Other supporting clinicopathologic findings consistent with ketosis and fatty liver include elevated NEFA concentration and hypoglycemia. Prepartal and postpartum NEFA concentrations exceeding 0.4 and 0.8 mEq/L, respectively, are indicative of negative energy balance of a magnitude that increases risk for ketosis and other periparturient diseases. Blood glucose concentrations less than 35 mg/dl often are associated with peak lactation ketosis, whereas cows with periparturient ketosis or fatty liver may have slightly higher concentrations.

Herd Diagnostics

More important than individual cow diagnosis is determination of herd risk for ketosis, fatty liver, or both. Herd diagnostics can be based on selective metabolic profiling and dairy production records evaluation. Serum NEFA concentrations ante partum and post partum can be used to evaluate risk for excessive negative energy balance. Serum samples are collected from a minimum of seven animals in the prefresh (–14 to –3 days) and postfresh (<30 days) groups. If more than two samples have NEFA concentrations exceeding 0.4 mEq/L (ante partum) or 0.7 mEq/L (post partum), then these groups are at higher risk for periparturient disease and subclinical ketosis.[23,29] Similarly, serum BHB concentration can be measured in selected early postpartum animals to evaluate risk of subclinical or clinical ketosis. If more than two samples out of 10^{23} or 12^{29} total samples with BHB concentration exceeding 14.5 mg/dl (1400 µmol/L) is suggestive of increased herd risk for subclinical ketosis.

Given the association between ketosis/fatty liver and lower milk production, herd records can be used to evaluate milk production in early lactation cows. Lower than expected first-test-day milk or low peak milk relative to overall herd production indicate potential transition cow problems. Lower 305-day mature equivalent (305ME) milk production for early-lactation than for later-lactation cows also indicates possible transition cow problems. Lower early-lactation milk production, however, is not specific for ketosis or fatty liver but reflects problems associated with most periparturient diseases.[2]

Alterations in milk composition, primarily fat as a result of increased lipid mobilization during negative energy balance, seem to better reflect risk for ketosis and

fatty liver. Milk fat content is elevated in clinical and subclinical ketotic cows,[14] a result of increased NEFA delivery to the mammary gland from fat mobilization. Herds in which milk fat content is elevated in 20% of the cows or greater (5% in Holsteins, 6% in Jerseys) on first test date are undergoing rapid fat mobilization and are at greater risk for ketosis. A better indicator of herd ketosis risk is protein-to-fat ratio. A milk crude protein–to–fat ratio of 0.75 (1.33 fat-to-protein ratio) on first test date in 40% or more cows suggests that the herd is at greater risk for ketosis.[23,30] Cows with a milk fat–to–crude protein ratio greater than 1.5 were 3.2 times more likely to have clinical ketosis.[2] Conversely, cows with ketosis before first test date were 4.4 times more likely to have a high fat-to-protein ratio (>1.5); however, these cows also were at greater risk for other periparturient diseases.[2]

Treatment

Fundamentally, ketosis treatment objectives of glucose replacement and reducing fat mobilization have not changed over the past 50 years.[31–33] Bolus intravenous glucose or dextrose (250 g; 500 ml of 50% solution) in conjunction with intramuscular glucocorticoid administration (0.03–0.04 mg/kg dexamethasone [Azium, Schering] or isoflupredone acetate [Predef 2X, Pfizer]) is surprisingly effective in many cases of clinical ketosis. Glucocorticoid therapy without glucose administration is less efficacious.[34] Initial therapy is followed by continued supplementation with glucogenic substrates and appetite stimulants.

Cows with periparturient ketosis are less responsive to bolus glucose administration than are cows with peak lactation ketosis, most likely because of confounding effects of fatty liver. Although peak lactation ketotic cows respond quickly to glucose therapy, relapses occur, often necessitating repeated therapy. Daily bolus glucose therapy may be needed over a 2- to 4-day period for full recovery. Hyperglycemia mediated by bolus glucose administration is short-lived but induces a marked decline in NEFA release[35] and ketone production[36] and stimulates insulin[36] release. Fructose and sorbitol have been advocated as alternative glucose substrates to prolong the hyperglycemic effect. These compounds are exclusively metabolized to glucose by the liver and not appreciably utilized by peripheral tissues. No therapeutic advantages of these sugars over glucose have been found.[16,33] Xylitol may hold some therapeutic advantage.[37]

An alternative to daily injections is continuous glucose infusion for difficult or refractory cases or for cows with periparturient ketosis and fatty liver. Infusion of 20 L of 2.5% glucose in normal saline over 24 hours is suggested.[17] Such intensive infusion therapy may not be practical in many situations but is of value in genetically superior animals and for treatment of more severe hepatic fatty infiltration. Urine ketones should be monitored for response, and blood glucose concentration should be monitored after therapy to detect possible rebound hypoglycemia.

Glucocorticoids stimulate tissue protein catabolism, generating amino acid substrates for gluconeogenesis, and redirect glucose away from tissue and mammary gland utilization. The combined effect results in reduced milk production and improved glucose kinetics. The milk reduction effect of glucocorticoids cancels out the milk stimulation effect of glucose administration, which may account for the improved clinical response with combination therapy. Use of multiple corticosteroid injections, however, probably should be avoided because of the negative immunosuppressive (dexamethasone) or K depletion (isoflupredone acetate) effects of these agents.

Insulin plays multiple regulatory roles in fat and glucose metabolism that would be beneficial in ketosis therapy. Insulin is a strong suppressor of adipose NEFA release and ketogenesis and facilitates peripheral tissue uptake of ketone bodies and glucose. Low doses of long-acting insulin every 24 to 48 hours, along with glucose infusion or glucocorticoid therapy, have been found to be effective.[17,33] Previously, 200 to 300 U of protamine zinc insulin every 48 hours was used, but this agent is no longer available. Human recombinant insulin (25 IU/100 kg of Ultralente) every 24 to 48 hours has been advocated as an alternative insulin source.[17] In one study, use of a slow-release insulin (0.14 IU/kg) showed promise for treatment of ketosis and fatty liver.[38] In this study, higher dosages (0.29 or 0.43 IU/kg) resulted in adverse hypoglycemia.

A variety of glucogenic substrates—namely, glycerol, propylene glycol, and propionate salts—can be provided orally as a drench or feed additive to complement glucose therapy and maintain substrate to support gluconeogenesis.[31,37,39–42] Propylene glycol (1,2-propanediol) is most commonly used at a typical dose of 225 to 400 g (8 to 14 oz) orally twice daily.[33] Excessive dosing of propylene glycol (>800 g) may have adverse effects on rumen function and neuromuscular activity.[33,37] Glycerol can be administered at 500 g twice daily (1 L/day).[43,44] Sodium (Na),[31] Ca,[39,40] or magnesium (Mg)[37] salts of propionic acid can provide glucogenic substrate, as well as readily available mineral. Dosage ranges from 50 to 250 g twice daily administered as a drench or applied to the feed. Caution must be taken to avoid oversupplementing mineral from these propionic acid salts. All of these glucogenic substrates are metabolized to glucose by the liver. In the face of liver dysfunction due to fatty infiltration, efficacy of these substrates is questionable.

Treatment approach to fatty liver should reflect severity of fatty infiltration and underlying etiologic disorder. Treatment objectives of establishing glucose homeostasis and minimizing lipid mobilization mimic those in ketosis. A paucity of studies exist defining efficacy of therapeutic protocols for fatty liver. Most promising is the potential therapeutic application of continuous glucagon infusion for treatment of moderate[45] or severe[46] fatty liver. Glucagon therapy also shows possible application to periparturient ketosis, because impaired gluconeogenesis is hypothesized as an underlying concern.[12] Fatty liver therapeutic protocols should undertake aggressive ketosis therapy coupled with good enteral nutritional support.

Beyond initial therapeutic procedures, cows with ketosis and especially fatty liver can benefit from various supportive therapy modalities. With various degrees of

inappetence, a common presentation, stimulation of appetite is critical. Often B-vitamin solutions, typically B_{12}, are administered to nonspecifically stimulate appetite. Offering fresh-cut grasses or a variety of feeds may help stimulate intake in some cows. If rumen function is compromised, rumen transfaunation may be required to stimulate intake. Force-feeding gruels to provide substrate for rumen microbes may be necessary in more severe cases of fatty liver. Gruels should contain sufficient fermentable fiber sources (beet or citrus pulp, wheat middlings), protein (alfalfa meal, soybean meal, distillers' grains) and fermentable energy sources, but in limited amounts to minimize acidosis potential. Complete commercial cow pellets often have been used to make gruels if individual feed ingredients are not readily available. Finally, because ketosis and fatty liver often are complicated by a number of secondary disorders, the overall treatment plan should include needed therapy to address these diseases.

Prevention

Preventive practices focused on reducing risk of ketosis and fatty liver must emphasize reduction of negative energy balance and resultant increased blood NEFA concentration. Collectively, three areas should be addressed relative to this objective: prepartal and postpartum dietary composition, DM intake, and hepatic metabolic processing of NEFA. Factors influencing and approaches to managing DM intake, as well as formulating balanced diets relative to preventing periparturient disease, are summarized later in the section "Key Control Points for Transition Success."

Emphasis has been placed on increasing dietary energy density in the immediate prepartal diet, compensating for decreasing DM intake, in an effort to minimize negative energy balance and predisposition to ketosis and fatty liver.[47–49] Minor and colleagues showed positive effects of increasing dietary content of nonstructural carbohydrate (NSC) (i.e., sugars and starches) on energy balance and liver fat infiltration.[50] When rumen-fermentable carbohydrates are increased, however, metabolizable protein supply also is increased, suggesting that energy and protein in ruminant diets are not independent. Cows fed a high-energy and high-protein prepartal diet had lower serum NEFA concentration, NEFA-to-cholesterol ratio, and fatty liver score compared with cows receiving high-energy, low-protein or low-energy, low-protein diets.[51] The association of high-energy, low-protein prepartal diets with hepatic lipidosis is consistent with the original case descriptions of fat cow syndrome.[52,53] Cows afflicted with either ketosis or hepatic lipidosis were found to have lower serum apoproteins associated with VLDL structures, suggesting an inability of the liver to export triglycerides.[54] Limited supply of methionine and lysine has been suggested to reduce VLDL production and predispose to hepatic lipidosis.[55,56] Protein content of the prepartal diet above National Research Council (NRC) recommendations has been associated with decreased ketosis incidence,[57,58] but positive metabolic response to protein has not been consistent across all studies.[48,59] In view of the multiplicity of roles amino acids play in glucose and lipid metabolism, potential exists for mediation of periparturient disease by manipulating metabolizable protein supply, but mechanisms are still not well understood. Part of the problem with animal response to diet may relate to confounding effects of BCS on dietary feeding strategies.[60,61]

Management practices related to feed intake and nutrient supply are equally important, if not more so, in preventing adverse responses to negative energy balance. Dry cows with obese body condition (BCS of 4 on a 5-point scale) are more predisposed to fatty liver[10] and ketosis.[12] BCS management must start in mid- to late lactation, in view of the inability to dramatically increase or decrease BCS during the dry period. Optimal range in dry cow BCSs is 3.0 to 3.75 (on a scale of 1 to 5), with a greater percentage of cows having 3.25 or 3.5 BCS. Proper feed bunk management should focus on ensuring appropriate feed quality, adequate feed availability (>21 hours/day), cow bunk space (30 inches per head), and water availability and quality. Grouping strategies, stocking density, and pen movements should consider cow social behaviors and the expression of agonistic interactions, often resulting in reduced feed intake with exacerbation of negative energy balance.[62] Suggested stocking density for free stall systems, based on observed DM intake effects, is less than 90%. Minimum suggested space per cow for free housing systems is 80, 100, and 120 square feet for far-off dry, close-up dry, and maternity cows, respectively. Additionally, environmental conditions of cold and heat stress need to be addressed. Behavioral and physical facility management issues related to transition cows recently have been reviewed.[62]

A number of dietary supplements and feed additives have been advocated to prevent ketosis and fatty liver. These supplements either act as lipotrophic agents (niacin, choline), helping the liver to process lipid better, or improve availability of glucogenic substrate (glycol, propionate, monensin sodium [Rumensin, Elanco]). Niacin (or nicotinic acid), fed at 6 g/day starting 2 weeks ante partum and 12 g/day at calving through 90 days in milk, has been shown to reduce ketosis incidence[63] and to increase milk production.[64] Not all niacin supplementation studies, however, have shown metabolic responses consistent with ketosis prevention.[50,65] Obese cows may respond more favorably to niacin supplementation, as a result of its antilipolytic activity. Niacin is degraded in the rumen,[64] which may limit efficacy with oral supplementation.

