemia of chronic disease would be expected to have which set of laboratory test results? (Objective 5)
 - a. MCV decreased, serum iron increased, serum ferritin increased, TIBC and % saturation increased
 - b. MCV normal, serum iron increased, serum ferritin decreased, TIBC and % saturation decreased
 - c. MCV normal, serum iron decreased, serum ferritin increased, TIBC and % saturation decreased
 - d. MCV decreased, serum iron decreased, serum ferritin decreased, TIBC and % saturation decreased

LEVEL II

3. From the results of these laboratory studies, how would you describe the patient's red blood cells? (Objective 8)
 - a. microcytic, hypochromic
 - b. dual population of microcytes and normocytes
 - c. macrocytic, normochromic
 - d. normocytic, normochromic
4. A bone marrow was performed and sections were stained with Prussian blue. Numerous sideroblasts were present with a large number of ringed sideroblasts. What is the most probable cause of this anemia? (Objectives 6, 8, 10)
 - a. poor diet
 - b. chronic blood loss
 - c. abnormality of ALAS2
 - d. increased iron requirement
5. A hematocrit is not recommended to screen for iron deficiency in children because: (Objectives 1, 2, 8, 9)
 - a. It is not sensitive enough to pick up anemia in children.
 - b. Iron deficiency can be present without the presence of anemia.
 - c. High levels of lead will affect the hematocrit accuracy.
 - d. Serum ferritin is more cost effective.
6. If a child with lead poisoning also had a significant microcytic, hypochromic anemia, what complicating pathology/pathologies should be considered? (Objective 14)
 - a. iron deficiency
 - b. thalassemia
 - c. iron deficiency and thalassemia
 - d. thalassemia and sideroblastic anemia
7. What laboratory test is best for screening for iron deficiency in a population of 1- to 3-year-old children who have a high incidence of elevated blood lead levels? (Objective 14)
 - a. hematocrit
 - b. serum ferritin
 - c. serum iron
 - d. ZPP
8. A 2-year-old child was tested for blood lead level. The result was 25 $\mu\text{g}/\text{dL}$. He also had microcytic, hypochromic anemia. The child's parents were questioned, and it was determined that the source of lead was a painted crib in his day care center. The child was enrolled in another day care center. Follow-up testing revealed that the blood lead level was within normal limits but the microcytic, hypochromic anemia was still present. Which follow-up test(s) would you recommend to help identify the etiology of this anemia? (Objectives 9, 14, 15)
 - a. serum iron, serum ferritin, TIBC, % saturation
 - b. hemoglobin electrophoresis
 - c. molecular diagnostic testing for sideroblastic anemia
 - d. molecular diagnostic testing for hemosiderosis

REVIEW QUESTIONS (continued)

LEVEL I

LEVEL II

9. A health maintenance organization (HMO) has a contract for laboratory testing services with your laboratory. The HMO has decided to screen its members for hereditary hemochromatosis. Which laboratory test will you recommend for this screening? (Objective 18)
 - a. serum iron
 - b. % transferrin saturation
 - c. serum ferritin
 - d. molecular test for mutated HFE gene
10. In regard to question 9, what test should you recommend to be done reflexively on patients with an abnormal screening test? (Objective 18)
 - a. molecular test for HFE gene
 - b. serum iron
 - c. serum ferritin
 - d. % saturation
11. Which protein regulates iron absorption in the gut and transport of iron from cells to the plasma? (Objective 3)
 - a. DcytB
 - b. DMT1
 - c. hepcidin
 - d. hephaestin
12. What effect would a high degree of ineffective erythropoiesis have on iron metabolism? (Objective 4)
 - a. Decreased amount of iron released from enterocytes
 - b. Increased absorption of iron in the intestine
 - c. Decreased hepcidin synthesis
 - d. Increased serum transferrin saturation

ANSWERS TO CASE STUDY QUESTIONS

Case Summary: Jose is suffering from IDA due to chronic blood loss from the GU tract. He has the typical blood picture of microcytic, hypochromic erythrocytes. His iron studies reveal a lack of total body iron. The serum iron and % transferrin saturation are low.

Question:

1. How would you describe his anemia morphologically?

Explanation:

MCV = 63 fL; MCH = 19.5 pg. The anemia is microcytic, hypochromic.

Question:

2. Calculate % saturation.

Explanation:

Serum iron/TIBC = 4%. The serum iron is low and the TIBC increased resulting in a low % saturation.

Question:

3. Is this value normal, decreased, or increased?

Explanation:

Decreased. Less than 15% saturation is considered decreased.

Question:

4. What disease, if any, is suggested by this value?

Explanation:

Iron deficiency (ID). The percent saturation of transferrin is decreased in ID, usually to less than 10%.

Question:

5. How do the iron study results of our patient help in differentiating the diagnosis of iron deficiency from ACD?

Explanation:

In ACD, the serum iron is low, and the TIBC and % saturation are normal or decreased. In ID, the total body iron is normal to increased. In ID, total body iron is decreased.

Question:

6. What additional iron test that was not done would be most helpful in this case?

Explanation:

Serum ferritin is a good indicator of iron stores and is less invasive than a bone marrow. The drawback to serum ferritin is that it is an acute phase reactant.

Question:

7. Do the iron studies in Jose (serum iron 17 $\mu\text{g/dL}$, TIBC 425 $\mu\text{g/dL}$) suggest sideroblastic anemia?

Explanation:

No, iron studies in this patient reveal a lack of total body iron. Sideroblastic anemia has a defect in the incorporation of iron into the porphyrin ring. Iron accumulates in the red cell and macrophage. Thus, the total body iron is increased in sideroblastic anemia.

Question:

8. Do Jose's laboratory test results and clinical history indicate that a bone marrow examination is necessary?

Explanation:

No, adequate information is present from other laboratory tests. The CBC and iron studies give important clues to a diagnosis of ID anemia. A bone marrow may be performed in difficult cases but is usually not necessary.

ANSWERS TO CHECKPOINTS**Checkpoint! 1**

A patient's iron studies revealed: serum iron 100 $\mu\text{g/dL}$; TIBC 360 $\mu\text{g/dL}$. Calculate % saturation and UIBC. Are these values normal or abnormal?

Answer

% saturation = serum iron/TIBC

% saturation = $100/360 = 28\%$

UIBC = TIBC - serum iron

UIBC = $360 - 100 = 260$

Normal results

Checkpoint! 2

A 30-year-old female and a 25-year-old male both had a bleeding ulcer. Assume that each acquired the ulcer at the same time, was losing about the same amount of blood, had equal amounts of storage iron to begin with, and was taking in about 15 mg dietary iron each day. Would you expect that the woman and man would develop ID at the same time? Explain.

Answer

The woman would probably develop ID sooner because she is also losing about 20 mg of iron per month through menstruation.

Checkpoint! 3

How does the peripheral blood picture in ACD differ from that seen in IDA?

Answer

In IDA, the erythrocytes are usually microcytic, hypochromic. In ACD, the erythrocytes are usually normocytic, normochromic; normocytic, hypochromic; or in long-standing cases, microcytic, hypochromic.

Checkpoint! 4

What is the risk of population genetic screening for HH? What is the benefit of population genetic screening for HH?

Answer

The risks are that individuals who have the mutated gene may be discriminated against by health insurance companies and that all of those who test positive may not develop the disease as disease penetrance has not yet been determined. The benefit is that individuals who have the mutated gene can be identified early before they develop clinical signs of the disease. Therapy by phlebotomy can then prevent chronic disease associated with HH.

Hemoglobinopathies: Qualitative Defects

Rebecca J. Laudicina, Ph.D.

■ OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. Define *hemoglobinopathy*.
2. Explain the basis of defects resulting in the production of abnormal hemoglobins.
3. Explain the basis of the hemoglobin electrophoresis method in identifying abnormal hemoglobins.
4. Describe the epidemiology of sickle cell anemia (SCA) and other hemoglobinopathies.
5. Identify the globin chain defects causing SCA and hemoglobin C disease.
6. Associate laboratory analyses with their use in detecting and identifying hemoglobinopathies.
7. Recognize and identify abnormal laboratory test results, including peripheral blood findings and screening and confirmatory tests, typically associated with homozygous and heterozygous conditions involving HbS, HbC, HbD, HbE, and compound heterozygous conditions involving hemoglobin S and other abnormal hemoglobins.
8. List major clinical findings typically associated with the hemoglobinopathies listed in Objective 7.

■ OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. Compare the synthesis and concentration of abnormal hemoglobins in homozygous and heterozygous conditions.
2. Compare the prevalence of hemoglobins S, C, D, and E.
3. Compare and contrast the pathophysiology of hemoglobin variants in terms of altered solubility, function, and stability.
4. Analyze the structure of the hemoglobin molecule in sickle cell anemia (SCA) and relate it to the pathophysiology of the disease.
5. Contrast clinical findings in persons who are homozygous and heterozygous for hemoglobins S, C, D, and E and in those who have compound heterozygotes for these abnormal hemoglobins.
6. Identify and explain current therapies for SCA.
7. Evaluate and interpret mobility patterns obtained on cellulose acetate and citrate agar gel hemoglobin electrophoresis when structurally abnormal hemoglobins are present.

CHAPTER OUTLINE

OBJECTIVES—LEVEL II (continued)

8. Select, evaluate, and interpret tests used in detecting and identifying abnormal hemoglobins.
9. Design a laboratory testing algorithm for optimizing tests used in detecting and identifying abnormal hemoglobins.
10. Evaluate laboratory test results and medical history of a clinical case for a patient with a hemoglobinopathy and suggest a possible diagnosis.
11. Explain the physiologic abnormality resulting in unstable hemoglobins, methemoglobinemia, and hemoglobin variants with increased or decreased oxygen affinity.
12. Interpret laboratory findings associated with the disorders in Objective 11.

KEY TERMS

Aplastic crisis
 Autosplenectomy
 Compound heterozygote
 Congenital Heinz body hemolytic anemia
 Hemoglobin electrophoresis
 Hemoglobinopathy
 Irreversibly sickled cells
 Methemoglobinemia
 Sequestration crisis
 Thalassemia
 Vaso-occlusive crisis

BACKGROUND BASICS

The information in this chapter builds on the concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study.

Level I

- ▶ Describe erythrocyte metabolism and erythrocyte destruction.
- ▶ Describe the structure and function of hemoglobin; list abnormal hemoglobins.
- ▶ Name and describe basic laboratory procedures used to screen for and assess anemia.
- ▶ Recognize abnormal values and results for basic hematologic procedures.)
- ▶ Describe the classification systems of anemias.)

Level II

- ▶ Describe bone marrow structure and explain laboratory examination of bone marrow aspirates and biopsy.

CASE STUDY

We will refer to this case throughout the chapter.

Shane, a 16-year-old African American male with a previously diagnosed hemoglobinopathy, was admitted to the hospital complaining of severe pain in his knees and back. Two of his four siblings have the same disorder. He has been admitted to the hospital on numerous occasions throughout his life for complications of his disease. Physical examination reveals a thin male in acute distress, complaining of severe pain. HEENT (head, eyes, ears, nose, and throat) exam is positive for corkscrew vessels of the sclerae, scleral icterus, and small, ill-defined, mobile (shotty) cervical lymph nodes. Abdominal exam revealed no splenomegaly, hepatomegaly, tenderness, or masses. Vital signs included temperature 37.8°C, blood pressure 95/70, and pulse 82. Blood was drawn for laboratory tests, and a chest radiograph and MRI of the head were ordered. Consider whether the patient's current condition is likely to be related to his previous diagnosis and what the laboratory's role is at this time.

OVERVIEW

When the hemoglobin's molecular structure is altered, the molecule's function, stability, and/or solubility can be altered, often resulting in anemia. Laboratory screening tests are based on the altered characteristics of the hemoglobin molecule. If screening tests are abnormal, reflex tests are required to confirm the presence of an abnormal hemoglobin. This chapter discusses the most common abnormal hemoglobins including epidemiology, pathophysiology, clinical findings, laboratory findings, and treatment. Emphasis is on the correlation of clinical history and symptoms with laboratory tests and interpretation of test results.

INTRODUCTION

Clinical diseases that result from a genetically determined abnormality of the structure or synthesis of the hemoglobin molecule are called **hemoglobinopathies**. The abnormal-

ity is associated with the globin chains; the heme portion of the molecule is normal. The globin abnormality can be either a qualitative defect in the globin chain (structural abnormality) or a quantitative defect in globin synthesis.

Qualitatively abnormal hemoglobin molecules result from genetic mutations in the coding region of a globin gene, resulting in amino acid deletions or substitutions in the globin protein chain. These mutations cause structural variation in one of the globin chain classes (structural hemoglobin variants). The nomenclature of these disorders is discussed in a later section. The most common clinical disorder of this type of mutation is sickle cell anemia.

The quantitative globin disorders result from various genetic defects that reduce synthesis of structurally normal globin chains. The quantitative disorders are known collectively as the **thalassemias**.

As a result of the globin chain defects, hemoglobinopathies can be associated with a chronic hemolytic anemia or can be asymptomatic. Clinical expression of the hemoglobinopathy varies depending on the class of globin chain involved (α , β , δ , or γ), the severity of hemolysis, and the compensatory production of other normal globin chains. Some of the hemoglobinopathies produce no clinical signs or symptoms of disease and are identified only through population studies specifically designed to reveal “silent” carriers. As discovery of silent carriers increases, the incidence of these genetic disorders is proving to be much higher than originally thought. Hemoglobinopathies are believed to be the most common lethal hereditary diseases in humans.¹

Hemoglobinopathies are found worldwide but occur most commonly in African blacks and ethnic groups from the Mediterranean basin and Southeast Asia. The geographic locations where the quantitative and qualitative hemoglobin disorders are found frequently overlap; thus, it is not uncommon for individuals to have both a structural hemoglobin variant and a form of thalassemia. This could partly explain the extreme variation in clinical findings associated with hemoglobinopathies.

This chapter discusses the structural hemoglobin variants and discusses the thalassemias.

▶ STRUCTURAL HEMOGLOBIN VARIANTS

The largest group of hemoglobinopathies results from an inherited structural change in one of the globin chains; however, synthesis of the abnormal chain usually is not significantly impaired. Any of the globin chain classes, α , β , δ , or γ , can be affected.

Sickle cell anemia, the most common structural hemoglobin variant, was reported by James Herrick of Chicago in 1910.² He described the typical crescent-shaped sickled erythrocytes in a young black student from the West Indies. Following this initial report, additional cases of the disease

were described, and the clinical pattern of sickle cell anemia was established. The pathophysiologic aspects of the disease, however, remained a mystery until Linus Pauling in 1949 discovered the altered electrophoretic mobility of the hemoglobin in patients with sickle cell disease.³ The molecule’s altered electrical charge was ascribed to a molecular abnormality of the globin chain.

More than 900 abnormal hemoglobins have since been discovered. A molecular data base can be accessed at globin.cse.psu.edu/globin/hbvar/menu.html. The number of identified β -chain mutations exceeds the number identified for α -, δ -, or γ -chains (Table 1). Part of the explanation for this distribution likely resides in the genetics and phenotypic expression of the globin gene loci. Hemoglobin F (γ -chain) is expressed to a significant extent only during fetal development; therefore, variant F hemoglobins are unlikely to be detectable after 3–6 months of age. Mutations affecting the γ -chain locus with the potential to produce a clinically significant abnormality would likely either cause fetal death or be insignificant at birth. At birth, as β -chain synthesis becomes predominant, the residual abnormal Hb F is likely masked by the increasing concentration of HbA.

Because HbA₂ (δ -chain) is usually a minor hemoglobin with a concentration of <4% of the total hemoglobin in adults, HbA₂ variants are also unlikely to cause clinical complications and are discovered “accidentally” during laboratory evaluation for other purposes.

The α -chain gene is duplicated on each of the 16 chromosomes. Thus, a mutation of a single α -locus resulting in a variant α -chain containing hemoglobin produces only a small amount of the abnormal hemoglobin and is less likely to cause clinical complications.

The β -gene, which is found in a single copy on each of the 11 chromosomes, is most likely to be associated with a clinical phenotype when mutated as the β -globin chain is a component of HbA, the major adult hemoglobin.

IDENTIFICATION OF HEMOGLOBIN VARIANTS

Most structural hemoglobin variants result from a single amino acid substitution or deletion in the globin polypeptide

★ TABLE 1

Globin Structural Variants*	
Globin Polypeptide	Number of Variants
α 1- and/or α 2-globin gene(s)	338
β -globin gene	518
δ -globin gene	53
A γ -globin gene	34
G γ -globin gene	48

*globin.cse.psu.edu/globin/hbvar/menu.html (accessed April 2008)

chain. Most structural variants result in no clinical or hematologic abnormality and have been discovered only by population studies or family studies. Mutations result in clinical manifestations only when the function (oxygen affinity) and/or the stability/solubility of the hemoglobin molecule are altered. These phenotypic variants produce both clinical and hematologic abnormalities of varying severity, depending on the nature and site of the mutation. Laboratory tests designed to detect hemoglobin variants are based on the molecule's altered structure or function.

METHODS OF ANALYSIS

Hemoglobin carries an electrical charge resulting from the presence of ionized carboxyl (COO^-) and protonated (H^+) amino (NH_3^+) groups. The type (net positive, net negative) and strength of the charge depend on both the amino acid sequence hemoglobin molecule and the pH of the surrounding medium. Many amino acid substitutions alter the molecule's electrophoretic charge, enabling detection of a structural hemoglobin variant by **hemoglobin electrophoresis**. However, different substitutions can cause identical changes in the net charge of the molecule; thus, two different mutant hemoglobins can have identical electrophoretic mobility. By varying the medium and pH of the procedure, many clinically significant hemoglobins can be identified.

The most common clinically symptomatic hemoglobinopathies involve abnormalities of the β -globin chain, resulting in a decrease or absence of HbA ($\alpha_2\beta_2$) and an increase in HbF ($\alpha_2\gamma_2$) and/or HbA₂ ($\alpha_2\delta_2$). Typically, an elevation in HbF and/or HbA₂ is the clue to the presence of a hemoglobinopathy, although HbF is frequently elevated in other hematologic disorders as well. HbF concentrations >10% can be measured by electrophoresis and densitometry. Smaller but significant increases in HbF can be measured more accurately by alkali denaturation. Hb F distribution among the erythrocyte population, however, is evaluated by the acid elution test. These tests are based on the fact that HbF is more resistant to alkali and acid treatment than other hemoglobins.

Various laboratory tests provide essential information when a hemoglobinopathy is suspected. The CBC indicates whether anemia is present, and RDW and erythrocyte indices should be evaluated to help distinguish hemoglobinopathies from thalassemia (which is usually a microcytic, hypochromic anemia). An important next step is to detect hemoglobin variants and quantify hemoglobins A₂ and F.⁴ Several options, ranging from traditional to newer methods are available; many laboratories use a combination of both. Some laboratories are using advanced testing methods such as isoelectric focusing (IEF) and high-performance liquid chromatography (HPLC). These laboratory methods are suitable for testing large numbers of individuals for hemoglobinopathies. They offer improved resolution and identifica-

tion of certain hemoglobin variants over results obtained with alkaline electrophoresis.⁵ HPLC also has the advantage over electrophoresis of quantifying low concentrations of Hb A₂ and Hb F and is emerging as the method of choice for this purpose.⁴ Most states have instituted newborn screening programs for sickle cell disease,⁶ often using HPLC or mass spectrometry methods that are appropriate for high-volume testing.

Other traditional tests for abnormal hemoglobins are based on altered physical properties of the structural variants. These include solubility tests, heat precipitation tests, and tests for Heinz bodies. The uses of these methods are included in the following discussion of the corresponding specific structural variants.

Techniques are also available to identify the specific molecular defect of hemoglobin disorders.⁷ The polymerase chain reaction (PCR) has been incorporated into diagnostic procedures for identifying point mutations because it enhances sensitivity and reduces the amount of DNA and time required for analysis. Prenatal diagnosis can be carried out in the first trimester of pregnancy using DNA obtained from chorionic villus sampling. In cases of hemoglobinopathies caused by known common mutations, such as sickle cell anemia, the fetal DNA can be analyzed directly. If prenatal diagnosis is desired in cases in which the exact mutation is not known, the parents' DNA could be analyzed first (e.g., RFLP—restriction fragment length polymorphism) to help identify the mutation.

Checkpoint! 1

Why can't all structural hemoglobin variants be identified by hemoglobin electrophoresis?

CASE STUDY (continued from earlier in this chapter)

1. Identify a laboratory test needed to determine Shane's hemoglobinopathy.

NOMENCLATURE

The first abnormal hemoglobin discovered was called *hemoglobin S (HbS)* because it was associated with crescent (sickle)-shaped erythrocytes (S for sickle). Subsequently, other hemoglobin variants were discovered and were given successive letters of the alphabet according to electrophoretic mobility beginning with the letter C. The letter A was already in use to describe the normal adult hemoglobin, HbA. The let-

ter *B* was not used to avoid confusion with the ABO blood group system. The letter *F* had been designated to describe fetal hemoglobin, HbF. The letter *M* was given to those hemoglobins that tended to form methemoglobin (HbM).

As more and more variants were discovered, it was recognized that the alphabetical system was not sufficient and a different nomenclature system was needed. Thus, subsequent hemoglobins were given common names according to the geographic area in which they were discovered (e.g., Hb Ft. Worth). It also became apparent that some variants with the same letter designation (same electrophoretic mobility) had different structural variations. If the hemoglobin has the electrophoretic mobility of a previously lettered hemoglobin, that letter is used in addition to the geographic area (e.g., HbG Honolulu).

A standardized hemoglobin nomenclature has been recommended for use when possible. All variants should be given a scientific designation as well as a common name. The scientific designation includes the following: (1) the mutated chain, (2) the position of the affected amino acid, (3) the helical position of the mutation, and (4) the amino acid substitution. (If the mutation affects amino acids between helices, the number of the amino acid and the letters of the two bracketing helices are used.) For example, HbS would be designated $\beta 6$ (A3) Glu \rightarrow Val. The mutation is in the β -chain affecting the amino acid in the sixth position of the chain located in the A3 helix position. The amino acid valine is substituted for glutamic acid. Hemoglobins with amino acid deletions include the word *missing* after the amino acid and helix designation (e.g., $\beta 56$ -59 [D7-E3] missing). The advantage of the helical designation is that amino acid substitutions in the same helix can lead to similar functional and structural alterations of the hemoglobin molecule, allowing a better understanding of the clinical manifestations of each.

Not all globin chain mutations cause symptoms of disease; thus, many go undetected. Only those that cause clinical symptoms are likely to be brought to a physician's attention. If an individual is homozygous for the gene coding for a structural β -globin mutant, no HbA is produced, and the term *disease* or *anemia* is used to describe the specific disorder (e.g., sickle cell anemia). If, however, one of the genes coding for the β -chain is normal and the other β -gene codes for a structural variant, both HbA and the abnormal hemoglobin are produced, and the word *trait* is used to describe the heterozygous disorder (e.g., sickle cell trait).

With the most common β -chain hemoglobin variants (HbS, HbC), the abnormal hemoglobin usually accounts for less than 50% of the total hemoglobin in the trait form whereas in the homozygous state of disease, the abnormal hemoglobin usually constitutes 90–95% of the total hemoglobin. This is explained by the effect of the abnormal globin chain on the formation of the hemoglobin tetramers. The normal α -chain has a net positive charge; the normal β -chain (β^A) has a negative charge, and $\alpha\beta$ dimers form ini-

tially through positive-negative electrostatic interactions. β -chain mutants with a lesser negative charge than β^A form $\alpha\beta$ dimers more slowly than do β^A (and, conversely mutations that increased the negative charge of the β -globin chain would form $\alpha\beta$ dimers more rapidly). Both β^S and β^C mutations cause a net reduction of the β -chain negative charge and form $\alpha\beta^S$ or $\alpha\beta^C$ dimers more slowly than $\alpha\beta^A$ dimers. As a result, heterozygotes have ~60% HbA and ~35–40% HbS or HbC. If HbS or HbC constitutes more than 50% of the total hemoglobin in a heterozygote, the patient could have inherited two different abnormal hemoglobin genes (**compound heterozygote**) or a form of thalassemia with the hemoglobin variant.

Checkpoint! 2

What does the term *silent carrier* mean when referring to a hemoglobinopathy?

CASE STUDY (continued from the previous page)

Results of hemoglobin electrophoresis were 90% HbS, 9% HbF, and 1% HbA₂.

2. What is the abnormal hemoglobin causing Shane's disease?
3. Is Shane heterozygous or homozygous for the disorder?
4. What is this disorder called?

PATHOPHYSIOLOGY

The structural hemoglobin variants cause symptoms if the amino acid substitution occurs at a critical site within the molecule. Most mutations cause clinical signs of disease because the mutation affects the solubility, function (oxygen-affinity), and/or stability of the hemoglobin molecule.

Altered Solubility

If a nonpolar amino acid is substituted for a polar residue near the molecule's surface, the solubility of the hemoglobin molecule can be affected. Hemoglobin S and hemoglobin C are examples of this type of substitution. In the deoxygenated state, the HbS molecule polymerizes into insoluble, rigid aggregates. The majority of surface substitutions, however, do not affect the tertiary structure, heme function, or subunit interactions and are therefore innocuous.

Altered Function

Some amino acid substitutions can affect the oxygen affinity of hemoglobin by stabilizing heme iron in the ferric state, producing methemoglobin, which cannot combine with oxygen. Hemoglobins M and Chesapeake are examples. Mutations within the subunit interface, $\alpha_1\beta_2$, can affect the allosteric properties of the molecule leading to increased or decreased oxygen affinity. Considerable movement occurs at the $\alpha_1\beta_2$

contact region on oxygenation, which triggers these allosteric interactions. High oxygen-affinity hemoglobin variants produce congenital erythrocytosis whereas decreased oxygen-affinity variants produce pseudoanemia and cyanosis.

Altered Stability

Amino acid substitutions that reduce the stability of the hemoglobin tetramer result in *unstable hemoglobins*. The mutations usually disrupt hydrogen bonding or hydrophobic interactions that retain the heme component within the heme-binding pocket of the globin chain or that hold the tetramer together. The result is a weakening of the binding of heme to globin and detachment of the heme or the disruption of the integrity of hemoglobin's tetrameric structure. Consequently, hemoglobin denatures, aggregates, and precipitates as Heinz bodies. Clinically, the unstable variants are known as **congenital Heinz body hemolytic anemias**. In addition to altering the molecule's stability, disruption of normal conformation also can affect the molecule's function.

✓ Checkpoint! 3

The mutation in HbJ-Capetown, $\alpha 92$, Arg \rightarrow Gln, stabilizes hemoglobin in the R state. What functional effect does this have on the hemoglobin molecule?

▶ SICKLE CELL ANEMIA

Worldwide, sickle cell anemia is the most common symptomatic hemoglobinopathy with greatest prevalence in tropical Africa (Table 2). Gene frequency in equatorial Africa can exceed 20%. The sickle cell gene is also common in areas around the Mediterranean, the Middle East, India, Nepal, and in geographic regions in which there has been migration from endemic areas, such as North, Central, and South America.⁸ Sickle cell disease occurs in 0.3–1.3%, and sickle cell trait occurs in 8–10% of African Americans.

It is interesting to note that geographic areas with the highest frequency of sickle cell genes are also areas where infection with *Plasmodium falciparum* is common. This correlation strongly suggests that HbS in heterozygotes confers a selective advantage against fatal malarial infections, resulting in an increase in the gene frequency. Children with sickle cell trait are readily infected with the malarial parasite, but the parasite counts remain low. It has been suggested that resistance to malaria occurs because parasitized cells sickle more readily, leading to sequestration and phagocytosis of the infected cell by the spleen. Other, as yet undefined, factors can also contribute to reduced malarial susceptibility in individuals with HbS.⁹ Epidemiological data also suggest there could be similar selective advantages to HbE and HbC.⁸ Molecular evidence indicates that the identical sickle mutation arose in these geographic areas independently at least five times.

PATHOPHYSIOLOGY

Hemoglobin S is the mutant hemoglobin produced when nonpolar valine is substituted for polar glutamic acid at the seventh position in the A3 helix of the β -chain ($\beta 7$ [A3] Glu \rightarrow Val). (Older literature refers to the mutation at the sixth position because of confusion about numbering.) This substitution is on the surface of the molecule, producing a net decrease in negative charge; hence, it changes the molecule's electrophoretic mobility. The solubility of HbS in the deoxygenated state is markedly reduced, producing a tendency for deoxyhemoglobin S molecules to polymerize into rigid aggregates. Following polymerization, the cells assume a crescent shape. Polymerization is reversible on reoxygenation.

Polymerization is time dependent. A time delay occurs between deoxygenation and the formation of a significant amount of HbS polymers. It takes ~2–4 minutes for the development of significant polymerization and red cell distortion. The delay time for polymerization is important in considering the overall clinical consequences of HbS. Even though most red cells contain some sickle hemoglobin poly-

TABLE 2

Summary of the Most Common Hemoglobin Variants

Hb	Peripheral Blood	Electrophoresis	Mutation	Geographic Distribution
HbS	Normocytic, normochromic anemia; reticulocytosis; poikilocytosis with sickled and boat-shaped cells	Homozygous: HbS, F, A ₂ Heterozygous: HbA, S, F, A ₂	$\beta 7$ (A3)Glu \rightarrow Val	Tropical Africa and Mediterranean areas, Middle East, India, Nepal
HbE	Microcytic, hypochromic anemia; target cells	Homozygous: HbE, F, A ₂ Heterozygous: HbA, E, F, A ₂	$\beta 26$ (B8)Glu \rightarrow Lys	Burma, Thailand, Cambodia, Malaysia, Indonesia
HbC	Normocytic, normochromic anemia with reticulocytosis; poikilocytosis with folded, irregularly contracted cells; target cells	Homozygous: HbC, F, A ₂ Heterozygous: HbA, C, F, A ₂	$\beta 6$ (A3)Glu \rightarrow Lys	West Africa

mer at the oxygen concentration in venous blood, the majority of the cells do not sickle during their journey through the circulation because they reach the lungs and are reoxygenated before significant polymerization and cell distortion occurs. The length of delay depends highly on temperature, pH, ionic strength, and oxygen tension in the cell's environment. Hypoxia, acidosis, hypertonicity, and temperatures higher than 37°C promote deoxygenation and the formation of HbS polymers. The spleen, kidney, retina, and bone marrow provide a sufficiently hypoxic, acidotic, and hypertonic microenvironment to promote HbS polymerization and sickling.

Sickling (delay time) also depends on intracellular hemoglobin composition (the proportion of HbA, HbS, HbA₂, and HbF present) as well as total hemoglobin concentration (MCHC). Non-S hemoglobins increase the delay time for polymerization, presumably by interfering with the HbS polymerization process. The delay time is also inversely related to the total hemoglobin concentration. The more concentrated the hemoglobin solution within the cell (the higher the MCHC), the shorter is the delay time and the greater is the potential for HbS aggregates to form. Using this concept, attempts are made to treat the disease by hydrating the cells, which would decrease the MCHC and prevent sickling.

Polymerization of deoxyhemoglobin S begins when the oxygen saturation of hemoglobin falls below 85% and is generally complete at about 38% oxygen saturation. The HbS aggregates cause the erythrocyte to become rigid and less deformable. With repeated cycles of deoxygenation, polymerization, and sickling, disruption of cation homeostasis occurs, resulting in an increase in intracellular Ca²⁺ and loss of K⁺ and water from the cell. This cellular dehydration increases the MCHC (predisposing the cell to sickling on subsequent deoxygenation). In addition, the increased MCHC is associated with an increase in cytoplasmic viscosity and a decrease in cell deformability. HbS is also prone to oxidation. Oxidation of membrane proteins and lipids weakens critical skeletal associations. In addition, repeated sickling tends to decouple the lipid bilayer from the membrane skeleton, and loss of membrane phospholipid asymmetry occurs. The aggregates also damage the erythrocyte membrane directly, and with the weakened cytoskeleton, the cell's fragility increases.

Irreversibly Sickled Cells

The sickled erythrocyte can return to a normal biconcave shape upon reoxygenation of the hemoglobin; however, as described above, with repeated cycles of sickling, the erythrocyte membrane undergoes changes that cause it to become leaky and rigid. After repeated sickling episodes, the cells become **irreversibly sickled cells** (ISC), which are locked in a sickle shape whether oxygenated or deoxygenated (i.e., regardless of polymerization state of the hemoglobin molecules). This is due to abnormal interactions of red cell skeletal proteins, most likely caused by oxidative damage and increased Ca²⁺ concentrations. The ISC is the

result of permanent alterations of the submembrane skeletal lattice.¹⁰ From 5 to 50% of the circulating erythrocytes in sickle cell anemia are ISC. This varies from person to person but is relatively constant for a given individual. The ISC have a very high MCHC and a low MCV. They are ovoid or boat shaped with a smooth outline and lack the spicules characteristic of deoxygenated sickled cells.

The ISC are removed by mononuclear phagocytes in the spleen, liver, or bone marrow. ISC account for most, if not all, of the sickle forms on a peripheral blood smear (most reversible sickle cells regain a discocyte shape when the blood is exposed to air while making the slide). The ISC can also initiate or increase the severity of vaso-occlusive crises because of impaired cell deformability and increased cell adherence to vascular endothelium. The mechanism for this interaction between sickled cells and the endothelium is unclear but could be related to changes in the surface properties of sickled cells and endothelial cells as well as plasma factors.^{11,12}

Oxygen Affinity of HbS

The oxygen affinity of HbS differs from that of HbA, resulting in important physiologic changes in vivo. HbS has decreased oxygen affinity, and the 2,3-BPG level of homozygotes is increased. This decreased oxygen affinity, depicted by a shift to the right in the oxygen dissociation curve, facilitates the release of more oxygen to the tissues. However, this phenomenon increases the concentration of deoxyhemoglobin S, promoting the formation of sickle cells.

RBC Destruction

The primary cause of anemia in sickle cell anemia is extravascular hemolysis. Erythrocyte survival depends on intracellular HbF concentration and degree of membrane damage.¹³ Changes in the erythrocyte membrane resulting in increased fragility coupled with Heinz body formation from denatured HbS lead to increased membrane shedding (vesiculation), a decreased cell surface area, and the removal of the cell by the mononuclear phagocyte system.¹⁴ The life span of circulating HbS erythrocytes can decrease to as few as 14 days. The sluggish blood flow and the hypoglycemic, hypoxic environment of the spleen promotes HbS polymerization and sickling, further slowing blood circulation in the splenic cords and enhancing phagocytosis of erythrocytes containing HbS. Eventually, however, the spleen loses its functional capacity as repeated ischemic crises (see below) lead to splenic tissue necrosis and atrophy. With splenic atrophy, other cells of the mononuclear phagocyte system in the liver and bone marrow take over the destruction of these abnormal cells.

CLINICAL FINDINGS

The first clinical signs of sickle cell anemia appear at about 6 months of age when the concentration of HbS predominates over HbF. Clinical manifestations result from chronic

hemolytic anemia, vaso-occlusion of the microvasculature, overwhelming infections, and acute splenic sequestration.

Anemia

A moderate to severe chronic anemia as the result of extravascular hemolysis is characteristic of the disease. Gallstones, a complication of any chronic hemolytic disorder, are a common finding due to cholestasis and increased bilirubin turnover. Folate deficiency due to increased erythrocyte turnover can further exacerbate the anemia, producing megaloblastosis.

Hemodynamic changes occur in an attempt to compensate for the tissue oxygen deficit; as a result, symptoms of cardiac overload including cardiac hypertrophy, cardiac enlargement, and eventually congestive heart failure are frequent complications of the disease.

The hyperplastic bone marrow, secondary to chronic hemolysis, is accompanied by bone changes, such as thinning of cortices and a “hair-on-end” appearance in x-rays of the skull. Hyperplasia results from a futile attempt by the marrow to compensate for premature erythrocyte destruction. Conversely, **aplastic crises** can accompany or follow viral, bacterial, and mycoplasmal infections. This temporary cessation of erythropoiesis in the face of chronic hemolysis leads to an acute worsening of the anemia. The aplasia can last from a few days to a week and because of the significantly decreased red cell life span can induce a catastrophic fall in the hemoglobin concentration. Increasing evidence suggests that many cases of aplasia occur as a result of infection with human parvovirus B19. Parvovirus also causes a cessation of erythropoiesis in normal individuals, but with a normal RBC life span, normal blood cell production in these individuals is restored before any clinically significant changes in erythrocyte concentration take place.

Vaso-Occlusive Crisis

HbS cells are poorly deformable. Sickled cells have difficulty squeezing through small capillaries, and consequently, the rigid cells tend to aggregate in the microvasculature, increasing vascular stasis. Erythrocytes behind the blockage release their oxygen to the surrounding hypoxic tissue, deoxygenate, polymerize, and sickle, increasing the plug's size (Figure 1 ■). Erythrocytes from nearby capillaries are forced to give up more oxygen than they normally would to feed the oxygen-deprived tissue around the blockage. These cells then form rigid aggregates of deoxyhemoglobin S, expanding the blockaded region. If severe, lack of oxygen can cause local tissue necrosis. Vaso-occlusion occurs more often in tissues prone to vascular stasis (spleen, marrow, retina, kidney).

The blockage of the microvasculature by rigid sickled cells accounts for the majority of the clinical signs of sickle cell anemia. The occlusions do not occur continuously but sporadically, causing acute signs of distress. These episodes are called **vaso-occlusive crises** and are the most frequent causes of hospitalization. The crises can be triggered by in-

■ **FIGURE 1** How sickle cells block a vessel and precipitate a vaso-occlusive crisis.

fection, decreased atmospheric oxygen pressure, dehydration, or slow blood flow, but frequently they occur without any known cause. The occlusions are accompanied by pain, low-grade fever, organ dysfunction, and tissue necrosis. The episodes generally last for 4 to 5 days and subside spontaneously.

Recurrent occlusive episodes can lead to infarctions of tissue of the genitourinary tract, liver, bone, lung, and spleen. The chronic organ damage is accompanied by organ dysfunction. Although splenomegaly is present in early childhood, repeated splenic infarctions eventually result in splenic fibrosis and calcifications (usually by age 4 or 5). This organ damage, secondary to infarction, is known as **autosplenectomy**. As a result, splenomegaly is rare in adults with this disease. Aseptic necrosis of the head of the femur is common. Dactylitis, a painful symmetrical swelling of the hands and feet (hand-foot syndrome) caused by infarction of the metacarpals and metatarsals, is often the first sign of the disease in infants. Recurrent priapism is a characteristic, painful complication that occasionally requires surgical intervention.

The slow flow of blood in occlusive areas can lead to thrombosis. Thrombosis of the cerebral arteries resulting in stroke is common. Magnetic resonance imaging shows evidence of subclinical cerebral infarction in 20–30% of children with sickle cell anemia. If the arterioles of the eye are affected, blindness can occur. Chronic leg ulcers, found also in other hemolytic anemias, can occur at any age. The ulcers ap-

pear without any known injury. These painful sores do not readily respond to treatment and can take months to heal.

Placental infarctions in pregnant women with sickle cell disease can be a hazard to the fetus. Maternal anemia often becomes more severe during pregnancy. In addition, other clinical findings can be exacerbated during pregnancy, endangering the life of both the mother and the fetus.

Bacterial Infection

Overwhelming bacterial infection is a common cause of death in young patients. The risk of septicemia from encapsulated microorganisms, such as *Streptococcus pneumoniae* and *Hemophilus influenzae*, is extremely high. Bacterial pneumonia is the most common infection, but meningitis is also prevalent. The reasons for this increased susceptibility to infection are not fully understood but could be related to functional asplenia, impaired opsonization, and abnormal complement activation.¹⁵ The spleen is particularly important to host defense in the young. Significant impairment of in vivo neutrophil adherence to vascular endothelium in HbS disease also occurs. This could prevent neutrophils from rapidly relocating to areas of inflammation.¹⁵ Prophylactic penicillin is given to children with sickle cell anemia to reduce morbidity and mortality from infection, but compliance with therapy may not be optimal. The pneumococcal and *H. influenzae* type B vaccines protect patients from infections with *S. pneumoniae* and *H. influenzae*, reducing the incidence of infection in children with sickle cell disease. Children with sickle cell disease are also routinely immunized for hepatitis B.

Checkpoint! 4

Why do newborns with sickle cell anemia not experience episodes of vaso-occlusive crisis?

Acute Splenic Sequestration

In young children, sudden splenic pooling of sickled erythrocytes can cause a massive decrease in erythrocyte mass within a few hours (**sequestration crisis**). Thrombocytopenia can also occur. Hypovolemia and shock follow. At one time, this was the leading cause of death in infants with sickle cell anemia. Early diagnosis, instruction of parents in detecting an enlarging spleen, and rapid intervention with transfusion have decreased morbidity and mortality associated with splenic sequestration.

Acute Chest Syndrome

This illness resembling pneumonia is the most common cause of death in children with sickle cell disease and the second most common cause of hospitalization.¹⁶ Clinical findings include cough, fever, chest pain, dyspnea, chills, wheezing, and pulmonary infiltrates. Hemoglobin concentration and oxygen saturation decrease.¹⁷ The etiology of acute chest syndrome is not clear. In children, an infectious

agent can often be identified. Other possible causes include pulmonary edema from overhydration, fat embolism from infarcted bone marrow, and hypoventilation due to pain from rib infarcts or from narcotic analgesics used to combat pain. The long-term effects of recurrent episodes of acute chest syndrome are unknown.

CASE STUDY (continued from earlier in this chapter)

The chest radiograph showed consolidation in the left lower lobe, indicating that Shane has pneumonia.

5. What physiological conditions does Shane have that could lead to sickling of his erythrocytes?
6. What is the cause of Shane's pain and acute distress?
7. Why might Shane be more susceptible to pneumonia than an individual without sickle cell disease?

LABORATORY FINDINGS

Peripheral Blood

A normocytic, normochromic anemia is characteristic of sickle cell anemia; however, with marked reticulocytosis, the anemia can appear macrocytic (Figure 2■). Reticulocytosis from 10–20% is typical. The hemoglobin ranges from 60 to 100 g/L and the hematocrit from 0.18 to 0.30 L/L. A calculated hematocrit from an electronic cell counter is more reliable than a centrifuged microhematocrit because excessive plasma trapped by sickled cells in centrifuged specimens falsely elevates the manual hematocrit.

The Cooperative Study of Sickle Cell Disease revealed that individuals homozygous for HbS have higher steady-state leukocyte counts than do normal individuals, especially children less than 10 years of age.¹⁸ Platelet counts are also frequently higher than normal. After the age of 40, the hemoglobin concentration, reticulocyte count, leukocyte count, and platelet count decrease.¹⁹

■ **FIGURE 2** Hemoglobin S disease (sickle cell anemia). Note abnormal boat-shaped, sickled, and ovoid erythrocytes. (Peripheral blood; Wright-Giemsa stain; 1000× magnification)

The blood smear shows variable anisocytosis with polychromatophilic macrocytes and variable poikilocytosis with the presence of sickled cells and target cells. Nucleated erythrocytes can usually be found. The RDW is increased. During and following a hemolytic crisis, the RDW increases linearly with increases in reticulocytes.²⁰ If the patient is not experiencing a crisis, sickled cells might not be present.

In older children and adults, signs of splenic hypofunction are apparent on the peripheral blood smear with the presence of basophilic stippling, Howell-Jolly bodies, siderocytes, and poikilocytes.

CASE STUDY (continued from the previous page)

Admission laboratory data on Shane included:

WBC	$16.4 \times 10^9/L$
RBC	$2.5 \times 10^{12}/L$
HGB	78 g/L
Hct	0.24/L
PLT	$467 \times 10^9/L$

Differential: Segs 76%, bands 10%, lymphs 9%, monos 3%, eos 1%, basos 1%

RBC morphology: Sickle cells 3+, target cells 1+, ovalocytes 1+, polychromasia, 3 NRBC/100 WBCs, Howell-Jolly bodies

- Which of Shane's hematologic test results are consistent with a diagnosis of sickle cell anemia?
- What does the presence of polychromatophilic erythrocytes signify?
- Why is the absolute neutrophil count elevated?
- What is the significance of ovalocytes on the blood smear?
- What is the significance of Howell-Jolly bodies on the smear?

Bone Marrow

Bone marrow aspiration shows erythroid hyperplasia, reflecting the attempt of the bone marrow to compensate for chronic hemolysis. Erythrocyte production increases to 4–5 times normal. If the patient is deficient in folic acid, megaloblastosis can be seen. Iron stores are most often increased but can be diminished if hematuria is excessive. Bone marrow examination is not usually performed because it yields no definitive diagnostic information.

Hemoglobin Electrophoresis

The presence of HbS is confirmed by hemoglobin electrophoresis. Electrophoresis on cellulose acetate at pH 8.4 shows 85–100% HbS. HbF is usually not more than 15%. Higher levels of HbF (25–35%) can indicate compound heterozygosity for HbS and hereditary persistence of fetal hemoglobin. HbA₂ is normal. Newborns have 60–80% HbF with the remainder HbS. In infants less than 3 months of age with small amounts of HbS, electrophoresis on citrate agar

gel at pH 6.2 permits more reliable separation of HbF from both HbA and HbS. Citrate agar gel electrophoresis is also useful in separating HbD and HbG from HbS. Both of these nonsickling hemoglobins migrate with HbS on alkaline electrophoresis with paper or starch gel but migrate with HbA on agar gel electrophoresis at acid pH.

Solubility Test

The solubility test is a rapid test for detecting HbS in the heterozygous or homozygous state. In severe anemia, the amount of HbS can be too low to be accurately detected, and the procedure may need to be altered. This test should not be used as a screening test for newborns because of the low concentration of HbS in this age group. Unstable hemoglobins can give a false positive test if many Heinz bodies are present. Other rare hemoglobin variants (e.g., HbC Harlem, HbI) can also give positive tests. False positive tests can also occur with elevated plasma proteins and lipids.

Sickling Test

Another confirmatory test that is performed less often is the sodium metabisulfite slide test for sickling. This test is positive in both sickle cell anemia and sickle cell trait.

Other Diagnostic Tests

IEF in agar gels and HPLC can be used to identify abnormal hemoglobins such as HbS. Preferred methods for prenatal screening and diagnosis use DNA-based analysis (polymerase chain reaction) to detect point mutations in globin gene sequences.⁷ This DNA testing provides a genotype diagnosis and eliminates the need for later neonatal testing when the phenotype results can be inconclusive.

Other Laboratory Findings

Other laboratory findings are less specific. The hemolytic nature of the disease causes indirect bilirubin to increase, haptoglobin to decrease, and uric acid and serum lactic dehydrogenase (LD) to increase. Osmotic fragility can be decreased due to the presence of target cells. These tests offer no diagnostic information on sickle cell anemia but can be performed to evaluate complicating conditions.

CASE STUDY (continued from above)

The LD level was reported as 1260 U/L (Reference interval 75–200 U/L)

- What is the significance of Shane's elevated LD?

THERAPY

Preventive therapy is aimed at eliminating conditions known to precipitate vaso-occlusion, such as dehydration and infection. Transfusion of packed erythrocytes or whole

blood can be required in aplastic crises or splenic sequestration. Preoperative transfusion is helpful in preventing the complications of anesthesia-induced sickling. Long-term transfusion therapy can be useful in preventing complications of sickle cell anemia but is usually not required. This therapy is aimed at suppressing the formation of new HbS-containing RBC by the patient's bone marrow. Complications of chronic transfusion therapy include transmission of blood-borne diseases, alloimmunization, expense, inconvenience, and iron overload.

Various pharmacologic agents have been used to reduce intracellular sickling by increasing the level of HbF including hydroxyurea (HU), 5-azacytidine, and 5-aza 2'-deoxycytidine. Of these, HU has been tested most extensively and elevates HbF in most HbS-containing erythrocytes. Children and adults respond well to HU, experiencing fewer vaso-occlusive crises and hospitalizations. The most frequent side effects are neutropenia, reticulocytopenia, and thrombocytopenia. HU is a potential teratogen, so contraceptive precautions are recommended. HU does not seem to produce serious irreversible toxicity; however, long-term effects are unknown.⁶

Hematopoietic stem cell transplantation (SCT) affords the potential cure of sickle cell disease. Results of multicenter case series show disease-free survival rates ranging from 80 to 85% with the best outcomes obtained when children received stem cells from HLA-identical siblings. Risk of complications, including graft versus host disease and neurological problems, is high for patients with sickle cell disease undergoing SCT. Because of a wide range of heterogeneity in clinical severity of sickle cell disease, it is difficult to predict which patients will benefit from SCT. Furthermore, SCT is extremely expensive and can be beyond the financial means of many patients. Gene therapy, in which normal genes are inserted into a patient's defective stem cells and returned to the patient, also holds a promise of cure but is not feasible at this time. Progress toward finding a stable gene vector capable of expressing therapeutic levels of normal β -globin chains over time has been slow.^{21,22}

✓ Checkpoint! 5

Outline the treatment options for a patient with HbS disease, pneumonia, and vaso-occlusive crisis. Discuss how each would affect the patient's clinical condition.

SICKLE CELL TRAIT

Sickle cell trait is the heterozygous β^S state, and typically the patient has one normal β -gene and one β^S -gene ($\beta^A\beta^S$). Sickle cell trait is not as severe a disorder as sickle cell anemia because the presence of HbA or other non-S hemoglobins interferes with the process of HbS polymerization, preventing sickling under most physiologic conditions. However, sickle cell trait cells can sickle under very low oxygen tension (~15 torr). Although some hemoglobins other than HbS (especially HbC, HbD, and HbE) can be incorpo-

rated into the polymer of deoxyhemoglobin S, the presence of molecules of these hemoglobins intermixed with the molecules of HbS creates a weakened structure and decreases the degree of polymerization. Because HbA constitutes more than 50% of the total hemoglobin in these individuals, sickle cell trait has no clinical symptoms, and results of physical examination appear normal. However, sickle cell trait is important to diagnose because, statistically, one of four children born to parents each of whom has the trait will have sickle cell anemia and two of four will have the trait.

Complications of splenic infarction and renal papillary necrosis have occasionally been reported in affected individuals subjected to extreme and prolonged hypoxia such as after flying at high altitude in unpressurized aircraft or following general anesthesia.

Hematologic parameters are normal. No anemia or sickled cells are found in routine blood counts and differentials. Sickling can be induced with the sodium metabisulfite test, however, and the solubility test is also positive. Hemoglobin electrophoresis results show 50–65% HbA, 35–45% HbS, normal HbF, and normal or slightly increased HbA₂. If HbA constitutes less than 50% of the total hemoglobin in sickle cell trait, the patient is probably heterozygous for another hemoglobinopathy such as thalassemia.

✓ Checkpoint! 6

A child's parents both have sickle cell trait. The physician orders a hemoglobin electrophoresis on the child. Results of electrophoresis on cellulose acetate at pH 8.4 show 65% HbS, 30% HbA, 3% HbF, 2% HbA₂. Explain these results and suggest further testing that could help in diagnosis.

▶ HEMOGLOBIN C DISEASE

Hemoglobin C, the second hemoglobinopathy to be recognized, is the third most prevalent hemoglobin variant worldwide.⁸ The first cases of HbC were discovered in the heterozygous state with HbS; this is not surprising because both hemoglobinopathies are prevalent in the same geographic area. Hemoglobin C is found predominantly in West African blacks in whom the incidence of the trait can reach 17–28% of the population. From 2–3% of African Americans carry the trait, and 0.02% have the disease.

Hemoglobin C is produced when lysine is substituted for glutamic acid at the sixth position (A3) in the β -chain (β_6 [A3] Glu → Lys). Because the nonpolar lysine amino acid substitution is in the same β -chain position as the substitution for HbS, a decrease in hemoglobin solubility can be expected. Intraerythrocytic crystals of oxygenated HbC can be found in the red cells, especially in splenectomized individuals. HbF inhibits the formation of crystals. Crystal formation is enhanced when cells are dehydrated or in hypertonic solutions. Erythrocytes with crystals become rigid and are

trapped and destroyed in the spleen. Erythrocyte life span is decreased to 30–55 days.

Hemoglobin C disease (β^C/β^C) is usually asymptomatic, but patients occasionally experience joint and abdominal pain. In contrast to sickle cell anemia, the spleen is most often enlarged. Variable hemolysis results in a mild to moderate anemia.

The hemoglobin ranges from 80 to 120 g/L and the hematocrit from 0.25 to 0.35 L/L. The anemia is accompanied by a slight to moderate increase in reticulocytes. The stained blood smear contains small cells that appear to be folded and irregularly contracted as well as many target cells (Figure 3■). Intracellular hemoglobin crystals can be found if the smear has been dried slowly. Microspherocytes are occasionally present. Osmotic fragility can be decreased, especially in the presence of large numbers of target cells.

Hemoglobin electrophoresis on citrate agar gel at acid pH demonstrates more than 90% HbC with a slight increase in HbF (not more than 7%). On cellulose acetate at an alkaline pH, HbC migrates with HbA₂, HbE, and HbO-Arab. HbC can be separated from these other hemoglobins by agar gel electrophoresis at an acid pH.

Hemoglobin C trait (β^C/β^A) is asymptomatic. No hematologic abnormalities are produced except that target cells are noted on blood smears. Mild hypochromia can be present. About 60–70% of the hemoglobin is HbA and 30–40% is HbC. Higher levels of HbC and microcytosis are found when HbC is associated with β -thalassemia ($\beta^C/\beta^{\text{thal}}$) (Figure 4■).

Considerable heterogeneity occurs in the clinical and hematological features of HbC/ β^{thal} , depending on the particular β -thalassemia gene interacting with HbC. HbC/ β^+ thalassemia is characterized by mild anemia similar to that found in heterozygous β -thalassemia. (β^+ -thalassemia is characterized by a decrease in β -chain synthesis.) There is 65–80% HbC, 2–5% HbF, and the remainder is HbA. HbC/ β^0 thalassemia is characterized by more severe anemia and an

absence of HbA (β^0 -thalassemia is characterized by an absence of β -chain synthesis). Hemoglobin electrophoresis reveals only HbC, HbA₂, and HbF with HbF ranging from 3–10%.

▶ HEMOGLOBIN S/C DISEASE

In hemoglobin S/C disease, both β -chains are abnormal. One β -gene codes for β^S -chains, and the other gene codes for β^C -chains ($\beta^S\beta^C$), thus, HbA is absent. This double heterozygous state for HbS and HbC results in a disease less severe than homozygous HbS but more severe than homozygous HbC. The concentration of hemoglobin in individual erythrocytes (MCHC) is increased, and the concentration of HbS is more than in sickle cell trait (the percent of HbS is higher than that of HbC because the β^C -globin has a less negative charge than β^S -globin, thus, the cell does not form $\alpha\beta^C$ -dimers as readily as $\alpha\beta^S$ -dimers). The presence of HbC makes the HbS/C cells more prone to sickling than cells that contain HbA/HbS because HbC molecules participate in the polymerization process with HbS molecules more easily than do HbA molecules. Increased erythrocyte rigidity is noted at oxygen tensions less than 50 mm Hg. Additionally, cells containing HbS/C have formation of aggregates of intracellular HbC crystals.²³ Thus, in HbS/C disease, both sickling and crystal formation contribute to the pathophysiology of the disease.

The clinical signs and symptoms of the disease are similar to those of mild sickle cell anemia. Because of the poorly deformable red cells, patients can develop vaso-occlusive crises leading to the complications associated with this pathology. A notable difference from sickle cell anemia, however, is that in HbS/C disease, splenomegaly is prominent.

Mild to moderate normocytic, normochromic anemia is present. The hematocrit is usually above 0.25 L/L, and the hemoglobin concentration is between 100 and 140 g/L. The

■ **FIGURE 3** Hemoglobin C disease. Note the cell in the center with HbC crystal, target cells, and folded cells. (Peripheral blood; Wright-Giemsa stain; 1000× magnification)

■ **FIGURE 4** Hemoglobin C/ β -thalassemia. Note the microspherocytes and target cells. This patient had 94% HbC and 6% HbF. (Peripheral blood; Wright-Giemsa stain; 1000× magnification)

higher hemoglobin concentration does not necessarily mean that hemolysis is less severe than in sickle cell anemia; it could be that the higher oxygen affinity of HbS/C cells stimulates higher erythropoietin levels. Peripheral blood smears reveal a large number of target cells (up to 85%), folded cells, and boat-shaped cells but rarely sickled forms (Figure 5 ■). Typical HbC crystals are rarely found. Some erythrocytes contain a single eccentrically located, densely stained, round mass of hemoglobin that makes part of the cell appear empty. These cells have been referred to as *billiard-ball cells*.²³ Anisocytosis and poikilocytosis range from mild to severe. Small, dense, misshapen cells, some with crystals of various shapes jutting out at angles, have been referred to as *HbSC poikilocytes*.²⁴ Hemoglobin electrophoresis shows a higher concentration of HbS than HbC. HbF can be increased up to 7%. No HbA is found due to the absence of normal β -chains.

✓ Checkpoint! 7

What is the functional abnormality of HbC and HbS? Why do these two abnormal hemoglobins have the same altered functions?

▶ HEMOGLOBIN D

Hemoglobin D is due to several molecular variants of which the identical variants HbD Punjab and HbD Los Angeles (β 121 [GH4] Glu \rightarrow Gln) are the most common in African Americans (<0.02%). HbD migrates with HbS on hemoglobin electrophoresis at alkaline pH. However, the HbD molecules do not sickle and have normal solubility properties. The heterozygous and homozygous states are both asymptomatic. Although there are no hematologic abnormalities, the homozygous state occasionally has an increase in target cells and a decrease in osmotic fragility. Although rare, the compound heterozygous state of HbD with HbS exists. HbD molecules can interact with HbS molecules, producing aggre-

■ **FIGURE 5** Hemoglobin S/C disease. Notice the elongated cells and boat-shaped cells. The small contracted cells are typical of those seen in hemoglobin C disease. (Peripheral blood; Wright-Giemsa stain; 1000 \times magnification)

gates of deoxyhemoglobin (Figure 6 ■). This produces a relatively mild form of sickle cell anemia.

In homozygous HbD, electrophoresis on cellulose acetate at pH 8.4 demonstrates 95% HbD with the same electrophoretic mobility as HbS. Electrophoresis on citrate agar at pH 6.0 allows separation of HbS and HbD. At acid pH, HbD migrates with HbA.

✓ Checkpoint! 8

A 13-year-old black female had a routine physical. Her CBC was normal, but the differential revealed many target cells. Hemoglobin electrophoresis revealed a band that migrated like HbS on cellulose acetate at pH 8.4. Her hemoglobin solubility test was negative. Explain the results and suggest a follow-up test to determine a diagnosis.

▶ HEMOGLOBIN E

Hemoglobin E is the second most prevalent hemoglobinopathy worldwide.⁸ It is most often encountered in individuals from southeast Asia. The trait has reached frequencies of almost 50% in areas of Thailand. It is estimated that 15–30% of immigrants from southeast Asia in North America have HbE with the highest frequencies occurring in those from Cambodia and Laos. Although found mainly in Asians, the HbE trait can also occur in blacks.

Hemoglobin E is the result of a substitution of lysine for glutamic acid in the β -chain (β 26 [B8] Glu \rightarrow Lys). The hemoglobin is slightly unstable when subjected to oxidant stress. Also, the nucleotide substitution creates a potential new splicing sequence so that some of the mRNA can be improperly processed. As a result, synthesis of the abnormal

■ **FIGURE 6** A blood film from a patient with hemoglobin D/S. Homozygous HbD does not usually cause anemia, but when combined with HbS, it potentiates the aggregating of deoxyhemoglobin and sickling of erythrocytes, producing a mild sickle cell anemia. Notice the boat-shaped cells and target cells. (Peripheral blood; Wright-Giemsa stain; 1000 \times magnification)

β -chain is decreased and HbE trait and disease have some thalassemia-like characteristics including an increased ratio of α :non- α -chain synthesis and α -chain excess. The oxygen dissociation curve is shifted to the right, indicating that HbE has decreased oxygen affinity.

Homozygous HbE is characterized by the presence of a mild, asymptomatic, microcytic hypochromic anemia (similar to thalassemia) with decreased erythrocyte survival (Figure 7 ■). Target cells are prominent and osmotic fragility is decreased. Electrophoresis demonstrates mostly HbE (90% or more) with the remainder HbA₂ and HbF. On alkaline electrophoresis, HbE migrates with HbA₂, HbC, and HbO-Arab. On agar gel at an acid pH, HbE migrates with HbA.

HbE trait is asymptomatic, and hematologic parameters are normal except for slight microcytosis. Hemoglobin electrophoresis at alkaline pH shows about 35–45% HbE. The remainder is HbA with normal HbA₂ and HbF.

▶ HEMOGLOBIN E/THALASSEMIA

Compound heterozygosity for HbE and β -thalassemia causes a moderate to severe anemia similar to thalassemia. This is a common combination in people from southeast Asia in whom both genes have a high frequency. The most severe type (β^E/β^0 -thalassemia) reveals only HbE and HbF. The amount of HbE, however, is less than that expected for homozygous HbE, and the HbF is increased proportionately. A more moderate anemia can result if the β^+ -thalassemia gene is inherited with HbE. In this form of the disease, there are HbE, HbA, HbF, and HbA₂. The HbA, however, is less than would be expected in HbE trait, but the anemia is more severe. When the β -thalassemia gene is inherited with the β^E gene, the result is microcytic, hypochromic anemia with significant poikilocytosis and nucleated erythrocytes.

Hemoglobin E can also be found in combination with α -thalassemia (Figure 8 ■). This combination produces a

■ **FIGURE 7** A blood film from a patient with homozygous hemoglobin E (HbEE). Note the microcytosis and prominent target cells. (Peripheral blood; Wright-Giemsa stain; 1000 \times magnification)

■ **FIGURE 8** A blood film from a splenectomized patient with homozygous hemoglobin E and α -thalassemia. The erythrocytes are microcytic, hypochromic with many target cells and poikilocytosis. The patient was from southeast Asia and had a lifelong history of anemia. (Peripheral blood; Wright-Giemsa stain; 1000 \times magnification)

more severe anemia than does HbE alone. The amount of HbE depends on whether the patient is heterozygous or homozygous for HbE and which α -thalassemia genotype is inherited.

✓ Checkpoint! 9

The red cell morphology in HbE disease and β -thalassemia are similar: microcytic, hypochromic anemia with target cells. What laboratory test(s) could differentiate these two conditions?

▶ UNSTABLE HEMOGLOBIN VARIANTS

Unstable hemoglobins can result from structurally abnormal globin chains, and more than 130 unstable variants have been described. The abnormal chains contain amino acid mutations at critical internal portions of the chains, which affect the molecular stability.²⁵ The disorders are characterized by denaturation and precipitation of the abnormal hemoglobin in the form of Heinz bodies, causing cell rigidity, membrane damage, and subsequent erythrocyte hemolysis. Although hemoglobin denaturation and hemolysis can occur spontaneously, symptoms associated with acute hemolysis often occur only after drug administration, infection, or other events that change the hemoglobin molecule's normal environment. Those variants that cause symptoms are known collectively as *congenital Heinz body hemolytic anemias*.

PATHOPHYSIOLOGY

Most affected individuals with unstable hemoglobins are heterozygous. Most unstable hemoglobins are inherited as autosomal-dominant disorders, but a large number arise

from spontaneous mutations with no evidence of hemoglobin instability in parents or other family members.

Unstable hemoglobin variants can result from a variety of globin chain amino acid substitutions or deletions that disrupt the stability of the globin subunit or hemoglobin tetramer or the binding of heme to globin. Such mutations resulting in unstable hemoglobin variants include:

1. Mutation of a globin amino acid that is involved in contact with the heme group or that results in a tendency to dissociate heme from the abnormal globin chains
2. Replacement of nonpolar by polar amino acids at the interior of the molecule resulting in a distortion of the folding of the globin chain
3. Deletion or insertion of additional amino acids, particularly in the helical regions of the molecule, creating instability
4. Mutations of amino acids at intersubunit contacts (especially the α_1 - β_1 contact points), creating instability and a tendency to dissociate into monomers
5. Replacement of a hydrophobic residue with a more hydrophilic amino acid in the hydrophobic pocket, disrupting the conformation of the hydrophobic heme cleft

Unstable hemoglobin denatures and precipitates as Heinz bodies, which attach to the inner surface of the membrane, thereby decreasing cell deformability. The inclusions are pitted by macrophages in the spleen, leaving the cell with less hemoglobin and decreased membrane. This process leads to rigid cells and their premature destruction in the spleen.

In addition to altering the molecule's stability, disruption of the normal conformation also can affect the molecule's function. Many of the unstable hemoglobins also have altered oxygen affinity. If the amino acid substitution is strategically located to affect the oxygen-binding site, oxygen affinity can be increased or decreased. In addition, some unstable hemoglobin variants have a tendency to spontaneously oxidize to methemoglobin.

CLINICAL FINDINGS

Congenital hemolytic anemia indicative of an unstable hemoglobin disorder requires further investigation to establish a definitive diagnosis. Family history is extremely important in defining the hereditary nature of the disease. Patient history can also provide information about the nature of events such as infection or drug administration, that precipitate acute hemolytic episodes. The severity of the disorder can range from asymptomatic to a chronic severe hemolytic anemia.

The severity of the anemia depends on the degree of instability of the hemoglobin tetramer and the change, if any, in oxygen affinity. For example, Hb Köln is an unstable hemoglobin (β -chain mutation) that also demonstrates increased oxygen affinity. Hemoglobins with increased oxygen affinity (hemoglobin-oxygen dissociation curve is shifted

left) release less oxygen to the tissues which result in relatively higher levels of tissue hypoxia and of erythropoietin as well as higher hematocrits than expected relative to the severity of hemolysis. Conversely, unstable hemoglobins with decreased oxygen affinity (e.g., Hb Hammersmith) have a hemoglobin-oxygen dissociation curve that is shifted right, increasing the oxygen delivery to the tissues and allowing patients to function at a lower hematocrit. When the oxygen affinity of an unstable hemoglobin is decreased, the reticulocyte count is not increased as much as would be expected for the degree of anemia relative to an uncomplicated hemolytic anemia.

Most clinical findings occur as the result of increased erythrocyte hemolysis. Jaundice and splenomegaly are common when there is chronic extravascular hemolysis. Cyanosis can result from the formation of sulfhemoglobin and methemoglobin that accompanies hemoglobin denaturation. Weakness and jaundice frequently follow the administration of oxidant drugs, which increase the hemoglobin's instability. Acute hemolysis can also be accompanied by the excretion of dark urine due to the presence of dipyrroles in the urine.

LABORATORY FINDINGS

Peripheral Blood

The anemia of congenital Heinz body hemolytic anemia is usually normocytic and normochromic and occasionally has a slightly decreased MCH and MCHC because of the removal of Heinz bodies from erythrocytes and loss of hemoglobin in the spleen. The reticulocyte count is typically increased. The blood film can show basophilic stippling, pitted cells (bite cells), and small contracted cells. Osmotic fragility is usually abnormal after 24 hours of incubation.

If splenic function is efficient, Heinz bodies are not detectable in peripheral blood cells. Heinz bodies can be found in the peripheral blood following splenectomy; however, this finding is not specific for unstable hemoglobin disorders. Heinz bodies can also be seen in erythrocyte enzyme abnormalities that permit oxidation of hemoglobin, in thalassemia, and after administration of oxidant drugs in normal individuals. Heinz bodies of unstable hemoglobins can be generated *in vitro* by incubation of the erythrocytes with brilliant cresyl blue or other redox agents. These intracellular inclusions cannot be observed on smears stained with Wright's stain.

Other Laboratory Findings

Many unstable hemoglobins identified to date have the same charge and electrophoretic mobility as normal hemoglobin. Only about 45% can be diagnosed by electrophoresis. Hemoglobin A₂ and HbF are sometimes increased, which could provide a clue to the presence of an abnormal hemoglobin when it is not detected by its electrophoretic pattern.

Diagnosis usually depends on the demonstration of the presence of an unstable hemoglobin (i.e., one that precipitates more readily than normal hemoglobin). The heat instability

test (heating a hemoglobin solution to 50°C) is always positive in unstable hemoglobin disorders. The unstable hemoglobin is also precipitated within 20 minutes in the isopropanol (17% by volume) precipitation test. Normal hemoglobin remains in solution 30–40 minutes.

✓ Checkpoint! 10

- Explain why patients with an unstable hemoglobin variant usually experience acute hemolysis only after administration of certain drugs or with infections.
- A patient is suspected of having a congenital Heinz body hemolytic anemia but hemoglobin electrophoresis is normal. Why is it necessary to perform additional tests?

THERAPY

Many patients with these disorders do not require any therapy. Splenectomy can be performed if hemolysis is severe. Patients are advised to avoid oxidizing drugs, which can precipitate a hemolytic episode.

▶ HEMOGLOBIN VARIANTS WITH ALTERED OXYGEN AFFINITY

Amino acid substitutions in the globin chains close to the heme pocket can affect the hemoglobin's ability to carry oxygen by preventing heme from binding to the globin chain or by stabilizing iron in the oxidized ferric state. Other substitutions that affect oxygen affinity include substitutions near the $\alpha_1\beta_2$ contacts, substitutions at the C terminal end of the β -chain, and substitutions near the 2,3-BPG binding site. These are critical sites involved in the allosteric properties of hemoglobin and/or in the physiologic regulation of hemoglobin affinity for oxygen. Either the α - or β -chain can be affected, but most substitutions are associated with the β -chain. Hemoglobinopathies causing perma-

nent methemoglobin formation are associated with pseudocyanosis while cyanosis characterizes hemoglobins with decreased oxygen affinity. Increased oxygen affinity results in congenital erythrocytosis, a compensatory mechanism for the reduced release of oxygen to the tissues.

METHEMOGLOBINEMIAS

Methemoglobin is hemoglobin with iron oxidized to the ferric state, which cannot carry oxygen. The amount of methemoglobin produced under normal physiologic conditions is maintained at concentrations less than 1% through the NADH-dependent enzyme, methemoglobin reductase. This system is capable of reducing methemoglobin to deoxyhemoglobin at a rate 250 times the rate at which heme is normally oxidized.

Methemoglobinemia is a clinical condition that occurs when methemoglobin encompasses more than 1% of the hemoglobin. This condition can occur when the methemoglobin reductase system is overwhelmed (acquired) or deficient (congenital) and when a structurally abnormal globin chain results in increased formation of methemoglobin by rendering the molecule relatively resistant to reduction by methemoglobin reductase (congenital) (Table 3 🌟).

Acquired methemoglobinemia can occur in normal individuals when drugs or other toxic substances oxidize hemoglobin in circulation at a rate that exceeds the reducing capacity of the methemoglobin reductase system.

Congenital methemoglobinemia can be inherited as a dominant or recessive characteristic. Recessive inheritance is usually associated with a defect in the methemoglobin reduction system, NADH diaphorase (NADH reductase, dehydrogenase) deficiency rather than with an alteration in the structure of the hemoglobin molecule. With defects in the methemoglobin reduction system, the small amount of methemoglobin formed daily cannot be reduced and consequently accumulates within the cell. Dominant inheritance of methemoglobinemia is usually ascribed to the presence of a structural variant of hemoglobin called *hemoglobin M*

🌟 TABLE 3

Causes and Characteristics of Methemoglobinemia

Type	Cause	Electrophoretic Pattern	NADH-Diaphorase Activity	Reduction with Methylene Blue
Acquired	Hb oxidized at a rate exceeding capacity of methemoglobin reductase system	Normal	Normal	Yes
Congenital				
Recessive	Defect in methemoglobin reductase system (recessive)	Normal	Decreased	Yes
Dominant	Structural abnormality of hemoglobin (HbM) (dominant)	HbM variant	Normal	No

(HbM). Nine variants of HbM have been described; however, all variants have been found only in the heterozygous state.

Most HbM variants are produced by a tyrosine substitution for the proximal or distal histidine in the heme pocket of the α - or β -chains. Tyrosine forms a covalent link with heme iron, stabilizing the iron in the ferric state. The stabilized, oxidized iron is relatively resistant to reduction by the methemoglobin reductase pathway. If the substitution occurs in the α -chain, cyanosis (or actually pseudocyanosis) is present from birth because the α -chain is a component of HbF ($\alpha_2\gamma_2$), the major hemoglobin at birth. If the substitution occurs in the β -chain, cyanosis does not occur until about the sixth month after birth when HbA ($\alpha_2\beta_2$) becomes the major hemoglobin. The presence of methemoglobin imparts a brownish color to the blood. Except for this abnormal color, no other hematologic abnormality is present because methemoglobin levels are rarely higher than 30%. Patients with methemoglobinemia appear to be cyanotic, but unlike truly cyanotic people, arterial blood pO_2 levels are usually normal (i.e., pseudocyanosis).

Hemoglobin M will not always separate from HbA at an alkaline pH. Hemoglobin electrophoresis on agar gel at pH 7.1 of a blood sample containing HbM reveals a brown band (HbM) running anodal to a red band (HbA). The pattern can appear sharper with gel electrofocusing. Oxidizing the erythrocyte hemolysate with ferricyanide before electrophoresis reveals a sharp separation of congenital HbM and methemoglobin formed from HbA. Methemoglobin formed from HbA by oxidation of iron has no change in molecular charge and therefore has the same electrophoretic mobility as HbA.

Although HbM can be detected by spectral abnormalities of the hemoglobin (absorption peaks at ~ 630 and 502 nm), methemoglobin formed in NADH-diaphorase deficiency has a normal absorption spectrum. In addition, methemoglobin formed as the result of NADH-diaphorase deficiency can be readily reduced by incubation of blood with methylene blue whereas methemoglobin caused by a structural hemoglobin variant such as HbM does not reduce with the methylene blue. To confirm NADH-diaphorase deficiency, a quantitative assay of the enzyme activity is necessary.

Congenital methemoglobinemia resulting from NADH-diaphorase deficiency and acquired toxic methemoglobinemia can be treated by administering ascorbic acid or methylene blue. Conversely, no treatment for the HbM structural variants exists because the abnormal hemoglobin resists reduction. However, most patients are asymptomatic and require no management. Most patients have methemoglobin levels $<30\%$, below the level at which symptoms of oxygen deprivation occur.

DECREASED OXYGEN AFFINITY

Low oxygen-affinity hemoglobins result from mutations that stabilize or favor the deoxygenated (T) conformation of the hemoglobin molecule or destabilize the oxygenated (R) form. These mutations impair oxygen binding or reduce

heme-heme subunit interactions (cooperativity). Low oxygen affinity hemoglobins are often associated with mutations involving the $\alpha_1\beta_2$ contact points, which are involved in intramolecular movement as hemoglobin goes from the oxy (R) to the deoxy (T) state. The low-affinity variants result in a right-shifted oxygen dissociation curve.

Most low oxygen-affinity hemoglobins possess enough oxygen affinity to become fully saturated in the lungs but at the capillary PO_2 in the peripheral tissues deliver higher than normal amounts of oxygen (i.e., become more unsaturated). Two physiologic effects result:

- Because oxygen delivery is so efficient, oxygen requirements of the tissues can be met by lower than normal hematocrits, producing a pseudoanemia (hematocrits lower than “normal”).
- The amount of deoxygenated hemoglobin in the capillaries and veins is increased, resulting in a cyanosis. However, no adverse clinical effect is associated with this cyanosis. Patients are asymptomatic and require no treatment. Diagnosis requires determining the P_{50} (the PO_2 at which hemoglobin is 50% saturated).

INCREASED OXYGEN AFFINITY

High-affinity hemoglobins are inherited as autosomal dominant traits. All such hemoglobins discovered have been in the heterozygous state. The variants also result from amino acid substitutions that involve the $\alpha_1\beta_2$ contacts. Mutations alter the quaternary structure of hemoglobin to favor the R (oxy) state by either stabilizing this conformation or destabilizing the T (deoxy) state. Other substitutions affect the C-terminal end of the β -chain, which is important in maintaining the stability of the T form. A few substitutions affect the 2,3-BPG binding sites, which alter oxygen affinity when bound to hemoglobin.

The high-affinity hemoglobins bind oxygen more readily than normal and retain more oxygen at lower PO_2 levels, which results in a shift to the left of the oxygen dissociation curve. The P_{50} of the hemoglobin is decreased to 12–18 mm Hg, meaning less oxygen is released to tissues at the tissue PO_2 of ~ 26 mm Hg. The resulting tissue hypoxia stimulates erythropoietin release and, subsequently, formation of a compensatory increased erythrocyte mass. In addition to the primary effect of increasing oxygen affinity, secondary effects of the mutations can also occur, including hemoglobin instability, reduced Bohr effect, and reduced cooperativity of the oxygen binding.²⁶

Erythrocyte counts and hematocrit levels are increased, and hemoglobin levels are increased to about 200 g/L. Other hematologic parameters are normal. About half of the hemoglobin variants have an altered electrophoretic mobility-enabling diagnosis by starch gel or cellulose acetate electrophoresis. Diagnosis is established by measuring oxygen affinity (determining the P_{50} of the patient's hemoglobin).

Individuals with these hemoglobin variants are asymptomatic. A ruddy complexion is occasionally apparent as a

result of the erythrocytosis. The importance of identifying the presence of a high-affinity hemoglobin is for the differential diagnosis of other causes of erythrocytosis and the avoidance of unnecessary and expensive diagnostic and therapeutic interventions.

✓ Checkpoint! 11

Why should red cell enzyme assays and hemoglobin electrophoresis both be performed on a patient with congenital cyanosis?

SUMMARY

The hemoglobinopathies are a group of chronic hemolytic anemias caused by either qualitative or quantitative defects in the globin chains of hemoglobin.

Qualitative defects are due to genetic mutations that cause a structural change in the globin chain. Although the mutation can affect any of the globin chain classes, most clinically significant mutations affect the β -chain. The mutation can affect the hemoglobin molecule's solubility, stability, or oxygen affinity. Hemoglobin electrophoresis can be used to detect those mutants in which amino acid mutations cause a change in the hemoglobin molecule's electrophoretic mobility. However, not all variants can be detected by electrophoresis. Other tests detect alterations in hemoglobin solubility and/or stability or oxygen affinity. Molecular techniques are

available to help definitively diagnose hemoglobinopathies but are not always necessary for routine diagnostic purposes.

In the United States, the most common structural variants are HbS and HbC. Both are characterized by decreased hemoglobin solubility and can be detected electrophoretically. Hemoglobin S has decreased solubility when deoxygenated, forming rigid aggregates and reduced erythrocyte deformability. The rigid cells aggregate in the microvasculature, resulting in tissue hypoxia. In HbC disease, the erythrocytes become trapped and destroyed in the spleen when intracellular crystals of HbC form. Generally, these variants produce a normocytic, normochromic anemia with anisocytosis and poikilocytosis characteristic for the specific hemoglobinopathy. The blood smear in HbS disease can show sickled forms and target cells. In HbC disease, there are numerous target cells and irregularly contracted cells and the erythrocytes occasionally contain HbC crystals. In the United States, both HbS and HbC are found in highest frequency among African Americans. Hemoglobin E is especially prevalent in people from southeast Asia and is characterized by a mild, asymptomatic microcytic anemia in the homozygous form.

Unstable hemoglobin variants are known as *congenital Heinz body hemolytic anemias*. The hemoglobin denatures in the form of Heinz bodies, decreasing cell deformability and resulting in membrane damage and premature destruction. Hemoglobin variants with increased or decreased oxygen affinity can result in erythrocytosis or cyanosis, respectively. Hemoglobin variants resulting in methemoglobin formation are associated with pseudocyanosis.

REVIEW QUESTIONS

LEVEL I

- Which ethnic group has the lowest incidence of hemoglobinopathies? (Objective 4)
 - African Americans
 - Caucasian Americans
 - immigrants from southeast Asia
 - immigrants from the Mediterranean basin
- The most common clinical disorder resulting from an amino acid substitution in the globin chain is: (Objectives 4, 5)
 - sickle cell disease
 - hemoglobin C disease
 - thalassemia
 - hemoglobin E disease
- Hemoglobinopathies are clinical diseases that result from genetically determined abnormalities of the hemoglobin molecule and include those involving: (Objective 1)
 - heme structure
 - decreased heme synthesis
 - globin chain structure
 - reduced globin chain synthesis
 - 1 and 3 only
 - 1 and 2 only
 - 3 and 4 only
 - all of the above

LEVEL II

- Rank the following hemoglobinopathies on the basis of quantity of HbS starting with the lowest amount. (Objective 1)
 - adult with sickle cell disease
 - adult with sickle cell trait
 - neonate with sickle cell disease
 - 3, 2, 1
 - 2, 3, 1
 - 1, 2, 3
 - 2, 1, 3
- Rank the following hemoglobinopathies in terms of worldwide prevalence, starting with the most common. (Objective 2)
 - HbE
 - HbS
 - HbC
 - 3, 1, 2
 - 1, 2, 3
 - 2, 3, 1
 - 2, 1, 3
- HbS is an example of a hemoglobin with a globin chain mutation that alters hemoglobin: (Objective 3)
 - function
 - solubility
 - stability
 - oxygen binding

REVIEW QUESTIONS (continued)

LEVEL I

4. Amino acid substitutions on globin chains often alter the hemoglobin molecule's charge and mobility. This is the principle of which test for identifying hemoglobins? (Objective 3)
 - a. HbA₂ quantitation
 - b. HbF quantitation
 - c. hemoglobin electrophoresis
 - d. solubility test
5. The defect resulting in production of HbC is: (Objective 5)
 - a. $\beta 6$ (A3) Glu \rightarrow Val
 - b. $\beta 6$ (A3) Glu \rightarrow Lys
 - c. $\beta 121$ (GH4) Glu \rightarrow Gly
 - d. $\beta 26$ (B8) Glu \rightarrow Lys
6. Tests that quantitate HbF and HbA₂ are useful in detecting hemoglobinopathies because: (Objective 6)
 - a. they are the only valid tests available for this purpose
 - b. they are routinely performed in most laboratories
 - c. HbF and HbA₂ are typically decreased in hemoglobinopathies
 - d. HbF and HbA₂ are typically increased in hemoglobinopathies
7. The presence of many sickled erythrocytes on a peripheral blood smear is most likely to be found in a person who is: (Objective 7)
 - a. heterozygous for HbC
 - b. homozygous for HbC
 - c. heterozygous for HbS
 - d. homozygous for HbS
8. Clinical findings for persons with sickle cell trait typically include: (Objective 8)
 - a. mild to moderate anemia
 - b. rare complications after exposure to prolonged hypoxia
 - c. increased susceptibility to infection
 - d. aplastic crisis
9. Synthesis of abnormal hemoglobins is the result of: (Objective 2)
 - a. genetic defects that result in amino acid substitutions in globin chains
 - b. genetic defects in genes that code for erythrocyte enzymes
 - c. presence of toxins (i.e., lead) during hemoglobin synthesis
 - d. genetic defects that result in abnormal synthesis of heme
10. A hemoglobin electrophoresis showed 45% HbS, 46% HbC, 6% HbF, and 3% HbA₂. These results are consistent with a diagnosis of: (Objective 7)
 - a. sickle cell anemia
 - b. sickle cell trait
 - c. hemoglobin S/C disease
 - d. hemoglobin C trait

LEVEL II

4. Anemia develops in persons with sickle cell disease because: (Objective 4)
 - a. the production of erythroid precursors is impaired.
 - b. antibodies coat the erythrocyte membrane leading to cell lysis.
 - c. erythrocytes have a greatly shortened life span.
 - d. marrow stem cells are inhibited or crowded out.
5. Cells containing large amounts of HbS sickle when the following conditions occur: (Objective 4)
 - a. high oxygen tension and acidosis
 - b. hypoxia and alkalosis
 - c. temperatures less than 37°C and alkalosis
 - d. temperatures greater than 37°C and hypoxia
6. Infants with sickle cell disease typically do not become symptomatic until 6 months of age. How can this be explained? (Objective 4)
 - a. Environmental conditions conducive to sickling are not experienced by infants.
 - b. Physical examinations are not sufficiently sensitive with infants.
 - c. The immature infant spleen is incapable of extravascular hemolysis.
 - d. The concentration of HbF predominates over HbS.
7. Hydroxyurea therapy for sickle cell disease is used to: (Objective 6)
 - a. increase the level of HbF within erythrocytes
 - b. decrease the production of mutated globin chains
 - c. increase the pH of the blood
 - d. decrease the risk of bacterial infection
8. A hemoglobin electrophoresis on cellulose acetate at pH 8.5 is performed on a 2-year-old African American patient with severe anemia. An abnormal band appears halfway between the HbA and HbA₂ positions on the strip. The HbF level is 10%, and the HbA₂ level is normal. No HbA is present. What is the most likely identity of the abnormal hemoglobin? (Objective 7)
 - a. HbC
 - b. HbS
 - c. HbD
 - d. HbE
9. The presence of HbE disease in an adult is best confirmed using which routine laboratory test? (Objective 8)
 - a. hemoglobin electrophoresis
 - b. the CBC and peripheral blood smear
 - c. solubility test
 - d. PCR for molecular defect

REVIEW QUESTIONS (continued)

LEVEL I

LEVEL II

10. When amino acid substitutions or deletions disrupt the stability of the globin subunit or hemoglobin tetramer, a likely consequence is production of a hemoglobin: (Objective 11)
 - a. with altered solubility
 - b. that tends to form crystals
 - c. that can result in the formation of Heinz bodies
 - d. that is composed of only alpha globin chains

ANSWERS TO CASE STUDY QUESTIONS

Case Summary: Shane, previously diagnosed with a hemoglobinopathy, was admitted to the hospital with symptoms of vaso-occlusive crisis. Testing revealed he had pneumonia and sickle cell disease. The infection was probably responsible for precipitating the crisis.

Question:

1. Identify a laboratory test needed to determine Shane's hemoglobinopathy.

Explanation:

Hemoglobin electrophoresis is needed to identify a hemoglobinopathy. HPLC may be done to quickly identify the percentage of HbS.

Question:

2. What is the abnormal hemoglobin causing this Shane's disease?

Explanation:

HbS.

Question:

3. Is Shane heterozygous or homozygous for the disorder?

Explanation:

We can assume that the patient is homozygous because of the very high concentration of HbS present and lack of HbA.

Question:

4. What is this disorder called?

Explanation:

This disorder is referred to as *sickle cell disease* or *sickle cell anemia*.

Question:

5. What physiological condition does Shane have that could lead to sickling of his erythrocytes?

Explanation:

This patient has fever, suggesting infection or inflammation. The chest radiograph indicated pneumonia. It is possible that the infection is causing hypoxia and other physiological alterations that promote sickling.

Question:

6. What is the cause of this Shane's pain and acute distress?

Explanation:

The patient is experiencing a vaso-occlusive crisis as a result of sickling of erythrocytes in the microvasculature. (Physicians refer to this as a "pain crisis.") It is possible he is also experiencing acute chest syndrome.

Question:

7. Why might Shane be more susceptible to pneumonia than an individual without sickle cell disease?

Explanation:

It is likely that he has functional asplenia as a result of repeated sickling episodes in the spleen. Without a functioning spleen, he is more susceptible to certain bacterial infections. Often sickle cell patients are treated with prophylactic antibiotics to prevent infections.

Question:

8. Which of Shane's hematologic test results are consistent with a diagnosis of sickle cell anemia?

Explanation:

His hemoglobin is markedly reduced and in the range typically seen in sickle cell disease. Also, leukocytes and platelets are increased, which are common findings. The presence of sickle cells and other findings on the blood smear are all consistent with a diagnosis of sickle cell disease.

Question:

9. What does the presence of polychromatophilic erythrocytes signify?

Explanation:

Polychromatophilic erythrocytes are actually reticulocytes. This indicates that the bone marrow is attempting to compensate for the deficit of erythrocytes in the peripheral blood by releasing these slightly immature cells.

Question:

10. Why is the absolute neutrophil count elevated?

Explanation:

Bacterial infection is associated with neutrophilia.

Question:

11. What is the significance of ovalocytes on the blood smear?

Explanation:

These cells are probably irreversibly sickled cells.

Question:

12. What is the significance of Howell-Jolly bodies on the smear?

Explanation:

The patient's spleen is not functional and is incapable of removing these inclusions from the erythrocytes.

Question:

13. What is the significance of Shane's elevated LD?

Explanation:

Lactic dehydrogenase is an enzyme found in high concentration in erythrocytes. Elevated LD levels are associated with increased hemolysis of erythrocytes, a typical finding in sickle cell disease.

ANSWERS TO CHECKPOINTS

Checkpoint! 1

Why can't all structural hemoglobin variants be identified by hemoglobin electrophoresis?

Answer

Not all point mutations in the hemoglobin molecule change its electrical charge. If the charge is not changed, the variant hemoglobin will travel as a normal hemoglobin.

Checkpoint! 2

What is meant by the term silent carrier when referring to a hemoglobinopathy?

Answer

The patient has an abnormal hemoglobin but it does not cause any symptoms of disease.

Checkpoint! 3

What functional effect would this have on the hemoglobin molecule?

Answer

It increases oxygen affinity. The R structure is the oxygenated form of hemoglobin while the T form is the deoxygenated form.

Checkpoint! 4

Why don't newborns with sickle cell anemia experience episodes of vaso-occlusive crisis?

Answer

The predominant hemoglobin in newborns is HbF, which does not sickle. HbS does not become the predominant hemoglobin until after the first 6 months of life.

Checkpoint! 5

Outline the treatment options that might be used for a patient with HbS disease, pneumonia, and vaso-occlusive crisis. Discuss how each would affect his clinical condition.

Answer

In the short term, the patient's pain would be managed and he would be hydrated. He would be given antibiotics and respiratory therapy for the pneumonia. Long-term therapy might include transfusions to reduce symptoms of anemia. He might be placed on hydroxyurea therapy to increase the amount of HbF, thus reducing the frequency of vaso-occlusive crises. If he has not suffered severe organ damage and a compatible donor can be found, he might be a candidate for bone marrow transplant to correct the genetic defect—causing sickle cell disease.

Checkpoint! 6

Explain these results and suggest further testing that may help in diagnosis.

Answer

In sickle cell trait, the amount of HbS is usually less than 50% while in sickle cell anemia, it is typically >90%. The presence of some

HbA suggests sickle cell trait in this patient. The patient may have inherited another abnormal hemoglobin gene such as thalassemia. Electrophoresis at acid pH should be performed to eliminate the possibility of hemoglobins with similar mobilities at alkaline pH. DNA testing may provide evidence of thalassemia. A microcytic hypochromic anemia is also a clue to the presence of thalassemia.

Checkpoint! 7

What is the functional abnormality of HbC and HbS? Why do these two abnormal hemoglobins have the same altered functions?

Answer

The HbS and HbC have decreased solubility and tend to crystallize. They both have a point mutation in the $\beta 6$ position where a nonpolar amino acid replaces glutamine.

Checkpoint! 8

Explain the results and suggest a follow-up test to determine a diagnosis.

Answer

The patient may have another abnormal hemoglobin that migrates similar to HbS. Electrophoresis on citrate agar at pH 6.0 should be performed to allow distinction of this hemoglobin from HbS.

Checkpoint! 9

What laboratory test might differentiate these two conditions?

Answer

Hemoglobin electrophoresis. HbE shows an abnormal band, but β -thalassemia has no abnormal hemoglobins present.

Checkpoint! 10

- Explain why patients with an unstable hemoglobin variant usually experience acute hemolysis only after administration of certain drugs or with infections.*
- If a patient is suspected of having a congenital Heinz body hemolytic anemia but hemoglobin electrophoresis is normal, why is it necessary to perform additional tests?*

Answer

- The hemoglobin becomes unstable when the normal red blood cell environment changes to a more acidic or hypoxic environment.
- The abnormal hemoglobin may have an electrophoretic mobility identical to that of normal hemoglobin, thereby masking the presence of the abnormal hemoglobin.

Checkpoint! 11

Why should red cell enzymes be measured and hemoglobin electrophoresis be performed on a patient with congenital cyanosis?

Answer

The defect may be due either to inheritance of HbM, which could be detected by hemoglobin electrophoresis or to a defect in the methemoglobin reduction system, which can be detected by enzyme analysis.

Thalassemia

Tim R. Randolph, Ph.D.

■ OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. Define *thalassemia*.
2. Differentiate thalassemias from hemoglobinopathies based on definition and basic pathophysiology.
3. Describe the typical peripheral blood morphology associated with thalassemia.
4. Compare and contrast the etiology of α - and β -thalassemia.
5. For each of the four genotypes of α -thalassemia describe the:
 - a. Number of affected alleles
 - b. Individuals affected
 - c. Basic pathophysiology
 - d. Symptoms
 - e. Laboratory results including blood cell morphology and hemoglobin electrophoresis
6. For each of the six genotypes of β -thalassemia describe the:
 - a. Individuals affected
 - b. Basic pathophysiology
 - c. Symptoms
 - d. Laboratory results including blood cell morphology and hemoglobin electrophoresis

■ OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. List and describe five genetic defects found in thalassemias.
2. Compare and contrast α - and β -thalassemia
3. Correlate the outcomes in hemoglobin synthesis resulting from the five genetic defects in thalassemia.
4. For all four genotypes of α -thalassemia:
 - a. Correlate all three nomenclature systems: genotype, genotype description, and phenotype.
 - b. Explain advanced pathophysiology.
 - c. Describe treatment and prognosis.

CHAPTER OUTLINE

- ▶ Objectives—Level I and Level II
- ▶ Key terms
- ▶ Background basics
- ▶ Case study
- ▶ Overview
- ▶ Introduction
- ▶ α -thalassemia
- ▶ β -thalassemia
- ▶ Other thalassemias and thalassemia-like conditions
- ▶ Differential diagnosis of thalassemia
- ▶ Summary
- ▶ Review questions
- ▶ References

■ OBJECTIVES—LEVEL II (continued)

5. For all four phenotypes of β -thalassemia
 - a. List expected genotypes.
 - b. Explain advanced pathophysiology.
 - c. Describe treatment and prognosis.
6. Correlate clinical severities of both α - and β -thalassemia with their respective genotypes.
7. Compare and contrast other thalassemia and thalassemia-like conditions to include:
 - a. $\delta\beta$ -thalassemia
 - b. $\gamma\delta\beta$ -thalassemia
 - c. Hemoglobin Constant Spring
 - d. Hereditary persistence of fetal hemoglobin (HPFH)
 - e. Hemoglobin Lepore
 - f. Thalassemia/hemoglobinopathy combination disorders
8. Differentiate iron deficiency anemia and HPFH from thalassemia based on results of laboratory tests and clinical findings.

BACKGROUND BASICS

The information in this chapter builds on concepts presented in previous chapters. To maximize your learning experience, you should review the following concepts before beginning this unit of study.

Level I

- ▶ Describe the pathophysiology of hemoglobinopathies.
- ▶ Describe the morphologic and functional classification of anemias and the associated lab tests.
- ▶ Interpret routine laboratory tests, such as CBC and differential, and apply both normal and abnormal results in the diagnosis of anemias.
- ▶ Describe the basic structure and function of hemoglobin and identify the globin chain composition of normal hemoglobin types.
- ▶ Describe the extravascular destruction of erythrocytes.

Level II

- ▶ Summarize the synthesis and molecular structure of hemoglobin and correlate alterations in structure with function; describe globin chain synthesis in utero and throughout life.
- ▶ Interpret hemoglobin migration patterns on electrophoresis, acid elution of fetal hemoglobins, hemoglobin solubility tests, and iron panels to distinguish iron metabolism disorders and hemoglobinopathies from thalassemias.

CASE STUDY

We will refer to this case throughout the chapter.

John is a 4-year-old boy who frequently complains of weakness, fatigue, and dyspnea. The family moved to the United States from Greece before the child's birth. Both parents experienced fatigue from time to time but never consulted a physician. Consider the types of anemia most often found at this age and the laboratory tests that could help establish a diagnosis. What is the significance, if any, of knowing the parents' background and medical history?

OVERVIEW

This chapter discusses a group of hereditary anemias collectively called *thalassemias*. It begins with a general description of thalassemias including the genetic defects and types, pathophysiology, and clinical and laboratory findings. Subsequently, each type is discussed in the following format: pathophysiology, clinical findings, laboratory findings, treatment, and prognosis. Other thalassemia-like conditions are described and compared and contrasted with thalassemia. The chapter concludes by describing the laboratory differential diagnosis of types of thalassemia and other disorders that have similar peripheral blood morphology.

INTRODUCTION

Thalassemia constitutes a family of **congenital** disorders in which mutations in one or more of the globin genes of hemoglobin cause decreased or absent synthesis of the corresponding globin chains. Almost 400 unique mutations have been described among this diverse group of disorders.¹ Consequences of the mutation depend on the particular chain affected and the amount of globin chain produced. Limited availability of globin chains results in a reduction in the assembly of hemoglobin. Patients with mild genetic defects are generally asymptomatic. Patients with more severe defects present with symptoms that result from one or more of the following: decreased production of normal hemoglobin, synthesis of abnormal hemoglobins, **ineffective erythropoiesis**, and disproportionate production of unaffected globin chains. Symptoms include anemia, hepatosplenomegaly, infections, gallstones, and bone deformities that alter facial features and result in pathologic fractures.

The most important thalassemias are alpha- (α) and beta- (β). α -thalassemia results from a decreased or absent production of α -globin chains, and β -thalassemia is caused by a reduction or absence of β -globin chains. Reduction in the quantity of α - and β -chains can cause anemia because approximately 97% of normal adult hemoglobin (HbA) is composed of α - and β -globin chains.

Thomas Cooley offered the first clinical description of thalassemia in Detroit in 1925.² At that time, thalassemia was thought to be a rare disorder restricted to the Mediterranean ethnicities. Dr. Cooley's work broadened our understanding of the nationalities that potentially could be affected by thalassemia and suggested that the disease was hemolytic in nature. By 1960, it was apparent that the thalassemias composed a heterogeneous group of genetic disorders. With the advent of molecular biology, many groups of researchers have widely studied thalassemias. Methods developed in the last 25 years have enabled researchers to measure the number of globin chains synthesized and identify specific genetic mutations.

Thalassemia is now recognized as one of the most common genetic disorders affecting the world's population. It is estimated that between 100,000 and 200,000 individuals worldwide are born each year with severe forms of thalassemia. In North America, about 20% of immigrants from Southeast Asia and 6–11% of African Americans have detectable α -thalassemia. Many more are silent carriers. About 6% of individuals with Mediterranean ancestry, 5% of Southeast Asians, and 0.8% of African Americans have β -thalassemia.

Thalassemia is a major health problem in countries where these disorders are prevalent. Prevention is seen as an essential part in the management of the problem. Thus, many of these countries now have large screening and education programs to detect carriers. This has drastically reduced the number of individuals born with both homozygous and heterozygous forms of the disease.

THALASSEMIA VERSUS HEMOGLOBINOPATHY

The system of categorizing thalassemias and hemoglobinopathies differs among hematologists. Some use hemoglobinopathy as a disease category that includes structural variants of hemoglobin, such as sickle cell anemia and thalassemias. Others categorize only structural variants as hemoglobinopathies and describe thalassemias as a separate disease entity. In this text, we refer to the two diseases separately.

In the preceding chapter, hemoglobinopathies were defined as qualitative defects in the structure of globin chains resulting in production of abnormal hemoglobin molecules. Thalassemias, on the other hand, are typically quantitative disorders of hemoglobin synthesis that produce reduced amounts of normal hemoglobin.

The different outcomes of hemoglobinopathies and thalassemia are a direct result of the types of mutations encountered in these disease states. Most hemoglobinopathies result predominantly from a point mutation in the β -globin gene that is translated into a β -globin chain containing a single amino acid substitution. Hemoglobin types containing a point mutation in the β -chains may be produced at normal levels but are structurally abnormal. In contrast, thalassemias result from both deletional and nondelational

★ TABLE 1

Comparison of Hemoglobinopathies and Thalassemias

Disease	RBC Count	Indices	Erythrocyte Morphology	Abnormal Hb	Hb Solubility Test	Ancestry	Reticulocyte Count
Hemoglobinopathy	↓	Normocytic, normochromic	Target cells, sickle cells (in HbS), HbC crystals (in HbC), others	HbS, HbC, HbE, etc.	+ in HbS, Hb Bart's, and HbC ^{Harlem}	African, Mediterranean, Middle Eastern, Southeast Asian	↑↑
Thalassemia	↑ Compared to what is expected for the Hb level	Microcytic, hypochromic	Target cells, basophilic stippling	HbH (β^4), Hb Bart's (γ^4)	Negative	Mediterranean, Southeast Asian, African	↑

↓ = slight decrease, ↑ = slight increase, ↑↑ = moderate increase, Hb = hemoglobin, RBC = red blood cell, + = positive

mutations in globin genes that reduce or eliminate the synthesis of the corresponding globin chain. This results in the assembly of inadequate amounts of normal hemoglobin and a reduced oxygen-carrying capacity of the blood. Unlike hemoglobinopathies, the amino acid sequence of the chain, if produced, is normal and is assembled into the appropriate hemoglobin as usual, albeit in reduced amounts. In some of the less common thalassemias, the globin chains can be lengthened or truncated (Table 1 ★).

GENETIC DEFECTS IN THALASSEMIA

Nearly all thalassemic mutations fall into one of five categories of genetic lesions: gene deletion, promoter mutation, nonsense mutation, mutated termination (stop) codon, and splice site mutation (Table 2 ★). Regardless of the type of mutation encountered, the results are the same: The globin chain corresponding to the mutated globin gene is absent, reduced in concentration, or occasionally somewhat longer or shorter than normal.

If all globin genes of a single type of globin chain are deleted, the corresponding hemoglobin is absent. Deleted genes are most common in α -thalassemia. Reduction in globin chain production from nondeletional mutations is more common in the β -thalassemias. The degree of reduction in globin chain production is a direct reflection of the type of

✓ Checkpoint! 1

Differentiate the etiology of thalassemias and hemoglobinopathies.

★ TABLE 2

Five Common Genetic Defects in Thalassemia

Mutation Type	Thalassemia Encountered	Effect on Gene	Effect on Globin Chain
Deletion (large)	Predominantly α -thalassemia, some β -thalassemia	Loss of gene	Absence of production
Promoter	Predominantly β -thalassemia	Impaired transcription	Reduced or absent production
Nonsense	Predominantly β -thalassemia	In frame substitution	Amino acid change
		Frame shift	Amino acid changes distal to shift Longer or shorter globin chains
Stop codon	Predominantly β -thalassemia	Convert stop codons to amino acid codons	Slightly lengthened globin chain (retained) Significantly lengthened globin chain (degraded)
Splice site	Predominantly β -thalassemia	Create new splice sites	Slightly shortened globin chain (retained) Significantly shortened globin chain (degraded)
		Loss of splice sites	Slightly lengthened globin chain (retained) Significantly lengthened globin chain (degraded) Unaltered globin chain

mutation encountered and parallels the severity of the clinical disorder (Table 2).

Checkpoint! 2:

What are the most common genetic mutations associated with α -thalassemia?

TYPES OF THALASSEMIA

Because six different normal globin genes (α , β , γ , δ , ϵ , ζ) exist, at least six versions of thalassemia are possible. In addition, deletions can occur to entire **gene clusters** concurrently affecting more than one globin chain. Of the six normal globin genes, epsilon and zeta (ϵ , ζ) are normally synthesized only in utero, and gamma (γ) is produced in high amounts from approximately the third trimester of pregnancy until birth. After birth, γ -chain synthesis begins to decrease but can still be detected in low amounts in adult life. The three remaining globin chains (α , β , and δ) and the γ -chains are considered normal adult globin chains and combine to form hemoglobin A ($\alpha_2\beta_2$), hemoglobin A₂ ($\alpha_2\delta_2$), and hemoglobin F ($\alpha_2\gamma_2$), respectively. Because approximately 97% of normal adult hemoglobin is HbA, a deficiency of either α - or β -chains affects hemoglobin A assembly, reducing HbA concentration and thus affecting the blood's oxygen-carrying capacity.

Two major types of classical thalassemia, α -thalassemia and β -thalassemia, have been described. When synthesis of the α -chain is impaired, the disease is α -thalassemia. When synthesis of the β -chain is affected, the disease is β -thalassemia. A third type of thalassemia, δ -thalassemia, has been reported, but its occurrence is rare and it is not clinically significant because the δ -chain is a component of the minor hemoglobin HbA₂, which composes only ~2.5% of total hemoglobin. Combinations of gene deletions like $\delta\beta$ -thalassemia or $\gamma\delta\beta$ -thalassemia occur but are rare. The affected chains are all synthesized at a reduced rate.

Occasionally, synthesis of a structural hemoglobin variant decreases hemoglobin concentration, giving the clinical picture of thalassemia. These structural variants include those hemoglobins with abnormally long or short globin chains (hemoglobin Constant Spring) as well as variants with a point mutation (hemoglobin E). Hemoglobin Lepore is a hemoglobin variant in which the non- α -globin chains are not only structurally abnormal but also ineffectively synthesized. Because of their clinical similarity to thalassemias, these particular structural variants are discussed in this section.

A variant of β -thalassemia known as *hereditary persistence of fetal hemoglobin (HPFH)* is characterized by continued production of HbF throughout life. This disorder is characterized by a failure in the switch of γ -chain production to β -chain production after birth. In the homozygotes, 100% of circulating hemoglobin is HbF.

PATHOPHYSIOLOGY

Normally equal amounts of α - and β -chains are synthesized by the maturing erythrocyte, resulting in a β -chain to α -chain ratio of 1.0. In α - and β -thalassemia, synthesis of one of these chains is decreased or absent, resulting in an excess of the other chain. If the α -chain is affected, there is an excess of β -chains, and if the β -chain is affected, there is an excess of α -chains. This imbalanced synthesis of chains has several effects, all of which contribute to anemia: (1) a decrease in total erythrocyte hemoglobin production, (2) ineffective erythropoiesis, and (3) chronic hemolysis.

Excess α -chains are unstable and precipitate within the cell. The precipitates bind to the cell membrane, causing membrane damage and decreased erythrocyte deformability. Macrophages may destroy the precipitate-filled erythrocytes in the bone marrow, resulting in a large degree of ineffective erythropoiesis. Circulating erythrocytes with precipitates are pitted and/or removed by the spleen, causing chronic extravascular hemolysis.

Excess β -chains can combine to form hemoglobin molecules with four β -chains, hemoglobin H (HbH). This hemoglobin has a high oxygen affinity and is also unstable. Thus, it is a poor transporter of oxygen. In the infant, when α -chains are decreased, excess γ -chains can combine to form hemoglobin molecules with four γ -chains, hemoglobin Bart's (Hb Bart's). This hemoglobin also has a very high oxygen affinity.

In addition to α - and β -thalassemia, other thalassemias and thalassemia-like conditions can occur. Structural hemoglobin variants can result in decreased synthesis of globin chains, giving the clinical picture of thalassemia (e.g., Hemoglobin E).

CLINICAL FINDINGS

Clinical findings are related to anemia, chronic hemolysis, and ineffective erythropoiesis (Table 3). The combination of reduced HbA synthesis, ineffective erythropoiesis, and hemolysis results in anemia. The severity of anemia varies widely depending on the specific genetic mutation and number of genes affected. Hypoxia from anemia is exacerbated in some cases by the presence of abnormal hemoglobins that have a high oxygen affinity (HbH and Hb Bart's). These hemoglobins do not release oxygen readily to the tissues.

Chronic hemolysis has several adverse effects. Splenomegaly is frequently present because the spleen is a major site of extravascular hemolysis. Occasionally, the spleen can become overburdened by the process of erythrocyte destruction resulting in **functional hyposplenism**. In this case, the spleen's function as a secondary lymphoid tissue is compromised, leading to an increase in infections. Chronic hemolysis can also result in the formation of gallstones.

The chronic demand for erythrocytes also has adverse effects. The bone marrow responds by increasing erythropoiesis,

★ TABLE 3

Clinical and Laboratory Findings Associated with Thalassemia

Clinical Finding	Pathophysiology	Laboratory Finding
Anemia/hypoxia	Decreased hemoglobin production/erythropoiesis Ineffective erythropoiesis Presence of high-affinity hemoglobins (HbH and Hb Bart's) Increased extravascular hemolysis	↓ -N RBC count, ↓ hemoglobin, ↓ hematocrit Microcytic/hypochromic RBCs ↓ MCV, ↓ MCH, ↓ MCHC ↑ Reticulocyte count Anisocytosis and poikilocytosis Target cells, basophilic stippling, nucleated RBCs BM erythroid hyperplasia ↑ RDW Abnormal hemoglobin electrophoresis
Splenomegaly/hemolysis	Splenic removal of abnormal erythrocytes Ineffective erythropoiesis	↑ Bilirubin ↓ Haptoglobin
Gallstones	Increased intravascular and extravascular hemolysis	↑ Bilirubin
Skeletal abnormalities	Expansion of bone marrow	BM erythroid hyperplasia
Pathologic fractures	Thinning of calcified bone	
Iron toxicity	Iron overload Multiple transfusions Increased iron absorption	↑ Prussian blue staining in BM ↑ Serum iron/ferritin and ↓ TIBC

resulting in erythroid hyperplasia and in some of the more severe thalassemias, in bone marrow expansion and thinning of calcified bone. Consequently, patients develop skeletal abnormalities and pathologic fractures. The increased iron demand needed to support the erythropoietic activity stimulates the absorption of more iron. This additional iron is not effectively incorporated into hemoglobin, so it accumulates in macrophages in the bone marrow, liver, and spleen. As this process continues, iron eventually accumulates in parenchymal cells of various organs and adversely affects organ function. Iron toxicity commonly affects such organs as the liver, pituitary, heart, and bone, resulting in dysfunctions such as cirrhosis, hypogonadism and growth failure, arrhythmias and cardiomyopathies, and pathologic fractures, respectively.³ Ineffective erythropoiesis in the bone marrow can be accompanied by **extramedullary erythropoiesis** in the liver and spleen. Extramedullary erythropoiesis can produce masses large enough to cause **compression syndromes** (Table 3).

Pregnant women with thalassemia have physiological demands that impact the developing baby to a greater extent than the mother. Developing infants can experience diminished growth, premature birth, and even intrauterine death if the woman's oxygen concentration falls below 70 mmHg. Pregnant women who present with a hemoglobin level of between 9 and 10 g/dL around the time of delivery are often given a blood transfusion to improve oxygen delivery. To avoid iron overload caused primarily by the combination of transfu-

sion therapy and increased iron absorption, pregnant women can be given deferoxamine during and after the transfusion.⁴

Checkpoint! 3

Why do α- and β-thalassemia result in more clinically severe disease than other types of thalassemia?

LABORATORY FINDINGS

Peripheral blood findings provide clues to the disease (Table 3). Thalassemias are characterized by microcytic, hypochromic anemia with a decrease in MCV, MCH, and usually MCHC. The erythrocyte count is often normal or slightly decreased but increased for the degree of anemia. The RDW can be increased although often is not. Target cells and microcytosis usually are present even in cases without anemia or symptoms of anemia. Basophilic stippling and nucleated erythrocytes can be present. Anisocytosis and poikilocytosis are common. Precipitates of excess chains or unstable hemoglobin can be visualized with supravital stains. Reticulocytes and bilirubin are usually increased due to the chronic hemolysis. Haptoglobin, a protein that transports free plasma hemoglobin to the liver, can be decreased depending on the degree of intravascular hemolysis.

Hemoglobin electrophoresis is always indicated if thalassemia is suspected. HbA is usually decreased. HbF and

HbA₂ are increased in β -thalassemia but decreased in α -thalassemia. Hemoglobin Bart's and HbH can also be present in α -thalassemia.

Bone marrow studies are not necessary for diagnosis but when performed show marked erythroid hyperplasia. Erythroblasts appear abnormal with very little cytoplasm, uneven cytoplasmic membranes, and striking basophilic stippling. Prussian blue stain reveals an abundance of iron and occasionally a few ringed sideroblasts. Phagocytic "foam" cells similar to Gaucher cells have been reported in the more severe forms of the disease. The foam probably results from partially digested red cell membrane lipids associated with intense ineffective erythropoiesis.

Because the emphasis is now on screening programs to detect thalassemia carriers in areas of high prevalence and in certain populations, laboratory professionals must look for assays that are uncomplicated, time efficient, and accurate. The reverse dot-blot procedure, a molecular technique, seems to be the most popular for this purpose because it is rapid and accurate. It allows for the screening of several mutations with a single hybridization reaction. In this procedure, probes for the mutated genes are fixed on a membrane. Because hundreds of different globin gene mutants lead to thalassemia, the probes selected are those commonly found in a particular geographic region. The patient's DNA is PCR-amplified, labeled, and added to the membrane with the probes. The patient's DNA hybridizes only to probes complementary to its sequence. The pattern of hybridization of the patient's DNA with the probes determines whether a particular mutation is present. Molecular techniques can also be performed on a fetus in utero within the first or second trimester of pregnancy by using fetal blood sampling or chorionic villous sampling followed by similar PCR-based methods of DNA analysis.⁴

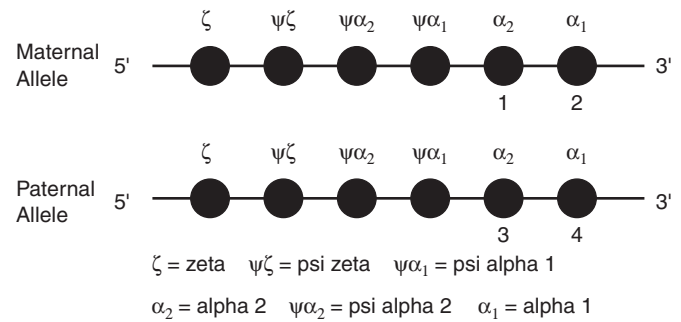

▶ α -THALASSEMIA

GENERAL CONSIDERATIONS

Alpha-thalassemia is a group of four disorders characterized by decreased synthesis of α -chains. Although each is discussed separately, several features common to each type are presented here.

Etiology

In the human genome, two α -genes are located on each of the two chromosome 16 structures, totaling four α -genes in the **diploid** state (Figure 1 ■). Mutations can affect one or more of the α -genes resulting in four discrete clinical severities that have been described. A patient in whom all four α -genes are deleted produces no α -chains, a condition referred to as *hydrops fetalis*. When three of the four α -genes are deleted, the disorder is known as *hemoglobin H (HbH) disease*. The deletion of two α -genes is known as *α -thalassemia minor*, and the deletion of a single α -gene is known as *silent carrier*. Though less common, nondeletional mutations and muta-

■ **FIGURE 1** A short section of chromosome 16 showing the 5' to 3' orientation of three functional genes ζ , α_2 , and α_1 along with three pseudogenes $\psi\zeta$, $\psi\alpha_2$, and $\psi\alpha_1$. Pseudogenes are the result of partial gene duplications but are not expressed. There are two α -genes on each chromosome; the α_2 -gene expresses 2 to 3 times as much protein product as the α_1 -gene.

tions that produce unstable α -chains are also found in α -thalassemia. The outcome is usually the same as a deletion mutation, a reduction in α -chains and in the corresponding α -containing hemoglobins.

Affected Alleles

The amount of α -chains synthesized is somewhat proportional to the number of affected **alleles**. In general, erythrocytes produce higher concentrations of α -chains than the number of affected alleles predict. There are two main reasons for this phenomenon. First, the four α -genes can be described as two pairs of genes designated as α_1 and α_2 . Each chromosome 16 contains an α_1 - and an α_2 -gene oriented with the α_2 -gene positioned upstream (5') from the α_1 -gene (Figure 1). It has been shown that the α_2 -gene produces two to three times the amount of mRNA as the α_1 -gene.⁵ Therefore, a deletion of the α_2 -gene would reduce α -chain production to a greater degree than would a deletion of the α_1 -gene. Second, the erythropoietic system has an internal mechanism designed to stimulate increased production of α -chains from the unaffected genes to compensate for deletions, thus minimizing the reduction of α -chains.

Affected Individuals

Alpha-thalassemia is concentrated in people of Mediterranean, Asian, and African ancestry. In particular, it is commonly seen in blacks, Indians, Chinese, and Middle Eastern people, with blacks expressing a milder version of the disease. The reason patients of African descent tend to present with a milder version of α -thalassemia is because the deletion in this ethnic group usually involves the α_1 -gene.

Genotypes

Three nomenclature systems—genotypic, genotypic description, and phenotypic—have been developed to classify the α -thalassemias into five discrete categories. The addition of the normal **genotype** produces a total of six possibilities.

The genotypic system designates deleted genes as (-) and unaffected genes as (α). The genotypic description system combines the **zygosity** state, **homozygous** or **heterozygous**, with either a gene symbol (α⁰ or α⁺) or a nominal descriptor (thal-1 or thal-2) to designate the number of deleted α-genes on each chromosome. Both thal-1 and α⁰ indicate the deletion of both α-genes on the same chromosome (-, -). Likewise, thal-2 and α⁺ refer to one deleted and one unaffected α-gene on a given chromosome (-, α). The phenotypic system describes four clinical types, hydrops fetalis, hemoglobin H disease, α-thalassemia minor, and silent carrier with the α-thalassemia minor type exhibiting two clinical severities (Table 4).⁵ Patients occasionally bear a nondeletional mutation of the α-thalassemia gene, designated as α^T, that functions to reduce but not eliminate α-chain production from that gene.

**α-THALASSEMIA MAJOR (α⁰-THAL-1/
α⁰-THAL-1; HYDROPS FETALIS)**

The most severe form of α-thalassemia, α-thalassemia major, involves the deletion of all four α-genes (-/-/-/-). Both parents of the thalassemia patient must have α-thalassemia to have a child with hydrops fetalis because both α-genes on each parental chromosome inherited by the child are deleted.

Pathophysiology

Because all four α-genes are deleted in hydrops fetalis, no normal adult hemoglobins can be synthesized. Therefore, this disorder is incompatible with life, and infants are either stillborn or die within hours of birth. In the absence of α-chains, erythrocytes assemble hemoglobin using the γ-, δ-, and β-chains available. Therefore, abnormal hemoglobin tetramers involving γ-chains (Hb Bart's, γ₄) and β-chains (HbH, β₄) are produced. Hb Bart's has a very high oxygen affinity and no Bohr effect. Therefore, this hemoglobin cannot supply tissues with sufficient oxygen to sustain life, and the developing infant dies of hypoxia and congestive heart failure. Hemoglobin Portland, although normally absent following the first trimester, continues to be synthesized until birth in α-thalassemia because it does not contain α-chains.

Clinical Findings

Infants who survive until birth exhibit significant physical abnormalities upon routine exam. The babies are underweight and edematous with a distended abdomen. The liver and often the spleen are enlarged due to extramedullary hematopoiesis. There is massive bone marrow hyperplasia. Hemolysis in the fetus is probably severe because there is extensive deposition of hemosiderin.

★ TABLE 4

Characteristics of α-thalassemia

Genotype	Genotypic Description	Phenotype	Hematologic Findings	Severity	Hemoglobins Present
(-/-/-/-)	Homozygous α ⁰ -thalassemia-1	Hydrops fetalis	Marked anemia Microcytic/hypochromic RBCs ↑↑↑ anisopoikilocytosis ↑ NRBC	Fatal	Hb Bart's (80–90%) Hb Portland (10–20%)
(-/-/-α)	Heterozygous α ⁰ -thalassemia-1/ α ⁺ -thalassemia-2	Hemoglobin H disease	Moderate to marked anemia Microcytic/hypochromic RBCs Target cells Basophilic stippling Poikilocytosis	Chronic, moderately severe hemolytic anemia	Birth=Hb Bart's; Adult=HbH
(-/-/αα)	Heterozygous α ⁰ -thalassemia-1	α-thalassemia-minor	Slight anemia Microcytic/hypochromic RBCs Target cells Basophilic stippling Poikilocytosis	Mild to moderate	Birth=Hb Bart's; Adult=normal
(-α/-α)	Homozygous α ⁺ -thalassemia-2	α-thalassemia-minor	Slight anemia Microcytic/hypochromic RBCs Target cells Basophilic stippling Poikilocytosis	Mild	Birth=Hb Bart's; Adult=normal
(-α/αα)	Heterozygous α ⁺ -thalassemia-2	Silent carrier	Normocytic or slightly microcytic RBCs	Normal	Normal
(αα/αα)	Normal	None	Normal	Normal	Normal

↑↑↑ = marked increase, ↑ = slight increase

α -thalassemia Major Laboratory Results

Laboratory results can confirm the diagnosis. There is severe anemia with hemoglobin values ranging from 3 to 10 g/dL. Hemoglobin electrophoresis on cellulose acetate agarose at alkaline pH shows 80–90% Hb Bart's and 10–20% Hb Portland with HbH sometimes detectable. HbA, HbA₂, and HbF are absent due to the lack of α -chain production (Figure 2 ■).

✓ Checkpoint! 4
Which of the three normal adult hemoglobins would be affected in hydrops fetalis?

HEMOGLOBIN H DISEASE (α^0 -THAL-1/ α^+ -THAL-2)

HbH disease, a symptomatic but nonfatal type of α -thalassemia, was the first type to be described, in 1956. It occurs when three of the four α -genes are deleted. African Americans seldom present with HbH disease because they rarely express a deletion of two α -genes on the same chromosome.⁶

This disorder usually results when two heterozygous parents, one with α^0 -thal-1 ($--/\alpha\alpha$) and the other expressing the α^+ -thal-2 ($-\alpha/\alpha\alpha$) genotype, bear children.⁵ All children from a patient with HbH disease will have one of the four types of α -thalassemia, the severity of which depends on the other parent's genotype.

	CA	CS	A2	Lepore	F	A	Portland	Bart's	H

Hgb H (adult)						■			
Hgb H/CS						■			
α -Thal minor						■			(neonates only)
Silent carrier						■			

CA = Carbonic anhydrase
CS = Constant spring

■ **FIGURE 2** Hemoglobin electrophoresis on cellulose acetate at pH 8.4 is helpful in distinguishing the type of thalassemia and in differentiating thalassemias from hemoglobinopathies. In α -thalassemias, there is a reduction in α -containing hemoglobins (HbA, HbA₂, and HbF) proportional to the number of deleted α -genes and in the more severe cases, the emergence of non- α -containing hemoglobins (HbH and Hb Bart's).

Pathophysiology

The dramatic reduction in α -chain synthesis results in a decrease in the assembly of HbA, HbA₂, and HbF. In addition, a decrease in α -chains creates a relative excess of β -chains, which unite to form tetrads of four β -chains called HbH. γ -chains are also produced in excess of α -chains, especially at birth, and combine to form Hb Bart's.

HbH is thermolabile, unstable, and tends to precipitate inside erythrocytes triggering chronic hemolytic anemia. Its oxygen affinity is 10 times that of HbA, reducing oxygen delivery to the tissues. Its high oxygen affinity is attributed to the lack of heme-heme interaction and absence of the Bohr effect. This increased oxygen affinity is reflected in the lower **P₅₀ value** of HbH relative to HbA and myoglobin (Figure 3 ■).

Hemoglobin H also occurs as an acquired defect in erythroleukemia and other myeloproliferative disorders. However, the clinical manifestations and hematological abnormalities of these acquired disorders make it possible to distinguish them from HbH disease. Acquired HbH is probably due to a defect that prohibits the transcription of the α -gene.

✓ Checkpoint! 5
Compare oxygen binding characteristics of HbH relative to HbA and myoglobin.

■ **FIGURE 3** The Hb dissociation curve illustrates the relative binding affinities of HbA, HbH, and myoglobin using the P₅₀ value. The monomeric myoglobin molecule lacks heme-heme interactions, causing it to bind oxygen tightly, decreasing the P₅₀ value relative to HbA. The P₅₀ value is even lower for HbH, indicating an even stronger affinity for oxygen estimated to be 10 times more than the oxygen affinity of HbA.

Clinical Findings

Symptoms are related to anemia and chronic hemolysis. Hemoglobin H disease shows a wide variation from mild to severe in the degree of anemia, which worsens during pregnancy, in infectious states, and during administration of oxidant drugs. Splenomegaly and, less often, hepatomegaly are present. Less than half of affected patients exhibit skeletal changes similar to those found in β -thalassemia major.

Laboratory Results

Hemoglobin H disease is characterized by a microcytic, hypochromic anemia with hemoglobin levels usually ranging from 8 to 10 g/dL. Reticulocytes are moderately increased from 5 to 10%, and nucleated red blood cells are observed on the peripheral blood smear (Figure 4a■).

Hemoglobin electrophoresis of affected neonates shows about 25% Hb Bart's with decreased levels of HbA, HbA₂, and HbF. After birth, β -chains begin to replace γ -chains, and HbH eventually replaces Hb Bart's. Hemoglobin H, a fast-migrating hemoglobin at alkaline pH, makes up from 2 to 40% of the hemoglobin in adults with HbH disease. HbA₂ is decreased to a mean of 1.5%, but HbF is normal. A trace of Hb Bart's can be demonstrated in approximately 10% of affected adults with remaining hemoglobin being HbA (Figure 2). Other laboratory tests are available to assess patients with HbH disease. Hemoglobin H inclusions are easily found upon incubation of blood with brilliant cresyl blue (Figure 4b■). These inclusions tend to cover the inside of the plasma membrane, giving the appearance of a golf ball.

Treatment and Prognosis for Hemoglobin H Disease

Treatment for patients with HbH disease is variable but when indicated involves long-term transfusion therapy and splenectomy. Regular transfusions minimize the stunting of growth and the other consequences of chronic severe ane-

mia. Iron chelation therapy with deferoxamine avoids iron overload and the effects of iron toxicity. Deferipone is an oral chelator that is an alternative to deferoxamine but has significant dose-related sequelae like neutropenia, arthropathy, and agranulocytosis. The increased and ineffective erythropoiesis places high demands on the bone marrow requiring folate supplementation to avoid a deficiency.³ Early treatment is necessary to prevent the typical clinical manifestations of thalassemia. With supportive and behavioral interventions, patients with HbH disease experience a normal life expectancy. For patients in whom transfusion and chelation therapy are not efficacious, a bone marrow transplant could be indicated.³

α -THALASSEMIA MINOR (α^+ -THAL-2/ α^+ -THAL-2, OR α^0 -THAL-1/NORMAL)

The α -thalassemia trait (homozygous α^+ -thal-2 or α^0 -thal-1 trait) occurs when two of the four α -genes, either on the same or opposite chromosomes, are missing. The condition is found in all geographic locations.⁷ In African Americans, the homozygous α^+ -thal-2 form is the most common presentation. Genetic testing has identified at least nine **haplotypes**, representing different mutations, all of which result in the deletion of both α -genes on the same chromosome, which is more common in patients of Southeast Asian or Mediterranean descent.⁸

Pathophysiology

Although a measurable decrease in the production of α -containing hemoglobins occurs, the unaffected globin genes are able to direct synthesis of α -globin chains to a greater than normal degree and therefore compensate for the affected genes. Only minor changes occur in the erythrocyte count, indices, hemoglobin electrophoresis patterns, and red cell morphology.

a

b

■ **FIGURE 4** **a.** This peripheral blood smear is from a patient with HbH disease. Note the microcytic, hypochromic anemia with target cells. **b.** Peripheral blood from patient in Figure 4a after incubation with brilliant cresyl blue. Notice the cells that have dimples and look like golf balls. These are the cells with precipitated HbH. (a. Brilliant cresyl blue stain; 1000 \times magnification)

Clinical Findings

Patients with α -thalassemia trait are asymptomatic with a mild anemia and are often diagnosed incidentally or when being evaluated for family studies. This mild **phenotype** is the reason this form is called *thalassemia minor*.

Laboratory Results

The most demonstrable laboratory abnormalities are observed in the newborn. The presence of 5–6% Hb Bart's in neonates can be helpful in diagnosing this condition.⁹ Three months after birth, Hb Bart's decreases to undetectable levels and hemoglobin electrophoresis becomes normal. The only persistent hematological abnormality thereafter is a variable microcytic, hypochromic anemia.

In adult patients, hemoglobin levels are above 10 g/dL and the erythrocyte count is above $5 \times 10^{12}/L$. The peripheral blood film usually demonstrates significant microcytosis with an MCV of 60–70 fL with few target cells (Figure 5■). Occasional cells can exhibit HbH inclusions after incubation with brilliant cresyl blue.

In some cases, α -thalassemia is masked by iron-deficiency anemia. Persistence of microcytes following successful treatment of iron deficiency is suggestive of thalassemia, but further investigation is suggested.

Treatment and Prognosis

These patients have a normal life span and do not require medical intervention for their thalassemia.

SILENT CARRIER (α^+ -THAL-2/NORMAL)

The silent carrier version of α -thalassemia (α^+ -thal-2 trait) is missing only one of four functioning α -genes. More than 25% of African Americans have been shown to express a deletion of one α -gene.^{10–12}

■ **FIGURE 5** This is a peripheral blood smear from a patient with α -thalassemia trait. The hemoglobin is 15 g/dL, RBC $6.4 \times 10^{12}/L$, MCV 69.4 fL. The high RBC count with microcytosis is typical of thalassemia minor or trait. (Peripheral blood; Wright-Giemsa stain; 1000 \times magnification)

Pathogenesis/Clinical Findings/ Laboratory Results

In silent carrier disease, the three remaining α -genes direct the synthesis of an adequate number of α -chains for normal hemoglobin synthesis. This carrier state is asymptomatic and totally benign, but adults often present with a borderline normal MCV of around 78–80 fL.⁸ In affected infants, 1–2% Hb Bart's is found at birth but cannot be detected after three months of age. The only definitive diagnostic test for thalassemias in adults with one or two gene deletions is globin gene analysis.

Treatment and Prognosis

Patients with silent carrier disease require no treatment and have a normal life span.

CASE STUDY (continued from earlier in this chapter)

Following are the CBC and differential results for John, the 4-year-old Grecian patient.

CBC		Differential	
WBC	$11.4 \times 10^9/L$	Segs	55%
RBC	$1.7 \times 10^{12}/L$	Bands	1%
Hb	8.3 g/dL	Lymphs	36%
Hct	0.24L/L	Mono	7%
MCV	69 fL	Eos	1%
MCH	21 pg	Moderate poikilocytosis, polychromasia, and target cells; few teardrop cells	
MCHC	29.2 g/dL		
Pit	$172 \times 10^9/L$		

1. Based on the indices, classify the anemia morphologically.
2. Name the dominant poikilocyte observed in this peripheral blood smear.
3. Name three disorders that frequently present with the same poikilocyte that dominates in this peripheral blood smear.

► β -THALASSEMIA

GENERAL CONSIDERATIONS

As with α -thalassemias, some features of β -thalassemias are common to all forms of the disease. The genetics of β -thalassemia and the individuals affected with the disorder are presented before the discussion of its various forms.

Genetics

Whereas a total of four α -globin genes result in four major genotypes of α -thalassemia, there are only two β -globin

FIGURE 6 Chromosome 11 is the location of four types of globin genes (ϵ , γ , δ , β). The 5' to 3' orientation of the genes is depicted. There is a gene for ϵ , δ , and β and two γ -genes. A β -pseudogene ($\psi\beta$) has been identified but does not express protein product.

genes, one located on each chromosome 11 (Figure 6). If the prominent type of mutation found in β -thalassemia were also deletional, one would expect two severities, the severe homozygote and the mild heterozygote. However, in β -thalassemia, most mutations are non-deletional, resulting in a near continuum of clinical severities. In an attempt to gain some control over nomenclature of this diverse group of diseases, two classification systems are currently used. The genotypic system classifies β -thalassemia patients into six genotypes based on zygosity and the degree of alteration of the β -genes, and the phenotypic system divides patients into four categories based on the severity of clinical symptoms.

In the genotypic system, all β -gene mutations are categorized into two groups based on the impact of the mutation on β -globin production. The two gene varieties are termed β^+ and β^0 . The β^+ -gene mutation causes a partial block in β -chain synthesis, and the β^0 -gene mutation results in a

complete absence of β -chain synthesis from that allele. In addition, a minimally affected β -allele called *silent carrier* has been identified. It is found only in the most benign version of β -thalassemia. When the two gene designations (β^0 and β^+) are combined with the normal allele (β) and the two possible zygosity patterns (homozygous and heterozygous), six possible genotypes (β^0/β^0 , β^0/β^+ , β^+/β^+ , β^0/β , β^+/β , β/β) emerge. When the silent carrier mutation is added, a total of seven β -genotypes can be described (Table 5).

β -thalassemia is the result of several different types of molecular defects. More than 180 mutations that result in partial to complete absence of β -gene expression have been described, but only 20 mutations account for 80% of the diagnosed β -thalassemias.^{1,6} β -thalassemia is rarely due to deletion of the structural gene as is the case in the α -thalassemias. Most defects in β -thalassemia are point mutations in regions of the DNA that control β -gene expression. These types of mutations can affect gene expression ranging from minor reductions in β -globin production to complete absence of synthesis. Mutations can affect any step in the pathway of globin gene expression including gene transcription, RNA processing, m-RNA translation, and post-translational integrity of the protein.^{13,14} Within a given population, a few genetic lesions account for most of the β -thalassemia mutations. For instance, in Greece, five mutations account for 87% of the gene defects.¹⁴

The phenotypic system recognizes four groups of patients categorized by the severity of symptoms, medical interventions, and prognoses. The four groups, listed in order from most severe to least severe, are β -thalassemia major, β -thalassemia intermedia, β -thalassemia minor, and β -thalassemia minima (Table 5).

One reason some prefer to organize β -thalassemias into a genotypic system is that phenotypic terms do not accurately

TABLE 5

Characteristics of β -Thalassemia

Genotype	Zygosity	Phenotype	RBC Count	RBC Morphology	Hb Electrophoresis	Severity
β^0/β^0	Homozygous	Major	Relative \uparrow	$\uparrow\uparrow\uparrow$ Target cells	No A, $\uparrow A_2$, $\uparrow\uparrow F$	Severe
β^0/β^+	Double heterozygous	Major	Relative \uparrow	$\uparrow\uparrow\uparrow$ Target cells	$\downarrow A$, $\uparrow A_2$, $\uparrow\uparrow F$	Severe
		Intermedia		$\uparrow\uparrow$ Target cells	$\downarrow A$, $\uparrow A_2$, $\uparrow\uparrow F$	Moderate
β^+/β^+	Homozygous	Major	Relative \uparrow	$\uparrow\uparrow\uparrow$ Target cells	$\downarrow A$, $\uparrow A_2$, $\uparrow\uparrow F$	Severe
		Intermedia		$\uparrow\uparrow$ Target cells	$\downarrow A$, $\uparrow A_2$, $\uparrow\uparrow F$	Moderate
β^0/β	Heterozygous	Intermedia	Relative \uparrow	$\uparrow\uparrow$ Target cells	$\downarrow A$, $\uparrow A_2$, $\uparrow F$	Moderate
		Minor		\uparrow Target cells	$\downarrow A$, $\uparrow A_2$, $\uparrow F$	Mild
β^+/β	Heterozygous	Minor	Relative \uparrow	\uparrow Target cells	$\downarrow A$, $\uparrow A_2$, $\uparrow F$	Mild
β^{SC}/β	Heterozygous	Minima	Normal	\pm Target cells	Normal	Normal
β/β	Homozygous	Normal	Normal	Normal	Normal	Normal

\uparrow = slight increase, $\uparrow\uparrow$ = moderate increase, $\uparrow\uparrow\uparrow$ = marked increase, +/- = occasionally seen, \downarrow = slight decrease, A = HbA, A_2 = HbA₂, F = HbF, β^{SC} = silent carrier

reflect the genetic description of the disease. However, a disadvantage to the genotypic system is that patients with identical genotype designations can express β -thalassemia that is phenotypically diverse. For instance, a severe form of β^+/ β^+ -thalassemia (Mediterranean form) is characterized by an increase in HbF (50–90%) and a normal or only slightly elevated HbA₂ whereas a milder form of β^+/ β^+ -thalassemia (black form) has 20–40% HbF with normal or elevated HbA₂ and the remainder HbA. For this reason, some clinicians prefer the phenotypic system that more closely parallels symptoms and better predicts clinical interventions necessary for appropriate management of the patient.

This section combines the genotypic and phenotypic systems with an emphasis on the phenotypic system. The two more recognized phenotypic groups, β -thalassemia major and minor, are discussed first followed by intermedia and minima (Table 5).

Affected Individuals

The most severe mutation (β^0) occurs more frequently in the Mediterranean regions—specifically in northern Italy, Greece, Algeria, Saudi Arabia—and Southeast Asia. Two severities of the β^+ mutation tend to originate in different ethnic populations. The more severe version is observed in the Mediterranean region, the Middle East, the Indian subcontinent, and Southeast Asia, the milder version is localized to patients of African descent.⁷

β -THALASSEMIA MAJOR
(β^0/β^0 , β^0/β^+ , $\beta^+ \beta^+$)

Expected Genotypes

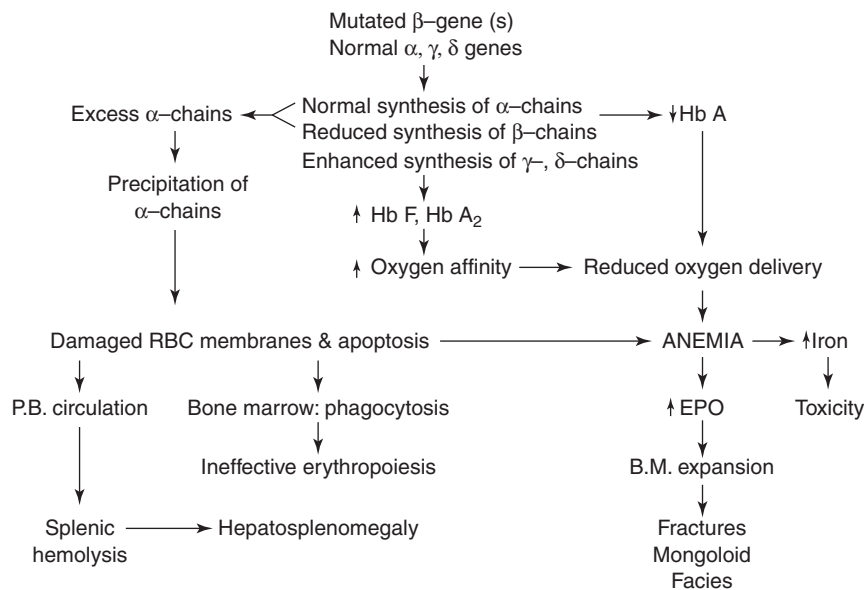

Beta-thalassemia major, also referred to as *Cooley's anemia*, is caused by a homozygous (β^0/β^0 , $\beta^+ \beta^+$), or **double heterozygous** (β^0/β^+), inheritance of abnormal β -genes resulting in marked reduction or absence of β -chain synthesis. As can be seen in Table 5, two of these three genotypes (β^0/β^+ , $\beta^+ \beta^+$) can also present as the milder β -thalassemia intermedia phenotype that will be discussed later.

Pathophysiology

The dramatic reduction or absence of β -chain synthesis affects the production of HbA. The symptoms that result from β -thalassemia major begin to manifest in infants approximately six months after birth. Other non- β -containing hemoglobins, HbA₂ and HbF, are increased in partial compensation for the decreased HbA levels.

The pathophysiologic mechanisms that result from a lack of β -chain production can be classified into four categories (Figure 7 ■):

- reduced HbA
- compensatory production of abnormal hemoglobins
- ineffective erythropoiesis with hemolysis
- erythroid hyperplasia

■ **FIGURE 7** In β -thalassemia major, the decreased synthesis of β -chains reduces the production of HbA and increases the production of non- β -chain containing hemoglobins (HbA₂ and HbF). Excess α -chains form insoluble precipitates inside erythrocytes, damaging the membranes and reducing RBC lifespan through splenic sequestration and ineffective erythropoiesis. All of these factors contribute to a reduced oxygen delivery to the tissues resulting in anemia and hypoxia. The compensatory erythroid hyperplasia in the bone marrow expands the marrow cavity, resulting in pathologic fractures and mongoloid facial features.

A dramatic reduction in HbA compromises the blood's oxygen-carrying capacity. Other non- β -containing hemoglobins, HbF and HbA₂, are increased. HbF has a higher affinity for oxygen than HbA. The result is to exacerbate the already compromised oxygen delivery to tissues.

In β -thalassemia major, reduced synthesis of β -chains results in an excess of free α -chains and a β -to- α chain ratio of less than 0.25. The free excess α -chains cannot form hemoglobin tetramers, so they precipitate within the cell, damaging the cell membrane, leading to chronic hemolysis.¹⁵ The accumulating α -chains contain free iron and hemichromes that generate reactive oxygen species (ROS). The ROS damage hemoglobin as well as the membrane's proteins and lipids, decreasing membrane stability.^{16,17} Oxidation of membrane band 3 produces clustering of the proteins, creating new antigens on the cell surface that bind IgG and complement.¹⁸ Many IgG- and complement-sensitized erythrocytes in the bone marrow are destroyed by binding to marrow macrophages via F_c receptors, resulting in phagocytosis and a large degree of hemolysis.

The majority of the hemolysis occurs within the bone marrow primarily at the polychromatophilic normoblast stage of erythroid development, resulting in ineffective erythropoiesis.¹⁹ The ineffective erythropoiesis is due to activation of apoptotic mechanisms by the precipitated α -globin chains and damaged cellular components.^{20,21} If the patient has inherited α -thalassemia with β -thalassemia, the symptoms associated with hemolysis can be reduced because the relative excess of α -chains is reduced by the α -thalassemia.

The combination of reduced HbA, increased HbF, ineffective erythropoiesis, and chronic hemolysis results in significant anemia. The body attempts to compensate by stimulating erythropoiesis. The resulting erythroid hyperplasia causes bone marrow expansion and thinning of calcified bone. Increased erythropoietic activity also stimulates the absorption of more iron in the gut, leading to iron toxicity. Ineffective erythropoiesis in the bone marrow can be accompanied by extramedullary hematopoiesis in the liver and spleen, often producing hepatosplenomegaly (Figure 7).

✓ Checkpoint! 6

Why do the symptoms of β -thalassemia major delay until approximately the sixth month of life?

CLINICAL FINDINGS

Early symptoms of β -thalassemia first observed in infants include irritability, pallor, and a failure to thrive and gain weight. Diarrhea, fever, and an enlarged abdomen are also common findings. If therapy does not begin during early childhood, the clinical picture of thalassemia develops within a few years.

Severe anemia is the clinical condition responsible for many of the problems experienced by these children. The

anemia places a tremendous burden on the cardiovascular system as it attempts to maintain tissue perfusion. Constant high output of blood usually results in cardiac failure in the first decade of life and is the major cause of death in untreated children. Growth is retarded, and a bronze pigmentation of the skin is notable. Chronic hemolysis often produces gallstones, gout, and icterus.

Bone changes accompany the hyperplastic marrow. Marrow cavities enlarge in every bone, expanding the bone and producing characteristic bossing of the skull, facial deformities, and “hair-on-end” appearance of the skull on x-ray (Figure 8 ■). The thinning cortical bone in long bones can lead to pathologic fractures.

Extramedullary hematopoiesis can be found in the liver and spleen and occasionally elsewhere in the body. The spleen can become massively enlarged and congested with abnormal erythrocytes.

Other clinical findings are associated with the body's attempt to increase erythrocyte production. Features that suggest an increased metabolic rate include fever, lethargy, weakened musculature, decreased body fat, and decreased appetite. Infection is a common cause of death. Folic acid deficiency can develop as a consequence of increased utilization by the hyperplastic marrow.

■ **FIGURE 8** Increased erythropoiesis in the bone marrow of patients with β -thalassemia major expands the marrow cavity producing the typical “hair-on-end” appearance as seen on this radiograph of the skull of a boy with β -thalassemia.

Laboratory Results

The hemoglobin level can be as low as 2 or 3 g/dL in the more severe forms of the disease. The anemia is markedly microcytic and hypochromic with an MCV of less than 67 fL²² and a markedly reduced MCH and MCHC. The peripheral blood smear shows marked anisocytosis and poikilocytosis (Figure 9 ■). Precipitates of α -chains can be visualized with methyl violet stain. Variable basophilic stippling and polychromasia are noted. Reticulocytes are not increased to the degree expected for the severity of the anemia because of the high degree of ineffective erythropoiesis. Nucleated erythrocytes are almost always found, and the RDW can be increased.²³ Secondary leukopenia and thrombocytopenia are produced because these components also become trapped in the enlarged spleen. Chronic hemolysis is reflected by increased unconjugated bilirubin. Urine can appear dark brown from the presence of dipyrroles.

Bone marrow studies are not usually necessary for diagnosis but when performed show marked erythroid hyperplasia with an M:E ratio of 0.1 or less.

Hemoglobin electrophoresis performed on cord blood samples provides evidence of deficient β -chain production at birth. Although normal cord blood contains about 20% HbA, cord blood from infants with β -thalassemia major has less than 2% HbA.¹³ In adults, hemoglobin electrophoresis shows variable results depending on the thalassemia genes inherited. Absence of HbA, 90% HbF, and low, normal, or increased HbA₂ is characteristic of β^0/β^0 -thalassemia.²⁴ The other genotypes, β^0/β^+ and β^+/β^+ , show some HbA, but the majority of the hemoglobin is HbF with normal to increased HbA₂²⁵ (Figure 10 ■). The increased HbF in thalassemia is thought to be due to the expansion of a subpopulation of erythrocytes that have the ability to synthesize γ -chains. The distribution of HbF among erythrocytes is heterogeneous.

Definitive diagnosis of β -thalassemia can be made by demonstration of a β -to- α -chain ratio of less than 0.25. Molecular techniques demonstrating specific genetic mutations can also define the presence of thalassemia.

■ **FIGURE 9** Peripheral blood smear from a patient with β -thalassemia major showing marked anisopoikilocytosis. Target cells, schistocytes, teardrops, and ovalocytes are the major poikilocytes observed. An NRBC is also present. (1000 \times magnification; Wright-Giemsa stain)

■ **FIGURE 10** Hemoglobin electrophoresis pattern from patients with β -thalassemia shows a reduction in β -containing HbA and an increase in non- β -containing HbA₂ and HbF.

TREATMENT

Most children with β -thalassemia major participate in a regular transfusion program, which prolongs life into the second or third decade and allows normal developmental and growth patterns. Initial treatment protocols were mainly palliative and designed to maintain the hemoglobin level \sim 7–8 g/dL; however, evidence of erythroid expansion and increased iron absorption persisted. Clinical evidence suggests that the more aggressive hypertransfusion programs (maintaining a hemoglobin level between 9 and 10.5 g/dL) offer the highest quality of life without significant sequelae.²⁶ The objectives of hypertransfusion programs are to minimize the anemia, reduce excess iron absorption, and suppress ineffective erythropoiesis. The large doses of iron received with these transfusions, however, lead to tissue damage from iron overload similar to that seen in hereditary hemochromatosis. Iron-chelating agents such as deferoxamine are given to decrease the deposition of iron in the tissues. Splenectomy can be performed in an attempt to decrease hemolysis and prolong red cell survival; however, it is usually reserved for patients over 5 years of age.

Within the last several years, bone marrow transplants have been attempted in an effort to provide the individual with stem cells capable of producing normal erythrocytes. Although bone marrow transplantation is an option for thalassemia patients with a suitable donor, this technology is not widely used at this time.²⁷ Clinical efficacy is questionable with the highest risk factor being lack of engraftment.

Drugs to treat leukemia are being used to induce the reexpression of latent γ -genes that would combine with the excess α -chains and produce HbF. The two major risk factors for this treatment approach include lack of γ -chain stimulation and induction of malignancy from the antileukemic drugs.^{28,29} Correction of the molecular defect with gene therapy may be achievable in the future.³⁰

Prognosis

Untreated patients generally expire during the first or second decade of life. Patients enrolled in a hypertransfusion program with chelation therapy can extend their life expectancy by at least a decade.³¹ Usually in the second decade of life, endocrine disorders (e.g., diabetes) and hepatic and cardiac disturbances develop from excessive deposits of iron in these tissues if chelation therapy has not been successful.

β -THALASSEMIA MINOR (β^0/β OR β^+/β)

Expected Genotypes

Beta-thalassemia minor results from the heterozygous inheritance of either a β^+ - or β^0 -gene with one normal β -gene (Table 5). Evidence is mounting that there is no major clinical difference in the expression between the two thalassemia genes in the heterozygous state due primarily to the enhanced output of β -chains from the normal β -allele. About 1% of African Americans are heterozygous for β -thalassemia.

Pathophysiology

The normal β -gene directs synthesis of sufficient amounts of β -chains to synthesize enough HbA for near normal oxygen delivery and erythrocyte survival. In the case of a heterozygous β^+ patient, the thalassemic gene can also contribute to β -chain production.

Clinical Findings

The heterozygote appears to be asymptomatic except in periods of stress as can occur during pregnancy and with infections and folic acid deficiency. Under such conditions, a moderate microcytic anemia can develop.

Laboratory Results

The anemia in β -thalassemia minor is mild with hemoglobin values ranging from 9 to 14 g/dL with the mean value for women being 10.9 g/dL and for men 12.9 g/dL.³²⁻³⁴ The erythrocyte count is increased ($> 5 \times 10^{12}/L$) for what is expected at the given hemoglobin concentration. The condition is usually discovered incidentally during testing for unrelated symptoms or during family study workups.

The erythrocytes are microcytic (MCV=55–70 fL) and hypochromic (MCHC=29–33 g/dL) or sometimes normochromic with an MCH that is usually less than 22 pg (Figure 11 ■). The degree of microcytosis, as indicated by the MCV, is directly related to the anemia's severity.²² Although the anemia is mild, the peripheral blood smear shows variable anisocytosis and poikilocytosis with target cells and basophilic stippling. Nucleated red blood cells are not usually found, but anemic patients can have a slightly elevated reticulocyte count. Bone marrow shows slight erythroid hyperplasia and normoblasts poorly filled with hemoglobin.

Hemoglobin electrophoresis demonstrates an increase in HbA₂ from 3.5 to 7% with a mean of 5.5%. Newborns have a normal HbA₂ concentration of $0.27 \pm 0.02\%$.²⁴ HbF is nor-

■ **FIGURE 11** Patients with β -thalassemia minor show minimal morphologic abnormalities to include microcytosis with target cells. The CBC in this patient showed the following results: Hb 11.1 g/dL; RBC count $5.2 \times 10^{12}/L$; MCV 61 fL; MCH 20.2 pg; MCHC 33 g/L. (Wright-Giemsa stain; 1000 \times magnification)

mal in approximately half of the patients and increased in the other half (Figure 10).^{35,36} If HbF exceeds 5%, however, the individual has probably inherited an HPFH gene (discussed later) in addition to the β -thalassemia gene. Vital stains to detect Heinz bodies are usually negative.

DNA-probing techniques can be performed to identify the type of mutation present and validate the heterozygous inheritance pattern but are of limited diagnostic value. Such information, however, can be helpful in counseling prospective parents with β -thalassemia minor.

Checkpoint! 7

In β -thalassemia, what erythrocyte parameter on the CBC differs significantly from that found in iron deficiency?

Treatment and Prognosis

Patients generally do not require treatment if they maintain good health and nutrition. They are generally asymptomatic except during periods of physiologic stress, and they have a normal life expectancy.

β -THALASSEMIA INTERMEDIA (β^+/β^+ , β^0/β^+ , β^0/β)

Expected Genotypes

All three patterns of inheritance—homozygous, double heterozygous, and heterozygous—can produce β -thalassemia intermedia (Table 5). The homozygous and double heterozygous forms represent a mutation in both β -alleles resulting in a moderate reduction in β -chain synthesis. Patients who inherit a mutation of one β -gene in conjunction with a nor-

mal β -gene occasionally exhibit clinical symptoms significant enough to be classified as β -thalassemia intermedia rather than β -thalassemia minor.

Patients with β -thalassemia intermedia who coexpress α -thalassemia or HPFH can actually experience milder symptoms as compared to those with pure β -thalassemia. In both cases, α -chain accumulation and precipitation is decreased, reducing the ineffective erythropoiesis and extravascular hemolysis responsible for much of the pathology. In the case of concomitant β -thalassemia intermedia and HPFH, the overexpressed γ -chains combine with the excessive α -chains to produce HbF, which reduces α -chain precipitation.

Clinical Findings

Patients with β -thalassemia intermedia can present with symptoms of intermediate hematologic severity between severe β -thalassemia major and mild β -thalassemia minor. The β^0/β^+ -genotype produces the greatest reduction in β -chain synthesis but has a variable clinical presentation; some patients have symptoms that can rival β -thalassemia major, and other patients have a much milder clinical phenotype. Patients expressing the β^0/β -genotype generally express mild symptoms. The generally accepted criterion for β -thalassemia intermedia is the ability to maintain a hemoglobin level associated with a comfortable survival without requiring regular transfusions.²⁶ The need for transfusions is defined by the quality of life, not the hemoglobin level per se. Some patients with a hemoglobin level of 7 g/dL can be relatively symptom free, but other patients with a hemoglobin of 9 g/dL can have clinical symptoms related to ineffective erythropoiesis. Clinical symptoms often intensify during periods of physiological stress as with pregnancy and infection and can require short-term transfusion therapy. Even in the absence of regular transfusions, some patients develop progressive iron overload and require iron-chelation therapy.

Laboratory Results

The CBC reflects a moderate microcytic hypochromic anemia with a hemoglobin value ranging from 7 to 10 g/dL. In the milder versions, patients express only a slight reduction in hemoglobin values. The red blood cell count is disproportionately higher than the hemoglobin values that often approach normal.

Target cells are the predominant poikilocytes observed. Basophilic stippling and nucleated red blood cells are also present. The bone marrow shows hypochromic normoblasts in the context of erythroid hyperplasia. However, bone marrow examination is not needed for diagnosis.

Hemoglobin electrophoresis patterns in patients with the more severe forms of β -thalassemia intermedia ($\beta^0\beta^+$ and $\beta^+\beta^+$) are nearly indistinguishable from those observed in the milder forms of β -thalassemia major ($\beta^+\beta^+$). Patients express elevated HbA₂ (5–10%) and HbF (30–75%) with the re-

mainder being HbA. Milder versions of β -thalassemia intermedia produce lower HbA₂ (>3.2%) and HbF levels (1.5–12.0%) (Figure 10). Although hemoglobin electrophoresis is helpful in the diagnosis of β -thalassemia intermedia, differentiation from β -thalassemia major and minor is a clinical decision.

Treatment and Prognosis

Splenomegaly is common. Functional hyposplenism leads to infections requiring regular interventions with antibiotic therapy. Chelation therapy is generally warranted to combat iron overload, which tends to develop later than in patients with β -thalassemia major. Most patients have a normal life span.

β -THALASSEMIA MINIMA (β^{SC}/β)

Beta-thalassemia minima is a form of asymptomatic β -thalassemia and exhibits no major laboratory abnormalities. The disorder is usually discovered serendipitously during family studies. The gene has been given the designation β^{SC} for silent carrier. The genotype used to describe a patient with β -thalassemia minima is β^{SC}/β .³⁷

CASE STUDY (continued from earlier in this chapter)

Additional tests were performed on John's blood to determine the cause of his anemia.

Hemoglobin Electrophoresis		Iron Panel	
HbA	66%	Serum iron	92 μ g/dL
HbA ₂	1.0%	TIBC	310 μ g/dL
HbF	1.0%	Serum ferritin	88 ng/mL
Hb Bart's	8%	Iron saturation	33%
HbH	24%		

- Is the hemoglobin electrophoresis normal or abnormal?
- If abnormal, list hemoglobins that are elevated, decreased, or abnormally present.
- If abnormal, which globin chain(s) is (are) decreased?
- If abnormal, which globin chains are produced in excess?
- Is the iron panel normal or abnormal?
- If the iron tests are abnormal, list those outside the normal range and indicate whether they are elevated or decreased.
- If the iron tests are abnormal, state the disorder(s) consistent with the abnormal iron panel.
- Given all the data supplied, what is the definitive diagnosis of John's anemia?

▶ **OTHER THALASSEMIAS AND THALASSEMIA-LIKE CONDITIONS**

In theory, any globin gene can be mutated, resulting in a reduction in the synthesis of globin chains and the corresponding hemoglobin. Patients have been observed with deficiencies in each of the normal adult globin chains. However, the thalassemias that involve globin chains other than α and β are relatively benign in their clinical course because they are not constituents of the major adult hemoglobin, HbA. Thalassemias have been observed involving more than one globin gene and in combination with structural hemoglobin disorders such as sickle cell anemia and HbC disease (Table 6 ) .

$\delta\beta$ -THALASSEMIA

Delta, beta-thalassemia is a rare thalassemia observed primarily in patients of Greek, African, Italian, and Arabian ancestry in which production of both β - and δ -chains is affected. The $\delta\beta$ -mutation can be categorized into two genotypes, $\delta\beta^0$ and $\delta\beta^+$. The $\delta\beta^0$ designation indicates a complete lack of synthesis of both β - and δ -chains from a given chromosome, whereas the $\delta\beta^+$ -genotype suggests a reduction in β - and δ -chain synthesis. The absence of β - and δ -chains is most often due to deletion of the structural β - and δ -gene complex. One or both of the γ -genes remain, resulting in 100% HbF in homozygous $\delta\beta^0/\delta\beta^0$.³⁰ However, increased γ -chain production fails to fully compensate for the loss of β -chain

 **TABLE 6**

Characteristics of Other Thalassemias and Thalassemia-Like Conditions

Disorder	Defect	Ancestry	CBC/diff	Hb Electrophoresis	Other
$\delta\beta$ thalassemia homozygous ($\delta\beta^0/\delta\beta^0$)	Deletion of $\delta\beta$ -gene complex	Greek, African, Italian, Arabian	Micro/hypo RBCs Hb 10–12 g/dL	↓↓ HbA, ↓↓ HbA ₂ , ↑↑ HbF	Thalassemia intermedia
heterozygous ($\delta\beta^0/\beta$)		Same as heterozygous	No anemia	↓ HbA, N- ↓ HbA ₂ , ↑ HbF	Thalassemia minor
$\gamma\delta\beta$ thalassemia heterozygous ($\gamma\delta\beta^0/\beta$)	Deletion or inactivation of β -gene complex	Mediterranean regions	Birth: Marked anemia; Adult: Slight anemia	↓ HbA, ↓ HbA ₂ , ↓ HbF	Thalassemia minor
homozygous ($\gamma\delta\beta^0/\gamma\delta\beta^0$)		Same as heterozygous	Unable to observe	No adult Hb	Fatal
Constant Spring homozygous ($\alpha\alpha^{CS}/\alpha\alpha^{CS}$)	Long α -chain, mutated stop codon, reduced synthesis	Thailand	Micro/hypo RBCs, Hb 9–11 g/dL, ↑ Reticulocytes	Hb Bart's at birth, ↑↑ HbCS, ↓ HbA, N-HbA ₂ and HbF	
heterozygous ($\alpha\alpha^{CS}/\alpha\alpha$)		Same as homozygous	Normal	↑ HbCS	Can be seen with α -thal2 trait
HPFH homozygous ($\delta\beta^0/\delta\beta^0$)	Deletion or inactivation of $\delta\beta$ -gene complex	Greek, Swiss, black	Mild micro/hypo RBCs, no anemia, ↑↑ RBC, Hb 14–18 g/dL	100% HbF	2 variants—pancellular, heterocellular Asymptomatic
heterozygous ($\delta\beta^0/\beta$)		Same as homozygous	Near normal	↑ HbF, ↓ HbA, ↓ HbA ₂	Asymptomatic
Hb Lepore homozygous ($\delta\beta^{Lepore}/\delta\beta^{Lepore}$)	$\delta\beta$ -hybrid chain	European	Marked micro/hypo RBCs, Hb 4–11 g/dL, ↑↑↑ anisopoikilocytosis	No HbA, No HbA ₂ , ↑↑ Hb Lepore, ↑↑ HbF	Thalassemia major or intermedia
heterozygous ($\delta\beta^{Lepore}/\beta$)		Same as homozygous	Slight micro/hypo RBCs, Hb 12 g/dL	↓ HbA, ↓ HbA ₂ , ↑ Hb Lepore	Thalassemia minor

↑↑↑ = marked increase; ↑↑ = moderate increase; ↑ = slight increase; ↓↓ moderate decrease; ↓ = slight decrease; N = normal

production, resulting in a thalassemic phenotype and anemia.

It appears that in $\delta\beta$ -thalassemia, the compensation of γ -chain synthesis is less than in HPFH but more than in homozygous β^0 -thalassemia. Clinically, the disease is classified as thalassemia intermedia and rarely requires blood transfusions except in cases of physiological stress such as in pregnancy or infection. Thus, most patients with $\delta\beta$ -thalassemia have a mild hypochromic, microcytic anemia. Patients have slight hepatosplenomegaly and some bone changes associated with chronic erythroid hyperplasia. Hemolysis probably contributes to the anemia because both reticulocytes and bilirubin are elevated.

The heterozygous form of $\delta\beta$ -thalassemia ($\delta\beta^0/\beta$) is not identified with any specific clinical finding. There is no anemia or splenomegaly. The hematological picture, however, is similar to that of β -thalassemia minor with microcytic, hypochromic erythrocytes. Hemoglobin A_2 is normal or slightly decreased while HbF is increased to 5–20%. HbA is usually less than 90% (Table 6).

$\gamma\delta\beta$ -Thalassemia

This rare form of thalassemia has several variants and is characterized by deletion or inactivation of the entire β -gene complex.²⁵ Deletion of the γ -, δ -, and β -genes would result in the absence of all normal adult hemoglobin production from that chromosome. Therefore, only the heterozygous state has been encountered, presumably because a homozygous condition would be incompatible with life. Although neonates have severe hemolytic anemia, as the child grows, the disease evolves to a mild form of β -thalassemia.

HEMOGLOBIN CONSTANT SPRING

Hemoglobin Constant Spring (HbCS) is a hemoglobin tetramer formed from the combination of two structurally abnormal α -chains, each elongated by 31 amino acids at the carboxy-terminal end, and two normal β -chains. This genetic mutation is common in Thailand. The chromosome with the α^{CS} gene carries one normal α -gene (remember that each chromosome 16 has 2 α -genes for a total of 4 α -genes); thus, the homozygous HbCS individual has two normal α -genes, one on each chromosome, and the heterozygous HbCS carrier has three normal α -genes.

The elongated α -chains of HbCS are thought to result from a mutation of the α -chain termination codon by a single base substitution.³⁸ The abnormal α -chains are synthesized at very low levels ($\sim 1\%$ of the output compared to a normal α gene) due to reduced stability of the mRNA. The result is an overall deficiency of α -chain synthesis producing an α -thalassemia-like phenotype.

Clinical Findings

The homozygous state is phenotypically similar to α -thalassemia minor. A slight anemia accompanied by mild jaundice and splenomegaly is typical. Heterozygotes show no clinical abnormalities.

Laboratory Results

In homozygotes, clinical findings are similar to a relatively mild form of HbH disease with a mild microcytic hypochromic anemia. Hemoglobin electrophoresis demonstrates the presence of Hb Bart's at birth. In homozygous adults, HbCS makes up 5–7% of the hemoglobin and HbA₂ and HbF remain normal. The remainder of hemoglobin is HbA (Figure 2).

Heterozygotes show no hematological abnormalities, but a small amount of HbCS (0.2–1.7%) can be found on electrophoresis. HbA₂ and HbF are normal with the remainder being HbA (Figure 2).

In some areas, the coexistence of HbCS with α -thalassemia trait ($--/\alpha\alpha^{CS}$) is a rather common finding. The clinical findings are similar to those of HbH disease. Hemoglobin electrophoresis characteristically shows HbA, HbH, Hb Bart's, HbA₂, and 1.5–2.5% HbCS³⁹ (Figure 2) (Table 6).

Checkpoint! 8

Why is $\gamma\delta\beta$ -thalassemia more severe than $\delta\beta$ -thalassemia and CS-thalassemia?

HEREDITARY PERSISTENCE OF FETAL HEMOGLOBIN (HPFH)

Hereditary persistence of fetal hemoglobin (HPFH) is actually a group of heterogeneous disorders in which the absence of δ - and β -chain synthesis is compensated for by increased γ -chain production into adult life. In homozygotes, the result is an absence of HbA and HbA₂ with 100% of hemoglobin production being HbF. Hemoglobin F production continues at high levels throughout life, preventing the clinical symptoms and hematological abnormalities associated with thalassemia. The condition occurs in 0.1% of African Americans.

Genetics

HPFH is characterized by either deletion or inactivation of the β - and δ -structural gene complex. Most α -chains combine with the available γ -chains to produce HbF. Consequently, no accumulation and no precipitation of excess α -chains occur. In HPFH, increased production of γ -chains with the corresponding elevations of HbF compensates for the reduction in HbA and A₂ synthesis and differentiates it from $\delta\beta$ -thalassemia, in which only modest elevations in HbF are observed.

Variants

HPFH can be categorized into two major groups, pancellular and heterocellular, based on the distribution of HbF in erythrocytes. The HbF distribution patterns can be visualized using the acid elution stain developed by Kleihauer and Betke. Pancellular refers to the observance of HbF in most of the erythrocytes; in the heterocellular version, HbF is concentrated in a small subset of erythrocytes.

Several different types of HPFH have been described: the black, Greek, and Swiss types. In the black and Swiss types, both $G\gamma$ - and $A\gamma$ -chains are produced in approximately equal amounts. The Greek form is characterized by production of both $G\gamma$ - and $A\gamma$ -chains, but most HbF is made up of the $A\gamma$ -chains. Both the black and Greek types have the characteristic pancellular distribution pattern of HbF in erythrocytes. However, the Swiss form exhibits a heterocellular distribution of HbF. This heterocellular distribution results from a hereditary increase (3%) in the number of fetal (F) cells.^{13,14} (Table 7 )

When present, the pancellular distribution of HbF in erythrocytes helps to distinguish this disorder from other disorders associated with an increase in HbF. Most other disorders with elevated HbF levels present with the heterocellular distribution pattern.

It has been suggested that the various categories of HPFH actually represent a continuum of a spectrum of β -thalassemias with homozygous β^0 -thalassemia at one end where the lack of β -chain synthesis is poorly compensated for by γ -chain production and with pancellular HPFH at the other end where the lack of β -chain synthesis is almost completely compensated for by γ -chain production.

Homozygotes

Homozygous HPFH is asymptomatic including no evidence of abnormal growth patterns or splenomegaly. The abundant γ -chains combine with the normal α -chains to produce HbF.

Erythrocytosis ranging from $6 \times 10^{12}/L$ to $7 \times 10^{12}/L$ occurs as the result of the higher oxygen affinity of HbF as compared to HbA. Correspondingly, high hemoglobin levels from 14.8 to 18.2 g/dL are also typical in HPFH. Erythrocytes are microcytic and slightly hypochromic with a mean MCV of 75 fL and a mean MCH of 25.0 pg. There is a mild degree of anisocytosis and poikilocytosis. The reticulocyte count

ranges from 1 to 2%. It is doubtful that this disorder has any significant degree of hemolysis because the reticulocyte count, bilirubin, and haptoglobin levels are normal. Electrophoresis demonstrates 100% HbF.

Heterozygotes

Heterozygous HPFH is usually found incidentally through family studies. Patients present with a slightly elevated erythrocyte count with the corresponding elevation of the hematocrit and a slightly decreased MCH (27 pg). HbF increases to 10 to 30%. Hemoglobin A_2 is decreased to 1–2% and the remainder is HbA. In the presence of iron deficiency, HbF levels are lower (Table 6).

HEMOGLOBIN LEPORE

Incidence and Affected Individuals

Hemoglobin Lepore was first described in 1958 as a structural hemoglobin variant with hematological changes and clinical manifestations resembling those of thalassemia.⁴⁰ The disorder is widely distributed throughout the world but is especially common in Middle and Eastern Europe.

Genetics

In Hb Lepore, the non- α -chain is a δ/β -globin hybrid in which the N-terminal end of a δ -chain is fused to the C-terminal end of a β -chain. The variant hybrid genes are thought to occur during meiosis from an aberrant **crossover** event resulting in recombination of misaligned δ - and β -genes on separate chromosomes. The result of the unequal crossover event is two fusion genes, the δ/β -Lepore and the β/δ -anti-Lepore fusion genes. The δ/β -Lepore fusion gene is transcribed and translated into the δ/β -fusion globin chain, two of which combine with two α -chains to form Hb Lepore. The chromosome containing the β/δ -anti-Lepore fusion gene still contains intact β - and δ -genes that are synthesized normally to form HbA and A_2 , respectively. Progeny bear genes from the involved chromosome that are neither fully paternal nor fully maternal. Because the recombination event occurred in the germ cells, the newly formed chromosomes become a permanent part of the family's gene pool. Hb Lepore is stable and has normal functional properties except for a slight increase in oxygen affinity.

Pathophysiology

The pathophysiology of hemoglobin Lepore is similar to that of β -thalassemia. No intact β -gene is present, so β -chain synthesis is absent. The Hb Lepore gene is under the influence of the δ -gene promoter, which limits synthesis of the Lepore hybrid chain to approximately 2.5% of normal β -chain production. Thus, the abnormal Lepore chains are inadequately synthesized, leading to an excess of α -chains. In the homozygous state, no normal β -chains or δ -chains would be synthesized to combine with the α -chains being produced, thus no HbA or HbA₂. The more severely affected children can

 TABLE 7

Characteristics of HPFH Variants

HPFH Type	Types of γ -chains Produced	Distribution of HbF in Erythrocytes
Black	$G\gamma$ - and $A\gamma$ -	Pancellular
Swiss	$G\gamma$ - and $A\gamma$ -	Heterocellular
Greek	Primarily $A\gamma$ -	Pancellular

become transfusion dependent and develop complications of hemosiderosis. The combination of ineffective erythropoiesis, decreased HbA, increased oxygen affinity of HbF, and chronic extravascular hemolysis produces a microcytic hypochromic anemia that is classified as β -thalassemia major in the more severe cases and as β -thalassemia intermedia in the remaining cases. As with β -thalassemia major, symptoms emerge within the first few years of life.

Patients with heterozygous Hb Lepore are asymptomatic and classified as β -thalassemia minor. The blood picture is similar to that seen in β -thalassemia minor.

Laboratory Results

In the homozygous state, hematologic findings are similar to β -thalassemia major. There is no detectable HbA or A₂ on hemoglobin electrophoresis, Hb Lepore ranges from 8–30%, and the remainder consists of HbF. Hemoglobin electrophoresis must be interpreted with caution because Hb Lepore comigrates with HbS on cellulose acetate agarose at an alkaline pH and with HbA on citrate agar at an acid pH.

In the heterozygous state, hematologic findings are similar to thalassemia minor (Figure 12■): Hemoglobin electrophoresis reveals a mean Hb Lepore concentration of 10%; HbA₂ is decreased with a mean of 2%; HbF is usually slightly elevated to 2–3%; and HbA makes up the remainder (Table 6).

The severely anemic cases of Hb Lepore require a regular transfusion protocol from early childhood. Splenectomy is also performed in an attempt to lessen the degree of anemia.

COMBINATION DISORDERS

Occasionally an individual is doubly heterozygous for a structural hemoglobin variant and thalassemia, inheriting one of the two abnormalities from each parent. The most common structural hemoglobin variants involved in combination disorders are HbS, HbC, and HbE. When a structural variant is inherited with a β -thalassemia gene, the severity of the combination disorder depends on the type of α - or

β -gene mutation. Patients expressing the β^0 -gene produce no HbA and experience moderate to severe symptoms. The β^+ -gene produces some β -chains resulting in HbA synthesis and fewer to no symptoms. The most common example is HbS/ β -thalassemia accounting for 1 in 1,667 births among African Americans.⁴¹ This has also been reported in patients of Greek, Turkish, Indian, North American, Mediterranean, and Rumanian ancestry.⁴² Three clinical severities have been identified: HbS/ β^0 -Type 1 (severe), HbS/ β^+ -Type 1 (moderate), and HbS/ β^+ -Type 2 (asymptomatic). Differentiating this combination disorder from sickle cell disease (HbSS) and trait (HbAS) is sometimes difficult, but a comparison of β/α ratio can be helpful (Web Table 1★). In sickle cell disorders, the β/α ratio is approximately 1/1, whereas it is closer to 0.5/1 in HbS/ β -thalassemia.⁴³

Combination disorders are more complex when the structural hemoglobin gene mutation is on the β -gene and the thalassemia mutation involves the α -gene because different chromosomes are involved. These patients can be either homozygous or heterozygous for the structural hemoglobin variant and coexpress any of the possible α -gene combinations.

The severity of the combination disorder is directly proportional to the total number of affected genes and ranges from moderate to asymptomatic.^{44–46} Coexistent α -thalassemia decreases synthesis of α -chains resulting in fewer α -globin chains available to combine with the structurally abnormal β -chain. Thus, the concentration of the structural variant is usually decreased because the limited number of α chains preferentially combine with the normal β or δ (or γ) chains. The percentage of HbA, HbF, and HbA₂ increases relative to a typical heterozygote, reducing the abnormal pathophysiology associated with the particular structural hemoglobin variant inherited.

In the case of a homozygous $\beta^S\beta^S$ individual with an α -thalassemia syndrome, the clinical severity of sickling is often reduced because of a net decrease in MCHC, which reduces the tendency of HbS to polymerize. Thus, cell hemolysis and the clinical symptoms associated with occlusion of the microvasculature decrease. HbF has also been shown to decrease the sickling process.⁷ The wide variety of clinical severities seen in sickle cell anemia can be related to the high incidence of α -thalassemia in the same population (Figure 13■).

Laboratory diagnosis is accomplished by applying the techniques used to identify each of the disorders individually. Patients present with a mild microcytic, hypochromic anemia with target cells and the poikilocytes associated with the structural hemoglobin variant inherited. Patients who inherit HbS can have sickle cells, and those with HbC sometimes show HbC crystals. Hemoglobin electrophoresis is helpful in resolving the structural hemoglobin variant and shows the quantitative changes in normal and abnormal hemoglobins associated with α - and β -thalassemias. In HbS/ α -thalassemia, the concentration of HbS is inversely

■ **FIGURE 12** Peripheral blood smear from a patient with hemoglobin Lepore. Note the anisocytosis, poikilocytosis, and microcytosis. (Wright-Giemsa stain; 1000× magnification)

FIGURE 13 Peripheral blood smear from a patient with hemoglobin S and α -thalassemia. The cells are microcytic. There are acanthocytes and cells with pointed ends present. (Wright-Giemsa stain; 1000 \times magnification)

proportional to the number α -gene deletions. HbS concentration is $\sim 35\%$ with one α -gene deletion, $\sim 28\%$ with two α -deletions, and $\sim 20\%$ with three α -genes deletions.⁴⁷

When less common structural variants (HbE, HbO, HbD, etc.) are coexpressed with thalassemias, more testing can be necessary because they comigrate with HbS or HbC on hemoglobin electrophoresis (Figure 2). Molecular techniques including automated sequencing, dot-blot analysis, or allele-specific amplification can be used in these cases.⁴⁸

The incidence of double heterozygotes expressing both HbE and β -thalassemia is increasing in Southeast Asia, and many patients are presenting with symptoms that rival β -thalassemia major in severity.⁴⁹ Approximately 3,000 of these people with double heterozygotes are born each year in Thailand, and many others are diagnosed in other parts of Southeast Asia, India, and Burma. In Thailand, Laos, and Cambodia, HbE penetrance is approximately 50%. HbE heterozygotes usually have relatively mild disease; HbE/ β -thal double heterozygotes might be expected to have a moderately severe disease.⁵⁰ However, the HbE mutation at the 26th position of the β -globin gene activates a cryptic splice site at codon 25, resulting in significantly reduced β -chain production. Therefore, in double heterozygotes of HbE and β^0 -thal, few to no β^E or β^A -chains are produced. This results in the accumulation of α -chains that precipitate within the erythrocytes, producing hemolysis as in β -thalassemia major.^{50,51}

Double heterozygotes for sickle cell and HPFH (deletion variant) exhibit a mild form of sickle cell trait with no occurrence of crises or anemia. It has been suggested that the surprisingly favorable clinical picture is related to the distribution of HbF in erythrocytes. The peripheral blood smear shows anisocytosis and target cells, and the sodium metabisulfite and solubility tests are positive. Hemoglobin electrophoresis produces a pattern that is easily confused with that of sickle cell anemia. Only HbS, HbF, and HbA₂ are present with HbF levels ranging from 15 to 35%. Hemoglo-

bin A₂ is normal or reduced. Family studies are helpful in identifying double heterozygous states.

Due to the significant variations in clinical expression of the various hemoglobin structural variants and β -thalassemia alleles, it is suggested that identification of these conditions should go beyond hematologic analysis and hemoglobin electrophoresis.⁴⁸ A diagnosis defined at the molecular level to identify the genetic mutation can lead to better clinical management of the disease. A summary of the differentiating characteristics of combination thalassemia and hemoglobinopathy disorders can be found in Web Table 1.

✓ Checkpoint! 9

In combination disorders of structural Hb variants and thalassemia, why is the severity less when α -thalassemia is inherited with sickle cell trait than when β -thalassemia is coexpressed with sickle cell trait?

▶ DIFFERENTIAL DIAGNOSIS OF THALASSEMIA

Clinical signs, symptoms, and CBC results are strikingly similar in microcytic hypochromic anemias regardless of the etiology of the anemia, making the clinical diagnosis difficult. Differentiating the various thalassemias is even more difficult because they are all inherited and occur in similar nationalities. Additional laboratory tests are therefore crucial in making the differential diagnosis.^{52,53} Web Table 2  summarizes the tests used to differentiate thalassemia from other anemias.

✓ Checkpoint! 10

Which laboratory tests should be done first to differentiate thalassemia and iron deficiency?

SUMMARY

Thalassemias result from genetic defects that affect the production of globin chains. Any of the globin chains can be affected, but the most clinically significant are α - and β -chain defects. The clinical severity of the disease is related to the number of mutated genes and the type of genetic defect. The human diploid genome normally has four α -genes. In α -thalassemia, from one to four of the α -genes can be deleted. If only one gene is affected, the condition is not clinically or hematologically apparent, but if two or three are affected, both clinical and hematological abnormalities of mild or moderate severity, respectively, occur. Deletion of all four α -genes is incompatible with life. There are two β -alleles and two β -thalassemia gene defects; one causes a complete absence of β -chain production (β^0 -thalassemia), and the other causes decreased synthesis of β -chain production (β^+ -thalassemia). This results in five potential

β -thalassemia genotypes ($\beta^0\beta^0$, $\beta^0\beta^+$, $\beta^+\beta^+$, $\beta^0\beta$, $\beta^+\beta$) that are categorized into four clinical severities (β -thalassemia major, intermedia, minor, and silent carrier) ranging from severe to asymptomatic.

The thalassemias generally produce a microcytic, hypochromic anemia with changes in the concentrations of HbF, HbA₂, and HbA. HbF and HbA₂ are elevated in β -thalassemia and decreased in α -thalassemia with decreased concentrations of HbA in both. In the more severe α -thalassemias, HbH (β^4) and Hb Bart's (γ^4) can be detected. Erythrocyte morphology is similar in both major forms of thalassemia and in iron deficiency anemia; however, hemoglobin

electrophoresis and iron studies assist in differentiating these two entities. Some structural hemoglobin variants are synthesized in decreased quantities (i.e., Hb Lepore, Hb Constant Spring, HbE) and have morphologic similarities to thalassemias. Molecular techniques are now available to identify the genetic mutation in the globin gene but are not always necessary for diagnostic purposes.

Current therapies are improving, and medical access in underdeveloped countries is expanding. As a result of these advances, the general health and quality of life are improving for patients with thalassemia.

REVIEW QUESTIONS

LEVEL I

- Select the statement that best defines thalassemia. (Objective 1)
 - a qualitative disorder of hemoglobin synthesis derived primarily from a genetic point mutation in one or more globin genes
 - a disorder of inappropriate iron metabolism due to abnormal transferrin
 - a quantitative disorder of hemoglobin synthesis resulting from deletional and nondeletional mutations of globin genes
 - a single amino acid substitution in a globin chain affecting the function of hemoglobin
- Which of the following statements is *false* for a patient with thalassemia but *true* in certain hemoglobinopathies? (Objective 2)
 - Abnormal hemoglobin will polymerize inside erythrocytes, altering red cell shape.
 - Novel hemoglobins composed of abnormal combinations of normal globin chains can be detected on hemoglobin electrophoresis.
 - Elevations in embryonic and fetal hemoglobins can be observed.
 - The amino acid sequence of the globin chains of the abnormal hemoglobins is normal.
- What is the typical morphologic classification of erythrocytes in thalassemia? (Objective 3)
 - macrocytic, normochromic
 - normocytic, normochromic
 - microcytic, hyperchromic
 - microcytic, hypochromic
- Select the disorder that is an α -thalassemia. (Objectives 5a, 5b)
 - HbH disease
 - Cooley's anemia
 - HPFH
 - Hb Lepore

LEVEL II

- Alpha-thalassemia most commonly results from which of the following genetic lesions? (Objective 1)
 - gene deletion
 - promoter mutation
 - termination codon mutation
 - splice site mutation
- Why is hydrops fetalis incompatible with life? (Objective 4b)
 - Life cannot exist without HbA.
 - Lack of embryonic hemoglobins precludes fetal development.
 - All three normal adult hemoglobins contain α -chains.
 - Fetal hemoglobin is essential to sustain life after birth.
- Which pathophysiologic event is involved in the pathogenesis of HbH disease? (Objective 4b)
 - HbH has a higher affinity for oxygen that hampers oxygen release.
 - HbH is an embryonic hemoglobin that is not present at birth.
 - HbH cannot bind and transport oxygen.
 - Polymerization of abnormal hemoglobin alters erythrocyte shape.
- The genetic designation heterozygous α^0 -thal-1/normal refers to: (Objective 4a)
 - α -thalassemia minor
 - Cooley's anemia
 - HbH disease
 - silent carrier
- The single best laboratory test to distinguish β -thalassemia minor from α -thalassemia, iron-deficiency anemia, HPFH, and hemoglobinopathies is: (Objective 8)
 - hemoglobin solubility
 - serum iron
 - Heinz body stain
 - HbA₂ level

REVIEW QUESTIONS (continued)

LEVEL I

5. Alpha-thalassemia is characterized by: (Objective 5c)
 - a. deletion of β -genes
 - b. amino acid substitutions in the α -chain
 - c. excess α -chain production
 - d. deletion of α -genes
6. Which nationality is *most* likely to be affected by thalassemia? (Objectives 5b, 6a)
 - a. Chinese
 - b. South American Indians
 - c. Southeast Asians
 - d. Europeans
7. Which of the following laboratory results would be expected in a patient with α -thalassemia? (Objective 5e)
 - a. MCH=32 pg
 - b. MCV=70 fL
 - c. stomatocytes
 - d. increased HbA
8. The pathogenesis of β -thalassemia includes: (Objective 6b)
 - a. decreased production of β -chains
 - b. abnormal structure of α -chains
 - c. bone marrow hypoproliferation
 - d. decreased synthesis of erythropoietin
9. In β -thalassemia major, hemoglobin electrophoresis will show: (Objective 6d)
 - a. reduced HbF
 - b. reduced HbA₂
 - c. reduced HbA
 - d. increased HbH
10. Select the thalassemia type in which the patient survives and presents with an abnormal hemoglobin that is sensitive to oxidation and precipitates in red cells after incubation with brilliant cresyl blue. (Objective 6d)
 - a. hydrops fetalis
 - b. HbH disease
 - c. β -thalassemia minor
 - d. silent carrier

LEVEL II

6. Hemoglobin constant spring can best be described as: (Objective 7c)
 - a. deletion of three α -genes
 - b. two normal β -chains and two elongated α -chains
 - c. two normal α -chains and two β/γ -fusion chains
 - d. continued synthesis of γ -chains throughout adult life
7. Select the statement that best describes hereditary persistence of fetal hemoglobin. (Objective 7d)
 - a. The homozygous state is incompatible with life.
 - b. HbF is elevated in adults.
 - c. It results from the deletion of the γ -gene.
 - d. It is a form of β -thalassemia.
8. A 4-year-old male patient has a microcytic, hypochromic anemia. Hemoglobin electrophoresis shows 46% HbS, 49% HbA, 3.5% HbA₂, 1.5% HbF. His parents have no symptoms of anemia. What are his parents' most likely phenotypes? (Objectives 5, 7)
 - a. sickle cell trait and β -thalassemia major
 - b. sickle cell anemia and α -thalassemia
 - c. sickle cell anemia and heterozygous β -thalassemia
 - d. sickle cell trait and normal
9. Which combination disorder would exhibit more severe symptoms? (Objective 7f)
 - a. HbS and β -thalassemia minor
 - b. HbC trait and α -thalassemia minor
 - c. HPFH and β -thalassemia minor
 - d. HbS and HPFH
10. A 28-year-old female from Laos who had a hemoglobin of 11.2 g/dL was diagnosed with iron deficiency anemia. She was given iron supplements. Her reticulocyte count increased from 4% to 5% after 6 days of treatment. Six months later, she returned for a follow-up CBC. Her hemoglobin was 11.5 g/dL, and the red cells were microcytic (75 fL), normochromic. What reflex test should be done? (Objective 8)
 - a. hemoglobin electrophoresis
 - b. serum iron
 - c. bone marrow
 - d. serum ferritin

ANSWERS TO CASE STUDY QUESTIONS

Case Summary: John had the typical symptoms of anemia. His CBC revealed a microcytic, hypochromic anemia. Tests for iron deficiency were negative. Hemoglobin electrophoresis was abnormal with the presence of hemoglobins H and Bart's. These hemoglobins indicate a deficiency of α -chains. The presence of some HbA, HbA₂, and HbF indicate that some α -chains are being produced. This suggests the presence of α -thalassemia. The parents also exhibit symptoms of anemia and should be tested to determine whether they have a form of α -thalassemia. This will help confirm the child's diagnosis.

Question:

1. Based on the indices, classify the anemia morphologically.

Explanation:

Microcytic, hypochromic

MCV = 69 fL

MCH = 21 pg

MCHC = 29.2 g/dL

The MCV is below the lower limit of normal (80 fL) indicating the presence of microcytic erythrocytes. The MCHC is the best indicator of hemoglobin content and is below the lower limit of normal (32 g/dL), suggesting hypochromasia. The below normal MCH (<27 pg) corroborates the decreased hemoglobin content.

Question:

2. Name the dominant poikilocyte observed in this peripheral blood smear.

Explanation:

The dominant poikilocytes are target cells.

Question:

3. Name three disorders that frequently present with the same poikilocyte that dominates in this peripheral blood smear.

Explanation:

Thalassemia

Hemoglobinopathy

Iron-deficient anemia

Liver disease

Question:

4. List two additional lab tests that would help confirm the diagnosis and predict the results of each.

Explanation:

Disorder	Hb Electrophoresis	Hb Solubility Test	Iron Panel
Thalassemia (α)	HbH Hb Bart's ↓ HbA, A ₂ , and F	Negative	Normal
Thalassemia (β)	Hb Bart's ↓ HbA ↑ HbA ₂ and HbF	Negative	Normal
Hemoglobinopathy	HbS or HbC or HbE, etc. ↓ HbA	Positive with some (HbS, etc.)	Normal
Iron deficiency anemia	Normal	Negative	↓ Serum iron ↓ Ferritin ↓ % Saturation ↓ BM iron ↑ TIBC

Question:

5. Is the hemoglobin electrophoresis normal or abnormal?

Explanation:

Abnormal.

Question:

6. If abnormal, list hemoglobins that are elevated, decreased, or abnormally present.

Explanation:

Elevated	Decreased	Abnormal
None	HbA HbF HbA ₂	Hb Bart's HbH

Question:

7. If abnormal, which globin chain(s) is(are) decreased?

Explanation:

α -chains and all α -chain containing hemoglobins (HbA, F, and A₂) are decreased.

Question:

8. If abnormal, which globin chain(s) is (are) produced in excess?

Explanation:

β -chain containing HbH and γ -chain containing Hb Bart's are elevated, ruling out a β -, γ -, $\delta\beta$ -, and $\gamma\delta\beta$ -thalassemia.

Question:

9. Is the iron panel normal or abnormal?

Explanation:

Normal.

Question:

10. If the iron test results are abnormal, list those outside the normal range and indicate whether they are elevated or decreased.

Explanation:

Normal, so nonapplicable.