Choline, a methyl donor and constituent of phosphatidylcholine, facilitates hepatic lipid export by increasing VLDL formation. Similar to niacin, choline is readily degraded in the rumen, necessitating delivery in a rumen-protected form to be efficacious when administered orally.[66] Early studies feeding increasing amounts of rumen-protected choline (regimens ranged from 0 to 20 g choline/day) showed modest to no impact of choline on energy balance and liver triglyceride measures.[67,68] In a controlled fatty liver induction study, feeding 15 g choline/day during the induction phase reduced blood NEFA and liver triglyceride.[69] Feeding 15 g choline/day after induction of fatty liver tended to increase liver triglyceride clearance. Liver triglyceride was reduced and

glycogen content increased when choline was fed at 25 g/day in the prepartal period (21 days) and at 50 g/day after parturition (60 days).[70] Other recent preliminary studies found no response to choline supplementation, possibly attributable to lower BCSs and a lesser risk for negative energy balance.[71,72]

Supplying glucogenic substrates, such as glycol, propionate, or propylene glycol, immediately before or after parturition has been advocated as a preventive for negative energy balance disease problems.[37,73–75] Prepartal fat supplementation also has been advocated to improve transition energy balance,[76] but drenching fat did not show a positive response.[77] Administration of 1 L of propylene glycol or glycerol per day as a drench for 10 days resulted in reduced blood NEFA and BHB concentrations. Shorter-term drenching protocols (3 days after calving) did not decrease BHB concentrations.[74,75,77] In view of the labor-intensive nature of daily drenching, oral glucogenic precursor supplementation has been investigated. Oral drenching or bolus treatment (1 L or 1 kg/day) of propylene glycol[78] or glycerol[79] was more effective in reducing blood NEFA concentration, a result of increased insulin secretion, than was feeding the glucogenic precursor incorporated into a total mixed ration (TMR). Feeding 250 g of dry propylene glycol (60%) per day for 3 weeks after calving tended to reduce blood BHB but not NEFA concentrations.[80] In this study, the response to propylene glycol in the TMR may have been confounded by the greater DM intake for this treatment group. DeFrain and associates[81] fed 1 kg glycerol in a TMR and observed a decline in DM intake; nevertheless, a modest effect on postpartum NEFA concentration was noted. Metabolic response to dietary incorporation of glucogenic precursors is promising relative to a practical control of ketosis.

Canadian research has shown supplementation of a controlled-release monensin capsule 21 days ante partum to be effective in reducing diseases associated with negative energy balance and improving cow health and production.[82–85] Most recently, monensin sodium (Rumensin, Elanco) has been approved in the United States as a feed additive for lactating dairy cows. Although monensin was approved as a feed additive to improve feed-to-milk efficiency, its effect on rumen microbial fermentation to increase propionate production may help stabilize glucose homeostasis in transition cows and be beneficial in preventing ketosis.[86] In agreement with studies using the controlled release capsule, daily prepartal monensin supplementation has been shown to reduce blood NEFA and BHB concentrations and to improve glucose kinetics and consequently has potential for ketosis prevention.[87–89]

In addition to implementing various targeted dietary and management preventive strategies, application of a herd ketosis monitoring program (refer to "Herd Diagnostics" section earlier) is warranted and cost effective.[23,29,90,91] Monitoring prepartal NEFA concentration will highlight risk potential for fatty liver, ketosis, and other periparturient diseases. Monitoring postpartum BHB concentration will more specifically target subclinical or clinical ketosis risk, as well as related risk for left displacement of the abomasum (LDA).[23,92,93]

DISTURBANCES OF MACROMINERAL HOMEOSTASIS

Although most often associated with skeletal mineral and blood electrolytes, macrominerals have many important metabolic roles. Most macrominerals are homeostatically regulated to various degrees, and this process often becomes perturbed around the time of calving, resulting in clinical signs. Primary disease syndromes, which commonly manifest with muscular weakness and recumbency, have been described for calcium (Ca), magnesium (Mg), phosphorus (P), and potassium (K) deficiency. Although critically low blood mineral concentration is a diagnostic hallmark of these diseases, elucidated mechanisms suggest that interactions among dietary macrominerals play some role in the disease process, especially for Ca and Mg deficiencies.

Hypocalcemia

Parturient hypocalcemia (milk fever, parturient paresis) is an acute Ca deficiency condition that manifests with progressive loss of skeletal, cardiac, and smooth muscle function. The disease most commonly occurs in high-producing adult cattle within 48 hours of calving, although a small percentage of cases occur ante partum and between 48 and 72 hours after calving. It is the most common metabolic disease of dairy cattle but also occurs in beef cattle infrequently. Parturient hypocalcemia is problematic as a result of its association with eight other periparturient disease processes and its negative effect on postpartum DM intake.[94] Costs associated with a clinical hypocalcemic event were estimated at $334 per case. Overall incidence of clinical hypocalcemia is approximated at 8% to 9%,[95] but variation between herds is tremendous, ranging from none to greater than 60% prevalence.[96]

Subclinical hypocalcemia is defined as total serum Ca concentration below 8.0 mg/dl in the absence of clinical signs of hypocalcemia.[97] Cows with subclinical hypocalcemia are thought to be predisposed to lower intake and other secondary diseases, including LDA.[98] Cows with subclinical hypocalcemia had higher NEFA concentrations compared with normocalcemic cows.[97] Cows experiencing one or more postpartum disease events had lower total Ca concentrations in the prepartal period (8.1 versus 8.5 mg/dl) and post partum (8.1 versus 8.9 mg/dl) compared with healthy cows.[99] When total serum Ca concentration before or after calving was below 8.0 mg/dl, cows were 1.6 times more likely to experience postpartum disease.[99] Using samples collected during the 2002 National Animal Health Monitoring dairy study, subclinical hypocalcemia was found in 25.3%, 43.9%, and 57.8% of samples collected (within 48 hours of calving) from first-, second-, and third- (and greater) lactation cows, respectively.[97]

Pathophysiology

In calcium homeostasis and mechanisms inducing hypocalcemia, the underlying pathogenesis has been related to a failure of the Ca homeostatic system to maintain blood Ca^{2+} concentrations with the onset of lacta-

tion.[100] Parathormone (PTH)—which responds to low blood Ca—and calcitonin (CT)—which responds to high blood Ca—are counterregulatory hormones precisely controlling blood Ca concentration within a narrow physiologic range. PTH, through its action on the kidney, hydroxylates circulating 25-hydroxycholecalciferol to 1,25-dihydroxycholecalciferol (1,25-DHCC), the biologically active form of vitamin D. Kidney, intestine, and bone—primary target organs for PTH and 1,25-DHCC to increase Ca entry into the plasma pool—appear to be unresponsive to calcitropic stimulation. The acute loss of Ca in colostrum and milk at calving is not ameliorated by influx from intestine or bone, and hypocalcemia develops. Pool size of labile bone Ca, as well as number of vitamin D receptors, decreases with age, accounting for observed greater hypocalcemia prevalence in older cows.[101] Similarly, Jersey cattle have fewer vitamin D receptors compared with Holstein cows,[102] possibly accounting for greater hypocalcemia prevalence in Jersey cattle.

Goff[103] has reviewed specific factors that have been implicated in altering target organ response leading to hypocalcemia. Beyond age effects on receptor numbers, responsiveness of target organs can be suppressed by hypomagnesemia, hyperphosphatemia, and acid-base status resultant from dietary alterations. Hypomagnesemia impairs release of PTH and the interaction between PTH and its target organ receptor. Hyperphosphatemia interferes with activation of vitamin D by inhibiting activity of renal 1-hydroxylase enzyme. Dietary cation-anion difference (DCAD), as defined by the formula (Na + K) − (Cl + S), influences blood acid-base status and ultimately Ca homeostasis. Feeding a diet relatively higher in cations than in anions induces a metabolic alkalizing effect that is believed to blunt target tissue response to PTH stimulation. Acidification, achieved by feeding a diet relatively higher in anions than in cations, induces a release of bone mineral, primarily Ca, in an effort to support blood buffering systems. This released bone Ca is lost through the kidneys but can be reabsorbed under appropriate stimulation during a hypocalcemic episode. Forage-based diets often are high in K content and greatly contribute to excessively high-DCAD dietary conditions. Sodium-based feed supplements, namely, calcium bicarbonate, also can contribute to excessive cation intake and initiate an alkalizing situation leading to dysregulation of Ca homeostasis.

Clinical Signs

Clinical signs associated with parturient hypocalcemia occur as a spectrum of progressive muscular weakness. Progression of clinical signs often is characterized into three clinical stages based on serum concentration of ionized Ca^{2+} (Table 46-2).[96,104] Association between ionized Ca and muscle function is a result of the multiple roles Ca plays in nerve conduction, neuromuscular stimulation and muscle fibril contractility.[96,104] Mild hypocalcemia results in destabilization of peripheral nerve membranes, which may account for observed hyperexcitability and fine muscle tremors. Ca facilitates movement of actin and myosin fibers during contractility and release of acetylcholine at the myoneural junction. Progressive hypocalcemia could result in decreased acetylcholine release and muscle contractility, accounting for the ensuing flaccid paralysis observed in more severe cases.

Diagnosis

Determination of low plasma or serum Ca concentration is diagnostic. Practical ability to timely measure blood Ca

Table **46-2**

Clinical Presentation of Hypocalcemic Cows Based on Blood Calcium (Ca) Concentration

Parameter	Stage 1	Stage 2	Stage 3
Serum total Ca*	5.5–7.7 mg/dl	4.0–6.0 mg/dl	<4.0 mg/dl
Serum ionized Ca	2.75–3.85 mg/dl	2.0–3.0 mg/dl	<2.0 mg/dl
Posture	Standing but ataxic and wobbly, stiffness to hind limbs; reluctance to move	Sternal recumbency	Lateral recumbency; complete muscle flaccidity
Attitude	Alert with hypersensitivity and excitability	Alert to depressed	Depressed to comatose
Appetite	Diminished especially for grain	Anorexic	Anorexic
Temperature	Normal to slightly elevated	Low normal to subnormal, 96.4–100.4°F (36–38°C)	Subnormal, <98.6°F (<37°C)
Pulse	Normal, somewhat muffled	Slightly increased (<90 bpm) and weak	Rapid (>110 bpm), weak, muffled heart sounds
Other signs	Ear twitching and fine muscle tremors	Cold extremities (ears, legs); dry muzzle; constipation with dry feces; urine stasis—filled bladder	Possible bloat with aspiration pneumonia

*Influenced by serum albumin concentration and pH relative to association between clinical signs and total Ca concentration. Low albumin increases and alkalosis decreases ionized Ca concentration, altering the association between presenting clinical signs and total Ca concentration.
bpm, beats per minute.

concentration before treatment is limited, however. History and presenting clinical signs, in conjunction with rapid response to Ca therapy, are more typically used in diagnosis.[96] Collection of a blood sample before therapy is encouraged because this sample can be analyzed later if response to therapy is unfavorable. In addition to hypocalcemia, clinical chemistry abnormalities observed in uncomplicated cases include hypophosphatemia (<3 mg/dl), hypermagnesemia (>3 mg/dl), and hyperglycemia (>100 mg/dl). Elevated PTH concentrations associated with hypocalcemia may account for observed hypophosphatemia, due to increased renal excretion, and hypermagnesemia, a result of increased renal reabsorption.[103] Elevated cortisol levels associated with parturition and other stress factors could account for observed hypoglycemia. Depending on duration and bedding conditions of a recumbent hypocalcemic cow, muscle enzymes, creatine kinase (CK), and aspartate transferase (AST) may be elevated. Other concurrent conditions, especially hepatic lipidosis, could alter blood specific liver function and energy balance analytes accordingly.

A thorough physical examination is critical in evaluating a recumbent cow. Many other disease conditions can mimic hypocalcemia or complicate cases. Considerations in the differential diagnosis include musculoskeletal (fractures, luxations, compartmental crush syndrome) and neurologic (nerve paralysis, calving paralysis) injuries, acute toxic infections (mastitis, metritis, peritonitis), metabolic derangements (hypomagnesemia, hypokalemia, ketosis/hepatic lipidosis), and hemorrhage.[96,104]

Treatment

Without appropriate timely treatment, hypocalcemia can be fatal in approximately 60% to 70% of cases. Notwithstanding, 6% of affected cows die during treatment. Therapy is directed at replacing and maintaining serum Ca concentration. Calcium solutions are cardiotoxic, so careful intravenous administration relative to rate and dosage is important. Calcium solutions should be administered intravenously to effect, while monitoring heart rate and rhythm and clinical response. As a general rule, Ca solutions should be dosed slightly less than 2 g Ca per 100 kg (220 lb) of body weight and at a rate of 1 g Ca per minute.[105] Underdosing is not effective and results in more relapses and increased risk for injuries from struggling to rise. Hypercalcemia is a concern not only from potential cardiotoxicity but for its suppressive effect on PTH release and delay in maintaining Ca homeostasis.[105]

Even though many different chemical forms of Ca can be administered effectively, most commercial Ca preparation solutions contain either calcium gluconate (9.3% Ca), a less caustic form compared with $CaCl_2$, or calcium borogluconate (8.3% Ca), a fairly soluble and stable solution. Typically, commercial Ca solutions contain between 8.5 and 11.5 g Ca per 500 ml. In spite of multiple blood chemistry abnormalities in hypocalcemic cows, therapeutic solutions need contain only Ca. Correction of hypocalcemia typically will correct other abnormalities.

Response to intravenous Ca therapy should be fairly immediate, with obvious changes in muscle function. Heart rate should return to normal, and heartbeat should increase in strength. Muscle fasciculations may become evident in the flank and spread throughout the body. As smooth muscle activity returns, the cow may eructate, defecate, and urinate. A large proportion (60%) of treated cows will rise soon after therapy, with another smaller proportion (15%) recovering within 2 hours. Cows should be reevaluated if they have not recovered within 8 to 12 hours.