Question:

11. If abnormal, state the disorder(s) consistent with the abnormal iron panel.

Explanation:

An abnormal iron panel usually presents with a pattern consistent with one of the iron metabolism disorders (i.e., iron deficiency, lead poison-

ing, anemia of chronic disease, sideroblastic anemia). A normal iron panel, as is the case here, rules out iron deficiency anemia.

Question:

12. Given all the data supplied, what is the definitive diagnosis of John's anemia?

Explanation:

A microcytic, hypochromic anemia with target cells suggests a thalassemia, hemoglobinopathy, or iron-deficiency anemia. The other microcytic, hypochromic anemias involving abnormal iron metabolism are also possibilities but usually do not present with significant numbers of target cells. The normal iron panel rules out iron deficiency anemia and the other disorders of iron metabolism. The negative hemoglobin solubility rules out some hemoglobinopathies. The abnormal hemoglobin electrophoresis confirms the diagnosis by further ruling out iron deficiency (which shows a normal Hb electrophoresis) and hemoglobinopathies by absence of structural hemoglobin variants that have an amino acid substitution (i.e., HbS, HbC, HbE). The decreased concentration of all three α -containing hemoglobins, HbA, HbA₂, and HbF, suggest an α -thalassemia. The presence of the abnormal hemoglobins, HbH and Hb Bart's, rule out a β - and γ -thalassemia, respectively. The severity of the symptoms, the inherited nature of the disease, the early age of onset, the microcytic, hypochromic peripheral blood picture with target cells, and the presence of HbH and Hb Bart's on Hb electrophoresis indicate a severe form of α -thalassemia called *HbH disease*.

ANSWERS TO CHECKPOINTS

Checkpoint! 1

Differentiate the etiology of thalassemias and hemoglobinopathies.

Answer

Thalassemia results from deletional or nondeletional mutations in one or more globin genes that reduce or eliminate synthesis of the corresponding globin chain(s). Hemoglobinopathy is a qualitative hemoglobin disorder caused by a point mutation in a globin gene, usually the β -gene, that results in an amino acid substitution in the corresponding globin chain and alters hemoglobin stability and function.

Checkpoint! 2

What are the most common genetic mutations associated with α -thalassemia?

Answer

Gene deletions.

Checkpoint! 3

Why do α - and β -thalassemia result in more clinically severe disease than other types of thalassemia?

Answer

HbA is composed of α - and β -chains and constitutes 97% of adult hemoglobin. Thus, a reduction in either α - or β -chains decreases the concentration of the most abundant normal adult hemoglobin. The other globin chains are associated with hemoglobins that are either low in concentration in adult blood or are designed to function in embryonic or fetal life.

Checkpoint! 4

Which of the three normal adult hemoglobins would be affected in hydrops fetalis?

Answer

Hydrops fetalis occurs when there is a deletion in all 4 α -genes; therefore, all three normal adult hemoglobins, HbA, HbA₂, and HbF, are affected because each contains α -chains.

Checkpoint! 5

Compare oxygen binding characteristics of HbH relative to HbA and myoglobin.

Answer

The allosteric interactions of the two α -chains and the two β -chains confer on HbA cooperative oxygen binding characteristics called *heme/heme interaction*. As a deoxygenated HbA molecule binds an oxygen molecule, hemoglobin incurs an increased affinity for oxygen at the other three available sites. Oxygen affinity continues to increase with each subsequent molecule bound. By virtue of the binding of hydrogen atoms and 2,3-DPG to oxyhemoglobin in the tissues, HbA releases oxygen molecules in an incremental fashion regulated by the oxygen, carbon dioxide, and hydrogen ion concentration in the tissue. The incremental binding and release of oxygen is expressed as a sigmoidal oxygen dissociation curve. HbH, by virtue of its four β -chain composition, does not exhibit heme/heme interaction and therefore functions as four separate subunits with identical oxygen affinities. The oxygen dissociation curve is therefore expressed as a hyperbolic curve similar to that of monomeric myoglobin.

Checkpoint! 6

Why do the symptoms of β -thalassemia major delay until approximately the sixth month of life?

Answer

β -thalassemia major is characterized by an absence or significant reduction in the synthesis of β -chains. Although the synthesis of β -chains begins at approximately the third trimester of fetal development, quantities sufficient to assemble significant amounts of HbA do not occur until approximately 6 months of age. Therefore, the lack of production of β -chains and the resultant lack of HbA is not manifested until 6 months of age when HbA synthesis is expected. The major hemoglobin at birth is HbF.

Checkpoint! 7

In β -thalassemia, what erythrocyte parameter from the CBC differs significantly from that found in iron deficiency?

Answer

The erythrocyte count in thalassemia is normal or high for the degree of anemia, but in iron deficiency, it is decreased. Both iron deficiency and thalassemia are characterized by microcytic, hypochromic anemia with target cells.

Checkpoint! 8

Why is $\gamma\delta\beta$ -thalassemia more severe than $\delta\beta$ -thalassemia and CS thalassemia?

Answer

All normal adult hemoglobin contains α -chains with either γ - (HbF), δ - (HbA₂), or β - (HbA) chains. A reduction or absence of all three chains in $\gamma\delta\beta$ -thalassemia decreases the production of all three adult hemoglobins. $\delta\beta$ -thalassemia can partially compensate by producing γ -chains (HbF). Patients with CS thalassemia bear some normal α -genes and can therefore make all adult hemoglobins, albeit at a reduced rate.

Checkpoint! 9

In combination disorders of structural Hb variants and thalassemia, why is the severity less when α -thalassemia is inherited with sickle cell trait than when β -thalassemia is coexpressed with sickle cell trait?

Answer

The severity of symptoms associated with HbS is related to the concentration of HbS. The combination of one HbS β -gene (β^s -gene) and one β -thalassemia-gene results in little to no HbA formation because both of the β -genes are mutated. In contrast, an α -gene mutation reduces the number of α -chains that can combine with β^s -chains, reducing the amount of the abnormal structural hemoglobin (HbS) and thus reducing the symptoms associated with the abnormal hemoglobin.

Checkpoint! 10

Which laboratory tests should be done first to differentiate thalassemia and iron deficiency?

Answer

The most cost-efficient and diagnostically effective studies should be done first. In this case, iron studies should be done first because iron deficiency is the most common cause of microcytic hypochromic anemia. The iron studies include serum ferritin, serum iron, TIBC, and percent saturation. If the iron studies do not reveal iron deficiency, hemoglobin electrophoresis should be done.

Megaloblastic and Nonmegaloblastic Macrocytic Anemias

Joel Hubbard, Ph.D.

■ OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. Explain the cause and process of megaloblastic maturation in the bone marrow.
2. Describe the body's requirements for vitamin B₁₂ and folate and their physiologic role.
3. List the laboratory tests used to confirm a diagnosis of vitamin B₁₂ deficiency and give expected results.
4. List the laboratory tests used to confirm a diagnosis of folic acid deficiency and give expected results.
5. Recognize the six most common disorders that result in a macrocytic anemia.
6. Name four causes of a vitamin B₁₂ deficiency and give two distinguishing clinical or laboratory characteristics of each.
7. Describe the etiology and pathophysiology of pernicious anemia, clinical symptoms, and clinical subtypes.
8. Name three causes of a folate deficiency and give two distinguishing clinical or laboratory characteristics of each.
9. Differentiate the pathophysiology and peripheral blood findings of nonmegaloblastic anemia from those of megaloblastic anemias.
10. Summarize the common or typical blood picture seen with a folate or vitamin B₁₂ deficiency.

■ OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. Summarize the process of vitamin B₁₂ and folic acid metabolism and explain how a deficiency can result in megaloblastosis.
2. Compare macrocytosis associated with a normoblastic marrow and macrocytosis associated with a megaloblastic marrow on the basis of physiological defect or cause, and differentiate based on the laboratory blood picture.
3. Summarize the mechanism of maturation defects that lead to megaloblastosis and recognize the morphologic blood cell abnormalities.

CHAPTER OUTLINE

- ▶ Objectives—Level I and Level II
- ▶ Key terms
- ▶ Background basics
- ▶ Case study
- ▶ Overview
- ▶ Introduction
- ▶ Megaloblastic anemia
- ▶ Macrocytic anemia without megaloblastosis
- ▶ Summary
- ▶ Review questions
- ▶ References

OBJECTIVES—LEVEL II (continued)

4. Compare and contrast the various clinical forms and causes of a vitamin B₁₂ and folate deficiency on the basis of clinical symptoms and laboratory results.
5. Categorize the causes and clinical variations of pernicious anemia.
6. Compare and contrast the various clinical forms and causes of a folic acid deficiency.
7. Demonstrate how a folate or vitamin B₁₂ deficiency results in megaloblastic maturation.
8. Choose and briefly explain four laboratory tests used to identify the cause of a macrocytic anemia; give the expected results of these four tests in a patient with an autoantibody directed against intrinsic factor.
9. Assess Schilling's test results and provide a differential diagnosis.
10. Compare and contrast the causes of macrocytosis with a normoblastic marrow.
11. Construct an algorithm of laboratory testing to distinguish between a megaloblastic anemia and a macrocytic, normoblastic anemia.
12. Evaluate a case study from a patient with anemia. Determine the most probable diagnosis from the medical history and laboratory results.

KEY TERMS

Achlorhydria
 Cobalamin
 Demyelination
 Dyspepsia
 Glossitis
 Intrinsic factor (IF)
 Megaloblastic
 Nuclear-cytoplasmic asynchrony
 Pernicious anemia (PA)
 Schilling test

BACKGROUND BASICS

The information in this chapter builds on the concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study.

Level I

- ▶ Describe the maturation process of erythrocytes in the marrow.
- ▶ Outline the functional and morphologic classification of anemia and list the basic laboratory tests to diagnose anemia.

Level II

- ▶ Summarize the concepts of cell development, regulation, and the process of cell division.
- ▶ List and describe the laboratory tests used in differential diagnosis of anemia.

CASE STUDY

We will refer to this case study throughout the chapter.

Kathy, a 36-year-old female, experienced a recent 35-pound weight loss. Her tongue was red and fissured. She also complained of chronic fatigue and shortness of breath upon exertion. Physical examination suggested signs of jaundice and increased numbness and a tingling sensation of fingers and toes. She was hospitalized with the general diagnosis of moderate anemia, jaundice, and neurological symptoms. Her admitting CBC demonstrated the following laboratory results:

WBC	4.5 × 10 ⁹ /L	Differential	
RBC	2.50 × 10 ¹² /L	Lymphs %	36.0
HGB	10.0 g/dL	Monos %	3.8
HCT	0.31 L/L	Neutrophils %	59.4
MCV	124.0 fL	Eosinophils %	1.0
MCH	40.5 pg/dL	Basophils %	0.0
MCHC	32.7 gm/dL	NRBCs/100WBCs	5
RDW	21.2	Moderate hyper-	
PLT	155 × 10 ⁹ /L	segmented	
		neutrophils	

The following abnormal erythrocyte morphology was reported:

Macrocytes:	2+
Anisocytosis:	3+
Poikilocytosis:	2+
Ovalocytes:	1+
Basophilic stippling:	1+
Occasional Howell-Jolly bodies	

Consider the reflex tests that might be important in identifying the etiology of this anemia.

▶ OVERVIEW

This chapter is a study of the macrocytic anemias, which can be megaloblastic or nonmegaloblastic. The first part of the chapter discusses the megaloblastic anemias beginning with a description of the clinical and laboratory findings. Because megaloblastic anemia is most often due to deficiencies or abnormal metabolism of folate or vitamin B₁₂, the metabolism of these vitamins is discussed in detail. The latter part of the chapter reviews the causes of nonmegaloblastic macrocytic anemia and compares the laboratory test results in nonmegaloblastic and megaloblastic anemia. The experienced laboratory professional can often identify diagnostic clues on review of a blood smear.

▶ INTRODUCTION

Macrocytic anemias are characterized by large erythrocytes (mean MCV >100 fL) with an increased MCH and a normal hemoglobin content (MCHC). This is an important group of anemias because macrocytosis is frequently a sign of a disease process that can result in significant morbidity if left untreated.

Macrocytosis is found in 2.5–4% of adults who have a routine complete blood count.¹ In up to 60% of cases, macrocytosis is not accompanied by anemia,² but isolated macrocytosis should always be investigated. Macrocytosis without anemia can indicate early folate or **cobalamin** (vitamin B₁₂) deficiency because macrocytosis precedes the development of anemia.

Macrocytosis detected by automated cell counters is not always apparent microscopically on stained blood smears. In some cases, the erythrocyte size on automated counters is falsely elevated due to hyperglycemia, cold agglutinins, and extreme leukocytosis. These causes of false macrocytosis need to be differentiated from true macrocytosis.

The most common cause of true macrocytosis is alcoholism. Other causes include folate and cobalamin deficiencies, drugs including chemotherapy, reticulocytosis due to hemolysis or bleeding, myelodysplasia, liver disease, and hypothyroidism.²

Macrocytic anemias are generally classified as **megaloblastic** or nonmegaloblastic (normoblastic) depending on morphologic characteristics of erythroid precursors in the bone marrow (Table 1). The megaloblastic anemias are the result of abnormal DNA synthesis (a nuclear maturation defect), most often due to vitamin B₁₂ or folate deficiencies. As a result, delayed nuclear development prevents cell division. RNA synthesis and cytoplasmic maturation are not affected. The result is production of large cells with **nuclear-cytoplasmic asynchrony**. The basis for the nonmegaloblastic anemias is not always as well defined but can be related to an increase in membrane lipids. The macrocytes in nonmegaloblastic macrocytic anemia often are round but in

★ TABLE 1

Conditions Associated with Megaloblastic and Nonmegaloblastic Macrocytic (Normoblastic) Anemias

Megaloblastic	Normoblastic
Folate deficiency	Alcoholism
Nutritional deficiency	Liver disease
Increased requirement (i.e., pregnancy)	Shift reticulocytosis in hemolytic anemia or hemorrhage
Intestinal malabsorption	Hypothyroidism
Drug inhibition	Aplastic anemia
B ₁₂ deficiency	Obstructive jaundice
Pernicious anemia	Splenectomy
Small bowel resection	Pregnancy
Gastrectomy	Artificial: hyperglycemia, cold agglutinins, leukocytosis
Intestinal malabsorption	
Nutritional deficiency	
Increased requirement (i.e., pregnancy)	
Transcobalamin II deficiency

megaloblastic anemia are oval. A flow chart for laboratory analysis to help distinguish causes of macrocytic anemia is shown in Figure 1.

✓ Checkpoint! 1

Explain why patients with B₁₂ or folate deficiency have megaloblastic maturation.

▶ MEGALOBLASTIC ANEMIA

Although very little was known about the function or origin of blood cells before the twentieth century, some perceptive individuals began to make associations between anemia and other clinical patient signs. In 1822, J. S. Coombe, a Scottish physician, made the initial clinical description of a patient who appeared to have megaloblastic anemia. He was the first to suggest that this anemia might be related to **dyspepsia**.³ In 1855, Thomas Addison reported his description of a macrocytic anemia, but he made no reference to the typical microscopic blood findings.⁴ The discovery and description of the abnormal erythroid precursors in the bone marrow associated with this anemia were made possible by the advent of triacid stains. Paul Ehrlich is credited with coining the term *megaloblast* in 1891 to describe the large abnormal precursors in megaloblastic anemia.⁵

■ **FIGURE 1** Algorithm to the differential diagnosis of the megaloblastic anemias from other macrocytic anemias. (HGB = hemoglobin; HCT = hematocrit; MCV = mean cell volume.)

Megaloblastic anemia is classified as a nuclear maturation defect. Anemia is attributed primarily to a large degree of ineffective erythropoiesis resulting from disrupted DNA synthesis. The anemia was called *megaloblastic* in an attempt to describe the giant, abnormal-appearing erythroid precursors (megaloblasts) in the bone marrow. The generic word *megaloblast* describes any maturation stage of the megaloblastic erythroid series (i.e., polychromatic megaloblast). Other nucleated cells of the marrow are also typically abnormal.

About 95% of megaloblastic anemias are caused by deficiencies of either vitamin B₁₂ or folic acid, vitamins necessary as coenzymes for nucleic acid synthesis. In the majority of cases, vitamin B₁₂ deficiency is secondary to a deficiency of the **intrinsic factor (IF)**, a factor necessary for absorption of vitamin B₁₂ rather than to a nutritional deficiency of the vitamin. Folic acid deficiency, on the other hand, is most often due to an inadequate dietary intake. Inherited disorders affecting DNA synthesis or vitamin metabolism are rare causes of megaloblastosis.

CLINICAL FINDINGS

The onset of megaloblastic anemia is usually insidious; because the anemia develops slowly, it produces few symptoms until the hemoglobin and hematocrit are significantly depressed. Patients can present with typical anemic symptoms of lethargy, weakness, and a yellow or waxy pallor. Dyspeptic symptoms are common. **Glossitis** with a beefy red tongue or, more commonly, a smooth pale tongue is characteristic. Loss of weight and loss of appetite are common complaints.

In pernicious anemia (see below), atrophy of the gastric parietal cells causes decreased secretion of intrinsic factor and hydrochloric acid. Bouts of diarrhea can result from epithelial changes in the gastrointestinal tract.

Neurological disturbances occur only in vitamin B₁₂ deficiency, not in folic acid deficiency. They are the most serious and dangerous clinical signs because neurological damage can be permanent if the deficiency is not treated promptly. The patient's initial complaints occasionally are related to neurological dysfunction rather than to anemia. Neurological damage has been reported to occur even before anemia or macrocytosis in some cases. The bone marrow, however, usually reveals megaloblastic changes even in the absence of anemia. Tingling, numbness, and weakness of the extremities reflect peripheral neuropathy. Loss of vibratory and position (proprioceptive) sensibilities in the lower extremities can cause the patient to have an abnormal gait. Mental disturbances such as loss of memory, depression, and irritability are sometimes noted by the patient's relatives. *Megaloblastic madness* is a term used to describe severe psychotic manifestations of vitamin B₁₂ deficiency. A patient with severe anemia occasionally is asymptomatic, which is probably a reflection of a very slowly developing anemia.

✓ Checkpoint! 2

Patients with megaloblastic anemia often present with a yellow or waxy pallor. What is the diagnostic significance of this clinical symptom?

LABORATORY FINDINGS

Laboratory tests are critical to a diagnosis of megaloblastic anemia. The routine CBC with a review of the blood smear gives important diagnostic clues and helps in selecting reflex tests.

Peripheral Blood

Megaloblastic anemia is typically a macrocytic, normochromic anemia. The MCV is usually higher than 100 fL and can reach a volume of 140 fL. However, an increased MCV is not specific for megaloblastic anemia. The MCH is increased because of the large cell volume, but the MCHC is normal. In vitamin B₁₂ deficiency, a macrocytosis can precede the development of anemia by months to years.^{6–8} On the other hand, the MCV can remain in the reference range. Epithelial changes in the gastrointestinal tract can cause iron absorption to be impaired. If an iron deficiency—which characteristically produces a microcytic, hypochromic anemia—coexists with megaloblastic anemia, macrocytosis can be masked and the MCV can be in the normal range.⁹ Other conditions that have been shown to coexist with megaloblastic anemia in the absence of an increased MCV include thalassemia, chronic renal insufficiency, and chronic inflammation or infection.⁸ Sometimes these coexisting causes of anemia are not recognized until after the megaloblastic anemia has been treated. It has been suggested that if coexisting

iron deficiency, thalassemia, or chronic disease is suspected, patient medical history, racial background, and previous MCV should be considered.¹⁰

Hematologic parameters vary considerably (Table 2). The hemoglobin and erythrocyte count range from normal to very low. The erythrocyte count is occasionally less than $1 \times 10^{12}/L$. However, anemia is not always evident. In one study of 100 patients with confirmed B₁₂ deficiency, only 29% had a hemoglobin of less than 12 g/dL.¹¹ This is significant because neurologic symptoms can be present even if the MCV and/or hematocrit are normal.¹² Because the abnormality is a nuclear maturation defect, the megaloblastic anemias affect all three blood cell lineages: erythrocytes, leukocytes, and platelets. This is unlike other anemias that typically involve only erythrocytes. The leukocyte count can be decreased due to an absolute neutropenia. Platelets can also be decreased but do not usually fall below $100 \times 10^9/L$. The relative reticulocyte count (percentage) is usually normal; however, because of the severe anemia, the corrected reticulocyte count is <2% and RPI is less than 2.

The distinguishing features of megaloblastic anemia on the stained blood smear include the triad of oval macrocytes (macroovalocytes), Howell-Jolly bodies, and hypersegmented neutrophils (Figure 2). Anisocytosis is moderate to severe with normocytes and a few microcytes in addition to the macrocytes. Poikilocytosis can be striking and is usually more severe when the anemia is severe. Polychromatophilia

TABLE 2

Comparison of Common Laboratory Values in Megaloblastic and Nonmegaloblastic Macrocytosis

Laboratory Value	Megaloblastic Macrocytosis	Nonmegaloblastic Macrocytosis
WBC count	Decreased	Normal
Platelet count	Decreased	Normal
RBC count	Decreased	Decreased
Hemoglobin	Decreased	Decreased
Hematocrit	Decreased	Decreased
MCV	Usually >110 fL	>100 fL
RBC morphology	Ovalocytes, Howell-Jolly bodies, polychromasia	Polychromasia, target cells, and stomatocytes (liver disease), schistocytes (hemolytic anemias)
Hypersegmentation of neutrophils	Present	Absent
Reticulocyte count	Normal to decreased	Normal, decreased, or increased
Serum B ₁₂	Decreased in B ₁₂ deficiency	Usually normal
Serum folate	Decreased in folate deficiency	Normal (except in alcoholism where it may be decreased)
FIGLU	Increased in folate deficiency	Normal
MMA	Increased in B ₁₂ deficiency	Normal
Homocysteine	Increased	Normal
Serum bilirubin	Increased	Normal to increased
LD	Increased	Normal to increased

MCV = mean corpuscular volume; FIGLU = formiminoglutamic acid; MMA = methylmalonic acid; LD = lactic dehydrogenase

■ **FIGURE 2** Peripheral blood film from a patient with pernicious anemia. Note the anisocytosis with oval macrocytes and the nucleated red blood cell with a Howell-Jolly body. (Wright-Giemsa stain; 1000× magnification)

and megaloblastic erythroblasts can be seen, especially when the anemia is severe, indicating the futile attempt of the bone marrow to increase peripheral erythrocyte mass. Erythrocytes can contain Cabot rings.

Granulocytes and platelets can also show changes evident of abnormal hematopoiesis. Hypersegmented neutrophils (>5 nuclear lobes) can be found in megaloblastic anemia even in the absence of macrocytosis (Figure 3 ■). Finding 5% or more PMNs with 5 lobes or one PMN with six or more lobes is considered hypersegmentation of neutrophils. This finding of hypersegmented neutrophils is considered highly sensitive and specific for megaloblastic anemia. Therefore, hypersegmented neutrophils can be an important clue to megaloblastic anemia in the face of a coexisting disease that tends to keep erythrocyte volume below 100 fL. One study showed that in patients with renal disease, iron deficiency, or chronic disease with a normal or decreased MCV and 1% hypersegmented neutrophils, 94% had vitamin B₁₂ or folic acid deficiency.⁸ If 5% hypersegmented neutrophils

■ **FIGURE 3** Hypersegmented neutrophils from the peripheral blood of a patient with pernicious anemia. (Wright-Giemsa stain; 1000× magnification)

were counted, the incidence of the vitamin B₁₂ or folic acid deficiency increased to 98%. Hypersegmented neutrophils tend to be larger than normal neutrophils. A mild shift to the left with large hypogranular bands can also be noted. Platelets can be large, especially when the platelet count is decreased.

✓ Checkpoint! 3

Why are abnormalities of leukocytes and platelets present in megaloblastic anemia?

🔍 CASE STUDY (continued from earlier in this chapter)

Based on the initial CBC results, further testing was ordered with the following results:

B ₁₂	50 pg/mL	Low
Folate	10.3 ng/mL	Normal
Total Bilirubin	2.5 mg/dL	High
Direct Bilirubin	0.8 mg/dL	Normal
AST	35 U/mL	Normal
ALT	30 U/mL	Normal

Examination of a bone marrow aspirate revealed an erythroblastic hyperplasia with megaloblastic erythroblasts.

1. What is the morphologic classification of the patient's anemia?
2. Based on the information obtained so far, what is the most likely defect?
3. What is the significance of the AST/ALT results?

Bone Marrow

If physical examination, patient history, and peripheral blood findings suggest megaloblastic anemia, a bone marrow examination helps establish a definitive diagnosis. In megaloblastic states, the bone marrow is hypercellular with megaloblastic erythroid precursors and a decreased M:E ratio. In a long-standing anemia, red marrow can expand into the long bones. About half the erythroid precursors show megaloblastic changes. Megaloblasts are large nucleated erythroid precursors with nuclear maturation lagging behind cytoplasmic maturation (Figure 4 ■). The nucleus of the megaloblast contains loose, open chromatin that stains poorly; cytoplasmic development continues in normal fashion. At each stage of development, the cells contain more cytoplasm with a more mature appearance relative to the size and maturity of the nucleus (resulting in a decreased nuclear:cytoplasmic [N:C] ratio). Thus, the term *nuclear-cytoplasmic asynchrony* is used to describe these cells.

The megaloblastic features are more easily noted in later stages of erythroid development, especially at the polychro-

■ **FIGURE 4** Basophilic and orthochromatic megaloblasts in the bone marrow from a patient with pernicious anemia. Note the large size of the cells, the open chromatin network in the nuclei, and the presence of Howell-Jolly bodies in the orthochromatic megaloblasts. There is also a large band neutrophil and segmented neutrophil with five nuclear lobes. (Wright-Giemsa stain; 1000× magnification)

matophilic stage in which the presence of hemoglobin mixed with RNA gives the cytoplasm the gray-blue color typical of this erythroid precursor. The megaloblast nucleus, however, still has an open (lacy) chromatin pattern more typical of a younger stage of development.

Leukocytes and platelets also show typical features of a nuclear maturation defect as well as ineffective leukopoiesis and thrombopoiesis. Giant metamyelocytes and bands with loose, open chromatin in the nuclei are diagnostic (Figure 5■). The myelocytes can show poor granulation as do more mature stages. Megakaryocytes can be decreased, normal, or

■ **FIGURE 5** Nuclear-cytoplasmic asynchrony in the bone marrow. There are basophilic (arrow on right), polychromatophilic (arrow on left), and orthochromatic megaloblasts with the typical immature looking nuclei. Note the large size of the cells. (Bone marrow; Wright stain; 1000× magnification)

increased. Maturation, however, is distinctly abnormal. Some larger than normal forms can be found with separation of nuclear lobes and nuclear fragments.

Other Laboratory Findings

Vitamin B₁₂ and serum or red cell folate are commonly measured to diagnose megaloblastosis. Measurement of erythrocyte folate is not influenced as much by recent dietary changes as is serum folate and gives an accurate estimate of the average folate levels over the preceding several months.¹⁴ Automated ligand binding measurements are the easiest to perform and are commonly used. These tests, however, are not the most sensitive indicators of megaloblastosis.

Early megaloblastic changes can be detected by testing for methylmalonic acid (MMA) and homocysteine levels in the blood. These components are intermediaries in folate and vitamin B₁₂ metabolism and are elevated early in functional vitamin deficiencies. By performing tests for both MMA and homocysteine, it is possible to differentiate between vitamin B₁₂ deficiency and folate deficiency. MMA is usually normal in folate deficiency and elevated in vitamin B₁₂ deficiency. Homocysteine is increased in both vitamin B₁₂ and folate deficiency. Clinical information is important to help distinguish vitamin B₁₂ deficiency from a combined vitamin B₁₂ and folate deficiency. A block in the metabolism of histidine to glutamic acid in folic acid deficiency causes urinary excretion of formiminoglutamic acid (FIGLU), an intermediate metabolite, to increase after the administration of histidine.

The large degree of ineffective erythropoiesis results in hemolysis in the marrow and an increase in plasma iron turnover, serum iron, indirect bilirubin, and urobilinogen. The characteristic marked increase in fractions 1 and 2 of serum lactic dehydrogenase (LD) is partially caused by the destruction of megaloblasts rich in LD. The increase is roughly proportional to the degree of anemia. Haptoglobin, uric acid, and alkaline phosphatase are decreased. These and additional tests are discussed in the following sections.

✓ Checkpoint! 4

What abnormal morphological findings on a stained blood smear compose the triad in megaloblastic anemia?

FOLIC ACID

A folic acid deficiency must be considered in the differential diagnosis of macrocytosis due to megaloblastic anemia. Folate deficiency can generally occur as the result of decreased dietary intake, an increased physiological requirement, malabsorption in the small intestine, or drug inhibition.

Structure and Function

Folic acid is the parent substance of a large group of compounds known as *folates*. Chemically, folate is known as

■ FIGURE 6 Molecular structure of the folic acid molecule.

pteroylglutamic acid. Structurally, folate is composed of three parts: (1) pteridine, a nitrogen-containing ring, (2) a ring of p-aminobenzoic acid, and (3) a chain of glutamic acid residues. This structure composes the inert form of folate (F) (Figure 6 ■). Tetrahydrofolate (THF or FH₄), the active form, is produced by a four-hydrogen reduction of the pteridine ring. Dihydrofolate (DHF or FH₂) is an intermediate in this reaction. The enzyme, DHF reductase, catalyzes both $F \rightarrow FH_2$ and $FH_2 \rightarrow FH_4$.

The function of THF is to transfer one-carbon compounds from donor molecules to acceptor molecules in intermediary metabolism. A variety of one-carbon substituents can be carried by THF, including formyl ($-\text{CH}=\text{O}$), formimino ($-\text{CH}=\text{NH}_2$), hydroxymethyl ($-\text{CH}_2\text{OH}$), methenyl ($=\text{CH}-$), methylene ($=\text{CH}_2$), and methyl ($-\text{CH}_3$). In this capacity, folate serves a vital role in the metabolism of nucleotides and amino acids:

1. The carbon transfer reaction most important in the development of megaloblastosis is initiated when the carbon side chain of serine is transferred to THF to form N⁵,N¹⁰-methylene THF (Figure 7a ■). This reaction requires the cofactor pyridoxal-5-phosphate (PLP), a derivative of vitamin B₆. The carbon of N⁵,N¹⁰-methylene-THF is then transferred to deoxyuridilate (dUMP) to form deoxythymidylate (dTMP), a pyrimidine of DNA. In this reaction, THF is oxidized to DHF. The DHF is reduced back to THF by DHF reductase and then to N⁵,N¹⁰-methylene THF by the serine reaction discussed above. Foliates also transport formate (as N¹⁰-formyl THF) for purine synthesis. Thus, folate is necessary for the de novo synthesis of DNA (Table 3 🔄).
2. The metabolism of histidine to glutamic acid requires THF (Figure 7b ■, Table 3). The intermediate metabolite of this reaction is formiminoglutamic acid (FIGLU), which requires THF for conversion to glutamic acid. A deficiency of folate blocks this reaction, resulting in an increase in FIGLU excretion.
3. The synthesis of methionine from homocysteine requires the donation of a methyl group from N⁵-methyl THF and the action of vitamin B₁₂ as a cofactor, resulting in methionine and THF (Figure 7a). A deficiency of either folate or B₁₂ blocks this reaction, resulting in an increase in homocysteine levels.

Metabolism

Folic acid is present in food and also is synthesized by microorganisms. Most folic acid in food is in the conjugated polyglutamate form. It is deconjugated in the intestine to a monoglutamate prior to absorption. Absorption can take place throughout the small intestine but is especially significant in the proximal jejunum. Once taken up by the intestinal epithelial cell, the folate is reduced to N⁵-methyl THF, the primary circulating form of THF in the blood. N⁵-methyl THF is distributed throughout the body via the blood and attaches to cells by means of specific receptors. Once inside the cell, N⁵-methyl THF must be demethylated and re-conjugated by the addition of seven or eight glutamic acid residues to keep it from leaking out again. Demethylation is a reaction that requires vitamin B₁₂ and methionine synthase (Figure 7a). Thus, a deficiency of vitamin B₁₂ traps folate in its methylated form and blocks the formation of other forms of THF. (This is commonly referred to as the *folate trap*.) Although free THF is easily conjugated within cells, methyl-THF is not; consequently, much of the methyl-THF taken up by a B₁₂-deficient cell leaks out before additional glutamates can be added.¹³ Consequently, the cells in vitamin B₁₂ deficiency are unable to retain their folate, leading to tissue folate depletion. In the demethylation of N⁵-methyl THF by vitamin B₁₂, homocysteine is methylated to methionine, a precursor of S-adenosylmethionine (SAM). This reaction requires methionine synthase and vitamin B₁₂. SAM is thought to be critical to nervous system function.

Requirements

Folic acid is present in most foods including eggs, milk, yeast, mushrooms, and liver but is especially abundant in green leafy vegetables (from which it gets its name). It is also synthesized by microorganisms. The vitamin is destroyed by heat; thus, when food is overcooked, much of the folate is destroyed. Ascorbate protects folate from oxidation and, when present, can protect folate to some extent from heat degradation. The recommended daily dietary allowance of food folic acid for adults is ~400 μg of which about 50–80% is absorbed in the intestine. This is adequate to provide the minimum daily requirement of ~50 μg/day needed to sustain normal metabolism. The liver stores from 5 to 10 mg of

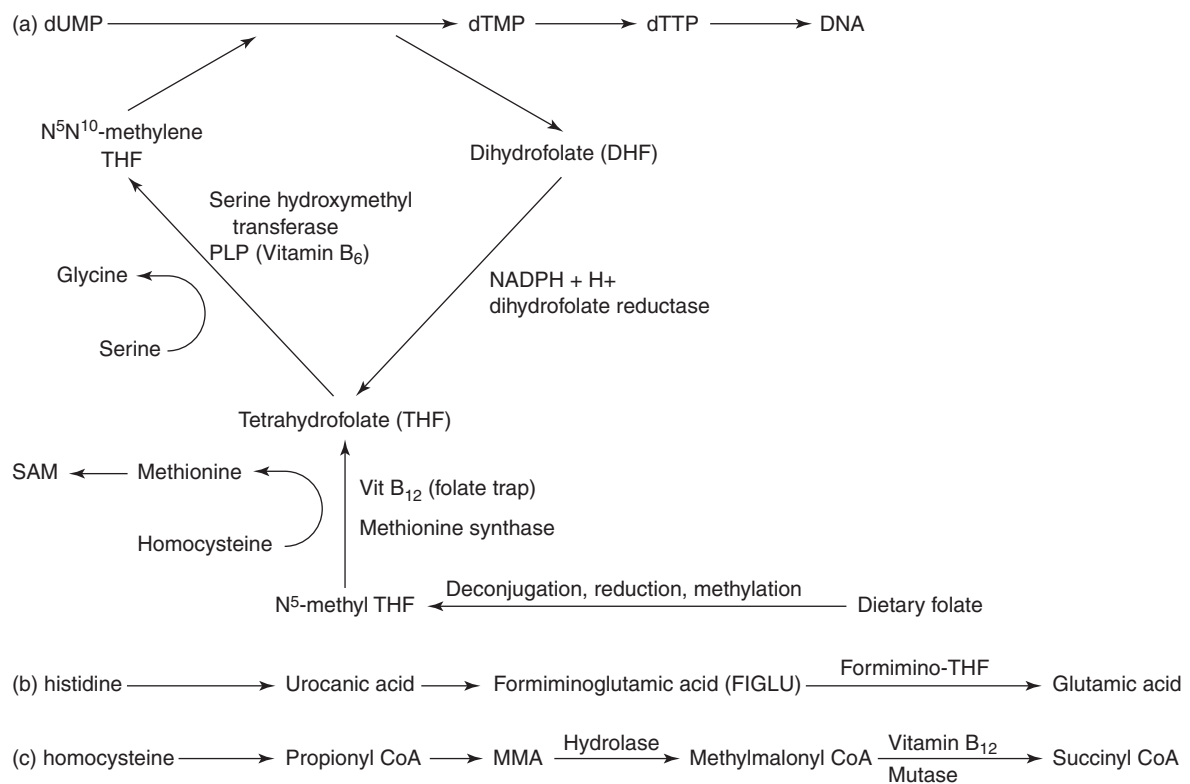

FIGURE 7 Biochemical reactions using folic acid, vitamin B₁₂, and derivatives. **a.** The role of folate and vitamin B₁₂ in the synthesis of DNA. A deficiency of methylcobalamin causes a failure of methylation of homocysteine, which leads to a reduction in tetrahydrofolate (THF) and the trapping of the folate as N⁵-methyl THF. This causes a deficiency of N⁵,N¹⁰-methylene THF, a coenzyme needed in the synthesis of dTTP, a nucleotide of DNA. **b.** The role of folate in the catabolism of histidine. **c.** The role of vitamin B₁₂ (adenosylcobalamin form) in the conversion of methylmalonic acid (MMA) to succinyl CoA. Tests to detect vitamin B₁₂ deficiency include direct measurement of vitamin B₁₂ and tests to detect increased MMA and homocysteine, intermediaries that require vitamin B₁₂ for metabolism. Tests to detect folic acid deficiency include direct measurement of folate or measurement of homocysteine and FIGLU, intermediaries that require folate for metabolism. With deficiencies of vitamin B₁₂ and/or folate, the intermediaries MMA, homocysteine, and FIGLU are trapped and increase in concentration.

folate, which is sufficient to provide the daily requirement for three to six months if folic acid is omitted from the diet.

Folate plays an important role in normal embryogenesis. Observations reveal a high incidence of low folate levels in

women who give birth to babies with neural tube defects (NTD) compared to women who give birth to normal babies. Several studies have shown that supplementation of folate during pregnancy can reduce the rate of neural tube closure birth defects by as much as one-half. The basis for this protective effect is not clear, but it has been suggested that the effect may be confined to a subset of women who have defective folate metabolism. In an effort to reduce NTDs, the United States government required the fortifications of grain products with folic acid beginning in the fall of 1997.¹⁵ The goal was to increase the daily dietary folate to 100 μg per person. It has been suggested that pregnant women need an intake of about 800 μg/day.

Folic acid can become depleted quickly in conditions with rapid cell turnover such as sickle cell anemia and other hemolytic anemias, during growth and in pregnancy and lactation. Thus, the daily requirement in patients with these conditions is increased.

TABLE 3

Metabolic Reactions Requiring Folic Acid Coenzymes

System	Reaction
Serine ↔ Glycine	Ser + THF ↔ N ⁵ ,N ¹⁰ -methylene THF + Gly
Thymidylate synthesis	dUMP + N ⁵ ,N ¹⁰ -methylene THF → DHF + dTMP
Histidine catabolism	Formiminoglutamate + THF → N ⁵ -formimino THF + glutamic acid
Methionine synthesis	Homocysteine + N ⁵ -methyl THF → THF + Methionine

✓ Checkpoint! 5

Hal had small bowel resection due to carcinoma. Explain why he is at high risk for folate deficiency.

Pathophysiology of Folic Acid Deficiency

Folate deficiency results in decreased synthesis of N⁵,N¹⁰-methylene THF, which is needed as a cofactor in DNA synthesis. Consequently, there is a marked slowing of DNA synthesis and the S phase is prolonged. The impairment of DNA synthesis is due to the inability to convert deoxyuridine monophosphate (dUMP) to deoxythymidine monophosphate (dTMP) (see below). The dUMP is subsequently phosphorylated to the triphosphate form (dUTP). DNA polymerase does not effectively distinguish dUTP from dTTP (which is synthesized from dTMP), and dUTP is erroneously incorporated into the DNA of folate-deficient cells. The DNA “proof-reading” function of the cells recognizes the mistake and tries to repair the DNA by replacing uridine with thymidine, but the repair attempt fails due to the lack of available dTTP. The result is ultimately DNA fragmentation and cell death by apoptosis.¹³ Increased apoptosis of the blood cell precursors (ineffective erythropoiesis) leads to increased heme catabolism and iron turnover and leads to signs of hemolysis and jaundice. Extramedullary hemolysis also occurs, and circulating red cell survival can be decreased by 30–50%. The intermediaries requiring folic acid as a cofactor for metabolism (homocysteine and FIGLU) accumulate. Mildly elevated levels of homocysteine are considered a major risk factor for atherosclerosis and venous thrombosis.

All rapidly dividing cells—including erythrocytes, leukocytes, platelets, and intestinal epithelium—are affected by a folate deficiency. Hematopoietic cells show characteristic megaloblastic changes. The bone marrow can exhibit a 3-fold increase in erythropoiesis, but the peripheral blood reticulocyte count is low, indicating a large degree of ineffective erythropoiesis. Survival of the erythrocytes in the peripheral blood also decreases significantly.

The clinical findings of folate deficiency develop sequentially. Serum folate decreases within 1 to 2 weeks of a folic acid deficiency. Hypersegmented neutrophils are the first morphologic change and occur at about 2 weeks. The urinary excretion of FIGLU increases next at about 13 weeks, and anemia appears last at about 19–20 weeks.

Causes of Folate Deficiency

Folate deficiency can occur as the result of an inadequate dietary intake, an increased requirement, malabsorption in the small intestine, or drug inhibition (Table 4).

Inadequate Diet The most common cause of folate deficiency is an inadequate dietary intake of folic acid. This is seen most often in poor and elderly people who fail to obtain enough of the appropriate foods to maintain adequate folic acid intake due to financial reasons, lack of motivation,

★ TABLE 4

Causes of Folate Deficiency

Cause	Examples
Inadequate diet	Low income, elderly people with limited function/income, people who are alcoholics
Increased requirement	Diseases associated with rapid cell turnover (sickle cell anemia, thalassemia, leukemias, other malignancies, pregnancy, infancy)
Malabsorption	Ileitis, tropical sprue, nontropical sprue, blind loop syndrome
Drug inhibition	Oral contraceptives, long-term anticoagulant therapy, phenobarbital, primidone, phenytoin, antimetabolite chemotherapy
Biologic competition	Bacterial overgrowth in small intestine

physical disabilities, or lack of knowledge concerning nutrition. People who are alcoholics whose diet consists mainly of large quantities of ethanol have a deficiency of many vitamins in addition to folic acid. Complicating the folate deficiency in alcoholic individuals, the ethanol appears to impair release of folate from the liver and can be toxic to erythroid precursors. (Erythroid precursors in alcoholism are frequently vacuolated.) In alcoholic individuals who have liver disease but have an adequate diet, the anemia is macrocytic but not megaloblastic.

Increased Requirement In individuals with increased cell replication, the normal daily intake of folic acid is perhaps not sufficient to maintain normal DNA synthesis. Without folate supplements, folate stores can be rapidly depleted. This occurs in hemolytic anemias such as sickle cell anemia and thalassemia, in myeloproliferative diseases such as leukemia, in pregnancy, and in metastatic cancers. Anemia in pregnancy is common and can be caused by deficiencies of iron and/or folic acid. The deficiency of folic acid is related to the limited reserves of this nutrient and a 5–10 time increased demand for its use created by the growing fetus. Prophylactic folic acid supplements are usually prescribed to prevent anemia during pregnancy. Supplements are also recommended preconception in an effort to decrease neural tube defects in the fetus.¹⁶

Malabsorption Intestinal diseases affecting the upper small intestine, which interfere with the absorption of nutrients, can cause a folate deficiency. The most common conditions of this type include ileitis, tropical sprue, and nontropical sprue. The blind loop syndrome associated with an overgrowth of bacteria can cause a folate deficiency because the bacteria preferentially utilize the folate.

Drug Inhibition Megaloblastic anemia has also been associated with certain drugs including oral contraceptives, long-term anticoagulant drugs, phenobarbital, primidone, and phenytoin. Anemia occasionally is not present even though serum and erythrocyte folate are depressed.

✓ Checkpoint! 6

What is the most common cause of folate deficiency and in what groups of individuals is it usually found?

Laboratory Analysis of Folate Deficiency

Both serum and erythrocyte folate levels must be decreased to diagnose folate deficiency. Serum folate reflects the folic acid intake over the last several days, whereas erythrocyte folate reflects the folate available when the red cell was maturing in the bone marrow and reflects the net folate level over the preceding several months. Serum folate can be falsely increased with even slight hemolysis of the sample. Erythrocyte folate, then, is a better indication of folate stores. Low serum folate can indicate an imminent folic acid deficiency and precedes erythrocyte folate deficiency.¹⁴

Neither serum nor erythrocyte folate is a good indicator of folate stores in the presence of vitamin B₁₂ deficiency. A deficiency of vitamin B₁₂ impairs methionine synthesis and leads to the accumulation of methyl-THF as the donation of the methyl group to homocysteine, and the generation of free THF is impaired. In addition, vitamin B₁₂ is required for normal transfer of methyl-THF to the cells and for keeping the folate in the cell as conjugated folate (methyl-THF is not easily conjugated and leaks out of the cell). Thus, serum folate can be falsely increased and erythrocyte folate falsely decreased in vitamin B₁₂ deficiency. In about two-thirds of vitamin B₁₂-deficient patients, erythrocyte folate is decreased.¹⁷ In addition, epithelial changes in the GI tract that accompany vitamin B₁₂ deficiency can lead to malabsorption of folic acid in which case both serum and erythrocyte folate are decreased. Care must be taken in interpreting the folate results because both serum and erythrocyte folate can be falsely increased or decreased in a variety of conditions (Table 5 🔄).

VITAMIN B₁₂ (COBALAMIN)

By the early 1900s, megaloblastic anemia was recognized as a unique anemia of adults with typical symptoms and clinical findings. The disease was called *pernicious anemia* because

🔄 TABLE 5

Causes of False Increases and Decreases in Folate Levels

	Erythrocyte Folate	Serum Folate
False increase	Early folate deficiency	Recent increase in dietary folate
	Reticulocytosis	Hemolysis of blood sample
	Recent RBC transfusion	Coexisting vitamin B ₁₂ deficiency
False decrease	B ₁₂ deficiency	Recent low dietary intake
	Recent alcohol consumption	Gallium or technetium administration

of the certainty of a fatal outcome. The average survival after the onset of the disease was from 1 to 3 years. It is now recognized that pernicious anemia is a specific form of megaloblastic anemia characterized by a deficiency of vitamin B₁₂ that is secondary to an absence of intrinsic factor.

Structure and Function

Vitamin B₁₂ is a commonly used generic term for a family of cobalamin vitamins in which ligands can be chelated to cobalt. The more accurate terminology when referring to this family of vitamins is *cobalamin*. Vitamin B₁₂ refers specifically to the therapeutic form of cobalamin that contains the ligand, cyanide (cyanocobalamin), a form not naturally found in the body but is the crystalline form used for treating cobalamin deficiency. In hematology literature, the terms *cobalamin* and *vitamin B₁₂* are often used interchangeably. However, in the following discussion, for sake of consistency with clinical testing, the term vitamin B₁₂ is used.

Vitamin B₁₂ (cobalamin) is structurally classified as a corrinoid, a family of compounds with a corrin ring. The molecule has three portions: (1) a corrin ring composed of four reduced pyrrole groups with a cobalt at the center (cobalamin gets its name from the central cobalt), (2) a nucleotide (5,6-dimethylbenzimidazole) that lies almost perpendicular to the ring attached to the cobalt, and (3) various ligands (a β-group) attached to the cobalt on the opposite side of the ring from the nucleotide (Figure 8 ■). The β-group in tissue cobalamins is either cyanide, methyl, adenosyl, or hydroxyl. Adenosylcobalamin (AdoCbl) and methylcobalamin (MeCbl) act as coenzymes in biological reactions. Hydroxycobalamin (OHCbl) and cyanocobalamin (CnCbl) are not metabolically active forms of cobalamin but can be converted to the active methyl and adenosyl forms by tissue enzymes.

■ FIGURE 8 Molecular structure of the cobalamin molecule.

As mentioned previously, methionine is formed from homocysteine when a methyl group is transferred from N⁵-methyl THF to homocysteine in a vitamin B₁₂-dependent reaction catalyzed by methionine synthase (Figure 7a). For this reaction, the vitamin must be in the MeCbl form. The significance of the reaction is that THF is formed from the demethylation of N⁵-methyl THF, which is then converted to N⁵N¹⁰-methylene THF, the folate form necessary for thymidylate synthesis that is needed for DNA synthesis. A vitamin B₁₂ deficiency traps newly acquired folate in the N⁵-methyl THF form (in which it is acquired from the plasma), which is not efficiently conjugated with glutamic acids and thus leaks back out of cells (see discussion of folate metabolism). The result is an intracellular functional deficiency of folate and a block of DNA synthesis. Methionine is the precursor of SAM, a metabolite thought to be critical to the normal functioning of the nervous system.

AdoCbl is required for only one mammalian reaction: the conversion of methylmalonyl CoA to succinyl CoA (Figure 7c). AdoCbl acts as a coenzyme with methylmalonyl CoA mutase in this reaction. Increased urinary excretion of methylmalonic acid (MMA), a precursor of methylmalonyl-CoA, is a diagnostic aid in vitamin B₁₂ deficiency.

✓ Checkpoint! 7

A patient has the following results: vitamin B₁₂ 50 pg/mL, serum folate 4 ng/dL, RBC folate 100 ng/mL. Interpret these results.

Metabolism

Defects in any of the steps of vitamin B₁₂ metabolism can lead to a vitamin B₁₂ deficiency and megaloblastic anemia. The laboratory plays a critical role in both assessing the level of the vitamin and determining the cause of low levels. Thus, it is important to understand the metabolism of this important nutrient.

Absorption Vitamin B₁₂ is present in most foods of animal origin including milk, eggs, and meat. The vitamin complex is released from food by peptic digestion at a low pH in

the stomach and binds to an R-protein, a vitamin B₁₂ binding protein secreted in the saliva and in the stomach. R-protein, named because of its rapid electrophoretic mobility compared with the intrinsic factor, is the preferred binding protein for vitamin B₁₂ released from food at the acid pH of the stomach. In the duodenum, pancreatic proteases degrade the R-proteins, releasing vitamin B₁₂. The released vitamin B₁₂ quickly binds to the intrinsic factor (IF), which is resistant to pancreatic degradation. The intrinsic factor is a glycoprotein secreted by parietal cells of the gastric mucosa in response to the presence of food, vagal stimulation, histamine, and gastrin. The IF binds vitamin B₁₂ in a 1:1 stoichiometry and is required for the absorption of vitamin B₁₂. The IF-B₁₂ complex resists digestion and passes through the jejunum into the ileum where it binds the specific IF receptor (cubulin) on the microvilli of ileal mucosal cells¹³ (Figure 9). Because the ileal receptors are specific for IF, not R-proteins, a lack of pancreatic protease ties up the vitamin B₁₂ in a form that cannot be absorbed (R-protein:cobalamin) and results in vitamin B₁₂ deficiency. Following attachment of the IF-B₁₂ complex to the receptor, the vitamin is taken into the mucosal cell. The entire IF-B₁₂ complex appears to be taken into the cell where the B₁₂ is released while the IF is degraded.¹³

Transport Vitamin B₁₂ leaves the mucosal cell and is transported in the blood by a group of transport proteins. These transport proteins include transcobalamin I (TCI), transcobalamin II (TCII), and transcobalamin III (TCIII). TCI and TCIII are R-proteins, but TCII is not.

The release of the vitamin from each of these transcobalamins is different. TCII is an α-globulin produced in the liver and the ileum and by macrophages. Although TCII carries only a small fraction of the total vitamin in the plasma, it is the primary plasma protein that mediates transfer of vitamin B₁₂ into the tissues. The vitamin B₁₂:TCII complex is thought to be formed within the ileal mucosal cells and released to the blood.¹³ TCII binds 90% of the newly absorbed vitamin B₁₂. This transport complex disappears rapidly from blood (T_{1/2} of 6–9 minutes) as it is taken up by cells in the liver, bone marrow, and other dividing cells that have spe-

■ FIGURE 9 Assimilation of vitamin B₁₂.

cific receptors for TCII. The B₁₂-TCII complex is internalized, and once inside the cell, vitamin B₁₂ is released and utilized, and the TC is degraded. Congenital deficiency of TCII produces a severe megaloblastic anemia in infancy. However, serum vitamin B₁₂ concentration in this condition is normal.

The functions of the R-proteins TCI and TCIII are less well understood. TCI has an electrophoretic mobility of α_1 -globulin and is produced in part by granulocytes. TCI is the main R-protein of plasma and carries 75% of the recycled endogenous vitamin B₁₂ in the body. TCI is only about 50% saturated, its turnover is slow (T_{1/2} of 10 days), and its function is unknown. It has been suggested that TCI serves to carry cobalamins to hepatocytes where they are excreted in the bile, thus serving to clear the body of nonphysiologic cobalamins. An alternative theory suggests that TCI is a storage protein for cobalamins.¹³ Lack of TCI produces no megaloblastosis or anemia but results in a decreased serum vitamin B₁₂ level.

TCIII has an electrophoretic mobility of the α_2 -globulins and is found in plasma and in granulocytes. It appears to be released from granulocytes during the clotting process and does not bind significant portions of cobalamin. Both TCI and III are increased in myeloproliferative disorders, presumably due to proliferation of granulocytes that produce the protein. Other vitamin B₁₂ binder proteins are present in plasma, saliva, gastric juice, pancreatic juice, amniotic fluid, and milk.

Requirements

About 3–5 μg of vitamin B₁₂ per day is needed to maintain normal biochemical functions. It is estimated that only about 70% of vitamin B₁₂ intake is absorbed, which suggests that the diet should include from 5 to 7 μg of the vitamin per day. This amount is available in a regular mixed (“balanced”) diet but a strict vegetarian diet does not. Vitamin B₁₂ stores (~5000 μg) are sufficient to provide the normal daily requirement for about 1000 days. Therefore, it takes several years to develop a deficiency if no vitamin B₁₂ is absorbed from the diet. About half of this storage vitamin is in the liver.¹⁸ The rest is located in the heart and kidneys.

Checkpoint! 8

Explain why there is a megaloblastic anemia in transcobalamin II deficiency when the serum vitamin B₁₂ concentration is normal.

Pathophysiology of Vitamin B₁₂ Deficiency

Deficiency of vitamin B₁₂ is reflected by (1) impaired DNA synthesis (megaloblastic anemia) and (2) defective fatty acid degradation (neurologic symptoms).

Impaired DNA Synthesis A deficiency in either vitamin B₁₂ or folic acid results in impaired production of methylene-THF, a defect in thymidylate synthesis, and ultimately a defect in DNA synthesis. This produces megaloblastic ane-

mia and epithelial cell abnormalities. All dividing cells including the hematopoietic cells in the bone marrow are affected.

Defective Fatty Acid Degradation AdoCbl is a cofactor in the conversion of methylmalonyl CoA to succinyl CoA. In vitamin B₁₂ deficiency, there is a defect in degradation of propionyl CoA to methylmalonyl CoA and, finally, to succinyl CoA. As propionyl CoA accumulates, it is used as a primer for fatty acid synthesis, replacing the usual primer acetyl CoA. This results in fatty acids with an odd number of carbons. These odd-chain fatty acids are incorporated into neuronal membranes causing disruption of membrane function. It is probable that **demyelination** (destruction, removal, or loss of the lipid substance that forms a myelin sheath around the axons of nerve fibers), a characteristic finding in vitamin B₁₂ deficiency is a result of this erroneous fatty acid synthesis.

A critical feature of demyelination in vitamin B₁₂ deficiency is neurological disease. Peripheral nerves are most often affected, presenting initially as motor and sensory neuropathy. The brain and spinal cord can also be affected leading to dementia, spastic paralysis, and other serious neurological disturbances. Demyelination has been known to occur occasionally without any sign of anemia or macrocytosis, making accurate diagnosis difficult but critical. The bone marrow, however, always shows megaloblastic hematopoiesis.¹⁹ Neurological disease might not be totally reversible but, if treated early, can be partially resolved. Neurological disease does not occur in folic acid deficiency. Administration of synthetic folic acid corrects the anemia of vitamin B₁₂ deficiency but does not halt or reverse neurological disease because synthetic folic acid, unlike dietary folic acid, is reduced directly to THF without the requirement of vitamin B₁₂ as a cofactor.²⁰ The THF can correct the megaloblastosis, but because there is a bypass of the vitamin B₁₂-dependent reaction of conversion of homocysteine to methionine, SAM—a metabolite considered critical to nervous system function—is not formed. Thus, it is essential to differentiate between folate deficiency and vitamin B₁₂ deficiency so that appropriate treatment can be given.

Gastritis and abnormalities of the gastrointestinal epithelium secondary to vitamin B₁₂ deficiency can interfere with the absorption of folic acid and iron, complicating the anemia.

Checkpoint! 9

Explain why severe B₁₂ deficiency sometimes presents with neurological disease.

Causes of Vitamin B₁₂ Deficiency

Vitamin B₁₂ deficiency has many causes including lack of intrinsic factor (pernicious anemia), malabsorption, nutritional deficiency, and impaired utilization by tissues due to defective or absent transport proteins or enzyme deficiencies (Table 6 ) .

Pernicious Anemia **Pernicious anemia (PA)** is a specific term used to define the megaloblastic anemia caused by an absence of IF secondary to gastric atrophy. An absence of IF leads to vitamin B₁₂ deficiency because the vitamin cannot be absorbed without it. PA is the most common cause of vitamin B₁₂ deficiency, accounting for 85% of all deficiencies. Total atrophy of gastric parietal cells is demonstrated by finding **achlorhydria** of gastric juice after histamine stimulation (these cells also produce HCl). It is generally a disease of older adults, usually occurring after 40 years of age. This anemia is seen more commonly among people of Northern European background, especially Great Britain and Scandinavia, but can be found in all racial groups. More women than men are affected. Although no particular genetic abnormality has been identified, some patients have prematurely graying or whitening hair. A positive family history of PA increases the

risk of developing it by 20 times. The incidence of gastric carcinoma in these patients is also increased.²¹

PA is an autoimmune disease. The gastric atrophy is thought to result from immune destruction of the acid-secreting portion of the gastric mucosa.¹³ Up to 90% of PA patients have antibodies against parietal cells.²³ However, these antibodies are not specific for pernicious anemia patients and are also found in patients with gastritis, thyroid disease, and Addison's disease. On the other hand, serum antibodies against intrinsic factor are found in ~75% of PA patients and are highly specific for PA. These IF antibodies are of two types: blocking and binding. Type I, or blocking, antibodies are antibodies to IF and prevent formation of the IF-vitamin B₁₂ complex. Type II, or binding, antibodies are directed against the IF-B₁₂ complex and prevent the IF-B₁₂ complex from binding to ileal receptors. Binding antibodies are found in about half the sera that contain blocking antibody. A number of findings suggest that the immune destruction of the gastric mucosa is not antibody mediated but more likely T cell mediated. Patients with agammaglobulinemia have a higher than expected incidence of PA. Also, lymphocytes from PA patients have been shown to be hyperresponsive to gastric antigens.¹³

Pernicious anemia frequently occurs with other autoimmune diseases such as Graves' disease and Hashimoto's thyroiditis, type I diabetes, and Addison's disease. In addition, a predisposition to PA can be inherited. Relatives of patients with PA have a higher incidence of antiparietal cell antibodies and anti-intrinsic factor antibodies than the general population.¹³

Juvenile pernicious anemia is rare in children. It can occur secondary to a variety of conditions, including a congenital deficiency or abnormality of IF (the more common type with lack of IF but otherwise normal gastric secretion), or more rarely, true PA of childhood. In true PA of childhood, there is absence of intrinsic factor and gastric atrophy, decreased gastric secretion, and antibodies against IF and parietal cells. Megaloblastic anemia in childhood due to malabsorption of vitamin B₁₂ can also be due to a congenital deficiency of TCII, a congenital R-protein deficiency, or selective malabsorption of vitamin B₁₂ (Imerslund-Gräsbeck disease). The latter can be due to abnormal vitamin B₁₂-IF receptors in the ileum.

Laboratory diagnosis of pernicious anemia and/or vitamin B₁₂ deficiency usually involves gastric analysis and/or the Schilling test, serum vitamin B₁₂ assay, and methylmalonic acid (MMA) assay. The serum vitamin B₁₂ and MMA assays establish the fact that a deficiency exists but does not provide a distinction of PA from other causes of vitamin B₁₂ deficiency. Gastric analysis and the Schilling test are more useful in establishing the specific diagnosis of PA but are rarely performed anymore.

Gastric Analysis Because atrophy of the parietal cells is a universal feature of PA, an absence of free HCl in gastric

 TABLE 6

Causes of Vitamin B₁₂ Deficiency and Associated Conditions

Cause	Associated Conditions
Malabsorption	Pernicious anemia (lack of IF)
	Gastrectomy or gastric bypass
	Crohn's disease
	Tropical sprue
	Celiac disease
	Surgical resection of the ileum
	Imerslund-Gräsbeck disease
	Pancreatic insufficiency
	Drugs (colchicine, neomycin, p-aminosalicylic acid, or omeprazole)
	Blind loop syndrome
	Diverticulitis
	Intestinal parasite— <i>Diphyllobothrium latum</i>
	Biologic competition
Leishmaniasis ²²	
Bacterial overgrowth	
Nutritional deficiency	Strict vegetarian diets
	Pregnant women on a poor diet
	Malnutrition
Impaired utilization	Transcobalamin II deficiency
	Nitrous oxide inhalation

juice after histamine stimulation is indicative of PA. Because parietal cells secrete both HCl and intrinsic factor, an absence of HCl is indirect evidence for lack of IF. After histamine stimulation in patients with pernicious anemia, the pH fails to fall below 3.5, and gastric volume, pepsin, and rennin are decreased. Approximately 80% of cases of PA have increased gastrin. Testing for anti-intrinsic factor antibodies, serum gastrin, and serum pepsinogen A and C together as a group provides a sensitive indication of gastric atrophy and pernicious anemia.²⁴

Schilling Test The **Schilling test** is a definitive test useful in distinguishing vitamin B₁₂ deficiency due to malabsorption, dietary deficiency, or absence of IF. The test measures the amount of an oral dose of radioactively labeled crystalline B₁₂ that is absorbed in the gut and excreted in the urine. The patient is given 0.5–1.0 µg dose of ⁵⁷Co-labeled B₁₂ orally. This is given with or followed within two hours by an intramuscular injection of 1000 µg of unlabeled vitamin B₁₂. The injection is termed the *flushing dose*; its purpose is to saturate all vitamin B₁₂ receptors in the tissues. Thus, any of the labeled oral dose absorbed in the gut and passing into the blood will be in excess of available uptake receptors. The excess is filtered by the kidney and appears in the urine. Urine is collected for 24 hours, and its radioactivity is determined. If more than 7.5% of the standard oral dose is excreted, absorption is said to be normal. In PA and in malabsorption, excretion is less than 7.5% because the labeled oral vitamin B₁₂ is not absorbed.

If excretion is less than 7.5%, part II of the Schilling test is performed to distinguish between PA and other causes of malabsorption. In part II, the oral dose of labeled B₁₂ is accompanied by a dose of intrinsic factor. The rest of the test is the same as in part I. If part II shows more than 7.5% excretion, absorption is considered normal with the lack of absorption in part I simply due to the lack of IF. The diagnosis is PA. If part II is abnormal, the patient can have another malabsorption defect such as sprue (Table 7 ⚡).

Several points must be considered when interpreting the results of a Schilling test. First, the test results are not valid with the presence of renal disease. The patient could have been able to absorb the vitamin but cannot filter the excess vitamin efficiently because of abnormal kidney function. Second, incomplete collection of urine invalidates the results. Incontinence or inability to empty the bladder gives false low values even when absorption was normal. Spuriously low urinary excretion in part II can also be due to the inability to absorb IF-B₁₂ because of megaloblastoid epithelial changes in the gut.

The Schilling test is seldom used now in this country because of the difficulties in using radioisotopes and the inconvenience of the test for the patient. An additional problem is that the absorption of crystalline vitamin B₁₂ used in the oral dose can differ from the absorption of vitamin B₁₂ in

★ TABLE 7

Conditions Associated with Abnormal Schilling Test Results

Corrected by Intrinsic Factor in Part II	Not Corrected by Intrinsic Factor in Part II
Pernicious anemia	Crohn's disease
Abnormal intrinsic factor molecule	Tropical sprue
Hereditary intrinsic factor deficiency	Celiac disease
Gastrectomy	Surgical resection of the ileum
	Imerslund-Gräsbeck disease
	Pancreatic insufficiency
	Drugs
	Blind loop syndrome
	Diverticulitis
	Intestinal parasite— <i>Diphyllobothrium latum</i>
	Transcobalamin II deficiency

food.^{14,25} For these reasons, MMA and homocysteine are emerging as better markers for early detection of PA or vitamin B₁₂ deficiency.

On the other hand, there are advantages of the Schilling test. First, the test results can suggest what further testing (i.e., stool analysis for *D. latum*) should be done. Second, results can help identify how to treat the clinical condition and the duration of treatment.²⁶

Other Causes of Malabsorption Pernicious anemia is only one specific cause of vitamin B₁₂ malabsorption, which also can be caused by a loss of IF secondary to gastrectomy or secondary to diseases that prevent binding of the IF-B₁₂ complex in the ileum. An iron deficiency usually precedes vitamin B₁₂ deficiency in patients who have had a gastrectomy. Diseases that can affect the absorption of the IF-B₁₂ complex in the ileum include Crohn's disease, tropical sprue, celiac disease, and surgical resection of the ileum. In Imerslund-Gräsbeck disease, the IF receptors are missing or abnormal, causing a form of juvenile megaloblastic anemia. In patients with severe pancreatic insufficiency, there is a lack of absorption of the vitamin B₁₂ because the vitamin cannot be released from the R-proteins and transferred to IF. Normally, pancreatic proteases are responsible for degrading the R-proteins. Certain medications can interfere with intestinal absorption. In addition, conditions that allow a buildup of bacteria in the small bowel can cause a vitamin B₁₂ deficiency. The bacteria preferentially take up the vitamin before it reaches the ileum. This situation occurs in the blind loop syndrome and in diverticulitis. Infestation with the fish tapeworm *Diphyllobothrium latum* can cause a deficiency as the worm accumulates the vitamin avidly.

CASE STUDY (continued from earlier in this chapter)

A Schilling test and antibody testing were done, with the following results:

Schilling test	Part I, before intrinsic factor, 1%
	Part II, after intrinsic factor, 8%
Intrinsic-factor-blocking antibodies	Positive to a titer of 1:6400

5. What is this patient's definitive diagnosis?

Nutritional Deficiency Dietary deficiency of vitamin B₁₂ is rare in the United States. Food from animal sources, especially liver, is rich in vitamin B₁₂. Strict vegetarian diets, however, do not supply vitamin B₁₂, and these individuals can develop a deficiency over a period of years. Occasionally, pregnant women with a poor diet can develop a deficiency presumably due to an increased demand by the developing fetus. However, folic acid deficiency is a more common cause of megaloblastic anemia in pregnancy due to the lower stores of this nutrient.

Other Causes TCII deficiency is the only transcobalamin deficiency that produces megaloblastic anemia because it is the major transport protein responsible for delivering the vitamin to the tissues. In TCII deficiency, vitamin B₁₂ is absorbed normally and serum vitamin B₁₂ is normal because of the relatively high levels bound to TCI. Tissue vitamin B₁₂ deficiency develops, however, including megaloblastic anemia, because the cellular receptors recognize only TCII, not the R-proteins (TCI and TCIII).¹³

Nitrous oxide, N₂O (“laughing gas”), abuse has been reported to result in a B₁₂ deficiency and megaloblastic anemias. N₂O rapidly inactivates methionine synthetase of which cobalamin is a coenzyme. Vitamin B₁₂ cleaves N₂O and at the same time is oxidized to an inert form. This leads to a rapid deficiency.

✓ Checkpoint! 10

Explain why some believe that pernicious anemia is an autoimmune disorder.

Laboratory Analysis of Vitamin B₁₂ Deficiency

Vitamin B₁₂ in serum is a reflection of vitamin stores. The normal range of serum vitamin B₁₂ varies from newborn to adult, in men, the concentration depends significantly on age.²⁷ Serum vitamin B₁₂ can appear falsely decreased (no actual vitamin B₁₂ deficiency) in folic acid deficiency, in pregnancy, with oral contraceptive use, with antibiotic therapy (using the microbiologic assay), and in multiple myeloma

★ TABLE 8

Causes of False Decrease and False Normal/Increase in Serum Vitamin B₁₂ Levels

False Decrease	False Normal/Increase
Folate deficiency	B ₁₂ treatment
Pregnancy (last trimester)	Liver disease
Oral contraceptive use	Nitrous oxide inhalation
Multiple myeloma	Chronic myelogenous leukemia
Elderly	Polycythemia vera
Transcobalamin I deficiency	Transcobalamin II deficiency

(Table 8 ★). Vitamin B₁₂ deficiency can be masked by folate therapy.

A specific test that measures the increased excretion of methylmalonic acid (MMA) in the urine indirectly indicates decreases in vitamin B₁₂ concentration. Up to 40% of patients may have increased MMA levels in the urine but normal serum B₁₂ levels.²⁰ These patients, however, show laboratory and clinical evidence of vitamin B₁₂ deficiency. The only condition in which methylmalonic acid is increased in addition to vitamin B₁₂ deficiency is in congenital methylmalonic aciduria. The congenital condition, however, has no megaloblastic anemia. Thus, determination of MMA concentration is useful in distinguishing a vitamin B₁₂ deficiency from folate deficiency.

Homocysteine is increased in the plasma of patients with vitamin B₁₂, or folate deficiency.²⁸ Monitoring serum levels can serve as an early detector of vitamin B₁₂ deficiency. Many recent studies have concluded that MMA and homocysteine are the most sensitive and specific indicators of vitamin B₁₂ deficiency.^{27–30} Some studies have shown that besides being a good indicator of vitamin B₁₂ deficiency, increased homocysteine levels could also predict a 3-fold increase risk in myocardial infarction as well as venous thrombosis.²⁹ Increased concentrations of both analytes can be found in many patients with normal serum vitamin B₁₂ concentrations.²⁹ Some clinicians now recommend initial testing for serum vitamin B₁₂ levels and following up low or borderline normal results with MMA and homocysteine measurements.³⁰ By contrast, some have found that MMA and homocysteine measurements are more sensitive tests of early pernicious anemia preceding hematologic abnormalities and decreased serum vitamin B₁₂ levels and recommend them as a superior testing regimen (Figure 10 ■).

Homocysteine and MMA tests are also helpful in determining a patient's response to treatment with vitamin B₁₂ and folate. The serum MMA level remains increased in vitamin B₁₂-deficient patients treated inappropriately with fo-

late. Folate-deficient patients treated inappropriately with cobalamin have increased serum homocysteine level.

A new technology, electrospray tandem mass spectrometry, could make testing for serum levels of MMA and homocysteine easier and more practical.³¹ The procedure does not require expensive immunodiagnostic reagents and chromatographic columns and can be performed in under five minutes.

Checkpoint! 11

What two lab tests are the most specific indicators of B₁₂ deficiency?

ThERAPY

Therapeutic trials in megaloblastic anemia using *physiologic* doses of either vitamin B₁₂ or folic acid produce a reticulocyte response only if the specific vitamin that is deficient is being administered. For instance, small doses (1 µg) of vitamin B₁₂ given daily produce a reticulocyte response in vitamin B₁₂ deficiency but not in folic acid deficiency. On the other hand, large therapeutic doses of vitamin B₁₂ or folic acid can induce a partial response to the other vitamin deficiency, as well as the specific deficiency.

Generally, it is best to determine which deficiency exists and treat the patient with the specific deficient vitamin. Large doses of folic acid are proven to correct the anemia in vitamin B₁₂ deficiency but do not correct or halt demyelination and neurologic disease. This makes diagnosis and specific therapy critical in vitamin B₁₂ deficiency. Specific therapy causes a rise in the reticulocyte count after the 4th day of therapy. Reticulocytosis peaks at about 5 to 8 days and returns to normal after 2 weeks. The degree of reticulocytosis is proportional to the severity of the anemia with more striking reticulocytosis in patients with severe anemia. The hemoglobin rises about 2–3 g/dL every 2 weeks until normal levels are reached. The marrow responds quickly to therapy as evidenced by pronormoblasts (normal) appearing within 4–6 hours and nearly complete recovery of erythroid abnormalities within 2–4 days. Granulocyte abnormalities disappear more slowly. Hypersegmented neutrophils can usually be found for 12–14 days after therapy is begun.¹⁸

Specific therapy can reverse the peripheral neuropathy of vitamin B₁₂ deficiency, but spinal cord damage is usually irreversible. Pernicious anemia must be treated with lifelong monthly parenteral doses of hydroxycobalamin (OHCbl) because of these patients' inability to absorb oral vitamin B₁₂. Recently it was reported that large doses of vitamin B₁₂ therapy (usually 1000 to 2000 µg/day) administered orally could be feasible if the patient is followed carefully.²³ The oral treatment can be better tolerated and less expensive.³² The rationale behind oral therapy using large doses of vitamin is that a small amount (from 1 to 3%) of the vitamin is absorbed by mass action without IF.

CASE STUDY (continued from earlier in this chapter)

6. How would the diagnosis change if the special testing results were as follows?

Schilling test	Part I, before intrinsic factor, 1% Part II, after intrinsic factor, 3%
Intrinsic-factor-blocking antibodies	Negative

7. What would you predict this patient's reticulocyte count to be?

OTHER MEGALOBlastic ANEMIAS

A megaloblastic anemia occasionally is associated drugs, congenital enzyme deficiencies, or other hematopoietic diseases.

Drugs

A large number of drugs that act as metabolic inhibitors can cause megaloblastosis (Table 9). Some of these drugs are used in chemotherapy for malignancy. Although aimed at eliminating rapidly proliferating malignant cells, these drugs are not selective for malignant cells. Any normal proliferating cell including hematopoietic cells, is also affected.

Enzyme Deficiencies

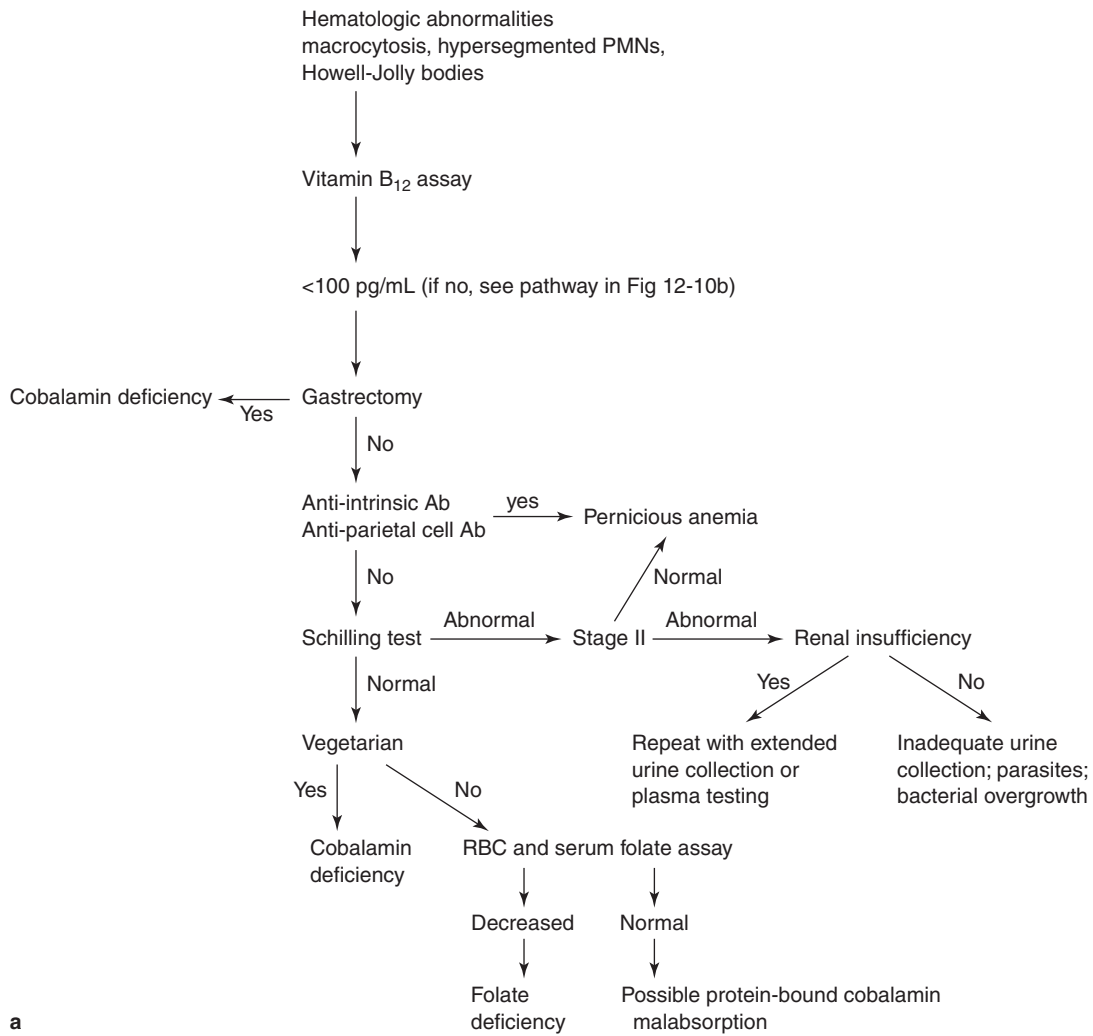

Methionine synthase reductase (MSR) deficiency is a rare autosomal recessive disorder. A deficiency of this enzyme leads to a dysfunction of folate/cobalamin metabolism and results in hyperhomocysteinemia, hypomethioninemia, and megaloblastic anemia.³³ MSR is necessary for the reductive activation of methionine synthase and the resultant folate/vitamin B₁₂ dependent conversion of homocysteine to methionine.

Congenital Deficiencies

A congenital deficiency is a physiological aberration present at birth. The following congenital deficiencies result in megaloblastosis.

Orotic Aciduria Inborn defects in enzymes required for pyrimidine synthesis or folate metabolism can result in megaloblastic anemia. Orotic aciduria is a rare autosomal recessive disorder in which there is a failure to convert orotic acid to uridylic acid. The result is excessive excretion of orotic acid. Children with this disorder also fail to grow and develop normally. The condition responds to treatment with oral uridine.

Congenital Dyserythropoietic Anemia Congenital dyserythropoietic anemia (CDA) is actually a heterogeneous group of refractory, congenital anemias characterized by

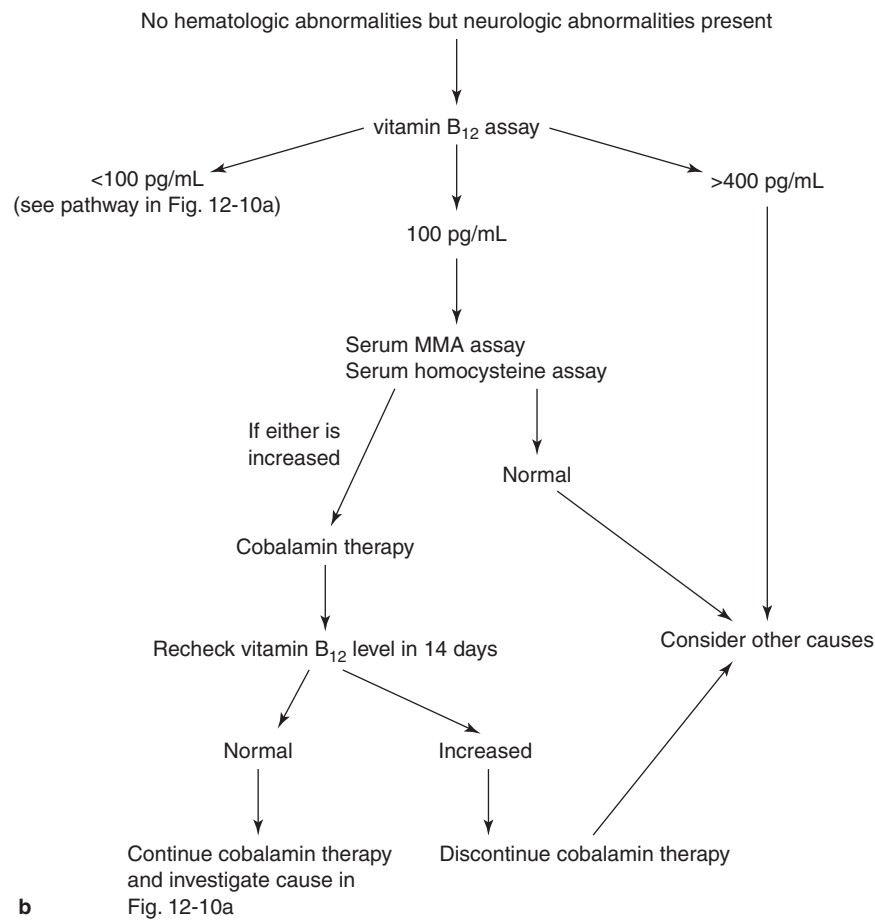

a

■ **FIGURE 10** Algorithm of diagnosis of vitamin B₁₂ and folic acid deficiency using laboratory tests. The algorithm above (a) is followed if the serum vitamin B₁₂ level is <100 pg/mL. If higher, follow the algorithm to the right (b) Use this figure with Figure 1 to determine whether macrocytosis is megaloblastic or nonmegaloblastic. (Adapted, with permission, from: Snow CF. Laboratory diagnosis of vitamin B₁₂ and folate deficiency. *Arch Intern Med.* 1999;159:1289–98.)

both abnormal erythropoiesis and ineffective erythropoiesis (Table 10). There are three types: CDA I, CDA II, and CDA III. Types I and II are inherited as autosomal recessive disorders, and Type III is inherited in an autosomal dominant fashion. Red cell multinuclearity in the bone marrow and secondary siderosis are recognized in all types; however, megaloblastic erythroid precursors are present only in Type I and Type III.

- **CDA I.** Bone marrow erythroblasts are megaloblastic and often binucleate with incomplete division of nuclear segments. The incomplete nuclear division is characterized by internuclear chromatin bridges.
- **CDA II.** Bone marrow precursors are not megaloblastic but are typically multinucleated with up to seven nuclei (Figure 11). Type II is distinguished by a positive acidified serum test (Ham test) but a negative sucrose

✦ **TABLE 10**

Comparison of Congenital Dyserythropoietic Anemia (CDA) Types

Characteristics	CDA I	CDA II	CDA III
Inheritance	Autosomal recessive	Autosomal recessive	Autosomal dominant

Siderosis	Present	Present	Present
Megaloblastosis	Present	Absent	Present
Other characteristics	Incomplete nuclear division	Positive Ham test (HEMPAS)	RBC agglutination by anti-I and anti-i antibodies

FIGURE 11 Peripheral blood of a case of congenital dyserythropoietic anemia type II (CDA-II). There is anisocytosis with microcytic, hypochromic cells as well as macrocytes and normocytes. Cabot's rings are visible. The nucleated cell is an orthochromic normoblast showing lobulation of the nucleus. (Wright-Giemsa stain; 1000× magnification).

hemolysis test. In the Ham test, only about 30% of normal sera are effective in lysing CDA II cells. This type has also been termed *hereditary erythroblastic multinuclearity* with positive acidified serum test (HEMPAS). CDA II is the most common of the three types of CDA.

- **CDA III.** This type of CDA is morphologically distinct from Types I and II because of the presence of giant erythroblasts (up to 50 μm) containing up to 16 nuclei. Sometimes the erythrocytes are agglutinated by anti-I and anti-antibodies.

Other Hematopoietic Diseases

The myelodysplastic syndromes are a group of stem cell disorders characterized by peripheral cytopenias and dysmatopoiesis. Erythroid precursors in the bone marrow frequently exhibit megaloblasticlike changes. There is occasionally a nonmegaloblastic macrocytic anemia.

✓ Checkpoint! 12

Which clinical type of CDA gives a positive HAM test result and presents with a normoblastic marrow?

▶ MACROCYTIC ANEMIA WITHOUT MEGALOBLASTOSIS

The typical findings of megaloblastic anemia are not evident in other macrocytic anemias. The macrocytes in macrocytic anemias without megaloblastosis are not usually as pronounced as the macrocytes in megaloblastic anemia. In addition, these macrocytes are usually round rather than oval as seen in megaloblastic anemia. Hypersegmented neutrophils are not present, and leukocytes and platelets are quantita-

tively normal. Jaundice, glossitis, and neuropathy, the typical clinical findings in megaloblastosis are absent. The cause of the macrocytosis without megaloblastosis is unknown in many cases. It has been suggested that macrocytes could be due to an increase in membrane lipids or to a delay in blast maturation. Some diseases associated with nonmegaloblastic macrocytic anemia are listed in Table 11. Three of the most common are discussed in this section: alcoholism, liver disease, and reticulocytosis (stimulated erythropoiesis).

ALCOHOLISM

Alcohol abuse is one of the most common causes of nonanemic macrocytosis. It has been suggested that all patients with macrocytosis should be questioned about their alcohol consumption.³⁴ The macrocytosis associated with alcoholism is usually multifactorial and can be megaloblastic. Macrocytosis is probably the result of one or more of four causes: (1) folate deficiency due to decreased dietary intake, (2) reticulocytosis associated with hemolysis or gastrointestinal bleeding, (3) associated liver disease, and (4) alcohol toxicity.

Folate deficiency associated with a megaloblastic anemia is the most common cause of the macrocytosis found in hospitalized alcoholic patients. The deficiency probably results from poor dietary habits, although ethanol also appears to interfere with folate metabolism.

The reduced erythrocyte survival with a corresponding reticulocytosis has been associated with chronic gastrointestinal bleeding secondary to hepatic dysfunction (de-

★ TABLE 11

Conditions Associated with Nonmegaloblastic Macrocytosis

Condition	Cause of Macrocytosis
Alcoholism	Direct toxic effect of alcohol on erythroid precursors
	Reticulocytosis associated with hemolysis or GI bleeding
	Liver disease: abnormal RBC membrane lipid composition
Liver disease	Can also be megaloblastic from folate deficiency
	Reticulocytosis associated with stimulated erythropoiesis; increased RBC membrane lipids
Hemolysis or post-hemorrhagic anemia	Reticulocytosis associated with stimulated erythropoiesis
Hypothyroidism	Unknown
Aplastic anemia	Unknown
Artifactual	Cold agglutinin disease
	Severe hyperglycemia
	RBC clumping
	Swelling of RBCs

creased coagulation proteins) or thrombocytopenia, hypersplenism from increased portal and splenic vein pressure, pooling of cells in splenomegaly, and altered erythrocyte membranes caused by abnormal blood lipid content in liver disease. Stomatocytes are associated with acute alcoholism, but there appear to be no significant cation leaks, and hemolysis of these cells is not significant.

Liver disease is common in alcoholic individuals; typical hematologic findings associated with this disease are discussed in the following section. Even when anemia is absent, most alcoholic individuals have a mild macrocytosis (100–110 fL) unrelated to liver disease or folate deficiency. This can be caused by a direct toxic effect of the ethanol on developing erythroblasts. Vacuolization of red cell precursors, similar to that seen in patients taking chloramphenicol, is a common finding after prolonged alcohol ingestion. If alcohol intake is eliminated, the cells gradually assume their normal size, and the bone marrow changes disappear.

The multiple pathologies of this type of anemia result in the possibility of a variety of abnormal hematologic findings. Thus, it is possible to have a blood picture resembling that of megaloblastic anemia, chronic hemolysis, chronic or acute blood loss, liver disease, or (more than likely) a combination of these conditions.

LIVER DISEASE

The most common disease associated with a nonmegaloblastic macrocytic anemia is liver disease (including alcoholic cirrhosis). The causes of this anemia are multifactorial and include hemolysis, impaired bone marrow response, folate deficiency, and blood loss (Table 12). Although macrocytic anemia is the most common form of anemia in liver disease, occurring in more than 50% of the patients, normocytic or microcytic anemia can also be found depending on the predominant pathologic mechanism.

Erythrocyte survival appears to be significantly shortened in alcoholic liver disease, infectious hepatitis, biliary cirrhosis, and obstructive jaundice. The reason for this is unknown. Cross-transfusion studies in which patient cells are infused into normal individuals demonstrate an increase in patient cell survival. These studies suggest an extracorporeal factor is probably responsible for cell hemolysis. The spleen is thought to play an important role in sequestration and hemolysis in individuals with splenomegaly or hypersplenism. In some cases, hemolysis is well compensated for by an increase in erythropoiesis and there is no anemia. In some patients with alcoholic liver disease, a heavy drinking spree produces a brisk but transient hemolysis. These patients also show abnormal liver function and have markedly increased levels of plasma triglycerides.

Abnormalities in erythrocyte membrane lipid composition are common in hepatitis, cirrhosis, and obstructive

jaundice. Both cholesterol and phospholipid are increased, resulting in cells with an increased surface-to-volume ratio. This abnormality is not thought to cause decreased cell survival. In contrast, in severe hepatocellular disease, erythrocyte membranes have an excessive amount of cholesterol relative to phospholipid, which decreases the erythrocyte deformability. This is associated with the formation of spur cells in which the erythrocyte exhibits spikelike projections. These cells have a pronounced shortened life span leading to an anemia termed *spur cell*.

Kinetic iron studies have revealed that the bone marrow response in liver disease can be impaired. It has been proposed that liver disease can affect the production of erythropoietin because this organ has been shown to be an important extrarenal source of the hormone in rats.³⁵ In alcoholic cirrhosis, the alcohol can have a direct suppressive effect on the bone marrow.

Clinical findings and symptoms in liver disease are secondary to the abnormalities in liver function. The liver is involved in many essential metabolic reactions and in the synthesis of many proteins and lipids. Therefore, the anemia is only a minor finding among the abnormalities associated with this organ's dysfunction.

The anemia is usually mild with an average hemoglobin concentration around 12 g/dL. With complications, the anemia can be severe. The erythrocytes can appear normocytic, macrocytic (usually not more than 115 fL MCV), or microcytic. A discrepancy between the MCV and the appearance of the cells microscopically often occurs. In these cases, thin, round macrocytes (as determined by diameter) with target cell formation are found on the blood smear, but the MCV is within normal limits. The reticulocyte count can be increased, but the RPI is usually less than 2 unless hemolysis is a significant factor. Thrombocytopenia is a frequent finding, and platelet function can be abnormal. Various nonspecific leukocyte abnormalities have been described including neutropenia, neutrophilia, and lymphopenia. The bone marrow is either normocellular or hypercellular, often with erythroid hyperplasia. The precursors are qualitatively normal unless folic acid deficiency is present. In this case, megaloblastosis is apparent with the typical associated blood abnormalities.

Other laboratory tests of liver function are variably abnormal including increased serum bilirubin and increased hepatic enzymes. Tests for carbohydrate and lipid metabolites are frequently abnormal depending on the degree of liver disease.

Checkpoint! 13

What is the main cause of nonanemic macrocytosis?

STIMULATED ERYTHROPOIESIS

Increased erythropoietin (stimulation) in the presence of an adequate iron supply (e.g., autoimmune hemolytic anemia) can result in the release of shift reticulocytes from the bone

★ TABLE 12

Causes and Characteristics of Anemia in Liver Disease

Causes	Anemia Type	Characteristics
Abnormal liver function	Macrocytic	MCV normal to increased Increased RBC membrane cholesterol resulting in target cells and acanthocytes Normal to slightly increased reticulocytes
Folic acid deficiency	Macrocytic	MCV increased Pancytopenia Ovalocytes and teardrop cells Normal to decreased reticulocytes Functional folate deficiency
Stimulated erythropoiesis	Macrocytic	MCV increased Slightly increased WBC count Normal platelet count Shift reticulocytosis
Hemolysis	Normocytic or macrocytic	MCV normal to increased Spur cells and schistocytes Increased reticulocytes
Hypersplenism	Normocytic	MCV normal Pancytopenia Increased reticulocytes Portal hypertension
Marrow hypoproliferation	Normocytic	MCV normal Pancytopenia Decreased reticulocytes Associated with renal disease or alcohol suppression
Chronic blood loss	Microcytic	MCV decreased Iron deficiency Leukocyte and platelet counts slightly increased Reticulocytes increased Commonly associated with gastrointestinal bleeding

marrow. These cells are larger than normal with an MCV as high as 130 fL. A reticulocyte count and examination of the blood smear allow distinction of this macrocytic entity from megaloblastic anemia. In the presence of large numbers of shift reticulocytes, polychromasia has a marked increase. In addition, the oval macrocytes typical of megaloblastic anemia are not present in conditions associated with increased erythropoietin stimulation.

HYPOTHYROIDISM

Anemia of hypothyroidism presents as a mild to moderate anemia with a normal reticulocyte count. Thyroid hormone regulates cellular metabolic rate, and therefore tissue oxygen requirement. With a decrease in thyroid hormone (i.e., hy-

pothyroidism), tissue oxygen requirement is smaller, which is interpreted by the kidneys as a more than adequate oxygen tension. The net result is a decrease in the production of EPO and, correspondingly, erythrocytes. This type of anemia often presents as a macrocytic, normochromic anemia but can also be a normocytic, normochromic anemia. The anemia can be complicated by iron, folic acid, or B₁₂ deficiencies, and the blood picture can reflect these forms of anemia.

Checkpoint! 14

What are three clinical or laboratory findings (besides assessing the bone marrow) that can distinguish a nonmegaloblastic macrocytic anemia from a megaloblastic anemia?

SUMMARY

Macrocytosis due to megaloblastic anemia must be differentiated from macrocytosis with a normoblastic marrow. The laboratory test profile of a patient with megaloblastic anemia commonly indicates pancytopenia. The blood smear reveals macrocytes (i.e., large ovalocytes), poikilocytosis, teardrop cells, Howell-Jolly bodies, and neutrophil hypersegmentation. The marrow is characterized by megaloblastosis of precursor cells due to a block in thymidine production. Because thymidine is one of the four DNA bases, the deficiency leads to a diminished capacity for DNA synthesis and a block in mitosis. The marrow is hypercellular, but erythropoiesis is ineffective. Causes of megaloblastosis are nearly always due to vitamin B₁₂ or folic acid deficiencies.

Folate is primarily acquired from the diet. Liver tissue is the main storage site of folic acid. Folate deficiency results in decreased synthesis of N⁵,N¹⁰-methylene THF, a cofactor in DNA synthesis. Consequently, DNA synthesis slows. Clinically, symptoms from inadequate dietary folate can occur within months as compared to years for a B₁₂ deficiency.