Although cows may show favorable response to intravenous therapy, 25% to 30% of cases relapse within 24 to 48 hours.[104] Some cows may have a delayed response to vitamin D activation, resulting in cyclic relapses.[106] Other cows, as a result of high milk production, are unable to maintain Ca homeostasis. Calcium solutions can be administered subcutaneously, but the time required for correction from hyper- to normocalcemia is 4 to 5 hours, similar to that with intravenous therapy.[105] Less severe hypercalcemia after subcutaneous administration is observed. Subcutaneous administration can be associated with local injection site reactions as a result of Ca-induced cellular necrosis. Solutions containing dextrose also can be injurious as a result of their high osmolarity. To limit potential injection site lesions, solutions without dextrose should be used, and the volume limited to 50 or 75 ml (1 to 1.5 g Ca) per site.[105] The injection site is massaged to help distribute the bolus injected. Response to subcutaneous Ca administration is dependent on peripheral perfusion; even so, it is not as therapeutically effective as intravenous treatment. Caution is warranted before administering intravenous treatment to a cow that has been repeatedly treated subcutaneously without success, because the risk of cardiotoxicity from the combined doses is more likely.[96,105]

Oral supplementation of highly soluble Ca salts can augment parenteral therapy to treat mild hypocalcemia or minimize relapses.[107,108] Passive diffusion of ionized Ca across cellular tight junctions can occur when Ca concentration is sufficiently high.[105] A dosage of at least 50 to 75 g Ca is needed to drive the passive absorption process. Calcium chloride ($CaCl_2$) (36% Ca) often is used but is irritating and can induce metabolic acidosis. Physical injuries to the pharyngeal area can occur with use of tubed gel products, as well as chemical injury when gel tubes contain $CaCl_2$. Aspiration pneumonia can occur when the solution is provided as a drench. Calcium propionate (21.5% Ca) can be used similarly to $CaCl_2$ as an oral supplement. Use of calcium propionate may be preferred because it is less irritating, does not induce metabolic acidosis, and provides propionate as a glucose precursor. Supplying 250 or 350 g calcium propionate provides approximately 54 or 75 g Ca, respectively. Oral Ca supplementation can maintain elevated blood Ca concentration for 5 to 7 hours. Besides amount of Ca supplied, form (gel, slurry, drench) and volume will influence degree of passive Ca absorption and response.[105,108,109] Oral and subcutaneous Ca administration should be used prophylactically, in early stages, or for relapsing cases. Recumbent cows should receive appropriate intravenous therapy. Caution is advised in combining therapies, because the potential for cardiotoxicity is increased and stabilization of Ca homeostasis is delayed. Prevention of

hypocalcemia is discussed later under "Maintaining Calcium Homeostasis."

Hypophosphatemia

Phosphorus (P), as the phosphate anion (PO_4^{2-}), plays important biologic roles in skeletal mineral content, blood and rumen acid-base status, cellular energy transfer, metabolic reactions, and phosphorylated molecules (phospholipids, nucleic acids, phosphoproteins). Homeostatic regulation of blood P mimics that of Ca, sharing the same regulators PTH, CT, and 1,25-DHCC. Unique to P regulation is salivary recycling in support of rumen microbes, which accounts for 30 to 90 g P lost per day, or nearly 10 times the total extracellular P pool.[103]

Profound dietary P deficiency will lead to altered bone mineralization, resulting in rickets or osteomalacia in young and growing or aged animals, respectively. Hypophosphatemia sometimes is associated with postparturient hemoglobinuria, a condition characterized by red blood cell membrane fragility and lysis with release of hemoglobin pigment into blood and urine. P deficiency is thought to impair red blood cell energy production via glycolysis, thereby impeding the red blood cell's deformability as it passes through small-diameter capillaries.[110] Acute profound hypophosphatemia (<1 mg/dl) has been observed in late-pregnancy beef cattle and early-lactation dairy cows. Affected cows typically present with hindlimb weakness, inability to rise, bright alert attitude, and willingness to eat; such animals often are referred to as "alert downer cows" or "creeper cows." Increased P losses to fetal development or colostrum and milk production can precipitate acute hypophosphatemia, especially if the diet is marginal in P, although these situations often are further complicated by concurrent hypocalcemia, hypomagnesemia, and hypoglycemia.[103,111] In dairy cattle, acute hypophosphatemia occurs after calving, even with a P-adequate diet, and typically is associated with an unresponsive treatment for a hypocalcemic episode.

Hypophosphatemia (phosphate level of 1–2 mg/dl; normal range, 4–8 mg/dl) accompanies parturient hypocalcemia, but after appropriate Ca therapy, blood P concentration returns to normal. Increasing PTH in response to lower blood Ca concentration at parturition induces a decline in blood P concentration as a result of increased renal P clearance and salivary P recycling.[103,111] Intestinal P absorptive efficiency is influenced by 1,25-DHCC; however, a portion of recycled P is inherently lost in feces, resulting in a net loss of exchangeable pool P. In a small number of cows, recovery of blood P concentration after Ca therapy fails, culminating in a hypophosphatemic downer cow. The mechanism responsible for this lack of response has not been elucidated. Reduced rumen motility might impair recycled salivary P absorption.[103] Metzner and Klee observed low blood P concentrations in downer cows who failed to ruminate; however, hypophosphatemia was not considered a significant contributor to recumbency in their downer cow survey.[112]

Recumbent cows with hypophosphatemia (<2 mg/dl) can be treated with P supplements given intravenously, orally, or both. The chemical form of P has been shown to be important for biologic utilization and effective therapy where only the phosphate anion is biologically available. Derivatives of phosphinic acid (hypophosphite [PO_2^{3-}], phosphite [PO_3^{3-}]) are not biologically available.[113] Phosphite salts are more water soluble and do not precipitate in the presence of Ca or Mg, thus allowing their common use in commercial multiple electrolyte solutions. For intravenous treatment, 6 to 7 g P is the desired total dosage, which can be supplied by 23 to 30 g monosodium phosphate or one sodium phosphate–based human enema product (Fleet Enema).[105,113] The mineral source should be diluted in 1 L saline and the enema in 1 L water to reduce adverse effects from pH and tonicity, respectively. Calcium solutions should not be added to either of these preparations because they will induce precipitation of calcium phosphate. A more sustained blood P concentration with lower peak concentration after therapy is achieved with oral monosodium phosphate supplementation. A dose of 50 to 60 g P from 200 to 300 g monosodium phosphate (25% P) mineral is desired.[105] The mineral can be suspended in water and administered as a drench, or preferably through a stomach tube. Gelatin boluses or gels containing the appropriate amount of phosphate source also are therapeutic. Other phosphate mineral sources (dicalcium phosphate, bone meal) are not soluble and will not evoke a change in blood P as rapidly. Intravenous phosphate supplementation will maintain blood concentrations for only a couple of hours, compared with longer than 6 hours with oral supplementation.[105,113] With the mechanism responsible for inhibiting P recovery after hypocalcemia uncertain, the best method of preventing hypophosphatemia is to minimize risk of parturient hypocalcemia (see "Maintaining Calcium Homeostasis" section).

Hypomagnesemia

Magnesium is an essential divalent cation (Mg^{2+}), the second most abundant intracellular cation, and supports a multitude of metabolic processes as an enzyme activator. A large proportion of body Mg (65% to 70%) is located in bone mineral matrix, yet extracellular Mg (1% of total body Mg) is critically responsible for synaptic transmission between nerve and skeletal muscle.[114] Calcium homeostasis and Mg are closely intertwined. Both PTH and 1,25-DHCC production and secretion are adversely affected by hypomagnesemia, accounting for concurrent hypocalcemia in hypomagnesemic animals.[115,116] Magnesium also influences ability of PTH to interact with its cell receptor on target organs.[111]

Plasma Mg concentration (normal range, 1.8 to 3.0 mg/dl) is controlled primarily through dietary Mg concentration and absorption. Net renal excretion, under PTH control (which stimulates renal Mg conservation), attempts to maintain plasma concentration in the face of changing dietary levels.[114,115] Preruminant calves absorb dietary Mg efficiently from the small intestine (as is observed in nonruminant species), but functional ruminant animals absorb Mg predominantly from the rumen and reticulum. Rumen-soluble Mg can be absorbed via

an Na^+,K^+-ATPase transporter or by non–transporter-mediated paracellular movement.[111,114] Paracellular movement (passive diffusion) is facilitated by high dietary Mg (0.35% to 0.4% of DM) concentrations.[111]

Dietary Mg absorption is constrained by a number of dietary factors. High dietary K, nitrogen (N), Ca, and fat and low dietary Na are associated with reduced Mg absorption.[114,117] High dietary K increases ruminal K concentration, thus changing the K gradient and decreasing the electrical potential difference necessary to drive the Na^+,K^+-ATPase pump for Mg absorption.[114] Lush spring growth grasses typically are high in K and low in Mg and Na. Forages with a K/(Ca + Mg) ratio greater than 2.25 (values as mEq/kg of DM) are suggested to have greater risk for inducing hypomagnesemia tetany.[118] Lush spring grasses also contain large amounts of sucrose and organic acids, a primary one being *trans*-aconitic acid. *Selenomonas ruminantium,* one of the most prevalent rumen bacteria, preferentially ferments sucrose and has been shown to reduce *trans*-aconitate to tricarbayllic acid, an extremely potent divalent cation chelator.[119] Crested wheat grass and other range grasses can contain between 2% and 6% of DM as *trans*-aconitate.[119] This level of organic acids, in combination with low plant Mg content, may further contribute to higher risk potential for hypomagnesemic tetany under range conditions. Excessive dietary K is most responsible for interfering with Mg availability in dairy rations.

Loss of Mg with late fetal development or milk production, in association with reduced dietary Mg intake or availability, or both, can lead to reduced plasma Mg concentration with precipitation of clinical signs. Clinical syndromes of hypomagnesemia are named according to their inciting cause, such as grass tetany, lactation tetany, wheat pasture tetany, or winter tetany. Clinical signs and presentation are reflected by plasma Mg concentration. Moderate hypomagnesemia (plasma magnesium concentration of 1.1 to 1.8 mg/dl) is characterized by nervousness, low production, and low feed intake and often has an insidious onset. Cows with moderate hypomagnesemia may be more prone to parturient hypocalcemia.[105] Weather or other stressors that acutely reduce feed intake may precipitate manifestations of clinical tetany. At plasma Mg concentrations below 1.1 mg/dl, initial clinical signs include excitability; hyperesthesia; muscle fasciculations of face, shoulder, and flank; ear twitching; and ataxia resulting from leg spasticity during walking.[117,118] As plasma Mg concentration falls below 0.5 mg/dl, signs progress from staggering to recumbency with clonic convulsions and muscle rigidity. Opisthotonos, leg paddling, involuntary nystagmus, and seizures follow as the condition progresses, culminating in coma and death.

Tremendous individual variation occurs in associating clinical signs with plasma Mg concentration. Tetanic signs may be related more closely to cerebrospinal fluid Mg concentration (<1 mg/dl), which is stable over a wide range of plasma Mg concentrations but critically declines when plasma Mg is below 0.6 mg/dl.[114] Low serum Ca concentrations also may play an important part in manifestation of tetany.[105,117] Diagnosis is based on history and clinical presentation and confirmed by blood analysis for Mg and Ca. Postmortem vitreous humor Mg concentrations below 1.16 mg/dl are suggestive of hypomagnesemia as a cause of death.[117] Cerebrospinal fluid and vitreous humor Mg concentrations can be used diagnostically between 12 and 48 hours post mortem. Urine Mg concentration can also be used diagnostically as concentrations decline rapidly as hypomagnesemia increases.[118] Herd dietary Mg status can be assessed by determining serum Mg concentration in blood samples collected from multiple cows during the immediate (12 hours to 3 weeks) postpartum period. Goff suggested that at least 9 of 10 cows should have serum Mg concentration of 2.0 mg/dl or greater for dietary Mg status to be considered adequate.[111]

Treatment of clinical hypomagnesemia requires timely intravenous Ca and Mg salt administration with additional supportive therapy using subcutaneous and oral Mg supplementation to minimize relapses. Death will occur within hours if the disorder is not appropriately treated.[117] A dose of 2 to 3 g Mg provided as the chloride, borogluconate, or hypophosphite salt delivered slowly over 10 minutes is safe and effective.[105,111] Commercial preparations also contain Ca salts; therefore, slower intravenous administration is recommended to prevent cardiac dysrhythmias due to effects of Mg or Ca. Care must be taken in administering intravenous therapy because treatment may initiate a tetanic seizure, and if responsive, recovered animals may display extremely aggressive behavior and are dangerous. For this reason, and in the face of a large herd outbreak, adequate therapeutic response can be achieved by administering a magnesium chloride or magnesium sulfate enema (60 g in 200 to 300 ml of water).[117,118]

Relapse rate after intravenous treatment can be high and clinical response disappointing. Additional Mg delivered by subcutaneous injection of 50% magnesium sulfate solution (100 to 200 ml) can help minimize relapse rate through prolonged maintenance of serum Mg concentration. Oral therapy also can be used to increase rumen Mg concentration, facilitating passive diffusion to augment uptake; 100 g of magnesium oxide or 200 to 400 ml of 50% magnesium sulfate is administered as a drench.[105] A combination drench that includes Ca, P, and Na sources has been advocated to treat multiple possible deficiencies and to augment Mg uptake.[105,111]

Prevention of hypomagnesemia requires attention to dietary Mg content, addressing agronomic practices to minimize plant factors leading to decreased Mg content and availability, and strategic prophylactic Mg supplementation.[114,117,118] Dietary Mg concentration during the periparturient period should be maintained between 0.35% and 0.4% of DM. Either magnesium sulfate or oxide mineral can be used to augment dietary content. Mg-fortified (5% to 8% Mg) salt blocks can be supplied; however, intake is variable because of poor palatability. Typically these blocks contain molasses to aid palatability. Another option is to blend one-third magnesium oxide, one-third trace mineral salt, and one-third soybean meal or distillers' grains as a free choice supplement. Salt blocks also increase Na intake, which can facilitate Mg absorption. Agronomic and management practices include grazing mixed grass-legume pastures, applying

dolomitic limestone, and controlling K and N fertilization practices.

Hypokalemia

Recent reports have recognized severe postpartum hypokalemia (1.4 to 2.3 mEq/L; normal range: 3.9 to 5.8 mEq/L) in dairy cattle as another possible metabolic cause of muscle weakness and alert downer cows.[120–122] Moderate hypokalemia (serum K concentration of 2.4–3.8 mEq/L) often is secondary to a disease process that reduces feed intake or intestinal and renal disease causing increased body K loss. Rarely is disease-induced hypokalemia significant enough to result in profound muscle weakness and recumbency. Common clinical signs included profound flaccid muscle weakness or recumbency, variable degrees of anorexia, and cardiac arrhythmias. The most common clinical chemistry findings include alkalosis and elevated muscle enzymes CK and AST. In one study, other possible causes of recumbency were not found, with the exception of severe hypophosphatemia in four cases.[120] In 92% (23 of 25) of cases cited in two reports,[120,122] a previous history of ketosis and repeated ketosis treatments were reported. In a third study, protracted disease, often infectious in origin, was reported as the most common historical event.[121] No age predilection across cases was found, but most commonly the hypokalemic event occurred in early lactation, typically before 60 days in milk. Multiple corticosteroid therapies or dosing beyond recommended amounts was a common historical finding. Isoflupredone acetate was administered in 79.5% (31 of 39) and dexamethasone in another 7.7% (3 of 39), and no corticosteroid was used in 12.8% (5 of 39) of reported cases in these studies.[120–122]

K is the predominant intracellular cation and serves many biologic functions including acid-base balance, osmotic pressure regulation, and water balance.[123] Only 2% of total body K is located extracellularly, with the remainder located in muscle. This differential distribution across cell membranes is responsible for resting electrical membrane potentials, and changes in this electrical potential are responsible for nerve cell conduction and muscle contraction.[123]

Intestinal absorption efficiency of dietary K exceeds 90%.[124] Forage-based diets then greatly exceed daily K requirements, thus necessitating a mechanism for excretion to prevent cardiotoxic hyperkalemia. Homeostatic regulation is weakly managed by aldosterone's effects on stimulating K excretion from colon and kidneys.[111,123] Potassium regulation becomes more convoluted, because muscle and liver cells can rapidly remove extracellular K into intracellular compartments. Insulin and β-adrenergic agents can facilitate intracellular movement, and acid-base status further modifies these relationships. K^+ moves either into or out of cells in exchange for H^+, in an effort to maintain proper blood pH.

In view of these regulatory relationships in which the system is essentially balanced to manage excessive K intake, early-lactation cows, which lose 1.5 g/kg K into milk[124] and have marginal DM intake at best, potentially could be at risk for hypokalemia under the right conditions. Factors increasing extracellular K removal, by either excretion or intracellular movement, exacerbate risk for hypokalemia. Corticosteroids with mineralocorticoid activity, such as isoflupredone, potentiate renal excretion of K. This was a common observation in reported studies.[120–122] A majority of hyperkalemic cows also were alkalotic, developed ketosis, and were treated multiple times with glucogenic compounds and insulin. All of these factors will cumulatively contribute to greater K loss and account for observed severe hypokalemia.

Diagnosis of severe hypokalemia is made on the basis of presenting signs, measured blood K concentration below 2.3 mEq/L, and absence of other factors responsible for recumbency. Characteristic myodegenerative changes with vacuolation can be seen in muscle biopsy specimens.[120,123] Treatment should focus on replacing lost K and ensuring a continuing adequate supply. Both intravenous and oral K supplements have been advocated, but reported response to therapy was poor (8 of 25 recovered) in two studies.[120,122] Reported recovery rate was better (11 of 14) in another study.[121] All studies used intravenous and oral K supplementation, but with different regimens. Intravenous K administration should not exceed 0.5 mEq/kg/hour to avoid potential cardiac toxicities.[111] Oral K supplementation can be administered as 100 to 150 g potassium chloride twice daily.[111] Mineral supplement should be mixed into several gallons of water to be administered. Including oral glucose precursors (calcium propionate or propylene glycol) or concurrent intravenous dextrose therapy can augment cellular K uptake by stimulating insulin release. Prevention of this syndrome evidently is more management related than nutritional, so long as cows have adequate feed intake. Flagrant use of corticosteroids should be discouraged. Aggressive oral K supplementation for anorectic early-lactation cows with typical postparturient problems may have some value, and further evaluation is warranted.[111]

DISEASE ASSOCIATED WITH IMMUNE DYSFUNCTION

Immune function of the dairy cow has been shown to decline in responsiveness during the transition period.[125–127] Kehrli and colleagues showed that both neutrophils[128] and lymphocytes[129] collected from periparturient cows had reduced immunologic responses immediately after parturition. More recent work has identified down-regulation of glucocorticoid receptors on neutrophils and mononuclear cells around the time of calving, which was proposed to be responsible for altered cell function and associated immunosuppression.[130,131] Stress factors that increase corticoid secretion can further down-regulate immune cell receptors and consequently impair cell function. In elegant studies in which mastectomy was performed on late-pregnancy cows, alterations in lymphocyte cell populations, impaired lymphocyte function, and reduced neutrophil bactericidal activity all were ameliorated in mastectomized compared with intact cows.[132–134] These findings suggest that metabolic or physiologic losses associated with initiation of lactation may account for part of the immunosuppression experienced

by periparturient cows. Although hormonal and metabolic factors may possibly play a primary role in this physiologic immunosuppression, it can be further suppressed by dietary insults. Energy, protein, macro- and microminerals, and fat-soluble vitamins all are potential nutritional mediators of immune function.[135]

A compromised immune system is associated with increased risk of metritis,[136] mastitis,[134,138] or other infectious disease process. Retained placenta recently has been characterized as a failure of the maternal immune system to adequately recognize fetal antigens to initiate the separation of maternal and fetal placental components.[134] Cows experiencing negative energy or protein balance are more predisposed to the development of infectious diseases. Relationship between vitamin E and selenium status and mastitis[139–141] and retained placenta[142,143] incidence has been well documented. Vitamin E and selenium supplementation was found to improve bactericidal activity of neutrophils, which may account for their effect on reducing mastitis incidence and severity.[138] Prepartal vitamin A status also has been shown to be protective for mastitis.[143] Parenteral vitamin E supplementation has been shown to reduce metritis incidence.[142] Activated vitamin D (1,25-DHCC) was shown to augment antibody production response to *Escherichia coli* vaccination against mastitis.[144] Efforts to minimize infectious problems during the transition period need to address factors associated with reducing the infectious agent challenge in the environment, improving immune responses (see "Maintaining Immune Function" section later on) and reducing stress.

DISEASE ASSOCIATED WITH RUMEN DYSFUNCTION

Etiologies of previously reviewed periparturient diseases were associated with deranged homeostasis of essential nutrients required in support of maternal metabolism. The rumen fermentation system is first to process consumed feeds and, through its microbial activity, provides a substantial portion of required nutritive substrates to support the host cow's needs. Ruminal microbial populations require a variety of nutrients in support of their metabolism and growth. Similar to the host cow, microorganisms require substrates to provide energy, nitrogen for protein synthesis, minerals, and vitamins. Tremendous variation exists among bacterial species in desired forms of nutritive substrates. Unique to the rumen system is a requirement for fiber in the form of complex carbohydrates comprising the plant cell wall that are indigestible to the cow. Dietary fiber content and form, in conjunction with feeding management practices, can determine success or failure of rumen function during the transition period.

Left Displaced Abomasum

Physical displacement and entrapment of the abomasum to the left side of the rumen (i.e., LDA) constitute a common disease of dairy cattle. Nearly 90% of LDA occurrences are diagnosed within 1 month of calving, with a majority occurring within the first 2 weeks.[145] Abomasal entrapment is thought to be caused by a combination of reduced rumen size as a result of lower intake, physical displacement of the rumen by the gravid uterus, and abomasal atony and gas accumulation.[146] Because this disease occurs soon after calving, transition nutrition is key to causation and prevention. Identified nutritional risk factors include amount of grain fed in the prepartal or postpartum diet, dietary fiber content and form, dry cow forage program, and feed bunk management (e.g., feed availability, abrupt feed changes, feed sorting potential).[145] Cows with high BCS at calving were predisposed to development of LDA,[147] as well as cows with twin pregnancy.[148,149] One or any combination of these factors could account for lower feed intake and subsequent reduced rumen fill, thus contributing to LDA prevalence.

Elevated blood NEFA concentration, a measure of negative energy balance and a reflection of low feed intake, has been associated with risk for LDA.[147,149] Similarly, a number of periparturient diseases have been associated with increased LDA risk. Cows with ketosis, metritis, and retained placenta all were at higher risk for LDA.[57,148–150] Again, the association between these diseases may be mitigated by adverse effects on DM intake. Ketosis is highly associated with LDA occurrence, evidenced by the eightfold higher risk for LDA in cows with serum BHB concentration 12.5 mg/dl or greater.[149] A similar risk between ketosis and LDA was found using milk ketone concentration.[92] Parturient paresis[148,150,151] and subclinical hypocalcemia[98] were found to increase LDA risk. Intuitively, hypocalcemia and its potential adverse effect on abomasal motility seem plausible. No association between blood Ca concentration and LDA incidence was found, however, when negative energy balance measures (NEFA, BHB) were evaluated. This observation suggests that the effect of hypocalcemia on LDA incidence was secondary, a result of reduced intake, rather than directly causal.[149,152]

Cows fed a diet to induce fatty liver infiltration (high energy, low protein) experienced a 25% LDA prevalence and had severe fatty liver with accompanying indicators of liver dysfunction and negative energy balance.[153] Cows with LDA from this study had a 56.6% reduction in DM intake during the 10 days before LDA diagnosis, compared with cows without an LDA. Although a causal relationship between negative energy balance and LDA incidence cannot be established, practices aimed at preventing negative energy balance and ketosis should provide some protection against LDA incidence.

Subacute Ruminal Acidosis

Ingestion of large amounts of readily fermented carbohydrates results in excessive production of VFAs and lactic acid beyond the capacity of epithelial cell absorption, lactate-utilizing bacteria, and rumen buffers to ameliorate a dramatic decline in the pH of ruminal contents. Clinical forms of ruminal acidosis can manifest as peracute, acute, or subacute disease processes. All forms may occur in any ruminant animal, but subacute ruminal acidosis (SARA) is most common and an economically

important disease of feedlot[154] and dairy[155,156] cattle. Although data are limited, prevalence of SARA has been reported to be as high as 40% of animals in specific herds, and across 15 herds, 19% and 26% of early- and mid-lactation cows, respectively, were affected in one study.[157]

Peracute and acute forms of ruminal acidosis (e.g., grain overload, carbohydrate engorgement) result in a life-threatening syndrome characterized by prolonged and dramatic decline in rumen pH (<4.5), systemic dehydration, and uncompensated metabolic acidosis from absorbed D-lactate.[158] Although ruminal acidosis is an important disease process, the peracute and acute forms of acidosis are sporadic individual or herd problems resulting from errors in feeding management or accidental exposure to high-grain-content diets. More detailed discussion of acute acidosis can be found elsewhere.[154,158,159] Of greater practical concern in both feedlot and dairy operations is the prevalence of SARA. Similar in pathogenesis to acute ruminal acidosis and situated along a continuum of problems involving duration and severity of ruminal pH reductions, SARA is defined as transient declines in rumen pH to between 5.0 and 5.5 observed after feeding bouts.[155,156,160] A similar definition could be attributed to chronic ruminal acidosis; however, the discriminatory issue between subacute and chronic acidosis is duration (hours versus days, respectively) of low-pH events.

Collective populations of microorganisms within the rumen environment are capable of using a tremendous variety of dietary substrates to support their metabolic functions and growth and to provide usable end products for support of host animal metabolism. Individual microbial species, however, have a more narrow substrate requirement, assigning them to a somewhat exclusive niche within the collective rumen environment. Interdependence of species occurs wherein one microbial group uses fermentation end products from another group or generates necessary metabolic cofactors for a different group. Most rumen microbes are pH sensitive, requiring an environmental pH of 6.0 or higher, especially for cellulolytic bacteria. The goal of feeding ruminant animals is to maximize microbial fermentation of fibrous feed sources in support of high-quality meat and milk production. Because fibrous feeds will not support high levels of productivity, use of concentrated energy feeds is necessary. Sugar- and starch- (i.e., NSC) fermenting bacteria have rapid rates of growth and generate lactate, which disproportionally contributes to low rumen pH. Diets containing large amounts of readily fermentable feed substrates will enhance growth of these NSC bacteria, with the potential for altered rumen pH and adverse effects on fiber fermentation.