Vitamin B₁₂ (i.e., cyanocobalamin) absorption occurs in the small intestine. Dietary vitamin B₁₂ is released from digestion of animal proteins in meats and bound by gastric R-proteins, and subsequently intrinsic factor (IF). Once absorbed, vitamin B₁₂ is bound to specific plasma proteins known as *transcobalamin I, II, or III*. Normal serum vitamin B₁₂ values are highly variable on age and sex. B₁₂ function is related to DNA synthesis because vitamin B₁₂ is a vital cofactor in the conversion of methyl tetrahydrofolate (i.e., folic

acid) to tetrahydrofolate. This product is an important cofactor needed for the production of DNA thymidine.

Defective production of intrinsic factor is the most common cause of vitamin B₁₂ deficiency (pernicious anemia—PA), which is caused by failure of the gastric mucosa to secrete IF. PA most commonly occurs in people after 40 years of age. Central nervous system symptoms such as numbness and tingling of the extremities, difficulty with balance and gait, loss of vibration sensation, weakness, spasticity, and personality changes can be present in advanced cases. The Schilling test is a definitive test useful in the diagnosis of intrinsic factor deficiency but is rarely used. Other causes of vitamin B₁₂ deficiency include gastrectomy, malabsorption diseases such as Crohn's disease, and drugs. Megaloblastic anemia rarely results from chemotherapeutic drugs or congenital enzyme deficiencies or with other hematopoietic diseases such as congenital dyserythropoietic anemia.

Serum and RBC folate can be measured to diagnose folate deficiency, but the tests do not reliably indicate folate stores in the presence of vitamin B₁₂ deficiency. Vitamin B₁₂ levels can be directly assessed by measuring serum vitamin B₁₂ or indirectly by measuring MMA in the urine/serum/plasma or homocysteine in plasma.

Macrocytosis due to megaloblastic anemia must be differentiated from macrocytosis with a normoblastic marrow. Normoblastic, macrocytic anemias can result from acute blood loss or hemolysis due to shift reticulocytosis from the marrow. Alcohol abuse is one of the most common causes of normoblastic macrocytosis. Liver disease, often resulting from alcohol abuse, is also commonly associated with macrocytosis without a megaloblastic marrow.

REVIEW QUESTIONS

LEVEL I

- The most common cause of macrocytosis is: (Objective 5)
 - folate deficiency
 - alcoholism
 - liver disease
 - pernicious anemia
- In the majority of cases, B₁₂ deficiency is due to a deficiency of: (Objective 6)
 - intrinsic factor
 - vitamin B₆
 - folate
 - methylmalonic acid
- Which of the following is the best clue in diagnosing megaloblastic anemia? (Objective 3)
 - decreased hemoglobin and hematocrit
 - leukocytosis
 - hypersegmented neutrophils
 - poikilocytosis

LEVEL II

- If a patient presents with anemia, macrocytosis, pancytopenia, and malnutrition, which of the following should be investigated first as a possible cause of the anemia? (Objectives 4, 12)
 - pernicious anemia
 - folate deficiency
 - B₁₂ deficiency
 - celiac disease
- Which laboratory tests are most sensitive to decreased levels of vitamin B₁₂? (Objectives 8, 11)
 - red cell and serum folate
 - serum vitamin B₁₂ and red cell folate
 - transcobalamin II and III assays
 - MMA and homocysteine

REVIEW QUESTIONS (continued)

LEVEL I

4. Increases in urinary excretion of formiminoglutamic acid (FIGLU) most likely indicates which of the following? (Objective 4)
 - a. vitamin B₁₂ deficiency
 - b. autoantibodies to intrinsic factor
 - c. folic acid deficiency
 - d. hemolysis
5. The liver stores enough folate to meet daily requirement needs for how long? (Objective 2)
 - a. 1 month
 - b. 6–8 weeks
 - c. 2 years
 - d. 3–6 months
6. Which of the following conditions increases the daily requirement for vitamin B₁₂? (Objective 2)
 - a. pregnancy
 - b. aplastic anemia
 - c. hypothyroidism
 - d. splenectomy
7. A deficiency of vitamin B₁₂ leads to impaired: (Objective 1)
 - a. folic acid synthesis
 - b. DNA synthesis
 - c. intrinsic factor secretion
 - d. absorption of folate
8. Laboratory diagnosis of pernicious anemia may include which of the following? (Objective 3)
 - a. urinary FIGLU
 - b. WBC count
 - c. Gastric analysis
 - d. LDH
9. Alcoholic individuals commonly develop a macrocytic anemia due to: (Objective 8)
 - a. folate deficiency
 - b. increased blood cholesterol levels
 - c. development of autoantibodies against intrinsic factor
 - d. intestinal malabsorption of B₁₂
10. Anemia due to liver disease is often associated with which of the following RBC morphological forms? (Objective 9)
 - a. ovalocytes
 - b. microcytes
 - c. spur cells
 - d. teardrop cells

LEVEL II

3. Which of the following can be found in a patient with megaloblastic anemia? (Objectives 2, 8, 11)
 - a. giant metamyelocytes and hypolobated neutrophils
 - b. Howell-Jolly bodies and Pappenheimer bodies
 - c. hypersegmented neutrophils and oval macrocytes
 - d. hypochromic macrocytes and thrombocytosis
4. The metabolic function of tetrahydrofolate is to: (Objective 1)
 - a. synthesize methionine
 - b. transfer carbon units from donors to receptors
 - c. serve as a cofactor with cobalamin in the synthesis of thymidylate
 - d. synthesize intrinsic factor
5. Folic acid deficiency can be caused by: (Objective 6)
 - a. alcoholism
 - b. chronic blood loss
 - c. strict vegetarian diet
 - d. vitamin B₆ deficiency
6. A lack of intrinsic factor could be due to: (Objective 7)
 - a. gastrectomy
 - b. vitamin B₁₂ deficiency
 - c. folate deficiency
 - d. large bowel resection
7. Which of the following is more typical of nonmegaloblastic than megaloblastic anemia? (Objectives 2, 3)
 - a. oval macrocytes
 - b. round macrocytes
 - c. Howell-Jolly bodies
 - d. hypersegmented PMN
8. If a patient excretes less than 7.5% of a radioactively tagged crystalline B₁₂ dose after 24 hours both before and after administration of a dose of oral intrinsic factor, which of the following is a possible diagnosis? (Objective 9)
 - a. pernicious anemia
 - b. liver disease
 - c. gastrectomy
 - d. celiac disease
9. Which type of congenital dyserythropoietic anemia (CDA) presents with giant multinucleated erythrocytes in the marrow? (Objective 10)
 - a. CDA I
 - b. CDA II
 - c. CDA III
 - d. CDA IV

REVIEW QUESTIONS (continued)

LEVEL I

LEVEL II

10. A 48-year-old Caucasian female experiencing fatigue, loss of appetite, and weight loss over a period of three months was seen by her physician. A medical history revealed she had a history of alcohol abuse. An initial laboratory workup demonstrated that she was anemic, had a leukocyte count of $3 \times 10^9/L$, and had an MCV of 119 fL. Macroovalocytes and neutrophil hypersegmentation was noted on her blood smear evaluation. Based on the initial laboratory test results, her physician obtained a serum vitamin B₁₂ and folate workup. Results were as follows:

Serum vitamin B ₁₂	550 pg/mL
Serum folate	4.0 ng/mL
RBC folate	105 ng/mL

Based on her clinical history and laboratory results, the best possible diagnosis is which of the following? (Objective 12)

- pernicious anemia
- folate deficiency
- primary B₁₂ deficiency
- anemia of liver disease

ANSWERS TO CASE STUDY QUESTIONS

Case Summary: This is the case of Kathy, a 36-year-old female with a megaloblastic anemia. An initial diagnosis of moderate anemia, jaundice, and neurological complications was made. Based on the patient's laboratory test results, she was diagnosed as having a vitamin B₁₂ deficiency. The Schilling test demonstrated that the deficiency was due to the absence of intrinsic factor. This patient can be diagnosed with a megaloblastic anemia due to a lack of intrinsic factor. The patient is suffering from the adult form of pernicious anemia with demonstrated anti-intrinsic factor antibodies.

Question:

1. What is the morphologic classification of the patient's anemia?

Explanation:

It is macrocytic. The morphologic classification of anemia includes normocytic, microcytic, and macrocytic. Macrocytic is the classification when the MCV >100 fL.

Question:

2. Based on the information obtained so far, what is the most likely defect?

Explanation:

There is a vitamin B₁₂ deficiency. The patient was admitted with signs of a moderate hemolytic anemia and neurological symptoms. Her CBC shows she has a macrocytic anemia. Her leukocyte and platelet counts are at the lower end of the normal range, indicating a developing pan-

cytopenia. The blood smear revealed hypersegmented neutrophils, ovalocytes, and Howell-Jolly bodies. Her bilirubin values support a diagnosis of hemolysis due to an increased indirect bilirubin. On a differential diagnosis, neurological symptoms typically accompany vitamin B₁₂ deficiency rather than a folate deficiency. Based on her serum vitamin B₁₂ and folate results, she can be definitively diagnosed as having a megaloblastic anemia due to a vitamin B₁₂ deficiency.

Question:

3. What is the significance of the AST/ALT results?

Explanation:

There is no liver disease. These are both liver enzymes. Because they are normal, liver disease is ruled out as a source of jaundice or the macrocytic anemia.

Question:

4. What further testing can be done to obtain a definitive diagnosis?

Explanation:

Testing for methylmalonic acid (MMA) and homocysteine are helpful to identify a vitamin B₁₂ deficiency. Both are increased in Vitamin B₁₂ deficiency. To help determine whether the deficiency is due to an absence of intrinsic factor, tests for intrinsic factor antibodies, the Schilling test, and/or gastric analysis may be done. A common cause of vitamin B₁₂ deficiency in a patient with no previous gastrointestinal history is pernicious anemia.

Question:

5. What is this patient's definitive diagnosis?

Explanation:

She has pernicious anemia. The Schilling test result in Part I showed less than 7% of the initial radioactively tagged dose of oral vitamin B₁₂ in the urine 24 hours later. When the test was repeated with intrinsic factor, a larger amount of the B₁₂ dose was found in the urine after 24 hours. Gastric analysis provides stomach pH levels. The diagnosis of pernicious anemia is supported by the finding of intrinsic factor blocking antibodies in her blood.

Question:

6. How would the diagnosis change if the special testing results were as follows?

Schilling Test:

Part I, before intrinsic factor: 1%

Part II, after intrinsic factor: 3%

Intrinsic factor-blocking antibodies: Negative

Explanation:

The diagnosis is not pernicious anemia. The vitamin B₁₂ deficiency is due to some other malabsorption disorder. An abnormal Schilling test result following Part II with oral intrinsic factor and the absence of autoantibodies suggest that her vitamin B₁₂ deficiency was due to some sort of malabsorption disorder such as Crohn's disease or bowel blindloop syndrome.

Question:

7. What would you predict this patient's reticulocyte count to be?

Explanation:

It is normal to low. The patient's reticulocyte count would probably be normal to decreased. Megaloblastic anemia results from ineffective erythropoiesis with intramedullary hemolysis, which blunts the number of reticulocytes in the marrow storage pool. In addition, polychromasia was *not* found on the patient's blood smear, which is a sign of reticulocytosis.

ANSWERS TO CHECKPOINTS**Checkpoint! 1**

Explain why patients with B₁₂ or folate deficiency have megaloblastic maturation.

Answer

The megaloblastic anemias are the result of abnormal DNA synthesis (a nuclear maturation defect). As a result, the delayed nuclear development prevents cell division. RNA synthesis and cytoplasmic maturation are not affected. The result is production of large cells with nuclear cytoplasmic asynchrony. The basis for the nonmegaloblastic anemias may be related to an increase in membrane lipids.

Checkpoint! 2

Patients with megaloblastic anemia often present with a yellow or waxy pallor. What is the diagnostic significance of this clinical symptom?

Answer

Ineffective erythropoiesis in the marrow is due to nuclear/cytoplasmic asynchrony of cell development as a result of the lack of thymidine and a diminished DNA synthesis. The abnormal cells are hemolyzed in the marrow. If intramedullary hemolysis is significant, all classic signs of hemolysis will accompany the megaloblastosis. Plasma unconjugated bilirubin levels will increase and result in jaundice, which results in a yellow and waxy skin pallor.

Checkpoint! 3

Why are abnormalities of leukocytes and platelets present in megaloblastic anemia?

Answer

Granulocytes and platelets may also show changes evident of abnormal hematopoiesis (nuclear maturation defect). Hypersegmented neutrophils (more than five nuclear lobes) may be found in megaloblastic anemia even in the absence of macrocytosis. This finding is considered highly sensitive and specific for megaloblastic anemia. Giant metamyelocytes and bands with loose, open chromatin in the nuclei are diagnostic. The myelocytes show poor granulation as do

more mature stages. Megakaryocytes may be decreased, normal, or increased. Maturation, however, is distinctly abnormal. Some larger than normal forms can be found with separation of nuclear lobes and nuclear fragments.

Checkpoint! 4

What abnormal morphological findings on a stained blood smear comprise the triad in megaloblastic anemia?

Answer

Macroovalocytes, Howell-Jolly bodies, and hypersegmentation of PMNs

Checkpoint! 5

Hal Jones had small bowel resection due to carcinoma. Explain why he is at high risk for folate deficiency.

Answer

Dietary folate must be deconjugated in the small intestine for absorption to occur. Intestinal villi in the small intestine contain receptors for folate binding and absorption into the body. An individual with a small bowel resection would require ongoing folate therapy because absorption is impaired. Pharmacological doses of folate are given periodically intramuscularly to maintain normal levels.

Checkpoint! 6

What is the most common cause of folate deficiency and in what groups of individuals is it usually found?

Answer

Nutritional insufficiency is the most common cause of folate deficiency. Body stores of folate are sufficient to maintain minimal body requirements for only 3–6 months. Folate deficiency develops more rapidly than B₁₂ deficiency. Once a negative folate balance occurs, serum folate values can begin to decrease within 2 weeks. In developed countries, the elderly, alcoholics, and pregnant women are considered high-risk groups for folate deficiency.

Checkpoint! 7

A patient has the following results: vitamin B₁₂: 50 pg/mL, serum folate: 4 ng/dL, and RBC folate: 100 ng/mL. Interpret these results.

Answer

Normal serum B₁₂ values range from 247–800 pg/ml in adults and 160–1200 pg/ml in newborns. Normal serum reference interval for serum folate is 2.5–20 ng/ml and for RBC folate is 160–700 ng/ml. These results indicate the patient is vitamin B₁₂ deficient with an accompanying decrease in RBC folate. Serum folate is normal. The RBC and serum folate are not good indicators of folate status in vitamin B₁₂ deficiency; a deficiency of vitamin B₁₂ impairs methionine synthesis and leads to the accumulation of methyl-THF in the serum. In addition, vitamin B₁₂ is required for normal transfer of methyl-THF to the cells and for conjugating the folate to keep it in the cell. Thus, serum folate may be falsely increased and erythrocyte folate may be falsely decreased in vitamin B₁₂ deficiency. In this case, the patient appears to have a vitamin B₁₂ deficiency. Even though the RBC folate is low, it is not a good indicator of folate deficiency. Homocysteine and MMA tests may help define the deficiency.

Checkpoint! 8

Explain why there is a megaloblastic anemia in transcobalamin II deficiency when the serum vitamin B₁₂ concentration is normal.

Answer

Although transcobalamin II is only about 5% saturated, it is the primary transport protein for vitamin B₁₂. Transcobalamin II binds 90% of the newly absorbed vitamin B₁₂. Congenital deficiency of transcobalamin II produces a severe megaloblastic anemia in infancy. However, serum vitamin B₁₂ concentration in this condition is normal. This is most likely due to the fact that transcobalamin I serves as a passive reservoir that is in equilibrium with liver stores of the vitamin. Transcobalamin I normally binds 75% of the recycled endogenous vitamin B₁₂ in the body but it is only about 50% saturated. With a deficiency of transcobalamin II, more vitamin B₁₂ is bound by transcobalamin I.

Checkpoint! 9

Explain why severe B₁₂ deficiency sometimes presents with neurological disease.

Answer

In vitamin B₁₂ deficiency, a defect in degradation of propionyl CoA to methylmalonyl CoA and, finally, to succinyl CoA occurs. As propionyl CoA accumulates, it is used as a primer for fatty acid synthesis replacing the usual primer acetyl CoA. It is probable that demyelination (destruction, removal, or loss of the lipid substance that forms a myelin sheath around the axons of nerve fibers), a characteristic finding in vitamin B₁₂ deficiency, is a result of this erroneous fatty acid synthesis. Because of the defective fatty acid degradation, a critical feature of demyelination in vitamin B₁₂ deficiency is neurological disease. Peripheral nerves are most often affected, presenting as motor and sensory neuropathy. The brain and spinal cord may also be affected leading to dementia, spastic paralysis, and other serious neurological disturbances.

Checkpoint! 10

Explain why some believe that pernicious anemia is an autoimmune disorder.

Answer

Pernicious anemia is often associated with autoimmune disease. Antibodies directed against the patient's own cells or proteins are found. Autoantibodies found in pernicious anemia (PA) are of two types, blocking and binding. Blocking antibodies prevent the formation of the intrinsic factor/B₁₂ complex, and binding antibodies prevent attachment and absorption of B₁₂ into the ileum mucosal epithelial cell. Antibodies against intrinsic factor are detected in up to 75% of PA patients. The majority of PA patients demonstrate antibodies against the parietal cells in the floor of the stomach. Patients with PA can have one or both types of antibodies.

Checkpoint! 11

What two lab tests are the most specific indicators of B₁₂ deficiency?

Answer

A specific test that measures the increased excretion of methylmalonic acid (MMA) in the urine indirectly indicates decreases in vitamin B₁₂ concentration. Homocysteine increases in the plasma of patients with vitamin B₁₂ or folate deficiency. Monitoring serum levels can serve as an early detector of vitamin B₁₂ deficiency. Many recent studies have concluded that MMA and homocysteine are the most sensitive and specific indicators of vitamin B₁₂ deficiency.

Checkpoint! 12

Which clinical type of CDA gives a HAM test result and presents with a normoblastic marrow?

Answer

With CDA-II, bone marrow precursors are normoblastic but are typically multinucleated with up to seven nuclei. Type II is distinguished by a positive acidified serum test (Ham test) but a negative sucrose hemolysis test. In the Ham test, only about 30% of normal sera are effective in lysing CDA II cells.

Checkpoint! 13

What is the main cause of nonanemic macrocytosis?

Answer

Alcohol abuse is one of the most common causes of nonanemic macrocytosis. The macrocytosis associated with alcoholism is usually multifactorial and may be megaloblastic. In up to 60% of cases, anemia does not accompany macrocytosis.

Checkpoint! 14

What are three clinical or laboratory findings (besides assessing the marrow) that can distinguish a nonmegaloblastic (normoblastic) macrocytic anemia from a megaloblastic anemia?

Answer

A normoblastic macrocytic anemia does not present with pancytopenia. Granulocytes and platelet counts are usually normal. Hypersegmented neutrophils are not found in nonmegaloblastic macrocytosis, and the abnormal RBC morphology is less pronounced. In addition, symptoms commonly found in megaloblastic anemia such as jaundice, glossitis, and neuropathy are absent in nonmegaloblastic anemia.

Hypoproliferative Anemias

Rebecca Laudicina, Ph.D.

■ OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. Define *hypoproliferative anemia*.
2. Cite the diagnostic criteria for aplastic anemia.
3. Describe the epidemiology and etiology of aplastic anemia.
4. Explain the pathophysiology of aplastic anemia.
5. Explain the difference between acquired and constitutional aplastic anemia.
6. List the major clinical and laboratory characteristics of aplastic anemia.
7. Identify environmental factors associated with the development of aplastic anemia.
8. Describe the etiology, bone marrow, and peripheral blood in pure red cell aplasia.
9. Identify peripheral blood findings associated with the following: aplastic anemia, pure red cell aplasia, and anemia due to renal disease.

■ OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. List and explain possible causes of aplastic anemia.
2. Discuss prognosis in aplastic anemia.
3. Compare methods of treatment and management of patients with aplastic anemia.
4. Contrast aplastic anemia with other causes of pancytopenia on the basis of clinical findings and peripheral blood and bone marrow findings.
5. Compare and contrast pure red cell aplasia with aplastic anemia and other causes of erythroid hypoproliferation.
6. Compare and contrast major characteristics of Diamond-Blackfan syndrome and transient erythroblastopenia of childhood.
7. Explain the pathophysiology of anemia due to renal disease.
8. Evaluate laboratory test results and medical history of a clinical case for a patient with hypoproliferative anemia and suggest a possible diagnosis.

CHAPTER OUTLINE

- ▶ Objectives—Level I and Level II
- ▶ Key terms
- ▶ Background basics
- ▶ Case study
- ▶ Overview
- ▶ Introduction
- ▶ Aplastic anemia
- ▶ Pure red cell aplasia
- ▶ Other hypoproliferative anemias
- ▶ Summary
- ▶ Review questions
- ▶ References

KEY TERMS

Aplasia
 Aplastic anemia
 Diamond-Blackfan anemia (DBA)
 Dyshematopoiesis
 Fanconi anemia (FA)
 Hypocellularity
 Hypoplasia
 Hypoproliferative
 Idiopathic
 Myelophthisic anemia
 Pancytopenia
 Pure red cell aplasia

BACKGROUND BASICS

The information in this chapter builds on the concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study.

Level I

- ▶ Describe basic laboratory procedures used to screen for and assess anemia.
- ▶ Identify abnormal values and results for basic hematologic laboratory procedures.
- ▶ Outline the classification of anemias.
- ▶ Explain the process of hematopoiesis.

Level II

- ▶ Explain the concepts of stem cell renewal and differentiation.
- ▶ Describe the normal bone marrow structure and cellularity and the process of bone marrow examination.

CASE STUDY

We will address this case study throughout the chapter.

Rachael, a 13-year-old female, was admitted to the hospital with complaints of progressive weakness and shortness of breath with minimal physical effort. She has experienced recurrent fevers reaching 102°F. Physical examination reveals a well-developed adolescent with good nutritional status and in no acute distress. There is no lymphadenopathy or organomegaly. Many petechial hemorrhages cover her chest and legs. Several bruises are found on her legs and thighs. Laboratory tests were ordered upon admission. Consider the diagnostic possibilities in this case and how laboratory tests can be used to assist in differential diagnosis.

▶ OVERVIEW

The finding of cytopenias in the peripheral blood is a cause for concern. Although there are a variety of causes, bone marrow hypoproliferation is one of the most serious. This chapter discusses the acquired and constitutional anemias that are associated with bone marrow hypoproliferation. The first section describes the classification of hypoproliferative anemias followed by a discussion of aplastic anemia and pure red cell aplasia. These anemias are contrasted to other causes of cytopenia.

▶ INTRODUCTION

The **hypoproliferative** anemias are a heterogeneous group of acquired and constitutional disorders in which there is a normocytic or macrocytic, normochromic anemia associated with chronic bone marrow **hypocellularity**. Much of the area in the bone marrow normally occupied by hematopoietic tissue is replaced by fat. The terms *aplastic*, **aplasia**, and *hypoplastic* refer to a bone marrow with an overall decrease in hematopoietic cellularity. If there is **hypoplasia** of only one of the cellular elements, the terms *erythroid*, *myeloid*, or *megakaryocytic hypoplasia* should be used to define the specific entity.

The hematopoietic defect is due to depletion, damage, or inhibition of stem and/or progenitor cells. Either the unipotent erythroid progenitor cell or a multilineage hematopoietic precursor cell can be affected. The peripheral blood findings provide important clues to help identify the bone marrow abnormality. If only the erythroid progenitor cells are affected (BFU-E, CFU-E), platelets and leukocytes remain normal, and the diagnosis is **pure red cell aplasia**. More commonly, the multilineage hematopoietic precursor cells are affected (HSC, MPP, CMP, CFU-GEMM, etc.), resulting in **pancytopenia** (decrease of all three cell lineages), and the diagnosis is **aplastic anemia**.

▶ APLASTIC ANEMIA

The mature blood cells produced in aplastic anemia usually appear normal. Aplasia of the bone marrow is only one of several possible causes of peripheral blood pancytopenia. The term *aplastic anemia* should be reserved to describe the pancytopenia that is associated with a hypocellular bone marrow. Diagnostic criteria for aplastic anemia include:

- Bone marrow cellularity <25% plus at least two of the following:
 - Granulocyte count <0.5 × 10⁹/L
 - Platelet count <20 × 10⁹/L
 - Anemia with corrected reticulocyte count <1% (absolute count <40 × 10⁹/L)

Additional diagnostic criteria are based on disease severity.¹ With progression, all three cell lines eventually become decreased. This reflects an impaired proliferative capacity of the marrow stem cells, which lose their ability for normal cellular renewal.

CASE STUDY (continued from the previous page)

1. Select laboratory tests appropriate for screening for aplastic anemia.
2. Justify the selection of laboratory screening tests based on Rachael's clinical signs and symptoms.

Checkpoint! 1

An anemic patient has a (corrected) reticulocyte count of 1.5%, hemoglobin of 100 g/L, hematocrit of 0.30 L/L, total neutrophil count of $0.4 \times 10^9/L$, and a platelet count of $30 \times 10^9/L$. Is it likely that this patient has aplastic anemia?

EPIDEMIOLOGY

These anemias are rare but are encountered more frequently now than at the beginning of the twentieth century. Aplastic anemia is most commonly seen in three age groups: 2–5 year olds, 15–25 year olds, and adults over 60. The occurrence of aplastic anemia in children is mostly due to inherited forms, but the occurrence in adults is due to acquired forms, although there are exceptions.^{1,2} A geographic variation in incidence occurs with more cases in Asia than in western countries. It is believed that this variation is related to environmental and occupational factors.³ Individual susceptibility can also play a role.

PATHOPHYSIOLOGY

Recent attention has been focused on immunologic suppression of hematopoiesis as a cause of acquired aplastic anemia. Response of marrow failure to immunosuppressive therapy has led to the characterization of most cases of acquired aplastic anemia as an autoimmune disease.⁴ The immune mechanism responsible is thought to involve the suppression of stem cell growth and differentiation by abnormal T lymphocytes. This is supported by finding that treatment of patients with immunosuppressive drugs including antilymphocyte globulin (ALG), antithymocyte globulin (ATG), and cyclosporine results in improvement in the majority.⁵

Immunosuppressive therapy presumably eliminates an abnormal population of activated T lymphocytes that produce interferon- γ (IFN- γ) and tumor necrosis factor (TNF), substances known to inhibit hematopoiesis.^{4,6} One mechanism of inhibition is likely cell killing through induction of apoptosis. Both IFN- γ and TNF induce overexpression of Fas

(a cell membrane receptor) by progenitor cells. When the Fas receptor is activated by binding with its ligand, apoptosis is initiated. It is estimated that stem cell concentration in severe acquired aplastic anemia is decreased to <1% of normal. Experimental studies using lymphocytes from patients with acquired aplastic anemia also tend to support the immunosuppression hypothesis. Flow cytometric analysis of lymphocyte subpopulations in acquired aplastic anemia has revealed a marked increase in activated CD8⁺ lymphocytes.

In Epstein-Barr viral infections as well as other viral infections, the virus can infect the hematopoietic stem cell, triggering an immune response. Cytotoxic lymphocytes then destroy the stem cell. Other mechanisms of stem cell damage in viral infections have been postulated, including direct cytotoxicity of the virus and inhibition of cellular proliferation and differentiation.⁴

The success of hematopoietic stem cell transplants (SCT) in many patients with aplastic anemia suggests that the bone marrow deficit can be corrected by repopulation of the marrow with normal stem cells. Thus, defective or deficient stem cells are apparently a common cause of this type of anemia rather than a defective marrow hematopoietic microenvironment. This is also supported by the results of long-term bone marrow culture assays in which marrow cells from patients with aplastic anemia exhibit defective hematopoiesis when grown on normal bone marrow stroma.^{7,8} Aplastic anemia bone marrow cells grow significantly lower numbers of colonies compared to normal marrow. Likewise, deficiency of hematopoietic cytokine stimulation does not appear to be causative because most patients have normal or even elevated levels of growth factors. The stem cell abnormality can either be acquired or hereditary in nature.

CLASSIFICATION AND ETIOLOGY

Aplastic anemia can be classified into two groups: acquired and constitutional (Table 1 ). Historically, much attention has focused on association between acquired aplastic anemia and environmental exposures. Drugs, chemicals, radiation, infectious agents, and other factors have been linked to the development of acquired aplastic anemia, which can be temporary or persistent. In most cases, no environmental link can be identified, and the cause is said to be **idiopathic**. The immune pathophysiologic model (discussed in previous section) provides a unifying basis for understanding the disorder regardless of the presence or absence of environmental factors. Although acquired aplastic anemia is more common in adults, it is also a cause of aplasia in children.

Constitutional aplastic anemia is a chronic failure of the bone marrow due to an inherited abnormality; it may or may not be present at birth. A congenital condition is one that is manifest early in life, often at birth, but that is not necessarily inherited or constitutional; it can be caused by acquired factors (e.g., maternal exposure to an environmental toxin

★ TABLE 1

Classification of Hypoproliferative Anemias

Aplastic Anemia	Pure Red Cell Aplasia	Other Hypoproliferative Anemias
<p>Acquired</p> <ul style="list-style-type: none"> Idiopathic Drugs: chloramphenicol, phenylbutazone, old compounds, sulfa drugs, antihistamines, antithyroid, tetracyclines, penicillin, methylphenylethylhydantoin Chemical agents: benzene, insecticides, hair dye, carbon tetrachloride, chemotherapeutics (vincristine, busulfan, etc.), arsenic Ionizing radiation Biological agents: parovirus, infectious mononucleosis, infectious hepatitis, measles, influenza, errors of amino acid metabolism, starvation Pregnancy Paroxysmal nocturnal hemoglobinuria <p>Constitutional</p> <ul style="list-style-type: none"> Fanconi anemia Familial aplastic anemia 	<ul style="list-style-type: none"> Transitory infections Acquired pure red cell aplasia Acute: infections, transient erythroblastopenia of childhood (TEC), drugs Chronic: thymoma, autoimmune disorders Constitutional: Diamond-Blackfan anemia 	<ul style="list-style-type: none"> Anemia of chronic renal disease Anemia associated with endocrine abnormalities

while pregnant). Constitutional aplastic anemia can be associated with other congenital anomalies. This form is rare and less understood than acquired aplastic anemia. The defect can be a quantitative or qualitative abnormality of stem cells.

CASE STUDY *(continued from the previous page)*

3. Evaluate the relationship between Rachael's age and the likelihood that she has aplastic anemia.
4. If aplastic anemia is present, would you expect her to have an idiopathic or secondary form? Explain your answer.

Acquired Forms of Aplastic Anemia

Idiopathic Approximately 50–70% of cases of aplastic anemia cannot be linked to an environmental factor; however, some unrecognized previous agent or event could be responsible for stimulation of the immune system.

Drugs About 30% of acquired forms of aplastic anemia are associated with drug exposure. It has been proposed that some drugs are not easily metabolized by the individual; as a result, the drug accumulates, causing injury to stem cells.⁹ It is also possible that drugs can induce an antibody-mediated suppression of the marrow. With drug injury, neutropenia usually develops before anemia or thrombocytopenia be-

cause of the relatively short life span of the neutrophil. Within 7 days after stem cell injury or suppression, the neutrophil bone marrow reserve is exhausted and neutropenia develops. The longer life span of erythrocytes and platelets provides a buffer for a limited time until stem cell differentiation can resume if it does.

Chloramphenicol, a broad spectrum antibiotic, is a well-known drug associated with aplastic anemia. Because of concerns about bone marrow toxicity, the drug is rarely prescribed in the United States.¹⁰

Because aplasia develops in some individuals after exposure to certain drugs and chemicals while in others it does not, there is probably a genetic or acquired defect in drug elimination or detoxification. Also perhaps some individuals have stem cells that are more vulnerable to damage or inhibition by drugs and chemicals than others.

Chemical Agents The widespread use of toxic chemical agents in industry and agriculture is probably responsible for the increased incidence of toxic bone marrow aplasia.⁹ Benzene derivatives are well established as a cause of bone marrow depression. Most cases develop within a few weeks after exposure, but some occur months or years after chronic exposure. Although stem cells can be damaged, the main toxic effect of benzene is usually expressed on transient stages of committed proliferating blood cells.

Most of the chemicals used in chemotherapy of malignant diseases kill rapidly proliferating cells. However, the

chemicals do not distinguish between malignant and normal cells. Therefore, all proliferating cells are damaged, including normal cells of the hematopoietic compartment. Although quiescent (G_0) stem cells are spared, repeated doses of the chemical over a long period of time can eventually deplete the remaining stem cells as they enter the proliferating pool.

Ionizing Radiation Aplastic anemia due to x-irradiation has been encountered in persons exposed in industrial accidents, military nuclear tests, and therapeutic regimens for malignancy. The effects of irradiation are dose dependent. Small doses affect all cells but are especially destructive to rapidly dividing cells. The bone marrow can recover from sublethal doses of irradiation because quiescent stem cells become active after exposure-induced depletion of more differentiated progeny. In high doses, more than 4000 rads, bone marrow aplasia and peripheral blood pancytopenia are usually permanent. The aplasia appears to be caused by damage of the supporting marrow matrix. Thus, bone marrow transplantation is usually unsuccessful in alleviating pancytopenia in these cases.

Infectious Agents Viral and bacterial infections can be followed by a transient cytopenia. The aplasia can be limited to the erythroid elements or can include all three cell lineages. Aplasia has been described in patients after recovery from infectious mononucleosis, tuberculosis, and hepatitis. Hepatitis-associated aplastic anemia does not appear to be caused by any of the known hepatitis viruses and is often fatal if untreated.^{11,12} In patients with hereditary hemolytic anemias, aplastic crisis is commonly associated with human parvovirus infection. This aplasia, however, is limited to the erythroid lineage.

Metabolic The rare inborn errors of amino acid metabolism, which result in accumulation of ketones and glycine, have been associated with aplastic anemia.

Starvation or protein deficiency results in hypoproliferative anemia after about three months of deprivation. Starvation that is not self-induced usually occurs in areas where other endemic pathologies are also present, such as parasitic infection and blood loss. Thus, the causes of this anemia can be multifactorial.

Decreased hormonal stimulation of hematopoietic stem cells is important primarily as a factor in erythroid hypoplasia. Renal disease and endocrine diseases are examples of hypoproliferation caused by a decrease in erythropoietin.

Rarely, a life-threatening pancytopenia occurs during pregnancy. The condition usually remits after delivery or abortion. It has been suggested that the aplasia can be related to estrogen inhibition of stem cell proliferation.¹³

Paroxysmal Nocturnal Hemoglobinuria Paroxysmal nocturnal hemoglobinuria (PNH) is an acquired stem cell disease in which a blood cell membrane abnormality makes

the cells susceptible to in vivo complement hemolysis. The defect is the absence of a membrane glycolipid that serves to attach and anchor proteins to the cell. Although considerable variation in clinical manifestations occurs, the typical picture in severe cases is pancytopenia and marrow hypoplasia. Between 10–25% of patients with an initial diagnosis of aplastic anemia develop an abnormal erythrocyte population typical of that seen in PNH, but they do not usually develop the full clinical manifestations (intravascular hemolysis and venous thrombosis) of PNH. PNH is a prominent, later complication in aplastic anemia patients who have received immunosuppressive ALG therapy.¹⁴

Other Diseases Aplastic anemia also is associated with myelodysplastic syndromes, leukemia, and solid tumors. Some evidence suggests that the high frequency of these neoplastic, clonal disorders in patients treated for aplastic anemia can be inherent in the disease, not simply secondary to treatment.¹⁴

CASE STUDY (continued from the previous page)

For the past three months, Rachael's family physician has been following her recovery from viral hepatitis. Her recovery was uneventful; her liver enzyme levels returned to normal within two months. She has no other past medical history. There is no family history of hematologic disorders.

5. What aspect of this patient's history could be associated with the occurrence of aplastic anemia?

Constitutional Aplastic Anemia

This group of anemias has a congenital predisposition. Included are Fanconi anemia and other causes of constitutional aplastic anemia.

Fanconi Anemia **Fanconi anemia (FA)** is an autosomal recessive disorder resulting from a heterogeneous molecular defect and is characterized by abnormal chromosomal fragility. It has a prevalence of about 1 in 350,000 live births in North America with a heterozygote frequency of ~ 1 in 300. Patients can have a complex assortment of congenital anomalies in addition to a progressive bone marrow hypoplasia. The congenital defects include dysplasia of bones, renal abnormalities, and other organ malformations as well as mental retardation, dwarfism, microcephaly, hypogonadism, and skin hyperpigmentation. Some patients lack congenital defects and may not be diagnosed until aplastic anemia develops, which may not occur until adulthood.¹⁵

Aplastic anemia eventually develops in $\sim 90\%$ of FA patients. The hematological manifestations are slowly progressive from birth and need to be monitored closely. Usually clinical signs of pancytopenia appear between the ages of 5 and 10 years with the median age of 7 at diagnosis. Anemia

is usually macrocytic (although it can be normocytic) with macrocytosis often preceding anemia. Erythrocytes often show increased levels of Hemoglobin F and the “i” antigen (reflecting hematologic stress and the development of erythrocytes from earlier erythroid progenitor cells). Leukopenia primarily involves the granulocytes. Thrombocytopenia often precedes anemia and leukopenia. Androgen therapy can reverse the pancytopenia for several years (in about 50% of FA patients). Cytokine therapy can help increase neutrophil counts.

SCT offers the only possible curative treatment for bone marrow failure in FA patients. In patients with HLA-matched sibling donors, 5-year survival is close to 75%. Stem cells from HLA-matched unrelated donors have also been used. Because FA patients are acutely sensitive to chemotherapeutic agents and radiation, pretransplant conditioning protocols must be altered to reduce toxicity.

The risk for developing cancer in FA is 20%.¹⁶ Acute non-lymphocytic leukemia and solid tumors are common complications. Leukemia is difficult to treat and survival is poor. The median survival for FA patients is now about 30 years of age.¹

Karyotyping of FA cells shows increased spontaneous chromosomal breakage, gaps, rearrangements, exchanges, and duplications. Diagnosis of FA has involved exposing blood lymphocytes or skin fibroblasts to crosslinking agents such as mitomycin C, diepoxybutane, or cisplatin that amplify chromosomal breakage.^{1,16} Molecular techniques are or will soon be available to identify the various FA molecular subtypes. Testing is performed when warranted based on clinical findings and/or abnormal blood counts.

Research to identify the genes involved in FA has revealed that the molecular defect is heterogeneous. Eleven FA genes have been identified (*FANCA*, *B*, *C*, *D1*, *D2*, *E*, *F*, *G*, *I*, *J*, and *L*), but the biologic role has not been determined for all of them.¹⁷ Interestingly, the breast cancer susceptibility gene, *BRCA2*, has been identified as the abnormal gene in *FANCB* and perhaps *FANCD1*. Six of the Fanconi proteins (A, B, C, E, F, and G) function in a common cellular pathway, activated in response to DNA damage, which in turn activates DNA repair proteins, including *BRCA1* and *FANCD1/BRCA2*. Defective FA proteins are thus responsible for the genetic instability and increased apoptosis of hematopoietic stem cells, resulting in aplastic anemia.^{1,17} In addition to the genetic defects leading to defective DNA repair and DNA instability, $\text{TNF}\alpha$ is elevated in most patients. Also the telomeres of the hematopoietic stem and progenitor cells are shortened, suggesting an abnormally high proliferative rate, ultimately leading to their premature senescence.

Other Causes of Constitutional Aplastic Anemia.

Several other, rare disorders have a predisposition to developing aplastic anemia. Congenital amegakaryocytic thrombocytopenia (CAT) presents in infancy with isolated thrombocytopenia due to reduced or absent marrow megakaryocytes. Aplastic anemia subsequently develops in ~45% of the pa-

tients, usually in the first years of life. The defect is a mutation in the gene for the thrombopoietin (TPO) receptor *MPL* with the loss of the antiapoptotic effect of TPO on hematopoietic stem cells.

Patients with Shwachman-Diamond Syndrome can present with some of the same congenital anomalies including aplastic anemia as is seen in FA patients. However, they also have exocrine pancreatic dysfunction and do not display increased chromosomal fragility and defective DNA repair processes. This disorder is due to mutations of the *SBDS* gene, although the exact pathogenesis of the disorder is still unknown.

Dyskeratosis congenita (DC) is also an inherited bone marrow failure syndrome, resulting in aplastic anemia in ~50% of cases. Types of physical abnormalities and mutations differ for patients with DC and FA. Mutations in two genes have been associated with DC: *DKC1* and *TERC*. Mutations in these two genes result in markedly reduced telomerase activity, telomere shortening, early progenitor senescence, and a reduced stem cell compartment. Because not all persons carrying these mutations develop aplastic anemia, it may be that an additional acquired factor(s) (e.g., viral infection) is needed for bone marrow failure to develop.¹

CASE STUDY (continued from the previous page)

6. Is it likely that Rachael has a constitutional form of aplastic anemia? Explain your answer.

CLINICAL FINDINGS

The onset of symptoms in aplastic anemia is usually insidious and related to the cytopenias. The most common initial sign is bleeding accompanied by petechial and fundal hemorrhages. Anemia and infection can occur separately or in combination with the bleeding. Hepatosplenomegaly and lymphadenopathy are absent. Splenomegaly has occasionally been noted in later stages of the disease, but if found in the early stages, the diagnosis of aplastic anemia should be questioned.

LABORATORY FINDINGS

Laboratory studies of peripheral blood and bone marrow are always indicated if a diagnosis of aplastic anemia is suspected.

Peripheral Blood

Pancytopenia is typical. Although the degree of severity can vary, it is good practice to question the diagnosis of aplastic anemia unless the leukocyte count, erythrocyte count, and platelet count are all below the reference intervals. Hemoglobin is usually < 70 g/L. Erythrocytes appear normocytic and

normochromic, or they can be slightly macrocytic. Mild to moderate anisocytosis and poikilocytosis occur. The presence of nucleated erythrocytes and teardrops is not typical of aplastic anemia but suggests marrow replacement (myelophthistic anemia). The relative reticulocyte count (%) alone can be misleading due to the severe anemia. Therefore, the reticulocyte count should always be determined in absolute numbers or be corrected for the anemia before interpretation. The absolute reticulocyte count is usually $< 25 \times 10^9/L$. The corrected reticulocyte count is less than 1%. Most often, thrombocytopenia is present at the time of diagnosis. Neutropenia precedes leukopenia; initially, lymphocyte and monocyte counts are normal. Because of the neutropenia, the differential count reflects a relative lymphocytosis. When the leukocyte count is below $1.5 \times 10^9/L$, an absolute lymphocytopenia is also present. The band to segmented neutrophil ratio increases, and occasionally more immature forms are found. Neutrophil granules are frequently larger than normal and stain a dark red; these granules should be distinguished from toxic granules, which are bluish black.

CASE STUDY (continued from the previous page)

7. Correlate Rachael's clinical findings of weakness and shortness of breath, as well as petechial hemorrhages and bruises, with her laboratory screening results, which follow.

Admission laboratory data for patient:

RBC	$2.42 \times 10^{12}/L$
Hb	71 g/L
Hct	0.24 L/L
PLT	$8.0 \times 10^9/L$
WBC	$1.2 \times 10^9/L$
Differential	
Segmented neutrophils	2%
Lymphocytes	94%
Monocytes	4%
Uncorrected reticulocyte count	0.7%

8. Evaluate each of the patient's laboratory results by comparing them to reference ranges.
9. Which of the patient's routine laboratory results are consistent with those expected for aplastic anemia?
10. Classify the morphologic type of anemia.
11. Calculate the absolute lymphocyte count. Are her lymphocytes truly elevated as suggested by the relative lymphocyte count?
12. Correct the reticulocyte count. Why is this step important?
13. Calculate the absolute reticulocyte count.

Bone Marrow

Examination of the bone marrow is necessary to differentiate aplastic anemia from other diseases accompanied by pancytopenia. In aplastic anemia, the bone marrow is

hypocellular with more than 70% fat (Figure 1 ■). This sometimes makes aspiration difficult. Bone marrow infiltration with granulomas or cancer cells can lead to fibrosis, also resulting in a hypocellular dry tap on aspiration. Thus, both aspiration and biopsy are needed for a correct diagnosis. It is recommended that several different sites be aspirated because spot sampling of an organ as large as the marrow can be misleading. Some areas of acellular stroma and fat can be infiltrated with clusters of lymphocytes, plasma cells, and reticulum cells. Areas of focal hyperplasia termed *hot spots* are found predominantly in early remission but can also be found in severe refractory cases. Iron stain reveals many iron granules in macrophages but granules are rarely seen in normoblasts.

CASE STUDY (continued)

Rachael was referred to a hematologist who ordered a bone marrow examination. The aspirate obtained was inadequate for evaluation due to lack of marrow spicules. Only a single site was aspirated. Touch preps made from the biopsy showed a markedly hypocellular marrow with very few hematopoietic cells. Cells present consisted of lymphocytes, plasma cells, and stromal cells. There were no malignant cells present.

14. Compare these results with those expected for a person with aplastic anemia.
15. Interpret the significance of the lack of malignant cells and hematopoietic blasts.
16. Suggest a way to improve the validity of bone marrow examination results for this patient.

Other Laboratory Findings

Other abnormal findings are not specific for aplastic anemia but are frequently found associated with the disease. Hemoglobin F can be increased, especially in children.

■ **FIGURE 1** Bone marrow preparation from a patient with aplastic anemia shows marked hypocellularity (10%). The patches of cells remaining are primarily lymphocytes. (Wright-Giemsa stain; 100× magnification)

Erythropoietin is often increased, particularly when compared to the erythropoietin levels in patients with similar degrees of anemia. Serum iron is increased with > 50% saturation of transferrin, reflecting erythroid suppression. The clearance rate of iron (Fe^{59}) from the plasma is decreased because of the decrease in iron utilization by a hypoactive marrow. Coagulation tests that reflect platelet activity are abnormal in relation to the degree of thrombocytopenia.

PROGNOSIS AND THERAPY

Recent advances in treatment have tempered the previously grim prognosis of patients diagnosed with aplastic anemia. Bone marrow transplantation and immunosuppression have improved survival. Presently the 2-year survival rate is 60–90%.¹⁸

The first aim in management of acquired aplastic anemia is removal of a putative causative agent. This can involve withdrawal of drugs or removal of the patient from a hazardous environment. The immediate mode of treatment is often supportive. Patients can require multiple transfusions of erythrocytes, platelets, and leukocytes.

Stem cell transplants using cells collected from bone marrow or peripheral blood have become a relatively common procedure and are curative in most patients with aplastic anemia. Treatment complications and posttransplant mortality remain high; therefore, the probability for long-term cure must be weighed against the inherent risks of complications, including graft-versus-host disease and early and late toxicities of the conditioning regimen.¹⁹ Survival rates range from 91% (identical-twin donor) to 37% (mismatched donors).²⁰ Although replacement of needed stem cells is successful in most cases, some transplants, even some performed between identical twins, do not induce remission. These unsuccessful transplants suggest that stem cell growth is immunosuppressed, or damage to the hematopoietic microenvironment may occur, preventing successful engraftment.¹⁹

Immunosuppressive therapy (IST) using ATG or ALG, either solely or in combination with cyclosporine A, has become standard treatment for the majority of patients with acquired aplastic anemia.⁵ IST with ALG or ATG is effective in restoring hematopoiesis in between 40–70% of patients.²¹ However, at least 15–20% of patients treated with IST develop some form of clonal disease. Long-term complications of IST include the development of marrow clonal disorders such as PNH, leukemia, and myelodysplasia.^{15,21}

Hematopoietic growth factors (HGF), G-CSF and GM-CSF, are also used in treatment. When used alone, HGF do not result in sustained hematologic responses but can be useful as an adjunct therapy to immunosuppression. Serious side effects and the potential for development of clonal disorders raise questions about HGF use in treating aplastic anemia. The use of HGF in combination with IST requires further study.²²

CASE STUDY (continued from the previous page)

17. Appraise the prognosis for Rachael.
18. Predict a treatment regimen.

DIFFERENTIATION OF APLASTIC ANEMIA FROM OTHER CAUSES OF PANCYTOPENIA

Pancytopenia can be associated with anemias other than aplastic anemia, but these anemias differ from aplastic anemia in that the pancytopenia is not the result of a defect in stem cell proliferation. Rather, the bone marrow is normocellular, hypercellular, or infiltrated with abnormal cellular elements. These anemias are mentioned here to help the health care professional differentiate them from the true hypoproliferative anemias.

Myelophthistic Anemia

Myelophthistic signifies marrow replacement or infiltration by fibrotic, granulomatous, or neoplastic cells. The abnormal replacement cells reduce normal hematopoiesis and disrupt the normal bone marrow architecture, allowing the release of immature cells into the peripheral blood. Anemia can be accompanied by normal, increased, or decreased leukocyte and platelet counts. The most characteristic findings are a leukoerythroblastic reaction and a moderate to marked poikilocytosis. Dacryocytes are common, as are large bizarre platelets. By contrast, nucleated erythrocytes and significant morphologic changes are almost never found in the peripheral blood in aplastic anemia. **Myelophthistic anemia** is associated with diffuse cancer of the prostate, breast, and stomach. It is also typical of myelofibrosis and lipid storage disorders.

Myelodysplastic Syndromes

Myelodysplastic syndromes (MDS) are a group of hematological disorders that have a propensity to terminate in acute leukemia. The principal peripheral blood findings are pancytopenia, bicytopenia, or isolated cytopenias with reticulocytopenia. A macrocytic anemia is common. The bone marrow, however, is usually normocellular or hypercellular with various degrees of qualitative abnormalities of one or more cell lines (**dys-hematopoiesis**). Signs of dys-hematopoiesis are also reflected in morphologic abnormalities of one or more cell lineages in the peripheral blood. These qualitative abnormalities of peripheral blood cells are useful in differentiating cytopenias due to true hypoproliferation of stem cells (aplastic anemia) from cytopenias due to dys-hematopoiesis (ineffective erythropoiesis).

On the other hand, a subgroup of patients with an MDS diagnosis has a hypocellular marrow. This condition is referred to as *hypoplastic MDS (HMDS)*. In these cases, differ-

entiation of MDS and aplastic anemia can be complicated if there are few bone marrow cells from a biopsy or aspirate to examine. If granulocytic and megakaryocytic dysplasia are seen and/or if an abnormal karyotype consistent with MDS is present, HMDS can be diagnosed. However, if only erythroid dysplasia is present, the evidence is insufficient to differentiate HMDS and aplastic anemia because erythroid dysplasia can be found in some cases of aplastic anemia.²³

Congenital Dyserythropoietic Anemia

Congenital dyserythropoietic anemia (CDA) is a very rare familial refractory anemia characterized by both abnormal erythropoiesis and ineffective erythropoiesis. The bone marrow is normocellular or hypercellular, but the peripheral blood is pancytopenic. In contrast to the normal erythroid precursors found in aplastic anemia, erythrocyte precursors in the bone marrow of CDA patients exhibit multinuclearity, and myeloblasts and promyelocytes are increased. The anemia can be normocytic, but most often it is macrocytic.

Hypersplenism

Hypersplenism from a variety of causes can result in a lack of one or more cellular elements of the blood as these elements become pooled and sequestered in the spleen. In this condition, the bone marrow is hyperplastic, corresponding to the peripheral blood cytopenia. Anemia is accompanied by a reticulocytosis as opposed to the reticulocytopenia found in the true hypoproliferative anemias. Granulocytopenia can be accompanied by a shift to the left in these cells. From a clinical standpoint, splenomegaly and other findings of the underlying disease are important in diagnosing this disorder. Splenectomy, although not always advisable, corrects the cytopenias.

Other

Deficiency of cobalamin or folic acid can be accompanied by pancytopenia. The bone marrow in these cases, however, reveals normocellularity or hypercellularity with megaloblastic changes. In the peripheral blood, hypersegmented neutrophils and Howell-Jolly bodies are typical but are not found in pancytopenia of aplastic anemia.

► **PURE RED CELL APLASIA**

Pure red cell aplasia is characterized by a selective decrease in erythroid precursor cells in the marrow and by peripheral blood anemia. The disease is thought to occur due to selective hypoproliferation of the committed erythroid progenitor cell. The term *aplastic anemia* should be avoided in describing this disease because there is no disturbance of granulopoiesis or thrombopoiesis. Reticulocytes can be present but are less than 1% when corrected for the degree of anemia. Pure red cell aplasia can be acquired (acute or chronic) or inherited. Acquired pure red cell aplasia is seen in thymoma with administration of certain drugs, in autoimmune disorders, and in infection. Transient erythroblastopenia of childhood (TEC) is an acquired, self-limiting form of erythroid hypoplasia found in children. Results of laboratory tests in pure red cell aplasia are shown in Table 2.

ACQUIRED ACUTE PURE RED CELL APLASIA

Viral (parvovirus, Epstein-Barr virus, and viral hepatitis) and/or bacterial infections can be associated with a temporary depression of erythropoiesis. Transient erythroblastopenia of childhood is a form of acquired acute pure red cell aplasia, but because of the importance of distinguishing this pediatric anemia from Diamond-Blackfan anemia (DBA), it will be discussed with DBA in a following section.

In individuals who have a normal erythrocyte life span and hemoglobin level, temporary erythroid hypoproliferation is not noticed. However, if the erythrocyte life span is decreased, the complication of erythroid hypoproliferation

★ TABLE 2

Laboratory Findings in Pure Red Cell Aplasia	
Test	Findings
Erythrocyte count, hematocrit, and hemoglobin	Decreased
Reticulocyte count	Severely decreased
Leukocyte count	Normal or possibly increased
Platelet count	Normal or possibly increased
Bilirubin	Low or normal
Bone marrow	Absence of erythroid cells if examined early in disease; if examined later in disease progression, increase in young erythroid cells, which can be mistaken for an erythroid maturation arrest. If the patient is followed, however, these cells show normal maturation and differentiation. There is normal myelopoiesis and granulopoiesis.

CASE STUDY (continued from the previous page)

19. What other hematologic conditions must be ruled out for this patient?
20. What laboratory test is most beneficial in differentiating aplastic anemia from these other disorders? Compare the expected results of aplastic anemia with those of the other disorders.

can be life threatening (aplastic crises). These aplastic crises are most frequently noted in hemolytic anemias including sickle cell anemia, paroxysmal nocturnal hemoglobinuria, and autoimmune hemolytic anemias.

The aplastic crisis cases brought to the attention of a physician probably represent only a minor fraction of the actual occurrence of temporary erythroid aplasia. The aplastic crises are often preceded by fever with upper respiratory and intestinal complaints. Several members of the same family are frequently affected with the illness. Patients with concurrent hemolytic anemia have a rapid onset of lethargy and pallor. Patients without hemolytic anemia may seek medical attention because of the primary illness, and anemia is only an incidental finding.

If the anemia is severe, supportive therapy of packed erythrocyte transfusions can be necessary until spontaneous recovery occurs. Pure red cell aplasia associated with viral hepatitis has a poor prognosis.

Acute erythroid hypoplasia also occurs with the administration of some drugs and chemicals. After removal of the inciting agent, normal erythropoiesis usually resumes.

ACQUIRED CHRONIC PURE RED CELL APLASIA

An acquired selective depression of erythroid precursors is a rare disorder encountered in middle-aged adults. This disease usually occurs in association with thymoma, autoimmune hemolytic anemia, systemic lupus erythematosus, rheumatoid arthritis, and hematologic neoplasms (CLL, Hodgkin Disease). The high incidence of autoimmune disorders in this anemia suggests that an immunologic mechanism may be responsible for the red cell aplasia. Cytotoxic antibodies to erythropoietin-sensitive cells in the marrow and to erythropoietin have been demonstrated in some cases. More commonly, the mechanism appears to be a T cell-mediated immunosuppression of erythropoiesis.

Clinical findings are nonspecific. Pallor is usually the only physical finding. Therapies include transfusion with packed erythrocytes, thymectomy if the thymus is enlarged, and immunosuppression. Various treatments including prednisone, cyclosporine, cytotoxic agents, antithymocyte globulin, and monoclonal antibodies against B lymphocytes (rituximab/anti-CD20, alemtuzumab/anti-CD52) have been used to suppress the immune response. Androgens or erythropoietin to stimulate erythrocyte production is rarely used. In drug-induced red cell aplasia, withdrawal of the drug is indicated. Approximately 80% of patients with acquired pure red cell aplasia have a spontaneous remission or remission induced by immunosuppression. About half will relapse, but with additional immunosuppression, 80% will enter a second remission. By retreating relapsing patients or continuing maintenance immunosuppression, many can be maintained transfusion free for years.²⁴ Stem cell transplants are rarely indicated for pure red cell aplasia.

DIAMOND-BLACKFAN SYNDROME

Diamond-Blackfan anemia (DBA) is a rare congenital progressive erythrocyte aplasia that occurs in very young children. In 90% of cases, symptoms of the anemia are apparent in the first year of life. Unlike Fanconi anemia, there is no leukopenia or thrombocytopenia.

DBA is actually a diverse family of diseases with a common hematologic phenotype. There is evidence for both autosomal dominant and autosomal recessive modes of inheritance. About 25% of cases have a mutation of the *RPS19* gene (which encodes a protein involved in ribosome assembly). Other genes related to DBA have been identified. A wide range of congenital defects can be observed in 47% of DBA patients, and patients are predisposed to occurrences of cancer.¹ Many cases have no familial pattern, suggesting spontaneous mutations or acquired disease.

The disease is not due to a deficiency of erythropoietin (EPO) because EPO levels are consistently increased and higher than expected for the degree of anemia. The EPO is active, and no antibodies are directed against this hormone, nor are there apparent mutations in either EPO or the EPO receptor. The most probable defect in DBA is an intrinsic defect of erythroid progenitor cells. BFU-E and CFU-E are decreased, but early erythropoietin-independent erythropoiesis is relatively normal in cell culture systems.

Physical findings and symptoms are those associated with anemia or related to congenital defects. Anemia is severe with erythroid hypoplasia in an otherwise normocellular bone marrow.

Diagnostic criteria for all cases of DBA are included in Table 3. ²⁴ Testing for *RPS19* mutations is helpful in only about 25% of cases.¹ Testing for the chromosomal breakage associated with FA is negative. Vitamin B₁₂ and folate levels are normal. Fetal-like erythrocytes are present, hemoglobin F is increased from 5 to 25%, and the i antigen is increased. The presence of fetal-like erythrocytes is not particularly useful, however, in diagnosing DBA in children younger than 1 year of age because children in this age group normally possess erythrocytes with fetal characteristics. Serum iron and serum ferritin are increased, and transferrin is 100% saturated.

TABLE 3

Diagnostic Criteria for Diamond-Blackfan Anemia

- Macrocytic (or normocytic) normochromic anemia in first year of life
- Reticulocytopenia
- Normocellular marrow with marked erythroid hypoplasia
- Increased serum erythropoietin (EPO)
- Normal or slightly decreased leukocyte count
- Normal or increased platelet count

★ TABLE 4

Comparison of the Features of Diamond-Blackfan Anemia and Transient Erythroblastopenia of Childhood (TEC)

Feature	Diamond-Blackfan	TEC
PRCA	Present	Present
Fetal erythrocyte characteristics (i antigen, HbF increased)	Present	Absent (if child is > 1 year old)
Etiology	Inherited	Follows viral infection (mechanism unknown)
MCV	Can be increased	Normal
Age at onset	Birth to 1 year	Up to 4 years
Therapy	Corticosteroids, transfusions	None, spontaneous recovery

PRCA = pure red cell aplasia

Therapy includes erythrocyte transfusions and administration of adrenal corticosteroids.²⁵ Up to half of patients develop prolonged remission, but most eventually require additional therapy. Transfusion dependence requires the initiation of iron-chelation therapy (desferroximine). Most deaths are due to complications of therapy such as hemosiderosis.

Diamond-Blackfan anemia must be distinguished from transient erythroblastopenia of childhood (TEC), a temporary suppression of erythropoiesis that frequently occurs after a viral infection in otherwise normal children (Table 4★). The age of onset of TEC ranges from 1 month to 10 years. Progressive pallor in a previously healthy child is the primary clinical finding. Fetal characteristics of erythrocytes (HbF, i antigen) seen in DBA are not found in TEC. The pathophysiology of TEC is thought to be either a virus-associated, antibody-mediated, or a T cell-mediated suppression/inhibition of erythroid precursors. Although a preceding viral infection is associated with TEC, parvovirus B19 is not the etiologic agent. Transient aplastic crisis is a similar disorder of temporary failure of erythropoiesis, usually seen in young children with an underlying hemolytic disease (sickle cell anemia, hereditary spherocytosis). It is associated with acute B19 parvovirus infection, a virus that infects erythroid progenitor cells, lysing the target cell and blocking erythropoiesis. Infection, as well as the block to erythropoiesis, is terminated by the production of neutralizing antibodies to the virus.

It is important that the distinction be made between DBA and TEC because DBA requires treatment that is unnecessary and potentially harmful to children with TEC.²⁶ Patients with TEC recover within 2 months of diagnosis. Therapy involves only supportive care.

▶ OTHER HYPOPROLIFERATIVE ANEMIAS

Other hypoproliferative anemias due primarily to defective hormonal stimulation of erythroid progenitor cells include the anemia associated with chronic renal disease and the

anemias associated with endocrine disorders. In most cases, these anemias can be traced to a decrease in erythropoietin production.

RENAL DISEASE

Chronic renal disease is a common cause of anemia. Anemia, however, is only an incidental finding; the patient primarily seeks medical attention for symptoms related to renal failure. The hemoglobin begins to decrease when the blood urea nitrogen level increases to more than 30 mg/dL. Anemia is slow developing, and most patients tolerate the low hemoglobin levels well.

Pathophysiology

Due to the complexity of the clinical settings in uremia, anemia is frequently the result of several different pathophysiologies (Table 5★):

1. The most important and consistent factor is bone marrow erythroid hypoproliferation attributed to a decrease in erythropoietin (EPO) production by the diseased kidney.
2. In some cases, the EPO level is normal, but the bone marrow does not respond. The unresponsiveness can be caused by the presence of a low molecular weight dialyzable inhibitor of erythropoiesis present in the serum of uremic patients. Improvement in hemoglobin levels is seen after dialysis.

★ TABLE 5

Possible Causes of Anemia in Chronic Renal Disease

- Decreased erythropoietin production
- Presence of an inhibitor of erythropoiesis
- Decreased erythrocyte survival
- Blood loss
- Iron deficiency
- Folate deficiency

3. In addition to hypoproliferation, decreased erythrocyte survival compounds the anemia. One factor responsible for the shortened survival is related to an unknown extracorporeal cause, perhaps an unfavorable metabolic environment or mechanical trauma. Another cause of hemolysis can be related to an acquired abnormality in erythrocyte metabolism that involves the pentose phosphate shunt. This abnormality causes impaired generation of NADPH and reduced glutathione.²⁷ Thus, when exposed to oxidants, the erythrocytes develop Heinz bodies, inducing acute hemolysis. Hemolysis can also be related to a reversible defect in erythrocyte membrane sodium-potassium ATPase.
4. The anemia can be related to blood loss from the gastrointestinal tract because of a decrease in platelets and/or platelet dysfunction. Blood is also lost during priming for dialysis. Patients receiving dialysis lose about 5–6 mg of iron daily. Thus, an anemia associated with iron deficiency is common.
5. Patients on dialysis can become folate deficient because folate is dialyzable. Without folate supplements, the patient can develop a megaloblastic anemia.

Laboratory Findings

A normocytic and normochromic anemia is typical in renal disease except when the patient is deficient in folate or iron; then a macrocytic anemia or microcytic anemia prevails. Moderate anisocytosis with some degree of microcytosis can be present. Hemoglobin levels are reduced to 50–80 g/L, and the reticulocyte production index is approximately 1. There is moderate to severe poikilocytosis with echinocytes and schistocytes. The number of echinocytes correlates roughly with the severity of azotemia. Spherocytes are associated with hypersplenism. Nucleated erythrocytes are noted in the peripheral blood. Leukocytes and platelets are usually normal. The bone marrow reveals erythroid hypoproliferation, especially when compared to the degree of anemia.

Other laboratory findings vary depending on the severity of renal impairment. Blood urea nitrogen is >30 mg/dL, serum creatinine is increased, and electrolytes are abnormal. Hemostatic abnormalities can be present. Serum ferritin levels are higher than normal in chronic renal failure even if iron deficiency is present. Therefore, it has been suggested that if the serum ferritin level is below 40 ng/mL, iron deficiency should be considered. Increased iron-binding capacity can be a useful predictor of iron deficiency in these cases.

Therapy

Therapy for chronic renal disease includes renal transplantation, hemodialysis, and continuous ambulatory peritoneal dialysis. All treatments tend to ameliorate the anemia, but hemodialysis exposes the patient to additional causes of anemia including blood loss, iron and folate deficiency, and hemolysis. Thus, iron and folic acid supplements are frequently given in conjunction with hemodialysis. Intermit-

tent doses of EPO three times a week cause improvement in 1–2 weeks. In some cases, a normal hemoglobin is achieved, and in all cases, the patients remain transfusion independent.

ENDOCRINE ABNORMALITIES

Endocrine deficiencies are sometimes associated with a decrease in EPO. The resulting anemia is usually normocytic, normochromic with normal erythrocyte morphology. The bone marrow findings suggest erythroid hypoproliferation.

A slowly developing normocytic, normochromic anemia is characteristic of hypothyroidism. Erythrocyte survival is normal, and reticulocytosis is absent. The anemia is most likely a physiologic response to a decrease in tissue demands for oxygen. With hormone replacement therapy, the anemia slowly remits.

Hypopituitarism is associated with an anemia more severe than that of hypothyroidism, and the leukocyte count can be decreased. However, anemia is a minor component of the other manifestations of hypopituitarism. The pituitary has an effect on multiple endocrine glands including the thyroid and adrenals. In males, a decrease in androgens (gonadal dysfunction) can be partly responsible for the anemia because they stimulate erythropoiesis. In addition, a decrease in the growth hormone can have a trophic effect on the bone marrow. Mild anemia has also been associated with hyperparathyroidism.

SUMMARY

The hypoproliferative anemias include a group of acquired and constitutional disorders in which a chronic marrow failure of erythropoiesis occurs. If only the erythrocytes are affected, the term *pure red cell aplasia* is appropriate. More commonly, a hypocellularity affects all cell lineages, and the diagnosis is aplastic anemia.

Immune suppression has been shown to underlie the hypocellularity in acquired aplastic anemia. Acquired aplastic anemia can be idiopathic or secondary to drugs, chemical agents, ionizing radiation, or infectious agents. Constitutional aplastic anemia has a congenital cause and can be associated with other congenital anomalies. Fanconi anemia is a form of constitutional anemia with progressive bone marrow hypoplasia and other congenital defects. The disorder is characterized by chromosomal instability and fragility, secondary to defective DNA repair mechanisms.

The laboratory findings in aplastic anemia reveal pancytopenia. The erythrocytes are usually normocytic, normochromic but can be macrocytic. The reticulocyte count is low and the corrected reticulocyte count is less than 1%. The bone marrow is less than 25% cellular.

Pure red cell aplasia is characterized by a selective decrease in erythroid cells. This disorder can be acquired or inherited. The acquired forms are seen in thymoma with administration of certain drugs, autoimmune disorders, and infection, especially viral infections. Diamond-Blackfan anemia is a constitutional progressive erythrocyte aplasia occurring in young children. This inherited form

of aplasia must be differentiated from TEC, a temporary aplasia occurring after viral infection.

Other hypoproliferative anemias are due primarily to defective hormonal stimulation of erythroid stem cells. These include anemia associated with renal disease and with endocrinopathies. The laboratory findings reflect not only anemia but also pathologies of the primary disorder.

Immunosuppressive therapy using antithymocyte globulin, anti-lymphocyte globulin, cyclosporine A, or monoclonal antibodies against B cell antigens is the treatment of choice for the majority of older patients who are not candidates for hematopoietic stem cell transplants (SCT). SCT is potentially curative but not without risks. Transplantation still remains unavailable for many patients due to the inability to find matched donors.

REVIEW QUESTIONS

LEVEL I

1. What is the typical morphologic classification of erythrocytes in aplastic anemia? (Objective 8)
 - a. hypochromic, microcytic
 - b. normochromic, normocytic
 - c. normochromic, microcytic
 - d. hypochromic, macrocytic
2. The bone marrow in aplastic anemia is typically: (Objective 8)
 - a. hypocellular
 - b. hypercellular
 - c. dysplastic
 - d. normal
3. Which of the following is (are) considered a cause of hypoproliferation in aplastic anemia? (Objective 3)
 1. damage to stem cells
 2. depletion of stem cells
 3. inhibition of stem cells
 - a. 1 only
 - b. 1 and 2 only
 - c. 2 and 3 only
 - d. 1, 2, and 3
4. What term best describes the peripheral blood findings of a person with aplastic anemia? (Objective 8)
 - a. pancytopenia
 - b. bicytopenia
 - c. granulocytopenia only
 - d. anemia only
5. Diagnostic criteria for aplastic anemia include: (Objective 2)
 - a. corrected reticulocyte count of more than 1%
 - b. platelet count less than $100 \times 10^9/L$
 - c. granulocyte count less than $0.5 \times 10^9/L$
 - d. bone marrow less than 50% cellular
6. Which age group is *least* likely to have a high incidence of aplastic anemia? (Objective 3)
 - a. 2–5 years old
 - b. 20–25 years old
 - c. 40–50 years old
 - d. adults over 60

LEVEL II

1. What confirmatory test should be performed in suspected cases of aplastic anemia? (Objective 4)
 - a. serum iron and TIBC
 - b. hemoglobin electrophoresis
 - c. bone marrow examination
 - d. direct antiglobulin test
2. A 3-year-old patient presents with severe normocytic, normochromic anemia. Platelet counts and leukocyte counts are normal. The mother reported that the child has been healthy since birth but recently had a cold. Which of the following laboratory test results would support a diagnosis of TEC? (Objectives 1, 5, 6)
 - a. decreased numbers of erythrocyte precursors on bone marrow examination
 - b. normal hemoglobin F level on hemoglobin electrophoresis
 - c. abnormal karyotype
 - d. i antigen on the patient's erythrocytes
3. A bone marrow from an anemic patient that demonstrates a marked erythroid hypoplasia but normal numbers of other cell lines is most consistent with a diagnosis of: (Objective 5)
 - a. Fanconi anemia
 - b. aplastic anemia
 - c. pure red cell aplasia
 - d. myelophthisic anemia
4. A male patient with previously diagnosed infectious mononucleosis infection has become suddenly anemic. A possible cause of the anemia is: (Objective 1)
 - a. iron deficiency
 - b. folic acid deficiency
 - c. anemia of chronic disease
 - d. aplastic anemia
5. What is the standard treatment for patients with acquired aplastic anemia? (Objective 3)
 - a. immunosuppressive therapy
 - b. bone marrow transplant
 - c. administration of growth factors
 - d. none; treatment typically not needed

REVIEW QUESTIONS (continued)

LEVEL I

7. Exposure to drugs, radiation, or infectious agents can result in which type of aplastic anemia? (Objective 7)
 - a. idiopathic
 - b. congenital
 - c. constitutional
 - d. acquired
8. If a patient with anemia had a decrease in only the red cells in the bone marrow, this might indicate: (Objective 8)
 - a. pure red cell aplasia
 - b. acquired aplastic anemia
 - c. megaloblastic anemia
 - d. constitutional aplastic anemia
9. Which of the following is most characteristic of the peripheral blood picture in pure red cell aplasia? (Objective 8)
 - a. pancytopenia
 - b. granulocytopenia and thrombocytopenia
 - c. leukocytosis
 - d. decreased hemoglobin and hematocrit
10. Peripheral blood findings in patients with chronic renal disease include: (Objective 9)
 - a. mild anemia with hemoglobin levels around 10 g/dL
 - b. poikilocytosis with echinocytes and schistocytes
 - c. normally shaped erythrocytes
 - d. decreased leukocytes and platelets

LEVEL II

6. The peripheral blood finding that helps differentiate aplastic anemia from myelophthitic anemia is: (Objective 5)
 - a. leukoerythroblastic reaction in aplastic anemia
 - b. fetal-like erythrocytes in aplastic anemia
 - c. poikilocytosis in myelophthitic anemia
 - d. microcytic anemia in myelophthitic anemia
7. Which patient with aplastic anemia could have the best prognosis for recovery? (Objective 2)
 - a. one with a parvovirus infection
 - b. one with idiopathic aplastic anemia
 - c. one who has severe bone marrow hypoplasia
 - d. one who has severe pancytopenia
8. A bone marrow biopsy is performed on an infant with severe congenital abnormalities and severe anemia. Results of the biopsy demonstrate marked hypoplasia of all cell lines. These findings are most consistent with a diagnosis of: (Objective 4)
 - a. transient erythroblastopenia of childhood
 - b. familial aplastic anemia
 - c. Diamond-Blackfan anemia
 - d. Fanconi anemia
9. Clinical signs and symptoms of aplastic anemia include: (Objective 4)
 - a. hepatomegaly
 - b. bleeding
 - c. splenomegaly
 - d. lymphadenopathy
10. A 75-year-old male was diagnosed with aplastic anemia. He has no known living blood relatives. What treatment would most likely be initiated? (Objective 3)
 - a. none
 - b. bone marrow transplant
 - c. immunosuppressive therapy
 - d. chemotherapy

ANSWERS TO CASE STUDY QUESTIONS

Case Summary: Rachael had symptoms of anemia and a bleeding disorder when she was first seen by her physician. Her past medical history was significant in that she had recently recovered from a viral infection. Her laboratory results revealed pancytopenia and a low reticulocyte count. Bone marrow examination showed hypoplasia. These findings suggest acquired aplastic anemia associated with past viral infection.

Question:

1. Select laboratory tests appropriate for screening for aplastic anemia.

Explanation:

The CBC is an important screening test for all anemias.

Question:

2. Justify the selection of laboratory screening tests based on Rachael's clinical signs and symptoms.

Explanation:

It is important to know the patient's hemoglobin and hematocrit because anemia may be one cause of her weakness and shortness of breath. A low platelet count may explain the presence of petechiae and bruises.

Question:

3. Evaluate the relationship between Rachael's age and the likelihood of having aplastic anemia.

Explanation:

Because approximately 25% of cases occur in persons younger than age 20, it is possible she may have aplastic anemia. Overall, however, the incidence of aplastic anemia is quite low.

Question:

4. If aplastic anemia is present, would you expect her to have an idiopathic or secondary form? Explain your answer.

Explanation:

It is difficult to estimate whether she has an idiopathic or secondary form without a more complete history. Idiopathic forms are more common in this age group, however. Approximately 50–70% of all cases of aplastic anemia cannot be linked to a specific cause.

Question:

5. What aspect of this patient's history may be associated with the occurrence of aplastic anemia?

Explanation:

Our knowledge of the previous infection with hepatitis is helpful. Some data suggest an association between aplasia and infections with viruses.

Question:

6. Is it likely that Rachael has a constitutional form of aplastic anemia? Explain your answer.

Explanation:

It is unlikely that a constitutional form of aplastic anemia would be detected at such an advanced age. Fanconi's anemia is first observed in much younger children who typically have other congenital abnormalities.

Question:

7. Correlate these clinical findings with her laboratory screening test results.

Explanation:

The patient's weakness and shortness of breath are related to the degree of anemia indicated by her decreased hemoglobin and hematocrit. Petechiae and bruising are caused by her severe thrombocytopenia. Recurrent fevers are suggestive of infection. She is severely neutropenic and, therefore, at high risk for infection.

Question:

8. Evaluate each of the patient's laboratory results by comparing them to reference ranges.

Explanation:

All CBC parameters are below reference range for a person of this age.

Question:

9. Which of the patient's routine laboratory results are consistent with those expected for aplastic anemia?

Explanation:

All are consistent with expected results for patients with aplastic anemia.

Question:

10. Classify the morphologic type of anemia.

Explanation:

The patient's MCV is 100 fL and MCHC is 29. The anemia is macrocytic, normochromic. This finding is consistent with aplastic anemia.

Question:

11. Calculate the absolute lymphocyte count. Are her lymphocytes truly elevated as suggested by the relative lymphocyte count?

Explanation:

The absolute lymphocyte count is $1.1 \times 10^9/L$, which is slightly decreased. The relative lymphocyte count (94%) is very high because the patient is severely neutropenic. Thus, examining the relative count without considering the total leukocyte count can be very misleading.

Question:

12. Correct the reticulocyte count. Why is this step important?

Explanation:

The patient's corrected reticulocyte count is 0.4%, which is below reference range. All reticulocyte counts need to be corrected when anemia is

present in order to assess the bone marrow's degree of compensation for the anemia.

Question:

13. Calculate the absolute reticulocyte count.

Explanation:

The patient's absolute reticulocyte count is $17 \times 10^9/L$, which is consistent with a diagnosis of aplastic anemia.

Question:

14. Compare these results with those expected for a person with aplastic anemia.

Explanation:

A markedly hypocellular marrow is consistent with a diagnosis of aplastic anemia. The hematopoietic material was insufficient to aspirate an adequate sample.

Question:

15. Interpret the significance of the lack of malignant cells and hematopoietic blasts.

Explanation:

If malignant cells were present in the marrow, a diagnosis of metastatic disease or lymphoma rather than aplastic anemia would have been likely. Bone marrows of patients with leukemias and myelodysplastic syndromes typically are hyperplastic with increased numbers of hematopoietic blasts present. Aplastic anemia vs hypoplastic MDS is a very difficult differential diagnosis.

Question:

16. Suggest a means of improving the validity of bone marrow examination results for this patient.

Explanation:

When aplastic anemia is suspected, it may be advisable to sample multiple areas of the bone marrow.

Question:

17. Appraise the prognosis for Rachael.

Explanation:

Prognosis is rather poor for patients with aplastic anemia unless a compatible donor can be found for bone marrow transplant.

Question:

18. Predict a treatment regimen.

Explanation:

Treatment would consist of supportive therapy using blood components. A platelet transfusion would probably be ordered immediately. Antithymocyte globulin (ATG) will most likely be administered. If the aplasia did not resolve, a bone marrow transplant would be considered.

Question:

19. What other hematologic conditions must be ruled out for this patient?

Explanation:

Other causes of pancytopenia of the peripheral blood include myelodysplastic syndromes (MDS) and megaloblastic anemia.

Explanation:

Serum B₁₂ and folic acid levels could be used to rule out anemia due to a deficiency of one of these nutrients. However, a bone marrow examination is essential to make a diagnosis in this case. If the patient had megaloblastic anemia, megaloblastic changes would be evident in the hematopoietic cells. Myelodysplastic changes, increased numbers of myeloblasts, and cytogenetic abnormalities would support a diagnosis of MDS.

Question:

20. What laboratory test is most beneficial in differentiating aplastic anemia from these other disorders? Compare the expected results for aplastic anemia with those of the other disorders.

ANSWERS TO CHECKPOINTS

Checkpoint! 1

An anemic patient has a corrected reticulocyte count of 1.5%, hemoglobin of 10.0 g/dL, hematocrit of 0.30 L/L, total neutrophil count of $0.4 \times 10^9/L$, and a platelet count of $30 \times 10^9/L$. Is it likely that this patient has aplastic anemia?

Answer

No, it is unlikely that this patient has aplastic anemia. Two of the peripheral blood findings are inconsistent with the diagnostic criteria.

Introduction to Hemolytic Anemia

Shirlyn B. McKenzie, Ph.D.

■ OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. List the laboratory tests that can be used to assess a hemolytic anemia and give expected results.
2. Define *hemolysis* and reconcile a normal hemoglobin in compensated hemolytic disease.
3. Assess laboratory results in intravascular and extravascular hemolysis.
4. Summarize the clinical findings associated with a hemolytic anemia.
5. Explain the difference between intrinsic and extrinsic erythrocyte defects and give an example of each.

■ OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. Evaluate clinical findings of hemolytic anemia and differentiate those associated with acute and chronic disease.
2. Compare and contrast the processes of intravascular and extravascular hemolysis and explain how laboratory results can be used to differentiate.
3. Interpret laboratory and clinical findings in hemolytic anemia and determine the type of hematologic defect present.
4. Recommend follow-up tests that could be necessary for a diagnosis of hemolytic disease.

KEY TERMS

- Compensated hemolytic disease
- Hemoglobinemia
- Hemoglobinuria
- Hemolysis
- Hemosiderinuria

BACKGROUND BASICS

The information in this chapter builds on the concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study.

Level I

- ▶ Diagram the process of intravascular and extravascular hemolysis.
- ▶ Identify and define types of poikilocytes.
- ▶ Explain the morphologic and functional classification of anemia.
- ▶ Identify laboratory tests used to assess anemia.

Level II

- ▶ Classify an anemia based on laboratory findings.
- ▶ Interpret results of laboratory tests and clinical findings based on type of hemolysis and functional defect.
- ▶ Review the erythrocyte membrane structure.

CASE STUDY

We will address this case study throughout the chapter.

Sashi is a 58-year-old female. Her amylase and lipase values were markedly increased. Her hemoglobin was 15.5 g/dL. Two months later she had surgery for a pancreatic pseudocyst. She received 3 units of packed red blood cells. Three days after surgery, her hemoglobin was 5.2 g/dL, RBC $1.5 \times 10^{12}/L$, hematocrit 0.148 L/L. The physician is concerned about the possibility of internal bleeding. Consider what other laboratory tests could be helpful in defining the source of blood loss in this patient.

OVERVIEW

The laboratory plays an important role in differentiating the etiology of hemolytic disease. This chapter introduces the next four chapters on hemolytic anemia. It describes the classification schemes of hemolytic disease and gives the general laboratory and clinical findings characteristic of this group of anemias. The use of laboratory tests in differentiating the intravascular or extravascular sites of erythrocyte destruction and in defining the source of defect (intrinsic or extrinsic to the red cell) is discussed.

INTRODUCTION

The hemolytic anemias are a heterogeneous group of normocytic, normochromic anemias in which the erythrocyte is prematurely destroyed. This premature destruction is referred to as **hemolysis**. Hemolytic anemia can be classified according to the source of the defect causing the hemolysis (intrinsic or extrinsic to the erythrocyte), mode of onset (inherited or acquired), and location of hemolysis (intravascular or extravascular) (Table 1). Intrinsic abnormalities are generally genetically determined, extrinsic abnormalities are acquired. There are exceptions to these classifications. For example, paroxysmal nocturnal hemoglobinuria (PNH) is an intrinsic erythrocytic defect that is acquired, and abetalipoproteinemia and LCAT deficiency are inherited extrinsic defects. Depending on the type and extent of injury, hemolysis can be intravascular or extravascular.

These anemias can also be classified by type of poikilocyte present on the blood smear: schistocytes or spherocytes (Figure 1). Schistocytes indicate physical/mechanical trauma to the erythrocyte. Hemolysis can be either extravascular or intravascular hemolysis, depending on the severity of cell damage. Spherocytes indicate that part of the cell's membrane has been removed by phagocytes or shed from the cell in the form of microvesicles. Membrane can be removed by phagocytes in the spleen because of antigen/antibody complexes on the membrane, a defective membrane, or abnormal inclusions in the cell. Spherocytes are hemolyzed extravascularly.

The ultimate aim of any classification is to help identify the etiology of the anemia so that the appropriate treatment

TABLE 1

Possible Classifications of Hemolytic Anemia Based on Pathophysiology, Etiology, and/or Laboratory Findings

Source of Defect	Mode of Onset	Site of Hemolysis	Predominant Poikilocyte
Intrinsic to red cell (intracorpuscular)	Inherited	Intravascular	Spherocyte
Extrinsic to red cell (extracorpuscular)	Acquired	Extravascular	Schistocyte (fragmented erythrocyte)/spherocyte

FIGURE 1 **a.** Peripheral blood smear from a patient with autoimmune hemolytic anemia. There is marked anisocytosis with numerous spherocytes and large polychromatophilic erythrocytes. **b.** Peripheral blood smear from a patient with thrombotic, thrombocytopenic purpura, a microangiopathic hemolytic anemia. Many schistocytes are present as are spherocytes, but the predominant poikilocyte is the schistocyte. (both: 1000 \times magnification; Wright-Giemsa stain)

can be given and prognosis determined. Laboratory tests are a very important part of this process.

Reticulocytosis is a constant feature of all hemolytic anemias reflecting the increased activity of the bone marrow as it attempts to maintain erythrocyte mass in the peripheral blood. If the bone marrow is able to increase erythropoiesis enough to compensate for the decreased erythrocyte life span, anemia does not develop. In this case, cells are being produced at the same or nearly the same rate as they are hemolyzed. This condition is called **compensated hemolytic disease**. Compensated hemolytic disease can rapidly develop into anemia if one of the following occurs: (1) erythrocyte destruction accelerates beyond the compensatory capacity of the marrow (hemolytic crises) or (2) the marrow suddenly stops producing erythrocytes (aplastic crisis).

It has been shown that in individuals scheduled for surgery who undergo aggressive autologous blood donation (two 450-ml units per week), the bone marrow can increase its production rate twofold to fourfold over the basal rate if sufficient iron is mobilized.¹ Thus, it is possible that the erythrocyte life span can drop to one-fourth of normal, or about 30 days, without anemia developing. If the life span decreases to less than 30 days, however, anemia can develop. The increase in erythropoiesis is limited by the amount of iron that can be mobilized for hemoglobin synthesis. The term *functional iron deficiency* is used when total body iron is adequate but iron stores cannot be mobilized fast enough for the increase in erythropoiesis. Patients with chronic hemolytic anemia can increase erythropoiesis sixfold if adequate iron is available. Individuals with hemochromatosis have very high serum iron and transferrin saturation levels, and it has been shown that they can increase erythropoiesis up to eightfold.²

▶ LABORATORY FINDINGS

Hematologic characteristics of hemolytic anemia reflect the increased activity of the bone marrow and the increased erythrocyte destruction (Table 2 \star). Erythroid hyperplasia of the bone marrow with decreased amounts of fat is more pronounced in hemolytic anemias than in any of the non-hemolytic anemias. Consequently, the myeloid-to-erythroid ratio (M:E) is decreased. Increased plasma iron turnover reflects the increased erythrocyte destruction and increased utilization of iron by erythroid precursors in the bone marrow.

Peripheral blood reticulocytosis, increased immature reticulocyte fraction (IRF), marked polychromasia, and nucleated erythrocytes in the peripheral blood are clues to the presence of increased erythropoietic activity in the bone marrow. The hemolytic anemias are the only anemias with a reticulocyte production index (RPI) of more than 2 (except in acute hemorrhage). Thus, the RPI is useful in differentiating hemolytic anemias from other normocytic, normochromic anemias in which the bone marrow is not increasing effective erythropoiesis. The degree of reticulocytosis occasionally is great enough to cause an increased MCV in which case the anemia is classified as macrocytic, normochromic. (Reticulocytes are larger than mature erythrocytes.)

Results of laboratory tests that are used to evaluate heme catabolism are usually abnormal. Unconjugated/indirect bilirubin is often increased, but the conjugated/direct fraction is usually normal unless hepatic or biliary dysfunction is present. (Reference intervals: total bilirubin = 0.2–1 mg/dL; unconjugated bilirubin = 0–0.2 mg/dL) However, a significant number of patients with hemolytic disease have normal serum bilirubin levels, suggesting that serum bilirubin is not

TABLE 2

Common Laboratory Findings Reflecting Increased Production and Destruction of Erythrocytes in Hemolytic Anemias

Increased Bone Marrow Production of Erythrocytes	Increased Erythrocyte Destruction
Reticulocytosis (RPI >2)	Anemia
Increased IRF	Presence of spherocytes, schistocytes, and/or other poikilocytes
Leukocytosis	Positive direct antihuman globulin test (DAT)
Nucleated erythrocytes in the peripheral blood	Decreased haptoglobin and hemopexin
Polychromasia of erythrocytes on Romanowsky-stained blood smears	Decreased glycosylated hemoglobin
Normoblastic erythroid hyperplasia in the bone marrow	Increased fecal and urine urobilinogen
	Increased bilirubin (unconjugated)
	Hemoglobinemia*
	Hemoglobinuria*
	Hemosiderinuria*
	Methemoglobinemia*
	Increased serum LD
	Increased expired CO

*Associated only with intravascular hemolysis. IRF = immature reticulocyte fraction; LD = lactic dehydrogenase; RPI = reticulocyte production index; CO = carbon monoxide

a reliable index of erythrocyte destruction. Bilirubin levels of more than 5 mg/dL are unusual in hemolytic disease except in neonates and in those with coexisting liver dysfunction. Urine and fecal urobilinogen is elevated.

The heme-binding plasma proteins, haptoglobin and hemopexin, are often decreased as a result of increased consumption. Haptoglobin levels less than 25 mg/dL are highly specific for hemolytic anemia.

Review of the peripheral blood smear is helpful in directing the course of laboratory investigation. Poikilocytes other than spherocytes suggest mechanical damage to the cell whereas spherocytes suggest membrane grooming (loss) by phagocytes in the spleen.

CASE STUDY (continued from earlier in this chapter)

Sashi's reticulocyte count is 19%, total serum bilirubin 9.8 mg/dL, and haptoglobin <13 mg/dL. The peripheral blood smear revealed many spherocytes.

1. What type of anemia do the laboratory results and clinical history suggest?

Checkpoint! 1

A patient is suspected of having a hemolytic disease. The reticulocyte count is increased, but the hemoglobin, serum bilirubin, and haptoglobin are within the normal range. Explain.

CLINICAL FINDINGS

Clinical signs of hemolytic anemia are associated with increases in both heme catabolism (erythrocyte destruction) and erythropoiesis (Table 3). Jaundice reflects an increase in bilirubin production. Gallstones consisting primarily of bilirubin are common in congenital and other chronic hemolytic anemias. Dark or red urine due to excretion of plasma hemoglobin can be noted in intravascular hemolysis.

Chronic severe hemolytic anemias stimulate the expansion of bone marrow, consequently thinning cortical bone and widening the spaces between inner and outer tables of bone. In children, this expansion is evident in skeletal abnormalities. These bone changes can result in spontaneous fractures and a type of arthritis termed *osteoarthritis*.³ Extramedullary hematopoietic masses can be found. Some of these masses are believed to represent extrusions of the marrow cavity through thinned bone cortex. Small colonies of erythrocytes also can be found in the spleen, liver, lymph nodes, and perinephric tissue. The hematopoietic masses can cause pressure symptoms on adjacent organs.³ In extravascular hemolysis, splenic hypertrophy is a constant finding.

Other clinical findings and the primary symptoms are those associated with anemia including pallor, fatigue, and cardiac symptoms.

SITES OF DESTRUCTION

Hemolysis can occur within the circulation (intravascular) or within the macrophages of the spleen, liver, or bone marrow (extravascular). In some cases, depending on the degree of

TABLE 3

Clinical Findings Associated with Hemolytic Anemia

- Jaundice
- Gallstones
- Dark or red urine (intravascular hemolysis)
- Symptoms of anemia
- Thinning of cortical bone (in chronic hemolytic anemia)
- Extramedullary hematopoietic masses (in chronic hemolytic anemia)
- Splenomegaly

damage to the cell, destruction occurs both intravascularly and extravascularly. The results of laboratory tests can provide important clues to the hemolytic process.⁴ To correlate laboratory results with the etiology and pathophysiology of the anemia, an understanding of intravascular and extravascular hemolysis is essential.

INTRAVASCULAR HEMOLYSIS

In intravascular hemolysis, the erythrocyte is destroyed within the blood vessels. When the erythrocyte is hemolyzed, free hemoglobin is released into the plasma. The hemoglobin is bound to the plasma protein haptoglobin, transported as a complex to the liver where it is metabolized to bilirubin, and excreted to the intestinal tract via the bile duct. Normally the concentration of hemoglobin in plasma is less than 5 mg/dL. In severe intravascular hemolysis, synthesis of haptoglobin might not be sufficient to replace that being used, and free hemoglobin accumulates in the plasma. It should be remembered, however, that haptoglobin is an acute phase reactant and can be normal or even increased in individuals with concomitant infections, inflammation, or malignant disease despite an increase in intravascular hemolysis. Levels also can be decreased in liver disease due to decreased synthesis of the protein and in hereditary deficiency of haptoglobin. Although haptoglobin functions as an intravascular heme-binding protein, it also can be decreased in association with extravascular hemolytic diseases. Thus, by itself, the haptoglobin level cannot be used to differentiate intravascular and extravascular hemolysis.

Another plasma protein, hemopexin, complexes with heme when haptoglobin is depleted. This complex can also be cleared from the plasma by the liver faster than hemopexin can be synthesized and is quickly depleted. A decrease in hemopexin is secondary to a reduction in haptoglobin.

Hemoglobin bound to haptoglobin or hemopexin forms complexes that are too large to pass through the glomerulus of the kidney. When these two transport proteins are depleted, free hemoglobin circulates in the plasma (**hemoglobinemia**). The liver directly removes some of this hemoglobin, but some dissociates into dimers small enough to be filtered by the glomerulus. Filtered hemoglobin can be reabsorbed in the proximal renal tubules, but when the rate of filtration exceeds the tubular reabsorption capabilities, free hemoglobin appears in the urine (**hemoglobinuria**). The presence of free hemoglobin in the urine is a sign of rapid and severe intravascular hemolysis.⁵ Depending on the degree of hemolysis, the urine can be pink, red, or brownish black.

Some renal tubular cells can become laden with hemoglobin iron. When these tubular cells are sloughed off into the urine, hemosiderin granules can be visualized by staining the urine sediment with an iron stain and examining it micro-

scopically. Hemosiderin in the urine (**hemosiderinuria**) is a sign that the kidney has filtered a significant amount of hemoglobin.³ In chronic intravascular hemolysis, hemosiderin granules can appear in the urine even in the absence of hemoglobinuria.

Free hemoglobin not bound to either of the two transport proteins or not excreted by the kidney is quickly oxidized to methemoglobin. Methemoglobin dissociates into heme (oxidized form of heme) and globin. Heme can bind to hemopexin if it is available or to albumin, forming methemalbumin. Methemalbumin is not excreted in the urine but circulates in the blood can be detected in the plasma by Schumm's test.