With any dramatic change in dietary feed ingredients or feed intake, there will be a period of adaptation by microbial populations until an optimal steady state is achieved. The objective of any feeding program should be to minimize deviations in ruminal pH. Unfortunately, the transition cow experiences numerous changes in dietary composition, reduced feed intake, and rapid exposure to large amounts of highly fermentable carbohydrates. The transition cow is inevitably at high risk for the development of SARA. Although microbial adaptation and rumen epithelial growth relative to sensitivity to SARA are pervasive, recent studies have not shown a significant effect of prepartal grain feeding on prevention of SARA.[157,161] This evidence suggests that the amount of consumed fermentable carbohydrate, with its inherent ability to ferment rapidly and overwhelm rumen buffer systems, is the primary mediator of SARA.

Clinical signs associated with SARA often are subtle and may not be seen until later in the clinical course. Affected cows also may show signs of laminitis-induced lameness,[162] reduced milk fat content and milk production, low and cyclic ("slug" feeding behavior) feed intake, loss of body condition, and loose or variable fecal consistency.[155,156,160] Many of these clinical signs can be attributed to other disease problems, but chronic laminitis within a herd should place SARA high on the differential diagnosis list.[155,162] As low ruminal pH episodes continue over time, pathologic changes consistent with chronic acid exposure can occur. Rumen papillae may undergo hyperkeratosis with matting, ultimately leading to ruminal wall ulcer formation with secondary mycotic or bacterial colonization.[158] Bacterial translocation across ruminal wall lesions into the portal vein will result in hepatic abscesses. More severe repercussions such as caudal vena cava syndrome, hemoptysis, and epistaxis can occur in some herds secondary to ruminitis–hepatic abscess complex.[155]

Diagnosis of SARA is accomplished by measuring rumen pH after feeding and finding pH values below 5.5. Oetzel[29] suggests obtaining samples from 12 animals within a group; in this approach, if three or more cows have pH values below 5.5, the group is considered to be at high risk. Analysis of samples obtained by means of percutaneous rumenocentesis has been advocated as the preferred method for accurate determination of pH.[155,163] Samples collected using orogastric tubes or specialized ruminal fluid collection devices generally have various degrees of saliva contamination elevating rumen fluid pH values by 0.5 to 1.0 unit.[164]

Dietary evaluation should be used to complement measurement of ruminal pH, to determine any potential problem source. Chemical analysis of feed ingredients and delivered diet should be undertaken to determine total content of fermentable and fibrous carbohydrates. Estimation of effective fiber and overall dietary particle size also can be done.[165] Grain sources can be sieved to determine particle size distribution, as a method to evaluate ruminal degradation ability. More important, dietary particle separation should be used to evaluate delivered dietary consistency and cow sorting behavior to better evaluate the consumed diet.

Prevention of SARA essentially revolves around proper management of dietary carbohydrate delivery and consumption. Carbohydrates that potentially contribute to lactic acid production (i.e., sugars, starches, fructosans) need to be controlled in their dietary content and inherent rate of degradation.[156,160] Starch source, hydration, particle size, and processing all can influence rate of microbial degradation, leading to more rapid production of VFA and lactic acid. Combining starch hydration (ensiling) and particle size reduction (grinding) can

greatly increase rate of ruminal degradation and risk of acidosis. An adequate amount of physically effective fiber must be consumed from the diet to ensure good rumination and saliva production. Ration particle separation should be used to evaluate proper distribution of particles and to determine whether sufficient amount of effective fiber is being consumed. Fermentable fiber sources (e.g., beet or citrus pulp, soybean hulls, wheat middlings) often can be used to replace a portion of the dietary NSC fraction, thereby reducing lactic acid load yet providing energy in support of microbial growth and milk production.

Feeding management practices are just as important as dietary composition, if not more so. Ensuring consistent feed availability and composition, adequate bunk space and minimization of environmental stressors will help to control variability and dramatic feed intake changes. These issues are especially challenging over the transition period. Use of ruminal buffers (sodium bicarbonate, magnesium oxide) in early-lactation rations is highly recommended.[166] Addition of yeast-based probiotic products has been shown to help maintain rumen microbial population stability and feed intake.[167] Recently the ionophore agent monensin sodium (Rumensin, Elanco) has been approved for use in lactating dairy cattle rations. Ionophores selectively inhibit gram-positive bacteria, especially those associated with fiber and starch fermentation, resulting in reduced lactate production and protection against ruminal acidosis.[168]

KEY CONTROL POINTS FOR TRANSITION SUCCESS

In preventing associated problems with periparturient metabolic disease, the focus must be on controlling but not eliminating negative energy balance, minimizing fatty infiltration of the liver, and maintaining normal Ca homeostasis. Reducing the incidence of hypocalcemia, ketosis, and fatty liver syndrome will go a long way toward preventing or minimizing other parturient problems such as mastitis, metritis, retained placenta, and LDA. To prevent periparturient disease, four critical control points during the transition period need to be addressed:

Optimizing DM intake
Feeding a balanced diet
Maintaining Ca homeostasis
Minimizing immune system dysfunction[126]

Optimizing Dry Matter Intake

Cows that experienced periparturient disease have been shown to have a greater decline in prepartal DM intake compared with unaffected cows.[169,170] Cows experiencing postpartum disease also continued to have lower postpartum DM intake compared with healthy cows.[171] It also is well documented that DM intake normally declines by 25% to 30% in late gestation.[124,172,173] Timing relative to parturition and severity of the DM intake decline in late gestation varies among individual animals within a group and between groups within herds. An interplay of various physiologic (e.g., physical distention) and metabolic (e.g., hormone and metabolite concentrations) factors primarily regulates intake capacity. Other factors, however, including diet composition (e.g., effective fiber, fiber quality), pregnancy status (twins versus singletons), parity, BCS, presence of inflammatory or immune mediators, environmental conditions (e.g., heat stress) and management (e.g., overcrowding, pen changes, feed availability) may further influence actual DM intake in late pregnancy and early lactation.[173–175] Cows with higher body condition (mean BCS of 4.4 of a maximum 5.0) had lower mean DM intake (1.68 versus 1.83% of body weight) across the prepartal period and a more dramatic decline (40% versus 29%) compared with moderate (BCS of 3.6/5.0) or thin (BCS of 2.8/5.0) body condition cows.[173] Mature Holstein cows pregnant with twins (13.1 kg/day, 1.8% of body weight) had lower DM intake compared with singleton-pregnant cows (14.9 kg/day, 2.0% of body weight) across the prepartal period.[176] These data may help explain why heavy condition and twin pregnant cows have greater incidence of periparturient diseases and suggest the need for a special dietary group in the prepartal period to account for altered intake. Similarly, first-lactation cows have lower intake capacity and would benefit from a diet tailored to their intake, rather than diets formulated to meet mature cow intake capacity.

Lower prepartal DM intake will result in a greater degree of negative energy balance placing cows at greater risk for excessive hepatic fatty infiltration and impending downward spiral into other associated periparturient diseases. In a classic study by Bertics and colleagues,[172] rumen-cannulated cows that had their refused feed placed through the rumen cannula had lower blood NEFA concentrations and less fatty infiltration of the liver compared with cows allowed to refuse feed, resulting in reduced total intake. Application of these data indicated that maximal prepartal DM intake would be encouraged by feeding amounts to ensure 5% to 10% refusals for a group. Alternatively, dietary energy and protein content can be increased to compensate for lower DM intake.[47]

Besides a potential role in preventing periparturient disease, maximizing prepartal intake is thought to help accelerate DM intake post partum. Prepartal and postpartum intake data from multiple studies showed a positive relationship (r = 0.54) between intake during the last week of pregnancy and subsequent early postpartum DM intake.[177] Efforts to increase postpartum DM intake will facilitate energy balance status, minimize risk for postpartum disease, and support milk production. Properly balanced diets and removal of obstacles impeding DM intake will promote consistent high intake, which is most desirable.

Although arguments for maximizing DM intake and cow health are persuasive, there may be practical limitations and consequences. Other studies[178–181] and a review of data[182] suggest that moderate prepartal feed restriction may increase DM intake post partum. Cows moderately restricted in feed intake (80% of energy requirement) had blunted prepartal NEFA curves, less hepatic fat content, and greater postpartum intake. Grummer and associ-

ates[182] suggest that this situation mimics that of first-lactation cows, which seem to be more resistant to hepatic lipid accumulation despite negative energy balance. Observations suggest that feed-restricted cows and heifers do not experience the dramatic decline in intake accounting for this response. Drackley proposed that the extent of prepartal DM intake reduction was more important than the amount of prepartal intake on postpartum DM intake and hepatic fat accumulation.[183] The message from these studies may be not so much that intake must be maximized, but rather that the potential for significant declines in feed intake around transition should be minimized. The gold standard in feeding the transition cow, however, would be to achieve consistently high prepartal and postpartum intakes, accomplished through well-balanced diets and good management practices.

Feeding Properly Balanced Diets

A successful transition cow program can be developed using any of a variety of methods. Diets must be appropriately formulated to work within the framework of the physical environment, management practices, observed intake, and available feed ingredients. Cow grouping strategies and intake potential probably are the most critical to success of the formulation process. The more cow groups can be separated by intake and nutrient needs, the more precise the nutritional program becomes in meeting all animals' nutrient needs. As groups are reduced across parity and days before parturition, greater variation in nutrient intake on an individual animal basis is introduced, increasing opportunities for metabolic disease problems. The current NRC dairy cattle publication has greatly improved its recommendations relative to transition dairy cows and should be used as a guideline[124] (Table 46-3).

Of primary concern is providing the appropriate balance between dietary fibrous and readily fermentable carbohydrates. Dietary fiber sources provide substrate to support cellulolytic activity, and the physical properties of fibrous feeds promote rumination, facilitate rumen buffering, and provide material for the fibrous rumen mat. As a result of their slower rate of fermentation and requirement for repeated mastication to reduce particle size, fibrous feeds limit intake capacity and dilute dietary energy density. Cereal grains and other readily fermentable carbohydrate (NSC) sources provide readily available energy to support rumen microbial growth and the cow. Theoretically, feeding of some NSC sources helps

Table **46-3**

General Nutrient Recommendations (Dry Matter Basis) for the Transition Cow

Nutrient	Parity	DRY COWS		Fresh Cow (1–21 d)
		Early	*Close-up*	
Dry matter intake, % of body weight	Heifers	1.7–1.9	1.4–1.6	>2.2
	Mature cows	1.9–2.1	1.6–1.8	>2.5
Net energy, Mcal/lb	Heifers	0.60–0.64	0.70–0.72	0.78–0.80
	Mature cows	0.55–0.60	0.68–0.71	0.77–0.79
Acid detergent fiber, %		21–30	21–25	17–21
Neutral detergent fiber, %		38–45	33–38	25–33
Neutral detergent fiber, % of body weight	Heifers	0.8–1.0	0.6–0.7	0.85–0.95
	Mature cows	0.9–1.1	0.7–0.9	0.95–1.05
Nonfiber carbohydrates, %	Heifers	29–32	35–40	36–38
	Mature cows	28–30	34–38	36–38
Crude protein, %	Heifers	13–14	15–16	18–19
	Mature cows	12–13	13–14	17–18
Soluble crude protein, %		30–35	28–32	30
Rumen-degradable protein, %		68–72	64–67	60
Rumen-undegradable protein, %		28–32	33–36	40
Metabolizable protein, g/d	Heifers	900–1000	1000–1100	1200–1800
	Mature cows	850–950	1050–1150	1700–2300
Calcium, %		0.4–0.6	0.6 (1–1.2)[†]	0.85–1.0
Phosphorus, %		0.25–0.30	0.30–0.40	0.35–0.40
Magnesium, %		0.2–0.25	0.35–0.40	0.25–0.3
Potassium, %		0.65–1.0	<1.5	1.2
Sodium, %		0.10	0.1	0.3–0.35
Chloride, %		0.15	0.15 (0.8)[2]	0.30–0.35
Sulfur, %		0.16–0.2	0.2 (0.4)[2]	0.2–0.25

Data from National Research Council: *Nutrient requirements of dairy cattle,* 7th rev ed. Washington, DC: National Academy Press, 2001; Van Saun RJ: Dry cow nutrition: The key to improving fresh cow performance. *Vet Clin North Am Food Anim Pract* 1991;7:599–620; and Hutjens MF: *Hoard's dairyman feeding guide.* Ft. Atkinson, WI: WD Hoard's & Sons Comp, 1998, p 73.

the rumen papillae, as well as the rumen microbial population, to adapt to higher-grain-content diets. Excessive NSC, however, can result in acidosis and excessive body condition gain. Use of fat as an energy source should be limited in transition cows without exceptional feeding management, because of adverse effects of fat on DM intake and rumen fermentation or a lack of beneficial effect on health and production.[8,184,185] Fermentable fiber sources are receiving much attention in transition diets, because they can replace NSC ingredients to provide readily fermentable energy but do not have a negative effect on DM intake, as do other fibrous sources.[186] A minimum amount of physically effective fiber must be supplied in the diet, however, to maintain good rumen function and fill.