As described above laboratory findings of intravascular hemolysis include hemoglobinemia, hemoglobinuria, hemosiderinuria, methemoglobinemia, decreased haptoglobin, and decreased hemopexin. In addition, the serum lactic dehydrogenase (LD) can increase to as much as 800 IU/L (upper limit of reference range is 207 IU/L). LD, an enzyme present in high concentration in erythrocytes, is released from the erythrocyte into the plasma in intravascular hemolysis, and it is cleared from plasma even more slowly than hemoglobin. It can be an early and sensitive indicator of intravascular hemolysis.⁶

Erythrocytes must be severely damaged to undergo intravascular destruction because phagocytes in the spleen or liver remove minimally or moderately damaged erythrocytes. Intravascular hemolysis can be caused by the (1) activation of complement on the erythrocyte membrane, (2) physical or mechanical trauma to the erythrocyte, or (3) the presence of soluble toxic substances in the erythrocyte's environment (Table 4 🌟).

EXTRAVASCULAR HEMOLYSIS

If premature erythrocyte destruction is the result of extravascular hemolysis, the erythrocytes are removed from circulation by phagocytes in the tissues. This type of hemolysis is more common than intravascular hemolysis. There is no hemoglobinemia, hemoglobinuria, or hemosiderinuria because hemoglobin is not released directly into the plasma. Instead, the hemoglobin is degraded within the phagocyte to heme and globin. The heme is further catabolized to iron, biliverdin, and carbon monoxide. The biliverdin then enters the plasma as bilirubin, binds to albumin, and is excreted by the liver.

Significant laboratory findings in hemolytic anemias associated with extravascular hemolysis are measurements of the products of heme catabolism. These findings include increases in expired carbon monoxide, carboxyhemoglobin, serum bilirubin (especially the unconjugated fraction), and both urine and fecal urobilinogen. In severe or chronic extravascular hemolysis, haptoglobin and hemopexin levels also can be decreased.

★ TABLE 4

Anemias Characterized by Intravascular Hemolysis

Activation of Complement on the Erythrocyte Membrane	Physical or Mechanical Trauma to the Erythrocyte	Toxic Microenvironment of the Erythrocyte
Paroxysmal nocturnal hemoglobinuria	Microangiopathic hemolytic anemia	Bacterial infections
Paroxysmal cold hemoglobinuria	Abnormalities of the heart and great vessels	<i>Plasmodium falciparum</i> infection
Some transfusion reactions	Disseminated intravascular coagulation	Venoms
Some autoimmune hemolytic anemias		Arsine poisoning
		Acute drug reaction in G6PD deficiency
		Intravenous administration of distilled water
		Thermal injury

G6PD = glucose-6-phosphate dehydrogenase

Extravascular hemolysis can occur in phagocytes of the spleen, liver, or bone marrow. The type and degree of erythrocyte damage determines the primary site of erythrocyte destruction. The spleen is more efficient at removing slightly damaged erythrocytes because of the unique circulation pattern in the splenic cords. In this relatively static environment, erythrocytes are susceptible to fine scrutiny by splenic macrophages. The liver blood flow exceeds blood flow in the spleen and is an important site for the removal and phagocytosis of extensively damaged erythrocytes. The bone marrow can remove intrinsically abnormal erythrocytes before they are released to the peripheral circulation (ineffective erythropoiesis).

Antibodies directed against the erythrocyte commonly cause hemolytic anemia associated with extravascular hemolysis. Antibody and complement attached to the cell membrane make the erythrocyte a target for removal from the circulation by phagocytes. The sites and extent of extravascular hemolysis depend on the class of antibody attached to the erythrocyte as well as on whether complement is present. Thus, in immune mediated hemolytic anemia, determining the specific class of antibody present is sometimes helpful. The antihuman globulin (AHG) test (or direct antiglobulin test, DAT) is helpful in identifying erythrocytes sensitized with antibodies and/or complement.

Erythrocytes sensitized with both complement and IgM are readily removed in the liver by hepatic macrophages, which have receptors for the complement component, C3b. However, if the terminal complement components are activated on the cell membrane, hemolysis is intravascular. Cells sensitized with IgM but without attached complement components appear to survive normally because macrophages lack Fc receptors for IgM. Clearance of IgM sensitized cells thus depends completely on activation of complement.

Erythrocytes sensitized with IgG may or may not activate complement because it takes multiple molecules of IgG on the erythrocyte membrane to bind one molecule of comple-

ment. However, cells sensitized with IgG can be removed by macrophages even in the absence of complement. IgG-sensitized erythrocytes are cleared primarily in the spleen by macrophages that have Fc receptors for IgG (Fc γ R) in addition to C3b receptors (CR3). The clearance of erythrocytes sensitized by both IgG and complement is accelerated because phagocytosis is mediated by two receptors.

Bone marrow macrophages are responsible for the removal of maturing precursor cells that are intrinsically abnormal. Cytoplasmic or nuclear maturation abnormalities (iron deficiency and megaloblastic anemia) are associated with this type of extravascular hemolysis resulting in a high degree of ineffective erythropoiesis. Many of the abnormal cells never enter the peripheral blood. Many hemolytic anemias that are associated with inherited defects of the erythrocyte membrane, hemoglobin, and intracellular enzymes have some degree of ineffective erythropoiesis. (This is a major factor in the clinical complications found in thalassemia, a disease with a large degree of ineffective erythropoiesis.) In most cases, however, a significant number of the defective cells gain access to the peripheral blood. These cells are not physiologically equipped to withstand the assaults of the peripheral circulation and are damaged. The damaged cells are then removed by liver or splenic macrophages. Anemias associated with extravascular hemolysis are listed in Table 5 ★.

CASE STUDY (continued from earlier in this chapter)

Hemoglobinuria and hemoglobinemia are not present in Sashi, but haptoglobin is decreased.

- Do the laboratory test results indicate intravascular or extravascular hemolysis? Explain.

★ TABLE 5

Anemias Characterized by Extravascular Hemolysis

Origin	Anemias
Inherited erythrocyte defects	Thalassemia
	Hemoglobinopathies
	Enzyme deficiencies
	Membrane disorders
Acquired erythrocyte defects	Megaloblastic anemia
	Spur cell anemia
	Vitamin E deficiency in newborns
Immuno-hemolytic anemias	Autoimmune
	Drug induced
	Some transfusion reactions

✓ **Checkpoint! 2**

Explain why it is helpful for the clinical laboratory professional to know whether a particular hemolytic anemia is characterized by intravascular or extravascular hemolysis.

ERYTHROCYTE SURVIVAL STUDIES

Erythrocyte survival studies are helpful in defining a hemolytic process in which erythrocyte survival is only mildly decreased. In mild hemolysis, laboratory findings typical of extravascular or intravascular hemolysis can be absent. Survival studies give insight into the rate and mechanism of hemolysis.

To study erythrocyte survival, a sample of the patient's blood is removed and labeled *in vitro* with tracer amounts of radionuclide. The most common random label for erythrocytes and that recommended by the International Committee for Standardization in Hematology is radioactive chromium (^{51}Cr). The chromium penetrates the erythrocyte and remains trapped there. This labeled sample is injected intravenously into the patient. To determine the erythrocyte survival pattern, small samples of the patient's blood are assayed at specified time intervals for radioactivity levels. The erythrocyte life span is expressed as the time it takes for blood radioactivity to decrease by one-half ($T\ 1/2\ ^{51}\text{Cr}$) starting 24 hours after injection. About 1% of the ^{51}Cr is normally eluted from surviving cells daily. In addition, only 1% of the labeled cells can be expected to have a life span of 100–120 days, because only 1% of the total erythrocyte mass is replaced each day. The remaining labeled cells have expected life spans from 0 to 100 days. Taking these facts into consideration, the normal $T\ 1/2$ with this method has been determined to be 25–32 days. A steady state is necessary for accurate interpretation of erythrocyte survival studies because blood loss or transfusions can alter the data significantly. Labeled erythrocytes in this method are also useful in

determining the sites of erythrocyte destruction. The amount of radioactivity taken up by an organ can be measured by scanning the body for ^{51}Cr deposition and is proportional to the number of erythrocytes destroyed there.

▶ **SOURCE OF DEFECT**

Hemolytic anemias can be classified as intrinsic or extrinsic according to the cause of the shortened erythrocyte survival (Table 6). *Intrinsic* refers to an abnormality of the erythrocyte itself. The abnormality can be in the membrane, cell enzymes, or hemoglobin molecule. *Extrinsic* refers to an antagonist in the cell's environment that causes injury to the erythrocyte. Contrary to intrinsic defects, the erythrocyte in extrinsic defects is normal.

INTRINSIC DEFECTS

With a few exceptions, intrinsic defects are hereditary. The site of hemolysis in intrinsic defects is usually extravascular. In some cases, intrinsic defects render the cell more susceptible than normal cells to damage by environmental (extracorporeal) factors. Although extracorporeal factors can be involved, the initiating event in hemolysis is considered to be the intrinsic abnormality. For example, a patient with a deficiency of glucose-6-phosphate dehydrogenase (G6PD; an enzyme in the erythrocyte that is necessary to reduce oxidants via production of glutathione) might not be able to produce enough glutathione to handle the oxidation products that occur when certain drugs are administered. Consequently, the erythrocytes suffer oxidant injury precipitated by the drug, which leads to hemolysis. Intrinsic defects causing hemolysis are discussed next.

Defects of the Erythrocyte Membrane

Structural defects of the erythrocyte membrane can cause the membrane to become abnormally permeable, rigid, or unstable and easily fragmented. In most cases, the defect is in one or more of the cytoskeletal proteins under the membrane lipid bilayer, causing abnormal interaction between the lipid bilayer and the cytoskeleton. In other cases, the membrane is abnormally permeable to cations because of defects in integral proteins and/or lipids.

In paroxysmal nocturnal hemoglobinuria, the erythrocyte membrane lacks a protein that serves a critical role in controlling complement attachment and activation on the cell membrane. As a result, the cell is abnormally sensitive to complement hemolysis. The defective membrane is an acquired abnormality.

Defects of Hemoglobin Structure or Production

Structurally abnormal hemoglobins that result in hemoglobin insolubility or instability can cause erythrocyte rigidity

★ TABLE 6

Classification of Hemolytic Anemias Based on Underlying Defect

Classification	Underlying Defect	Examples	
Intrinsic (inherited)	Membrane defects	Hereditary spherocytosis Hereditary elliptocytosis Hereditary pyropoikilocytosis Hereditary stomatocytosis Hereditary xerocytosis Paroxysmal nocturnal hemoglobinuria (acquired)	
	Enzyme disorders	Glycolytic pathway enzyme deficiencies Hexose-monophosphate shunt enzyme deficiencies	
	Abnormal hemoglobins	Thalassemia Structural hemoglobin variants (i.e., sickle cell anemia)	
Extrinsic (acquired)	Antagonistic plasma factors	Chemicals, drugs Animal venoms Infectious agents Plasma lipid abnormalities Intracellular parasites Splenomegaly	
		Traumatic physical cell injury	Microcirculation lesions Thermal injury March hemoglobinuria
		Immune mediated cell destruction	Autoimmune Alloimmune Drug induced

and, ultimately, hemolysis. In thalassemia, precipitates of excess globin chains (Heinz bodies) damage the erythrocyte membrane and cause erythrocytes to become rigid, and a severe hemolytic anemia develops.

Defects of Erythrocyte Enzymes

Deficiencies of erythrocyte enzymes necessary for maintaining hemoglobin and membrane sulfhydryl groups in the reduced state or for maintaining adequate levels of adenosine triphosphate (ATP) for cation exchange can result in hemolytic anemia. The enzyme disorders can be divided into two groups: (1) deficiencies in enzymes of the glycolytic pathway and (2) deficiencies in enzymes of the hexose-monophosphate shunt.

EXTRINSIC DEFECTS

Extrinsic defects are usually acquired. The erythrocytes, as innocent bystanders, are damaged by chemical, mechanical, or physical agents. Hemolysis can be either intravascular or extravascular. Discussion of the external factors causing hemolysis follows.

Antagonistic Plasma or Soluble Factors in the Erythrocyte's Environment

These factors include substances in the circulation that are toxic to the cell, cause direct cell hemolysis, or in the case of lipid abnormalities, alter the cell membrane and lead to removal of the cell in the spleen. Many drugs and chemicals are known to cause hemolysis. The European Union (EU) recognizes that prolonged exposure to a variety of chemical substances can result in hemolytic anemia.⁷ They propose criteria that can be used to classify these chemicals as dangerous.⁷

Physical or Mechanical Trauma

Trauma to the erythrocyte in the peripheral circulation can cause the erythrocyte to fragment, producing striking abnormalities on the blood smear (schistocytes). In addition, splenomegaly can cause anemia by hypersequestration of erythrocytes.

Immune Mediated Cell Destruction

Antibodies or complement attached to the erythrocyte membrane sensitize the cell, and it is prematurely removed

by macrophages in the spleen or liver. This can be an autoimmune or alloimmune process or can be drug induced.

CASE STUDY (continued from earlier in this chapter)

- The indirect AHG test (used to detect antibodies in patient's serum) on Sashi is positive. Her serum was tested with panel cells that revealed anti-Jk^b and anti-S alloantibodies and possible anti-K (antibodies against red cell antigens). Is this anemia due to an intrinsic or extrinsic erythrocyte defect?

Checkpoint! 3

Why is it helpful for the clinical laboratory professional to know the clinical history and suspected cause of a hemolytic anemia?

The next three chapters discuss these various kinds of hemolytic anemia. Note that many anemias, although not primarily hemolytic, have a hemolytic component. These include the hemoglobinopathies, thalassemia, iron-deficiency anemia, and megaloblastic anemia.

SUMMARY

Hemolytic anemias are characterized by decreased erythrocyte survival. Hemolysis can be caused by an intrinsic erythrocyte abnormality or an abnormality extrinsic to the cell. Intrinsic abnormalities are generally inherited and include defects in the cell's membrane, hemoglobin, or enzymes. Extrinsic abnormalities are generally acquired. These include hemolysis due to factors in the erythrocyte environment such as drugs, toxins, antibodies, complement, and physical or mechanical trauma to the erythrocyte.

Laboratory findings in hemolytic anemia reflect increased bone marrow production as well as increased erythrocyte destruction. Reticulocytosis, increased IRF, erythroid hyperplasia of the bone marrow, and increased iron turnover, all signs of increased bone marrow activity, can be present. Findings associated with increased erythrocyte destruction include decreased haptoglobin, hemosiderinuria, hemoglobinuria, increased unconjugated serum bilirubin, increased LD, and increased urine and fecal urobilinogen. Schistocytes are signs of intravascular erythrocyte trauma whereas spherocytes are indications that part of the cell's membrane has been removed by phagocytes. Hemolysis is usually extravascular but also can occur intravascularly. Laboratory test results can be used to help differentiate sites of hemolysis.

REVIEW QUESTIONS

LEVEL I

- Which of the following is characteristic of severe intravascular hemolysis? (Objective 3)
 - decreased bilirubin
 - increased hemopexin
 - decreased urobilinogen
 - decreased haptoglobin
- Hemolytic anemias caused by intrinsic erythrocyte abnormalities include: (Objective 5)
 - immune hemolytic anemia
 - hereditary spherocytosis
 - microangiopathic hemolytic anemia
 - thermal injury anemia
- Which of the following indicates that compensated hemolytic disease is present in a patient with hereditary spherocytosis? (Objective 2)
 - increased carboxyhemoglobin
 - normal hemoglobin
 - increased hemoglobin
 - decreased hemoglobin
- Which of the following is helpful in defining the presence of a hemolytic process? (Objective 1)
 - RPI >2
 - decreased IRF
 - reticulocytopenia
 - increased M:E ratio in bone marrow

LEVEL II

- A 2-year-old child was seen by his physician for pallor and an enlarged abdomen. Results of laboratory tests showed a severe anemia. Family history revealed a mother and maternal uncle who had lifelong anemia. Further testing revealed the child had thalassemia. This anemia is an example of an: (Objective 3)
 - extrinsic erythrocyte defect
 - erythrocyte enzyme defect
 - intrinsic erythrocyte defect
 - acquired hemolytic anemia
- Which of the following findings are characteristic of the bone marrow in a hemolytic anemia? (Objective 3)
 - erythroid hyperplasia
 - increased M:E ratio
 - increased amount of fat
 - hypoplasia
- A patient is suspected of having an autoimmune hemolytic anemia. Many spherocytes are present on the blood smear, and the reticulocyte count is 20%. What test should be done to determine whether this is an autoimmune process? (Objective 4)
 - serum bilirubin
 - serum LD
 - urinalysis
 - AHG (DAT) test

REVIEW QUESTIONS (continued)

LEVEL I

5. This clinical finding is common in a patient with hemolytic anemia. (Objective 4)
- pica
 - kidney stones
 - jaundice
 - lymph node enlargement

LEVEL II

4. A 4-year-old boy has thalassemia. His x-rays reveal thinning cortical bone, and he had splenomegaly. This diagnosis and clinical symptoms indicate: (Objective 1)
- a chronic hemolytic process
 - an acute hemolytic anemia
 - intravascular hemolysis
 - extravascular hemolysis
5. A 50-year-old male has a hemoglobin of 8 g/dL. The serum bilirubin is elevated, and schistocytes are on the blood smear. Microangiopathic hemolytic anemia is suspected. What laboratory test would assist in determining whether intravascular hemolysis is present? (Objective 2)
- serum bilirubin
 - haptoglobin level
 - reticulocyte count
 - amount of CO exhaled

ANSWERS TO CASE STUDY QUESTIONS

Case Summary: Sashi had a severe drop in her hemoglobin after pancreatic surgery. Thinking that she was bleeding internally, the physician was ready to take her back to surgery. Laboratory tests revealed a high reticulocyte count indicating that her bone marrow was producing erythrocytes at an accelerated rate. Her bilirubin was increased indicating accelerated hemolysis. The blood smear revealed the presence of spherocytes, which suggests cell membrane damage and grooming by the spleen. Patient history revealed that the patient had received multiple transfusions for previous illness as well as several units during this hospitalization. Workup for a delayed transfusion reaction revealed the presence of alloantibodies and suggested that the spherocytes were due to antigen–antibody complexes on the cell membrane. Based on laboratory results, the decision was made that the patient was not bleeding internally but that her low hemoglobin was due to extravascular hemolysis of red cells.

Question:

1. What type of anemia is suggested by the laboratory results and clinical history?

Explanation:

Decreased survival is suggested by the laboratory results. This is most probably an immune hemolytic anemia because spherocytes are present. The bone marrow's production of cells is increased as indicated by reticulocytosis ($285 \times 10^9/L$, RPI >2).

Question:

2. Do the laboratory test results indicate intravascular or extravascular hemolysis? Explain.

Explanation:

It is extravascular as suggested by laboratory results and presence of spherocytes on the blood smear. The haptoglobin is probably decreased because of severity of hemolysis.

Question:

3. Is this anemia due to an intrinsic or extrinsic erythrocyte defect?

Explanation:

It is extrinsic. Patient history suggests an acquired defect. Presence of spherocytes, a positive DAT, and presence of antibodies suggest immune hemolytic anemia, probably as a result of the transfusions given.

ANSWERS TO CHECKPOINTS

Checkpoint! 1

A patient is suspected of having a hemolytic disease. The reticulocyte count is increased, but the hemoglobin, serum bilirubin, and haptoglobin are within the normal range. Explain.

Answer

The patient may have compensated hemolytic disease, which explains the normal hemoglobin. Serum bilirubin is not a sensitive test for hemolysis and is not always increased in hemolytic disease. *Haptoglobin* is an acute phase reactant and may be normal if the patient has concurrent infection, inflammation, or malignancy.

Checkpoint! 2

Explain why it is helpful for the laboratory professional to know whether a particular hemolytic anemia is characterized by intravascular or extravascular hemolysis.

Answer

By knowing whether there is intravascular or extravascular hemolysis, one can recommend laboratory tests to help define the etiology of the

hemolysis and evaluate laboratory test results accordingly. Hemoglobinuria, hemoglobinemia, and hemosiderinuria are present only if there is intravascular hemolysis.

Checkpoint! 3

Why is it helpful for the laboratory professional to know the clinical history and suspected cause of a hemolytic anemia?

Answer

It will assist in making recommendations for reflex and confirmatory laboratory tests and evaluation of test results. For instance, a spherocytic hemolytic anemia could be due to an intrinsic erythrocyte abnormality (hereditary spherocytosis, HS) or to an immune process. HS is a chronic anemia and can often be found in other family members. Test follow-up for HS should include osmotic fragility. Testing to determine the deficient or defective protein include SDS-PAGE, densitometry, ELISA, PCR and flow cytometry. Immune hemolytic anemia is usually an acute problem. Follow-up for an immune hemolytic anemia is a DAT (AHG) test to confirm the presence of antibodies on the erythrocyte.

Hemolytic Anemia: Membrane Defects

Diana Cochran-Black, Ph.D.

■ OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. List the hereditary membrane disorders involved with erythrocyte skeletal protein abnormalities.
2. List the hereditary erythrocyte membrane disorders involved with abnormal membrane permeability.
3. Describe the pathophysiology and recognize laboratory features associated with hereditary spherocytosis, hereditary elliptocytosis, and hereditary pyropoikilocytosis.
4. Discuss the principle of the osmotic fragility test and interpret the results.
5. Describe the etiology, pathophysiology, and laboratory features of paroxysmal nocturnal hemoglobinuria (PNH).
6. Explain the principle of the sugar water (sucrose hemolysis) test and interpret its results.

■ OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. Differentiate the protein defects associated with each hereditary membrane defect discussed in the chapter.
2. Create a flow chart using laboratory tests to differentiate hereditary spherocytosis, elliptocytosis, pyropoikilocytosis, stomatocytosis syndromes, and paroxysmal nocturnal hemoglobinuria.
3. Explain the role of decay-accelerating factor (DAF) and membrane inhibitor of reactive lysis (MIRL) in PNH.
4. Explain the results of the sucrose hemolysis test and immunophenotyping to determine a diagnosis of paroxysmal nocturnal hemoglobinuria (PNH).
5. Evaluate a clinical case study and determine the type of membrane disorder present by correlating clinical history and laboratory features.

KEY TERMS

Cholecystitis
 Cholelithiasis
 Decay-accelerating factor (DAF)
 Exchange transfusion
 Hereditary elliptocytosis (HE)
 Hereditary pyropoikilocytosis (HPP)
 Hereditary spherocytosis (HS)
 Dehydrated hereditary stomatocytosis (DHS)
 Overhydrated hereditary stomatocytosis (OHS)
 Horizontal interactions
 Paroxysmal nocturnal hemoglobinuria (PNH)
 Rh null disease
 Spur cell anemia
 Vertical interactions

BACKGROUND BASICS

The information in this chapter builds on concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study.

Level I

- ▶ Describe the function, composition, and metabolism of the erythrocyte membrane.
- ▶ Identify the differences between extravascular and intravascular erythrocyte destruction.
- ▶ Describe the general clinical and laboratory features associated with hemolytic anemias.
- ▶ Calculate erythrocyte indices, recognize abnormal erythrocyte morphology, and list reference ranges for common hematology parameters.

Level II

- ▶ List the erythrocyte membrane proteins associated with cell deformability and permeability, and describe their involvement in horizontal and vertical interactions.

**CASE STUDY**

We will refer to this case study throughout the chapter. Jack, a 12-year-old male, was brought to his family physician for evaluation of right-upper-quadrant pain. He has a lifelong history of hemolytic and aplastic crises. Consider why this patient history is important in selecting and evaluating laboratory tests.

OVERVIEW

This chapter is a study of a group of hemolytic anemias that result from defects in the erythrocyte membrane. These defects include hereditary spherocytosis, hereditary elliptocytosis,

hereditary pyropoikilocytosis, overhydrated and dehydrated hereditary stomatocytosis, membrane lipid disorders, and paroxysmal nocturnal hemoglobinuria. The format for presentation of each of these disorders is pathophysiology, clinical features, laboratory findings, and therapy. Because these anemias are due to defects in the erythrocyte membrane, the reader should have a good understanding of the normal erythrocyte membrane structure before beginning.

INTRODUCTION

Erythrocyte life span can be significantly shortened if the cell is intrinsically defective (intracorpuscular defect). Hemolytic anemia has been associated with defective erythrocyte membranes, structurally abnormal hemoglobins (hemoglobinopathies), defective globin synthesis (thalassemias), and deficiencies of erythrocyte enzymes. Almost all of these defects are hereditary. The hemoglobinopathies and thalassemias, which have a significant hemolytic component, have been discussed previously. This chapter includes the hemolytic anemias due to membrane defects.

An erythrocyte membrane that is normal in both structure and function is essential to the survival of the cell. Composed of proteins and lipids, the membrane is responsible for maintaining stability and the normal discoid shape of the cell, preserving cell deformability, and retaining selective permeability.

MEMBRANE DEFECTS

Hemolytic anemia can result from abnormalities in constituent membrane proteins or lipids, both of which can alter the membrane's stability, shape, deformability, and/or permeability. The abnormal cells are particularly susceptible to entrapment in the splenic cords. Anemia results when the rate of hemolysis is increased to the point at which the bone marrow cannot adequately compensate. Most hemolysis associated with abnormal membranes is extravascular, occurring primarily in the splenic cords.

SKELETAL PROTEIN ABNORMALITIES

The membrane protein and lipid interactions associated with abnormal erythrocyte membranes can be divided into two categories, vertical and horizontal¹ (Figure 1 ■; Table 1 ✎).

Vertical Interactions

Vertical interactions are perpendicular to the plane of the erythrocyte membrane and include interactions between

FIGURE 1 Pathobiology of the red cell lesions in hereditary red blood cell membrane defects. Vertical interactions of membrane lipids and proteins are perpendicular to the plane of the membrane. These interactions stabilize the lipid bilayer. Deficiencies of spectrin, ankyrin (2.1), or band 3 protein causes decoupling of the lipid bilayer from the underlying skeletal lattice and subsequent membrane loss in the form of microvesicles. This leads to the formation of spherocytes (hereditary spherocytosis). Horizontal interactions are parallel to the plane of the membrane. These interactions provide mechanical stability to the membrane. Horizontal defects include abnormal spectrin heterodimer association to form tetramers and defective skeletal protein interactions of junctional complexes at the end of the spectrin tetramers (spectrin, actin, protein 4.1) Horizontal defects result in fragmentation of the red blood cell. (Hereditary elliptocytosis, hereditary pyropoikilocytosis). Sp = spectrin; GP = glycoprotein; SpD-D = spectrin dimer dimer. (This figure was published in *Seminars in Hematology*, vol 30, Palek J, Jarolim P, Clinical expression and laboratory detection of red blood cell membrane protein mutations, p. 249–83. Copyright Elsevier. 1993. Used with permission.)

the skeletal lattice on the cytoplasmic side of the membrane and its attachment to the integral proteins and lipids of the membrane. These interactions stabilize the lipid bilayer membrane. Defects in vertical contacts between the skeletal lattice proteins and the membrane's integral proteins and

lipids cause uncoupling of the lipid bilayer from the underlying skeletal lattice, causing a selective loss of portions of the lipid bilayer. The net loss of cell membrane results in a decrease in the surface area-to-volume ratio, the formation of a spherocyte, and the eventual hemolysis of the cell. The skeletal lattice, however, is not disrupted, and the cell is mechanically stable. The genetic defects associated with the vertical protein interaction of the red cell membrane are listed in Table 1.

TABLE 1

Protein Mutations in the Erythrocyte Membrane That Result in Vertical or Horizontal Interaction Defects and Cause Hemolytic Anemia

Interaction Defect	Causes
Vertical	Ankyrin
	Band 3
	Protein 4.2
	α-spectrin
	β-spectrin
Horizontal	Protein 4.1
	Glycophorin C
	α-spectrin β-spectrin

Horizontal Interactions

Horizontal interactions are parallel to the plane of the membrane and are important in the formation of the stress-supporting skeletal protein lattice. This lattice provides mechanical stability to the membrane. Horizontal interactions include spectrin heterodimer head-to-head association to form tetramers as well as skeletal protein interactions in the junctional complexes at the distal ends of spectrin tetramers (spectrin, actin, protein 4.1, glycoprotein C, and adducin contacts). Horizontal defects characterized by defects of the skeletal protein interactions beneath the lipid bilayer lead to disruption of the skeletal lattice and, consequently, membrane destabilization. This causes cell fragmentation with formation of poikilocytes.

LIPID COMPOSITION ABNORMALITIES

Disorders that affect the composition of the membrane lipid bilayer lead to the formation of acanthocytes. The erythrocyte membrane normally contains equal amounts of free cholesterol and phospholipids. Excess free plasma cholesterol in patients accumulates in the outer bilayer of the erythrocyte. It has been hypothesized that preferential expansion of the outer face of the lipid bilayer in comparison to the inner face leads to formation of acanthocytes as the spleen attempts to remodel the cell.² Acanthocytes are more spheroidal cells with sharp irregular projections and an absence of central pallor. These cells are poorly deformable and readily trapped in the spleen. A variety of conditions can lead to acanthocytosis.

Hemolytic anemias associated with the various membrane defects are listed in Table 2. In general, vertical interaction defects are characterized by the presence of spherocytes; horizontal defects are characterized by the presence of other types of poikilocytes; and lipid composition defects are characterized by the presence of acanthocytes.

CASE STUDY (continued from earlier in this chapter)

A CBC was ordered on the patient and the results follow:

WBC	$8.0 \times 10^9/L$
RBC	$4.0 \times 10^{12}/L$
Hgb	108 g/L
Hct	0.292 L/L
Platelets	$504 \times 10^9/L$

1. Calculate the erythrocyte indices.
2. Based on the calculated indices, describe the patient's red blood cells.

▶ HEREDITARY SPHEROCYTOSIS

Hereditary spherocytosis (HS) is a common inherited membrane disorder that affects 1 in 2000 northern Europeans. In about two-thirds of patients, the disease is inherited in an autosomal-dominant fashion.³ De novo mutations

TABLE 2

Hemolytic Anemias Associated with Erythrocyte Membrane Defects

Disorder	Inheritance Pattern	Membrane Defect	Abnormal Membrane Function	Erythrocyte Morphology
Hereditary spherocytosis (HS)	Usually autosomal dominant; autosomal recessive; de novo mutations	Ankyrin and spectrin deficiency or deficiencies of band 3 and protein 4.2	Defective vertical protein interaction between RBC skeleton and membrane; loss of lipid bilayer and subsequent formation of a spherocyte with decreased deformability; abnormal permeability to Na^+	Spherocytes
Hereditary elliptocytosis (HE)	Autosomal dominant or rare de novo mutation; Melanesian variant is autosomal recessive	Defective spectrin Deficiency or defect in band 4.1 Abnormal integral proteins	Defect in horizontal protein interactions resulting in membrane instability; also can be a defect in permeability	Elliptocytes
Hereditary pyropoikilocytosis (HPP)	Autosomal recessive	Two defects: Partial spectrin deficiency and presence of a mutant spectrin	Defect in horizontal protein interactions resulting in membrane instability	Schistocytes, elliptocytes, and microspherocytes
Overhydrated hereditary stomatocytosis	Autosomal dominant	Unknown	Abnormally permeable to Na^+ and K^+ ; overhydration and swelling; decreased deformability	Stomatocytes
Dehydrated hereditary stomatocytosis	Autosomal dominant	Unknown	Abnormally permeable resulting in loss of K^+ ; water loss; decreased deformability	Target cells
Acanthocytosis (abetalipoproteinemia)	Autosomal recessive	Increased sphingomyelin, which can be secondary to abnormal plasma lipid composition	Expansion of outer lipid layer causes abnormal shape; increased membrane viscosity and decreased fluidity/deformability	Acanthocytes
Paroxysmal nocturnal hemoglobinuria (PNH)	Acquired	Deficiency of DAF and MIRL	Increased sensitivity to complement lysis	Normocytic or macrocytic; microcytic, hypochromic if iron deficient

DAF = decay-accelerating factor; MIRL = membrane inhibitor of reactive lysis

account for about one-half of sporadic cases⁴ with the rest assumed to be caused by a recessive gene.

PATHOPHYSIOLOGY

Hereditary spherocytosis is a clinically heterogeneous disorder characterized by mild to moderate hemolysis. The erythrocytes in this disorder are deficient in spectrin and are abnormally permeable to Na^+ . These features lead to erythrocytes that have problems with both deformability and permeability.

The membrane defect in hereditary spherocytosis is a disorder of vertical protein interactions most often characterized by a combined deficiency of spectrin and ankyrin, although there is considerable genetic heterogeneity at the molecular level.^{5,6} The spectrin deficiency can be a primary deficiency of spectrin or a secondary deficiency due to defective attachment of the skeleton to the lipid bilayer. Defective attachment can occur as a result of mutations of ankyrin, α - or β -spectrin, protein 4.2, or band 3 protein.⁷⁻⁹

These defects in spectrin and ankyrin and their interactions with other skeletal proteins result in a weakening of the vertical connections between the skeletal proteins and lipid bilayer membrane. The uncoupling between the inner membrane skeleton and outer lipid bilayer leads to the shedding of the lipid bilayer in the form of microvesicles.³ Secondary to membrane loss, the cell has a decreased surface-area-to-volume ratio, changing the morphology of the cell from a discocyte to a spherocyte. The most spheroidal cells have a greatly increased cytoplasmic viscosity. The spheroidal shape and increased viscosity result in reduced cellular flexibility. Reticulocytes in HS are normal in shape, emphasizing the fact that erythrocytes lose their membrane fragments after encountering the stress of the circulation.

In addition to the abnormal cytoskeleton of HS erythrocytes, other membrane abnormalities may be present. The total lipids in the HS erythrocyte membrane is decreased both before and after splenectomy. Although the organization of lipids in the membrane is known to affect membrane fluidity, an association between abnormal fluidity and HS erythrocytes has not been established. The HS erythrocytes also are abnormally permeable to sodium, causing an influx of Na^+ at 10 times the normal rate.¹⁰ An increase in the activity of the cation pump can compensate for the leak if adequate glucose is available for ATP production. The increased permeability is probably related to a functional abnormality of the membrane proteins.

The spherocytic shape, increased cytoplasmic viscosity, and increased membrane permeability account for the eventual destruction of HS cells in the spleen. Spherocytes lack the flexibility of normal cells, causing them to become trapped in the splenic cords. In this environment of very low glucose concentrations, the cell quickly runs out of the ATP needed to pump out excess Na^+ . As energy production ceases, splenic macrophages destroy the metabolically stressed cells.

CLINICAL FINDINGS

The clinical severity of HS varies among families and even among patients in the same family. About 25% of the patients have compensated hemolytic disease, no anemia, little or no jaundice, and only slight splenomegaly. In contrast, the disease can be lethal for some patients, especially in those homozygous for dominant HS. Most patients, however, develop a partially compensated hemolytic anemia in childhood and appear asymptomatic. HS in some asymptomatic individuals can be detected only when family studies are done on patients with more severe forms of the disease. Intermittent jaundice can occur. The jaundice is especially apparent during viral infections. Splenomegaly is present in about 50% of affected infants increasing to 75–95% in older children and adults. Aplastic crisis is a life-threatening complication that can occur in childhood during or following a viral infection. Untreated older patients commonly develop pigment bile stones from excess bilirubin catabolism (**cholelithiasis**). These patients also are predisposed to **cholecystitis**.

LABORATORY FINDINGS

Hemoglobin levels in patients with HS can be normal or decreased, varying directly with the age of the individual upon presentation of symptoms. Infants have the lowest values, 8–11 g/dL. Older children usually have concentrations above 10 g/dL. The reticulocyte count is usually more than 8%. The diagnosis of hereditary spherocytosis is suspected with the finding of many densely stained spherocytic cells with a decreased diameter and increased polychromasia on the blood smear (Figure 2■). Small, dense microspherocytes with a decreased MCV and increased MCHC also can be found. The number of microspherocytes varies considerably, and microspherocytes might not be prominent in 20–25% of

■ **FIGURE 2** Peripheral blood from a patient with hereditary spherocytosis shows the presence of many densely staining spherocytes. (Peripheral blood; Wright-Giemsa stain; 1000 \times magnification)

patients. In mild forms of HS, the changes in erythrocyte morphology can be too subtle to detect even by experienced hematologists. Nucleated erythrocytes can be found in children with severe anemia.

When the inheritance pattern of HS cannot be established, HS must be distinguished from other conditions causing spherocytosis. Spherocytes also can be found in acquired immune hemolytic anemia (AIHA), but in HS, the spherocytes are more uniform in size and shape than in AIHA.

Erythrocyte indices are helpful in the diagnosis of HS. The MCV usually is normal or only slightly decreased (77–87 fL). If reticulocytosis is marked, the MCV can be increased. The MCH is normal, but the MCHC is generally more than 36 g/dL.¹¹ Spherocytes are the only erythrocytes with an increased MCHC. Modern generation blood analyzers utilizing laser or aperture impedance methodology are extremely sensitive in detecting erythrocytes with an MCHC of more than 41 g/dL (hyperhemoglobin).¹² These erythrocytes are typically spherocytes. This technology can detect even the mild forms of HS. It is important to remember that the indices can vary depending on iron and folate stores. Folate frequently becomes depleted in chronic hemolytic states.

As in other hemolytic states, the bone marrow demonstrates normoblastic erythroid hyperplasia with an increase in storage iron.

✓ Checkpoint! 1

List various factors related to changes in the erythrocyte that can lead to a decrease or increase in the MCV in hereditary spherocytosis.

Osmotic Fragility Test

The principal confirmation test in the diagnosis of HS, the osmotic fragility test, measures the erythrocyte’s resistance to hemolysis by osmotic stress, which depends primarily on the volume of the cell, the surface area, and its membrane function. Erythrocytes are incubated in varying concentrations of hypotonic sodium chloride (NaCl) solution. Because of their decreased surface-area-to-volume ratio, spherocytes are unable to expand as much as normal discoid shaped cells can. Very little fluid needs to be absorbed before the cells hemolyze. The spherocytes also may have increased membrane permeability, contributing to their increased fragility. Lysis of HS erythrocytes, therefore, begins at higher NaCl concentrations than normal cells. These HS cells are said to exhibit increased osmotic fragility.

The osmotic fragility test is not abnormal unless spherocytes constitute at least 1–2% of the erythrocyte population; thus, patients with mild HS can have a normal osmotic fragility. These cells, however, show marked abnormal hemolysis if the blood is incubated overnight (24 hours) at 37°C before it is added to the NaCl solution. Incubation increases the loss of erythrocyte surface area. Because of its increased sensitivity, this incubated osmotic

FIGURE 3 Graph depicting the osmotic fragility of normal cells, spherocytes, and cells from a patient with thalassemia. Spherocytes show an increased fragility with a shift to the left in the osmotic fragility curve, and the thalassemia cells show a decreased fragility with a shift to the right in the osmotic fragility curve. The decreased fragility in thalassemia is caused primarily by the presence of target cells.

fragility test is the most reliable diagnostic test for hereditary spherocytosis.

In most laboratories, the osmotic fragility test results are graphed to depict the degree of fragility in comparison to the normal state (Figure 3). A shift to the left of normal in the curve indicates increased osmotic fragility, whereas a shift to the right indicates decreased osmotic fragility (Table 3). Decreased osmotic fragility occurs in thalassemia, sickle cell anemia, and conditions associated with target cells.

★ TABLE 3

Example of Increased Osmotic Fragility

	Patient	Normal Control
Initial hemolysis	0.65% NaCl	0.45% NaCl
Complete hemolysis	0.45% NaCl	0.30% NaCl

✓ Checkpoint! 2

Interpret the results of the following osmotic fragility test:

	Patient	Control
Initial hemolysis	0.35% NaCl	0.45% NaCl
Complete hemolysis	0.25% NaCl	0.30% NaCl

Autohemolysis Test

The autohemolysis test also is used in the diagnosis of HS but does not have an advantage over the osmotic fragility test. It is of more value in differentiating various types of congenital, nonspherocytic hemolytic anemias. This test measures the degree of spontaneous hemolysis of blood incubated at 37°C. The degree of hemolysis depends on the integrity of the cell membrane and the adequacy of cell enzymes involved in glycolysis. Incubation of blood in vitro probably causes the alteration of membrane lipids. This alteration leads to a change in cell permeability and an increase in the utilization of both glucose and ATP.

In HS, autohemolysis is increased to between 5 and 25% at 24 hours (normal is 0.2–2.0%) and can increase to 75% at 48 hours. If glucose is added to the blood before incubation, hemolysis is significantly decreased. If large numbers of microspherocytes are present, hemolysis might not be corrected with glucose. Autohemolysis also is increased in the immune spherocytic anemias, but glucose does not usually affect the test results.

Other Lab Tests

Other laboratory tests including increased indirect serum bilirubin, and increased fecal urobilinogen reflect the usual findings of increased extravascular hemolysis. Lactic dehydrogenase (LD) can be increased, and haptoglobin levels are often decreased. The antihuman globulin (AHG) test is negative, a finding helpful in distinguishing HS from immune hemolytic anemias in which large numbers of spherocytes also are found. The AHG test detects antibodies or complement bound to erythrocytes in vivo (direct antiglobulin test, DAT) or free antibodies in the serum (indirect antiglobulin test, IAT). Immune hemolytic anemias are usually associated with a positive DAT.

IDENTIFICATION OF DEFICIENT MEMBRANE PROTEIN

To determine which erythrocyte membrane protein is deficient, initial studies usually include sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) followed by densitometric quantitation and enzyme linked immunosorbent assay (ELISA) techniques.¹¹ Genetic linkage analysis using PCR-based techniques can be used to determine a patient's precise molecular defect.² A test utilizing flow cytometry technology that can detect band 3 binding by the dye eosin-5-maleimide (EMA) has recently been introduced. This test is highly specific and sensitive for HS.¹³

THERAPY

Mild forms of HS do not require therapeutic intervention. Total or partial splenectomy is the standard treatment in patients with symptomatic hemolysis.^{14,15} This therapy corrects the anemia and hemolysis, but the basic membrane defect, however, remains, and spherocytes can still be found in the peripheral blood. Fragments of the unstable membrane are probably removed in the liver.

CASE STUDY (continued from page 311)

The patient's peripheral smear revealed numerous elliptocytes, spherocytes, teardrop cells, and micropoikilocytes.

3. What additional lab tests should be ordered?

▶ HEREDITARY ELLIPTOCYTOSIS

Hereditary elliptocytosis (HE) is inherited as an autosomal-dominant trait except for a rare Melanesian type that is inherited as a recessive trait. Worldwide, the incidence is 1 case per 2000–4000 individuals, although the true incidence is unknown because many patients with HE are asymptomatic.³ The disease is heterogeneous in the degree of hemolysis and in clinical severity. As its name indicates, the most prominent peripheral blood finding is an increase in oval and elongated erythrocytes (elliptocytes).

Three classifications of HE can be distinguished based on erythrocyte morphology:⁹ (1) common HE, (2) spherocytic HE (hemolytic ovalocytosis), and (3) stomatocytic HE, Melanesian ovalocytosis, or Southeast Asian ovalocytosis (SAO) (Table 4 ★).

PATHOPHYSIOLOGY

The abnormal erythrocyte shape in hereditary elliptocytosis is the result of a defect in one of the skeletal proteins. It is interesting to note that similar to HS, reticulocytes and nucle-

★ TABLE 4

Classification of Hereditary Elliptocytosis (HE) Based on Erythrocyte Morphology

Type of HE	Hemolysis	Erythrocyte Shape
Common HE	Variable; minimal to severe	Elliptocytes
Spherocytic HE (hemolytic ovalocytosis)	Present	Spherocytes and fat elliptocytes
Southeast Asian ovalocytosis (SAO) (stomatocytic HE; Melanesian ovalocytosis)	Mild or absent	Roundish elliptocytes that are also stomatocytic

ated erythrocytes in this disorder are normal in shape; therefore, the elliptical erythrocyte form is acquired in the circulation. In the microcirculation, erythrocytes are subjected to shear stress and normally acquire an elliptical shape. Normal erythrocytes, however, revert to a biconcave shape in the absence of the circulatory stress while HE erythrocytes remain in the elliptical shape. It is possible that the stress in the microcirculation causes disruption of the skeletal protein contacts in the membrane of HE erythrocytes that leads to the formation of new protein contacts that prevent HE erythrocytes from resuming the normal biconcave shape.

The principal defect involves horizontal membrane protein interactions. Evidence indicates that several different membrane protein defects can be linked to this disease:^{16,17}

1. decreased association of spectrin dimers to form tetramers due to defective spectrin chains
2. a deficiency or defect in band 4.1 that aids in binding spectrin to actin
3. abnormalities of the integral proteins including deficiency of glyophorin C and abnormal anion transport protein (band 3) with increased affinity to ankyrin (vertical interaction defect).

Each of these defects can lead to skeletal disruptions that can cause the cell to become elliptical in shape and/or fragment under the stresses of the circulation, depending on the extent of the defect. Mildly dysfunctional proteins cause only elliptocytosis whereas severely dysfunctional proteins cause membrane fragmentation in addition to elliptocytosis. Alteration in shape only does not appear to affect cell deformability, and the cells have a nearly normal life span. Elliptocytosis with membrane fragmentation, however, causes a decrease in cell surface area and reduced cell deformability. The life span of these cells is severely shortened.

In addition to membrane instability, HE erythrocytes are abnormally permeable to Na^+ . This altered permeability demands an increase in ATP to run the cation pump and maintain osmotic equilibrium. Cells detained in the spleen can quickly deplete their ATP and become osmotically fragile.

The defect in the SAO variant of HE is an abnormal band 3 protein rather than a defect in the cytoskeletal proteins under the lipid bilayer. There is a deletion of nine amino acids near the boundary of the membrane and cytoplasmic domains of the protein. This is associated with a tighter binding of band 3 to ankyrin, a lack of transport of sulfate anions, and a restriction in the lateral and rotational mobility of band 3 protein within the membrane. As a result, these erythrocytes are very rigid.⁹

CLINICAL FINDINGS

Ninety percent of patients with HE show no overt signs of hemolysis. Although erythrocyte survival can be decreased, the hemolysis is usually mild and well compensated for by the bone marrow (compensated hemolytic disease). Anemia is not characteristic.

Common HE is rare in the Western population but more common in blacks, particularly in equatorial Africa. The severity ranges from asymptomatic to severe clinical disease. There can be minimal hemolysis and only mild elliptocytosis (15%) or severe hemolysis with cell fragmentation and formation of poikilocytes.

A variant of common HE noted in black infants is associated with a moderately severe anemia at birth and neonatal jaundice. The peripheral blood smear exhibits erythrocytes similar to those seen in hereditary pyropoikilocytosis with budding and fragile bizarre poikilocytes. Variable numbers of elliptocytes are noted. Between 6 and 12 months of age, the hemolysis decreases, and the number of elliptocytes increases. One of the parents of affected infants has mild hereditary elliptocytosis.

The spherocytic HE variant constitutes a relatively rare form of HE characterized by the presence of hemolysis despite minimal changes in erythrocyte morphology. The erythrocytes have characteristics of both HS and HE cells: Some are spherocytic and others are fat elliptocytes.

The Southeast Asian variant of HE (SAO, stomatocytic HE) is characterized by a mild or absent hemolytic component. Erythrocyte cation permeability appears to be increased, and the expression of blood group antigens is muted. The elliptocytes are roundish and stomatocytic with one or two transverse bars or a longitudinal slit. Evidence indicates these cells can have more stable cytoskeletons than normal.¹⁶

The high prevalence of the SAO variety of HE in some parts of the world is related to the resistance of the HE erythrocytes to invasion by malarial parasites. The resistance can result from the abnormal rigidity of the erythrocyte membrane. This protection against malaria has led to natural selection of individuals with HE in areas of the world where malaria is endemic and, thus, the incidence of HE increases.^{18,19}

HE cells are poorly agglutinable with antisera against erythrocyte antigens. This is presumably the result of defective lateral movement and clustering of surface antigens associated with the abnormal band 3 protein. The laboratory scientist should be aware of this problem because it can interfere with testing of patients' cells in the blood bank.

LABORATORY FINDINGS

The most consistent and characteristic laboratory finding in all variants is prominent elliptocytosis (Figure 4■). Elliptocytes also can be found in association with other diseases, but elliptocytes in these conditions usually constitute less than 25% of the erythrocytes. Acquired elliptocytosis is seen in megaloblastic anemias and iron-deficiency anemia. In contrast, the elliptocytes in HE make up more than 25% of the erythrocytes and usually more than 60%. In the asymptomatic variety of HE, elliptocytes can be the only morphologic clue to the disease. Hemoglobin levels are usually higher than 12 g/dL. Reticulocytes are mildly elevated, up to about 4%.

FIGURE 4 Peripheral blood from a patient with nonhemolytic HE reveals almost 100% elliptocytes. (Peripheral blood; Wright-Giemsa stain; 1000× original magnification)

In the hemolytic HE variants, hemoglobin concentration is 9–10 g/dL, and reticulocytes are elevated to as high as 20%. Microelliptocytes, bizarre poikilocytes, schistocytes, and spherocytes are usually evident (Figure 5). The bone marrow shows erythroid hyperplasia with normal maturation.

The incubated and unincubated osmotic fragility tests and autohemolysis tests are usually abnormally increased in the overt hemolytic variants. However, the obvious blood picture suggests that there is no need to perform these tests.

THERAPY

The hemolytic variants of HE respond well to splenectomy. As in HS, splenectomy prevents hemolysis and protects the patient from complications of chronic hemolysis. The membrane defect, however, remains, and elliptocytes are still present. The asymptomatic variants require no therapy.

FIGURE 5 Blood smear from a patient with the hemolytic hereditary elliptocytosis. Schistocytes as well as elliptocytes are present. (Wright-Giemsa stain; 1000× original magnification)

✓ Checkpoint! 3

Why do the elliptocytes in HE demonstrate normal osmotic fragility?

🔍 CASE STUDY (continued from earlier in this chapter)

Jack's osmotic fragility test revealed the following:

	Patient	Control
Initial hemolysis	.65% NaCl	.45% NaCl
Complete hemolysis	.40% NaCl	.30% NaCl

4. Interpret the results of the osmotic fragility test.

▶ HEREDITARY PYROPOIKILOCYTOSIS (HPP)

Hereditary pyropoikilocytosis (HPP), a rare autosomal recessive disorder, is closely related to HE. Based on recent genetic and biochemical data, it has now been established that HPP is a severe subtype of HE.¹⁷ It occurs primarily in blacks, although it also has been diagnosed in Arabs and Caucasians.³ The disease presents in infancy or early childhood as a severe hemolytic anemia with extreme poikilocytosis. The morphological similarities of erythrocytes in HPP and that of erythrocytes associated with thermal injury led investigators to examine the thermal stability of HPP cells. In contrast to normal erythrocytes that fragment at 49–50°C, HPP cell membranes fragment when heated to 45–46°C. In addition, pyropoikilocytes disintegrate when incubated at 37°C for more than 6 hours.

PATHOPHYSIOLOGY

The HPP cells have two defects with one inherited from each parent. One is related to a deficiency of α -spectrin and the other to the presence of a mutant spectrin that prevents self-association of heterodimers to tetradimers.¹⁶ The parent carrying the mutant spectrin trait either has mild HE or is asymptomatic. The other parent, with the deficiency of spectrin trait, is hematologically normal. The HPP phenotype also is found in patients who are homozygous or doubly heterozygous for one or two spectrin mutations characteristically found in HE trait.¹⁶ The defects lead to a disruption of the membrane skeletal lattice and cell destabilization followed by erythrocyte fragmentation and poikilocytosis.⁹ Poikilocytes are removed in the spleen.

CLINICAL FINDINGS

Clinical features consistent with a hemolytic anemia are present at birth. Hyperbilirubinemia requiring **exchange transfusion** (a procedure involving simultaneous withdrawal of blood and infusion with compatible blood) or

■ **FIGURE 6** Peripheral blood from a patient with hereditary pyropoikilocytosis. (Peripheral blood; Wright-Giemsa stain; 1000× original magnification)

phototherapy (therapeutic exposure to sunlight or artificial light) is present.¹⁶ Laboratory serologic studies for hemolytic disease of the newborn, however, are negative.

LABORATORY FINDINGS

Stained blood smears exhibit striking erythrocyte morphologic abnormalities including budding, fragments, microspherocytes (2–4 fL), elliptocytes, triangulocytes (fragmented erythrocytes that are triangle shaped), and other bizarre erythrocyte shapes (Figure 6 ■). The MCV is decreased (25–55 fL), most likely as a result of the many erythrocyte fragments. The osmotic fragility is abnormal, especially after incubation, and the thermal sensitivity test demonstrates an increase in erythrocyte fragmentation (Figure 7 ■). Autohemolysis is increased and the hemolysis is not corrected with glucose.

■ **FIGURE 7** Peripheral blood from a patient with hereditary pyropoikilocytosis (in Figure 6). Smear made after incubation of blood for 10 minutes at 46°C. (Peripheral blood; Wright-Giemsa stain; 1000× original magnification)

THERAPY

Patients show improvement after splenectomy, but the membrane defect remains, and fragmented erythrocytes are still present.

CASE STUDY (continued from previous page)

A thermal sensitivity test demonstrated that Jack's erythrocytes fragment when incubated for 10 minutes at 46°C.

5. What do the results of the thermal sensitivity test reveal about the patient's red blood cells?

Checkpoint! 4

Interpret the results of the following thermal sensitivity test:

Patient's erythrocytes	Marked erythrocyte fragmentation after 10-minute incubation at 46°C
Normal control	No significant change in erythrocyte morphology after 10-minute incubation at 46°C

▶ HEREDITARY STOMATOCYTOSIS SYNDROMES

The hereditary stomatocytosis syndromes are rare autosomal dominant hemolytic anemias in which the erythrocyte membrane exhibits abnormalities in cation permeability.¹ These syndromes include **overhydrated hereditary stomatocytosis (OHS)** and **dehydrated hereditary stomatocytosis (DHS)** (formally known as hereditary xerocytosis). The red cell membrane in OHS is abnormally permeable to both Na^+ and K^+ . The net gain of Na^+ ions is more than the net loss of K^+ ions because the capacity of the cation pump (fueled by ATP derived from glycolysis) to maintain normal intracellular osmolality is exceeded. As a result, the intracellular concentration of cations increases, water enters the cell, and the overhydrated cells take on the appearance of stomatocytes. Stomatocytes (hydrocytes) on dried, stained blood films are erythrocytes with a slitlike (mouthlike) area of pallor (Figure 8 ■). These cells are uniconcave and appear bowl shaped on wet preparations.

The primary defect in DHS is a net loss of intracellular K^+ that exceeds the passive Na^+ influx and thus net intracellular cation and water content are decreased. Consequently, the cell dehydrates and the cells appear targeted or contracted and spiculated.¹²

PATHOPHYSIOLOGY

The specific membrane defect for OHS and DHS has not been identified. Patients with OHS demonstrate a deficiency of stomatin, an integral red cell membrane protein, which is secondary to an unknown protein mutation.^{1,20}

■ **FIGURE 8** This peripheral blood picture from a patient with hereditary overhydrated stomatocytosis reveals erythrocytes with slitlike or mouthlike (stoma = mouth) areas of pallor. (Peripheral blood; Wright-Giemsa stain; 1000× magnification)

Abnormalities of erythrocyte lipids have been demonstrated to induce stomatocytosis with impaired sodium transport. However, stomatocytosis also occurs when membrane lipids are normal. In these cases, membrane proteins can be abnormal. Although membrane proteins are usually electrophoretically normal, there can be an alteration in their conformation. A deficiency in band 7 proteins has been described.

From the variability of clinical findings, laboratory results, and response to splenectomy, these disorders appear to be caused by several different membrane defects. Some patients have marked stomatocytosis but no abnormal sodium transport. Up to one-third of patients with stomatocytosis do not have overt hemolysis.^{21,22} **Rh null disease** (a disorder associated with the lack of Rh antigen on erythrocytes) also is associated with the presence of stomatocytes.²³ The association between a lack of the Rh complex and the membrane abnormality has not been explained.

The stomatocytic cells in OHS are osmotically fragile and less deformable than normal cells, and, as a result, the cells are sequestered in the spleen where glucose supplies are readily exhausted. As the ATP levels fall, the cation pump is unable to maintain osmotic equilibrium, causing cell lysis or phagocytosis.

OHS must be differentiated from acquired stomatocytosis. Stomatocytes are seen as an acquired defect in acute alcoholism, liver disease, and cardiovascular disease. However, these acquired conditions, have no cation leaks, and little hemolysis is present.

The cells are dehydrated in DHS, which is reflected by an increased MCHC. As the MCHC of the cell increases beyond 37 g/dl, the cytoplasmic viscosity increases, and cellular deformability decreases. The rigid cells become trapped in the spleen.

LABORATORY FINDINGS

Anemia is usually mild to moderate with a hemoglobin concentration of 8–10 g/dL. Bilirubin is increased and reticulocytosis is moderate. The MCHC of the stomatocytes seen in OHS is decreased, and the MCV can be increased. The blood smear is remarkable for 10–50% stomatocytes. Osmotic fragility and autohemolysis are increased, and autohemolysis is partially corrected with glucose and ATP.

Target cells and erythrocytes that have hemoglobin puddled at the periphery are observed in DHS. The cells demonstrate a slightly increased MCV and decreased osmotic fragility.

THERAPY

Splenectomy is not a required therapeutic measure for OHS and DHS. In fact, this procedure is usually contraindicated because some patients have experienced catastrophic thrombotic episodes after splenectomy.^{1,24} Most patients are able to maintain an adequate hemoglobin level without this procedure.

✓ Checkpoint! 5

Determine the type of erythrocyte membrane disorder present based on the following lab results: retic count: 4%; osmotic fragility: increased; autohemolysis: increased; bilirubin: increased; peripheral smear: 30% stomatocytes present.

✓ Checkpoint! 6

Explain why the osmotic fragility is decreased in DHS.

▶ ABNORMAL MEMBRANE LIPID COMPOSITION: ACANTHOCYTOSIS

Acanthocytosis is most often associated with acquired or inherited abnormalities of the membrane lipids. This occurs in liver disease and in a rare inherited condition, *abeta-lipoproteinemia*. Although the mature cell has no capacity for de novo synthesis (new synthesis) of lipids or proteins, the lipids of the membrane continually exchange with plasma lipids. Thus, erythrocytes can acquire excess lipids when the concentration of plasma lipids increases. Excess membrane lipids expand the membrane surface area and cause the cell to acquire abnormal shapes, including target cells (codocytes), leptocytes, or acanthocytes. If portions of the membrane are lost due to “grooming” of excess lipids in the spleen or if the membrane’s lipid viscosity increases, the cells lose their ability to deform and are sequestered in the spleen. On the other hand, a significant decrease in one or more lipids in

the cell membrane can also lead to increased destruction. The rare hereditary forms of acanthocytosis also can result from abnormal proteins.

SPUR CELL ANEMIA

Spur cell anemia is an acquired hemolytic condition associated with severe hepatocellular disease such as cirrhosis in which serum lipoproteins increase, leading to an excess of erythrocyte membrane cholesterol. The total phospholipid content of the membrane, however, is normal. As the membrane ratio of cholesterol to phospholipid increases, the cell becomes flattened (leptocyte) with a scalloped edge. The increased cholesterol to phospholipid ratio also causes a decrease in membrane fluidity and an associated decrease in cell deformability. During repeated splenic passage or conditioning, membrane fragments are lost, and the cell acquires irregular spikelike projections typical of acanthocytes (spur cells). Eventually, the cell is hemolyzed. In patients with cirrhosis, this hemolysis is enhanced by congestive splenomegaly.

The peripheral blood shows a moderate to severe normocytic, normochromic anemia with a hemoglobin concentration of 5–10 g/dL. Reticulocytes are increased to 5–15%. Approximately 20–80% of the erythrocytes are acanthocytes (Figure 9■). On the peripheral blood smear, acanthocytes must be distinguished from echinocytes (burr cells) and keratocytes. (Echinocytes have regular, small, spiny projections throughout the cell membrane; keratocytes have just a few large surface projections.) Spherocytes and echinocytes can also be found. An increase in indirect bilirubin and liver enzymes and a decrease in serum albumin reflect evidence of liver disease.

Studies with transfused cells have shown that spur cells acquire their shape as innocent by-standers and that when

normal cells are transfused into the patient, they acquire the abnormal shape and are hemolyzed at the same rate as the patient's cells, suggesting that the diseased liver can contribute to the transformation of normal red cells into spur cells.²⁵

Biliary obstruction is often associated with the presence of normocytic or slightly macrocytic target cells that result from an acquired excess of lipids on the cell membrane. However, in contrast to the acanthocytes found in severe hepatocellular disease, the excess lipid on target cells associated with biliary obstruction includes an increase in both cholesterol and phospholipids in a ratio similar to that of normal cells. As a result, lipid viscosity and membrane deformability are normal. These target cells have a normal survival.

ABETALIPOPROTEINEMIA (HEREDITARY ACANTHOCYTOSIS)

This rare autosomal recessive disorder is characterized by the absence of serum β -lipoprotein, low serum cholesterol, low triglyceride, and low phospholipid and an increase in the ratio of cholesterol to phospholipid.^{26,27} The primary abnormality is the defective synthesis of apoprotein B, a microsomal triglyceride transfer protein. Mutations in band 3 protein of the erythrocyte membrane that alters band 3 conformation have also been described in hereditary acanthocytosis.^{28,29} Acanthocytes are typically found, but hemolysis is minimal with little or no anemia. Reticulocytes are usually normal but can be slightly increased. The acanthocytes have normal cholesterol levels, but lecithin decreases and sphingomyelin increases. This is in contrast to spur cells found in severe liver disease, which have increased membrane cholesterol. Membrane fluidity is decreased, presumably because of the increase in sphingomyelin, which is less fluid than other phospholipids. The degree of distortion of erythrocytes increases with cell age. The acanthocytes have normal membrane permeability, normal glucose metabolism, and normal osmotic fragility. Autohemolysis at 48 hours is increased and only partially corrected by glucose. In addition to hypolipidemia, the disorder is characterized by steatorrhea, retinitis pigmentosa, and neurological abnormalities. Transport of fat soluble vitamins (A, D, E, K) is impaired, and prothrombin time can be increased due to decreased vitamin K stores.

LECITHIN-CHOLESTEROL ACYL TRANSFERASE (LCAT) DEFICIENCY

This rare autosomal recessive disorder affects metabolism of high-density lipoproteins. Onset is usually during young adulthood. The disorder is characterized by a deficiency of LCAT, the enzyme that catalyzes the formation of cholesterol esters from cholesterol. As a result, patients with this deficiency demonstrate low levels of high-density

■ **FIGURE 9** Spur cell anemia in a patient with alcoholic cirrhosis. Note the echinocytes and acanthocytes (spur cells). Spherocytes are also present. (Peripheral blood; Wright-Giemsa stain; 1000 \times magnification)

lipoprotein (HDL) and low-density lipoprotein (LDL) and elevated levels of very low-density lipoproteins (VLDL) and lipoprotein X.³⁰ Because erythrocyte membrane cholesterol is in a comparatively rapid equilibrium with unesterified plasma cholesterol, the activity of LCAT indirectly regulates the amount of free cholesterol in the cell. The most characteristic hematologic findings include a mild hemolytic anemia marked by the presence of numerous target cells. The target cells are loaded with cholesterol. LCAT activity is decreased in most patients with spur cells and target cells, but the relationship to lipid abnormalities of the membrane is not known.

RARE FORMS

The rare forms of acanthocytosis associated with abnormalities of membrane proteins include the McLeod phenotype with a deficiency of Kx substance and the K antigen, chorea-acanthocytosis syndrome, and acanthocytosis with band 3 protein abnormalities.

✓ Checkpoint! 7

Compare the membrane lipid abnormalities seen in LCAT deficiency, spur cell anemia, and abetalipoproteinemia, and explain how they result in hemolysis of the cell.

▶ PAROXYSMAL NOCTURNAL HEMOGLOBINURIA (PNH)

All erythrocyte membrane disorders discussed so far are hereditary in nature except spur cell anemia. **Paroxysmal nocturnal hemoglobinuria (PNH)** is a rare acquired disorder of the erythrocyte membrane. The membrane defect makes the cell abnormally sensitive to lysis by complement. The disease derives its name from the classic pattern of intermittent bouts of intravascular hemolysis and nocturnal hemoglobinuria. The condition is exacerbated during sleep and remits during the day. However, many patients have chronic hemolysis that is not associated with sleep and with no obvious hemoglobinuria.

PATHOPHYSIOLOGY

An intrinsic erythrocyte disorder, PNH results from an acquired stem cell somatic mutation that leads to an abnormal clone of differentiated hematopoietic cells. The abnormal stem cell clone produces erythrocytes, platelets, and neutrophils that bind abnormally large amounts of complement and that are abnormally sensitive to complement lysis. Complement is composed of at least 20 proteins responsible for a variety of biologic activities. These proteins are abbreviated as C1, C2, C3, etc. They normally circulate in an inac-

tive form. Under some circumstances, complement components are activated. If the components attach to the erythrocyte membrane and are activated, the cell can be hemolyzed.

The susceptibility of PNH cells to complement-induced lysis is related to deficient regulation of complement activation. At least two regulatory proteins found on normal cell membranes are responsible for preventing amplification of complement activation. The first, **decay-accelerating factor (DAF)** (CD55), a complement regulatory protein that amplifies the decay of C3 convertase, accelerates decay (dissociation) of membrane-bound C3bBb, and thus prevents amplification of C3 convertase and activation of other complement components. Membrane inhibitor of reactive lysis (MIRL) (CD59) is the second regulatory protein that is deficient on PNH erythrocytes.³¹ Its major role is to prevent the interaction between C8 and C9, and it thus interferes with the formation of membrane attack complex (MAC) (the final steps of complement activation). These regulating factors help normal cells avoid lysis by autologous complement. Lack of DAF and MIRL on PNH cells is causally related to excessive sensitivity of these cells to complement.³¹

Evidence suggests that deficiency of DAF and MIRL in PNH is not due to lack of production of these proteins but to the absence of a membrane glycolipid that serves as an anchor that attaches these proteins to the cell membrane. Other proteins anchored to the cell membrane in a similar manner also are deficient on hematopoietic cells in PNH. It appears that the common link to these membrane protein deficiencies is the lack of the glycolipid anchoring structure. This anchor has been identified as glycosyl-phosphatidyl inositol (GPI), a molecule embedded in the cell membrane that is important for the covalent linkage of a wide variety of proteins to the cell membrane. These GPI-linked proteins vary in structure and function. They include adhesion molecules, hydrolases, and receptors.³¹

The GPI-anchoring deficiency is due to a somatic mutation of the *PIGA* gene,³² which encodes an enzyme (phosphatidyl inositol glycan Class A) essential for synthesis of the GPI anchor. More than one hundred PIG-A mutations have been identified.³³ Analysis of stem cells in the bone marrow indicates that hematopoietic progenitor cells are affected by the genetic defect. Although not understood, the mutated progenitor cell has a proliferative advantage in the bone marrow. Before the genetic mutation discovery, evidence that PNH was a clonal disease came from the finding that all blood cell lines in the patient with PNH are deficient in DAF activity. This explains why many patients with PNH are not only anemic but also granulocytopenic and thrombocytopenic. The abnormal clone can appear after damage to the marrow or spontaneously (idiopathic). A significant number of patients with PNH have or eventually develop another clonal blood disorder such as acute nonlymphocytic leukemia, chronic lymphocytic leukemia, myeloproliferative disorder, or myelodysplastic syndrome.³⁴

The increased sensitivity of PNH cells to complement can be demonstrated to occur in vitro whether the complement is activated by the classic or the alternate pathway. In vivo, however, activation is probably by the alternate pathway.

CLINICAL FINDINGS

PNH occurs most often in adults but is occasionally found in children. The four basic disease mechanisms are hyperhemolysis, venous thrombosis, infection, and bone marrow hypoplasia.³⁵ The disease begins insidiously with irregular brisk episodes of acute intravascular hemolysis accompanied by hemoglobinuria. The patient usually seeks medical attention when reddish-brown urine is noted. In some patients, the irregular exacerbations of hemolysis are associated with sleep, hence the name *paroxysmal nocturnal hemoglobinuria*. In other patients, these hemolytic episodes can follow infections, transfusions, vaccinations, surgery, or ingestion of iron salts. In a large number of patients, hemolysis is unrelated to any specific event. Iron-deficiency anemia can occur due to the chronic blood loss through the kidneys. Renal functions can become abnormal as the result of chronic iron deposition. Folic acid deficiency can occur because of increased demand for this nutrient. Abdominal and lower back pain, eye pain, and headaches can occur during hemolytic episodes.

Even with moderate thrombocytopenia, venous thrombosis is a prominent and severe complication. Thrombosis is a common cause of death. Thrombotic events may be related to abnormal platelet or neutrophil function due to lack of GPI-anchored proteins.

When leukopenia is present, infections are common. Propensity for infection also can be related to the absence of granulocyte glycoproteins and altered response of granulocytes. Immunological abnormalities may be present.

LABORATORY FINDINGS

Most patients with PNH experience anemia with a hemoglobin concentration of 8–10 g/dL. The erythrocytes are normocytic or macrocytic but can appear microcytic and hypochromic if iron deficiency develops. Reticulocytes are increased (5–10%) but not to the extent expected for a hemolytic anemia. Nucleated red blood cells can be found on the blood smear. Isolated development of leukopenia and/ or thrombocytopenia often occurs during the course of the disease. Neutrophil alkaline phosphatase and erythrocyte acetylcholinesterase are decreased. Although hemoglobinuria can be intermittent or even mild, hemosiderinuria is a constant finding, indicating chronic intravascular hemolysis.

The bone marrow usually exhibits normoblastic hyperplasia but can be hypocellular. In some cases, marrow failure develops during the course of the disease. Interestingly, aplastic anemia can be the initial diagnosis with an abnormal clone of PNH cells developing during the course of the

disease (in up to 50% of patients with aplastic anemia). PNH rarely precedes aplastic anemia and should be considered as a diagnosis when hypoplastic anemia is found in association with hemolysis.³⁵ Bone marrow iron is decreased or absent.

The osmotic fragility is normal. Autohemolysis is increased after 48 hours, and when glucose is added, the hemolysis can increase even more. The DAT is negative for immunoglobulin (Ig) but can be positive for complement given the fact that PNH cells have a propensity to bind C3b.

The screening sucrose hemolysis (sugar-water) test is useful in identifying erythrocytes that are abnormally sensitive to complement lysis. The patient's blood is incubated in a sucrose solution. The sucrose provides a low-ionic-strength medium that promotes the binding of complement to the erythrocytes. PNH cells show hemolysis in this medium.

The Ham (acid-serum lysis) test is a more specific test for PNH cells, but laboratories have replaced it with immunophenotyping for confirmation of PNH. Immunophenotyping uses monoclonal antibodies directed against the GPI anchored molecules. When the GPI link is missing, these molecules are also missing. This technology can detect three types of cells in PNH related to the degree of deficiency of GPI-linked proteins on cell membranes:

- Type I Little or no hemolysis by complement; nearly normal GPI expression
- Type II Moderately sensitive to complement lysis; intermediate GPI expression
- Type III Highly sensitive to complement lysis; no expression of GPI

Because different hematopoietic cells display different kinds of GPI-anchored proteins, it is recommended that at least two different antibodies be used for a diagnosis of PNH (CD55, CD59, CD14). CD55 (DAF) and CD59 (MIRL) antibodies are used most frequently and are most attractive because they are involved in the complement pathway that leads to the hemolysis in PNH. PNH cells show low-intensity staining for these molecules. CD55 and CD59 are both normally found on neutrophils, and CD59 also is present on normal erythrocytes. CD14 is normally on monocytes, and some use it to verify PNH. Analyzing molecules that can be expressed on the membrane in a GPI-anchor form as well as a transmembrane form is not so useful because it can give false normal results.

The most accurate measurement of the PNH defect with immunophenotyping is performed using nucleated cells rather than erythrocytes because the patient with PNH often receives red blood cell transfusions. In addition, test results on erythrocytes might not be accurate because PNH type III erythrocytes have a shorter life span than do type I or II, thus underestimating type III erythrocyte concentration.

Recently a fluorochrome that binds to the GPI anchor itself, not to an attached protein, was developed.³⁶ This is a

more direct technique to detect GPI deficient cells and is more sensitive in detecting abnormal granulocyte populations.

✓ Checkpoint! 8

Explain why immunophenotyping with CD14, CD55, and CD59 is used to establish a diagnosis of PNH.

THERAPY

Treatment is primarily supportive in the form of transfusions, antibiotics, and anticoagulants. A humanized monoclonal antibody has shown to relieve the hemoglobinuria in PNH patients by inhibiting the formation of the membrane attack complex (MAC).³⁷ In patients with PNH-induced marrow aplasia, bone marrow transplantation may be indicated.

🌀 CASE STUDY (continued from earlier in this chapter)

This case study depicts a young man who presented with right-upper-quadrant pain. The complete blood count disclosed anemia with a decreased MCV and an increased MCHC. The peripheral blood smear revealed numerous elliptocytes, teardrop cells, and micropoikilocytes. The patient's erythrocytes demonstrated increased osmotic fragility and thermal sensitivity.

6. What disorder is suggested by the patient's lab findings?

SUMMARY

The erythrocyte life span can be significantly shortened if the erythrocyte has intrinsic defects such as an abnormal membrane, structurally abnormal hemoglobin, defective globin synthesis, or

deficient erythrocyte enzymes. These abnormalities are almost always inherited defects. When the bone marrow is unable to compensate, hemolytic anemia results.

Erythrocyte membrane defects can be caused by abnormalities of membrane proteins or lipids, which can affect cell deformability, stability, shape, and/or permeability. The abnormal erythrocytes become trapped in splenic cords and are removed from the circulation. Interactions between the skeletal lattice proteins and integral proteins and lipids of the membrane are vertical interactions that when disrupted cause a reduced density of spectrin and uncoupling of the lipid bilayer. This causes selective loss of lipid bilayer and formation of spherocytes. Skeletal lattice proteins interact horizontally to form the stress-supporting skeletal protein lattice. Defects in these proteins result in the cell's mechanical instability and fragmentation. Inherited defects in membrane proteins produce the hereditary hemolytic anemias including hereditary spherocytosis, hereditary elliptocytosis, and hereditary pyropoikilocytosis. Abnormally permeable membranes can cause hereditary overhydrated and dehydrated stomatocytosis, but the specific abnormality of the membrane in these two disorders has not been definitively identified. Abnormalities in the lipid portion of the membrane can be inherited or acquired. These disorders result in the formation of acanthocytes.

Paroxysmal nocturnal hemoglobinuria (PNH), a stem cell disorder, is an acquired membrane abnormality in which complement-mediated destruction of the cell occurs. The defect is due to a lack of decay-accelerating factor (DAF) and membrane inhibitor of reactive lysis (MIRL) on the erythrocytes, secondary to the absence of a membrane glycolipid, glycosyl-phosphatidyl inositol (GPI) to anchor these proteins to the cell membrane. Hemolysis is intravascular, resulting in hemoglobinuria and decreased haptoglobin. Leukopenia and thrombocytopenia are common because these cells also are susceptible to complement destruction. The sucrose hemolysis test is a screening test for PNH. Although the Ham test was used in the past, immunophenotyping is now the standard technology for confirming a diagnosis of PNH.

REVIEW QUESTIONS

LEVEL I

1. What is the most common type of erythrocyte found in hereditary spherocytosis? (Objectives 1, 3)
 - a. spherocyte
 - b. acanthocyte
 - c. schistocyte
 - d. elliptocyte
2. What erythrocyte membrane disorder has erythrocytes that are thermally unstable and fragment when heated to 45–46°C? (Objectives 1, 3)
 - a. hereditary spherocytosis
 - b. hereditary elliptocytosis
 - c. hereditary pyropoikilocytosis
 - d. PNH

LEVEL II

1. Which of the following is the red blood cell membrane protein defect associated with hereditary pyropoikilocytosis? (Objective 1)
 - a. deficiency of band 3
 - b. defective ankyrin protein
 - c. mutant spectrin
 - d. excess cholesterol

REVIEW QUESTIONS (continued)

LEVEL I

3. Choose the principal confirmation test for a diagnosis of hereditary spherocytosis. (Objective 3)
 - a. autohemolysis test
 - b. sucrose hemolysis test
 - c. thermal stability test
 - d. osmotic fragility test
4. Erythrocyte membrane disorders associated with known skeletal protein mutations include all of the following *except*: (Objective 1)
 - a. hereditary spherocytosis
 - b. hereditary overhydrated stomatocytosis
 - c. hereditary elliptocytosis
 - d. hereditary pyropoikilocytosis
5. Which of the following erythrocyte disorders is associated with abnormal membrane permeability? (Objective 2)
 - a. hereditary elliptocytosis
 - b. hereditary dehydrated stomatocytosis
 - c. PNH
 - d. HPP
6. Laboratory features associated with hereditary spherocytosis include: (Objective 3)
 - a. spherocytes on the peripheral smear
 - b. MCHC more than 36%
 - c. increased osmotic fragility
 - d. all of the above
7. The red blood cells in paroxysmal nocturnal hemoglobinuria (PNH) demonstrate a(n) _____ osmotic fragility test. (Objectives 4, 5)
 - a. decreased
 - b. increased
 - c. normal
 - d. unpredictable
8. Which of the following statements describes the basic principle behind the sucrose hemolysis test? (Objective 6)
 - a. This test determines whether a patient's erythrocytes incubated in their own serum will demonstrate increased hemolysis.
 - b. This test determines whether a patient's erythrocytes are sensitive to complement lysis when exposed to acidified serum.
 - c. This test determines whether the patient's erythrocytes incubated in a low ionic medium such as sucrose will demonstrate increased hemolysis.
 - d. This test determines whether the patient's erythrocytes will resist acid elution.
9. The laboratory features associated with asymptomatic common hereditary elliptocytosis include: (Objective 3)
 - a. fragmented erythrocytes on the peripheral smear
 - b. increased osmotic fragility
 - c. positive autohemolysis test
 - d. mild reticulocytosis

LEVEL II

2. Which of the following erythrocyte disorders will demonstrate an increased osmotic fragility pattern? (Objective 2)
 - a. hereditary elliptocytosis and paroxysmal nocturnal hemoglobinuria
 - b. hereditary overhydrated stomatocytosis and hereditary spherocytosis
 - c. paroxysmal nocturnal hemoglobinuria and hereditary xerocytosis
 - d. sickle cell anemia and thalassemia

Use this case study to answer questions 3 and 4.

A 5-year-old white male was admitted with the diagnosis of a fractured tibia following a playground accident. His admission laboratory results follow:

WBC: $12.5 \times 10^9/L$	<i>Differential</i>
RBC: $3.6 \times 10^{12}/L$	Segmented neutrophils: 70%
Hgb: 10.2 g/dL	Lymphocytes: 22%
Hct: 27%	Monocytes: 5%
MCV: 96.3 fL	Eosinophils 2%
MCH: 28.3 fL	Basophils 1%
MCHC: 38 g/dL	

RBC morphology: Slight polychromasia and spherocytes present

Osmotic fragility test: Initial hemolysis: .65% NaCl
Complete hemolysis: .45% NaCl

3. Which erythrocyte index differentiates this membrane disorder from most of the other erythrocyte membrane disorders discussed in this chapter? (Objectives 2, 5)
 - a. MCV
 - b. MCH
 - c. MCHC
 - d. both the MCV and MCH
4. The patient's osmotic fragility test demonstrates that his erythrocytes have what type of osmotic fragility. (Objectives 2, 5)
 - a. increased
 - b. decreased
 - c. normal
 - d. questionable
5. Immunophenotyping for a diagnosis of PNH uses the following monoclonal antibodies: (Objective 4)
 - a. CD 55 and CD59
 - b. CD11b/CD18
 - c. CD 33 and CD34
 - d. CD56 and CD10
6. The RBC membrane permeability in hereditary overhydrated stomatocytosis is _____, and the cells have a(n) _____ osmotic fragility. (Objective 2)
 - a. increased, decreased
 - b. decreased, increased
 - c. increased, increased
 - d. decreased, decreased

REVIEW QUESTIONS (continued)

LEVEL I

10. The osmotic fragility test determines whether a patient's erythrocytes are osmotically fragile by: (Objective 4)
- measuring the amount of hemolysis that occurs after a patient's erythrocytes have been incubated for 24 hours in acidified serum
 - measuring the amount of hemolysis that occurs when a patient's erythrocytes are incubated in various concentrations of hypotonic saline
 - measuring the amount of hemolysis that occurs when the patient's erythrocytes are incubated in a sucrose solution
 - measuring the amount of hemolysis that occurs when the patient's erythrocytes are incubated in their own serum for 48 hours

LEVEL II

7. The following results were obtained on an osmotic fragility test.
- | | Normal Control | Patient |
|--------------------|----------------|------------|
| Initial hemolysis | 0.50% | 0.65% NaCl |
| Complete hemolysis | 0.30% | 0.45% NaCl |
- These results most closely relate to which of the following statements? (Objective 2)
- The patient's peripheral smear will reveal spherocytes.
 - The patient's peripheral smear will reveal target cells.
 - The patient's peripheral smear will reveal sickle cells.
 - The test is out of control and should be repeated.
8. A decrease in the level of which erythrocyte enzyme is seen in PNH? (Objective 3)
- leukocyte alkaline phosphatase (LAP)
 - acid phosphatase
 - C5 convertase
 - acetylcholinesterase
9. Which of the following statements best describes the role of the decay-accelerating factor (DAF)? (Objective 3)
- This regulatory protein enhances the amplification of complement lysis.
 - This complement regulatory protein stimulates erythrocyte lysis.
 - This regulatory protein prevents the amplification of C3/C5 convertase activity.
 - None of the above adequately describes the role of decay-accelerating factor.
10. The function of the membrane inhibitor of reactive lysis (MIRL) is to: (Objective 3)
- induce erythrocyte aggregation
 - interfere with the end stages of complement activation
 - prevent production of an autoantibody
 - all of the above

ANSWERS TO CASE STUDY QUESTIONS

Case Summary: Jack is a 12-year-old with a lifelong history of hemolytic crises suggesting a hereditary condition. Laboratory results reveal a microcytic anemia with an increased MCHC. The blood smear shows a variety of poikilocytes suggestive of hemolysis. The osmotic fragility test is increased. The test that is most helpful in this case is the thermal sensitivity test. The cells are heat sensitive, which with the other laboratory results and clinical history suggests hereditary pyropoikilocytosis.

Question:

1. Calculate the erythrocyte indices.

Explanation:

$$\text{MCV} = \frac{29.2 \times 10}{4.0} = 73 \text{ fL} \qquad \text{MCH} = \frac{10.8 \times 10}{4.0} = 27 \text{ pg}$$

$$\text{MCHC} = \frac{10.8 \times 100}{29.2} = 37 \text{ g/dL}$$

Question:

2. Based on the calculated indices, describe the patient's red blood cells.

Explanation:

The patient's erythrocytes are microcytic, hyperchromic. The term *hyperchromic* is technically correct, but most laboratory professionals use this term sparingly. This term signifies that the erythrocytes have too much hemoglobin when in essence that is not true. Instead, these erythrocytes have lost part of their membrane, which causes a decrease in the surface-area-to-volume ratio. This changes the erythrocyte from a discocyte to a spherocyte. The only erythrocyte that will reflect an MCHC of $>36\text{g/dL}$ is the spherocyte.

Question:

3. What additional lab tests should be ordered?

Explanation:

This patient has a hemolytic type of anemia with erythrocytes that are microcytic. Erythrocyte morphology on the peripheral smear revealed elliptocytes, spherocytes, and fragmented erythrocytes. It is important to know whether this problem is the result of a stimulated immune system (antibodies present). A DAT test should be ordered to determine whether this is true. If the DAT is negative, the patient may have an inherited erythrocyte membrane defect. Lab tests that could be used to differentiate the erythrocyte membrane disorders include the osmotic fragility test and the thermal sensitivity test.

Question:

4. Interpret the results of the osmotic fragility test.

Explanation:

The patient's erythrocytes lysed at a higher NaCl concentration than the control cells. This signifies that the patient's erythrocytes cannot take on as much water as normal cells and, thus, they are said to have increased osmotic fragility.

Question:

5. What do the results of the thermal sensitivity test reveal about the patient's red blood cells?

Explanation:

The results of the thermal sensitivity test reveal that the patient's erythrocytes are abnormally heat sensitive. Normal erythrocytes will not fragment until heated to $49^{\circ}\text{--}50^{\circ}\text{C}$.

Question:

6. What disorder is suggested by the patient's lab findings?

Explanation:

The patient has a hemolytic anemia that is not a result of a stimulated immune system. The erythrocyte morphology reveals microcytosis, spherocytes, elliptocytes, teardrop cells, and micropoikilocytes. The osmotic fragility is increased and the thermal sensitivity test shows that the erythrocytes are heat sensitive. These findings suggest that the patient has hereditary pyropoikilocytosis.

ANSWERS TO CHECKPOINTS

Checkpoint! 1

List various factors related to changes in the erythrocyte that may lead to a decrease or increase in the MCV in hereditary spherocytosis.

Answer

Erythrocyte factors that may cause a change in the MCV include spherocytes, polychromasia, and depleted iron stores or folate levels. Many densely stained spherocytes on the peripheral smear may cause a decrease in the MCV. Increased polychromasia may lead to an increase in the MCV. Chronic hemolysis can lead to depleted iron stores and folate levels. Low iron stores will lead to microcytic erythrocytes and thus a decreased MCV; depleted folate levels will lead to the formation of macrocytes and an increased MCV.

Checkpoint! 2

Interpret the results of the following osmotic fragility test:

	Patient	Control
Initial hemolysis	0.35 % NaCl	0.45 % NaCl
Complete hemolysis	0.25 % NaCl	0.30 % NaCl

Answer

The osmotic fragility test reveals that the patient's erythrocytes lysed at a lower concentration of NaCl than the control cells. This indicates that the patient's erythrocytes are more resistant to hemolysis or less osmotically fragile than the control cells. Target cells and sickle cells are able to resist hemolysis in hypotonic saline solutions longer than normal cells.

Checkpoint! 3

Why do the elliptocytes in HE demonstrate normal osmotic fragility?

Answer

The elliptocytes in HE demonstrate a normal osmotic fragility curve because the defect does not lead to a change in the surface-area-to-volume ratio of the erythrocyte. The elliptocyte can take on as much fluid as a normal cell and lyse at the same concentration of hypotonic saline as a normal cell.

Checkpoint! 4

Interpret the results of the following thermal sensitivity test. Patient's erythrocytes: Marked erythrocyte fragmentation after 10-minute incubation at 46°C . Normal control: No significant change in erythrocyte morphology after 10-minute incubation at 46°C .

Answer

The patient's erythrocytes are demonstrating an increased sensitivity to heat by fragmenting at 46°C . Normal erythrocytes do not fragment until heated to $49\text{--}50^{\circ}\text{C}$. Hereditary pyropoikilocytosis is an inherited disorder that demonstrates erythrocytes that are sensitive to heat.

Checkpoint! 5

Determine the type of erythrocyte membrane disorder based on the following lab results—retic count: 4%; osmotic fragility: increased; autohemolysis: increased; bilirubin: increased; peripheral smear: 30% stomatocytes present.

Answer

The erythrocyte membrane disorder that best fits these lab results is hereditary overhydrated stomatocytosis. Key features include a large percentage of stomatocytes and an increased osmotic fragility test. The patient's bilirubin level is elevated, which signifies increased erythrocyte hemolysis. Other disorders presenting with an increased number of stomatocytes include acute alcoholism, liver disease, and cardiovascular disease. These disorders, however, show little hemolysis.

Checkpoint! 6

Explain why the osmotic fragility is decreased in DHS.

Answer

The erythrocytes in DHS are dehydrated. They can take on more water than a normal erythrocyte and display complete lysis at a lower concentration of hypotonic saline than normal erythrocytes.

Checkpoint! 7

Compare the membrane lipid abnormalities seen in LCAT deficiency, spur cell anemia, and abetalipoproteinemia and explain how they may result in hemolysis of the cell.

Answer

Spur cell anemia—increase in serum lipoproteins, increase in membrane cholesterol, but normal membrane concentration of phospholipid. As the ratio of the membrane cholesterol to phospholipid increases, the cell is flattened and loses deformability. After repeated splenic passages, portions of membrane fragment, and the cell acquires the spur shape resulting in eventual hemolysis.

Abetalipoproteinemia—absence of serum β -lipoprotein, low serum cholesterol, triglycerides, phospholipids. There is an increase in the ratio of cholesterol to phospholipid. Erythrocyte membrane cholesterol is normal, but sphingomyelin is increased. Membrane fluidity is decreased because of increased sphingomyelin. As the cell ages, the degree of distortion increases, resulting in hemolysis.

LCAT deficiency—LCAT catalyzes formation of cholesterol esters from cholesterol. In LCAT deficiency, increased levels of cholesterol, phospholipids, and triglycerides in serum occur. High-density lipoproteins are decreased. Increased serum cholesterol results in increased cholesterol in the erythrocyte. Target cells are formed with high cholesterol levels. Hemolysis is mild.

Checkpoint! 8

Explain why immunophenotyping with CD14, CD55 and CD59 is used to establish a diagnosis of PNH.

Answer

PNH is characterized by a deficiency of GPI necessary to link a variety of proteins to the cell. CD55, CD59, and CD14 are GPI linked proteins. CD55 and CD59 are found on neutrophils. CD59 is found on erythrocytes, and CD14 is found on monocytes. These proteins are linked to the cell membrane by GPI. It is recommended that at least two different antibodies be used to detect different kinds of GPI anchored proteins.

Hemolytic Anemia: Enzyme Deficiencies

CHAPTER OUTLINE

- ▶ Objectives—Level I and Level II
- ▶ Key terms
- ▶ Background basics
- ▶ Case study
- ▶ Overview
- ▶ Introduction
- ▶ Glucose-6-phosphate dehydrogenase deficiency
- ▶ Other defects and deficiencies of the HMP shunt and GSH metabolism
- ▶ Pyruvate kinase (PK) deficiency
- ▶ Other enzyme deficiencies in the glycolytic pathway
- ▶ Abnormal erythrocyte nucleotide metabolism
- ▶ Summary
- ▶ Review questions
- ▶ References

Hemolytic Anemia: Enzyme Deficiencies

Martha Lake, Ed.D.
Dan Bessmer, M.S.

■ OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. Identify the two main pathways by which erythrocytes catabolize glucose.
2. Explain the role of erythrocyte enzymes in maintaining the cell's integrity, and describe how deficiencies in these enzymes lead to anemia.
3. Identify the most common erythrocyte enzyme deficiency.
4. Describe the inheritance pattern for glucose-6-phosphate dehydrogenase (G6PD).
5. Explain how the diagnosis of G6PD deficiency is made.
6. List the tests used to detect G6PD deficiency and describe their principles.
7. Recognize the erythrocyte morphology in a Romanowsky-stained blood smear associated with G6PD deficiency.
8. Identify common compounds that induce anemia in G6PD deficiency.

■ OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. Recommend appropriate laboratory testing and interpret results for suspected G6PD deficiency following a hemolytic episode.
2. Explain the function of glutathione in maintaining cellular integrity.
3. Associate the mechanisms of hemolysis with defects in the glycolytic and hexose-monophosphate shunt pathways.
4. Correlate clinical and laboratory findings with the common G6PD isoenzyme variants.
5. Diagram the reaction catalyzed by pyruvate kinase, and explain how a defect of this enzyme can cause hemolysis.
6. Recognize erythrocyte morphology associated with pyruvate kinase deficiency.
7. Review and interpret laboratory findings in a case study presentation of G6PD deficiency.

KEY TERMS

Bite cells
 Blister cells
 Chronic nonspherocytic hemolytic anemia
 Favism
 Hypoxia
 Lyonization

BACKGROUND BASICS

The information in this chapter builds on concepts learned in previous chapters. To maximize your learning experience, you should review the following concepts from previous chapters.

Level I and Level II

- ▶ Describe the normal erythrocyte metabolic processes.
- ▶ Recognize RBC morphology as it relates to hemolytic disease processes.
- ▶ Understand basic enzymology and techniques to measure enzyme activity.

**CASE STUDY**

We will address this case study throughout the chapter.

The patient, Henry, is a 25-year-old African American male soldier who was in the process of being deployed to West Africa for a 3-month temporary duty. Because of the high prevalence of malaria in the area, he was started on antimalarial prophylaxis (primaquine) 3 days prior to leaving to join his command. Twenty-four hours after starting the medication, he developed fever, chills, and general malaise. He subsequently reported to the emergency department and was admitted to the hospital for observation and additional testing.

The physical exam revealed a normal appearing, well-nourished adult male in no acute distress. His family history was noncontributory, and he had no known drug allergies. Laboratory analysis yielded the following.

CBC	
White blood cells	$12 \times 10^9/L$
Hemoglobin	9.1 g/dL (91 g/L)
Hematocrit	27% (0.27 L/L)
MCV	90 fL
Platelet count	$423 \times 10^9/L$
Total bilirubin	5.0 mg/dL
Conjugated	0.2 mg/dL
Unconjugated	4.8 mg/dL
Haptoglobin	39 mg/dL

Based on the clinical history and these laboratory results, consider what could have precipitated this patient's condition.

OVERVIEW

Intrinsic defects in the erythrocyte membrane, hemoglobin, or enzymes can lead to hemolysis. This chapter discusses defects of enzymes within the erythrocyte that lead to hemolytic anemia. The most common enzyme deficiencies are those associated with the hexose monophosphate shunt and the glycolytic pathway. Thus, the chapter begins with a description of the role of these two pathways in erythrocyte metabolism and a general overview of the clinical and laboratory findings in enzyme deficiencies associated with the pathways. The two most common enzyme deficiencies, glucose-6-phosphate dehydrogenase and pyruvate kinase, are discussed in detail in the format of pathophysiology, clinical and laboratory findings, and therapy.

INTRODUCTION

The erythrocyte life span can be significantly shortened if the cell is intrinsically abnormal. Although the enzymes in the erythrocyte are limited, those involved in processes that protect the cell from oxidant damage and provide the cell with energy through glycolysis are essential for cell survival. As reticulocytes mature, they lose their nucleus, mitochondria, and microsomes. Consequently, reticulocytes also lose their ability to synthesize protein and undergo oxidative phosphorylation for ATP production. Thus, the mature erythrocyte depends entirely on anaerobic glucose metabolism for its energy needs. Maturation of the reticulocyte is associated with a decline in the activity of some enzymes, but the activity is usually stable in the mature erythrocyte.¹ The erythrocyte cannot synthesize new enzymes. An inherited deficiency in one of the erythrocyte enzymes can compromise the integrity of the cell membrane or hemoglobin and cause hemolysis. The more common hereditary enzyme deficiencies known to cause hemolytic anemia are listed in Table 1. Most are associated with the two erythrocyte metabolic pathways: hexose monophosphate (HMP) shunt and the glycolytic (Embden-Meyerhof, EM) pathway. To understand how defects in these two pathways can result in hemolysis, they will be reviewed next.

HEXOSE MONOPHOSPHATE SHUNT

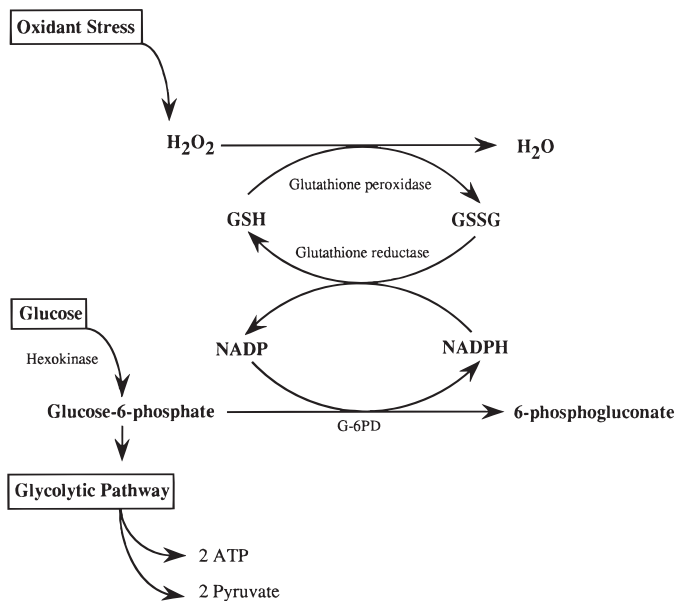

Glucose, the cell's primary metabolic substrate, enters the cell in a carrier-mediated, energy-free transport process and is catabolized via the glycolytic pathway or the HMP shunt. The HMP shunt catabolizes approximately 10% of the glucose, which is essential for maintaining adequate concentrations of reduced glutathione (GSH). GSH levels are maintained by conversion of NADPH to NADP; NADP is reduced back to NADPH in a reaction catalyzed by glucose-6-

★ TABLE 1

Erythrocyte Enzyme Deficiencies Associated with Congenital (Chronic) Nonspherocytic Hemolytic Anemia

Metabolic Pathway	Enzyme Deficiency
Glycolytic (Embden-Meyerhof)	Pyruvate kinase (PK)
	Glucose phosphate isomerase (GPI)
	Hexokinase (HK)
	Phosphoglyceratekinase (PGK)
	Phosphofructokinase (PFK)
	Triosephosphate isomerase (TPI)
Hexose-monophosphate	Glucose-6-phosphate dehydrogenase (G6PD)
	Glutathione synthetase
	Glutamylcysteine synthetase
Nucleotide	Pyrimidine 5'-nucleotidase (P5N)

phosphate dehydrogenase (G6PD) (Figure 1 ■). GSH protects the erythrocyte from oxidant damage; it maintains hemoglobin in the reduced functional state and preserves vital cellular enzymes from oxidant damage. When the cell is exposed to an oxidizing agent, the metabolism of NADPH increases. NADPH is consumed as part of the cell's protective mechanism and subsequently reduced back to NADPH via

■ **FIGURE 1** G6PD is needed for maintaining adequate quantities of glutathione (GSH), an important buffer to oxidants within the erythrocyte. As GSH reduces H_2O_2 to H_2O , it is oxidized (GSSG). G6PD generates NADPH in the conversion of glucose-6-phosphate to 6-phosphogluconate. NADPH, in turn, regenerates reduced glutathione from oxidized glutathione.

G6PD. If enzymes in the HMP shunt are deficient, the cell's reducing power is compromised, and oxidized hemoglobin accumulates, subsequently denaturing in the form of Heinz bodies. Heinz bodies aggregate at the cell membrane, causing membrane damage. As the cells pass through the spleen, the macrophages attempt to remove the Heinz bodies, leading to premature extravascular hemolysis. The most common enzyme deficiency of the HMP shunt is G6PD deficiency.

GLYCOLYTIC PATHWAY

Most of the cell's energy is produced via glycolysis in the glycolytic pathway. About 90% of the glucose is utilized by this pathway as 1 mole of glucose is catabolized to lactic acid with a net production of 2 moles of ATP. ATP is needed for active cation transport of Na^+ , K^+ , and Ca^{++} , maintaining membrane deformability (membrane's ability to temporarily change shape in response to multiple forces in the cell's environment); and maintaining normal erythrocyte biconcave disc shape in the resting or steady state.¹ The erythrocyte's ability to deform is an important determinant of its survival. Deficiencies in enzymes of the glycolytic pathway decrease ATP production and lead to hemolysis. Heinz bodies are not formed because the cell's reducing power is primarily linked to the HMP shunt. The mechanism of hemolysis is related to decreased ATP leading to impaired cation pumping. Membrane integrity is compromised, and increased osmotic fragility results. The osmotically fragile cells are trapped in the hostile splenic environment and phagocytosed.

The Rapoport-Luebering shunt of the glycolytic pathway provides the erythrocyte with 2,3-bisphosphoglycerate (2,3-BPG). If this shunt is used, there is no net gain of ATP from glycolysis. The activity of this shunt is stimulated during **hypoxia**, a state of decreased oxygen tension and delivery to tissues. This is sometimes evidenced by a blue appearance of normally pink tissues, such as the fingernail beds. When 2,3-BPG combines with hemoglobin, the hemoglobin's oxygen affinity decreases, making more oxygen available to the tissues.

CLINICAL AND LABORATORY FINDINGS IN ERYTHROCYTE ENZYME DEFICIENCIES

Most erythrocyte enzyme deficiencies are inherited as autosomal recessive traits. However, the most common enzyme deficiency, G6PD, is inherited as an X-linked recessive (sex-linked) disorder. Patients with the homozygous autosomal recessive enzyme deficiencies and males with X-linked G6PD deficiency generally have chronic normocytic, normochromic anemia, reticulocytosis, hyperbilirubinemia, and neonatal jaundice. The direct antiglobulin test (DAT) is negative, indicating an absence of antibodies coating the erythrocytes, and no evidence suggests a defect in either the

erythrocyte membrane or hemoglobin. Sometimes no anemia is present or hemolysis is sporadic, depending on the specific allele(s) inherited. These anemias associated with inherited defects of erythrocyte metabolism are often collectively referred to as **chronic** (hereditary or congenital) **nonspherocytic hemolytic anemias**. The preferred term is *hereditary nonspherocytic hemolytic anemia*, for this heterogeneous group of anemias does not have significant poikilocytosis. Although the anemias are not life threatening, they can be disabling and lead to debilitating complications.²

DIAGNOSIS

Definitive diagnosis of enzyme deficiencies requires spectrophotometric measurement of the suspected deficient enzyme. The time of testing and interpreting the results is important for accurate diagnosis. Sometimes the abnormal cells are selectively removed from circulation *in vivo*, and the enzyme activity of the remaining circulating cells is normal. Some abnormal enzymes have normal activity in the reticulocytes, but enzyme activity decreases as the cell ages (G6PD-A⁻). Thus, depending on the degree of reticulocytosis, the enzyme content can appear normal. For these reasons, it is important not to test the patient immediately after a hemolytic attack when most of the enzyme deficient cells have been hemolyzed and there is a compensatory reticulocytosis. It has been reported that diagnosis during or shortly after a hemolytic attack can be made if the blood is centrifuged and the older dense erythrocytes at the bottom of the column of blood are tested.^{2,3} If a patient has been transfused, testing should be delayed until the transfused cells have outlived their life span.¹

✓ Checkpoint! 1

Transfusion of red blood cells in a patient with chronic nonspherocytic, hemolytic anemia due to an erythrocyte enzyme deficiency does not reverse or prevent the recipient's condition. However, a transfusion does help to raise the patient's hemoglobin. If tests are performed to quantitate the enzyme after a transfusion, the results can be within the normal reference intervals. Explain.

▶ GLUCOSE-6-PHOSPHATE DEHYDROGENASE DEFICIENCY

G6PD deficiency is the most common erythrocyte enzyme disorder. It was first recognized during the Korean War when 10% of African American soldiers who were given the anti-malarial drug primaquine developed a self-limited hemolytic anemia. G6PD deficiency is found worldwide in Caucasians, blacks, and Asians. It occurs most frequently in the Mediterranean area, Africa, and China. The geographic distribution coincides with that of malaria, suggesting that G6PD-defi-

cient cells may be more resistant to malarial parasites than normal cells and/or are more readily phagocytosed.^{4,5}

The disease is a sex-linked disorder carried by a gene on the X chromosome (band Xq28) and therefore fully expressed in males with the genetic mutation or in females homozygous for the mutation. Heterozygote females appear to have two populations of cells, one deficient in G6PD and one normal. This occurs because of **lyonization** (random inactivation of one set of X-linked genes in each cell) of an X chromosome. The degree to which females are affected depends on the relative amount of deficient cells present. Web Figure 1 ■ illustrates the expected progeny from G6PD deficient males or females.

The disease is heterogenous with differences in severity among races and sexes. The majority of people with G6PD deficiency have no clinical expression of the deficiency unless they have neonatal jaundice, are exposed to oxidative chemicals or drugs, or have severe infections. Compounds that have been associated with hemolytic anemia in G6PD deficiency are listed in Table 2 🌟.

🌟 TABLE 2

Compounds Associated with Hemolysis in G6PD Deficiency

Antimalarials	primaquine
	pamaquine
	pentaquine
	quinacrine (Atabrine)
Sulfonamides	sulfanilamide
	sulfacetamide
	sulfapyridine
	sulfamethoxazole (Gantonol)
	sulfasalazine (Azulfidine)
Sulfones	thiazosulfone
	diaphenylsulfone (DDS, Dapsone)
	sulfoxone (Diasone)
Nitrofurans	nitrofurantoin (Furadantin)
Analgesics	acetanilid
Miscellaneous	fava beans
	hydroxylamines
	methylene blue
	naphthalene (moth balls)
	naxidlic acid
	niridazole
	phenylhydrazine
	toluidine blue
	trinitrotoluene (TNT)

✓ Checkpoint! 2

Oxidant compounds are harmful because they result in the production of harmful peroxides or other oxygen radicals that overwhelm the body's natural mechanisms to scavenge them. Why is the mechanism of protection against oxidants easily compromised in G6PD deficiency?

PATHOPHYSIOLOGY

G6PD is necessary for maintaining adequate levels of GSH for reducing cellular oxidants (Figure 1). In G6PD deficiency, the generation of NADPH, and subsequently GSH, is impaired and cellular oxidants accumulate. The buildup of cellular oxidants leads to erythrocyte injury and hemolysis. Hemoglobin is oxidized to methemoglobin, which precipitates in the form of Heinz bodies. Heinz bodies attach to the erythrocyte membrane causing increased membrane permeability to cations, osmotic fragility, and cell rigidity. Heinz bodies are removed from the erythrocytes by splenic macrophages, producing “bite” cells and **blister cells**. With progressive membrane loss, spherocytes can be formed. Spherocytes are less deformable than normal and become trapped and hemolyzed in the spleen (extravascular hemolysis). Heinz bodies require a supravital stain to be visualized because they are not evident on Romanowsky-stained blood smear stains. Oxidant stress also can oxidize membrane lipids and proteins. This disruption of the membrane structural integrity results in removal of the cell from circulation by splenic macrophages. Cell membrane damage can be severe enough for the cell to hemolyze in the circulation. This intravascular hemolysis can be acute and accompanied by hemoglobinemia and hemoglobinuria.

Normally, G6PD activity is highest in young cells and decreases as the cell ages. Normal erythrocytes have been shown to use only 0.1% of their maximum G6PD enzyme capacity.⁶ Thus, even older cells normally retain enough G6PD activity to maintain adequate GSH levels. This also explains why even G6PD-deficient cells can maintain normal

function and hemolysis is sporadic. It is in situations that create excessive oxidant stress that the G6PD activity usually is inadequate to maintain normal metabolic function. Those cells that are most deficient undergo oxidant damage and are rapidly removed from circulation. This accounts for the sporadic hemolysis that accompanies oxidant stress in G6PD deficiency. In most G6PD variants, hemolysis is self-limited (referring to the fact that hemolysis stops after a time even if the oxidant stress continues). Self-limited hemolysis occurs because the older, most G6PD-deficient erythrocytes initially are destroyed, but the younger cells remain because they have sufficient enzyme activity to avoid hemolysis. The reticulocytes released from the bone marrow in response to the hemolytic episode also have enough enzyme activity to maintain metabolic activity even under oxidant stress. However, it is important to recognize that under the stress of severe oxidants (drugs, chemicals), even normal cells can experience oxidant damage and hemolyze.

✓ Checkpoint! 3

Erythrocyte morphology should always be examined carefully. The ability to pick up subtle clues as to the cause of a disease process can be acquired from a comprehensive evaluation of abnormal erythrocyte morphology. How is this likely to aid the diagnosis of G6PD deficiency?

G6PD VARIANTS

More than 400 variants (isoenzymes) of the G6PD enzyme have been identified.¹ Many of them differ in activity, stability, and electrophoretic mobility. The mutant enzymes have been categorized into four classes according to the degree of deficiency and hemolysis (Table 3).² Most variants have normal enzyme activity. Deficient enzyme variants tend to have mutations clustered in domains responsible for stable dimerization of the protein or the NADP binding site.⁷ Variants except G6PD-B, G6PD-A⁺, and G6PD-A⁻ are given geographic names or other types of names.

★ TABLE 3

Classes of Mutant G6PD Isoenzymes

Class	G6PD Activity	Hemolysis	Important Variants
I	Severely deficient	Chronic (nonspherocytic hemolytic anemia); not self-limited	Minnesota; Iowa
II	Severely deficient (<10%)	Acute, episodic; can be chronic and not self-limited	G6PD-Mediterranean
III	Moderately to mildly deficient (10–60%)	Acute, episodic	G6PD-A ⁻ ; G6PD-Canton
IV	Normal (60–150%)	Absent	G6PD-B, G6PD-A ⁺

FEMALES WITH G6PD DEFICIENCY

Female heterozygotes for G6PD deficiency always contain two populations of cells, one normal and one with G6PD deficiency. In contrast, all cells in affected males are G6PD deficient. The dual population in females is caused by random inactivation of one X chromosome in a given stem cell. Depending on the proportion of abnormal erythrocytes, females may have no clinical expression of the deficiency or may be affected as severely as males. Although rare, there are case reports of homozygous-deficient females.⁸

CLINICAL FINDINGS

A spectrum of clinical presentations is associated with this disorder: acute, acquired hemolytic anemia (episodic) including favism; congenital nonspherocytic hemolytic anemia (chronic); and neonatal hyperbilirubinemia with jaundice. Homozygotes and heterozygotes can be symptomatic depending on the severity of the deficiency. G6PD deficiency is most common in those of African, Asian, Mediterranean, and Middle-Eastern descent.

Acute, Acquired Hemolytic Anemia

Most persons with G6PD deficiency have no clinical symptoms, and they are not anemic. Diagnosis usually occurs during or after infectious illnesses or following exposure to certain drugs because these conditions commonly precipitate hemolytic attacks. Hemolysis is variable and depends on the degree of oxidant stress, the G6PD isoenzyme, and sex of the patient. The symptoms are those of acute intravascular hemolytic anemia. Drug-induced hemolysis usually occurs within 1 to 3 days after exposure to the drug. Sudden anemia develops with a 3–4 g/dL drop in hemoglobin. Jaundice is not prominent. The patient may experience abdominal and low back pain, as well as dark or black urine due to hemoglobinuria. In one study of 35 G6PD-deficient children in India, the most common significant complication, occurring in more than 50% of the cases, was renal failure.⁹ Hemoglobinemia is prominent. Often, however, hemolysis is less striking and is not accompanied by hemoglobinuria or conspicuous symptoms.

Favism refers to the sudden severe hemolytic episode that develops in some individuals with G6PD deficiency after the ingestion of fava beans (broad beans). Hemolytic episodes occur in much the same way as drug-induced hemolytic episodes. The most likely components of the bean responsible for the sensitivity are isouramil and divicine. This complication is often thought to be associated with severe G6PD deficiency, especially the G6PD Mediterranean variant. It is now clear, however, that other forms of G6PD deficiency are also associated with favism, including G6PD-A⁻ and G6PD Aures, a type identified in Algerian subjects.¹⁰

The hemolysis is similar to the acute hemolytic episodes that occur after primaquine administration in individuals

with the G6PD-A⁻ variant. Consumption of fava beans is widespread in the Mediterranean area and the Middle East. The first signs of favism are malaise, severe lethargy, nausea, vomiting, abdominal pain, chills, tremor, and fever.¹ Hemoglobinuria occurs a few hours after ingestion of the beans. Persistent hemoglobinuria usually prompts the individual to seek medical attention. Jaundice can be intense. Severe favism usually affects children between the ages of 2 and 5 years. The age distribution is changing in some countries, however, due to neonatal screening and parental education. Even though favism occurs more often in males due to the X-linked nature of the disease, females are also affected depending on the proportion of enzyme deficient erythrocytes present.

Congenital Nonspherocytic Hemolytic Anemia

Congenital nonspherocytic hemolytic anemia syndrome is associated with G6PD variants (Class I) that have low in vitro activity or are markedly unstable. Hemolysis is chronic and not associated with ingestion of drugs or infections, although drugs and infections can exaggerate the hemolysis. The hemolysis is usually compensated so anemia can be mild. Reticulocytosis is in the range of 4–35%.

Leukocyte and platelet G6PD are controlled by the same gene as erythrocyte G6PD. Thus, it has been found that some patients with G6PD-deficient red cells also have leukocyte G6PD deficiency. An increase in pyogenic infections has been reported in those with <5% normal activity.^{11–13} However, a group of Israeli patients with severe G6PD deficiency without an increased incidence of infections had bactericidal activity in their G6PD-deficient neutrophils within the range of healthy controls.¹⁴ Considerable fluctuation of the enzyme activity was found to depend on the time of day it was measured. This fluctuation can produce enough NADPH to initiate the respiratory burst and prevent infection. Neutrophils also are relatively short lived, so those with unstable variants might not show functional impairment.

Neonatal Hyperbilirubinemia

Some neonates with G6PD deficiency have severe hyperbilirubinemia with the potential of kernicterus if left untreated. The prevalence of this severe jaundice occurs twice as often in G6PD-deficient male neonates than in neonates from the general population. The mechanism is unknown. Although hemolysis can be present, other factors appear to play a more important role including inability to conjugate and clear bilirubin.¹⁵ In a recent study, G6PD deficiency was identified in at least 21% of infants who were readmitted with kernicterus.¹⁶ Exchange transfusion and phototherapy may be required.

Neonates and preterm infants (29–32 weeks gestation) have higher G6PD activity than do adults. However, the higher activity does not affect the diagnosis of G6PD because neonates and preterm infants with G6PD deficiency have lower activity than do normal neonates.¹⁷

LABORATORY FINDINGS

Anemia is absent and peripheral blood findings are normal except during hemolytic attacks for most of the common G6PD variants. Patients with the congenital nonspherocytic hemolytic anemia form can exhibit chronic hemolysis. During or immediately following a hemolytic attack, polychromasia, occasional spherocytes, small hypochromic cells, erythrocyte fragments, and bite cells can be seen on the blood smear. **Bite cells**, which have a chunk of the cell removed from one side, are frequently thought to be typical of G6PD deficiency (Figure 2■). However, bite cells are more characteristic of drug-induced oxidant hemolysis in individuals with normal hemoglobin and enzyme activity.¹⁸

A peculiar cell referred to by a variety of descriptive terms (blister cell, irregularly contracted cell, eccentrocyte, erythrocyte hemighost, double-colored erythrocyte, and cross-banded erythrocyte) has been described in G6PD deficiency after oxidant-related hemolysis (Figure 3■). The red cell membrane is oxidized. The hemoglobin is confined to one side of the cell and the other side is transparent. The transparent side often contains Heinz bodies and has flattened membranes in which the opposing membrane sides are juxtaposed. This cross-bonding of the membrane appears to decrease deformability and destine the cell for phagocytosis by macrophages. These cells have a decreased volume and increased MCHC.

A variety of abnormal laboratory findings related to hemolysis can be found during or after a hemolytic attack. Reticulocytosis is characteristic following a hemolytic episode.¹⁹ Leukocytes can increase during hemolytic attacks, but platelets are usually normal. Unconjugated bilirubin and serum LD can be increased. Haptoglobin commonly decreases during the acute hemolytic phase. Absence of haptoglobin in the recovery stage indicates chronic hemolysis.

■ **FIGURE 2** Heinz body hemolytic anemia. Peripheral blood from a patient with G6PD deficiency during a hemolytic episode. There are erythrocytes with a portion of the cell missing, known as bite cells. The spleen pits the Heinz body with a portion of the cell producing these misshapen erythrocytes. Some of the cells reseal and become spherocytes. (Wright-Giemsa stain; 1000× magnification)

■ **FIGURE 3** The arrows are pointing to “blister cells,” which have been described by various names (see text). Hemoglobin is condensed to one side of the cell, leaving a transparent area (blister) on the other. These cells can be found in G6PD deficient individuals after a hemolytic attack.

Definitive diagnosis depends on the demonstration of a decrease in erythrocyte G6PD enzyme activity. In affected individuals, the enzyme activity can appear normal during and for a time after a hemolytic attack because older cells with less G6PD are preferentially destroyed during the attack and reticulocytes have normal activity. A reticulocytosis of more than 7% is generally associated with a normal enzyme screen after hemolysis.²⁰ For this reason, assays for G6PD should be performed 2 to 3 months after a hemolytic episode. In G6PD Mediterranean, however, even young cells have gross deficiencies of G6PD, and enzyme activity appears abnormal even with reticulocytosis. Both severe and mild types of G6PD deficiency are detected by measuring the enzyme if the patient is not undergoing hemolysis.

CASE STUDY (continued from earlier in this chapter)

Because of the low hemoglobin, Henry was transfused with 2 units of packed red cells. Examination of the peripheral blood smear was remarkable for occasional spherocytes and bite cells. This blood smear finding, presentation of anemia, and onset of illness coinciding with the initiation of primaquine suggested shortened RBC life span due to oxidative damage.

1. What test should be considered after finding bite cells on a blood smear?

Fluorescent Spot Test

The fluorescent spot test is a reliable and sensitive screening test for G6PD deficiency. Whole blood is added to a mixture of glucose-6-phosphate (G6P), NADP, and saponin. A drop of

this mixture is placed on a piece of filter paper and examined under ultraviolet light for fluorescence. The G6PD enzyme present in erythrocytes normally metabolizes G6P, producing NADPH, which fluoresces, but NADP does not, so lack of fluorescence indicates G6PD deficiency.

Dye Reduction Test

The dye reduction screening test incubates a hemolysate of patient's blood, G6P, NADP, and the dye brilliant cresyl blue together. If the hemolysate contains G6PD, the NADP is reduced to NADPH, which in turn reduces the blue dye to its colorless form. The time it takes for this change to occur is inversely proportional to the amount of G6PD present. Normal blood is also tested as a control. The test is specific and is available in commercial kits.

Ascorbate Cyanide Test

The ascorbate cyanide test is the most sensitive screening test for detecting heterozygotes and G6PD deficiency during hemolytic attacks. The test is not specific for G6PD deficiency but also detects other defects or deficiencies in the HMP shunt. The test is also positive in PNH, pyruvate kinase deficiency, and unstable hemoglobin disorders. The test's principle is that G6PD-deficient cells fail to reduce hydrogen peroxide. A patient's blood is incubated with sodium ascorbate, sodium cyanide, and glucose. Hydrogen peroxide is generated by the interaction of ascorbate with hemoglobin. The sodium cyanide inhibits the activity of normal erythrocyte catalase, an inhibitor of the formation of hydrogen peroxide. With the inhibition of catalase, hydrogen peroxide is formed. Erythrocytes deficient in G6PD cannot reduce the peroxide, and hemoglobin is oxidized to methemoglobin, which imparts a brown tint to the solution.

Cytochemical Staining

This method detects the enzyme activity in individual cells. The G6PD in the red cells reacts with a sensitive tetrazolium salt to ultimately form formazan. The level of formazan is directly related to the G6PD activity. The activity in the cells can be scored by hand, but automated methods utilizing flow cytometry are being developed.²¹

Quantitative Rate Reduction Test

An erythrocyte hemolysate is incubated with G6P and NADP, and the rate of reduction of NADP to NADPH is measured at 340 nm in a spectrophotometer. In the case of heterozygotic females, when the quantitation of the enzyme can yield misleading results especially during or after a hemolytic episode, it is best to perform polymerase chain reaction (PCR) tests to reveal the genetic abnormality.

DNA-Based Screening Test

DNA is extracted from spots of dried blood and then submitted for PCR. Fluorescent-labeled probes are used to detect mutant G6PD alleles.

CASE STUDY (continued from the previous page)

A spectrophotometric assay for G6PD was performed on the patient's peripheral blood. The result was borderline normal, and a preliminary diagnosis of G6PD deficiency was made. Primaquine usage was discontinued, and the patient recovered without complications. Upon follow-up, the patient was retested for G6PD deficiency and was found to be abnormal, confirming the diagnosis.

2. Why was the initial G6PD test result normal but the repeat test was abnormal?

THERAPY

Most of the patients with G6PD deficiency are asymptomatic and do not experience chronic hemolysis; thus, no therapy is indicated. However, patients should avoid exposure to the oxidant drugs and foods that can precipitate hemolytic episodes. In acute hemolytic episodes, supportive therapy including blood transfusions, treatment of infections, and removal of the precipitating agent are used. Exchange transfusion can be necessary in cases of severe neonatal jaundice. Dialysis can be indicated in patients with oliguria and severe azotemia.⁹

CASE STUDY (continued)

3. What was the precipitating cause of the patient's anemia?

▶ OTHER DEFECTS AND DEFICIENCIES OF THE HMP SHUNT AND GSH METABOLISM

Erythrocytes synthesize about 50% of their total glutathione every 4 days. Deficiencies in the enzymes needed for glutathione synthesis (glutathione synthetase and glutamylcysteine synthetase) have been reported to be associated with a decrease in GSH and a congenital nonspherocytic hemolytic anemia. Hemolysis increases during administration of certain drugs. Deficiencies in glutathione reductase, an enzyme that catalyzes the reduction of GSSG to GSH, are not associated with a hematologic disorder. Glutathione peroxidase catalyzes the detoxification of hydrogen peroxide by GSH. Deficiencies in this enzyme, although common, are not a cause of hemolysis. This might be explained by the fact that peroxide reduction by GSH occurs nonenzymatically at a significant rate.

▶ PYRUVATE KINASE (PK) DEFICIENCY

Pyruvate kinase deficiency is the most common enzyme deficiency in the glycolytic pathway and the second most common erythrocyte enzyme deficiency. Many pyruvate kinase

enzyme mutations coincide with the disorder's variety of clinical manifestations. The more severe types are noted in infancy, whereas the milder types may not be detected until adulthood. Inheritance is autosomal recessive. Clinically significant hemolytic anemias of PK deficiency are associated with the homozygous state or double heterozygosity for two mutant enzymes. The variation in clinical phenotype associated with the genetic mutations appear to reflect not only the aberrant properties of the mutant protein but also interactions of the genotype with physiological and environmental factors including epigenetic modifications, ineffective erythropoiesis, splenic function, and coexisting polymorphisms of other enzymes.²² Single heterozygotes are usually asymptomatic. Acquired PK deficiency is seen in some leukemias and myelodysplastic disorders.

PATHOPHYSIOLOGY

More than 180 different mutations in the PK gene (PKLR gene on chromosome 1q21) affecting the enzyme activity have been identified. Most are missense mutations, but nonsense mutations, deletions, and insertions are found also. PK catalyzes the conversion of phosphoenol pyruvate (PEP) to pyruvate, concurrent with the conversion of ADP to ATP (Figure 4 ■). In PK deficiency, this energy-producing reaction is prevented, resulting in a loss of two ATP molecules per molecule of glucose catabolized. The cell's inability to maintain normal ATP levels results in alterations of the erythrocyte membrane; failure of the cation pumps causing potassium loss as well as sodium and calcium gain; and dehydration (echinocytes). The decrease in echinocyte deformability enhances erythrocyte sequestration in splenic cords and phagocytosis by macrophages.

■ **FIGURE 4** Glucose is metabolized to pyruvate in the glycolytic pathway. ATP is generated as phosphoenolpyruvate and is converted to pyruvate with a net gain of 2 ATP. Two molecules of pyruvate are formed from 1 glucose molecule. In pyruvate kinase deficiency, this reaction is slowed, resulting in deficient ATP production.

CLINICAL FINDINGS

Clinical symptoms vary depending on the degree of anemia, which is mild to severe. Individuals tolerate the anemia well because of the increase in 2,3-BPG that accompanies the distal block in glycolysis. The two to three times normal increase in 2,3-BPG enhances the release of oxygen to the tissues. Jaundice can occur with intermittent hemoglobinuria. Gallstones are a common complication.

PK deficiency can be life threatening in neonates. When anemia is present at birth, PK deficiency should be considered with and differentiated from other etiologies associated with anemia in this population (ABO/Rh incompatibility, thalassemia, G6PD deficiency, and hereditary spherocytosis).²³ Neonates with a severe phenotype usually have severe jaundice that may require exchange transfusions.²² Splenectomy can result in stabilization of the hemoglobin and decrease the need for transfusions. Patients with milder forms of PK deficiency are commonly diagnosed in early adulthood although they could have had neonatal jaundice.¹⁹

LABORATORY FINDINGS

Patients with PK deficiency have a normocytic, normochromic anemia with hemoglobin levels of 6–12 g/dL. Reticulocytosis ranges from 2 to 15% and increases more after splenectomy, often above 40%. The degree of reticulocytosis before splenectomy is not proportional to the degree of anemia as it is in most other hemolytic anemias because the spleen preferentially sequesters the younger PK deficient erythrocytes. The blood smear exhibits irregularly contracted cells and occasional echinocytes before splenectomy (Figure 5 ■). After splenectomy, these abnormal cells present a more conspicuous finding. In contrast to G6PD deficiency, Heinz bodies and spherocytes are not found in PK deficiency.

■ **FIGURE 5** Blood smear from a patient with pyruvate kinase deficiency. Note the echinocyte, acanthocyte, target cells, and irregularly contracted cells. Howell-Jolly bodies are also present. (Wright-Giemsa stain; 1000× magnification)

Serum unconjugated indirect bilirubin and LD are increased, and haptoglobin is decreased or absent. Osmotic fragility is normal, but cells demonstrate increased hemolysis when incubated at 37°C. Autohemolysis is increased at 48 hours and is not corrected with the addition of glucose but is corrected with the addition of ATP.

In performing enzyme tests for PK, the erythrocytes are separated from leukocytes because leukocytes contain more PK than erythrocytes. Two genes located on chromosomes 15q22 and 1q21 encode for pyruvate kinase. The first locus produces PK active in muscle, leukocytes, platelets, and various other tissues. The second locus produces the PK active in erythrocytes. Thus, in erythrocyte PK deficiency (mutations of the second locus), only the erythrocytes are deficient; leukocytes are normal. The screening procedure is based on the disappearance of fluorescence as erythrocytes are incubated with phosphoenol-pyruvate (PEP), LD, ADP, and NADH.²⁴

Some mutant PK enzymes have normal activity at high substrate concentrations and abnormal activity at low substrate concentrations. A modification of this procedure has been developed to improve the interpretation of the endpoint.²⁵ In this modification, patient blood is frozen and thawed to ensure complete hemolysis of the specimen before testing.

Fluorescence in normal erythrocytes disappears in 30 minutes. In PK-deficient erythrocytes, fluorescence persists 45–60 minutes. The quantitative test for PK deficiency is performed in the same manner as the screening test except that the rate of disappearance of fluorescence is measured in a spectrophotometer at 340 nm. A rapid potentiometric method has also been developed to measure enzymatic activity by monitoring the change in pH in a reaction buffer during the conversion of the substrate to pyruvate.

OTHER ENZYME DEFICIENCIES IN THE GLYCOLYTIC PATHWAY

OTHER ENZYME DEFICIENCIES IN THE GLYCOLYTIC PATHWAY

When associated with anemia, other enzyme deficiencies in the glycolytic pathway have clinical manifestations and laboratory findings that resemble those of PK deficiency.

- **Glucose phosphate isomerase deficiency (GPI)** is the second most common disorder of the glycolytic pathway. Almost all GPI mutants are unstable, causing hemolytic anemia. Affected individuals show a partial response to splenectomy.
- **Hexokinase (HK) deficiency** is the first enzyme in the glycolytic pathway and thus is responsible for priming the glycolytic pump. There are two types of HK deficiency. One is associated with hemolytic anemia that responds to splenectomy. The other is associated not only with hemolytic anemia but also with an array of other abnormalities. A deficiency in this enzyme interferes with production of 2,3-BPG, and patients tolerate the anemia poorly.
- **Phosphoglyceratekinase (PGK) deficiency** is a sex-linked disorder that causes hemolytic anemia and mental retardation in males. Females have a milder form of the disorder.
- **Phosphofructokinase (PFK) deficiency** is indicated when subunits of the PFK enzyme are found in various tissues. Deficiency of this enzyme can appear as myopathy or hemolytic anemia or both.²⁶
- **Triosephosphate isomerase (TPI) deficiency** causes severe abnormalities in erythrocytes resulting in severe hemolysis. Abnormalities are also noted in striated muscle and the central nervous system. Death in infancy is common.

ABNORMAL ERYTHROCYTE NUCLEOTIDE METABOLISM

Pyrimidine 5'-nucleotidase (P5N) contributes to the degradation of nucleic acids by cleaving pyrimidine nucleotides into smaller nucleosides that can diffuse out of the cell. The buildup of pyrimidine nucleotides decreases the adenine nucleotide pool needed for normal function. P5N deficiency is an autosomal recessive disorder that leads to a severe hemolytic anemia unresponsive to splenectomy. Partially degraded mRNA and rRNA accumulate within the cell and are visualized as basophilic stippling in stained smears. Lead inhibits this enzyme, which can explain the similar coarse basophilic stippling seen in lead poisoning.

SUMMARY

The erythrocyte life span can be significantly shortened if the erythrocyte has intrinsic defects such as deficient metabolic machinery. Maintaining a balance of intracellular constituents is

✓ Checkpoint! 4

What are the differentiating characteristics of PK and G6PD deficiencies found on the peripheral blood smear?

compromised when enzymes responsible for various metabolic pathways are deficient or fail to function properly. These abnormalities are almost always inherited defects. Erythrocytes with intrinsic defects are susceptible to early destruction, and when this destruction exceeds the marrow capacity to replace cells, hemolytic anemia results. These hemolytic anemias are known as *chronic* or *congenital nonspherocytic hemolytic anemias*.

Erythrocyte enzyme deficiencies can compromise the integrity of the cell membrane or hemoglobin and lead to hemolysis. The HMP shunt provides the cell reducing power, protecting it from oxidant damage. Defects in this shunt allow hemoglobin to be oxidized and denatured to Heinz bodies. The Heinz bodies damage the cell membrane. The finding of bite cells on the blood smear is evidence that Heinz bodies have been pitted from the cells. The most common deficiency in this pathway is G6PD deficiency, a sex-linked disorder. This enzyme has many different variants, some of which cause severe hemolysis and others mild hemolysis. In most cases, hemolysis is sporadic, occurring during infections or with the administration of certain drugs, and is self-limited. In these variants, the younger cells have adequate enzyme activity, but the

older cells are severely deficient and selectively hemolyzed. Testing for the enzyme should be delayed until 2 months after the hemolytic episode when reticulocytes are at a steady state (normal) and the erythrocytes produced after the hemolytic episode have aged. Screening tests for the enzyme include the fluorescent dye test, cytochemical staining, dye-reduction test, and ascorbate cyanide test. Definitive testing requires quantitation of the enzyme or genetic testing for mutations.

Deficiencies of enzymes in the glycolytic pathway decrease ATP production and lead to hemolysis. There can be impaired cation pumping and increased osmotic fragility. Pyruvate kinase (PK) is the most common enzyme abnormality in this pathway. There are many PK enzyme mutants, resulting in a diverse array of clinical and laboratory findings. There can be significant reticulocytosis. The blood film is remarkable for the presence of irregularly contracted cells and echinocytes. Heinz bodies and bite cells are not found. Screening and definitive tests for the enzyme are based on fluorescence. Several other rare enzyme defects that also lead to hemolysis have been identified.

REVIEW QUESTIONS

LEVEL I

- What are the two main metabolic pathways that erythrocytes use for glucose metabolism? (Objective 1)
 - Krebs cycle and glycolytic
 - hexokinase and Krebs cycle
 - oxidative phosphorylation and glycolytic
 - hexose-monophosphate shunt and glycolytic
- The main protective functions of erythrocyte enzymes result from which of the following? (Objective 2)
 - electron transport and cation pumping using ATP
 - cation pumping using ATP and protection of hemoglobin by reduced glutathione
 - protection of hemoglobin by reduced glutathione and electron transport
 - cation pumping and bilirubin production
- In G6PD deficiency, anemia ultimately results from: (Objective 2)
 - buildup of 2,3-BPG and poor iron binding
 - inability to maintain enough ATP to pump cations
 - oxidative damage to hemoglobin and splenic removal of erythrocytes
 - membrane protein defects and loss of erythrocyte flexibility
- Which is the most common erythrocyte enzyme deficiency? (Objective 3)
 - pyruvate kinase
 - hexokinase
 - glucose phosphate isomerase
 - glucose-6-phosphate dehydrogenase

LEVEL II

- Why should G6PD testing be delayed for an individual following a hemolytic episode? (Objective 1)
 - The level of glucose must have time to replenish.
 - Heinz bodies can interfere with the test method.
 - Deficient cells have been selectively destroyed.
 - The patient needs time to build up iron stores.
- An 18-year-old black male was suspected of having G6PD deficiency when he experienced hemolytic anemia after administration of primaquine. An erythrocyte G6PD analysis performed on blood taken 2 days after symptoms appeared was normal. A reticulocyte count revealed 12% reticulocytes at this time. These results suggest that: (Objective 7)
 - the patient definitely does not have G6PD deficiency but could have pyruvate kinase deficiency
 - another G6PD test should be done in several months when the reticulocyte count returns to normal
 - leukocytes could be contaminating the sample giving a false result
 - the patient probably has the G6PD Mediterranean variant
- The main consequence of enzyme defects in the glycolytic pathway is: (Objective 3)
 - decreased ATP production
 - Heinz body formation
 - decreased formation of reduced glutathione
 - decreased formation of 2,3-BPG

REVIEW QUESTIONS (continued)

LEVEL I

5. Which is true for the inheritance pattern for G6PD? (Objective 4)
 - a. It is X-linked and only found in males.
 - b. It is autosomal dominant and affects all offspring.
 - c. It is X-linked; however, females can be affected.
 - d. It is autosomal, and males are affected; females are carriers.
6. Which of the following is a quantitative test for G6PD? (Objective 6)
 - a. rate reduction test
 - b. fluorescent spot test
 - c. dye reduction test
 - d. ascorbate cyanide test
7. Following a hemolytic attack, which of the following is a common finding in G6PD deficiency? (Objective 5)
 - a. reticulocytosis
 - b. appearance of burr cells on the blood smear
 - c. increased haptoglobin
 - d. decreased unconjugated bilirubin
8. An abnormal erythrocyte resulting from splenic removal of Heinz bodies in erythrocytes is called: (Objective 7)
 - a. macrocyte
 - b. target cell
 - c. bite cell
 - d. dacryocyte
9. The type of hemolysis arising from G6PD deficiency is classified as: (Objective 2)
 - a. extravascular
 - b. intravascular
 - c. complete
 - d. rapid
10. What compound can induce anemia in G6PD deficiency? (Objective 8)
 - a. aspirin
 - b. vitamin C
 - c. iron
 - d. primaquine

LEVEL II

4. Which of the following G6PD isoenzyme variants will *not* result in hemolysis? (Objective 4)
 - a. G6PD Mediterranean
 - b. G6PD-B
 - c. G6PD Canton
 - d. G6PD-A⁻
5. The blood smear of a patient with chronic nonspherocytic hemolytic anemia reveals echinocytes, acanthocytes, target cells, and irregularly contracted cells. Which follow-up test could help define the cause of this anemia? (Objective 6)
 - a. PEP fluorescent test
 - b. ascorbate cyanide test
 - c. fluorescent spot test
 - d. quantitation of G6PD
6. Explain why bite cells are *not* characteristic of pyruvate kinase deficiency. (Objectives 3, 5, 6)
 - a. The spleen removes them as they are formed.
 - b. The erythrocyte forms a spherocyte as inclusions are removed.
 - c. Heinz bodies are not formed in pyruvate kinase deficiency.
 - d. Pyruvate kinase deficiency does not cause abnormal erythrocyte morphology.
7. Congenital nonspherocytic hemolytic anemia syndrome is associated with which G-6-PD variants? (Objective 4)
 - a. Class I
 - b. Class II
 - c. Class III
 - d. Class IV
8. Harmful peroxides in the erythrocyte are neutralized by which of the following? (Objective 2)
 - a. ATP production
 - b. Heinz bodies
 - c. bilirubin
 - d. glutathione
9. A patient is suspected of having a form of G6PD deficiency but is *not* affected by ingestion of fava beans. How can this be explained? (Objective 4)
 - a. The patient has the G6PD Mediterranean type.
 - b. The type of G6PD present is G6PD-B.
 - c. The patient does not have G6PD deficiency.
 - d. A mild form of G6PD is present.
10. Which lab test is most useful in diagnosing G6PD deficiency? (Objective 1)
 - a. fluorescent spot test
 - b. CBC
 - c. reticulocyte count
 - d. PEP fluorescent test

ANSWERS TO CASE STUDY QUESTIONS

Case Summary: Henry, a 25-year-old black male experienced fever, chills, and general malaise 3 days after receiving prophylactic primaquine. Laboratory testing revealed that he was anemic and the bilirubin was increased. In

addition, haptoglobin was decreased. Review of the blood smear revealed bite cells and spherocytes. A Heinz body stain was positive. Based on these results, a hemolytic anemia was suspected. He received two units of packed

red blood cells. A test for G6PD was performed and results were borderline low. Follow-up testing revealed a low G6PD.

Question:

1. What test should be considered after finding bite cells on a blood smear?

Explanation:

The appearance of bite cells on a blood smear suggests physical damage to the RBCs as the spleen attempts removal of Heinz bodies. Therefore, a Heinz body stain can be employed to reveal their presence as a cause of the anemia.

Question:

2. Why was the initial G6PD test result normal and the repeat test abnormal?

Explanation:

The initial test for G6PD was normal for two reasons. First, the older, more deficient erythrocytes were selectively destroyed during the hemolytic crisis, leaving younger cells with more normally functioning enzyme. Second, the patient had been transfused, and therefore any blood sample would not be representative of his own cells but would contain G6PD contributed by the donor erythrocytes.

Question:

3. What was the precipitating cause of the patient's anemia?

Explanation:

The patient developed anemia because of treatment with the oxidant drug primaquine. Oxidant damage to hemoglobin due to lack of reducing power supply by G6PD in the hexose-monophosphate shunt leads to erythrocyte destruction.

ANSWERS TO CHECKPOINTS

Checkpoint! 1

Transfusion of red blood cells in a patient with chronic nonspherocytic, hemolytic anemia due to an erythrocyte enzyme deficiency does not reverse or prevent the recipient's condition. However, a transfusion does help to raise the patient's hemoglobin. If tests are performed to quantitate the enzyme after a transfusion, the results may be within the normal reference interval. Explain.

Answer

Presence of transfused cells contribute to a falsely normal test result because these cells are normal and contain a normal amount of the enzyme.

Checkpoint! 2

Oxidant compounds are harmful because they result in production of harmful peroxides or other oxygen radicals that overwhelm the body's natural mechanisms to scavenge them. Why is the mechanism of protection against oxidants easily compromised in G6PD deficiency?

Answer

Protection from oxidants is easily overcome in G6PD deficiency because the enzyme cannot supply enough NADPH to keep glutathione in the reduced state. Reduced glutathione is the cell's primary protection from oxidants.

Checkpoint! 3

Erythrocyte morphology should always be examined carefully. The ability to pick up subtle clues as to the cause of a disease process can be acquired from a comprehensive evaluation of abnormal erythrocyte morphology. How is this likely to aid the diagnosis of G6PD deficiency?

Answer

Careful evaluation of a blood smear and reporting of bite cells will alert the health care practitioner as to the mechanism of cell destruction. When the mechanism of destruction is considered, this will lead to the selection of more diagnostically effective definitive tests to find the root cause of the anemia.

Checkpoint! 4

What are the differentiating characteristics of PK and G6PD deficiencies found on the peripheral blood smear?

Answer

PK deficiency has echinocytes and irregularly contracted cells; G6PD deficiency has bite cells and spherocytes. After splenectomy, additional cell abnormalities may be found.

Hemolytic Anemia: Immune Anemias

Linda A. Smith, Ph.D.

■ OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. List the antibody systems or specificities usually involved in:
 - a. cold agglutinin syndrome
 - b. paroxysmal cold hemoglobinuria (PCH)
 - c. warm autoimmune hemolytic anemias (WAIHA)
2. Describe the DAT, its purpose and identify the typical DAT profile (polyspecific AHG, anti-IgG, anti-C3) found in patients with cold agglutinin syndrome and warm autoimmune hemolytic anemia.
3. Describe and recognize the characteristic hematologic findings associated with the following conditions:
 - a. cold agglutinin syndrome
 - b. warm autoimmune hemolytic anemia (WAIHA)
4. Describe and recognize the typical hematologic laboratory findings in ABO and Rh hemolytic disease of the fetus and newborn (HDFN).
5. Contrast alloimmune and autoimmune hemolytic anemias including stimulus for antibody production, site of hemolysis, type of antibody involved, and direct antiglobulin test (DAT) and indirect antiglobulin test (IAT) reactions.
6. List the most common antibody specificities involved in immediate and delayed hemolytic transfusion reactions.

■ OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. Compare the pathophysiology of extravascular and intravascular hemolysis in immune hemolytic anemia including site of destruction, immunoglobulin class of antibody, and underlying mechanism.
2. Given a set of laboratory data, determine the underlying mechanism of hemolysis and suggest confirmatory tests.
3. Contrast the different mechanisms of drug-induced immune hemolytic anemia and identify the drugs commonly involved.
4. Describe the mechanism of hemolysis, select the confirmatory tests for paroxysmal cold hemoglobinuria (PCH), and evaluate the results.
5. Compare the prenatal and postnatal pathophysiology of hemolytic disease of the newborn.

CHAPTER OUTLINE

- ▶ Objectives—Level I and Level II
- ▶ Key terms
- ▶ Background basics
- ▶ Case study
- ▶ Overview
- ▶ Introduction
- ▶ Classification of immune hemolytic anemias
- ▶ Sites and factors that affect hemolysis
- ▶ Mechanisms of hemolysis
- ▶ Laboratory identification of sensitized red cells
- ▶ Autoimmune hemolytic anemias (AIHA)

OBJECTIVES—LEVEL II (continued)

6. Interpret the results of laboratory tests for HDFN and determine whether evidence of hemolysis is present.
7. Compare and contrast the pathophysiology and clinical findings of an immediate transfusion reaction with those of a delayed reaction.
8. List the causes of the secondary types of cold agglutinin syndrome and warm autoimmune hemolytic anemia and identify key laboratory results linking the cause and the autoimmune condition.
9. Compare the typical laboratory findings in immediate versus delayed transfusion reactions.

KEY TERMS

Alloimmune hemolytic anemia
 Antihuman globulin (AHG)
 Autoimmune hemolytic anemia (AIHA)
 Direct antiglobulin test (DAT)
 Donath-Landsteiner antibody
 Drug-induced hemolysis
 Erythroblastosis fetalis
 Hemolytic disease of the fetus and newborn (HDFN)
 Hemolytic transfusion reaction
 Immune hemolytic anemia (IHA)
 Indirect antiglobulin test (IAT)
 Kernicterus
 Paroxysmal cold hemoglobinuria (PCH)

BACKGROUND BASICS

The information in this chapter builds on the concepts learned in previous chapters. Additionally, a basic understanding of immunology principles and an introduction to immunohematology will be helpful. To maximize your learning experience, you should review these concepts before starting this unit of study.

Level I

- ▶ Summarize the normal production, life span, and destruction of erythrocytes.
- ▶ List the reference interval for the hematology parameters: hemoglobin, hematocrit, erythrocyte count, and reticulocytes.
- ▶ List the different intrinsic and extrinsic factors that can result in hemolytic anemia.
- ▶ Describe the basic structure of immunoglobulin and its normal physiologic role.

Level II

- ▶ Describe the role of erythropoietin and regulation of its production.
- ▶ Differentiate intravascular and extravascular destruction of erythrocytes and relate to laboratory parameters in the diagnosis of abnormal hemolysis.
- ▶ Choose laboratory tests to assist in diagnosing anemia in a cost-efficient and effective manner.
- ▶ Identify clinical signs of hemolytic anemia and changes that occur in laboratory tests that signal possible hemolytic anemia.

CASE STUDY

We will refer to this case study throughout the chapter.

Nancy, a 28-year-old female, makes an appointment with her physician because she is tired all the time and is short of breath with minor exertion. She indicates that the symptoms have been ongoing for about 3 weeks. She has no known history of chronic diseases. Consider the initial laboratory tests that should be done to evaluate this patient's condition based on clinical history and symptoms.

OVERVIEW

This chapter compares the different types of immune mediated hemolytic anemias: autoimmune, alloimmune, and drug induced. The underlying mechanism for each of these anemias involves the reaction of an antibody with erythrocyte antigens and subsequent cell destruction either by intravascular or extravascular processes. The mechanisms of intravascular and extravascular hemolysis are compared. The tests necessary to detect erythrocyte sensitization and identify the causative antibody are described.

The pathophysiology, clinical and laboratory findings, differential diagnosis, and therapy are discussed for each of the major types of autoimmune hemolytic anemia. Hemolytic transfusion reactions and hemolytic disease of the fetus and newborn are included as examples of alloimmune hemolytic anemia. The causative antibody and clinical presentation for acute and delayed transfusion reactions are compared and the laboratory tests required to confirm hemolytic transfusion reactions are described. In the section on hemolytic disease of the newborn (HDFN), ABO-HDFN and Rh-HDFN are compared. The treatment of a fetus and the newborn with this condition as well as preventative measures is included.

INTRODUCTION

When erythrocytes are destroyed prematurely by an immune mediated process (antibody and/or complement), the disorder is referred to as an **immune hemolytic anemia (IHA)**. The individual, however, might or might not become

TABLE 1

Classification of Immune Hemolytic Anemias

Classification	Causes
Autoimmune	Warm-reactive antibodies
	Primary or idiopathic
	Secondary
	Autoimmune disorders (systemic lupus erythematosus, rheumatoid arthritis, and others)
	Chronic lymphocytic leukemia and other immunoproliferative diseases
	Viral infections
	Neoplastic disorders
	Chronic inflammatory diseases
	Cold-reactive antibodies
	Primary or idiopathic (cold hemagglutinin disease)
	Secondary
	Infectious diseases (<i>Mycoplasma pneumoniae</i> , Epstein-Barr virus and other organisms)
	Lymphoproliferative disorders
Paroxysmal cold hemoglobinuria	
Mixed-type	
Drug induced	Drug adsorption
	Immune complex
	Autoantibody induction
	Membrane modification
Alloimmune	Hemolytic transfusion reaction
	Hemolytic disease of the fetus and newborn

anemic, depending on the severity of hemolysis and the ability of the bone marrow to compensate for erythrocyte loss. Initial confirmation of the underlying immune mechanism is accomplished by demonstrating attachment of antibody or complement to the patient's erythrocytes. Diagnosis of anemia (and underlying hemolysis) is determined by laboratory findings such as a decrease in hemoglobin and hematocrit, an increase in reticulocytes and/or indirect bilirubin, and a decrease in serum haptoglobin. Table 2 summarizes some common laboratory values and clinical findings characteristically seen in hemolytic anemia.

► CLASSIFICATION OF IMMUNE HEMOLYTIC ANEMIAS

Determining the underlying process of immune hemolysis is important because each type requires a specific treatment regimen. Initially, IHA can be classified into three broad categories based on the stimulus for antibody production^{1,2} (Table 1 🌟): These are:

- Autoimmune hemolytic anemia
- Drug-induced hemolytic anemia
- Alloimmune hemolytic anemia

Autoimmune hemolytic anemia (AIHA) is a complex and incompletely understood process characterized by an immune reaction against self-antigens and shortened erythrocyte survival.^{1,2} Individuals produce antibodies against their own erythrocyte antigens (autoantibodies). These autoantibodies are usually directed against high-incidence antigens (antigens present on the erythrocytes of most people). The autoantibodies characteristically react not only with the erythrocytes of the individual but also with the erythrocytes of other individuals carrying the antigen. The antibody in cold autoimmune hemolytic anemia is usually directed against antigens of the Ii system. The autoantibody in warm autoimmune hemolytic anemia most commonly has a complex specificity that reacts with epitopes on cells that possess Rh antigens. These complex-specific antibodies do not react with Rh null cells or some Rh deleted cells. However, some autoantibodies have a single specificity such as anti-e. In these patients, the autoantibody reacts with the patient's own cells and only with cells of individuals who possess the specific antigen. The reactions that occur with autoantibodies include erythrocyte lysis, sensitization (attachment of antibody or complement), or agglutination.

Autoimmune hemolytic anemias are further classified as warm or cold hemolytic anemia based on clinical symptoms and on the optimal temperature at which the antibody reacts (in vivo and in vitro)¹⁻³ (Table 2 🌟). Some antibodies react best at body temperature (37°C); the anemia they produce is termed *warm autoimmune hemolytic anemia* (WAIHA). About 70% of the AIHAs are of the warm type. The majority of warm autoantibodies are of the IgG class (most frequently IgG1) and cause extravascular hemolysis of the erythrocyte. A few warm-reacting autoantibodies of either the IgM or the IgA class have been identified.⁴⁻⁸ Cold hemolytic anemias, on the other hand, are usually due to the presence of an IgM antibody with an optimal thermal reactivity below 30°C. Hemolysis with cold-reacting antibodies results from the binding and activation of complement by IgM. The IgM antibody attaches to erythrocytes in the cold and fixes complement. After warming, the antibody dissociates from the cell, but the complement remains, either causing direct cell lysis or initiating extravascular hemolysis. Included in the cold hemolytic anemia classification is a special condition, paroxysmal cold hemoglobinuria (PCH), which is characterized by a cold-reacting IgG class antibody.

A third major category, mixed-type autoimmune hemolytic anemia, demonstrates both warm-reacting (IgG) autoantibodies and cold-reacting (IgM) autoantibodies.

Drugs that attach to the erythrocyte membrane or alter it in some way can cause **drug-induced hemolysis**. Historically, several different mechanisms of hemolysis have been hypothesized based on whether the drug binds directly to the cell, reacts with an antibody in the circulation to form

★ TABLE 2

Characteristics of Agglutinins in Hemolytic Anemia

	Warm-Reacting Antibodies	Cold-Reacting Antibodies
Immunoglobulin (Ig) class	IgG IgM (rare) IgA (usually with IgG)	IgM IgG (PCH only)
Optimal reactivity	37°C	<30°C, usually <10°C
Mechanism of hemolysis	Attachment of membrane-bound IgG or C3b to macrophage receptors (extravascular)	Complement-mediated lysis (intravascular), or attachment of membrane-bound C3b to macrophage receptors (extravascular)
Specificity	Usually broad specificity anti-Rh	Usually autoanti-I Occasionally autoanti-i PCH-autoanti-P

PCH = paroxysmal cold hemoglobinuria

an immune complex that binds to the cell, or alters the erythrocyte antigens to stimulate formation of autoantibodies. These mechanisms are discussed in detail later in this chapter.

Alloimmune hemolytic anemia occurs as a result of antibody development to an erythrocyte antigen that the individual lacks. When an individual is exposed to erythrocytes from another person, antigens on the transfused cells may be lacking on the erythrocytes of the recipient. Therefore, these antigens on the transfused cell can be recognized as foreign by the recipient's lymphocytes and stimulate the production of antibodies (alloantibodies). In contrast to autoantibodies, these alloantibodies react only with the antigens on the transfused cells or cells from individuals who possess the antigen. The alloantibodies do not react with the individual's erythrocytes. Examples of alloimmune hemolytic anemia are:

- Hemolytic disease of the fetus and newborn in which the mother makes antibodies that react with the antigens on the fetal erythrocytes
- Transfusion reactions in which the recipient makes antibodies to antigens on the transfused (donor) cells

The presence of alloantibodies can be demonstrated *in vitro* by performing an antibody screen. In this test, the patient's serum is reacted with commercial erythrocytes containing most of the clinically significant antigens. An autocontrol consisting of the patient's serum and erythrocytes can also be set up. When only alloantibodies are present, the autocontrol will show no hemolysis or agglutination while the mixture of patient's serum and the commercial cells will produce agglutination and, in rare cases, hemolysis.

✓ Checkpoint! 1

What are the three major categories of immune hemolytic anemia, and how is antibody production stimulated in each type?

🔍 CASE STUDY (continued from earlier in this chapter)

Nancy's initial CBC shows a hemoglobin value of 7.0 g/dL (70 g/L) and a hematocrit of 0.21 L/L (21%). Her WBC count and platelet count are within reference interval.

1. What are some reasons that she could have a low hemoglobin value?

▶ SITES AND FACTORS THAT AFFECT HEMOLYSIS

Regardless of whether it is caused by alloantibodies or autoantibodies, hemolysis can be intravascular or extravascular, depending on the class of antibody involved and whether or not the complement cascade has been completely activated. Most immune-mediated hemolysis is extravascular. Erythrocytes sensitized with antibody or complement components attach to macrophages in the spleen or liver via macrophage receptors for the Fc portion of immunoglobulin or the C3b component of complement. These cells are then phagocytized (Figure 1). Intravascular hemolysis occurs if the complement cascade is activated through C9 (the membrane attack complex), resulting in

■ **FIGURE 1** Immune mediated extravascular hemolysis. Erythrocytes sensitized with antibody or complement (C3b) attach to macrophages via specific cell receptors for these immune proteins.

★ TABLE 3

Factors Affecting the Rate of Hemolysis in Immune Hemolytic Anemias

Factor	Effect
Class of immunoglobulin coating the erythrocytes	For the IgG subclasses, the affinity of macrophage receptors and rate of hemolysis is greatest for IgG3 and IgG1
The number of Ig molecules per erythrocyte	Immunoglobulins will coat a cell with a high density of antigens (large number of antigens) more heavily than a cell with low density (fewer) antigens
Ability of the Ig to activate complement	IgM and IgG can activate complement; for IgG, the ability to activate complement, is IgG3>IgG1>gG2
Thermal amplitude of the antibody	Warm-reacting (37°C) antibodies can cause hemolysis but cold-reacting (0–4°C) antibodies usually do not
The activity level of macrophages	Suppression of F _c receptors will decrease rate of hemolysis

lysis of the cell. The rate at which hemolysis occurs in hemolytic anemia is related to several factors.^{9–11} The major factors and their effects are summarized in Table 3★. A full description of the mechanisms is found on the web (Factors Affecting Hemolysis).

✓ **Checkpoint! 2**

Explain how the class of immunoglobulin, amount of antibody bound, and thermal reactivity of the antibody affect hemolysis.

▶ **MECHANISMS OF HEMOLYSIS**

The mechanisms for hemolysis are based on whether IgM, IgG, and/or complement is/are present on the erythrocyte. Specific phagocytic cells in the spleen or liver initiate extravascular hemolysis of cells coated with IgG or complement. Complete activation of the complement cascade results in intravascular hemolysis.

IgG-MEDIATED HEMOLYSIS

IgG mediates erythrocyte destruction by first attaching to the erythrocyte membrane antigens through the Fab portion of the Ig molecule. The Fc portion of IgG is exposed to the environment. Fc receptors (FcγR-I, -II, -III) on macrophages in the red pulp of the spleen bind to the Fc portion of the attached IgG. After binding, the macrophage pits the antigen-antibody (Ag/Ab) complex, fragmenting the cell membrane. The erythrocyte membrane initially reseals itself. With repeated splenic passage, however, the erythrocyte continues to lose membrane and gradually assumes a spherocytic

shape. As the cell becomes more spherocytic, it becomes rigid and less deformable and is eventually phagocytized by splenic macrophages. Alternatively, the antibody-sensitized cell can be entirely engulfed by the macrophages (phagocytosis). Natural killer (NK) cells and neutrophils also have FcγR. Neutrophils are capable of phagocytosis (FcγR-I, -III), and interaction of antibody-coated cells with NK cells usually results in antibody-dependent cell-mediated cytotoxicity (ADCC), the recognition and lysis of cells by NK cells. This occurs through binding of IgG by the FcγRIII (CD16) on NK cells. Any target cell coated with IgG can be bound to NK cells and lysed.

As the spleen becomes saturated with “sensitized” RBC (cells coated with antibody and/or complement), the liver assists in removal of the cells. Lightly opsonized cells are more efficiently removed in the spleen due to the sluggish blood flow there. The liver can also be of some importance in removing heavily sensitized cells. The splenic tissue proliferates in response to an increase in erythrocyte sequestration, accounting for splenic enlargement (splenomegaly) in chronic warm-immune hemolytic anemias. In the immune hemolytic anemias in which complement is activated, complement as well as IgG can be detected on the erythrocyte membrane. This enhances the phagocytosis of sensitized cells by increasing the likelihood of the cell binding to either the Fc and/or C3b receptors of macrophages.

COMPLEMENT-MEDIATED HEMOLYSIS

The complement system consists of more than 20 serum proteins responsible for a number of diverse biological activities including the mediation of acute inflammatory responses and destruction of cells and microorganisms. The major roles of complement in immune hemolytic anemias are sensitization and lysis of erythrocytes.¹² Sensitization occurs when only a portion of the cascade is activated and deposited on the erythrocyte membrane; lysis results when the entire system is activated.

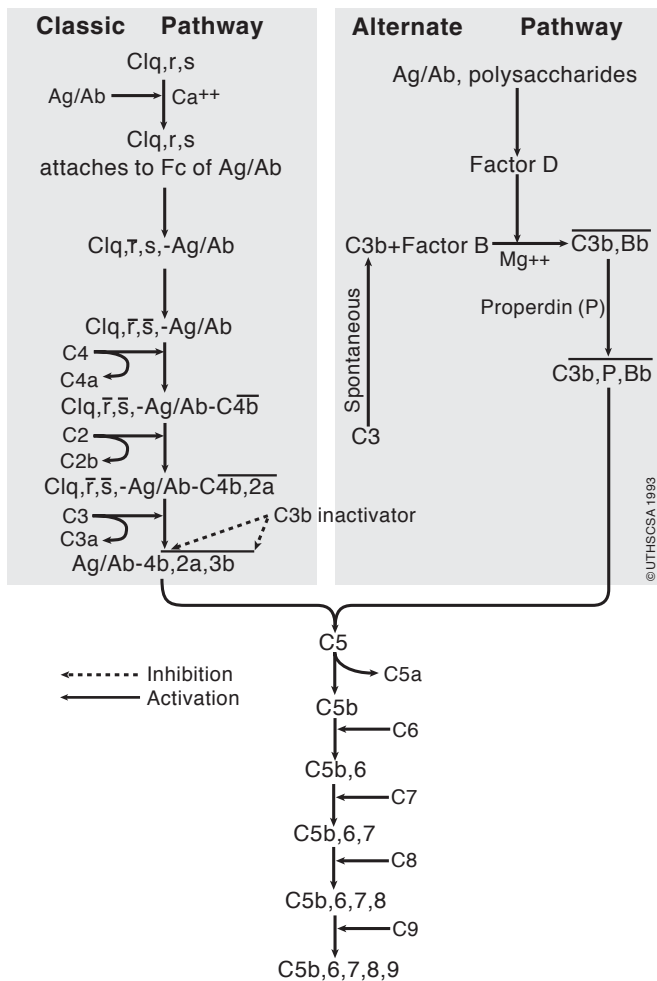

The complement proteins are designated numerically (i.e., C1, C2, C3) or by letters or historical names. Complement proteins normally circulate in an inactive state. Under certain circumstances, the proteins become sequentially activated in a cascade-like fashion, similar to the components of the coagulation cascade. Activation of parts of the cascade is enzymatically mediated while other portions occur without enzymatic cleavage of the molecules. An activated component is identified by placing a bar over the component (C₅).

The complement cascade can be initiated by at least three separate mechanisms:

- Classic
- Alternate
- Lectin

The usual and most important activation pathway in IHA is the classic, although on some occasions the alternate

pathway can be activated (Figure 2 ■). The classic complement pathway can be initiated by an antigen-antibody reaction. Antibodies of the IgM class as well as IgG1 and IgG3 (IgG2 less efficiently) subclasses can activate this pathway. The first complement component (C1q) must attach to the

■ **FIGURE 2** The complement cascade. The central event in complement activation is the activation of C3 by C3 convertases. This can occur by two separate but interrelated mechanisms, the classic and alternate pathways. The classic complement pathway can be initiated by an antigen-antibody reaction. The antigen-antibody complex activates the C1q, r, s complex, which in turn activates C4 by proteolytic cleavage to C4a and C4b. C2 binds to C4b and is proteolytically cleaved by C1s to form C2a and C2b. The C4b2a complex serves as C3 convertase. In the alternate pathway, C3b serves as the cofactor of the C3-cleaving enzyme complex (C3b, P, Bb), also known as *C3 convertase*. Thus, the C3b serves to prime its own activation. The C3b formed through the classic pathway can directly initiate the assembly of the alternate pathway C3 convertase. C3 can also be activated by spontaneous hydrolysis. The C3b complexes formed by the classic and alternate pathways activate C5 to C5a and C5b. Membrane damage is initiated by the assembly of C5b with C6, 7, 8, 9.

Fc regions of an antibody, requiring that two antibody-binding sites be in close proximity. Thus, the attachment of complement depends highly on the density or concentration of antibody molecules and their spatial arrangement on the cell surface. The IgG molecule is much less efficient than IgM in providing these side-by-side antibody Fc regions. Only one IgM molecule is required to activate the complement pathway whereas two IgG molecules are required; thus, IgM is much more likely to activate complement than IgG. Therefore, the nature of the antibody involved is an important determinant of the extent of erythrocyte destruction by complement.

Activation of the cascade is initiated when the first complement component, C1, binds to the Fc portion of an IgG or IgM antibody molecule. C1 is a tri-molecular complex that initially binds via its C1q portion and subsequently via C1r and C1s. This attachment initiates activation of the other complement components (C4, C2, C3). The complex containing C3b activates the terminal components, C5 to C9. Activation of these terminal complement components, known as the *membrane attack complex (MAC)*, is responsible for the lytic attack on the erythrocyte membrane and is common to both pathways. Membrane leakage begins at the C8-activation stage when a transmembrane pore is formed. C9 prevents the pore from resealing, resulting in osmotic lysis. The alternate pathway of complement activation can be initiated by aggregated IgG, IgA, and IgE, as well as by a number of polysaccharides and liposaccharides. In this pathway, C3 is activated directly, bypassing C1, C2, and C4 activation.

If complement activation on the erythrocyte membrane is complete (C1–C9), intravascular hemolysis will occur. However, activation of complement is not always complete (through C9) and thus does not always lead to direct cell lysis. More commonly, activation proceeds only through C3 on the erythrocyte membrane (in which case the cell is said to be *sensitized*). In this scenario, the C3 is broken down into two fragments: C3a, which is released into the plasma, and C3b, which remains attached to the cell membrane. The sensitized cell with attached C3b is totally or partially engulfed by binding to the C3b receptors (CR1, CR3) of macrophages in the liver (most complement-coated cells are removed in this organ). Because of the enzymatic action of C3b inactivator in plasma, C3b on erythrocytes can be further cleaved to form C3c and C3d before the cell encounters macrophages. C3c dissociates from the membrane, but C3d remains attached. Erythrocytes coated with C3d have a normal survival because macrophages have no receptors for this complement component. Thus, the balance between C3b deposition on the membrane and C3b inactivation determines the susceptibility of erythrocytes to phagocytosis by macrophages via the C3b receptors.

In addition to C3b inactivator, other inhibitors of complement activation exist. Some of these inactivators and their functions are listed in Web Table 1 🌐.

IgM-MEDIATED HEMOLYSIS

In cold immune hemolytic anemia, the IgM molecule becomes attached to the erythrocyte membrane, but these sensitized cells are not removed from circulation in the same manner as those sensitized with IgG because macrophages do not have receptors for the Fc portion of IgM. However, IgM is an efficient activator of complement, and cells can be lysed intravascularly if complement activation through C9 is complete. If activation is incomplete and only C3b coats the cells, they can be destroyed extravascularly via adherence to CR1 and CR3 receptors on macrophages. Adherence of the cell to macrophages via complement receptors and subsequent phagocytosis, however, is less efficient than immune adherence (adherence mediated via immunoglobulin) and phagocytosis via Fc γ R macrophage receptors. It has been estimated that more than 100,000 molecules of the complement component C3b are required on the cell surface to induce phagocytosis by macrophages via complement. C3b is also inefficient in promoting adherence to macrophages because much of the C3b is inactivated to C3d. Thus, extravascular hemolysis of cells sensitized with complement is not as severe as hemolysis of cells sensitized with IgG.

In addition to activating complement, IgM antibodies agglutinate cells. *In vitro*, agglutination is a useful phenomenon for detecting the presence of cold agglutinins.

✓ Checkpoint! 3

Compare the mechanisms of IgG mediated hemolysis with those of IgM mediated hemolysis.

▶ LABORATORY IDENTIFICATION OF SENSITIZED RED CELLS

When immune hemolytic anemia is suspected, tests to detect and identify the causative antibody are indicated. In general, two distinct techniques are used:

- Agglutination in saline, which will detect antibodies of the IgM class
- **Antihuman globulin (AHG)** test, which will detect antibodies of the IgG class and/or complement

IgM antibodies can be detected by agglutination reactions between test sera and appropriate erythrocytes suspended in saline but IgG antibodies cannot. This difference in the ability of IgG and IgM to cause agglutination in saline can be explained on the basis of the difference in size of the two antibodies in relation to the zeta potential. The erythrocyte zeta potential is an electrostatic potential created by a difference in the charge density of the inner and outer layers of the ionic cloud around erythrocytes when they are suspended in saline. This force tends to keep the erythrocytes about 25 nm apart in solution. Thus, any antibody that causes agglutina-

tion of saline- or plasma-suspended cells must be large enough to span the 25 nm gap between cells. The IgM pentamer has a possible span of 35 nm; therefore, it can overcome the electrostatic forces separating the cells and cause agglutination (Figure 3 ■). However, the maximum span of the IgG molecule is about 14 nm, and it cannot reach antigens on two separate cells to cause agglutination. Thus, detection of IgG antibodies requires a different technique using a substance that will connect the antibody molecules on separate cells and cause agglutination. The substance used is AHG, essentially an antiserum to human IgG.

The AHG test, sometimes referred to as the *Coombs test*, is the specific laboratory procedure designed to detect erythrocytes sensitized with IgG and/or complement. AHG is a broad-spectrum antiserum produced in rabbits that reacts against human immunoglobulin and complement. It contains divalent antibodies that are capable of attaching to the Fc region of immunoglobulins or to complement components on two separate cells, thus bridging the distance between cells and leading to the lattice formation known as *agglutination*.

The two applications of the AHG test are:

- Direct: detects erythrocytes coated with antibody *in vivo*
- Indirect: detects antibodies in the plasma or serum

DIRECT ANTIGLOBULIN TEST

The **direct antiglobulin test (DAT)**, or direct Coombs test) detects erythrocytes that have been sensitized with antibody and/or complement *in vivo* (Web Figure 1 ■). This

■ **FIGURE 3** The zeta potential of erythrocytes keeps the cells about 25 nm apart when suspended in saline. IgG antibodies have a span of about 14 nm, not enough to bridge the gap between cells and cause agglutination. IgM antibodies, however, are pentamers with a span of about 35 nm, a distance sufficient to bridge the space between cells and cause agglutination.

test should always be performed in suspected cases of AIHA because it differentiates AIHA from all other types of hemolytic anemia. Specimens collected in tubes with ethylenediaminetetraacetate (EDTA) are preferred to clotted specimens for the DAT procedure because EDTA chelates Ca^{++} and Mg^{++} , preventing the in vitro binding of complement to red cells that can be mediated by naturally occurring cold reactive antibodies (e.g., anti-I). However, complement that has been bound in vivo will be detected when using an EDTA specimen. The procedure involves two steps. First, the cells are washed to remove any traces of plasma proteins not actually attached to the cell membrane. Then polyspecific AHG (anti-IgG and anticomplement) is added to the saline-washed patient cells. Agglutination of patient cells by AHG is considered positive evidence for the presence of IgG and/or complement components on the cells due to in vivo coating.

A positive test with polyspecific AHG should be followed by a DAT with monospecific AHG antiserum that reacts specifically with either immunoglobulin (IgG) or complement to determine the type of proteins bound to the erythrocyte. IgG antibodies are found with or without complement attached. Therefore, if the DAT with anti-IgG is positive, the test with anticomplement (anti-C3d or anti-C3b) can be positive or negative. If the anti-IgG test is positive, the antibody can be removed from the cell by an elution process. The resulting eluate (solution containing the antibody) is reacted with a panel of cells of known antigenic makeup to identify the specificity of the antibody.

If an autoantibody is IgM, only complement will be detected on the erythrocytes as the IgM dissociates from the cells in the warmer part of the circulation. The polyspecific and the anti-C3 monospecific DAT test will be positive; the anti-IgG will be negative. An elution procedure is not used if only complement is detected on the erythrocyte because the complement alone will not cause a reaction with screening cells and the eluate will thus give a negative reaction.

INDIRECT ANTIGLOBULIN TEST

The **indirect antiglobulin test (IAT)** is used to detect antibodies in the patient's serum. A positive IAT indicates alloimmunization (immunization to antigens from another individual) and/or the presence of free autoantibody in the patient's serum. In the IAT, free antibody is detected by incubating the patient's serum with erythrocytes of known antigenic makeup (commonly referred to as *screening cells*). An autocontrol consisting of the patient's serum and erythrocytes is also performed. After a specified incubation period, the cells are washed free of excess serum, and the AHG antiserum is added. If antibody has attached to its corresponding erythrocyte antigen during the initial incubation period, the cells will agglutinate with AHG (Web Figure 2 ■).

Checkpoint! 4

Compare the purpose of the DAT and the IAT, and state the type of specimen used for each test.

NEGATIVE DAT IN AIHA

In a few cases of AIHA, antibody cannot be detected on the cells or in the serum.^{13,14} This can result from an insufficient number of IgG molecules on the erythrocyte, autoantibodies of the IgA or IgM class, or the presence of autoantibodies with a low affinity for the erythrocyte.^{1,15–16} The DAT will detect as few as 100–500 molecules of IgG per cell or 400–1100 molecules of complement per cell,³ but in vivo removal of sensitized cells by macrophages can occur when cells are coated with fewer IgG molecules. Thus, the in vivo life span of the sensitized cell can be significantly shortened as evidenced by the clinical findings of a typical hemolytic anemia, but the concentration of antibodies on the cell can be insufficient to give a positive DAT. Newer, more sensitive techniques, such as enzyme linked DAT, gel tests, and flow cytometry can detect lower concentrations of antibodies than the conventional DAT technique.^{17–19} IgA or IgM autoantibodies themselves are not detected using polyspecific AHG. However, if complement has been activated, it can be detected if sufficient molecules are present.

POSITIVE DAT IN NORMAL INDIVIDUALS

In contrast, some healthy blood donors and hospitalized patients can have a positive DAT but not shortened erythrocyte survival. The reason that some individuals have autoantibody coating their erythrocytes but have no evidence of hemolytic disease is not clear.¹ Factors that could be responsible for this phenomenon include the following:

1. The individual's macrophages may not be as active in removing sensitized cells as the macrophages in individuals with hemolytic disease.
2. The amount of antibody bound to cells might not be sufficient to cause decreased erythrocyte life span.
3. The subclass of antibody sensitizing the cell might not be recognized by macrophages. Macrophage Fc receptors have low affinity for the IgG2 and IgG4 subclasses. Erythrocytes coated with these immunoglobulins will give a positive direct DAT but in vivo survival of the cells will be normal.
4. The thermal amplitude of the antibody may be less than 37°C.
5. The positive DAT can be due to the presence of complement on erythrocytes. Increased amounts of C3d can be found on the erythrocytes, but because this component is not detected by macrophage receptors, erythrocytes do not have decreased survival.

6. Patients with hypergammaglobulinemia or receiving high-dose intravenous immunoglobulin (IVIG) could have a positive DAT because of nonspecific binding of immunoglobulins to the erythrocytes.

CASE STUDY (continued from earlier in this chapter)

When the laboratory professional examined the patient's peripheral blood smear, she noted that spherocytes were present. The reticulocyte count was elevated. She called the blood bank and found that the DAT on Nancy was positive with polyspecific AHG, anti-IgG, but negative with anticomplement.

2. What is the significance of the spherocytes?
3. Based on these results what do you suspect is going on in this patient? Explain.

▶ AUTOIMMUNE HEMOLYTIC ANEMIAS (AIHA)

During fetal life, a person's immune system recognizes self-antigens (those that appear on the individual's cells) and in turn does not usually mount an immune response to these antigens. The immune system normally prevents autoimmunization by ignoring self-antigenic determinants such as those that occur on an individual's erythrocytes. These antigens can, however, stimulate an immune response if injected into another individual because that person's immune system recognizes them as "foreign." The immune regulatory mechanisms that govern response to foreign or self-antigens are collectively known as *immune tolerance*.

It is generally accepted that autoimmune diseases occur because of a number of factors including genetic predisposition (familial or presence/absence of specific HLA antigens), exposure to infectious agents that can induce antibody production due to molecular mimicry, and defects in the mechanism regulating immune tolerance.²⁰ Suppressor T lymphocytes normally induce tolerance to self-antigens by inhibiting the antibody-producing activity of B lymphocytes to these antigens. Loss of this suppressor cell activity could result in the formation of antibodies against self. This loss of self-tolerance and resulting AIHA can occur at any age. The mechanism of antibody formation in AIHA is unknown, but because many cases of AIHA are associated with microbial infection, neoplasia, or drug administration, these agents may be involved in alteration of self-antigens and subsequent immune system response. Either warm or cold AIHA also can be categorized based on whether an underlying disease is associated with it. The two categories are:

- Primary or idiopathic: no underlying disease
- Secondary: underlying disease present

WARM AUTOIMMUNE HEMOLYTIC ANEMIA

Warm autoimmune hemolytic anemia (WAIHA) is the most common form of AIHA (70% of cases).² It is mediated by IgG antibodies whose maximal reactivity is at 37°C. In a majority (90%) of WAIHA cases, erythrocytes are sensitized with IgG and complement or IgG alone. Only 7% of cases are sensitized with complement alone. Most often, the antibody involved is IgG1 or IgG3. The antibody involved is rarely IgM or IgA.^{4,6-8}

WAIHA can occur at any age although the incidence increases after age 40. Childhood incidence peaks in the first 4 years of life.^{21,22} About 60% of the cases of warm AIHA are idiopathic.² In acute idiopathic WAIHA, severe anemia develops over 2 to 3 days, but the hemolysis is self-limited with duration of several weeks to several years. In other instances, the hemolysis is chronic and unabating.

The underlying disorders most frequently associated with secondary AIHA are:

- Lymphoproliferative disease, including chronic lymphocytic leukemia, and Hodgkin's disease. Chronic lymphocytic leukemia (CLL), found most frequently in older adults, is the disease most frequently associated with the development of secondary AIHA.²³ WAIHA often develops late in the disease when the immune dysregulation is greatest. In one study, more than 60% of the cases of WAIHA were in patients with CLL.²⁴ Many children with idiopathic WAIHA will eventually develop a lymphoproliferative disease.
- Neoplastic diseases
- Other autoimmune disorders, including systemic lupus erythematosus and rheumatoid arthritis, ulcerative colitis, Crohn's disease²⁵⁻²⁹
- Certain viral and bacterial infections^{30,31}
- Vaccinations³²⁻³⁴

Presence of the underlying disorder can complicate diagnosis and treatment of hemolytic anemia. In many cases, the AIHA is resolved by treating the underlying disease.

Pathophysiology

The warm autoantibody in AIHA is reactive with antigens on the patient's erythrocytes. Most often the specificity of the antibody is directed against antigens of the Rh system, although other antigen systems can be involved. When directed against the Rh system, the antibody can be specific for a single antigen (such as autoanti-e) or, more commonly, the antibody will react with a complex Rh antigen found on all erythrocytes except Rh null cells.^{1,2,35,36} The epitope against which these antibodies are directed has not been defined. Recent research suggests that the antibody can be against a component of the erythrocyte membrane such as glycophorins or protein band 4.1.^{1,7,37}

Most hemolysis in WAIHA is extravascular via splenic macrophages. Although complement is not needed for cell

destruction, if both antibody and complement are on the cell membrane, phagocytosis is enhanced. If erythrocyte destruction exceeds the compensatory capacity of the bone marrow to produce new cells, anemia develops. Direct complement-mediated intravascular hemolysis associated with IgM antibodies in warm AIHA is rare.

Clinical Findings

The most common presenting symptoms in idiopathic AIHA are related to anemia. Progressive weakness, dizziness, dyspnea on exertion, back or abdominal pain, and jaundice are common. In secondary AIHA, signs and symptoms of the underlying disorder can obscure the features of the hemolytic anemia. The patient can present with signs and symptoms of both the underlying disease and hemolysis or just the disease. The signs of WAIHA in a few patients can precede development of the underlying disease. While mild to moderate splenomegaly is present in more than 50% of patients with WAIHA, massive splenic enlargement suggests an underlying lymphoproliferative disorder. Hepatomegaly is found in about one-third of patients with primary WAIHA.

✓ Checkpoint! 5

What are the clinical findings and the immune stimuli for WAIHA?

Laboratory Findings

The most common laboratory findings associated with WAIHA are listed in Table 4. Findings such as the positive DAT, autoantibody in the serum, and presence of spherocytes on the peripheral blood smear reflect the immune-mediated destruction of the erythrocyte.

Peripheral Blood Moderate to severe normocytic, normochromic anemia is typical. In well-compensated hemolytic disease, anemia can be mild or absent, and the only abnormal parameters can be a positive DAT and an increase in reticulocytes. Reticulocytes are invariably increased in uncomplicated hemolytic disease. The reticulocyte production index can be as high as 6 or 7. Depending on the degree of reticulocytosis, macrocytosis can be present.

The blood smear frequently shows erythrocyte abnormalities that suggest a hemolytic process. Polychromasia, nucleated red blood cells, spherocytes, schistocytes, and other poikilocytes are characteristic (Figure 4). The spherocytes of AIHA are usually more heterogeneous than are the spherocytes associated with hereditary spherocytosis. This anisocytosis is readily noted upon examining the blood smear and is indicated by an increase in red cell distribution width (RDW) on automated hematology analyzers. Erythrophagocytosis by monocytes can be seen. The engulfed erythrocyte is readily detected if the cell still contains its pink-staining hemoglobin. If the hemoglobin has leaked out of the cell, however, only colorless vacuoles are seen. Leukocyte counts are normal or increased with neutrophilia in id-

TABLE 4

Laboratory Findings Associated with WAIHA

Common findings	Positive DAT Normocytic, normochromic anemia Increased reticulocytes Spherocytes and other erythrocyte abnormalities Presence of autoantibody in the serum Increased serum bilirubin (total and unconjugated) Decreased serum haptoglobin Positive antibody screen with all cells including autocontrol Incompatible crossmatches with all donors
Other laboratory findings that can be associated with hemolysis in WAIHA	Increased osmotic fragility Increased urine and fecal urobilinogen Hemoglobinemia,* hemoglobinuria, methemoglobinemia, hemosiderinuria

*Seen only in acute hemolytic episode

idiopathic WAIHA but can vary in the secondary form based on the underlying disease. Platelet counts are usually normal or slightly increased. When severe thrombocytopenia accompanies warm AIHA, the disease is called *Evan's syndrome*.

Bone Marrow Bone marrow examination is not necessary for the diagnosis of WAIHA. The bone marrow can show

■ FIGURE 4 A blood smear from a patient with warm autoimmune hemolytic anemia (WAIHA). There is marked anisocytosis due to the presence of spherocytes and large polychromatophilic erythrocytes. The nucleated cells are normoblasts. (Wright stain; 1000× original magnification)

erythroid hyperplasia depending on the degree of hemolysis. Erythrophagocytosis by macrophages can be seen. Compensatory bone marrow response can be less than expected in concomitant folic acid deficiency. In chronic hemolysis, the folic acid requirement increases two to three times normal; without folic acid supplements, the stores of this vital nutrient are quickly depleted. If the patient contracts viral infections associated with bone marrow suppression, life-threatening anemia (aplastic crisis) can occur.

Other Laboratory Tests The DAT is a useful test to distinguish the immune nature of this hemolytic anemia from non-immune-mediated hemolytic anemias. The test is usually positive with polyspecific AHG and anti-IgG monospecific AHG antiserum. Only about 30% of the cases of WAIHA have a reaction with anti-C3, either with or without the concurrent presence of IgG.²

Reaction of patients' serum with screening cells typically shows agglutination with all cells when AHG is added. The autocontrol (patient serum and patient erythrocytes) shows similar reactions. Other laboratory findings are nonspecific but reflect the hemolytic component of the condition (Table 4).

Differential Diagnosis

Warm AIHA with the presence of spherocytes can be differentiated from hereditary spherocytosis (HS) by the DAT. Antibodies are not responsible for the formation of spherocytes in hereditary spherocytosis (HS); therefore, the DAT is negative. The autohemolysis test is abnormal in both HS and in AIHA with spherocytes. In HS, autohemolysis is significantly corrected by the addition of glucose; however, glucose does not correct hemolysis in AIHA. The peripheral blood smear also gives clues to diagnosis. The spherocytes in HS appear as a rather homogeneous population, but in AIHA there is a mixture of spherocytes, microspherocytes, and normocytes.

Checkpoint! 6

What is the DAT pattern in WAIHA? Explain why spherocytes are commonly seen in WAIHA.

Therapy

In self-limiting hemolytic disorders without life-threatening anemia, transfusion therapy is not necessary. When transfusion is indicated, finding a suitable donor is difficult because the patient's autoantibody usually reacts with all donor cells in the crossmatch. In addition, approximately 30% of patients with WAIHA have underlying alloantibodies, which can present an additional challenge to finding compatible blood because the autoantibody can mask their presence.^{38,39}

If the patient has an alloantibody, blood negative for the specific antigen must be administered. If serologically compatible blood cannot be found because of the presence of the autoantibody, donor cells demonstrating the least incompat-

ibility are usually chosen. The clinical problems, however, are twofold: Donor cells are often destroyed as rapidly as the patient's own erythrocytes, and they can also stimulate the production of alloantibodies. In some cases, the use of flow cytometry can help evaluate the survival of donor cells in patients with WAIHA.⁴⁰ In other cases, such as individuals who must receive serial transfusions, finding phenotypically matched donor blood can decrease the risk of stimulating alloantibodies.^{38,41–44} If the autoantibody has an identifiable single specificity (such as autoanti-e), the donor blood chosen for the compatibility test should be negative for the antigen.

Therapies for WAIHA focus on decreasing the production of autoantibodies and slowing down the destruction of erythrocytes. These include:

- **Corticosteroids.** Initial therapy for patients with AIHA is often a course of immunosuppressive drugs such as corticosteroids, which are used to produce immunosuppression by decreasing lymphocyte proliferation and suppressing macrophage sequestration of sensitized cells by affecting the Fc receptors. Few patients undergo complete remission with this therapy, but most show a decrease in erythrocyte destruction. Response usually occurs within 10–14 days, and many patients require low-dose maintenance.⁴⁴
- **Cytotoxic drugs.** A number of alternative therapies are available for patients who do not respond to corticosteroids and/or splenectomy.^{1,44} Cytotoxic drugs such as cyclophosphamide and azathioprine are used to cause general suppression of the immune system, which decreases synthesis of autoantibody.
- **High-dose intravenous immunoglobulin (IVIg).** This can block Fc receptors on macrophages and affect T and B cell function by increasing T suppressor cells or reducing B cell function. It has a variable success rate and is most often used as an adjunct therapy with corticosteroids or in selected patients with severe anemia who are refractory to drugs.⁴⁵
- **Plasma exchange and plasmapheresis.** This can dilute or temporarily remove the autoantibody from the patient's circulation. It has been successful in reducing antibody load for a short time in some cases but is not a satisfactory long-term therapy.
- **Splenectomy.** Indicated when severe anemia is unresponsive to medical therapies including glucocorticoid therapy or other cytotoxic drugs, splenectomy provides long-term remission for some patients. Removal of the spleen decreases the destruction of IgG-coated erythrocytes that would normally adhere to Fc receptors on splenic macrophages. If, however, the antibody concentration remains high, the destruction of sensitized erythrocytes may continue in the liver. Some evidence suggests that splenectomy can be more beneficial in patients with idiopathic WAIHA than in those with the secondary type.⁴⁶

- **Rituximab (monoclonal anti-CD20).** It has been used in the treatment of clonal B-cell malignancies including chronic lymphocytic leukemia and has been effectively used in patients with idiopathic and secondary WAIHA that are refractory to other treatments.^{44,47–49}

In patients with secondary AIHA, treatment of the underlying disease is important. Often resolution of the disease leads to decreased production of the autoantibody.

COLD AUTOIMMUNE HEMOLYTIC ANEMIA (AIHA)

Cold AIHA, also termed *cold agglutinin disease (CAD)*, is associated with an IgM antibody that fixes complement and is reactive below 37°C. This disorder, which comprises 16–30% of the AIHAs, is less common than anemia associated with warm antibodies and is less common in children than adults.^{1,2} IgA and IgG antibodies rarely have been implicated in hemolysis in CAD.^{34,50}

CAD, like warm AIHA, is either idiopathic or secondary (Table 5). Idiopathic CAD is usually chronic, occurring after age 50 with a peak onset after age 70.²¹ The antibody involved is usually a monoclonal IgM/kappa paraprotein with autoanti-I specificity.⁵¹ The idiopathic form has been linked to a lymphoproliferative disorder characterized by CD20+, kappa (κ)+, B cells. Trisomy and translocations have also been found in some patients.⁵² The secondary type can occur after an infectious disease or be associated with lymphoproliferative disease.^{21,50} The secondary type associated with infectious disease is usually an acute, self-limiting form that has an onset 1–3 weeks after infection and resolves within 2–3 weeks.^{21,50} Most of these autoantibodies are polyclonal and have a specificity for antigens of the Ii system. Anti-I is usually associated with *Mycoplasma pneumoniae* infections and anti-i can be seen in infectious mononucleosis. Infectious agents including varicella (chickenpox) and rubella are associated with anti-Pr but rarely with anti-I

specificity.^{34,53} HIV patients can develop anti-I.⁵⁴ The secondary chronic form of CAD, typically found in older individuals, is often associated with lymphoproliferative disorders such as lymphoma or Waldenstrom's macroglobulinemia.⁵⁰ The antibody in these cases is usually a monoclonal IgM κ protein. A more severe type of cold AIHA, paroxysmal cold hemoglobinuria (PCH), is associated with a biphasic cold-reacting IgG antibody and is discussed in the next section.

Pathophysiology

The severity of CAD is related to the thermal range of the antibody. Those cold-reacting antibodies with a wide range of thermal activity (up to 32°C) can cause problems when the peripheral circulation cools to this temperature. Complement-mediated lysis accounts for most of the erythrocyte destruction.

The cold-reacting antibody is usually directed against the I antigen, which is expressed on erythrocytes of almost all adults. The I antigen specificity of the antibody can be defined by reactivity of the patient's serum with all adult erythrocytes but minimal or no reactivity with cord cells (which lack the I antigen). In CAD associated with infectious mononucleosis and lymphoproliferative disease, however, the antibody can have anti-i specificity. These antibodies would react strongly with cord cells as the i antigen is generally expressed strongly on cord cells and erythrocytes of children younger than 2 years old and weakly or not at all with adult erythrocytes. The second most common specificity for cold autogglutinins is anti-Pr.¹ The Pr antigens are expressed on both adult and infant erythrocytes. Other specificities that have been reported include anti-M, anti-Vo, anti-Gd, anti-ZSa, and anti-Lud.^{1,55}

Clinical Findings

In some instances, CAD is associated with a chronic hemolytic anemia with or without jaundice. In others, hemolysis is episodic and associated only with chilling. Erythrocyte agglutination occurs in areas of the body that cool to the thermal range of the antibody and cause sludging of the blood flow within capillaries. Vascular changes including acrocyanosis in which the hands and/or feet turn blue and cold can occur. In *Raynaud's phenomenon*, pain can be accompanied by a characteristic pattern of color changes in the skin from white due to spasm of the vessels to blue caused by cyanosis to red, which indicates a return of blood flow to the area. These conditions primarily affect the extremities, especially the tip of the nose, fingers, toes, and ears. Hemoglobinuria accompanies the acute hemolytic attacks. Splenomegaly can be present (Table 6).

★ TABLE 5

Checkpoint! 7

Describe the mechanism of cell destruction in CHD.