In balancing feed ingredients to meet dietary fiber and energy needs, feed nitrogen sources need to be balanced to meet rumen microbial nitrogen needs (rumen-degradable protein should be 11% of DM) to support microbial protein synthesis. The cow's protein requirement is best gauged by metabolizable protein, which is the sum of digestible amino acids delivered to the small intestine from microbial and feed protein sources. Too often (especially with hay crop silage diets), dietary crude protein content is much higher than needed (12–14%), yet predicted metabolizable protein is less than estimated requirements.[187] Unfortunately, metabolizable protein cannot be measured directly in feed ingredients. Metabolizable protein delivery from a given diet must be predicted using sophisticated dynamic rumen models such as the NRC dairy[124] or beef[188] cattle software package or Cornell-Penn-Miner program. Hay crop forage-based diets often are unbalanced relative to rumen-available nitrogen and readily available energy, resulting in predicted low metabolizable protein amounts. Adding fermentable carbohydrates or corn silage can potentially better balance the diet for metabolizable protein.

Maintaining Calcium Homeostasis

Most factors responsible for predisposing the cow to parturient hypocalcemia (age, breed, milk production) are not easily altered to reduce incidence, with the exception of prepartal diet. Beyond initial attempts at manipulating dietary Ca-to-P ratio, reducing dietary Ca and P intakes, and various modes of supplementing vitamin D metabolites or their analogues, manipulating prepartal DCAD shows the greatest opportunity for a practical method of hypocalcemia prevention.[95,111,189,190] Boda and Cole[191] first proposed manipulation of dietary Ca-to-P ratio to control milk fever incidence. To achieve the desired 1.5:1 to 2.0:1 ratio, dietary P often was fed in excess of requirements. Kirchura and co-workers[192] showed that high P intake increased the risk of parturient hypocalcemia. Massive doses of vitamin D (>1 million units/day) were advocated,[193] but problems with timing of administration relative to calving, recurrent hypocalcemia post partum and toxicity concerns were problematic.[194] Research studies showed potential application of prolonged-release vitamin D analogues[195] or PTH.[196] Neither protocol has been translated into a practical method to be applied in clinical practice.

Targeted Calcium Therapy

Although bordering on therapy (see previous section on hypocalcemia) rather than prevention, supplementation of soluble Ca sources around the time of calving can help to minimize parturient hypocalcemia. Administration of subcutaneous Ca solutions to all mature cows at the time of calving has been used to minimize potential for subclinical hypocalcemia. Alternatively, oral Ca salts can be given. It is not advisable to administer both Ca sources, because the potential for toxicity is increased. Highly soluble Ca salts are necessary to provide sufficient ruminal Ca concentration to passively drive Ca between epithelial cells. Calcium chloride (36% Ca), propionate (21.5% Ca), gluconate (9.3% Ca), and borogluconate (8.3% Ca) formulations can be used as oral supplements. Dosage should be between 50 and 125 g Ca.[111] Toxicity may occur with Ca dosages in excess of 250 g.[40] To prevent parturient hypocalcemia, mature cows can be dosed by commercial oral gels, drench, or stomach tube with an appropriate soluble Ca source just before or at the time of calving. Additional dosing could be administered once or twice after calving at 24-hour intervals. If cows become recumbent or fail to respond adequately, further diagnostic evaluation should be undertaken.

Dietary Calcium Content

Following the inability to prevent parturient hypocalcemia by manipulating dietary Ca-to-P ratio, preventive emphasis should focus on absolute dietary Ca intake. Assuming that the Ca homeostatic response was blunted or delayed when cows were fed Ca in excess of prepartal requirement, efforts were directed at reducing prepartal dietary Ca. Two studies feeding very low dietary calcium (<20 g/day) for 2 weeks before calving showed complete prevention of mild fever.[197,198] These diets provided less than required absorbed Ca (22 g/day in Holsteins)[124] and thus induced activation of the Ca homeostatic system to maintain blood Ca concentration. Unfortunately, routine formulation of such diets with available feedstuffs on most dairy farms is not practical. The successful reduction in milk fever observed in these studies, however, led to general recommendations of feeding reduced Ca (<80 g/day).[199] Field results for this preventive approach were variable and often did not reduce subclinical hypocalcemia. Later studies failed to show any effect of prepartal dietary Ca intake on milk fever incidence.[200–202] Other confounding factors such as effects of dietary K and Mg most likely accounted for differing responses. Successful use of low-Ca diets is accomplished by concurrently supplementing dietary Mg intake (0.35% to 0.4% DM) and reducing dietary K (<1.5% DM). Mineral sources containing Ca should be removed from the diet, so that most of the dietary Ca is derived from forage sources, which will provide less absorbable Ca intake.

As previously stated, formulating prepartal diets for extremely low Ca intake with typical feeds is difficult at best. An alternative to reducing dietary Ca content is to reduce dietary Ca availability with binding agents such as vegetable oil and sodium aluminum silicate (Zeolite A). Vegetable oils can generate insoluble Ca soaps, as well as Mg soaps, and may adversely affect prepartal DM intake and energy metabolism. Zeolite added to prepartal diets

has been shown to reduce parturient hypocalcemia,[203,204] but it is a nonspecific binding agent and must be added in significant amounts (0.7–1 kg/day). Both blood P and Mg concentrations were reduced in cows receiving diets supplemented with zeolite showing the nonspecific binding properties.[204] Binding agents are best used when dietary Ca content is already marginally low (30–50 g/day) to help attain the desired amount of absorbable Ca intake (<25 g/day). Zeolite may be of benefit in controlling hypocalcemia in pasture-based feeding systems to reduce absorbable Ca intake, because reducing K intake on pasture is less manageable.[205]

Dietary Cation-Anion Difference

The role of systemic acid-base status mediated by the relative difference between strong dietary cations (Na, K) and anions (Cl, S) in Ca homeostasis and as a mechanism for milk fever prevention has been well studied (see available reviews[95,190,206,207]). It is proposed that marginal differences in systemic pH influence the interaction between PTH and its target organ (bone, kidney) receptor. Metabolic alkalosis induced by an excess of absorbable cations (positive DCAD) diminishes PTH's stimulation of renal vitamin D activation, resulting in perturbed Ca homeostasis.[95,111] Inducing a state of metabolic acidosis by feeding an excess of absorbable anions (negative DCAD) augments Ca mobilization from labile bone. Additionally, activation of vitamin D is enhanced resulting in greater efficiency of intestinal Ca absorption.

The ubiquitous equation used to describe DCAD is (Na + K) − (Cl + S), with all values given in milliequivalents (mEq) per 100 g or kg of dietary DM. Factors used to convert dietary mineral content to mEq units are shown in Table 46-4. A number of alternative equations to describe DCAD have been proposed, accounting for the contribution of all potential dietary cations and anions and their availability.[95,207] Recommendations for desired DCAD to evoke an appropriate response, however, are equation specific, and definitive criteria for these alternative equations have not been established. Using the simple equation accounting for Na, K, Cl, and S, a desired range for DCAD to prevent milk fever is between –50 and –100 mEq/kg DM.[95] This is slightly less negative than what has been recommended (–150 mEq/kg DM),[206] and the current trend in the field is not to reduce DCAD to such low levels, owing to negative effects on DM intake and energy balance. Summarizing multiple studies, Oetzel showed an 11.7% reduction in DM intake when DCAD was reduced by 300 mEq/kg.[206] Palatability of anionic mineral salts has been a concern[208,209]; however, hydrochloric acid–treated protein products seemingly have alleviated some of this problem.

Application of the DCAD concept initially was daunting as a result of the required mathematical conversions and dietary mineral content bookkeeping for successful milk fever prevention. The primary goal of formulating DCAD-based diets is to remove dietary cations by selecting feed ingredients with lower K content and minimizing Na and K mineral or additive sources. This is followed by addition of dietary anion sources (mineral salts or acid-treated supplements) to achieve the desired cation-anion difference. Chloride-based salts seem to have the greatest impact on altering acid-base status.[95,111] Response to cation-anion manipulation of the diet can be easily monitored by measuring urinary pH.[210] Urinary pH is sensitive to acid load and is highly correlated ($R^2 = 0.77$) with change in blood pH.[206] Desired range in urinary pH to achieve sufficient metabolic acidosis to prevent milk fever is 6.5 to 7.0 in Holsteins or 6.0 to 6.5 in Jersey cattle.[111,206] Urinary pH values below 5.5 suggest excessive acidification, and some anions should be removed from the diet.

Although all macrominerals potentially mediate Ca homeostasis, practical experience with urinary pH measurements and rationalization of mineral requirements relative to their contribution to acid-base status has simplified the application of DCAD to milk fever prevention.[111] Dietary Mg should be increased to 0.35% to 0.4% DM to counter antagonism from higher dietary K content and to ensure adequate Mg to support the Ca homeostatic system. Because of inhibitory effects of high blood P concentration on vitamin D activation and inherently

Table **46-4**

*Factors used to convert dietary mineral content (% DM) to equivalent weights.
DM, dry matter.

low acidifying effects, there is no need to increase dietary P beyond current NRC[124] recommendations (0.3–0.35% DM). Dietary sulfur (S) should be supplemented between 0.22% and 0.4% DM. In view of the questionable acidifying effect of sulfate ions and the potential toxicity of S (e.g., polioencephalomalacia),[211] supplementing to greater than this level is not recommended. Na requirement can be met with a diet containing 0.12% Na.[124] Forages typically are low in Na (<0.1%), and minimal salt could be added to the diet to meet requirements. Suggested Ca content of anionic diets was thought to be in excess of requirement to account for induced renal Ca diuresis with acidosis. Calcium intake in excess of 150 g/day often was recommended; however, Beede and colleagues showed reduced DM intake with anionic diets containing 1.5% or 1.95% Ca, and blood Ca concentration was reduced on diets containing 0.47% Ca.[212] Recommended dietary Ca content with anionic diets is between 0.85% and 1.2%.[111,212] Exclusive use of calcium carbonate as the Ca source is to be avoided, owing to its potential alkalizing effects. This approach then reduces dietary manipulations to achieve a desirable DCAD to variability in dietary K and Cl content. Monitoring forage K content, application of agronomic practices to reduce forage K content, and substituting low-K by-product feeds for forages are potential methods to reduce dietary K content. Chloride sources from mineral salts or acids can be titrated into the diet to achieve the desired effect as measured by urinary pH change. As a general guideline, dietary Cl content should be 0.5 percentage unit less than dietary K content.[111] Acidogenic diets should be fed for at least 10 days, and preferably 2 to 3 weeks, before calving, to achieve the best preventive response.

Maintaining Immune Function

Based on the information presented, a decline in immune cell functional capacity to control infectious agents is inevitable with initiation of lactation. Stressor increasing cortisol production and inadequate nutrition can further exacerbate the duration and severity of immune suppression. Cow management during the transition period should focus on minimizing pen moves, because such changes force reestablishment of social order among individual animals, resulting in increased cow-to-cow interactions and lower DM intake.[62] Parturient cows can be moved into maternity pens only to deliver the calf and then moved to a postfresh pen, in an effort to decrease pen moves. Overcrowding of prefresh, maternity, and immediate postfresh groups can alter behavior (i.e., stress) and decrease DM intake. Based on differences in girth for pregnant cows, greater bunk space per cow is suggested (27 to 30 inches per cow), and a stocking density of 85% to 90% is recommended.[62] Environmental management to address pathogen exposure and ambient temperature extremes also is necessary to reduce potential stressors.

First and foremost, negative energy balance and protein deficiency need to be minimized throughout the gestational period, in accordance with the feeding recommendations described previously. Second, gestational micromineral and vitamin losses to fetus and colostrum may significantly affect maternal reserves and their metabolic function, especially when mineral and vitamin supplementation is reduced or interrupted during the dry period. In view of the proven role of trace minerals and fat-soluble vitamins in modulating immune function, diets should be fortified to a level at least equivalent to current NRC recommendations. In recognition of data suggesting improved mammary health and milk production effects and to compensate for colostral losses, vitamin A (110 IU/kg of body weight, for a total intake of 70,000–77,000 IU/day) and vitamin E (1.6 IU/kg, for a total of 1000 IU/day) recommendations for transition dairy cows were increased.[124] These are supplemental amounts and do not take into account endogenous vitamin sources in forages. In one study, supplementing vitamin E at 2000 to 4000 IU/day for 2 weeks ante partum, followed by 2000 IU/day for 1 week post partum, resulted in much-reduced mastitis incidence and lower somatic cell counts.[213] Another study also reported improved somatic cell counts in cows receiving 2000 IU/day vitamin E 2 weeks ante partum through 1 week post partum, compared with cows receiving 1000 IU/day for this period.[214] Parenteral vitamin E supplementation (2000–3000 IU total dose), given within 2 weeks of calving, also resulted in improved health status for those cows and heifers with inadequate vitamin E status.[142,215] No data are available to suggest that supplementation of vitamin A above current NRC recommendations has any beneficial effects. Research is only starting to identify animal performance and health responses to supplemental B-vitamins. Anecdotal evidence may suggest that supplementation of probiotic products containing yeast and mixtures of B-vitamins may be beneficial.