TABLE 6

Criteria for Clinical Diagnosis of Cold Agglutinin Disease (CAD)

Clinical history	Acrocyanosis Hemoglobinuria on exposure to cold
Laboratory findings	Serological <ul style="list-style-type: none"> • DAT: Positive with polyspecific AHG Negative with anti-IgG Positive with anti-C3 • IAT: antibody showing characteristic reactions at <math><25^{\circ}\text{C}</math> • Cold agglutinin titer >1000 at 4°C False increase in MCV, MCH, and MCHC False decrease in erythrocyte count Normocytic, normochromic anemia Reticulocytosis Spherocytes, agglutinated RBCs, rouleaux, nucleated RBCs on blood smear Increased bilirubin (total and unconjugated) Decreased haptoglobin Hemoglobinemia, hemoglobinuria in acute hemolysis Hemosiderinuria in chronic hemolysis

Laboratory Findings

The first indication of the presence of unsuspected cold agglutinins often is from blood counts performed on electronic cell counters. The erythrocyte count is inappropriately decreased for the hemoglobin content and the MCV is falsely elevated (Table 6). These erroneous values occur when erythrocyte agglutinates are sized and counted as individual cells. The hematocrit calculated from this erroneous erythrocyte count and the MCV is falsely low. The MCH and MCHC calculated from the erythrocyte count and hematocrit are falsely elevated. The hemoglobin assay is accurate because the cells are lysed to determine this parameter. Accurate cell counts can be obtained by warming blood and diluting reagents to 37°C. Visible autoagglutination in tubes of anti-coagulated blood can be observed as the blood cools to room temperature.

When blood counts are performed at 37°C, the results indicate a mild to moderate normocytic, normochromic anemia. The blood film shows polychromasia, some spherocytes, rouleaux, or clumps of erythrocytes, and sometimes nucleated red cells (Figure 5■). Erythrophagocytosis can be seen but is more typical on smears made from buffy coats after the blood has incubated at room temperature. Leukocyte and platelet counts are usually normal. Leukocytosis can occur during acute hemolysis as the result of a bone marrow stress response. The bone marrow exhibits normoblastic hyperplasia. Patients with chronic CAD can show

■ **FIGURE 5** Cold autoimmune hemolytic anemia from a patient with chronic lymphocytic leukemia. Some of the erythrocytes are in small clumps. Spherocytes are also present. (Peripheral blood; Wright stain; 1000× original magnification)

decreased C3 and/or C4 levels.⁵¹ Patients also can have a decreased value for the CH50 assay, a functional hemolytic assay, that measures the integrity of the entire complement cascade.

✓ **Checkpoint! 8**

Explain why the MCV, MCH, and MCHC can be falsely increased when blood from someone with CHD is tested using an automated cell counter.

Differentiation of CAD Agglutinins from Benign Cold Agglutinins

The serum of most normal individuals exhibits the presence of cold autoantibodies when the serum and cells are incubated at 4°C. These antibodies are termed *benign cold autoagglutinins* because their thermal amplitude and concentration (titer) are not high enough to cause clinical problems. When pathologic cold agglutinins are suspected as the cause of anemia, laboratory tests should be performed to differentiate pathologic cold agglutinins from the benign ones. (Table 7★). The DAT with polyspecific AHG and monospecific anticomplement antiserum is positive in pathologic cold agglutinin disease but negative or only weakly positive with benign cold agglutinins. The DAT, utilizing monospecific anti-IgG, is negative both in CAD and benign cold agglutinins.

The cold agglutinin test should be performed when a diagnosis of cold AIHA is suspected. This test demonstrates the ability of the pathologic antibody to agglutinate the patient's cells at temperatures from 0°C to 20°C in saline and up to 32°C in albumin suspensions. The reaction is reversible with agglutinates dispersing at 37°C. With benign cold antibodies, agglutination occurs at 0–4°C and can occur

★ TABLE 7

Comparison of Characteristics of Pathologic Cold Agglutinins Found in CAD with Those of Benign Cold Agglutinins Found in Normal Individuals

	Pathologic Agglutinins	Benign Agglutinins
Antibody class	IgM	IgM
Antibody specificity	Usually anti-I but in secondary CAD can be anti-i	anti-I
Antibody clonality	Monoclonal in idiopathic type and secondary type due to lymphoproliferative disease; polyclonal in secondary type due to infectious disease	Polyclonal
Thermal amplitude	0–31°C	0–4°C
Agglutination at room temperature	Significant	Not present
Titer	Usually >1:1000	<1:64
DAT	Positive with polyspecific AHG and monospecific anticomplement	Negative

up to 20°C. Agglutination is not enhanced, however, in albumin suspensions. Titers of benign cold agglutinins reach 1:64 in normal individuals; in cold agglutinin disease, the titer is usually more than 1:1000. Titers of 1:256 or more with a positive DAT using monospecific anti-C3 antisera and a negative DAT using monospecific anti-IgG antisera are highly suggestive of cold agglutinin disease.

✓ Checkpoint! 9

Compare the DAT findings and the antibody specificity in WAIHA and CHD.

Therapy

The most effective therapy is usually achieved by keeping the individual's extremities warm. Corticosteroids are not usually effective. Chemotherapy using cyclophosphamide or chlorambucil can be instituted, especially if the CAD is associated with an underlying lymphoproliferative disease.^{44,55} Plasma exchange can be used in acute hemolytic episodes because the majority of IgM is distributed in the intravascular spaces. However, it is effective for only a short time because protein regeneration half-life is ~5 days.^{14,55} Splenectomy, which can be effective in WAIHA, is not effective in CAD because the C3b coated cells are destroyed primarily by Kupffer cells in the liver. In recent years, anti-CD20 (rituximab) has been used as treatment in both primary and secondary disease.^{21,56,57} Patients with strongly reacting cold agglutinins can have complications if surgical procedures requiring hypothermia are undertaken.^{50,55}

PAROXYSMAL COLD HEMOGLOBINURIA

Paroxysmal cold hemoglobinuria (PCH) is a rare autoimmune hemolytic disorder that can occur at any age and is characterized by massive intermittent acute hemolysis and hemoglobinuria. It is the cause of 30–40% of all AIHA in

children and is most frequent in children under the age of 5 years.^{1,22,58} Historically, PCH was associated with congenital or tertiary syphilis in adults. It is now most often seen in children with viral and bacterial infections although it has been reported in association with some lymphoproliferative diseases in adults.⁵⁹ The infections linked to PCH include Epstein-Barr virus, cytomegalovirus, measles, mumps, *Haemophilus influenzae*, and *Klebsiella pneumoniae*.^{1,60} Parvovirus 19, which has an affinity for the P antigen, has also been linked to PCH.⁶¹ PCH is usually a transient disorder that has its onset from 5 days to 3 weeks after onset of the infection.⁵⁸ It generally resolves spontaneously, but transfusion can be required in cases of severe anemia.

Pathophysiology

PCH was the first hemolytic anemia for which a mechanism of hemolysis was established. This hemolytic anemia is distinct from the other cold AIHA because of the nature of the antibody involved. It is caused by a biphasic complement-fixing IgG antibody, the **Donath-Landsteiner (D-L) antibody**. *Biphasic* refers to the two temperatures necessary for optimal lysis of the erythrocytes. The antibody reacts with erythrocytes in the capillaries at temperatures less than 20°C and avidly binds the early acting complement components. Upon warming to 37°C, the antibody molecule disperses from the cell, but the membrane attack complement components are activated on the cell membrane causing cell lysis. Because the antibody repeatedly attaches and detaches from erythrocytes with subsequent complement activation, it can cause significant hemolysis.⁶² The PCH antibody is specific for the P-antigen (autoanti-P).

Clinical Findings

Hemoglobinuria is the most common clinical symptom. The patient can also experience jaundice, pallor, and hepatosplenomegaly. Raynaud's phenomenon can occur during acute episodes followed by jaundice.

Laboratory Findings

The degree of anemia depends on the frequency and severity of hemolytic attacks. During the attack, hemoglobin concentration drops sharply accompanied by hemoglobinemia, methemalbuminemia, and hemoglobinuria. Hemoglobin values can decrease to as low as 5 g/dl. Neutropenia, a neutrophilic shift to the left, reticulocytopenia, and spherocytes can accompany erythrocyte lysis. Serum bilirubin, BUN, and LD are elevated but serum complement and haptoglobin are decreased. Erythrophagocytosis occurs more commonly in PCH than in other types of AIHA, and the phagocytic cells usually involved are segmented neutrophils, not monocytes.⁶³

Antibodies on the cells are not usually detected by the DAT because the D-L antibody elutes at warm temperatures. A weakly positive DAT with anticomplement antisera can appear and persist for several days after the hemolytic episode. The IAT can be positive if performed in the cold. Normal erythrocytes incubated with patient serum react more positively in the IAT than patient cells.

D-L antibodies are usually present in low titers (<1:32) and express a low thermal amplitude, but their presence can be verified by the D-L test, which employs a biphasic reaction (Table 8 ). In this test the patient's blood is collected in two clot tubes; one is incubated at 4°C for 30 minutes and the other at 37°C for 30 minutes. Both tubes are then incubated at 37°C. If the D-L antibody is present, it will cause hemolysis in the tube initially incubated at 4°C and then warmed to 37°C. No hemolysis is present in the tube kept at 37°C. Hemolysis in this test can also occur in cold agglutinin disease, but the hemolysis occurs very slowly. Table 9  compares PCH and CAD.

Therapy

PCH associated with acute infections terminates upon recovery from the infection. Steroids are not usually helpful. Transfusion can be required if the hemolysis is severe. In rare cases when the hemolysis persists, plasmapheresis can be used.⁶² Rituximab (anti-CD20) has also been used as therapy

 TABLE 8

Donath-Landsteiner (D-L) Test for Detecting the Presence of D-L Antibodies*

Patient's Whole Blood*	Control	Test
Incubate for 30 min at	37°C	4°C
Incubate for 30 min at	37°C	37°C
Centrifuge: observe plasma for presence of hemolysis		
Interpretation		
D-L antibodies present	No hemolysis	Hemolysis
No D-L antibodies present	No hemolysis	No hemolysis

*Two tubes of patient's whole blood are used; one tube serves as the control and the other as the test.

 TABLE 9

Comparison of Cold Agglutinin Disease (CAD) and Paroxysmal Cold Hemoglobinuria (PCH)

	CAD	PCH
Patient	Usually adults >50 years of age	Usually children after viral infection
Clinical findings	Acrocyanosis	Chills, fever, hemoglobinuria
DAT	Positive with polyspecific AHG and monospecific C3	Positive with polyspecific AHG and monospecific C3
Donath-Landsteiner test	Negative	Positive
Antibody class	IgM	Biphasic IgG (D-L)
Antibody specificity	Anti-I	Anti-P
Thermal amplitude of antibody	Up to 31°C	Under 20°C
Hemolysis	Chronic extravascular/intravascular	Acute intravascular
Therapy	Avoid the cold	Supportive; treatment of underlying illness

in rare adult cases.⁶⁴ The chronic form of the disease is best treated by avoiding exposure to the cold.

Checkpoint! 10

Compare the antibody specificity and the confirmatory test for PCH and CHD.

MIXED-TYPE AIHA

Mixed-type AIHA is characterized by the presence of a warm-reacting IgG autoantibody and a cold-reacting IgM autoantibody that has both high titer and increased thermal amplitude (reacts at >30°C). About 50% of the cases are idiopathic; most of the remainder are associated with diseases such as systemic lupus erythematosus, lymphoma, and HIV.^{29,55,65} Patients frequently present with an acute, severe anemia. The IgG class antibody mediates extravascular hemolysis, and the IgM is responsible for complement fixation and intravascular hemolysis. Some patients can have a chronic course with intermittent exacerbations. Most patients respond to steroid therapy and require few or no transfusions.

In the DAT procedure, both C3 and IgG can be detected on the erythrocyte. The cold-reacting antibody often has a specificity for the Ii system antigens. The warm-reacting autoantibody is similar to those found in classic WAIHA and has a complex specificity.

Patients usually respond well to treatment with corticosteroids and do not require transfusion. Rituximab has been used in cases with underlying lymphoproliferative disease.^{66,67}

DRUG-INDUCED HEMOLYTIC ANEMIAS

It is recognized that certain drugs can cause immune cytopenias that involve one or several cell lines including neutrophils, platelets, and erythrocytes. Anemia, thrombocytopenia, and agranulocytosis can occur together or separately. It has been proposed that a drug's ability to induce production of antibodies against different cell lines is related to its affinity for the cells.⁶⁸ The greater the affinity, the more likely sensitization against the drug-cell complex is to occur. Drug-induced immune hemolytic anemia is a relatively uncommon acquired condition that is precipitated by certain drugs. The drug itself does not cause erythrocyte injury, and not all individuals taking the drug develop this immune hemolytic anemia.

More than 100 drugs have been found to induce a positive DAT or an immune-mediated hemolytic anemia.⁶⁸ The classes of drugs implicated include antimicrobials, nonsteroidal anti-inflammatory drugs, antineoplastic drugs, diuretics, and antidiabetic.^{69–76} Some of the specific drugs are listed in Web Table 2 . It should be noted that second- and third-generation cephalosporins such as cefotetan and ceftriaxone constitute the majority of cases of drug-induced immune hemolytic anemia and are responsible for most fatalities.^{63,72,76} Drug-induced immune hemolysis must be distinguished from both drug-induced, nonimmune hemolysis that occurs secondarily to erythrocyte metabolic defects such as G6PD deficiency and from spontaneous autoimmune disorders. This is important because drug-induced, immune hemolytic anemias are the result of an immune response to drug-induced alteration of the erythrocyte. The resolution for this immune hemolysis involves withdrawal of the offending drug and supportive treatment, not the use of immunosuppressives or other therapy.

The actual mechanisms of drug-induced hemolytic anemia are controversial. Three classic hypotheses have been proposed to explain them:^{1,2,68}

- Drug adsorption
- Immune complex formation
- Autoantibody induction

A fourth mechanism, membrane modification, has not been strongly correlated with immune hemolysis despite the changes noted in the erythrocyte.

Table 10  contains a summary of the characteristics of each mechanism. Regardless of the underlying mechanism, erythrocytes sensitized with either antibody and/or complement have a shortened life span. Each of these mechanisms will cause a positive DAT with polyspecific AHG and with either anti-IgG and/or anti-C3 AHG.

Drug Adsorption (Hapten Type)

Some drugs such as penicillin are antigenic but lack the molecular size or complexity to initiate an immune response. It is proposed that in the hapten/drug adsorption mechanism, the drug or its metabolites bind to proteins on the erythrocyte membrane, creating an immunogenic complex on the cell surface. Antibodies are produced against the drug and react with the drug complex on the erythrocyte membrane (Web Figure 3 .

Only patients receiving high doses of intravenous penicillin develop significant penicillin coating on their cells, and only a small percent of these individuals will have a positive DAT; even fewer develop hemolysis. The hemolytic anemia usually develops over a 7- to 10-day period. Hemolysis is extravascular and mediated by Fc receptors on splenic macrophages. Spherocytes can be present, and the reticulocyte count is usually elevated. Hemoglobinemia and hemoglobinuria do not occur. The DAT is usually positive. Although both IgG and IgM antibodies can be formed, only the IgG antibody causes hemolysis. Complement activation does not usually occur. Although the IAT is negative, a high

 TABLE 10

Summary of Classic Mechanisms of Drug-Induced Immune Hemolytic Anemia

Type (Prototypic Drug)	Action	Direct Antiglobulin Test	Mechanism of Cell Destruction
Drug adsorption (high-dose intravenous penicillin)	Drug bound to cell → antibody binds to drug	Polyspecific AHG positive, Anti-IgG positive, Anti-C3 may be positive	Extravascular lysis due to reaction with macrophages (Fc receptors) and phagocytosis
Immune complex (quinidine cephalosporins [2nd & 3rd generations])	Forms immune complex (drug antibody) → immune complex adsorbs to cell membrane → activates complement cascade	Polyspecific AHG positive, Anti-IgG negative, Anti-C3 positive	Intravascular complement-mediated lysis
Autoantibody induction (α -methyl dopa procainamide)	Drug adheres to cell membrane → alters membrane structure → forms neoantigen → stimulates production of autoantibody	Polyspecific AHG positive, Anti-IgG positive, Anti-C3 positive or negative	Extravascular adhesion to macrophages via Fc and phagocytosis
Membrane modification (cephalosporins [first generation])	Modification of cell membrane that results in non immunologically absorbed IgG, IgA, IgM, C3	Polyspecific AHG positive, Monospecific can be positive or negative	No hemolysis

titer of the IgG penicillin antibody is present in the serum. This can be detected by incubating the patient's serum with normal erythrocytes and erythrocytes that have been coated with penicillin. If antibodies to the penicillin-protein membrane complex are present in the patient's serum, the test with the "penicillinized" erythrocytes is positive, but it is negative with cells that were not coated with penicillin.

Immune Complex Formation

In this mechanism, a drug or drug metabolite with a low affinity for the cell membrane combines with a plasma protein, forming a new antigenic complex in the plasma and stimulating either IgM or IgG antibodies. A drug/antidrug immune complex forms in the plasma, and this immune complex attaches to the erythrocyte in a nonspecific (non-immune) manner (usually via the Fc portion of the antibody) (Web Figure 4■). The attached immune complex usually has the ability to activate complement. After the immune complex activates complement on the cell membrane, it can dissociate from the membrane and attach to another cell; thus, only a small amount of drug is necessary to initiate complement-mediated hemolysis. The C3b coated red cells are cleared from circulation by macrophages, or the cells may be lysed if the terminal complement components are activated. Most often the hemolytic episode is acute with signs of intravascular hemolysis (hemoglobinuria, hemoglobinemia). Spherocytes can be present on the blood smear.

The DAT with anti-C3 is positive but negative with anti-IgG because the antibody complex has dissociated from the membrane. The anti-C3 DAT can remain positive for several months after the hemolytic episode because of the persistence of inactivated complement components (C3d) on the red cell. Quinidine is the classic drug associated with this mechanism. Although a large number of drugs can cause this type of reaction, the incidence of drug-induced immune hemolysis by this mechanism has been low. However, in recent years, increased reports of fatal intravascular hemolysis by this mechanism have been reported in patients receiving intravenous third-generation cephalosporins.^{72,76}

In the laboratory, the antibody is detected only if the drug and complement are present in the test system. Diagnosis is confirmed by incubating the patient's serum with normal erythrocytes in the presence of the suspected drug. If the antibody is present in the patient's serum, it combines with the drug-protein complex and the erythrocytes. Subsequently, complement is activated. Specific antiserum to complement is utilized to demonstrate the deposition of complement on the cell membrane.

Autoantibody Induction

In approximately 10–20% of patients receiving the antihypertensive drug Aldomet (α -methyldopa), a positive DAT develops after about 3–6 months. However, hemolytic anemia develops in only 1% of these patients. The mechanism by which antibody production is induced is unknown; how-

ever, evidence indicates that the drug alters normal erythrocyte antigens so they are no longer recognized as self.⁷⁷ Erythrocyte destruction is extravascular, and anemia develops gradually. If the drug is withdrawn, the antibody production gradually stops, but the DAT can remain positive for years.

The DAT is dose dependent: The larger the dose of Aldomet, the more likely the patient is to have a positive DAT. The DAT using anti-IgG is positive but because complement is rarely activated, the DAT using anti-C3 is usually negative. Patients with this form of drug-induced IHA have serum antibodies that not only react with their own cells but also with normal erythrocytes. This condition mimics warm autoimmune hemolytic anemia.

Membrane Modification

In addition to causing a positive DAT and immune hemolysis due to the drug adsorption mechanism, cephalosporins, especially the first generation drugs, are capable of modifying the erythrocyte membrane so that normal plasma proteins including immunoglobulins and complement bind to the membrane in a nonimmunologic manner. The adsorbed antibodies are not specific to any drug or drug/cell complex. The DAT is positive with polyspecific antisera and can be positive or negative with anti-IgG and anti-C3.

✓ Checkpoint! 11

Compare the different types of drug-induced hemolysis including the type of hemolysis, the drug usually associated with the mechanism, and the DAT profile.

Unifying Theory

A unifying theory has been proposed to explain antibody formation in drug-induced hemolytic anemias.^{1,2,78} Once the drug binds to the erythrocyte membrane, antibodies that are produced can react with epitopes specifically to the drug, combined drug and erythrocyte membrane epitopes, or epitopes on the erythrocyte membrane. Patients can develop more than one type of drug-induced antibody.^{79,80}

🌀 CASE STUDY (continued from earlier in this chapter)

Two days later, Nancy's hemoglobin dropped to 50 gm/L. The physician ordered several more tests. She had a positive IAT, and the antibody reacted with all cells including her own. Other test results indicated that this patient had systemic lupus erythematosus.

4. What type of antibody appears to be present in this patient? Explain.
5. What is the relationship of the patient's primary disease, systemic lupus erythematosus, and her anemia?

▶ ALLOIMMUNE HEMOLYTIC ANEMIA

Hemolytic anemia induced by immunization of an individual with erythrocyte antigens on the infused cells of another individual is known as *alloimmune hemolytic anemia*. The patient's erythrocytes lack the antigen(s) present on infused cells. These transfused antigens are recognized as foreign and induce the recipient to form antibodies that, in turn, react with the transfused cells. This type of immunologic destruction of erythrocytes is characteristic of transfusion reactions and hemolytic disease of the fetus and newborn (HDFN). Factors such as immunogenicity of the antigen, number of transfusions, and function of the recipient's immune system can influence the development of alloantibodies.⁸¹

In recent years, there has been evidence of not only the production of alloantibodies in patients undergoing solid organ and allogeneic bone marrow/stem cell transplants but also the production of autoantibodies.^{82–88} Posttransplant immune-mediated hemolysis can be linked to major blood group incompatibility, passive transfer of antibody from the donor, development of autoimmunity, or passenger lymphocyte syndrome. Passenger lymphocyte syndrome is an immune hemolytic process that develops following solid organ, bone marrow, or stem cell transplant. The donor B lymphocytes that are transplanted with the organ or bone marrow produce antibodies against the recipient's blood group antigens. Although ABO incompatibility is most frequently implicated, Rh, Kell, Kidd, and/or other blood group systems can be involved. Development of autoantibodies after solid organ transplant is rare but more common after bone marrow or stem cell transplants.^{82,86,87} Some evidence also suggests that blood transfusions can lead to development of autoantibodies in some patients.^{83,85,88}

HEMOLYTIC TRANSFUSION REACTIONS

Transfusion of blood may cause a **hemolytic transfusion reaction** as the result of interaction of foreign (non-self) antigens on transfused erythrocytes and the patients' plasma antibodies. In contrast to AIHA, the antibodies produced in transfusion reactions cause immunologic destruction of donor cells but do not react with the erythrocytes of the person making the antibody. The two types of transfusion reactions involving antibodies to erythrocyte antigens are immediate (occurring within 24 hours) and delayed (occurring 2–14 days after transfusion) (Table 11 🔄). An acute or immediate hemolytic transfusion reaction results when the infused erythrocytes react with antibodies that already exist in the recipient, usually ABO system antibodies. This type of reaction usually results from clerical or other human error that results in an ABO mismatch between donor and recipient. For example, the patient is given the wrong unit of blood or is misidentified by the phlebotomist, nurse, or laboratory personnel. Most errors occur in patient care areas, not in the transfusion service area.³² Patients given the wrong blood ex-

TABLE 11

Comparison of Acute and Delayed Hemolytic Transfusion Reactions

	Acute	Delayed
Timing	Immediate (within 24 hours)	2–14 days
Underlying cause	Usually ABO antibodies	Other antibodies: often Kidd system (anamnesic response)
Hemolysis	Intravascular	Extravascular
Symptoms	Fever, chills, back pain, hypotension, pain at site of infusion	Uncommon (fever, hemoglobinuria)
Laboratory findings	Hemoglobinemia Positive DAT (transient)	Positive DAT Antibody in eluate

hibit classic clinical signs including increased pulse rate, hypotension, chills and fever, pain, or difficulty in breathing. When an acute transfusion reaction is suspected, the transfusion must be stopped immediately because of the potential severity of the reaction. Laboratory investigation of the reaction must be performed.

The delayed hemolytic transfusion reaction is usually the result of an anamnestic response in which the donor erythrocytes contain an antigen to which the patient has been previously sensitized. In these cases, the antibody was not detectable prior to transfusion but the infused erythrocytes restimulate antibody production. The donor cells are destroyed, and the patient shows a decrease in hemoglobin. In cases of a delayed transfusion reaction, some patients show no clinical signs, and the reaction is detected only by laboratory testing. Other patients may present with dark urine or vague symptoms such as fever. Patients at highest risk for delayed reactions are those who have received multiple transfusions over their lifetime.⁸⁹

Pathophysiology

An acute hemolytic transfusion reaction is characterized by intravascular hemolysis with hemoglobinuria as a result of complete activation of the complement cascade. This type of hemolysis of donor cells is usually mediated by IgM antibodies, although IgG antibodies are rarely involved. This type of reaction is typical of an ABO incompatibility and begins very shortly after the infusion of the donor unit has begun. As cells are lysed, the release of thromboplastic-like substances from the erythrocyte membrane can activate the intrinsic and extrinsic coagulation cascade. The resulting consumptive coagulopathy (disseminated intravascular coagulation) can damage the kidney by deposition of fibrin in the microvasculature. Presence of increased tumor necro-

sis factor-alpha (TNF- α) and other interleukins in certain diseases can mediate some of the clinical symptoms.⁹⁰ The usual antibodies involved in an acute hemolytic transfusion reaction are anti-A or anti-B. Other antibody specificities such as anti-I, anti-P₁ have been implicated only rarely. Mortality rates from ABO acute hemolytic transfusion reactions range from 10 to 50%.

Extravascular hemolysis is typical of a delayed hemolytic transfusion reaction. This occurs when erythrocytes are coated with IgG antibodies and removed via macrophage Fc receptors in the spleen. The speed of the removal depends on the amount of antibody on the cell. Complement is not usually involved but when present can enhance phagocytosis.

Delayed transfusion reactions occur 2–14 days after a transfusion. Although the antibody cannot be detected in pretransfusion testing because the antibody concentration is lower than the test's sensitivity level, antigens on infused donor cells induce a secondary (anamnestic) antigenic stimulus. The antibody produced is usually IgG, and hemolysis is extravascular. The first indication of a delayed reaction is a sharp drop in the hemoglobin concentration several days after the transfusion. Intravascular hemolysis can also occur but is less pronounced than in acute reactions. Laboratory investigation reveals a positive DAT because of antibody-coated donor cells in the patient's circulation. Antibodies characteristically associated with a delayed transfusion reaction are in the Kidd System (anti-Jk^a, anti-Jk^b). Antibodies to antigens in the Rh system (especially anti-D, anti-E, anti-c), as well as anti-Kell, and anti-Fya have also caused delayed reactions.⁸¹

Clinical Findings

Symptoms of an immediate transfusion reaction begin within minutes to hours after the transfusion is begun. The reaction between antigen and antibody can trigger cytokine release, activation of the complement cascade, and the coagulation cascade. A variety of nonspecific symptoms including fever, chills, low back pain, sensations of chest compression or burning at the site of infusion, hypotension, nausea, and vomiting can occur. Unless the transfusion is immediately stopped, shock may occur. Anuria due to tubular necrosis secondary to inadequate renal blood flow and bleeding due to DIC are common complications. The severity of the reaction and extent of organ damage are directly proportional to the amount of blood infused.

Most delayed transfusion reactions cause few signs or symptoms. The most common signs are malaise and unexplained fever several days after the transfusion. Some patients notice the presence of hemoglobin in the urine.

Checkpoint! 12

Compare the underlying mechanisms, pathophysiology, and clinical symptoms of an acute hemolytic transfusion reaction and a delayed one.

Laboratory Findings

The laboratory findings vary depending on whether the transfusion reaction is acute or delayed. Intravascular hemolysis usually accompanies the acute reaction, and extravascular hemolysis usually accompanies the delayed reaction. The DAT is usually positive in both types of reaction but might not be detected until days after transfusion in the delayed type of reaction.

Acute Transfusion Reaction If an acute transfusion reaction is suspected, the transfusion should be stopped immediately and blood samples should be drawn and sent to the laboratory. Three things must be done to determine whether a transfusion reaction has occurred:²

- Check for clerical errors
- Perform a DAT
- Do a visual plasma hemoglobin test

The clerical check will reveal any errors in patient or specimen identification. The visual hemoglobin test involves comparing the patient's pretransfusion plasma against the posttransfusion plasma to detect signs of posttransfusion hemolysis (hemoglobinemia). If there is hemolysis, the plasma can have pink, red, or brown discoloration. The pretransfusion and posttransfusion specimens should be compared side by side to detect subtle changes between them. The DAT performed on the posttransfusion specimen will detect the presence of cell-bound immunoglobulin and/or complement. Often the DAT is only weakly or transiently positive in an acute hemolytic transfusion reaction because the antibody-coated cells are rapidly destroyed. If the DAT is positive and/or there is evidence of hemolysis and/or clerical error, an extended transfusion reaction workup is indicated.

In an extended workup, the pretransfusion specimen is retyped for ABO and Rh blood groups and retested for the presence of alloantibodies and recrossmatched with the donor units. The posttransfusion specimen will have an ABO, and Rh typing as well as an antibody screen performed. Donor units are also retyped and crossmatched with the posttransfusion specimen. Despite the fact that posttransfusion specimens drawn several hours after the reaction might not contain free hemoglobin, hemoglobinuria in the first posttransfusion urine can usually be detected if intravascular hemolysis occurred. Free red cells (hematuria) in the urine, however, are not associated with intravascular or extravascular hemolysis.

Delayed Transfusion Reaction In many cases, the clinical signs of a delayed transfusion reaction are so mild that the reaction is discovered only if the patient is crossmatched again several days later for another transfusion.⁸¹ Hemoglobinemia and hemoglobinuria are not usually found. Other laboratory tests such as haptoglobin and bilirubin analyses can be helpful. If a reaction has occurred, the haptoglobin can be decreased and serum bilirubin increased.

In a delayed transfusion reaction, the posttransfusion specimen will show a positive DAT. A mixed field positive DAT can be seen because only donor cells, not the patient's cells, are coated by immunoglobulin or complement and agglutinated by AHG.

If the DAT is positive, an elution procedure should be performed to determine the specificity of the antibody. This procedure releases the antibody bound to the erythrocyte membrane so that the antibody can be identified. In some cases, antibody on the erythrocytes is not sufficient to provide a positive reaction when the eluate is tested against the commercial screening cells. After several days, the antibody level may be increased enough to allow identification of its specificity. Antibody produced in a delayed transfusion reaction might not be detectable in the serum until several days after the transfusion.

✓ Checkpoint! 13

What are the required laboratory tests for investigating a suspected transfusion reaction? Compare the characteristic laboratory findings in acute hemolytic transfusion reactions and delayed transfusion reactions.

Therapy

The most important immediate action taken when an acute transfusion reaction occurs is prompt termination of the transfusion. A major effort is made to maintain urine flow to prevent renal damage. Shock and bleeding require immediate attention. In a delayed reaction, treatment is generally not required. Future units of blood given to the patient, however, must lack the antigen to which the patient has made an antibody.

CASE STUDY (continued from earlier in this chapter)

The clinician wants to start Nancy on therapy and give her a transfusion.

- How would knowing that the patient had not been transfused in the last several months help you make a decision on the underlying cause of the antibody?
- What would you tell the clinician about giving a transfusion?
- What kind of therapy could be used?

HEMOLYTIC DISEASE OF THE FETUS AND NEWBORN (HDFN)

Hemolytic disease of the fetus and newborn (HDFN)

is an alloimmune disease associated with increased erythrocyte destruction during fetal and neonatal life and is caused by fetomaternal blood group incompatibility. The three categories of HDFN are ABO caused by anti-A, anti-B and/or antiA,B; Rh (D) caused by anti-D; and "other" caused by alloantibodies to other Rh system antigens (C,c,E,e) or antibodies to other blood group system antigens (e.g., Kell, Kidd, Duffy). More than 95% of HDFN cases are due to either anti-D or ABO system antibodies. Although HDFN caused by ABO antibodies is more common than HDFN caused by anti-D, D incompatibility causes more severe disease (Table 12). The antibodies most commonly associated with the remaining HDFN cases include anti-K, anti-c, anti-C, and anti-E, although any IgG antibody can be implicated.⁹¹ HDFN caused by anti-D and anti-K are the most severe.⁹¹

★ TABLE 12

Comparison of Hemolytic Disease of the Fetus and Newborn Caused by ABO and D

Feature	Rh	ABO	Other
Antibody	Immune IgG	Nonimmune or immune IgG	Immune IgG
Blood group	Mother Rh negative Baby Rh positive	Mother, group O; baby, group A or B	Mother lacks antigen that is on fetal cell
Obstetric history	Only pregnancies after the first are usually affected	First pregnancy and subsequent pregnancies can be affected	Pregnancy can be first if mother previously sensitized by transfusion. If pregnancy is sensitizing event, usually second and subsequent pregnancies affected
Clinical findings	Moderate to severe anemia and bilirubinemia	Mild anemia, if present; mild to moderate bilirubinemia with a peak 24–48 hours after birth	Mild to severe anemia and bilirubinemia
Laboratory findings	DAT positive No spherocytes	DAT weakly positive or negative Spherocytes present	DAT positive
Therapy	Exchange transfusion, if severe	Phototherapy	Phototherapy and/or exchange transfusion, if severe

Pathophysiology

The pathophysiology of HDFN involves initial sensitization and antibody production, in utero effects, and postnatal effects. Four conditions must be met for HDFN to occur:

- The mother must be exposed (sensitized) to an erythrocyte antigen that she lacks.
- The fetus must possess the antigen to which the mother is sensitized.
- The mother must produce antibodies to the foreign antigens.
- The mother's antibody must be able to cross the placenta and enter the fetal circulation.

Sensitization The mother could have been exposed to foreign (nonself) erythrocyte antigens by previous pregnancy or transfusion. Normally, the placenta does not allow free passage of erythrocytes from fetal to maternal circulation, but small numbers of erythrocytes can enter the maternal circulation during gestation. Additionally, small amounts of blood also can enter the mother's circulation during delivery. The risk of sensitization increases as the volume of the fetal bleed increases. If the fetal-maternal bleed is sufficient to stimulate the production of maternal antibodies, subsequent pregnancies could be at risk for HDFN.

Three classes of immunoglobulins can be produced during the mother's immunization—IgG, IgM, IgA—but only IgG has the ability to cross the placenta and cause HDFN. The IgG antibody is actively transported across the placenta and causes destruction of fetal erythrocytes. The fetus/newborn will have anemia and bilirubinemia of varying degrees of severity based on the strength of the immune response and degree of hemolysis.

Approximately 15% of the Group A or Group B babies born to Group O mothers will develop serologic evidence (positive DAT) of ABO-HDFN.⁹² In ABO-HDFN, the mother already has the naturally occurring antibodies of the ABO system (IgG class anti-A, anti-B, and anti-A,B), which can cross the placental barrier to destroy fetal cells. In contrast to Rh-HDFN, stimulation and production of these antibodies does not require previous fetal erythrocyte sensitization; therefore, the first pregnancy can be affected.

In HDFN caused by anti-D, the mother is D negative (Rh negative) and the baby is D positive (Rh positive). The first-born is not usually affected, because the first pregnancy serves as the sensitizing event. In each subsequent pregnancy with a D positive fetus, the risk for HDFN increases as the antibody response increases.

In HDFN caused by other Rh system or other blood group system antibodies, the sensitization event is similar to that of Rh-HDFN. It has been found that anti-K can inhibit erythroid progenitor cells (that express the K antigen), contributing to the increased severity of fetal anemia.^{93,94}

Prenatal Period If destruction of fetal erythrocytes is severe enough in utero, the fetus becomes severely anemic and

can develop complications as a result. Extramedullary hematopoiesis occurs in the liver and spleen, causing their enlargement. Because of hemolysis, the unconjugated (indirect) bilirubin concentration increases. In the fetus, this bilirubin traverses the placenta and is conjugated and excreted by the mother. With procedures such as amniocentesis, the amount of bilirubin in amniotic fluid can be measured to help determine the relative severity of hemolysis. Other noninvasive procedures such as Doppler ultrasound can help predict anemia based on blood flow in the fetus.⁹⁵ In recent years, noninvasive methods to obtain fetal cells or cell-free DNA from the maternal circulation have been introduced. These methods help in the prediction of Rh-HDFN and eliminate the need for invasive procedures such as amniocentesis and chorionic villus sampling. Although prenatal diagnostic procedures were initially designed to detect the D antigen, they have been expanded to detect K, Fy, and JK genotypes.⁹⁶⁻⁹⁹

The most serious complication of HDFN is cardiac failure and hydrops fetalis, which occurs when the fetus is unable to produce sufficient erythrocytes. **Erythroblastosis fetalis**, another term used to describe this condition, reflects the presence of large numbers of nucleated erythrocytes found in the baby's peripheral blood in very severe cases.

Postnatal Period Erythrocyte destruction persists after birth because of maternal antibodies in the newborn's circulation. After birth, the newborn must conjugate and excrete the bilirubin on its own. In the neonate, albumin levels for bilirubin transport are limited, and liver glucuronyl transferase for bilirubin conjugation is low; therefore, considerable amounts of toxic unconjugated bilirubin can accumulate in the baby after delivery. In the unconjugated state, bilirubin is toxic because it is lipid soluble and can easily cross cell membranes. This form of bilirubin has a high affinity for basal ganglia of the CNS. Thus, the excess unconjugated bilirubin can lead to **kernicterus**, an irreversible form of brain damage. The conjugated form of bilirubin will not cause this type of problem because it is water soluble, lipid insoluble, and cannot cross cell membranes.

Clinical Findings

Anemia due to the increased cell destruction is the greatest risk to the infant with HDFN both in utero and in the first 24 hours of life. Bilirubinemia is the greatest risk thereafter. In Rh incompatibility, the cord blood hemoglobin can be low normal at birth (normal hemoglobin at birth is 14–20 g/dL), and the baby does not appear jaundiced. However, significant hemolysis occurring in the first 24 hours of life outside the womb results in anemia with pallor and jaundice. In severe cases, hepatosplenomegaly can be present. Severe anemia can be accompanied by heart failure and edema. As the level of unconjugated bilirubin rises, kernicterus can occur. In Rh-HDFN, some infants with severe kernicterus can die. The risks of hyperbilirubinemia in

premature infants are even greater because of the inability of the premature liver to excrete the excess bilirubin.

ABO incompatibility is not as severe as Rh incompatibility. The clinical course is usually benign, and hemolysis is minimal. Within 24–48 hours after birth, the infant appears jaundiced but kernicterus is extremely rare. Anemia is mild and pallor is uncommon. Hepatosplenomegaly, if present, is mild. However, cases of severe ABO-HDN requiring exchange transfusion as well as phototherapy, especially in blacks and children of mixed race parents, have been reported.^{92,100,101}

✓ Checkpoint! 14

Compare the pathophysiology and clinical findings of ABO-HDFN and Rh-HDFN.

Laboratory Findings

Laboratory tests are essential to identify the etiology of HDFN, determine prognosis, and select appropriate treatment. Classic prenatal testing on a pregnant woman includes ABO and Rh typing of the erythrocytes as well as an antibody screen (IAT) on her serum. If the IAT is positive, the antibody is identified so that an assessment of HDFN risk can be performed.

The postnatal HDFN workup consists of laboratory tests on both the mother and the infant. Classically this has included ABO and Rh typing of the mother's erythrocytes as well as an antibody screen (IAT) on her serum. The infant was typed for ABO and D antigen and had a DAT performed on the cord cells. If the DAT was positive, an elution procedure was performed, and the specificity of the antibody coating the fetal erythrocytes was identified. With the changes in the health care system and reimbursement patterns, the American Association of Blood Banks has revised its guidelines for prenatal and postnatal testing to eliminate unnecessary repeat testing or testing that does not affect treatment.^{102,103} For example, testing of cord blood specimens for ABO, Rh, and DAT is not recommended unless the maternal serum has clinically significant antibodies or if there is a workup to determine RhIG candidacy for the mother.

Rh Incompatibility The DAT is usually positive, reflecting antibody coating of the newborn's erythrocytes. About 50% of affected infants have a cord blood hemoglobin concentration of less than 14 g/dL. Because the capillary blood hemoglobin can be up to 4 g/dL higher due to placental transfer of blood at birth, the cord blood hemoglobin concentration is most useful as an indicator of anemia at birth and as a baseline to follow destruction of erythrocytes after birth. A direct relationship exists between the initial cord blood hemoglobin level and the severity of the disease. Lower cord hemoglobin levels at birth are associated with a more severe clinical course. After birth, hemoglobin levels can fall at the rate of 3 g/dL/day. Lowest hemoglobin values are present at 3–4

days. The erythrocytes are macrocytic and normochromic. Reticulocytes are markedly increased, sometimes reaching 60%. Nucleated red cells are markedly increased in the peripheral blood ($10\text{--}100 \times 10^9/\text{L}$), reflecting the rapid formation of cells in response to erythrocyte destruction. Normal infants also have nucleated red cells in the peripheral blood, but their values are much lower ($0.2\text{--}2.0 \times 10^9/\text{L}$).

A blood smear shows marked polychromasia, mild or absent poikilocytosis, and few, if any, spherocytes. The leukocyte count is increased to $30 \times 10^9/\text{L}$ or more due to an increase in neutrophils reflecting the marrow response to stress. (The normal leukocyte count at birth is $15\text{--}20 \times 10^9/\text{L}$.) A significant neutrophilic shift to the left often occurs. The platelet count is usually normal, but thrombocytopenia can develop with an increase in disease severity.

Cord blood bilirubin is elevated but is usually less than 5.5 mg/dL. However, cord blood bilirubin does not accurately reflect the severity of hemolysis since bilirubin produced before birth readily crosses the placenta and is metabolized by the mother. The infant's serum bilirubin peaks on the third or fourth day and may reach 40–50 mg/dL if the baby is not treated. Most bilirubin is in the unconjugated form. Only unconjugated bilirubin not bound to albumin is toxic to the CNS. Full-term infants with bilirubin concentrations >10 mg/dL are at increased risk for kernicterus, and premature infants can develop it with levels as low as 8–10 mg/dL.

ABO Incompatibility A weakly positive DAT is found in the cord blood, but it often becomes negative within 12 hours. The weak reaction is due to the small number of anti-A or anti-B antibody molecules attached to the erythrocyte. Bilirubin is not usually significantly elevated, but the bilirubin level 6 hours after birth can be used to predict development of hyperbilirubinemia in severe cases.¹⁰⁴ The peripheral blood smear in severe cases can show increased numbers of nucleated erythrocytes and the presence of schistocytes, spherocytes, and polychromasia.

✓ Checkpoint! 15

Compare the laboratory findings including the peripheral blood smear and the DAT for infants born with ABO-HDFN and those with Rh-HDFN.

Therapy

The major efforts of therapy are the prevention of hyperbilirubinemia and anemia. If the destruction of erythrocytes and degree of anemia appears to affect the viability of the fetus, an intrauterine transfusion can be given. Methods such as amniocentesis and cordocentesis and now the use of molecular methods to identify fetal DNA for detecting in utero hemolysis have allowed decisions to be made on whether an intrauterine transfusion should be given.⁹⁹ The transfused cells in an intrauterine transfusion are Group O

Rh-negative, fresh, washed, and irradiated. The cells must be compatible with the maternal serum. The antigen-negative cells lack the specific binding site for antibody and therefore have a normal life span. Transfusions often must be given on a routine basis until the fetus reaches a gestational age that will allow successful delivery.

In mild cases postnatally, the infant is treated with phototherapy, which slowly lowers the toxic bilirubin level. Although toxic levels of bilirubin are 19–20 mg/dL, exchange transfusion is usually performed before that level is reached. Exchange transfusions can also be indicated if the bilirubin is rising more than 1 mg/dL/hour or if there is significant anemia. The transfusion has several beneficial effects:

- Removes plasma containing maternal antibodies and dilutes the concentration of remaining antibodies
- Removes some of the antibody-coated erythrocytes
- Lowers the level of bilirubin
- Treats the anemia

Cells used in the exchange transfusion are usually Group O, washed and irradiated, and must be compatible with maternal serum.

Rh Immune Globulin (RhIG)

The passive injection of Rh immunoglobulin (RhIG) that contains anti-D prevents maternal immunization. About 7–8% of Rh-negative women develop antibodies to Rh positive cells after the birth of an Rh-positive ABO-compatible infant. The routine use of prophylactic RhIG in Rh-negative women during gestation (at 28 weeks) and following the birth of an Rh positive child has decreased the incidence of HDFN considerably, although other changes in prenatal care and number of pregnancies also could have contributed.¹⁰⁵ The majority of women (92%) who develop anti-D during pregnancy do so at 28 weeks or later. Therefore, antepartum administration of RhIG is given between weeks 28 and 30 of gestation to any woman who has not developed anti-D. The RhIG acts as an immunosuppressant, depressing the production of immune IgG. The RhIG binds to fetal cells in maternal circulation, mediating their removal in the spleen, thereby preventing the possibility of maternal sensitization to the Rh antigen.

Postnatally, a dose of RhIG given within 72 hours of birth protects against the consequences of a fetal-maternal bleed. If the Rh-positive erythrocytes of a fetus enter the mother's circulation at birth, they can stimulate the mother's immune system to make antibodies. As in the antepartum administration of RhIG, postnatal RhIG can bind fetal cells and mediate their removal in the spleen. The dose of RhIG should be determined based on the number of fetal cells in the maternal circulation. Several tests can be used for this including the Rosette and the Kleihauer-Betke tests. The Rosette test, which detects fetal Rh positive cells, can be used as a screening test for fetal maternal hemorrhage. This test detects a fetal bleed of as little as 2.5 ml of fetal blood.¹⁰² The Klei-

hauer-Betke test, in which cells with fetal hemoglobin are detected, is the traditional method employed for quantitation of fetal-maternal bleed to determine dose of RhIG. Newer methods such as immunofluorescent flow cytometry using monoclonal antibody to fetal hemoglobin to determine the number of fetal cells present are available.¹⁰⁶

SUMMARY

Immune hemolytic anemia (IHA) is mediated by antibodies and/or complement and can be classified as autoimmune, alloimmune, or drug induced, depending on the underlying process. All of these will have a positive DAT due to immunoglobulin and/or complement on the cell. The autoimmune hemolytic anemias (AIHA) are caused when the offending antibody reacts with an antigen on the patient's erythrocytes (self-antigen) and have the ability to react with erythrocytes of most other persons. AIHA are either idiopathic or secondary to an underlying disease, and are further classified as warm or cold, depending on the thermal reactivity of the causative antibody. WAIHA is most often caused by IgG antibodies that react at body temperature (37°C) and cause extravascular hemolysis. Cold hemagglutinins are IgM antibodies that generally react at less than 20°C but are efficient complement activators and can cause intravascular hemolysis. In both cases, the DAT is positive, and the antibody can be detected by the IAT procedure. PCH, another type of cold autoimmune hemolytic condition, is mediated by an IgG biphasic antibody that binds complement in the cool peripheral circulation. As the coated cells reach warmer portions of the circulation, the complement cascade is activated and intravascular hemolysis occurs.

Drug-induced immune hemolytic conditions are mediated by several mechanisms depending on the causative drug. The antibodies can be drug dependent, and the drug must be present for the antibody to react. In autoantibody formation (drug independent), the drug appears to cause a change in the erythrocyte membrane that causes the body to recognize it as foreign and produce an antibody against the cell.

Alloimmune hemolytic anemia has two presentations: transfusion reaction and hemolytic disease of the newborn. In both conditions, the antibody is stimulated by infusion of erythrocytes containing foreign (nonself) antigens. This sensitization causes the production of alloantibodies to the foreign antigens, resulting in the cell's destruction. The antibody can be detected in the serum and will cause a positive DAT.

Transfusion reactions can be acute (immediate) or delayed (2–14 days after transfusion). Acute reactions most often involve an ABO mismatch between donor and recipient and result in intravascular hemolysis as a result of complement activation. Delayed transfusion reactions are due to non-ABO antibodies such as anti-JK^a, anti- \bar{c} , anti-K. These reactions result in extravascular lysis and are characterized by a positive DAT. The causative antibody must be identified so that future transfused erythrocytes lack the antigen corresponding to the patient's antibody.

Hemolytic disease of the fetus and newborn (HDFN) may be caused by ABO, Rh (D), or other blood group system antibodies that react with fetal erythrocytes. ABO-HDFN is generally milder

than Rh-HDFN and can occur in any pregnancy because prior antigenic sensitization is not required. In Rh and other types of HDFN prior sensitization is necessary. Maternal antibodies that coat fetal

cells may cause anemia or elevated bilirubin in the baby. Maternal and baby's ABO and Rh group, maternal antibody, and baby's DAT are used in evaluating HDFN.

REVIEW QUESTIONS

LEVEL I

- The characteristic erythrocyte seen in a peripheral blood smear in WAIHA is a(n): (Objective 3)
 - macrocyte
 - spherocyte
 - dacrocyte
 - elliptocyte
- Which of the following might be observed on a peripheral blood smear in cases of cold autoimmune hemolytic anemia? (Objective 3)
 - helmet cells
 - macrocytes
 - agglutination
 - spherocytes
- Which of the following parameters on an automated hematology instrument could be seen in cases of cold agglutinin disease (CAD)? (Objective 3)
 - falsely elevated MCV
 - falsely elevated RBC count
 - falsely decreased MCHC
 - falsely decreased hemoglobin
- One purpose of the DAT is to: (Objective 2)
 - detect erythrocytes coated with immunoglobulin in vivo
 - detect antibodies in the serum
 - neutralize serum complement
 - prevent agglutination by IgM antibodies
- Intravascular hemolysis is characteristic of which of the following alloantibody situations? (Objective 5)
 - delayed hemolytic transfusion reaction
 - ABO-HDFN
 - Rh-HDFN
 - acute hemolytic transfusion reaction
- A patient with WAIHA would most likely have serum that reacts in which of these patterns? (Objective 5)

Serum + Own Erythrocytes	Serum + Erythrocytes of Others
a. negative	negative
b. negative	positive
c. positive	positive
d. positive	negative
- Which of the following is *not* considered a condition caused by autoantibodies? (Objective 5)
 - PCH
 - CAD
 - delayed transfusion reaction
 - drug-induced hemolytic anemia

LEVEL II

- The drug-induced mechanism that leads to intravascular hemolysis is: (Objective 3)
 - drug adsorption
 - immune complex
 - membrane modification
 - autoantibody formation
- A newborn shows evidence of jaundice and a workup for HDFN is started. The baby has a weakly positive DAT with anti-IgG. The mother is Group O, Rh negative. The baby is Group A, Rh negative. The blood smear shows evidence of spherocytes. What is the most likely cause? (Objective 6)
 - Rh-HDFN
 - ABO-HDFN
 - combined ABO- and Rh-HDFN
 - cold agglutinins
- Which autoimmune syndrome is characterized by the presence of a biphasic complement-fixing IgG antibody? (Objective 4)
 - PCH
 - WAIHA
 - cold agglutinin disease
 - immune complex drug induced
- High-dose intravenous administration of what drug is characteristically associated with the drug adsorption mechanism? (Objective 3)
 - penicillin
 - aldomet
 - quinidine
 - third-generation cephalosporins
- Based on maternal and fetal testing, a newborn is suspected of having Rh HDFN. Which of the following peripheral blood smear morphologies might be seen? (Objective 6)
 - microcytic, hypochromic erythrocytes, decreased reticulocytes
 - microcytic, normochromic erythrocytes, increased nucleated red blood cells
 - macrocytic, hypochromic erythrocytes, decreased reticulocytes
 - macrocytic, normochromic erythrocytes, increased nucleated red blood cells

REVIEW QUESTIONS (continued)

LEVEL I

8. A patient who is receiving a transfusion shows evidence of intravascular hemolysis. What antibody specificity and immunoglobulin class would most likely be involved? (Objective 6)
 - a. Rh/IgG
 - b. ABO/IgM
 - c. Kidd system/IgG
 - d. I system/IgM
9. Which of the following is *not* part of the typical peripheral blood picture in Rh-HDFN? (Objective 4)
 - a. macrocytes
 - b. polychromasia
 - c. spherocytes
 - d. increased nucleated erythrocytes
10. The antibody found in PCH is: (Objective 1)
 - a. IgM
 - b. IgG
 - c. directed against the Rh antigens
 - d. directed against the ABO antigens

LEVEL II

6. What is the *most likely* mechanism of hemolysis in WAIHA? (Objective 1)
 - a. increased sensitivity to complement
 - b. fixing of complement by IgM antibody
 - c. biphasic reactions by IgG antibodies
 - d. phagocytosis of IgG coated erythrocytes
7. A patient who received a transfusion 6 days ago is suspected of having a delayed transfusion reaction. Which of the following would *not* be a characteristic finding? (Objective 7)
 - a. positive DAT
 - b. positive IAT
 - c. hemoglobinuria
 - d. decreased hemoglobin
8. How would you interpret the following results of a Donath-Landsteiner test? (Objective 4)

Patient incubated at 4°C and then 37°C	hemolysis
Control incubated only at 37°C	no hemolysis

 - a. positive
 - b. negative
 - c. invalid because of control reaction
 - d. equivocal—repeat in 2 weeks
9. A 75-year-old man presents to the physician with complaints of weakness and fatigue. His leukocyte count is elevated, and his hemoglobin is 60 gm/L. The peripheral blood smear shows that a majority of the cells are small, mature lymphocytes. The diagnosis is CLL. Spherocytes are present. The physician suspects hemolytic anemia, and laboratory tests suggest a hemolytic process with an increase in reticulocytes and bilirubin. Based on this information, what is the most likely problem? (Objective 8)
 - a. secondary CAD
 - b. secondary PCH
 - c. secondary WAIHA
 - d. secondary cold agglutinins
10. The following DAT results were seen in a 35-year-old female who was being investigated for a drug-induced hemolytic anemia. She had a hemoglobin of 70 gm/L, and her serum reacted with all cells against which it was tested. What drug is the most likely cause? (Objective 3)

DAT (polyspecific)	positive
DAT anti-IgG	positive
DAT anti-C3	negative

 - a. penicillin
 - b. quinidine
 - c. cephalosporin
 - d. aldomet

ANSWERS TO CASE STUDY QUESTIONS

Case Summary: Nancy's data demonstrate reactions seen in warm autoimmune hemolytic anemia secondary to systemic lupus erythematosus. Spherocytes indicate extravascular hemolysis, and reticulocytosis suggests compensation by increased bone marrow production of erythrocytes. The positive DAT (anti-IgG) is a clue that the cell destruction is immune mediated. Her serum reacts with all antibody screening cells and panel cells after addition of antihuman globulin. The diagnosis of systemic lupus erythematosus (SLE)—an autoimmune disease character-

istically diagnosed in women between the ages of 24 and 40—provides additional support for the secondary nature of the immune mediated hemolysis. Patients with SLE often develop not only antibodies against nuclear components of all cells in the body but also to erythrocytes, as demonstrated in this patient. Treatment would begin initially with steroids, and if the patient was nonresponsive, other modalities would be considered. Transfusion is discouraged unless the hemoglobin value drops to a very low level.

Question:

1. What are some reasons that she could have a low hemoglobin value?

Explanation:

Low hemoglobin may be due to iron deficiency, occult bleeding, or extravascular hemolysis.

Question:

2. What is the significance of the spherocytes?

Explanation:

They indicate damage to the cell membrane and extravascular hemolysis.

Question:

3. Based on these results, what do you suspect is going on with this patient? Explain.

Explanation:

Some type of immune-mediated hemolysis is occurring due to the presence of IgG on the erythrocyte.

Question:

4. What type of antibody appears to be present in this patient? Explain.

Explanation:

It is an autoantibody. The patient's serum is reacting with her own cells, which indicates that the antigen is present on her own cells.

Question:

5. What is the relationship of the patient's primary disease, systemic lupus erythematosus, and her anemia?

Explanation:

SLE is an autoimmune disease in which the patient often develops a WAIHA secondary to the disease.

Question:

6. How would knowing that the patient had not been transfused in the last several months help you make a decision on the underlying cause of the antibody?

Explanation:

If the patient had been transfused, the foreign antigens on the transfused cells could have stimulated an alloantibody. However, the alloantibody would not be reacting with the patient's own cells.

Question:

7. What would you tell the clinician about giving a transfusion?

Explanation:

Transfusions are discouraged in WAIHA because the transfused cells contain an antigen that will react with the antibody and be destroyed just as the patient's own cells are. If the patient's oxygen carrying capacity is low and the patient is demonstrating symptomatic anemia, transfusion should not be denied, as the red cells will provide increased oxygen carrying capacity even if their survival is reduced.

Question:

8. What kind of therapy might be used?

Explanation:

The most common therapy is the use of corticosteroids, which depress the immune reaction. If the patient does not respond to this drug, other cytotoxic drugs or splenectomy may be indicated.

ANSWERS TO CHECKPOINTS
Checkpoint! 1

What are the three major categories of immune hemolytic anemia, and how is antibody production stimulated in each type?

Answer

Autoimmune—alteration of self-antigen or immune system regulation dysfunction

Alloimmune—response to foreign erythrocyte antigen

Drug induced—immune response to epitope on drug in combination with erythrocyte antigen

Checkpoint! 2

Explain how the class of immunoglobulin, amount of antibody bound, and thermal reactivity of the antibody affect hemolysis.

Answer

IgM is able to activate complement efficiently causing intravascular hemolysis. IgG is less able to activate complement, and the coated cells are removed in the spleen (extravascular) via interaction with Fc receptors on splenic macrophages.

Because a minimum amount of antibody molecules must be bound for hemolysis to occur, the more antibody molecules on the cell, the more likely it is that hemolysis will occur.

IgG antibodies typically have optimal reactivity at 37°C (body temperature) whereas IgM antibodies have an optimal thermal amplitude of 20–25°C.

Checkpoint! 3

Compare the mechanisms of IgG mediated hemolysis with those of IgM mediated hemolysis.

Answer

IgM mediated hemolysis has two possible outcomes. The first occurs when the IgM molecule fixes complement and the complement cascade goes to completion (C1–C9). This results in intravascular hemolysis. If, however, the IgM molecule fixes complement but the cascade does not go to completion, the C3b molecules that remain on the erythrocytes interact with C3b receptors on macrophages resulting in extravascular hemolysis.

In IgG mediated hemolysis, complement is infrequently activated and most hemolysis is extravascular. The Fc portion of the attached IgG molecule reacts with Fc receptors on splenic macrophages. The cell may be completely phagocytized by the macrophage or portions of the membrane may be removed resulting in spherocytes.

Checkpoint! 4

Compare the purpose of the DAT and the IAT and state the type of specimen used for each test.

Answer

DAT is used to detect erythrocytes that have been coated with antibody or complement fragments in vivo. The specimen used is serum or plasma collected in EDTA anticoagulant. The IAT is used to detect the presence of antibodies in the patient's serum. The specimen used is EDTA plasma or serum.

Checkpoint! 5

What are the clinical findings and the immune stimuli for WAIHA?

Answer

Clinical findings—symptoms related to anemia including weakness, jaundice, pallor. *Idiopathic WAIHA*: no identifiable cause. *Secondary WAIHA*—associated with disease such as lymphoproliferative diseases including CLL, neoplasms, and autoimmune disorders such as SLE, chronic inflammatory diseases, and viral/bacterial infections.

Checkpoint! 6

What is the DAT pattern in WAIHA? Explain why spherocytes are commonly seen in WAIHA.

Answer

The most common pattern is reaction with:

Polyspecific AHG	positive
anti-IgG	positive
anti-C3	negative

In some cases, the anti-C3 is positive.

Spherocytes are seen because the erythrocyte is coated with IgG, and as it passes through the spleen, the splenic macrophages (with Fc receptors) interact with the cell and remove portions of the erythrocyte membrane. As more portions are removed, the cell becomes round (spherocyte).

Checkpoint! 7

Describe the mechanism of cell destruction in CHD.

Answer

The antibody in CHD is usually an IgM that is capable of activating complement and causing intravascular hemolysis. The IgM activates complement in the cooler portions of the circulation. As the erythrocytes move into warmer parts of the circulation, IgM leaves the cell and complement cascade goes through C9. In other instances, the IgM antibody fixes complement but the cascade does not go to completion. Cells are then destroyed via the C3b receptors on macrophages.

Checkpoint! 8

Explain why MCV, MCH, and MCHC may be falsely increased when blood from someone with CHD is tested using an automated counter.

Answer

If the blood is cool, the IgM antibodies cause agglutination of the cells. As these clumps of cells are measured for MCV, they are measured as a single cell and thus appear macrocytic.

Hematocrit (which is calculated) is incorrect because of the incorrect erythrocyte count. Hemoglobin is correct because this parameter is determined by lysis of the cells. The erythrocyte count is falsely decreased because the clumps are counted as one cell.

MCH, which is derived from the hemoglobin and erythrocyte count, then is falsely elevated as is the MCHC, which is derived from the hemoglobin and hematocrit values.

Checkpoint! 9

Compare the DAT findings and the antibody specificity in WAIHA and CHD.

Answer

	WAIHA	CHD
Polyspecific AHG:	+	+
Anti-IgG:	+	–
Anti-C3:	– or +	+
Antibody specificity:	directed to a complex Rh antigen molecule	anti-I

Checkpoint! 10

Compare the antibody specificity and the confirmatory test for PCH and CHD.

Answer

	PCH	CHD
Antibody specificity:	anti-P	anti-I
Confirmatory test:	Donath-Landsteiner test	Cold agglutinin test

Checkpoint! 11

Compare the different types of drug-induced hemolysis including the type of hemolysis, the drug usually associated with the mechanism, and the DAT profile.

Answer

	Drug adsorption	Immune complex	Autoantibody
Hemolysis	Extravascular	Intravascular	Extravascular
Drug	Penicillin	Quinidine	Aldomet
DAT profile:			
Poly	Positive	Positive	Positive
Anti-IgG	Positive	Negative	Positive
Anti-C3	Negative	Positive	Negative

Checkpoint! 12

Compare the underlying mechanisms, pathophysiology, and clinical symptoms of an acute hemolytic transfusion reaction and a delayed one.

Answer

	Acute	Delayed
Mechanism	IgM (usually ABO system)	IgG (usually Kidd system)
	Intravascular hemolysis	Extravascular hemolysis
Pathophysiology	Naturally occurring; ABO antibodies react immediately with foreign antigen on transfused cells	Immune stimulated; Secondary exposure to foreign antigen causes antibody titer to increase

Clinical symptoms	Chills, fever, hypotension; Difficulty in breathing; Increased pulse rate	Malaise, fever, drop in hemoglobin, dark or red urine, usually one week post-transfusion
-------------------	---	--

Checkpoint! 13

What are the required laboratory tests for investigating a suspected transfusion reaction? Compare the characteristic laboratory findings in acute hemolytic transfusion reactions and delayed transfusion reactions.

Answer

Required tests are clerical check, DAT, and comparison for visible hemoglobin between the pretransfusion and posttransfusion specimens.

	Acute	Delayed
DAT	Positive but may be weak because of intravascular hemolysis; sometimes negative	Positive (may take 12–24 hours)
Visible hemoglobin	Positive	Negative

Checkpoint! 14

Compare the pathophysiology and clinical findings in ABO-HDFN and Rh-HDFN.

Answer

ABO-HDFN—usually occurs when mother is Group O and baby is Group A or B.

Pathophysiology—The naturally occurring IgG anti-A, anti-B or anti-A,B is able to cross the placenta and coats the fetal cells. Does not require previous sensitization.

Clinical findings—Generally mild anemia (or none) present in newborn. May present with jaundice 24–48 hours after birth, but kernicterus resulting from high levels of bilirubin is rare.

Rh-HDFN—occurs when mother is Rh negative and baby is Rh positive.

Pathophysiology—Occurs when mother has been previously sensitized to the Rh (D) antigen through previous pregnancy or transfusion. As the fetal erythrocytes containing the D antigen (Rh positive) enter maternal circulation, they serve as a secondary immune stimulus and increase titer of anti-D. This is an IgG-class antibody that crosses the placenta and coats the baby's cells.

Clinical findings—Anemia may be mild to severe. Baby may become jaundiced in first 24 hours after birth. Hepatosplenomegaly may be present. As level of unconjugated bilirubin rises due to increased hemolysis of erythrocytes, it may reach toxic levels and deposit in the brain causing kernicterus.

Checkpoint! 15

Compare the laboratory findings including the peripheral blood smear findings and the DAT for infants born with ABO-HDFN and those with Rh-HDFN.

Answer

	ABO-HDFN	Rh-HDFN
DAT	Weakly positive with polyspecific AHG and anti-IgG	Positive with polyspecific AHG and anti-IgG
Blood smear	Spherocytes (severe cases) Polychromatophilia Nucleated erythrocytes (severe cases)	Macrocytic, normochromic (rare spherocyte) Polychromatophilia Nucleated erythrocytes Increased leukocytes with shift to the left
Hemoglobin	Increased reticulocytes Normal to slight decrease	Increased reticulocytes Moderate to severe decrease

Hemolytic Anemia: Nonimmune Defects

Linda A. Smith, Ph.D.

■ OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. Define *microangiopathic hemolytic anemia (MAHA)*; list several associated disorders and the age group most commonly affected.
2. Describe the general morphology and hematologic values associated with MAHA and criteria that distinguish disseminated intravascular coagulation (DIC), thrombotic thrombocytopenic purpura (TTP), and hemolytic uremic syndrome (HUS).
3. Recognize the characteristic erythrocyte morphology of MAHA on a stained blood film.
4. Identify several organisms that can cause erythrocyte hemolysis.

■ OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. Summarize the general pathophysiology for MAHA.
2. Compare and contrast the clinical findings, underlying cause, treatment, and characteristic findings for erythrocytes, platelet count, and coagulation tests for each of the following types of MAHA:
 - a. Hemolytic uremic syndrome (HUS)
 - b. Thrombotic thrombocytopenic purpura (TTP)
 - c. Disseminated intravascular coagulation (DIC)
3. Define *exercise-induced hemoglobinuria*.
4. Given a set of data and clinical history, determine whether MAHA is a probable diagnosis, or the possible etiology, and propose follow-up tests that should be performed.
5. Compare the cause of hemolysis by the following infectious agents:
 - a. Plasmodium parasites (malaria)
 - b. Babesia parasites
 - c. Bartonella bacteria
 - d. Clostridium bacteria

CHAPTER OUTLINE

- ▶ Objectives—Level I and Level II
- ▶ Key terms
- ▶ Background basics
- ▶ Case study
- ▶ Overview
- ▶ Introduction
- ▶ Hemolytic anemia caused by physical injury to the erythrocyte
- ▶ Hemolytic anemias caused by antagonists in the blood
- ▶ Summary
- ▶ Review questions
- ▶ References

KEY TERMS

Cryosupernatant
 Disseminated intravascular coagulation (DIC)
 Fresh frozen plasma (FFP)
 Hemolysis, elevated liver enzymes and low platelet (HELLP) syndrome
 Hemolytic uremic syndrome (HUS)
 Microangiopathic hemolytic anemia (MAHA)
 Plasma exchange
 Thrombotic thrombocytopenic purpura (TTP)
 von Willebrand factor (VWF)

BACKGROUND BASICS

The information in this chapter builds on concepts learned in previous chapters. To maximize your learning experience, you should review the following concepts:

Level I

- ▶ Describe the normal production, life span, and destruction of the erythrocyte.
- ▶ List the reference intervals for basic adult hematology parameters.
- ▶ Identify sources of defects that lead to hemolytic anemia.
- ▶ Review the immune hemolytic anemias, and describe how they differ from other hemolytic anemias.
- ▶ Identify the intrinsic hemolytic anemias, and describe how they differ from extrinsic hemolytic anemias.

Level II

- ▶ Describe the structure and function of the major proteins of the erythrocyte membrane.
- ▶ Identify the key tests that can be used in diagnosis of anemia, and identify clinical signs of anemia.
- ▶ Describe the different nonimmune mechanisms of hemolysis and how they are detected.
- ▶ Identify the laboratory tests that differentiate immune from nonimmune anemia.

**CASE STUDY**

We will refer to this case study throughout the chapter.

Mai, a 35-year-old woman, was seen by her physician. She complained of weakness, low-grade fever, periods of forgetfulness, and memory loss for the last week or so. She denied any viral illness prior to onset of symptoms. She was on oral contraceptives but was not taking any other drugs. Her initial laboratory tests showed:

Hemoglobin: 60 g/L (6g/dL)

Hematocrit: 0.18 L/L (18%)

White blood cell count: $8.9 \times 10^9/L$

Consider reflex testing (further testing based on abnormal test results) that could be helpful in identifying the cause of the anemia.

OVERVIEW

This chapter deals with the mechanisms of hemolysis not included in the chapters on membrane defects, metabolic deficiencies, or immune mechanisms. It includes microangiopathic hemolytic anemias (MAHA). Hemolytic uremic syndrome (HUS), a MAHA, is discussed in detail including disease association, pathophysiology, and clinical and laboratory findings. There is a brief overview of thrombotic thrombocytopenic purpura (TTP). Uncommon causes of hemolysis such as hypertension, mechanical heart devices, burns, exercise, and infectious agents are also discussed.

INTRODUCTION

Erythrocytes that have normal hemoglobin structure, enzymes, and membranes can be prematurely destroyed by factors extrinsic to the cell. This destruction can be immune mediated via antibodies and/or complement. However, non-immune factors can also cause either extravascular or intravascular hemolysis, depending on the type and extent of injury to the erythrocyte. This chapter discusses the non-immune causes that lead to premature erythrocyte destruction including different types of physical trauma to the erythrocyte and antagonists such as toxins and infectious agents (Table 1).

HEMOLYTIC ANEMIA CAUSED BY PHYSICAL INJURY TO THE ERYTHROCYTE

Hemolytic anemia caused by traumatic physical injury to the erythrocytes in the vascular circulation is characterized by intravascular and/or extravascular hemolysis and striking abnormal shapes of the circulating peripheral blood erythrocytes, including fragments (schistocytes) and helmet cells.

MICROANGIOPATHIC HEMOLYTIC ANEMIA

Microangiopathic hemolytic anemia (MAHA) is an inclusive term referring to a hemolytic process caused by micro-circulatory lesions. Damage to the endothelial lining of the small vessels results in deposits of fibrin within the vessel. As the erythrocytes are forced through the fibrin strands, the membrane can be sliced open. In some erythrocytes, the membrane seals itself, leading to abnormal erythrocyte shapes that are noted as schistocytes and keratocytes on the peripheral blood smear. These damaged cells are often removed in the

★ TABLE 1

Hemolytic Anemias Caused by Nonimmune Antagonists in the Erythrocyte Environment

Category	Antagonist	Mode of Hemolysis
Microangiopathic hemolytic anemia (HUS, TTP, DIC)	Thrombi in microcirculation	Physical damage to erythrocytes by microthrombi
Malignant hypertension	Unknown	Physical damage to erythrocytes
Other physical trauma		
Exercise-induced hemoglobinuria	External force	Fragmentation of erythrocytes due to excessive external force as they pass through microcapillaries
Thermal injury	Heat	Thermal damage to erythrocyte membrane proteins
Traumatic cardiac	Physical stress	Erythrocyte fragmentation
Infectious agents	<i>Plasmodium</i> sp.	Direct parasitization of erythrocyte; hypersplenism; acute intravascular hemolysis (<i>P. falciparum</i> infection)
	<i>Babesia</i> sp.	Invasion of the erythrocyte and cell lysis
	<i>Bartonella</i> sp.	Invasion of the erythrocyte and cell lysis
	<i>Clostridium</i> sp.	Hemolytic toxins
Animal venoms	Snake bites	Mechanical cell damage due to DIC
	Spider bites	Venom?
	Bee stings	Venom?
Chemicals and drugs	Water	Osmotic lysis
	Oxidants	Hemoglobin denaturation
	Lead	Erythrocyte membrane damage

spleen (extravascular hemolysis). Severely damaged erythrocytes can be destroyed intravascularly. Depending on the underlying pathology, leukocytes may be increased and platelets may be decreased. Evidence of intravascular coagulation and fibrinolysis may be present. The plasma concentration of markers of hemolysis (bilirubin and haptoglobin) varies depending on the type and extent of hemolysis.

The underlying diseases and conditions responsible for microangiopathic hemolytic anemia include hemolytic uremic syndrome (HUS), thrombotic thrombocytopenic purpura (TTP), malignant hypertension, disseminated cancer, and pregnancy (eclampsia, preeclampsia). A severe form of preeclampsia characterized by **hemolysis, elevated liver enzymes and low platelet counts (HELLP) syndrome** can also cause MAHA. HUS and TTP may present with similar initial clinical symptoms, but the underlying etiology, the age group affected, and the target organ(s) differ (Table 2).

Checkpoint! 1

What abnormal erythrocyte characterizes microangiopathic hemolytic anemia? How is this cell formed?

CASE STUDY (continued from the previous page)

Mai's peripheral blood smear showed moderate schistocytes and polychromasia.

1. What are some conditions that result in the presence of schistocytes?

HEMOLYTIC UREMIC SYNDROME

Hemolytic uremic syndrome (HUS) is a multisystem disorder first described in the mid-1950s. It is characterized by a triad of clinical findings including hemolytic anemia with erythrocyte fragmentation, thrombocytopenia, and acute nephropathy, which can include renal failure. Most individuals, however, recover renal function.¹⁻³ In some cases, there can also be evidence of mild neurologic problems although only a small percentage develop severe symptoms.

HUS can be subdivided into two groups (D+ HUS and D- HUS) based on the presence or absence of a bloody diarrheal prodrome (Table 3). The diarrhea-associated (D+ HUS) is the most common form and represents about 90% of cases. Onset of D+ HUS tends to occur between the

★ TABLE 2

Comparison of Characteristics Associated with HUS and TTP

TTP	HUS
Adults ages 20–50	Children <5 years old
Hemolytic anemia with red cell fragmentation	Hemolytic anemia with red cell fragmentation
Renal dysfunction (mild to moderate)	Acute renal failure
Thrombocytopenia	Thrombocytopenia
Severe CNS symptoms	Mild CNS symptoms
Fever	

★ TABLE 3

Types of HUS and Associated Conditions That Can Precipitate HUS

Type of HUS	Associated Condition
Diarrhea related (classic) HUS (D+)	<i>Escherichia coli</i> O157:H7 <i>Shigella dysenteriae</i> serotype 1
Nondiarrhea-related HUS (D−)	Postinfectious <i>S. pneumoniae</i> Viral infections Immunosuppression related Chemotherapy/cytotoxic drugs Renal and bone marrow transplantation Pregnancy or oral contraceptive related Toxins

ages of 6 months and 10 years; however, most cases are seen in children up to the age of 5 years. It is also considered the most common cause of acute renal failure in children and can lead to chronic renal insufficiency (Table 2). Adult-onset D+ HUS, which is less frequently seen, occurs in those over 16 years of age, and the elderly are at highest risk for severe disease.

D+ HUS is characterized by a bloody diarrhea with more than 90% of the cases associated with gastrointestinal infections by *Escherichia coli*, which produces Shiga toxin (Stx). The other cases are associated with infection by *Shigella dysenteriae* Type 1. The incubation period from infection to onset of diarrhea is usually 3–4 days but can range from 1 to 14 days. However, only about 15% of individuals who are infected with Shiga toxin-producing *E. coli* develop HUS.^{3–6}

The most common serotype of Shiga toxin-producing *E. coli* (enterohemorrhagic *E. coli*) in the United States is *E. coli* O157:H7. In other countries there are different serotypes linked to D+ HUS.^{3,7} The organism is not a part of the normal flora of humans, but is found in the gastrointestinal tract of a small percentage of cattle. The majority of human infections have been traced to the ingestion of incompletely cooked beef contaminated with the organism, but the organism can also be transmitted by the fecal-oral route (inadequate hand washing).^{4,8}

Other factors such as elevated neutrophil counts, increased C-reactive protein (CRP), and fever are associated with an increased risk for developing HUS.^{9–12} The use of antibiotics or antimotility drugs in treating individuals with diarrhea due to *E. coli* O157:H7 has also been associated with increased risk for developing HUS.^{13–15}

The second category of HUS is that of nondiarrhea-associated (D− HUS), also referred to as *atypical HUS (aHUS)*. This condition has been reported in both children and adults and is

the type that is more likely to recur.^{16,17} D− HUS has been attributed to various causes¹⁷ (Table 3). It has been associated with connective tissue diseases such as systemic lupus erythematosus and lupus anticoagulant, as well as some types of cancer (especially stomach, colon, and breast) and diabetes.^{18,19} The disease has been reported in young women with complications of pregnancy, after normal delivery, or with the use of oral contraceptives.²⁰ In recent years, atypical HUS also has been associated with immunosuppressive therapy used in solid organ and bone marrow transplantation.^{21–24} D− HUS has been linked to invasive *Streptococcus pneumoniae* infections as well as viral infections such as Epstein-Barr virus, human immunodeficiency virus, and cytomegalovirus.^{16,17,25–28}

Many drugs including antiplatelet drugs and antineoplastic agents have been reported to cause rare cases of atypical HUS.^{21,29} HUS secondary to other diseases has a higher risk of recurrence and a lower survival rate than cases that are associated with colitis or have no identifiable trigger (primary).³⁰ In recent years, several complement regulatory gene mutations have been associated with atypical HUS; in these cases, episodes of HUS often recur. Almost 50% are mutations related to three regulatory proteins associated with the alternate complement pathway.^{31–35} The three regulatory proteins, which function to control amplification of the pathway by C3bBb, are Factor H, membrane cofactor protein (MCP), and factor I. An autoantibody against Factor H has also been implicated in some cases.³⁶

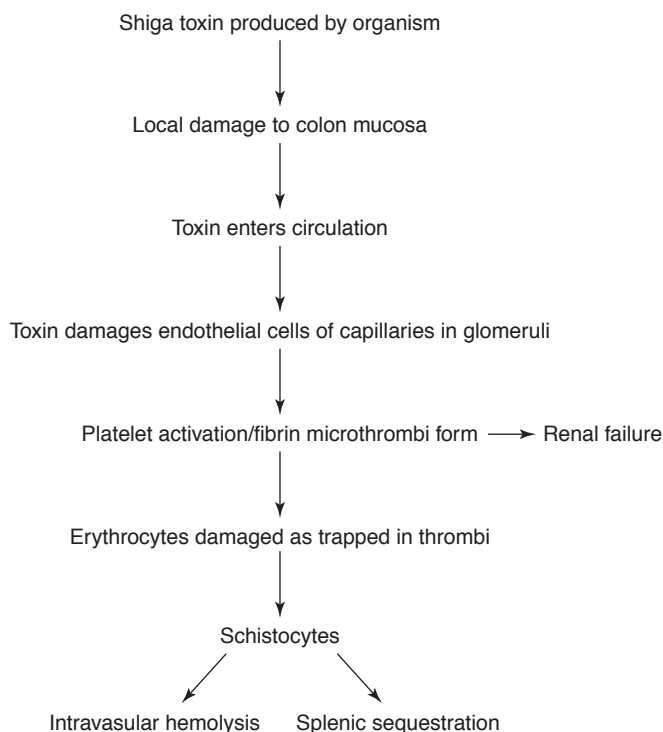

Checkpoint! 2

What are the two types of HUS, and what organisms or diseases are most commonly associated with each type?

Pathophysiology

More than 70% of the cases of HUS have been associated with damage to the renal glomerular capillary endothelium by the Shiga toxin produced by *E. coli* O157:H7 and *S. dysenteriae* Type 1.^{3,7} Once the organism enters the human gastrointestinal tract, it begins to damage the intestinal mucosa. The organism's toxin is absorbed into the circulation through damaged gastrointestinal tissue and onto the surface of neutrophils^{1,37,38} (Figure 1■). This toxin has a predisposition for endothelial cells of the microvasculature of the glomerulus and exerts a direct toxic effect.¹ The B subunits of the toxin bind to plasma membrane Gb3 receptors while the A subunit of the toxin inhibits protein synthesis at the ribosomal level, leading to cell death.^{4,38} Infiltrates of inflammatory cells and production of cytokines such as IL-8 and tumor necrosis factor- α contribute to the cytotoxic damage in glomerular and renal tubular cells.^{38–40} Endothelial damage leads to the release of prothrombotic-, vasoactive-, and platelet-aggregating substances that cause platelet activation with the subsequent formation of thrombi.^{40,41} Although damage primarily occurs in the renal microvasculature, other

■ **FIGURE 1** A possible mechanism for damage by Shiga-like toxin of *Escherichia coli* O157:H7.

organ systems (central nervous system, heart, liver) can be affected. The resulting thrombotic microangiopathy that traps erythrocytes and causes fragmentation is responsible for the schistocytes commonly seen in HUS.

In infections with *Streptococcus pneumoniae*, the bacterial enzyme neuraminidase is responsible for the capillary damage. Neuraminidase cleaves cell membrane glycoproteins and glycolipids, facilitating tissue invasion by the bacteria and exposing the normally hidden T-antigen (Thomsen-Friedenreich antigen) on capillary walls, platelets, and erythrocytes. Naturally occurring anti-T antibodies cause agglutination of cells and platelets leading to thrombosis in the small vessels.^{26,42} Catabolic enzymes (especially leukocyte elastase) and oxidative products released from the granules of activated neutrophils have been implicated in causing additional endothelial damage.⁴⁰

✓ Checkpoint! 3

Explain how infection with *E. coli* O157:H7 results in intravascular hemolysis.

Clinical Findings

D+ HUS occurs in previously healthy children with the highest incidence in the first year of life. The onset is acute with sudden pallor, abdominal pain, vomiting, foul-smelling and

bloody diarrhea, and macroscopic hematuria. Other symptoms include a low-grade fever, hypertension, petechiae, bruising, and jaundice. The most important and/or serious complication of HUS is acute renal failure, which can lead to chronic renal insufficiency in some children. The duration of oliguria and anuria is variable.

Regardless of what organ is affected in addition to the kidneys, the pathology is the same (i.e., thrombosis of the microcirculation). Central nervous system symptoms, which are less severe than those associated with TTP, can result directly from microangiopathy of the central nervous system or from resulting hypertension. Lethargy and minor seizures are the most common symptoms. Hepatomegaly can be present; splenomegaly is less common. Hyperglycemia is common in children due to pancreatic damage secondary to HUS.

Laboratory Findings

A moderate to severe normocytic, normochromic anemia is typical with hemoglobin levels as low as 3–4 g/dL (median values 7–9 g/dL) (Table 4). The peripheral blood smear shows fragmented and deformed cells (schistocytes, burr cells, helmet cells, spherocytes), with the degree of anemia correlated directly with the degree of morphologic change (Figure 2). Polychromasia and an occasional nucleated erythrocyte can be seen. A leukocytosis with a shift to the left is common. Platelet counts vary from low normal to markedly decreased with a median value of $50 \times 10^9/L$. The duration of thrombocytopenia is 1–2 weeks.

Hemoglobinemia with an increase in total serum bilirubin (2–3 mg/dL) and a decrease in serum haptoglobin reflects chronic intravascular hemolysis. Serum lactate dehydrogenase is markedly elevated, and cardiac enzymes can be

★ TABLE 4

Laboratory Findings in HUS and TTP

Evidence of hemolysis	Decreased hemoglobin/hematocrit Increased reticulocytes/polychromasia Thrombocytopenia Leukocytosis with shift to the left Presence of schistocytes
Evidence of intravascular hemolysis	Hemoglobinemia Hemoglobinuria Decreased haptoglobin Increased total and unconjugated serum bilirubin
Evidence of thrombotic microangiopathy	Thrombocytopenia Fibrin degradation products (normal to slightly increased); D-dimer increased PT and APTT (normal to slightly abnormal) Factors I, V, VIII (normal to increased)

FIGURE 2 A peripheral blood smear from a patient with hemolytic uremic syndrome (HUS). The platelets are markedly decreased. Schistocytes and spherocytes are present. (Wright-Giemsa stain; 1000× magnification)

elevated due to myocardial damage.² Blood urea nitrogen and creatinine levels are increased, reflecting renal failure. Metabolic acidosis, hyponatremia, and hypokalemia are common.

Screening tests for coagulation abnormalities include the prothrombin time (PT) and activated partial thromboplastin time (APTT). In many cases of HUS, there is no detectable consumption of coagulation factors.⁴⁰ The PT can be normal or slightly prolonged, but the APTT is usually normal. Although fibrin split products (fragments of fibrin produced by plasmin degradation of fibrin) and D-dimer are elevated, disseminated intravascular coagulation (DIC) is rare. In DIC, when there is an uncontrolled inappropriate formation of fibrin within the blood vessels and subsequent consumption of coagulation factors, coagulation screening tests are abnormal. The direct and indirect antiglobulin tests (Coombs' tests) are usually negative reflecting a nonimmune pathology.

Urinalysis results show moderate to massive amounts of protein (1–2 g/24 hours to 10 g/24 hours), gross and microscopic hematuria, increased numbers of neutrophils (pyuria), and casts (hyaline, granular, and renal epithelial) reflecting the damage to the glomerulus. The presence of hemosiderin in the urine sediment reflects chronic intravascular hemolysis.

✓ Checkpoint! 4

What are the typical erythrocyte morphology and coagulation test results in children with HUS?

Therapy

Mild to moderately severe cases of D+ HUS have the best prognosis for recovery (more than 80%). With improvement in early diagnosis and supportive care, especially during oli-

gurgic or anuric phase, the mortality of the disease has been reduced to 5–15%. Supportive care includes close observation, blood transfusion, control of electrolyte and water imbalances, control of hypertension, and peritoneal dialysis in anuria. Platelet transfusions are not recommended because they can exacerbate the thrombotic process but may be required in some patients with bleeding. The beneficial use of fresh frozen **plasma exchange** has not been shown to be efficacious in patients with D+ HUS. In contrast, patients with atypical HUS may benefit from plasma exchange. Plasma infusions are contraindicated in patients with HUS who have a positive direct antiglobulin test or who are infected with *S. pneumoniae* due to the presence of naturally occurring anti-T in the plasma.^{26,42}

A potentially promising preventative measure in individuals infected with Shiga toxin-producing *E. coli* is the use of monoclonal antibodies against Shiga toxin to provide passive immunity.⁴³ There is only a small window of time, 3 to 5 days, from onset of diarrhea to HUS for treatment, so detection of the toxin in stool or blood by flow cytometry must be performed.^{44,45}

Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura (TTP) is another relatively uncommon disorder in which platelet aggregation on the microvascular endothelium results in serious complications. In most cases, it is an acute disorder that affects young adults (ages 20–50 with a peak incidence in the third decade). TTP occurs more frequently in females than males. It is characterized by several of the same clinical findings as HUS such as thrombocytopenia and microangiopathic hemolytic anemia and is often associated with mild renal dysfunction and fever. Neurological symptoms are more frequent, severe, and prominent in TTP than HUS (Table 2). TTP may be familial (chronic or relapsing forms) or acquired.

Various clinical events have been identified as possible precipitating factors in the acquired type (Table 5 ⚡). Infections are the most common precipitating factor (40%) followed by pregnancy (10–25%). Without treatment, TTP has a mortality rate in excess of 90% due to multiorgan failure. An overview comparison with HUS in this chapter highlights several key findings.

Pathophysiology TTP is characterized by microthrombi composed of platelets and unusually large forms of **vonWillebrand factor (VWF)** that occlude capillaries and arterioles in a number of organs including the kidneys, heart, brain, and pancreas. These thrombi contain platelets and sometimes immunoglobulin and complement, but there is little fibrin, inflammation, or subendothelial exposure as in disseminated intravascular coagulation (DIC).^{46–48}

Normally large multimers of VWF are broken into smaller forms by the circulating protease, a disintegrinlike and metalloprotease domain with thrombospondin type motifs (ADAMTS13). It is now known that a deficiency in the protease ADAMTS13 is the cause of TTP.^{49–53} As a result of the

ADAMTS13 deficiency, these large VWF multimers remain attached to the endothelial cells and adhere to platelets, inducing platelet aggregation and formation of platelet thrombi. As erythrocytes are forced through the thrombi, fragmentation occurs. In the familial form, a mutation in the ADAMTS13 gene occurs, resulting in a deficient/dysfunctional enzyme. The acquired type is due to autoantibodies against ADAMTS13 blocking its activity. The clinical aspects of TTP are similar to those of HUS except that TTP occurs most often in young adults and involves more organ systems. Neurologic symptoms are more prominent, renal dysfunction is less severe, and the mortality rate is higher than in HUS.

Symptoms can be eliminated if treated early, although some patients recovering from TTP can have permanent manifestations of renal damage and require dialysis.

Laboratory Findings Typical laboratory results are shown in Table 4. The hemoglobin is usually less than 105

g/L (10.5 g/dL) (average 80–90 g/L). The MCV is variable, either normal, or decreased if there is marked erythrocyte fragmentation, or increased in the presence of reticulocytosis. The MCH and MCHC are normal. Nucleated erythrocytes can be found in the peripheral blood reflecting the bone marrow response to hemolysis. The most striking blood finding is the abundance of schistocytes (generally >1%).⁵⁴ Leukocytosis with counts of more than $20 \times 10^9/L$ occurs in 50% of patients and is usually accompanied by a shift to the left. Thrombocytopenia is often severe ($8\text{--}44 \times 10^9/L$) due to consumption of platelets in the formation of microthrombi. Megakaryocytes are abundant in the bone marrow.

Coagulation tests are usually normal or only mildly disturbed in TTP, which helps differentiate TTP from DIC, in which there is an increase in D-dimer, as well as prolonged PT, APTT, and thrombin time increase.

Hemoglobinemia, hemoglobinuria, decreased haptoglobin levels, and increased total and unconjugated serum bilirubin are direct evidence of intravascular hemolysis.

Therapy Studies have shown that plasma exchange with **fresh frozen plasma (FFP)** can be effective in providing the needed ADAMTS13 protease and removing autoantibody.^{55–58} **Cryosupernatant**, which lacks the large VWF multimers present in FFP, yet still contains the VWF cleaving protease missing in TTP patients, can be used.^{58,59} Drug treatment with monoclonal antibody (rituximab), antiplatelet or platelet-inhibiting agents, intravenous administration of steroids, or combinations of corticosteroids and plasma have been used.^{56,60}

 **Checkpoint! 5**

How does the clinical presentation of TTP differ from that of HUS? How is it similar?

 **CASE STUDY** (continued from earlier in this chapter)

As Mai was questioned further, she indicated that she noticed a large number of bruises on her extremities. Her platelet count was $31 \times 10^9/L$. She had a 2.5% reticulocyte count.

2. What is the significance of these results?
3. Why might the clinician order coagulation tests?

Disseminated Intravascular Coagulation
Disseminated intravascular coagulation (DIC) is a complex thrombohemorrhagic condition in which the normal coagulation process is altered by an underlying condition. The more common conditions that precipitate DIC include bacterial sepsis, neoplasms, immunologic disorders or trauma⁶¹ (Table 6 ). DIC is initiated by damage to the endothelial lining of vessels. This damage causes release of thromboplastic substances that activate the coagulation

★ TABLE 6

Causes of Disseminated Intravascular Coagulation (DIC)

mechanism in vivo. As a result, platelet activation and aggregation lead to deposition of fibrin and formation of microthrombi in the microvasculature. As erythrocytes become entangled in the fibrin meshwork in the capillaries (clothesline effect), they fragment to form schistocytes. Complications that result include thrombotic occlusion of vessels, bleeding, and ultimately organ failure. Hemolysis is not usually severe, but the effects of consumptive coagulopathy (consumption of various coagulation proteins and platelets) can cause thrombocytopenia and serious bleeding complications.

The typical findings on the blood smear include the presence of schistocytes and thrombocytopenia (Figure 3■). The presence of schistocytes is not specific for DIC. However, the abnormal coagulation tests help distinguish this condition from others (TTP and HUS) that give a similar picture on a peripheral blood smear and increase diagnostic accuracy.^{62,63} Abnormal coagulation tests include:

- Prolonged prothrombin time (PT), activated partial thromboplastin time (APTT), and thrombin time (TT)
- Elevated D-dimer test

■ FIGURE 3 Peripheral blood from patient with disseminated intravascular coagulation. Notice the schistocytes and thrombocytopenia. (Wright stain; 1000× magnification)

- Increase in fibrin degradation products (FDP)
- Decrease in fibrinogen

Treatment can include erythrocyte and platelet transfusions as well as infusion of fresh frozen plasma or factor concentrates to replace coagulation factors. Most important, however, are the treatment and resolution of the underlying disorder responsible for the DIC.

✓ Checkpoint! 6

Explain how DIC can be differentiated from TTP and HUS based on coagulation tests.

HELLP Syndrome

The **HELLP syndrome** is an obstetric complication characterized by **h**emolysis, **e**levated **l**iver enzymes, and a **l**ow platelet count. The etiology and pathogenesis are not well understood but an association may exist with abnormal concentrations of vascular growth factors.⁶⁴ As with TTP and HUS, the precipitating factor is unknown, but the clinical aspects are characterized by capillary endothelial damage and intravascular platelet activation as well as microangiopathic anemia.^{64,65} However, there does not seem to be an association with presence of IgM or IgG anti-cardiolipin antibodies or anti-beta2-glycoprotein-I antibodies as seen in antiphospholipid syndrome.⁶⁶ Some experts consider HELLP to be a severe form of preeclampsia and to share some of the characteristics of preeclampsia and eclampsia such as hypertension and proteinuria, but it is distinguished from them by the presence of the three aspects that gave it its name (hemolysis, elevated liver enzymes, and low platelet count). Severe cases can compromise fetal growth and survival. Approximately 10% of pregnancies with eclampsia develop HELLP syndrome with a mortality rate of about 1%.⁶⁷

The peripheral blood findings are similar to those found in TTP, HUS, or other microangiopathic conditions. Overall, however, the hemolysis and thrombocytopenia are less severe than those associated with TTP or HUS. Liver damage is due primarily to obstruction of hepatic sinusoids and can lead to subsequent hepatic hemorrhage or necrosis.⁶⁷ There are fibrinlike deposits that resemble those in TTP/HUS. These deposits are responsible for the presence of schistocytes. Laboratory markers are used in determining the presence of HELLP. The liver enzyme most frequently measured is aspartate aminotransferase (AST), and levels >70 IU/L are common. Increased total and/or unconjugated bilirubin, increased lactic dehydrogenase (generally >600 IU/L), and decreased haptoglobin can also be seen in HELLP.⁶⁸ Coagulation tests such as the PT and APTT are usually normal until late in the course of the disease.^{68,69} The platelet count is decreased (usually <100 × 10⁹/L) as a result of platelet consumption at the site of endothelial damage. Although DIC

infrequently occurs as a complication of HELLP, patients can have an undetectable underlying coagulopathy.⁶⁵ Acute tubular necrosis with renal failure, hepatic rupture, and pulmonary edema can also occur as complications.^{68,69}

Corticosteroid therapy may be useful in controlling cell destruction and decreasing liver enzymes if the fetus cannot be immediately delivered. Plasma exchange is rarely used as a treatment. The use of cortisone dexamethasone has eliminated the need for platelet transfusions in most patients with platelet counts $<50 \times 10^9/L$.⁶⁹⁻⁷²

CASE STUDY (continued from earlier in this chapter)

Mai's PT and APTT were slightly prolonged. The fibrinogen levels were slightly decreased.