Most NRC recommendations for microminerals are based on dietary density, rather than a factorially derived daily amount required, reflecting the paucity of available data. Even though allowances are made for differences in availability depending on dietary ingredients, variation in DM intake from expectations will result in consumption of less mineral. To compensate for intake variation, dietary nutrient density could be increased 20% to 50% above NRC recommendations, or more biologically available mineral sources could be chosen, or some combination of the two approaches could be used. Dietary selenium content cannot be increased above the legal limit of 0.3 mg/kg of diet; accordingly, a portion of the inorganic selenium supplement could be substituted with the yeast-based selenomethionine product to improve availability. Whole-blood selenium and glutathione peroxidase activity was higher at birth in calves from dams supplemented with seleno-yeast than in calves from dams given selenite or no selenium.[216] A suggested starting point would be to replace between 20% and 30% of inorganic mineral sources with available organic forms during the periparturient period. Data in pigs showed improved fetal survival and greater fetal mineral content when a portion (25%) of the trace mineral supplement in the sow's gestational diet was replaced with organic mineral sources.[217] Available data must be evaluated in deciding which organic mineral sources to use and whether or not a response to supplementation is elicited.

Beyond Nutritional Management

In a 1991 survey of 61 top production farms based on DHI records reported mean incidence rates for common periparturient diseases were within expectations; however, the range for each disease was extremely wide.[218] Some farms reported a 44.1% incidence of milk fever or 22.6% incidence of retained placenta. How could farms experience such high periparturient disease rates and still achieve high production? Even with the great strides forward with research on the nutritional management of the transition cow, veterinary science has not solved problems of periparturient disease or reduced reproductive performance. There still is much room for improvement in increasing milk production efficiency. One consistent frustration with managing transition cows is the seeming lack of consistency in response to a given program. To this end, Drackley stated: "Why do vastly different nutrition and management programs produce similarly good, or similarly poor, transition success?"[8] Similarly, Bell, in summarizing the current state of knowledge relative to transition metabolism, suggested that the direction of future research should focus on why individual cows show such wide variation in performance and health responses relative to intake and BCS.[60]

Drackley best answered his own question in suggesting that the traditional approach focusing solely on nutrition is inadequate, and that other important factors include how a given nutrition program is delivered and the environment in which it is consumed.[219] Overcrowding, exposure to pathogens, and changing social organization, among other factors, can induce stress-mediated physiologic and metabolic changes. Immune responses to generate acute-phase proteins and support increased metabolic activity cost energy over and above maintenance requirements. Animals alter how they utilize and partition available nutrients in response to these stress situations, which may compromise availability of nutrients to support productive functions. Other metabolic responses to stress can result in increased fat mobilization, leading to greater potential for hepatic lipidosis, wasting of muscle tissue, and immune suppression. A number of physiologic and metabolic responses to stress can result in a decline in DM intake, further compromising nutrient availability to support production. It is believed that the effects of stressors are additive; thus, as stress situations accumulate, greater physiologic and metabolic changes occur, ultimately resulting in abnormality seen as metabolic dysfunction or infectious disease. These stress responses will be more exaggerated in animals consuming an imbalanced diet but also may overwhelm an animal consuming an adequate diet. The foundation for a successful transition period is the ability to provide a properly formulated close-up ration within a reasonably stress-free environment.

CHAPTER 47

Ovarian Follicular Cysts

H. ALLEN GARVERICK

Ovarian follicular cysts (cysts) are anovulatory follicular structures that persist for various periods of time and have been found in a number of mammalian species.[1] Cysts in most cases are larger than normally developing follicles; however, cysts also may be similar in size to ovulatory follicles. Cysts have traditionally been defined as follicular structures of 2.5 cm in diameter or larger that persist for a variable period in the absence of a corpus luteum (Fig. 47-1). More recently, a diagnosis of ovarian follicular cyst was based on a diameter of 17 mm or larger, particularly if more than one follicular/cyst structure was present.[2,3]

The condition affects approximately 10% of dairy cows annually and is a serious cause of infertility in dairy herds. Occurrence of cysts is less frequent in beef cows, but cysts have become more prevalent in recent years. Cows generally are infertile so long as the condition persists. In our experience, the calving interval is about 50 days longer in cows diagnosed with cysts than in cows without postpartum abnormalities. *Cystic ovaries, ovarian cysts,* and *cystic ovarian degeneration* all are terms that have been used synonymously with ovarian follicular cysts.

This chapter describes ovarian cyst dynamics and reviews the etiology, diagnosis, treatment, and management of cysts in cattle.

OVARIAN FOLLICULAR CYST DYNAMICS

Overview of Follicular Changes during Bovine Estrous Cycle

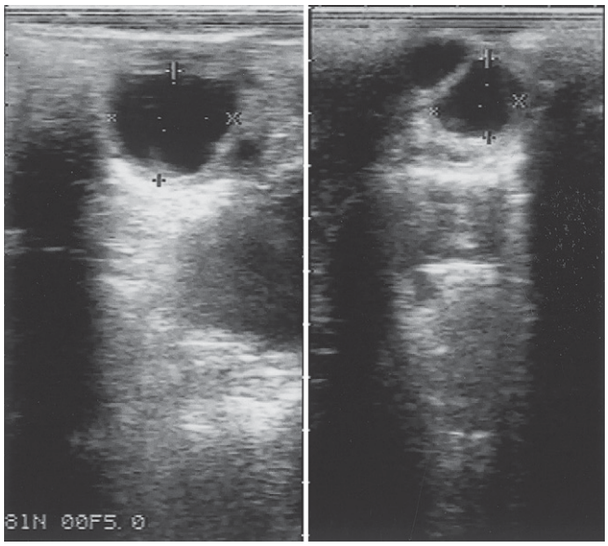
With the development of real-time ultrasonographic technology, ovarian follicular changes during the bovine estrous cycle have been well characterized (follicular dynamics and mechanisms controlling follicular growth and development are reviewed elsewhere[4–9]). The bovine estrous cycle is characterized by growth of follicular waves, usually two or three per cycle. After ovulation subsequent to estrus, a cohort of follicles (usually 3 to 5) is recruited, and these follicles grow to be greater than 5 mm in diameter. Growth continues for approximately 2 days until the follicles reach approximately 8.5 mm in diameter. From the cohort, one follicle is selected to continue growth and become dominant over the other follicles.[10] The fate of the other follicles in the cohort is atresia. If luteal regression occurs during the growing phase of the dominant follicle, that follicle continues growth and ovulates. If luteal regression does not occur during the growth phase of the dominant follicle, the dominant follicle undergoes atresia. Luteal regression usually occurs during the growth phase of the second- or third-wave dominant follicle. Initiation of each wave of follicular growth is preceded by a transient increase in circulating follicle-stimulating hormone (FSH). Initiation of each wave occurs in the absence of a dominant follicle that secretes estradiol and inhibin.

Dynamic Nature of Follicular Growth and Atresia

Ovarian follicular cysts have been described in the literature since the mid 1800s.[11] It was long assumed that most cysts were static structures that persisted for extended periods of time. As indicated by the findings outlined in the previous section, the classic definition of static cystic structures was not consistent with the dynamic nature of follicular growth and atresia. Kesler and associates reported short- and long-term changes in cystic structures and circulating reproductive hormone concentrations that suggested that cysts were not static structures.[12] None of the cows in that study resumed ovulatory ovarian cycles, but cysts appeared to regress and were replaced by new structures in some cows.

Recent studies have shown that cysts are indeed dynamic, with three potential outcomes.[1,10,13–17] In some instances, cysts persist for extended periods (up to 70 days) and remain dominant over the others; growth of additional follicular waves is inhibited by estradiol and inhibin secreted by the active cyst. Two other responses also have been demonstrated[10,13]: The original cyst may regress and be replaced by a new follicular structure that ovulates. Such self-correction occurs in approximately 20% of cows with cysts.[18] The lifespan of most cysts, however, is characterized by turnover whereby the original cyst decreases in size and is replaced by a new follicular structure that develops into a new cyst. With the occurrence of cyst turnover, intervals between follicular/cyst waves are longer and more variable in cows with cysts (13 days) than in cows with normal estrous cycles (8.5 days).

Follicular growth dynamics during development of cysts is similar to recruitment, selection, and dominance of ovulatory follicles during normal estrous cycles.[10] That is, recruitment of a cohort of follicles (usually 3 to 5) is initiated by a transient increase in circulating FSH. The cohort continues to grow until follicles reach 8.5 mm in diameter; then, selection and dominance of one follicle occur. When the dominant follicle reaches ovulatory size, however, ovulation does not occur, and growth of the dominant follicle continues for several additional days



A B

Fig. 47-1 **A,** Ovarian follicular cysts approximately 25 mm in diameter. **B,** Ovarian follicle approximately 17 mm in diameter, which is near ovulatory size

and a cyst develops. The growth rate of follicles that develop into cysts is similar to the growth rate of normal dominant follicles.[10] Cysts that are dominant over other follicular structures (other follicular growth inhibited) are steroidogenically active (producing large amounts of estradiol) and are morphologically healthy. When cyst turnover occurs, a new wave of follicular growth is initiated (with recruitment, selection, and dominance of the new wave). Thus, the original dominant cyst has lost dominance (nondominant cyst). Observation of nondominant cysts has shown that they are not steroidogenically active (low levels of estradiol and androstenedione) and have a morphologic appearance similar to that of atretic follicles. Granulosa cell layers have thinned or are missing.[19] Growth of follicles that developed into cysts and follicular dynamics of waves of follicular/cyst growth are therefore similar in many aspects to those in cows with normal estrous cycles.

ETIOLOGY OF CYSTS

Extrafollicular Mechanisms

It was suggested in the early literature that cysts probably result from an excess of secretion of FSH and an insufficient amount of luteinizing hormone (LH). Subsequently, however, two studies from the 1990s showed no difference in serum concentrations of FSH in cows experiencing development and maintenance of cysts and in normal control animals.[10,13] By contrast, mean serum concentrations of LH are nearly twice as high in cows with cysts as in control animals. Pulsatile secretion of LH during cyst growth and development is characterized by high pulse frequency and high pulse amplitude. A preovulatory-like surge of LH, however, is not detected in cows with cysts. Concentrations of LH in serum of cows that spontaneously recover without exogenous treatment are intermediate between those in control animals and those in cows that develop cysts.[10] Infusion of LH at levels that mimic circulating levels in cows with cysts into cycling of postpartum dairy cows did not result in induction of development of cysts.[20] Thus, increased pulsatile secretion of LH alone is not sufficient to induce cysts.

Another characteristic of cows with cysts is the lack of an LH surge when follicles reach ovulatory size.[10,13] In addition, exogenous treatment in cows with cysts with estradiol fails to induce an LH surge in some cows, and the LH surge is delayed in other cows with cysts that did exhibit an LH surge.[21] In two different studies, ablation of follicles followed by an estradiol-induced LH surge with no dominant follicle present was followed by development of large follicles that resembled cysts.[22,23] In those studies, treatment of the cows with cysts with exogenous progesterone was followed by development of a large follicle that ovulated. Thus, cows with cysts appear to be refractory to the stimulatory effects of estradiol on the gonadotropin-releasing hormone (GnRH) surge center; the lack of responsiveness of the GnRH surge center is associated with development of cysts. This observation is consistent with the observation that successful treatments for cysts involve exposure of the cow to progesterone (see later "Treatment" section). Exposure to either exogenous or endogenous progesterone decreases tonic secretion of LH and restores hypothalamic responsiveness to estradiol.

The pituitary gland does not seem to be involved in development of cysts. Pituitary gland content of FSH and LH in cows with cysts is similar to that in cows with normal estrous cycles, and cows with cysts can release LH in response to exogenous GnRH.[1,24]

Molecular Characteristics and Mechanisms

Previous experiments have shown differential expression of messenger RNAs for the gonadotropin receptors and key steroidogenic enzymes during growth of normal follicles at critical stages of development, and expression also has been shown to occur during abnormal follicular development (cysts). In addition, steroid concentrations and content have been shown to be different. Concentration of estradiol (ng/ml) and total content of steroids (ng/follicle) is higher in dominant cysts than in dominant follicles.[2] Messenger RNA expression for the LH receptor in granulosa and theca cells and 3β-HSD in granulosa cells also is elevated in dominant cysts compared with that in dominant follicles. Conversely, nondominant cysts have higher concentrations of progesterone but lower concentrations of estradiol in cyst fluid. In addition, messenger RNA concentrations for the gonadotropin receptors and steroidogenic enzymes, except for cytochrome P-450scc and 3β-hydroxysteroid dehydrogenase (3β-HSD) are nearly undetectable in nondominant cysts. Granulosa and theca cells usually are degenerated in nondominant cysts. Nevertheless, nondominant cysts are still, in general, larger than dominant follicles.

Cysts also have been classified as follicular or luteal. **Follicular cysts** may be single or multiple and are thin-

walled. Follicular cysts with several layers of granulosa cells secrete estradiol (dominant cysts), whereas those with few granulosa cells have low intrafollicular concentrations of estradiol (nondominant). **Luteal cysts** have thickened walls and theca cells, and sometimes granulosa cells are luteinized. Luteal cysts usually secrete progesterone at various levels, sometimes in enough quantity to raise circulating concentrations of progesterone similar to normal luteal phase levels. In some cases, luteal cysts may not be producing significant quantities of progesterone, and circulating concentrations of progesterone may be low. It is believed that luteal cysts develop from follicular cysts when theca and granulosa cells luteinize over time.