4. What do these findings indicate about the underlying problem?

Malignant Hypertension

The microangiopathic hemolytic anemia associated with malignant hypertension is characterized by a low platelet count and erythrocyte fragmentation. In addition, the presence of schistocytes, platelet count, and increased LD have been used to predict renal insufficiency as well as recovery.⁷³ The mechanism of hemolysis is unknown. It has been suggested that it can be caused by endothelial injury, fibrinoid necrosis of arterioles, or deposition of fibrin fed by thromboplastic substances released from membranes of lysed erythrocytes.

Traumatic Cardiac Hemolytic Anemia

Hemolytic anemia is an uncommon complication following surgical insertion of prosthetic heart valves. Unlike the microangiopathic anemia seen with TTP or DIC, the platelet count is not significantly decreased. Excessive acceleration or turbulence of blood flow around the valve tears the erythrocytes apart from shear stress. The term *Waring blender syndrome* has been used to describe this disorder because of the localized turbulent blood flow. Many erythrocyte fragments are apparent on the blood smear. Some of the severely traumatized cells are removed by the spleen, but most undergo intravascular hemolysis. Newly designed prosthetic valves help decrease the shear stress and resulting erythrocyte fragmentation.⁷⁴ Rarely, hemolysis and erythrocyte fragmentation have been associated with formation of large vegetations in patients with infective endocarditis. It is theorized that the same mechanisms of turbulence and pressure as are seen in prosthetic valves cause the fragmentation in endocarditis.⁷⁵

Thermal Injury

Hemolytic anemia occurs within the first 24–46 hours after extensive thermal burns, and the degree of hemolysis depends on the percentage of body surface area burned. He-

molysis probably results from the direct effect of heat on spectrin in the erythrocyte membrane. (If erythrocytes are heated to 48°C in vitro, spectrin degradation causes a loss of elasticity and deformability.) In addition, the fatty acid and lipoprotein metabolism in both plasma and erythrocytes are altered after burn injuries, which can contribute to abnormal erythrocyte morphology.⁷⁶ Peripheral blood smears show erythrocyte budding, schistocytes, and spherocytes. After 48 hours, signs of hemolysis such as hemoglobinuria and hemoglobinemia decrease. Thermal injury to erythrocytes also has occurred during hemodialysis when the dialysate is overheated.

Exercise-Induced Hemoglobinuria

Exercise-induced hemoglobinuria (sometimes described as *march hemoglobinuria*) describes a transient hemolytic anemia occurring after strenuous exercise and often involves contact with a hard surface (e.g., running, tennis). The hemolysis is probably due to physical injury to erythrocytes as they pass through the capillaries of the feet. Plasma hemoglobin and haptoglobin results show that the primary cause of the intravascular lysis is due to footstrike.⁷⁷ However, it is not seen in every individual participating in these activities and can be seen in other physical activities such as swimming, cycling, and rowing in which footstrike is limited. In recent years, the role of exercise-induced oxidative stress and red cell age have been recognized as potential additional causes of lysis, especially in normally sedentary individuals who participate in strenuous exercise.⁷⁸ Increased osmotic fragility and decreased deformability leading to intravascular hemolysis were noted in these individuals.⁷⁹ In addition, changes in erythrocyte membrane proteins such as spectrins, especially in older cells, can increase susceptibility to extravascular hemolysis during strenuous exercise.

In contrast to the other hemolytic conditions discussed so far in this chapter, no erythrocyte fragments are seen on the peripheral blood smear, but the hallmarks of intravascular hemolysis—hemoglobinemia and hemoglobinuria—are present. The passage of reddish urine immediately after exercise and for several hours thereafter is usually the only complaint from affected individuals. Anemia is uncommon because less than 1% of the erythrocytes are hemolyzed during an attack. Individuals can present with slightly increased mean corpuscular volumes (MCV) due to increased reticulocytes.^{77,80} Iron deficiency can occur if exercise and hemolysis are frequent.

Other Conditions Associated with MAHA

Several reports have linked MAHA with diabetes. It is theorized that in these cases, the cholesterol to phospholipid ratio is altered, leading to a rigidity in the erythrocyte membrane.¹⁹ Stem cell transplant recipients can show increased evidence of transplant-associated microangiopathy (TAM) characterized by schistocytes. TAM may represent a form of graft-vs-host disease (GVHD) and result from endothelial damage induced by donor cytotoxic T cells.^{22,24}

CASE STUDY (continued from the previous page)

Mai's symptoms continued to become worse with frequent seizures, headaches, and dizziness. Her urinalysis results showed a 2+ protein and moderate blood. However, she had normal urinary volume.

5. Based on these results, what is the most likely condition associated with these clinical and laboratory results? Explain.
6. What therapy might be used?

▶ HEMOLYTIC ANEMIAS CAUSED BY ANTAGONISTS IN THE BLOOD

Antagonists such as drugs or venoms and infectious organisms in the environment of the erythrocyte can cause premature destruction (Table 1). This hemolysis is precipitated by either injury to the erythrocyte membrane or to denaturation of hemoglobin.

INFECTIOUS AGENTS

Parasites and bacteria can infect erythrocytes and directly lead to their destruction. Alternatively, toxins produced by infectious agents can cause hemolysis.

Malarial Parasites

The anemia accompanying malaria is due directly and indirectly to the intracellular malarial parasites that live part of their life cycle in the erythrocyte (Figure 4 ■). The anemia resulting from this infection is usually a mild, normocytic normochromic anemia but can be severe in infection with *Plasmodium falciparum* because of the high levels of parasitemia. Thrombocytopenia can also be present. Diagnosis involves finding the life cycle stage within the erythrocyte. Infection with *P. falciparum*, a cause of severe anemia in children, can be accompanied by ineffective erythropoiesis and decreased reticulocytes. The hemoglobin in these cases can reach levels as low as 5 gm/dL.⁸¹ In addition, poor diet, malnutrition, decreased iron stores, and folate stores contribute to the severity of anemia. Exchange transfusions can be used in the severest cases to remove infected erythrocytes.⁸²

a

b

c

■ **FIGURE 4** Peripheral blood smears from patients with malaria. **a.** There is a ring form of malaria in the erythrocyte. **b.** There is an immature schizont form of malaria in the erythrocyte. **c.** This is a gametocyte of *Plasmodium falciparum* in the erythrocyte. (Wright stain; 1000× magnification)

The release of the intraerythrocytic parasite from the cell results in the cell destruction. On the other hand, the spleen can remove the entire parasitized cell, or splenic macrophages can pit the parasite from the erythrocyte, damaging the cell membrane. This resulting decreased deformability can lead to removal of the cell by the spleen. Anemia can also result from an immune-mediated process. Antimalarial antibodies react with malarial antigens on the erythrocyte membrane, resulting in removal of the sensitized cell by the splenic macrophages. In some cases, the concentration of complement regulatory proteins decrease, which can facilitate complement-mediated hemolysis.⁸³

Blackwater fever, an uncommon complication of infection with *P. falciparum*, is characterized by massive acute intravascular hemolysis with hemoglobinemia, hemoglobinuria, methemalbuminemia, and hyperbilirubinemia. However, the parasitemia level is often low. The mechanism that precipitates this is unclear. One possible mechanism is development of an autoantibody to the infected erythrocyte. Another is a direct reaction to the drug quinine or to repeated incomplete treatment with the drug. The drug can act as a hapten to stimulate formation of a drug-dependent antibody that has complement-fixing ability.⁸¹ In some cases, the direct antiglobulin test (DAT) can be positive with either monospecific anticomplement or anti-IgG.⁸⁴ Use of synthetic quinine drugs has considerably decreased frequency of this complication. There is some evidence, however, that other antimalarial drugs including mefloquine can also trigger this response.⁸⁴

Babesiosis

Babesiosis, a protozoan infection of rodents and cattle, is most commonly transmitted to humans by the bite of a hard tick. However, the organism can be acquired transplacentally and through blood transfusions. In the United States, the most common organism is *Babesia microti*. On the peripheral blood smear, the parasites appear as intracellular, pleomorphic, 1–5 μm ringlike structures resembling ring form trophozoites of *Plasmodium falciparum* (Figure 5 ■). Some can appear as doubles or tetrads in the form of a Maltese cross. Travel history, the absence of the characteristic banana-shaped gametocytes, and the lack of pigment help distinguish it from *P. falciparum*. Most infections are asymptomatic but some present with a flulike syndrome. Generally there is 1–10% parasitemia.⁸⁵ Extravascular hemolysis can occur in a manner similar to that seen with malaria. A mild to moderate anemia as well as thrombocytopenia can be present. Other possible laboratory findings include increased reticulocyte count, liver enzymes, and bilirubin.⁸⁶ In a rare fulminating infection, severe anemia, intravascular hemolysis, and hemoglobinuria are seen. Complications associated with intravascular hemolysis include renal failure and disseminated intravascular coagulation. Patients who are splenectomized generally have a more severe clinical presentation and higher levels of parasitemia. In severe cases of hemolysis or renal complications, exchange transfusion may be indicated.

■ **FIGURE 5** Peripheral blood smear of a patient with babesiosis. Several infected erythrocytes are in the field. One cell in the upper left contains two organisms. Infected cells are in the center and upper right. (Wright stain; 1000 \times magnification)

Checkpoint! 7

Why do malaria and babesiosis result in anemia?

Bartonellosis

Organisms in the genus *Bartonella* are transmitted by blood-sucking arthropods and by direct inoculation by scratch or bite of a mammal. The organisms infect erythrocytes and endothelial cells. Infection by *Bartonella bacilliformis* is associated with Carrion's disease, which is restricted to Columbia, Peru, and Ecuador. The disease is transmitted by sandflies. One part of this biphasic disease is characterized by an often fatal syndrome consisting of myalgia, high fever, and an acute, severe hemolytic anemia (Oroya fever).⁸⁷ The disease can progress to coma and death within weeks. If the patient survives, a chronic phase will present weeks to months later. This is characterized by a granulomatous reaction with the appearance of cutaneous hemangioma-like lesions that may contain bacteria, neutrophils, macrophages, and endothelial cells. Other *Bartonella* species infect erythrocytes but are not associated with hemolytic manifestations.⁸⁷ The pleomorphic (cocci-bacillary) organisms are readily visualized as single, paired, or chained organisms on or within erythrocytes on Wright- or Giemsa-stained peripheral blood smears during the course of the disease. The organism releases several proteins including deformin that are responsible for inducing the pitting or invagination of the erythrocyte membrane. These structures, as well as other proteins such as hemolysins, can serve as entry portals for the bacteria and help explain the mechanism of cell destruction.^{87,88}

Clostridium Perfringens

C. perfringens is a member of the normal flora of the gastrointestinal tract. Infection can present as a transient bacteremia or a life-threatening condition. It is one of the few organisms (along with *C. septicum* and *C. novyi*) that can cause a rapid, massive intravascular hemolysis. The bacteria produce potent exotoxins that affect host cell membranes. The major hemolytic toxin (α -toxin) is a phospholipase C that hydrolyzes sphingomyelin and lecithin present in the erythrocyte membrane and leads to changes in membrane integrity. Fever, thrombocytopenia, neutrophilia, hemoglobinemia, and hemoglobinuria are present.⁸⁹ Anuria or acute renal failure can develop as a result of the hemoglobinuria. Lysis of the erythrocyte or other cells can cause DIC. Bacterial neuraminidase can expose crypt antigens such as Thomsen-Friedenrich (T antigen), which can react with nonimmune autoantibody. The peripheral blood smear shows many microspherocytes and few erythrocyte fragments.

ANIMAL VENOMS

Venoms injected by bees, wasps, spiders, and scorpions can cause hemolysis in some susceptible individuals. One of the more common bites that can result in hemolysis is that of the brown recluse spider (*Loxosceles reclusa*). The characteristic symptoms of envenomation are a localized lesion that shows central thrombosis surrounded by ischemic areas. However, up to 15% of individuals, especially children, develop systemic symptoms including intravascular hemolysis that can be severe.^{90,91} The mechanism of venom damage appears to involve sphingomyelinase D2, which cleaves glycophorin from the erythrocyte membrane. This decreases the structural integrity of the membrane and increases its sensitivity to complement-mediated lysis.^{91,92} Although snake bites rarely cause hemolysis directly, they can cause hemolysis secondary to disseminated intravascular coagulation.⁹³

Chemicals and Drugs

Various chemicals and drugs have been identified as possible causes of erythrocyte hemolysis; many of these are dose dependent. In addition to causing erythrocyte hemolysis, chemicals and drugs can also produce methemoglobinemia and cyanosis or, in some instances, aplasia of the bone marrow.

Hemoglobinemia and hemoglobinuria can occur as a result of osmotic lysis of erythrocytes when water enters the vascular system during transurethral resection or when inappropriate solutions are used during a blood transfusion.

Some drugs known to cause hemolysis in G6PD-deficient persons can also cause hemolysis in normal persons if the dose is sufficiently high. The mechanism of hemolysis is similar to that in G6PD deficiency with hemoglobin denaturation and Heinz body formation due to strong oxidants.

Lead poisoning anemia is usually classified with sideroblastic anemias because the pathophysiologic and hematologic findings are similar. Lead inhibits heme synthesis, causing an accumulation of iron within mitochondria. However, it is apparent that lead also damages the erythrocyte membrane. This damage is manifested by an increase in osmotic fragility and mechanical fragility.

SUMMARY

Mechanisms of nonimmune damage to the erythrocyte are varied. Of those discussed in this chapter, HUS and TTP are the more commonly encountered, presenting with a classic picture of microangiopathic hemolytic anemia with schistocytes. Classic D+ HUS is mediated by the Shiga-like toxin of *E. coli* O157:H7. The underlying cause of TTP is a deficiency in the ADAMTS13 cleaving protease. Intraerythrocytic parasitic infections with organisms such as malaria or babesiosis can cause hemolysis and anemia without the presence of schistocytes. In susceptible individuals, drugs or chemicals can also lead to hemolysis.

REVIEW QUESTIONS

- Which of the following conditions is not associated with the formation of schistocytes? (Objective 2)
 - hemolytic uremic syndrome
 - exercise-induced hemoglobinuria
 - thrombotic thrombocytopenic purpura
 - disseminated intravascular coagulation
- One of the major criteria that distinguishes DIC from other causes of microangiopathic hemolytic anemia is: (Objective 2)
 - the presence of schistocytes
 - thrombocytopenia
 - decreased hemoglobin
 - an abnormal coagulation test

LEVEL II

- A 43-year-old woman presents to her physician with a 3-week history of fatigue, constant headache, and low-grade fever. Selected laboratory results include:
 Hemoglobin: 7.5 g/dL (75 g/L) Platelet count: $16 \times 10^9/L$
 Hematocrit: 0.23 L/L (23%) Reticulocytes: 11%
 RDW: 15
 Peripheral blood smear showed schistocytes. Which of the following drugs that the patient was taking could cause these symptoms and lab values? (Objectives 2, 4)
 - ticlopidine
 - aspirin
 - estrogens
 - penicillin

REVIEW QUESTIONS (continued)

LEVEL I

3. A patient who has anemia with an increased reticulocyte count, increased bilirubin, and many schistocytes on the blood smear could have: (Objective 2)
 - a. MAHA
 - b. high cholesterol in the blood
 - c. spur cell anemia
 - d. immune hemolytic anemia
4. Which of the following organisms does *not* cause damage of the erythrocyte because of an intraerythrocytic life cycle? (Objective 4)
 - a. *Plasmodium falciparum*
 - b. *Babesia* sp
 - c. *Bartonella* sp
 - d. *Clostridium perfringens*
5. A characteristic finding on a blood smear in MAHA is the presence of: (Objective 3)
 - a. target cells
 - b. spur cells
 - c. schistocytes
 - d. echinocytes
6. All of the following are characterized as causes of MAHA *except*: (Objective 1)
 - a. TTP
 - b. prosthetic heart valves
 - c. HUS
 - d. March hemoglobinuria
7. All of the following are associated with HUS *except*: (Objective 2)
 - a. thrombocytosis
 - b. nucleated RBCs
 - c. schistocytes
 - d. reticulocytosis
8. MAHA is most frequently caused by: (Objective 1)
 - a. physical trauma to the cell
 - b. immune destruction
 - c. antagonists in the blood
 - d. plasma lipid abnormalities
9. Intravascular hemolysis in MAHA would be associated with which of the following parameters? (Objective 2)

<i>Bilirubin</i>	<i>Haptoglobin</i>
a. decreased	decreased
b. decreased	increased
c. increased	decreased
d. increased	increased
10. MAHA due to HUS is usually seen in which age group? (Objective 1)
 - a. children under 1 year old
 - b. females between 20 and 50 years of age
 - c. either sex under 50 years of age
 - d. males older than 16 years of age

LEVEL II

2. A 34-year-old woman is brought into the ER after falling off a ladder while painting her house. Selected lab results include:

Hemoglobin: 8.0 g/dL (80 g/L) PT: 36 seconds
 Hematocrit: 0.25 L/L (25%) APTT: >75 seconds
 Platelet count: $20 \times 10^9/L$ Fibrinogen: 100 mg/dL

 Peripheral blood smear shows schistocytes. Given these results, what is the most likely diagnosis? (Objectives 2, 4)
 - a. HELLP syndrome
 - b. TTP
 - c. DIC
 - d. traumatic hemolytic anemia
3. Results of tests obtained on a small child who had easy bruising, tiredness, difficulty breathing, and decreased urinary output were hemoglobin: 65 g/L; platelets: $41 \times 10^9/L$; PT and PTT within normal reference intervals. His mother indicated he had an episode of bloody diarrhea about 2 weeks earlier but it had not recurred. Based on the clinical and limited laboratory findings, what is the most likely condition? (Objectives 2, 4)
 - a. TTP
 - b. bartonellosis
 - c. *Clostridium* sp infection
 - d. HUS
4. The most likely age group for developing TTP is: (Objective 2)
 - a. female children under 1 year old
 - b. females between 20 and 50 years of age
 - c. either gender under 5 years of age
 - d. males older than 16 years of age
5. Which of the following disorders is *not* characterized by the presence of schistocytes? (Objective 3)
 - a. march hemoglobinuria
 - b. insertion of a prosthetic valve
 - c. third-degree burns
 - d. malignant hypertension
6. A patient with a deficiency in the VWF protease ADAMTS13 would be at risk to develop what condition? (Objective 2)
 - a. HUS
 - b. spur cell anemia
 - c. TTP
 - d. hereditary acanthocytosis
7. The formation of schistocytes in MAHA is primarily due to: (Objective 1)
 - a. pitting by splenic macrophages
 - b. defective cell membranes
 - c. increased membrane phospholipids
 - d. shearing of erythrocytes by fibrin threads

REVIEW QUESTIONS (continued)

LEVEL I

LEVEL II

8. Plasma exchange is used as a primary treatment for which of the following? (Objective 2)
 - a. HUS
 - b. TTP
 - c. abetalipoproteinemia
 - d. DIC
9. The peripheral blood smear from a 6-months pregnant woman showed the presence of schistocytes. Platelet count was $<60 \times 10^9/L$, and her hemoglobin was 7.5 g/dL (75 g/L). She has no history of chronic disease. What laboratory test(s) might give a clue to the underlying cause? (Objective 4)
 - a. haptoglobin
 - b. reticulocyte count
 - c. liver enzymes
 - d. APTT and PT
10. Hemolytic toxins are the major cause of intravascular hemolysis in diseases or conditions caused by which of the following organisms? (Objective 5)
 - a. *Plasmodium falciparum*
 - b. *Babesia* sp.
 - c. *Bartonella bacilliformis*
 - d. *Clostridium perfringens*

ANSWERS TO CASE STUDY QUESTIONS

Case Summary: This case demonstrates the sequence of testing that might be used to determine the cause of microangiopathic hemolytic anemia. The presence of schistocytes may be seen in a number of conditions, but additional laboratory tests such as platelet count and coagulation studies will help in identifying the underlying cause. In addition, medical history such as age, diarrheal episodes, pregnancy status, or

other physical conditions (acquired or inherited) will help in differential diagnosis and in deciding a sequence of additional testing. In this case, age and lack of diarrheal prodrome rule out HUS. The low platelet count but normal coagulation tests help rule out DIC. The most likely condition is TTP. The lack of an identifiable precipitating condition and the adult age onset indicate that this is most likely of the single episode, nonrecurrent type.

Question:

1. What are some conditions that result in the presence of schistocytes?

Explanation:

Some conditions that result in the presence of schistocytes include disseminated intravascular coagulation, hemolytic uremic syndrome, thrombotic thrombocytopenic purpura, mechanical trauma due to artificial heart valves, malignant hypertension, and burns (thermal injury).

Question:

2. What is the significance of these results?

Explanation:

The platelet count indicates a thrombocytopenia, which correlates with the patient's increased tendency to bruising. Her reticulocyte count was elevated and indicates a response by the bone marrow.

Question:

3. Why might the clinician order coagulation tests?

Explanation:

The presence of unexplained bruises may indicate an abnormality in the hemostatic mechanism. This can be screened for by coagulation tests.

Question:

4. What do these findings indicate about the underlying problem?

Explanation:

The PT and APTT showed slightly prolonged levels, and the fibrinogen was only slightly decreased. This rules out DIC because with DIC, you would expect greatly prolonged PT and APTT values, decreased fibrinogen, increased FDP, and positive D-dimer.

Question:

5. Based on these results, what is the most likely condition associated with these clinical and laboratory results? Explain.

Explanation:

It is most likely TTP. The patient's age, normal urinary volume, and lack of diarrheal prodrome help rule out HUS. The neurological symptoms in concert with the other laboratory values point to TTP.

Question:

6. What therapy might be used?

Explanation:

Plasma exchange with either fresh frozen plasma (FFP) or with cryoprecipitated FFP can be used.

ANSWERS TO CHECKPOINTS**Checkpoint! 1**

Microangiopathic hemolytic anemia is characterized by what abnormal erythrocyte? How is this cell formed?

Answer

The abnormal erythrocytes are schistocytes. As erythrocytes are forced through the fibrin deposits in the blood vessels, the membranes may be sliced open. When the membrane reseals itself, abnormal forms such as the schistocytes result.

Checkpoint! 2

What are the two types of HUS, and what organisms or diseases are most commonly associated with each type?

Answer

Diarrhea positive HUS is due primarily to Shiga-like toxin I and II from *Escherichia coli* O157:H7 but is occasionally due to Shiga toxin of *Shigella dysenteriae*.

Diarrhea negative HUS is caused by *Streptococcus pneumoniae*.

Checkpoint! 3

*Explain how infection with *E. coli* O157:H7 results in intravascular hemolysis.*

Answer

There is damage to the intestinal mucosa from the Shiga-like toxins of *E. coli* O157:H7, and this allows toxin and inflammatory mediators to enter the circulation. Toxins attach to receptors on the endothelial

cells of the vessels. Platelet aggregating substances are released and cause platelet activation and formation of thrombi. As erythrocytes pass through the thrombi, the membrane is damaged.

Checkpoint! 4

What are the typical erythrocyte morphology and coagulation test results in children with HUS?

Answer

Schistocytes, spherocytes, and burr cells may be present. There may be polychromasia. The PT may be normal or slightly prolonged, the APTT is normal, and the fibrin split products are slightly elevated.

Checkpoint! 5

How does the clinical presentation of TTP differ from that of HUS? How is it similar?

Answer

The conditions share four traits: thrombocytopenia, central nervous system abnormalities, renal dysfunction, and presence of schistocytes. The degree of renal dysfunction in HUS is more severe; in TTP, the neurologic symptoms are more severe. The diagnosis of TTP requires only two criteria: microangiopathic hemolytic anemia (schistocytes) and thrombocytopenia. The entire range of symptoms is rarely seen.

Checkpoint! 6

Explain how DIC can be differentiated from TTP and HUS based on coagulation tests.

Answer

In DIC, the PT, APTT, and thrombin time are prolonged. There is an increase in fibrin degradation products and a decrease in fibrinogen. In HUS and TTP, the PT is usually normal or only slightly prolonged; the APTT is normal. Any increase in fibrin degradation products is slight.

Checkpoint! 7

Why do malaria and babesiosis result in anemia?

Answer

Both organisms (*Plasmodium* sp. and *Babesia* sp.) are intraerythrocytic parasites. After they have completed part of the life cycle within an erythrocyte, the organism causes rupture of the cell, resulting in intravascular hemolysis. High levels of parasitemia and chronic infection result in anemia. Some cells containing the organisms may also be removed in the spleen, resulting in extravascular hemolysis.

Nonmalignant Granulocyte and Monocyte Disorders

Wanda C. Reygaert, Ph.D.

OBJECTIVES—LEVEL I

At the end of this unit of study, the student should be able to:

1. Recognize neutrophilia from hematologic data and name the common disorders associated with neutrophilia.
2. Explain the quantitative and qualitative neutrophil response to acute bacterial infections.
3. Identify immature granulocytes and morphologic changes (toxic granulation, Döhle bodies, intracellular organisms, and vacuoles) often seen in reactive neutrophilia.
4. Define and recognize *leukemoid reaction*, *leukoerythroblastosis*, and *pyknotic nuclei*.
5. Distinguish leukemoid reaction from chronic myelogenous leukemia based on laboratory data including the leukocyte alkaline phosphatase stain.
6. Identify neutropenia from hematologic data and list the common disorders associated with neutropenia.
7. Recognize the conditions associated with spurious, or false, neutropenia.
8. Identify neutrophil nuclear alterations including Pelger-Huët, hypersegmentation, and pyknotic forms.
9. Recognize as abnormal and seek assistance for identification of rare or unusual cytoplasmic abnormalities such as morulae, Alder-Reilly granules, or Chédiak-Higashi inclusions.
10. State the common conditions associated with abnormal eosinophil, basophil, and monocyte counts.
11. Define *Gaucher* and *Niemann-Pick diseases*.

OBJECTIVES—LEVEL II

At the end of this unit of study, the student should be able to:

1. Assess the etiology, associated conditions, and peripheral blood findings for immediate, acute, chronic, and reactive neutrophilia.
2. Contrast the hematologic and clinical features for leukemoid reaction and chronic myelogenous leukemia (CML).
3. Organize neutropenia to include etiology and associated conditions as well as blood and bone marrow findings.

CHAPTER OUTLINE

- ▶ Objectives—Level I and Level II
- ▶ Key terms
- ▶ Background basics
- ▶ Case study
- ▶ Overview
- ▶ Introduction
- ▶ Neutrophil disorders
- ▶ Eosinophil disorders
- ▶ Basophil and mast cell disorders
- ▶ Monocyte/Macrophage disorders
- ▶ Summary
- ▶ Review questions

OBJECTIVES—LEVEL II (continued)

4. Recognize, evaluate, and select appropriate corrective action for spurious or false neutropenia.
5. Appraise the nuclear abnormalities of neutrophils including Pelger-Huët, pseudo-Pelger-Huët, hypersegmentation, and pyknotic nuclei, and reconcile them with the appropriate clinical conditions of the patient.
6. Appraise the cytoplasmic abnormalities of neutrophils including toxic granulation, Döhle bodies, vacuoles, intracellular organisms, and morulae and reconcile them with the appropriate clinical conditions of the patient.
7. Recognize and summarize the clinical features of the inherited granulocyte functional disorders (Chédiak-Higashi, Alder-Reilly, May-Hegglin, and chronic granulomatous diseases) and differentiate their cellular abnormalities.
8. Evaluate alterations in the relative and/or absolute numbers of eosinophils, basophils, and monocytes and associate them with the clinical condition of the patient.
9. Evaluate the etiology, laboratory findings, and clinical features of the lysosomal storage disorders.
10. Identify and differentiate the abnormal macrophages seen in Gaucher disease, Niemann-Pick disease, and sea-blue histiocytosis.
11. Construct an efficient and cost-effective reflex testing pathway for follow-up neutrophilia, neutropenia, and qualitative granulocyte abnormalities.
12. Evaluate a case study from a patient with a nonmalignant granulocyte disorder.

BACKGROUND BASICS

The information in this chapter builds on concepts learned in previous chapters. To maximize your learning experience, you should review this material before starting this unit of study.

Level I

- ▶ Summarize the production, kinetics, distribution, life span, and basic function of neutrophils and monocytes.
- ▶ Describe how leukocytes are counted and differentiated; recognize normal and immature granulocytes.

Level II

- ▶ Describe the role of specific neutrophil granules and enzymes in antimicrobial systems.
- ▶ Identify normal macrophages and discuss their role in the bone marrow and the rest of the monocyte-macrophage system.
- ▶ Describe leukocyte maturation and proliferation pools in the bone marrow; describe the role of cytokines in bone marrow release of leukocytes; describe the process of leukocyte egress to tissue.
- ▶ Correlate the function of the reticuloendothelial organs to leukocyte distribution and demise.

CASE STUDY

We will address this case throughout the chapter. Dennis, a 24-year-old male, was taken to emergency surgery to repair several bone fractures sustained in an automobile accident. His previous medical history was unremarkable. He was in excellent health prior to the accident. Consider why this patient's condition could cause abnormal hematologic test results and the possible complications that could occur in this patient during his treatment and recovery. Also consider how this could affect his hematologic test results.

OVERVIEW

This chapter discusses benign changes in granulocytes and monocytes as a response to various nonmalignant disease states and toxic challenges. These changes include both quantitative and qualitative variations that can be detected by laboratory tests. The chapter is divided into sections covering changes in quantity and morphology of neutrophils, eosinophils, basophils, and monocytes in acquired and inherited states. Emphasis is on recognition of these abnormalities by the laboratory professional and correlation to the patient's clinical condition.

INTRODUCTION

It is well recognized that changes in leukocyte concentration and morphology are the body's normal responses to various disease processes and toxic challenges. Most often, one type of leukocyte is affected more than the others, providing an important clue to diagnosis. The type of cell affected depends in a large part on that cell's function (i.e., bacterial infection commonly results in an absolute neutrophilia, viral infections are characterized by an absolute lymphocytosis, and certain parasitic infections cause an eosinophilia). Thus, determination of absolute concentrations of cell types aids in differential diagnosis, especially when the total leukocyte concentration is abnormal.

Leukocytosis refers to a condition in which the total leukocyte count is more than $11.0 \times 10^9/L$ in an adult. Be aware that reference ranges vary significantly among different sources and laboratories. Refer to Table B on inside cover for leukocyte and differential reference ranges compiled from numerous references.¹⁻⁴ Although leukocytosis is usually due to an increase in neutrophils, it may also be related to an increase in lymphocytes or (rarely) in monocytes or eosinophils.

Quantitative variations of different types of leukocytes are evaluated by performing a total leukocyte count and a differ-

ential count. The absolute concentration of each type of leukocyte can be calculated from these two values as follows:

$$\text{Absolute cells/L} = \text{Total leukocyte count/L} \times \text{Percent of cell type from differential}$$

Checkpoint! 1

A patient's total leukocyte count is $5.0 \times 10^9/L$. There are 60% segmented neutrophils, 35% lymphocytes, and 5% monocytes on the differential. Calculate the absolute number of each cell type. Is each of these relative and absolute cell counts normal or abnormal?

Leukopenia refers to a decrease in leukocytes below $4.5 \times 10^9/L$. This condition is usually due to a decrease in neutrophils, but lymphocytes and other cell types can also contribute.

Morphologic or qualitative variations of leukocytes are noted by examination of the stained blood smear. Some qualitative changes affect cell function while others do not. Variations in the appearance of the cell together with its concentration can provide specific clues to the pathologic process.

NEUTROPHIL DISORDERS

Quantitative disorders of neutrophils are usually reflected by changes in the total leukocyte count because neutrophils are the most numerous white blood cells in the peripheral blood. Automated cell counters flag results outside the reference range. Neutrophilia is more common than neutropenia. On the other hand, automated cell counters do not detect qualitative changes in the neutrophils. Detection of these changes requires careful microscopic examination of stained blood smears. Qualitative changes may provide important diagnostic information.

QUANTITATIVE DISORDERS

Quantitative abnormalities of neutrophils occur because of a malignant or benign disorder. The malignant disorders are caused by neoplastic transformation of hematopoietic stem cells. Benign disorders are usually acquired and may cause an increase (**neutrophilia**) or decrease (**neutropenia**) in neutrophils, but neutrophilia is more common. Table 1  lists three interrelated mechanisms affecting neutrophil concentration in the peripheral blood.

Neutrophilia

The normal neutrophil concentration varies with age and race, so it is important to evaluate the count based on reference ranges for each demographic group. *Neutrophilia* refers

★ TABLE 1

Factors Affecting Neutrophil Concentration in Peripheral Blood

- Bone marrow production and release of neutrophils
- Rate of neutrophil egress to tissue or survival time in blood
- Ratio of marginating to circulating neutrophils in peripheral blood

to an increase in the total circulating absolute neutrophil concentration (ANC). In adults, neutrophilia occurs when the ANC of neutrophils exceeds $7.0 \times 10^9/L$. (See Table B on inside cover for age- and race-specific reference ranges.)

Benign neutrophilia occurs most often as a result of a reaction to a physiologic or pathologic process and is called **reactive neutrophilia**. Reactive neutrophilia can be immediate, acute, or chronic and may involve any or all of the three mechanisms listed in Table 1.

Immediate Neutrophilia Immediate neutrophilia can occur without pathologic stimulus and is probably a simple redistribution of the marginated granulocyte pool (MGP) to the circulating granulocyte pool (CGP). Of the neutrophils inside a blood vessel, 50% normally are freely circulating and the other 50% are loosely attached to the vessel endothelial cells (marginated). Routine laboratory testing counts only freely circulating cells.

The neutrophil increase in immediate neutrophilia is immediate but transient (lasting about 20–30 minutes) and appears to be independent of bone marrow input and tissue **egress**. This type of neutrophilia is also referred to as **pseudoneutrophilia** or **shift neutrophilia** because no real change in the number of neutrophils within the vasculature occurs. The increased circulating neutrophils are typically mature, normal cells. This redistribution of neutrophils is responsible for the physiologic neutrophilia that accompanies active exercise, epinephrine administration, anesthesia, and anxiety.

Acute Neutrophilia Acute neutrophilia occurs within 4–5 hours of a pathologic stimulus (e.g., bacterial infection, toxin). This type of neutrophilia results from an increase in the flow of neutrophils from the bone marrow storage pool to the blood. The neutrophilia is more pronounced than in pseudoneutrophilia, and the proportion of immature neutrophils may increase. More bands appear if the tissue demand for neutrophils creates an acute shortage of segmented neutrophils in the storage pool. Continued demand may result in the release of metamyelocytes and myelocytes. As bone marrow production increases and the storage pool is replenished, the leukocyte differential returns to normal.

Chronic Neutrophilia Chronic neutrophilia follows acute neutrophilia. If the stimulus for neutrophils continues beyond a few days, the storage pool will become depleted. The mitotic pool will then increase production in an at-

tempt to meet the demand for neutrophils. In this state, the marrow shows increased numbers of early neutrophil precursors including myeloblasts, promyelocytes, and myelocytes. The blood contains increased numbers of bands, metamyelocytes, myelocytes, and (rarely) promyelocytes. An increase in the concentration of immature forms of leukocytes in the circulation is termed a **shift to the left**.

Conditions Associated with Neutrophilia

Reactive Chronic Neutrophilia Chronic neutrophilia caused by benign or toxic conditions usually is characterized by total leukocytes less than $50 \times 10^9/L$ and a shift to the left. The immature cells are usually bands and metamyelocytes, but myelocytes and promyelocytes also may be seen. Toxic changes including toxic granulation, **Döhle bodies** (light grayish-blue cytoplasmic inclusions made up of residual endoplasmic reticulum), and cytoplasmic vacuoles are often found even if the neutrophil count is normal (Figure 1 ■). The leukocyte alkaline phosphatase score may be elevated. Conditions associated with reactive chronic neutrophilia are listed in Table 2 ★.

Bacterial Infection The most common cause of neutrophilia is bacterial infection, especially with pyrogenic organisms such as staphylococci and streptococci. Depending on the virulence of the microorganism, extent of infection, and response of the host, the neutrophil count may range from $7.0 \times 10^9/L$ to $70 \times 10^9/L$. Usually, the count is in the range of $10\text{--}25 \times 10^9/L$. As the demand for neutrophils at the site of infection increases, the early response of the bone marrow is to increase output of storage neutrophils to the peripheral blood, causing a shift to the left. The inflow of neutrophils from the bone marrow to the blood continues until it exceeds the neutrophil outflow to the tissues, caus-

■ **FIGURE 1** A leukemoid reaction. There is an increased leukocyte count and a shift to the left. The cells have heavy toxic granulation and Döhle bodies suggesting an infectious or toxic reactive leukocytosis. (Peripheral blood; Wright-Giemsa stain; 1000× magnification)

TABLE 2

Conditions Associated with Neutrophilia

Acute bacterial and fungal infections
Inflammatory processes:
Tissue damage from burns, trauma, or surgery
Collagen, vascular, and autoimmune disorders
Hypersensitivity reactions
Metabolic alterations: uremia, eclampsia, and gout
Neoplasms
Acute hemorrhage or hemolysis
Rebound from bone marrow transplant or treatment with colony-stimulating growth factors
Certain chemicals, toxins, and drugs
Physiologic neutrophilia:
Strenuous exercise, stress, pain, temperature extremes, childbirth labor, and in newborns
Chronic myeloproliferative disorders*

*In these disorders, increases in neutrophils are not reactive but due to a neoplasm of the hematopoietic stem cell.

ing an absolute neutrophilia. In very severe infections, the storage pool of neutrophils may become exhausted, the mitotic pool may be unable to keep up with the demand, and a neutropenia develops. Neutropenia in overwhelming infection is a very poor prognostic sign. Chronic bacterial infection may lead to chronic stimulation of the marrow whereby the production of neutrophils remains high and a new steady state of production develops.

Neutrophilia is neither a unique nor an absolute finding in bacterial infections. Infections with other organisms such as fungi, rickettsia, spirochetes, and parasites also may cause a neutrophilia. Certain bacterial infections are characterized by neutropenia rather than neutrophilia. In a few types of infection such as whooping cough, lymphocytosis rather than neutrophilia is typical.⁵ Viral infections, although typically accompanied by a lymphocytosis, may present with neutrophilia early in their course.

CASE STUDY (continued from earlier in this chapter)

Laboratory results on Dennis, the trauma patient, two days after surgery are as follows:

WBC: $14.5 \times 10^9/L$	WBC Differential
HGB: 12.9 g/dL (129 g/L)	Segmented neutrophils: 5%
PLT: $180 \times 10^9/L$	Band neutrophils: 50%
	Lymphocytes: 40%
	Monocytes: 5%

Urine, blood, and wound cultures were ordered.

1. What results, if any, are abnormal?
2. What is the most likely reason for these results?

Tissue Destruction/Injury, Inflammation, Metabolic Disorders

Conditions other than infection that can result in a neutrophilia include tissue necrosis, inflammation, certain metabolic conditions, and drug intoxication. All of these conditions produce neutrophilia by increasing neutrophil input from the bone marrow in response to increased egress to the tissue. Examples of these conditions include rheumatoid arthritis, tissue infarctions, burns, neoplasms, trauma, uremia, and gout.

Although defenders of the body, leukocytes are also responsible for a significant part of the continuing inflammatory process. Damaged tissue releases cytokines that act as chemotactins, causing neutrophils to leave the vessels and move toward the injury site. In gout, for example, deposits of uric acid crystals in joints attract neutrophils to the area. In the process of phagocytosis and death, the leukocytes release toxic intracellular enzymes (granules) and oxygen metabolites. These toxic substances mediate the inflammatory process by injuring other body cells and propagating the formation of chemotactic factors that attract more leukocytes.

Leukemoid Reaction Extreme neutrophilic reactions to severe infections or necrotizing tissue may produce a **leukemoid reaction** (Figure 1). A leukemoid reaction is a benign leukocyte proliferation characterized by a total leukocyte count usually greater than $50 \times 10^9/L$ with many circulating immature leukocyte precursors. In a neutrophilic-leukemoid reaction, the blood contains many bands and metamyelocytes, increased myelocytes and promyelocytes, and (rarely) blasts.

Leukemoid reactions may produce a blood picture indistinguishable from that of chronic myelocytic leukemia. If the diagnosis cannot be made by routine hematologic parameters, genetic studies, molecular analysis, and leukocyte alkaline phosphatase (LAP) stain scores may be helpful (Table 3).⁶ Contrary to leukemia, a leukemoid reaction is transient, disappearing when the inciting stimulus is removed. A leukemoid reaction may be seen in chronic infections (such as tuberculosis); carcinoma of the lung, stomach, breast, or liver and other inflammatory processes.⁶

Checkpoint! 2

How can CML be distinguished from a leukemoid reaction?

Leukoerythroblastic Reaction

Leukoerythroblastic reaction (Figure 2) is characterized by the presence of nucleated erythrocytes and a neutrophilic shift to the left in the peripheral blood. The total neutrophil count may be increased, decreased, or normal. Often, erythrocytes in this condition exhibit poikilocytosis with teardrop shapes and anisocytosis. Leukoerythroblastosis is most often associated with chronic neoplastic myeloproliferative conditions, especially myelofibrosis, **myelophthisis** (replacement of normal

★ TABLE 3

Comparison of Laboratory Results in Leukemoid Reactions and Chronic Myelocytic Leukemia (CML)

	Leukemoid Reaction	CML
Leukocyte count	Increased up to $50 \times 10^9/L$	Markedly increased (usually $>50.0 \times 10^9/L$)
Leukocyte differential	Shift to the left with bands, metamyelocytes, and myelocytes; neutrophil toxic changes	Shift to the left with immature cells including promyelocytes and blasts; increased eosinophils and basophils
Erythrocyte count	Normal	Often decreased
Platelets	Usually normal	Increased or decreased
LAP	Increased	Decreased
Philadelphia chromosome	Absent	Present
BCR/ABL mutation	Absent	Present
Clinical	Related to primary condition	Systemic (splenomegaly, enlarged nodes, bone pain)

LAP: leukocyte alkaline phosphatase

hematopoietic tissue in the bone marrow by fibrosis, leukemia, or metastatic cancer cells), and severe hemolytic anemias such as Rh hemolytic disease of the fetus and newborn (HDFN).

Stimulated Bone Marrow States When the bone marrow is stimulated to produce erythrocytes in response to hemorrhage or hemolysis, neutrophils may also become caught up in the process, resulting in neutrophilia and a slight shift to the left. Patients whose bone marrow has been stimulated by hematopoietic growth factor hormones such as granulocyte/monocyte colony-stimulating factor (GM-CSF) can demonstrate rapidly increasing total white cell counts and leukocyte precursors including blasts. Growth

■ **FIGURE 2** A leukoerythroblastic reaction. There are nucleated erythrocytes and a shift to the left with band neutrophils and a myelocyte. (Peripheral blood; Wright-Giemsa stain; 500 \times magnification)

cytokines are used to replenish leukocytes after bone marrow transplant, high-dose chemotherapy, bone marrow failure, or prior to autologous blood donation or stem cell apheresis⁷.

Corticosteroid therapy produces a neutrophilia that occurs as a result of increased bone marrow output accompanied by a decreased migration of neutrophils to the tissues (by inhibition of the ability of neutrophils to adhere to vessel walls). This inhibition of neutrophil migration to the tissues may in part explain the increased incidence of bacterial infections in patients on steroid therapy even though the blood neutrophil count is increased. Steroids also decrease the number and inhibit the function of monocytes/macrophages.⁸

Physiologic Leukocytosis Physiologic leukocytosis and neutrophilia are present at birth and for the first few days of life. The leukocytosis can be accompanied by a slight shift to the left. Physiologic stress including exposure to extreme temperatures, emotional stimuli, exercise, and labor during delivery can cause neutrophilia generally without a shift to the left.

✓ Checkpoint! 3

What is the difference between a leukemoid reaction and a leukoerythroblastic reaction?

Neutropenia

Neutropenia occurs when the neutrophil count falls below $1.5\text{--}2.0 \times 10^9/L$ (varies with ethnic group). **Agranulocytosis**, a term that refers to a neutrophil count below $0.5 \times 10^9/L$, is associated with high probability of infection.

Basophils and eosinophils are also commonly depleted in severe neutropenia.

True neutropenia may occur because of (1) decreased bone marrow production, (2) increased cell loss (due to immune destruction or increased neutrophil egress to the tissue), or (3) pseudoneutropenia (increased neutrophilic margination). Spurious, or false, neutropenia can result from neutrophil agglutination, disintegration and laboratory instrument problems. (See Table 4 🌟 for the most common causes.)

Decreased Bone Marrow Production Neutropenia may develop as a result of decreased bone marrow production. In this case, the bone marrow shows myeloid hypoplasia, and the M:E ratio is decreased. With defective production, the bone marrow storage pool is decreased, neutrophil egress to tissues is decreased, and both the peripheral blood circulating pool and the marginal pool decrease. Immature cells may enter the blood in an attempt to alleviate the neutrophil shortage. Cells younger than bands, however, are less efficient in phagocytosis. The end result is a lack of neutrophils at inflammatory sites, resulting in a huge risk for overwhelming infections.

Stem Cell Disorders. Decreased bone marrow production may occur with stem cell failure such as aplastic anemia, radiotherapy, or chemotherapy, or with infiltration of hematopoietic tissue by malignant cells (myelophthisis). Of new leukemia cases, 40% present with a total white count of $<10 \times 10^9/L$.⁹ This occurs when normal precursor cells in the bone marrow are replaced, but the malignant cells have not yet egressed to the peripheral blood in significant numbers.

Megaloblastic Anemia. Neutropenia is a characteristic finding in megaloblastic anemia and myelodysplastic syndromes. In these cases, however, the marrow is usually hyperplastic. Neutropenia results not from marrow failure but

from the abnormal myeloid cells being destroyed before release to the blood (ineffective granulopoiesis).

Chemicals/Drugs. A wide variety of drugs and chemicals is associated with leukopenia and neutropenia if given in sufficient dosage (Table 4). Chemotherapy and radiation treatments for cancer are a common cause of neutropenia. Pancytopenia from decreased bone marrow production of granulocytes predisposes patients with malignancies to frequent and serious infections. Chemotherapy drugs act to cause apoptosis of dividing cells by a variety of mechanisms including direct DNA damage, altering folate receptors, or inhibiting enzymes needed for mitosis. Because blood cell precursors in the bone marrow are also actively dividing, their proliferation is inhibited as well. Prophylactic use of antibiotics and GM-CSF have reduced mortality in patients receiving chemotherapy, but infections due to neutropenia remain a serious complication.^{7,10} Drug-induced neutropenia can also be caused by allergic (immunologic) reactions to drugs. Women, older patients, and patients with a history of allergies are more often affected.¹¹

Congenital Neutropenia. Several rare inherited disorders cause neutropenia related to decreased bone marrow production. Periodic or cyclic neutropenia is a curious form of neutropenia that begins in infancy or childhood and occurs in regular 21- to 30-day cycles. It is believed to be inherited as an autosomal dominant trait with variable expression.¹² The severely neutropenic period lasts for several days and is marked by frequent infections. Between the neutropenic attacks, the patient is asymptomatic. Severe congenital neutropenia (SCN) is a rare, often fatal autosomal recessive disorder marked by extreme neutropenia (less than $0.5 \times 10^9/L$). The total leukocyte count is often in the normal range. The basic mechanism underlying this disorder is unknown, but studies have focused on the responsiveness of neutrophil precursors to the hematopoietic growth factor G-CSF.¹³ Familial neutropenia is a rare benign anomaly characterized by an absolute decrease in neutrophils but usually a normal total leukocyte count. It is transmitted as an autosomal dominant trait and is usually detected by chance. (See Table 5 🌟 for a more complete list of congenital neutropenic disorders.^{11,14})

Increased Cell Loss Neutropenia may occur as the result of increased neutrophil diapedesis (passage of white cells through blood vessel walls into extravascular tissue). In severe or early infection, the bone marrow may not produce cells as rapidly as they are being utilized, resulting in neutropenia. Various viral, bacterial, rickettsial, and protozoal infections induce tissue damage, increasing the demand and destruction of neutrophils. Neutropenia resulting from severe infections is often accompanied by marked toxic changes to the granulocytes. Prognosis in these cases is very poor due to the organisms prevailing over the body's immune system.

🌟 TABLE 4

Causes of Leukopenia and/or Neutropenia

Infections, especially viral and overwhelming bacterial such as sepsis
Physical agents and chemicals (e.g., radiation and benzene)
Drugs: chemotherapy, certain drugs in the classes of sedatives, anti-inflammatory, antibacterial, antithyroid, and antihistamines*
Hematologic disorders:
Acute leukemia
Megaloblastic and aplastic anemia
Splénomegaly
Alloantibodies or autoantibodies (e.g., systemic lupus erythematosus [SLE])
Hereditary or congenital disorders

*See *Wintrobe's Clinical Hematology*, 11th ed., Chapter 63, for a more complete list of drugs associated with neutropenia.

AD: autosomal dominant, AR: autosomal recessive, XLR: X-linked recessive

Immune Neutropenia. Antibodies directed against neutrophil-specific antigens (NA) may cause a decrease in the number of neutrophils. Leukocytes are destroyed in a manner similar to erythrocytes in immune hemolytic anemia. In some cases, drugs precipitate an immunologic response accompanied by the sudden disappearance of cells from the circulation. The immunologic mechanism may include direct cell lysis or sensitization and subsequent sequestration in the spleen.¹² The two types of immune neutropenia are alloimmune and autoimmune.

Alloimmune neonatal neutropenia occurs when there is transplacental transfer of maternal alloantibodies directed against antigens on the infant's neutrophils (the infant's antigens are of paternal origin). Affected infants may develop infections until the neutropenia is resolved, usually in a few weeks. This immune process is similar to that found in Rh hemolytic disease of the fetus and newborn except that the firstborn child can be affected. Alloimmune neutropenia can also be the result of a transfusion reaction.

Two forms of autoimmune neutropenia (AIN) are recognized: primary and secondary. Primary AIN is not associated with other diseases. It develops as antibody-coated neu-

trophils are sequestered and destroyed by the spleen. This condition of unknown etiology occurs predominantly in young children who subsequently develop fever and recurrent infections. Spontaneous remission usually occurs after a period of 13–20 months. Secondary autoimmune neutropenia is generally found in older patients, many of whom have been diagnosed with another autoimmune disorder such as systemic lupus erythematosus (SLE) or rheumatoid arthritis. In the secondary form of AIN, the antineutrophil antibodies are not the only cause of the neutropenia, and the actual target of the antibodies is not known.¹⁵

Infections associated with autoimmune neutropenia are not usually life threatening and are treated with routine antibiotic therapy. Intravenous doses of immunoglobulin may be used in severe cases. Laboratory findings are variable. The total leukocyte count may range from normal to decreased, but the neutrophil count is often quite low. GM-CSF is usually given when the neutrophil count is $<1.0 \times 10^9/L$. Immune neutropenia can be confirmed by testing for antineutrophil antibodies or neutrophil surface antigens by various methods including agglutination tests, immunofluorescence, and enzyme-linked immunosorbent assay (ELISA). The availability of these complex tests varies widely among laboratories.¹⁶

Hypersplenism. Hypersplenism may result in a selective splenic culling of neutrophils producing mild neutropenia. The bone marrow in this case exhibits neutrophilic hyperplasia. Thrombocytopenia and (occasionally) anemia may also accompany hypersplenism.

Pseudoneutropenia Pseudoneutropenia is similar to pseudoneutrophilia in that it is produced by alterations in the circulating and marginated pools. Pseudoneutropenia results from the transfer of an increased proportion of circulating neutrophils to the marginal neutrophil pool with no change in the total peripheral blood pool. This temporary shift is characteristic of some infections with endotoxin production and of hypersensitivity. Because of the selective margination of neutrophils, the total leukocyte count drops and a relative lymphocytosis develops.

Spurious, or False, Neutropenia It is important for the laboratory professional to recognize when neutropenia is a result of laboratory *in vitro* manipulations of blood. Table 6★ summarizes four *in vitro* causes of a low neutrophil count:

1. Neutrophils may (rarely) adhere to erythrocytes when the blood is drawn in EDTA, causing an erroneously low automated white count. If observed on the stained smears, blood can be recollected by fingerstick to make manual dilutions and blood smears without utilizing EDTA.
2. Neutrophils disintegrate over time faster than other leukocytes. If there is a delay in testing the blood, the neutrophil count may be erroneously decreased.
3. In some pathologic conditions, the leukocytes are more fragile than normal and may rupture with the manipulations of preparing blood for testing in the laboratory.

TABLE 6

Causes of False Low Neutrophil Counts in Clinical Laboratory Testing

- EDTA induced neutrophil adherence to erythrocytes
- Disintegration of neutrophils over time prior to testing
- Disruption of abnormally fragile leukocytes during preparation of the blood for testing
- Neutrophil aggregation

4. The neutrophil count may be falsely decreased if the neutrophils clump together as occurs in the presence of some paraproteins.

Checkpoint! 4

How can the correct white cell count be determined when neutrophils clump in the presence of EDTA?

QUALITATIVE OR MORPHOLOGIC ABNORMALITIES OF NEUTROPHILS

Automated cell counters do not detect or flag morphologic abnormalities of neutrophils. Abnormalities are identified only by observation of cells on stained blood smears. Cytoplasmic abnormalities are more common than nuclear abnormalities. Most of these cytoplasmic changes (Döhle bodies, toxic granulation, and vacuoles) are reactive transient changes accompanying infectious states. The correct identification of alterations such as intracellular microorganisms can lead to the prompt diagnosis and treatment of life-threatening infections. Recognizing Pelger-Huët or hypersegmented neutrophils can point to the diagnosis of specific conditions that may prove elusive without the morphologic information.

Nuclear Abnormalities

Pelger-Huët **Pelger-Huët anomaly** (Figure 3■) is a benign anomaly inherited in an autosomal dominant fashion and occurring in about 1 in 5000 individuals. The neutrophil nucleus does not segment beyond the two-lobed stage and may also appear round with no segmentation. The presence of excessive coarse clumping of chromatin in the nucleus aids in the differentiation of bilobed cells from true bands. The bilobed nucleus has a characteristic dumbbell shape with the two lobes connected by a thin strand of chromatin. Cells with this appearance are often called “*pince-nez*” cells. Rod-shaped and peanut-shaped nuclei are also found. The cell is functionally normal. The significance of recognizing this anomaly lies in differentiating the benign hereditary defect from a shift to the left occurring with infections.

Acquired, or pseudo, Pelger-Huët anomaly can be seen in myeloproliferative disorders and myelodysplastic states. The

■ **FIGURE 3** Pelger-Huët anomaly. Note pince-nez, or eye-glass-shaped, nuclei. These mature cells could easily be confused for bands if not for the highly clumped chromatin. (Peripheral blood; Wright-Giemsa stain; 1000× magnification)

acquired form is frequently accompanied by hypogranulation because of a lack of secondary granules, and the nuclei acquire a round rather than a dumbbell shape. The chromatin shows intense clumping, aiding in differentiation of these mononuclear cells from myelocytes.

Hypersegmentation Larger-than-normal neutrophils with six or more nuclear segments (hypersegmented neutrophils) are a common and early indicator of megaloblastic anemia. These cells are found together with pancytopenia and macro ovalocytes that typically accompany deficiencies of folate or vitamin B₁₂. Rarely reported cases of hereditary hypersegmentation of neutrophils, a benign condition, are significant only by their need to be distinguished from multilobed nuclei that are associated with disease.¹⁷

Pyknotic Nucleus Pyknotic, or degenerating, nuclei (Figure 4■) are found in dying neutrophils in blood or

■ **FIGURE 4** In the center is a dying cell with a pyknotic nucleus. Note the smooth nuclear material that is breaking up. Above this cell is a band neutrophil with vacuoles and toxic granulation. (Peripheral blood; Wright-Giemsa stain; 1000× magnification)

★ TABLE 7

Cytoplasmic Inclusions Found in Neutrophils in Infectious Conditions

Inclusion	Morphologic Characteristics	Composition	Associated Conditions
Döhle body	Light gray-blue oval near cell periphery	Rough endoplasmic reticulum (RNA)	Infections, burns, cancer, toxic, or inflammatory states
Toxic granules	Large blue-black granules	Primary granules	Same as Döhle body
Cytoplasmic vacuole	Clear, unstained circular area	Open spaces from phagocytosis	Same as Döhle body
Bacteria	Small basophilic rods or cocci	Phagocytized organisms	Bacteremia or sepsis
Fungi	Round or oval basophilic inclusions slightly larger than bacteria	Phagocytized fungal organisms	Systemic fungal infections often in immunosuppressed patients
Morulae	Basophilic, granular; irregularly shaped	Clusters of <i>Ehrlichia rickettsial</i> organisms	Ehrlichiosis

body fluid preparations. The nuclear chromatin condenses and the segments disappear, becoming smooth, dark-staining spheres. If the nucleus is round, these necrotic cells may be confused with nucleated erythrocytes.¹⁸

✓ Checkpoint! 5

Describe the difference between hypersegmented and hyposegmented neutrophils and pyknotic nuclei. In what conditions is each seen?

Cytoplasmic Abnormalities

Cytoplasmic inclusions are often found in infectious states and, when present, give important diagnostic information to the health care provider (Table 7★). These inclusions are Döhle bodies, toxic granules, vacuoles, and intracellular organisms.

Döhle Bodies Döhle bodies are light gray-blue oval inclusions in the cytoplasm of neutrophils and eosinophils (Figure 5■). Found near the periphery of the cell, Döhle bodies are composed of aggregates of rough endoplasmic reticu-

■ **FIGURE 5** A band neutrophil with a large bluish inclusion (Döhle body). (Peripheral blood; Wright-Giemsa stain; 1000× magnification)

lum. They may be seen in severe infections, burns and cancer, and as a result of toxic drugs. Döhle bodies should be looked for whenever toxic granulation or other reactive morphologic changes are present because they frequently occur together. Döhle bodies are similar in appearance to the cytoplasmic inclusions found in May-Hegglin anomaly.

Toxic Granules **Toxic granules** are large, deep, blue-black primary granules in the cytoplasm of segmented neutrophils and sometimes in bands and metamyelocytes (Figure 6■). Primary (nonspecific) granules normally lose their basophilia as the cell matures, so even though about one-third of the granules in the mature neutrophil are primary granules, their presence is not detectable. In contrast, toxic primary granules retain their basophilia in the mature neutrophil, perhaps because of a lack of maturation. Also, primary granules may become more apparent as the secondary granules are discharged, fighting bacteria. Toxic granulation is seen in the same conditions as Döhle bodies. Toxic-like granules or inclusions can appear as artifacts with

■ **FIGURE 6** PMNs and a band neutrophil with vacuoles, toxic granulation. There are also Döhle bodies in the center cell, but they are difficult to see. (Peripheral blood; Wright-Giemsa stain; 1000× magnification)

increased staining time or decreased pH of the buffer used in the staining process.

Cytoplasmic Vacuoles Cytoplasmic vacuoles appear as clear, unstained areas. Vacuoles probably represent the end stage of phagocytosis (Figure 6). They are usually seen in the same conditions as toxic granulation and Döhle bodies. Cytoplasmic vacuoles in neutrophils from a fresh specimen correlate highly with the presence of septicemia.

Vacuoles may also appear as an artifact in blood smears made from blood that has been collected and stored in EDTA. Vacuoles related to storage are more likely to be smaller and more uniformly dispersed than those in toxic states. This artifact can be eliminated by making smears from fresh blood without anticoagulant.

CASE STUDY (continued from earlier in this chapter)

All cultures were negative for bacteria and fungi. On further examination of the blood smear, it was noted that *no* abnormal cytoplasmic features were observed in the neutrophils. However, the nuclei of most of the bands appeared more condensed than normal, and many had two lobes in a dumbbell shape.

- Given the leukocyte morphology and cultures, what additional condition must now be considered?
- Explain the clinical significance of the nuclear anomaly described in this patient.
- Why is the white cell count elevated?

Intracellular Organisms In most infections, including septicemia, the causative agents are not demonstrable in the peripheral blood. However, microorganisms seen inside of neutrophils should always be considered a significant finding, and the physician should be notified immediately (Figure 7 ■).

Bacteria/Fungi. Intracellular histoplasmosis or *Candida* are sometimes found in the blood of patients with HIV or

■ **FIGURE 7** Intracellular microorganisms. Note the vacuoles and toxic granulation in the cells. (Peripheral blood; Wright-Giemsa stain; 1000× magnification)

other severe immunosuppression. Organisms found outside of cells must be interpreted with care. On stained blood smears, it is crucial to distinguish whether the microorganisms came from contaminated equipment or stain or are actually present in the patient's blood. Organisms must also be distinguished from other cytoplasmic material and precipitated stain. All bacteria and yeasts stain basophilic with Wright's stain.

Ehrlichia sp. has become a significant tick-borne pathogen in humans over the last decade. Ehrlichiosis was first described in a human in the United States in 1986. The disease is characterized by high fever, leukopenia, thrombocytopenia, and elevated liver enzymes. Most cases of ehrlichiosis occur in April through September when nymphal ticks are most active. *Ehrlichia* sp. are small, obligate intracellular, coccobacilli bacteria. They infect leukocytes, where they multiply within phagosomes. The intracellular organisms are pleomorphic, appearing as basophilic, condensed, or loose aggregates of rickettsial organisms, which tend to appear spherical. The intracellular microcolonies of *Ehrlichia*, called **morulae**, are observed in leukocytes on stained blood films (Figure 8 ■). The presence of morulae in leukocytes may be the first diagnostic finding of *Ehrlichia*. The leukocyte eventually ruptures and releases the organisms that then infect other leukocytes. In the United States, two known species of *Ehrlichia* infect humans. *E. chaffeensis* infects monocytes and is the causative agent of human monocytic ehrlichiosis (HME). *E. ewingii* infects granulocytes and is the causative agent of human granulocytic ehrlichiosis (HGE). The pathogenesis of ehrlichiosis may be related to direct cellular injury by the bacteria or a cascade of inflammatory or immune events.

Confirmation of infection is made through serologic determination of antibody titers using indirect fluorescent antibody (IFA) assays or by identification of DNA sequences by polymerase chain reaction (PCR). Peripheral blood cytopenia is probably the result of sequestration of infected cells in the

■ **FIGURE 8** Morulae in ehrlichiosis. This segmented neutrophil from a patient with human granulocytic ehrlichiosis contains two dense, basophilic inclusions called *morulae*. (Peripheral blood; Wright-Giemsa stain; 1000× magnification)

★ TABLE 8

Inherited Qualitative Neutrophil Abnormalities

Condition	Morphologic or Functional Defect	Clinical Features
Alder-Reilly anomaly	Large, dark cytoplasmic granules in all leukocytes; cells function normally	Associated with mucopolysaccharidosis such as Hurler's syndrome
Chédiak-Higashi syndrome	Giant fused granules in neutrophils and lymphs; cells engulf but do not kill microorganisms	Serious, often fatal condition with repeated pyrogenic infections
May-Hegglin anomaly	Blue, Döhle-like cytoplasmic inclusions in all granulocytes; cells function normally	Bleeding tendency from associated thrombocytopenia
Chronic granulomatous disease (CGD)	Defective respiratory burst; cells engulf but don't kill microorganisms	Recurrent infections especially in childhood
Myeloperoxidase deficiency	Low or absent myeloperoxidase enzyme; cell morphology normal	Usually benign; other bactericidal systems prevent most infections
Leukocyte adhesion deficiency (LAD)	Absence of cell-surface adhesion proteins affecting multiple cell functions; cell morphology normal	Serious condition with recurrent infections and high mortality

spleen, liver, and lymph nodes. The bone marrow is usually hypercellular.^{19,20}

Inherited Functional Abnormalities

Functional neutrophil abnormalities are almost always inherited and can be accompanied by morphologic abnormalities. It is suggested that granulocyte functional abnormalities be suspected in patients with recurrent, severe infections, abscesses, delayed wound healing and in antibiotic resistant sepsis. Table 8 ★ summarizes the functional defects and their clinical features.

Alder-Reilly Anomaly Alder-Reilly anomaly is an inherited condition characterized by the presence of large purplish granules in the cytoplasm of all leukocytes in disorders such as Hurler's syndrome and Hunter's syndrome. (Figure 9 ■). These disorders are lysosomal storage disorders (more on these later in this chapter) in which the accumulated substrates in the lysosomes are mucopolysaccharides.²¹ The

■ **FIGURE 9** Lymphocyte from Hurler's disease (mucopolysaccharidosis). Note the halo around the granules. (Peripheral blood; Wright-Giemsa stain; 1000× magnification)

granules can be distinguished from toxic granulation by their staining metachromatically with toluidine blue. These inclusions in lymphocytes tend to occur in clusters in the shape of dots or commas and are surrounded by vacuoles (Gasser's cells). The inclusions frequently are seen only in cells of the bone marrow, not in the peripheral blood. The blood cells function normally.

Chédiak-Higashi Syndrome Chédiak-Higashi syndrome is a rare autosomal recessive disorder in which death usually occurs in infancy or childhood because of recurrent bacterial infections (Figure 10 ■). Giant gray-green peroxidase-positive bodies and giant lysosomes are found in the cytoplasm of leukocytes as well as most granule-containing cells of other tissues. These bodies are formed by fusion of primary nonspecific and secondary specific neutrophilic granules. This abnormal fusion of cytoplasmic membranes prevents the granules from being delivered into the phagosomes to participate in killing of ingested bacteria. Neutropenia and thrombocytopenia are frequent complications as the disease progresses. The patients have skin hypopigmentation, silvery hair, and photophobia from an abnormality of melanosomes. Lymphadenopathy and hepatosplenomegaly are characteristic.²²

May-Hegglin Anomaly May-Hegglin anomaly is a rare, inherited, autosomal dominant trait in which granulocytes contain inclusions similar to Döhle bodies consisting mainly of RNA from rough endoplasmic reticulum (Figure 11 ■). The bodies can be distinguished from true Döhle bodies because they are usually larger and more round in shape.²³ Variable thrombocytopenia with giant platelets is characteristic. The only apparent clinical symptom patients may exhibit is abnormal bleeding related to the low platelet count.

Chronic Granulomatous Disease Chronic granulomatous disease (CGD) is an inherited disorder (65% X-linked, the rest AR)²⁴ characterized by defects in the respi-

■ **FIGURE 10** a. Neutrophil from Chédiak-Higashi syndrome. b. Lymphocyte from the same patient as in a. Note the bluish-gray inclusion bodies. (Peripheral blood; Wright-Giemsa stain; 1000× magnification)

ratory burst oxidase system. The affected cells cannot generate antimicrobial oxygen metabolites, such as H_2O_2 . The morphology of the neutrophil is normal. Affected children suffer from recurrent infections with opportunistic pathogens that result in granuloma formation. Although CGD is an inherited disorder, the onset of symptoms may not occur until early adulthood. The abnormal neutrophils can phagocytize the microorganisms but cannot kill them. Catalase-positive microorganisms are not killed because they are capable of destroying the H_2O_2 of their own metabolism. They continue to grow intracellularly where they are protected from antibiotics. Catalase-negative organisms, however, kill themselves by generating H_2O_2 , which they cannot break down.²⁵

The peripheral blood neutrophil count is normal but increases in the presence of infection. Immunoglobulin levels

are often increased due to chronic infection.²³ Treatment involves the use of prophylactic antibiotics and early treatment of infections.

The nitroblue tetrazolium slide test (NBT) is useful in detecting the abnormal oxygen metabolism of neutrophils in CGD. Neutrophils are mixed with nitroblue tetrazolium and microorganisms. In normal individuals, the leukocytes phagocytize the microorganisms, initiating an increase in oxygen uptake. This process leads to an accumulation of oxygen metabolites that reduce the NBT to a blue-black compound, which shows up in the cell as dark crystals. Neutrophils from individuals with CGD cannot mobilize a respiratory burst, so no dark crystals are seen.²⁵

The dihydrorhodamine 123 (DHR123) assay using flow cytometry is replacing the NBT test in some laboratories. In the DHR123 assay (also referred to as the *neutrophil oxidative burst assay*), granulocytes are incubated with bacteria and the dye DHR123.²⁶ After the neutrophils phagocytize the bacteria, they activate the NADP oxidase and produce the reactive oxygen metabolites (respiratory burst). These metabolites oxidize the DHR123 to fluorescent rhodamine 123, which is detected by flow cytometry. The mean fluorescence intensity (MFI) of control granulocytes (unstimulated) and of the bright population of stimulated granulocytes is calculated. The ratio between these two populations, called the *stimulation coefficient*, can be used to compare the respiratory burst between blood samples. In healthy adults, the reference interval for granulocytes with phagocytic activity is 80–100%.

■ **FIGURE 11** May-Hegglin syndrome. There is a neutrophil with a Döhle-like structure in the cytoplasm and a large platelet (arrow). (Peripheral blood; Wright-Giemsa stain; 1000× magnification)

Myeloperoxidase Deficiency Myeloperoxidase deficiency is, for the most part, a benign autosomal recessive disorder characterized by an absence of myeloperoxidase in neutrophils and monocytes. Although myeloperoxidase is involved in the bacteriocidal process in neutrophils, an increase in infections is not usually a complication of myeloperoxidase deficiency even in homozygous individuals because the cells are able to utilize an alternative system to

kill the microorganisms (somewhat more slowly). Patients who also have diabetes mellitus may experience disseminated fungal infections (usually with *Candida albicans*).

Current hematology analyzers such as the ADVIA 2120 (Siemens) detect MPO deficiency using the intracellular myeloperoxidase enzyme of the cell in a two-stage cytochemical reaction to differentiate cells based on stain and size characteristics. Neutrophils, eosinophils, and monocytes are usually MPO positive, and basophils and lymphocytes are MPO negative. Neutrophils in the blood of MPO deficiency patients show up on the cytogram as “Large Unstained Cells,” resulting in an overall decreased neutrophil count.²⁷ This discrepancy is flagged and can be resolved by reviewing the stained blood smear. The neutrophils are present on the stained smears and appear morphologically normal.

Leukocyte Adhesion Deficiency Leukocyte adhesion deficiency (LAD) is a rare, autosomal recessive disorder characterized by decreased or absent leukocyte cell-surface adhesion proteins (β_2 -integrins), the CD11/CD18 complex. Neutrophils from patients with LAD have multiple defects related to adhesion to endothelial cells, chemotaxis, phagocytosis, respiratory burst activation, and degranulation. Because of defective adhesion proteins, the neutrophils cannot adhere to endothelial cells of the blood vessel walls and exit the circulation. In addition, LAD neutrophils are not able to recognize the presence of the complement C3bi fragment on microorganisms, so phagocytosis is not stimulated.

Features of LAD include recurrent soft tissue bacterial and fungal infections with persistent leukocytosis and granulocytosis due to increased stimulation of bone marrow. The frequency and severity of the infections depends on the amount of CD11/CD18 expressed by the cells. Diagnosis can be made by flow cytometric analysis of neutrophil CD11b levels using a monoclonal antibody.²⁵ Treatment includes prophylactic antibiotics and early, aggressive treatment of infections. Mortality rate in childhood is high, and bone marrow transplantation is recommended in severe cases.

✓ Checkpoint! 6
 Explain how you can determine whether toxic granulation and vacuoles in the PMNs are due to the patient's condition or to artifact.

▶ EOSINOPHIL DISORDERS

Disorders involving exclusively eosinophils are rare. An increase in the circulating number of these cells may indicate a potentially serious condition. Because the lower limit of the reference range is very low, a decrease is difficult to determine and is probably not significant. Eosinopenia can be seen in acute infections and inflammatory reactions and with the administration of glucocorticosteroids. Glucocorticosteroids and epinephrine inhibit eosinophil release from

the bone marrow and increase margination.²⁸ Eosinophilia can be classified as primary (neoplastic phenotype) or secondary (reactive). Primary eosinophilia can be further classified as clonal (known molecular marker) and idiopathic (unknown cause).²⁹

REACTIVE (SECONDARY) EOSINOPHILIA

Eosinophilia refers to an increase in eosinophils above $0.40 \times 10^9/L$. Reactive eosinophilia appears to be induced by substances secreted from T lymphocytes. This type of eosinophilia is polyclonal and the common myeloid progenitor (CMP) cell is normal. Various conditions associated with the cellular immune response (mediated by T lymphocytes) are characterized by eosinophilia including (1) tissue-invasive parasites, (2) allergic conditions, (3) respiratory tract disorders, (4) gastrointestinal diseases, and (5) skin and connective tissue disorders and diseases.³⁰ Parasites are the most common cause of secondary eosinophilia worldwide. When the eosinophil concentration is high and immature forms are present, the blood picture may resemble that seen in chronic eosinophilic leukemia. The conditions associated with eosinophilia are listed in Table 9 .

★ TABLE 9

Conditions Associated with Quantitative Changes of Eosinophils, Basophils, and Mast Cells

Eosinopenia	Acute infections, inflammatory reactions, administration of glucocorticosteroids
Eosinophilia	
Secondary (reactive)	Parasitic infection Allergic conditions, especially asthma, dermatitis, and drug reactions
Primary (HES)	
Clonal	Certain clonal hematologic malignancies, Hodgkin lymphoma, CML, and eosinophilic leukemia
Idiopathic	No apparent cause
Basopenia	Inflammatory states following immunologic reactions
Basophilia	Immediate hypersensitivity reactions Endocrinopathies Infectious diseases Chronic myeloproliferative disorders, especially CML; chronic basophilic leukemia
Mastocytosis	Immediate hypersensitivity reactions Connective tissue disorders Infectious diseases Neoplastic disorders such as lymphoproliferative diseases and Hematopoietic stem cell diseases

HES = hypereosinophilic syndrome

Tissue invasion by parasites produces an eosinophilia more pronounced than parasitic infestation of the gut or blood. Eosinophils are especially effective in fighting tissue larvae of parasites. Eosinophils can readily adhere to larvae coated with IgG, IgE, and/or complement. The larva is too large for the eosinophil to phagocytose; instead, the cell molds itself around the larva. Intracellular eosinophilic granules fuse with the eosinophil membrane and expel their contents into the space between the cell and the larva. The granular substances attack the larva wall, partially digesting it.³¹

Allergic disorders (asthma, dermatitis, and drug reactions) are frequently characterized by a moderate increase in eosinophils. Large numbers can also be found in nasal discharges and sputum of allergic individuals as well as in the peripheral blood.

Pulmonary infiltrate with eosinophilia (PIE) syndrome consists of asthma, pulmonary infiltrates, central nervous system involvement, peripheral neuropathy, periarteritis nodosa, and local or systemic eosinophilia. This syndrome may be produced by parasitic or bacterial infections, allergic reactions, or collagen disorders. In some cases, no cause can be found.

PRIMARY EOSINOPHILIA

Primary eosinophilia is collectively known as **hypereosinophilic syndrome** (HES). HES is a catchall term used to describe a persistent blood eosinophilia over $1.5 \times 10^9/L$ with tissue infiltration. If there is no apparent cause it is called idiopathic HES (Figure 12 ■). On the other hand, primary eosinophilia may be associated with a clonal molecular marker. Clonal eosinophilia, including eosinophilic leukemia, are considered myeloproliferative disorders. The classification of HES is changing as genetic mutations are identified and fewer cases of HES are considered idiopathic.

■ **FIGURE 12** Hypereosinophilic syndrome. Note that the cells are all mature eosinophils. (Peripheral blood; Wright-Giemsa stain; 1000× magnification)

Chronic eosinophilia may cause extensive tissue damage as the granules are released from disintegrating eosinophils. In many cases of HES, the heart is damaged by large numbers of circulating eosinophils. Charcot-Leyden crystals, which are formed from either eosinophil cytoplasm or granules, can be found in exudates and tissues where large numbers of eosinophils migrate and disintegrate. Treatment of HES with corticosteroids, hydroxyurea, and/or α -interferon is sometimes effective in reducing the eosinophil count. HES is most commonly seen in males (more than 90%) and is rarely seen in children.²⁹

Idiopathic HES needs to be differentiated from reactive eosinophilias and clonal eosinophilias (such as eosinophilic leukemia). Eosinophilic leukemia usually is characterized by increased numbers of myeloblasts and eosinophilic myelocytes, whereas in idiopathic HES and reactive eosinophilia, the eosinophils are mature. In addition, an abnormal clonal chromosome karyotype or molecular mutation suggests eosinophilic leukemia or other clonal variant rather than idiopathic HES or reactive eosinophilia.

▶ BASOPHIL AND MAST CELL DISORDERS

Both basophils and mast cells are important in inflammatory and immediate allergic reactions because they are both able to release inflammatory mediators. Their cytoplasmic inflammatory granules can be stimulated for release by many of the same mediators. In addition, each type of cell has individual mediators. Extracellular release of inflammatory granules may be induced by physical destruction of the cell, chemical substances (toxins, venoms, proteases), endogenous mechanisms (tissue proteases, cationic proteins), and immune mechanisms. The immune mechanisms may be IgE-dependent (IgE binds to high-affinity receptors on these cells) or IgE-independent (triggered by complement fragment C5a binding to C5a receptors on these cells).

The number of basophils and mast cells increases at inflammation sites. Basophils migrate from the blood by adhering to the endothelium (mediated by several families of adhesion molecules and receptors).^{32,33}

Basophilia refers to an increase in basophils above $0.20 \times 10^9/L$. Basophilia is associated with immediate hypersensitivity reactions and chronic myeloproliferative disorders (Table 9) (Figure 13 ■). An absolute basophilia is often helpful in distinguishing CML from a leukemoid reaction or other benign leukocytosis. When the basophil count exceeds 80% of the total leukocyte population and the Philadelphia chromosome and/or BCR/ABL1 gene rearrangement are not present, some hematologists prefer to call the disease *basophilic leukemia*, an extremely rare condition.

A decrease in basophils is even more difficult to establish than eosinopenia. Scanning a blood smear with 100× magnification will reveal a rare basophil in normal individuals.

■ **FIGURE 13** Peripheral blood from a patient with CML and 30% basophils. (Peripheral blood; Wright-Giemsa stain; 500× magnification)

■ **FIGURE 14** Peripheral blood from a patient with reactive monocytosis showing two reactive monocytes. (Peripheral blood; Wright-Giemsa stain; 1000× magnification)

Decreases in basophils are seen in inflammatory states and following immunologic reactions.

Mastocytosis can be found in a number of disorders in which the number of mast cells is increased up to fourfold in tissues affected by the disorder (most commonly the skin) and in conjunction with certain neoplastic disorders (Table 9). No clinical disorder that involves a decrease in mast cell numbers has been identified, however, long-term treatment with glucocorticoids can lower the number of mast cells.³³

✓ **Checkpoint! 7**

Why are the basophil and eosinophil counts important when assessing the benign or neoplastic nature of a disorder?

► **MONOCYTE/MACROPHAGE DISORDERS**

Quantitative disorders are associated with monocytes whereas the qualitative disorders are associated with monocytes/macrophages. The qualitative disorders are inherited lysosomal storage disorders.

QUANTITATIVE DISORDERS

Monocytosis occurs when the absolute monocyte count exceeds $0.8 \times 10^9/L$ (Figure 14■). It is seen most often in inflammatory conditions and certain malignancies (Table 10✚). Monocytosis occurring in the recovery stage of acute infections and in agranulocytosis is considered a favorable sign. Monocytes play an important role in the immune cellular response in tuberculosis.

Unexplained monocytosis has been reported to be associated with as many as 62% of all malignancies. Myelodysplastic states, acute myelocytic leukemia, and chronic myelo-

cytic leukemia are associated with monocytosis. About 25% of Hodgkin lymphomas are characterized by an increase in monocytes. In these conditions, the monocyte is probably a part of a reactive process to the neoplasm rather than a part of the clonal neoplasm itself. Neoplastic proliferation of monocytes occurs in acute monocytic leukemia and acute and chronic myelomonocytic leukemia.

Monocytopenia refers to a concentration of monocytes below $0.2 \times 10^9/L$ and is found in stem cell disorders such as aplastic anemia. A decreased number of circulating monocytes is difficult to establish because of the low normal levels of these cells.

QUALITATIVE DISORDERS

Lysosomal storage disorders are a large group of inherited disorders. All nucleated cells contain lysosomes that are part of the cell's recycling system. Lysosomes contain vari-

✚ **TABLE 10**

Conditions Associated with Quantitative Changes of Monocytes	
Neoplastic	Myelodysplastic/myeloproliferative diseases Chronic myelomonocytic leukemia Juvenile myelomonocytic leukemia Chronic myelogenous leukemia Acute monocytic, myelomonocytic, and myelocytic leukemias
Reactive	Inflammatory conditions Collagen diseases Immune disorders Certain infections (e.g., TB, syphilis)
Monocytopenia	Stem cell disorders such as aplastic anemia

ous enzymes (including glucosidases, lipases, proteases, and nucleases) that are involved in degradative processes, and defects in any of these enzymes can lead to the accumulation of either undegraded substrates or catabolic products that are unable to be transported out of the lysosome. This accumulation can lead to cell dysfunction and pathological phenotypes. Most of these disorders are inherited in an autosomal recessive pattern.³⁴

Lysosomal storage disorders can be classified by the type of storage material that accumulates (glycoproteins, glycosphingolipids, mucolipids, mucopolysaccharides, etc.). Many of these disorders cause detectable morphology in leukocytes with a few that appear in granulocytes (see Alder-Reilly anomaly earlier in this chapter) and monocytes/macrophages. The disorders that are diagnosed based on the presence of abnormal macrophages in hematologic tissue include Gaucher disease, Niemann-Pick disease, and sea-blue histiocytosis (see Histiocytoses).

Gaucher Disease Gaucher (pronounced go-shay) disease is an inherited autosomal recessive trait that is characterized by a deficiency of glucocerebrosidase (an enzyme needed to break down the lipid glucocerebroside). In this disease, the macrophage is unable to digest the stroma of ingested cells, and the lipid glucocerebroside accumulates. The clinical findings (splenomegaly and bone pain) of the disease are related to the accumulation of this lipid in macrophages mainly in the spleen, liver, and bone marrow. The macrophages (Gaucher cells) are large (20–100 μm) with small eccentric nuclei and the cytoplasm appears wrinkled or striated (Figure 15 ■).³⁵ The spleen and liver may become greatly enlarged. Leukopenia, thrombocytopenia, and anemia may occur as the result of their sequestration by an enlarged spleen. A consistent finding useful in the diagnosis of Gaucher disease is an increase in serum acid phosphatase activity.

■ **FIGURE 15** Gaucher macrophages in bone marrow. (Wright-Giemsa stain; 1000 \times magnification)

Cells similar to Gaucher cells may be found in the marrow of individuals with a rapid granulocyte turnover, especially in chronic myelocytic leukemia. The accumulation of lipid in these disorders does not result from a deficiency of an enzyme but from the inability of the macrophage to keep up with the flow of fat into the cell from the increased cell turnover. Gaucher disease can be confirmed by demonstrating a decreased leukocyte β -glucosidase activity whereas the enzyme level is normal or increased in myeloproliferative disorders.

Niemann-Pick Disease Niemann-Pick disease includes a group of rare disorders that are related autosomal recessive diseases. Signs of the disease begin in infancy with poor physical development. The spleen and liver are greatly enlarged. The disease is often fatal by 3 years of age. In Niemann-Pick type A and type B disease, the defect is a deficiency of sphingomyelinase (an enzyme needed to break down lipids) resulting in excessive sphingomyelin storage. Foamy macrophages are found in lymphoid tissue and the bone marrow. (Figure 16 ■) The foam cells are large (20–100 μm) with an eccentric nucleus and globular cytoplasmic inclusions. Leukopenia and thrombocytopenia may occur from increased sequestration from the enlarged spleen, and blood lymphocytes may contain several vacuoles that are lipid-filled lysosomes.³⁶

Miscellaneous Lysosomal Storage Disorders Tay-Sachs disease, Sandhoff disease, and Wolman's disease are inherited diseases characterized by a deficiency of one or more enzymes that metabolize lipids. As a result of these enzyme deficiencies, abnormal concentrations of lipids accumulate in the lysosomes of tissue cells. These often fatal conditions affect mostly nonhematologic tissue. There are no specific findings in the peripheral blood. Lipid-laden macrophages may be present in the bone marrow.³⁷

■ **FIGURE 16** Macrophage in the bone marrow of a patient with Niemann-Pick disease. Note the foamy cytoplasm with inclusions. (Wright-Giemsa stain; 1000 \times magnification)

HISTIOCYTOSES

Two different types of cells are known as histiocytes: Langerhans cells/dendritic cells and monocytes/macrophages. Both types of cells are antigen processing and antigen presenting cells and share a common CD34⁺ progenitor. The three classes of histiocytoses are class I—Langerhans cell histiocytoses (LCH); class II—non-Langerhans histiocytoses (non-LCH), which encompasses the histiocytoses of mononuclear phagocytes; and class III—malignant histiocytoses.³⁸

The Langerhans cell is an immature dendritic cell that is usually found in the epidermis, oral and vaginal mucosa, and lungs. They differ from other tissue cells by characteristic racquet-shaped structural inclusions known as Birbeck granules.³⁹ Monocyte/macrophage histiocytes contribute to reactive (in response to an inflammatory stimulus) and malignant disorders. Reactive macrophage histiocytes can be seen in benign proliferative diseases (xanthoma disseminata, juvenile xanthogranuloma), in nonmalignant hemophagocytic diseases (fulminant hemophagocytic syndrome, histiocytosis with massive lymphadenopathy), and in several of the storage disorders (Gaucher, Niemann-Pick, and sea-blue histiocytosis).⁴⁰

Sea-Blue Histiocytosis Syndrome Sea-blue histiocytosis syndrome is a rare inherited disorder characterized by splenomegaly and thrombocytopenia. Sea-blue staining macrophages are found in the liver, spleen, and bone marrow (Figure 17 ■). The cell is large (20–60 μm in diameter) with a dense eccentric nucleus and cytoplasm that contains blue or blue-green granules. Considerable variation in clinical manifestations is present, but in most patients, the course of the disease is benign. Sea-blue histiocytes may also be seen in a variety of disorders of lipid metabolism and in association with various other disorders including Niemann-

■ **FIGURE 17** Sea-blue histiocyte from bone marrow. (Wright stain; 1000× magnification)

Pick disease, some hematopoietic diseases, and in certain infections.⁴¹

SUMMARY

Leukocytes respond to toxic, infectious, and inflammatory processes to defend the tissues and limit and/or eliminate the disease process or toxic challenge. This may involve a change in leukocyte concentration, most often increasing one or more leukocyte types. The type of cell affected depends on the cell's function. Thus, a differential count as well as the total leukocyte count aids in diagnosis.

Neutrophilia, an increase in neutrophils, most often occurs as a result of a reaction to a physiologic or pathologic process. The most common cause is bacterial infection. Tissue injury or inflammation may also cause a neutrophilia. Web Figure 1 ■ summarizes the laboratory evaluation of neutrophilia.

Neutropenia, a decrease in neutrophils, is less commonly encountered. It may be caused by drugs, immune mechanisms, or decreased bone marrow production. Several inherited conditions are characterized by neutropenia and recurrent infections. Web Figure 2 ■ summarizes the laboratory evaluation of neutropenia.

Morphologic abnormalities of neutrophils may be found in infectious states and are important to identify on stained blood smears. These include Döhle bodies, toxic granulation, and cytoplasmic vacuoles. Other morphologic abnormalities include pince-nez cells found in Pelger-Huët anomaly and morulae found in ehrlichiosis.

A number of inherited conditions are characterized by functional and morphologic abnormalities of the leukocyte. Chronic granulomatous disease and myeloperoxidase deficiency are characterized by defects in the generation of oxidizing radicals after phagocytosing bacteria. The nitroblue tetrazolium dye test is used to detect abnormal oxygen metabolism in CGD. Peroxidase-deficient cells can be demonstrated with peroxidase stain. The neutrophil oxidative burst assay uses the dye DHR 123 to detect neutrophils that produce reactive oxidative intermediates after ingestion of bacteria. The oxygen metabolites oxidize the colorless dye into fluorescent rhodamine 123, which is detected by a flow cytometer. Leukocyte adhesion deficiency (LAD) is identified by the absence of leukocyte cell-surface adhesion proteins. Diagnosis can be made by flow cytometric analysis of neutrophil CD11/CD18 levels using monoclonal antibodies. Other rare leukocyte functional abnormalities include Alder-Reilly, Chédiak-Higashi, and May-Hegglin anomalies.

Eosinophils are increased in infections with parasites, allergic conditions, hypersensitivity reactions, cancer, and chronic inflammatory states. Basophilia is seen in hypersensitivity reactions, infections, and chronic myeloproliferative disorders, especially chronic myelogenous leukemia. Monocytosis is found in a wide variety of conditions, especially malignancies. Macrophages are associated with a group of lysosomal storage disorders in which these cells are unable to completely digest phagocytosed material because of a deficiency of a particular enzyme needed for the degradation process. Macrophage histiocytes may be seen in various reactive and malignant disorders.

REVIEW QUESTIONS

LEVEL I

- Which of the following hematologic values would you expect if the peripheral blood smear revealed toxic granulation of PMNs, Döhle bodies, and vacuoles in PMNs? (Objectives 1, 2)
 - WBC: $4 \times 10^9/L$
 - differential: 50% neutrophils, 15% bands, 30% lymphs, 5% monocytes
 - 20% eosinophils
 - Hb: 10 g/dL; platelets $20 \times 10^9/L$
- The white count in an adult is $2.0 \times 10^9/L$. The differential has 60% segmented neutrophils. Which of the following correctly describes these results? (Objective 6)
 - normal
 - leukocytosis and neutrophilia
 - leukopenia with normal number of neutrophils
 - leukopenia and neutropenia
- Which of the following is the most common cause of neutrophilia? (Objective 1)
 - bacterial infection
 - acute leukemia
 - following chemotherapy
 - aplastic anemia
- Blue-gray oval inclusions composed of RNA near the periphery of neutrophils is a description of: (Objective 3)
 - toxic granules
 - Döhle bodies
 - vacuoles
 - primary granules
- Which of the following is associated with an acute bacterial infection? (Objective 2)
 - neutrophilia
 - neutropenia
 - eosinophilia
 - leukocytopenia
- Which of the following is a common reason for neutropenia in hospitalized patients? (Objective 6)
 - chronic myeloproliferative disorders such as CML
 - chemotherapy and/or radiation treatment for cancer
 - childbirth
 - lack of exercise
- Which of the following causes a false neutropenia? (Objective 7)
 - EDTA induced agglutination
 - bone marrow aplasia
 - splenomegaly
 - immune neutropenia

LEVEL II

Use the following case study to answer review questions 1–5.

A patient's white count is $30.0 \times 10^9/L$. The differential is as follows:

Segmented neutrophils	54%
Band neutrophils	10%
Metamyelocytes	2%
Lymphocytes	26%
Monocytes	5%
Eosinophils	3%
6 Nucleated RBCs/ 100 WBCs	

- Select the additional information most important to assess whether these results are normal or indicate a disease process. (Objective 1)
 - platelet count
 - LAP stain
 - patient history
 - patient age
- Which of the following correctly describes the absolute neutrophil count (ANC) for the patient? (Objectives 1, 12)
 - normal for both an infant and an adult
 - neutrophilia for both an infant and an adult
 - normal for an infant and neutrophilia for an adult
 - normal for an adult and neutrophilia for an infant
- Which of the following correctly describes the neutrophil concentration if the patient is an infant? (Objective 1)
 - pseudoneutrophilia
 - leukemoid reaction
 - leukoerythroblastic reaction
 - physiologic neutrophilia
- Which of the following correctly describes the differential if the patient is an adult? (Objective 1)
 - pseudoneutrophilia
 - leukoerythroblastic reaction
 - agranulocytosis
 - physiologic neutrophilia
- A leukoerythroblastic reaction can be associated with: (Objectives 1, 2, 12)
 - chronic granulomatous disease
 - Chédiak-Higashi syndrome
 - severe hemolytic anemia
 - leukocyte adhesion deficiency

REVIEW QUESTIONS (continued)

LEVEL I

8. Which of the following is the most common cause of eosinophilia? (Objective 10)
 - a. parasitic infection
 - b. eosinophilic leukemia
 - c. CML
 - d. asthma and other allergies
9. What substances build up and are ingested by macrophages in the qualitative macrophage disorders such as Gaucher disease? (Objective 11)
 - a. proteins
 - b. carbohydrates
 - c. lipids
 - d. rough endoplasmic reticulum
10. Distinct, large, unidentified inclusions are found in the cytoplasm of many granulocytes. Select the best course of action. (Objective 9)
 - a. Ignore them because they probably are not significant.
 - b. Report them as intracellular yeast.
 - c. Have a supervisor or pathologist examine the smear for rare or unusual conditions such as Chédiak-Higashi.
 - d. Report them as toxic granulation.

LEVEL II

- Qualitative neutrophil abnormalities can sometimes be confused with reactive or toxic conditions. For each set of conditions in questions 6–11, list all lettered features that could help evaluate the patient.
- a. presence of other toxic features (leukocytosis, toxic granulation, Döhle bodies, vacuoles)
 - b. abnormal inclusions found in other cells besides neutrophils
 - c. other CBC parameters abnormal (RBC, HCT, or PLT)
 - d. patient symptoms
 - e. patient and family history
6. Alder-Reilly versus toxic granulation. (Objectives 7, 11)
 7. May-Hegglin versus toxic Döhle bodies. (Objectives 7, 11)
 8. Pelger-Huët versus bands. (Objectives 5, 11)
 9. Chédiak-Higashi versus intracellular yeasts or morulae. (Objectives 6, 7, 11)
 10. Leukemia versus infection. (Objectives 2, 11)
 11. Toxic vacuoles versus sample with prolonged storage. (Objectives 4, 6, 11)