DIAGNOSIS OF CYSTS

Early diagnosis of cysts was based on behavioral and physical characteristics. Some cows with cysts expressed nymphomaniac behavior by exhibiting frequent periods of prolonged estrus. It was observed, however, that most cows with cysts did not exhibit estrus. Many long-term anestrous cows had cysts. It is now recognized that greater than 80% of cows with cysts are anestrous. As stated earlier, diagnosis is made on examination of the reproductive tract per rectum by tactile or ultrasound examination based on the presence of one or more structures 2.5 cm in diameter or larger in the absence of a corpus luteum (see Fig. 47-1). As previously mentioned, however, some cysts may be only slightly larger than ovulatory follicles.

Based on the previous description of the dynamic nature of cyst growth dynamics, and the presence of dominant versus nondominant cysts and follicular versus luteal cysts, accurate diagnosis is difficult with use of only a single examination. In addition, diagnosis is more accurate with ultrasonographic examination of the ovaries than with rectal palpation. Early developing corpora lutea, which often are soft to touch, frequently are misdiagnosed as cysts by palpation per rectum. The clinician also should check for pregnancy because some corpora lutea of pregnancy also are soft to tactile examination. Nondominant cysts often are larger than the newly developing cyst. Because nondominant cysts are atretic, they do not respond to exogenous treatment with GnRH or human chorionic gonadotropin (hCG). When nondominant cysts are present, the follicular structure that responds to treatment usually is another follicular structure, sometimes smaller in size than the nondominant cyst. Nondominant cysts often are not greatly reduced in size when a new follicular/cyst wave has proceeded through selection and dominance. Thus, in subsequent examinations, it may be erroneously assumed that treatment was not successful if the nondominant cyst has not decreased in size and the new developing luteal structure is overlooked.

Differentiation of follicular from luteal cysts is not accurate with a single examination by palpation per rectum. Farin and associates report inability to differentiate between follicular and luteal cysts using palpation per rectum, even for experienced clinicians.[25,26] The same clinicians, however, were successful in such differentiation (in approximately 90% of examinations) when using ultrasonographic evaluation. In a few cases, luteal-appearing tissue was detected with low circulating levels of progesterone, and in a few others, circulating progesterone was observed in the absence of thickened cyst walls.

TREATMENT OF CYSTS

Evaluation of treatments is complex because some cysts spontaneously recover, and misdiagnosis is possible. When cysts develop before first ovulation during the postpartum period, up to 50% of the cysts recover spontaneously. If cysts develop after first ovulation, approximately 20% recover spontaneously.[18] Historically, treatment of cysts has included manual rupture and various hormonal regimens. From information provided in the earlier section on etiology, it is evident that successful treatment requires exposure of the central nervous system to endogenous or exogenous progesterone.

Successful treatment of cysts in cows has been with GnRH or with LH or LH-like products (hCG) (see the review by Kesler and Garverick).[18] Both agents induce luteinization, but not ovulation, of cysts and production of progesterone, followed by the development of a dominant follicle that ovulates. After treatment with GnRH or hCG, pulsatile release of LH is greatly decreased. The luteinized cysts produce progesterone for 15 to 18 days, and the cow returns to estrus in about 21 days after GnRH treatment. The progesterone from the luteinized cyst sets up the cascade of events leading to release of $PGF_{2\alpha}$ from the uterus, which induces regression of the luteinized cyst. The interval to the subsequent estrus can be shortened by treatment with $PGF_{2\alpha}$ 9 days after injection of GnRH.[27]

Another regimen also has recently been shown to be effective. Treatment with exogenous progesterone was shown to decrease pulsatile secretion of LH and to induce atresia of cysts and development of an ovulatory follicle.[19,28,29] Thus, successful treatments for cysts have been associated with decreased pulsatile secretion of endogenous LH and an increased secretion of progesterone after treatment, with both endogenous and exogenous sources of progesterone. With exogenous progesterone sources, endogenous LH secretion is reduced, and the hypothalamic-hypophyseal axis "sees" progesterone and can respond to the estradiol produced by the subsequent dominant ovarian follicle by releasing an ovulatory dose of LH. It is probable that a near-luteal level of circulating progesterone is needed to reduce pulsatile LH secretion and sensitize the hypothalamus to respond to the endogenous estradiol produced by the developing follicle.

With GnRH or hCG treatment, LH pulsatility is reduced after treatment, luteinization of the steroidogenically active cyst occurs, and the hypothalamic-hypophyseal axis "sees" progesterone produced by the cyst and can respond to the increasing levels of estradiol from the subsequent dominant follicle to release a preovulatory surge of LH for ovulation. It should be noted that nondominant cysts that have characteristics of atretic follicles do not respond to the GnRH-induced

release of LH or the exogenous LH-like compounds. In such instances, another follicular structure responds to the treatment, or corrective response does not occur. It is important to fully examine the ovaries of cows treated for cysts to determine whether another structure has responded to treatment when the diagnosed cystic structure has not done so.

The recent development of the Ovsynch protocol for timed breeding of large groups of cows in dairy herds also is effective when cows with cysts are included in the breeding program. In this protocol, cows are treated with GnRH, followed 7 days later with $PGF_{2\alpha}$; treatment with another GnRH injection 2 days later; and timed breeding of cows 12 to 16 hours later.[28] Thus, this treatment is similar to that in the study reported earlier whereby the GnRH injection induces luteinization of the cystic structure, which is followed by $PGF_{2\alpha}$-induced luteolysis.[27] The difference is that the interval from GnRH to $PGF_{2\alpha}$ injection is shortened from 9 to 7 days in the Ovsynch protocol.

PREVENTION OF CYSTS

Several studies have reported that cysts are heritable. In one study, the incidence of cysts in Sweden was reduced from 10% to 3% by selection against sires producing daughters that developed cysts.[29] Estimated risk of transmission of the relevant trait, however, typically is small (0.11 to 0.15).[30] Selection against cysts will be slow as a result of the low heritability.

Treatment with GnRH given at days 12 to 14 after parturition reduces the incidence of cysts in the postpartum period.[21,31] Of interest is the finding that cysts do not develop in cows that have a dominant follicle and ovulate in response to the GnRH treatment. This finding indicates that early establishment of estrous cycles during the postpartum period and exposure of cows to luteal levels of progesterone may reduce incidence of cysts in postpartum cows. Nevertheless, attempts to program ovarian function with an intravaginal device during the postpartum period have not reduced the incidence of cyst development.[32]

CHAPTER 48

Infertility Due to Noninflammatory Abnormalities of the Tubular Reproductive Tract

CHRISTIAN W. STEENHOLDT

Infertility in the cow can be attributed to a number of conditions affecting the tubular reproductive tract. Studies have confirmed that inflammatory disease (e.g., endometritis) is considerably more likely to compromise fertility than is noninflammatory disease.[1,2] In these limited surveys, noninflammatory lesions of the tubular tract accounted for approximately 5% of all lesions detected and were more prevalent among nulliparous animals. As expected, a larger proportion of nulliparous than of multiparous animals will be affected by noninflammatory lesions, in keeping with the absolute state of infertility in many congenital conditions. Although noninflammatory abnormalities are of relatively minimal importance overall, the cases provide for interesting discussion, particularly with regard to mode of development. The embryology of the reproductive system often is a critical factor in the pathogenesis of most such conditions, and the reader is encouraged to review the development of the female tract. This chapter focuses on several conditions that are responsible for infertility due to noninflammatory abnormalities of the tubular reproductive tract.

FREEMARTINISM

Freemartinism is the most commonly recognized noninflammatory condition resulting in infertility involving the tubular reproductive tract in the bovine. Freemartin heifers result from 92% of heterosexual twin births,[3] and it is estimated that at least 86,000 freemartins are born annually in dairy cattle breeds in the United States.[4]

The development of the freemartin heifer is a result of the fusion of the chorioallantoic portions of the twin placentas, which usually is established between days 28 and 30 of gestation and results in a common blood supply between twin fetuses. This common supply allows the exchange of humoral and cellular elements between fetuses, producing calves that are blood cell chimeras. **Chimeras** are individual animals that contain two cell types originating from separate zygotes. Testicular devel-

CHAPTER 48

Infertility Due to Noninflammatory Abnormalities of the Tubular Reproductive Tract

CHRISTIAN W. STEENHOLDT

Infertility in the cow can be attributed to a number of conditions affecting the tubular reproductive tract. Studies have confirmed that inflammatory disease (e.g., endometritis) is considerably more likely to compromise fertility than is noninflammatory disease.[1,2] In these limited surveys, noninflammatory lesions of the tubular tract accounted for approximately 5% of all lesions detected and were more prevalent among nulliparous animals. As expected, a larger proportion of nulliparous than of multiparous animals will be affected by noninflammatory lesions, in keeping with the absolute state of infertility in many congenital conditions. Although noninflammatory abnormalities are of relatively minimal importance overall, the cases provide for interesting discussion, particularly with regard to mode of development. The embryology of the reproductive system often is a critical factor in the pathogenesis of most such conditions, and the reader is encouraged to review the development of the female tract. This chapter focuses on several conditions that are responsible for infertility due to noninflammatory abnormalities of the tubular reproductive tract.

FREEMARTINISM

Freemartinism is the most commonly recognized noninflammatory condition resulting in infertility involving the tubular reproductive tract in the bovine. Freemartin heifers result from 92% of heterosexual twin births,[3] and it is estimated that at least 86,000 freemartins are born annually in dairy cattle breeds in the United States.[4]

The development of the freemartin heifer is a result of the fusion of the chorioallantoic portions of the twin placentas, which usually is established between days 28 and 30 of gestation and results in a common blood supply between twin fetuses. This common supply allows the exchange of humoral and cellular elements between fetuses, producing calves that are blood cell chimeras. **Chimeras** are individual animals that contain two cell types originating from separate zygotes. Testicular devel-

opment occurs before ovarian development in the bovine, and anti-müllerian hormone (müllerian-inhibiting substance) from the testes of the male fetus inhibits the development of the paramesonephric (müllerian) ducts in the female.[5] This results in dysfunction in the differentiation of the ovaries, oviducts, uterus, cervix, and cranial vagina. The pathomechanism in 8% of the cases in which a fertile female is born as a twin to a male probably is failure of fusion of fetal membranes or timing of membrane fusion after a critical point in reproductive organ differentiation.[6] The male co-twin usually also is chimeric and may exhibit deficient reproductive capacity.[7] Approximately 6% of twin pregnancies result in the birth of a single calf,[8] and in rare cases a female freemartin calf is born as an apparent singleton as a result of death of the male co-twin in utero.[9] Freemartinism occasionally occurs in conjunction with other congenital abnormalities such as atresia recti[10] and urethral hypoplasia.[11,12]

Clinically, freemartin heifers exhibit broad variation in appearance of the external genitalia, with features ranging from apparent normality (most common) to a small vulva, increased anogenital distance, an enlarged clitoris, and a prominent tuft of hair on the ventral commissure of the vulva. The internal reproductive organs usually are abnormal, with vestigial or masculinization of the ovaries, reduced development of the paramesonephric (müllerian) duct system, and development of the mesonephric (wolffian) duct system. Freemartin females show a range in the internal reproductive organs dependent on the level of masculinization. The least masculinized form is most common, with a small genital tract with hypoplastic ovaries, a short vagina, and an absent cervix. Masculinization appears to be due to in part to a probably indirect role of antimüllerian hormone on gonadal development[13] and the influences of H-Y antigen[14] and results in ovaries with parenchyma that contains tubules and interstitial tissue, resembling testes. In animals that have undergone masculinization, development of the mesonephric (wolffian) ducts also occurs, which may result in epididymides, vasa deferentia, and vesicular glands.[15] It is suggested that the extent of transformation of the female freemartin is dependent on the stage in gestation at which extensive anastomosis exposed her to circulating male hormones.[16] Of interest, the proportion of male blood cells in circulation apparently has no relationship with the degree of masculinization in freemartin heifers.[17]

The diagnosis of freemartin heifers usually is based on a history of heterosexual multiple births, appearance of the external genitalia, and palpation or ultrasound evaluation of the internal reproductive tract. Visualization via vaginal speculum usually will reveal a short vagina and no external cervical os in freemartin heifers. The vagina in suspected freemartin heifers may be probed using a suitable instrument (a test tube, insemination pipette, or thermometer is commonly used); alternatively, commercial probes are available (Ru-an Freemartin Probe, $US25.95, Valleyvet.com). Freemartin heifers generally have a vagina that is approximately one-third the length of vaginas in normal heifers of the same age. Among heifers younger than 1 month of age, the freemartins usually will have a vagina length of 5 to 6 cm, whereas in normal heifers, vaginas are 13 to 15 cm long.[18,19] The vaginal length in suspected freemartin heifers should be compared with that in normal heifers of the same size. Occasional false positives using the vaginal length test can be due to interference by a persistent hymen with the deposition of the probe. False negatives also may be encountered, because some freemartins have a vagina that is of normal length. Eighty percent of freemartin heifers will be correctly identified using a vaginal probe,[20,21] with the remaining 20% of heifers likely to consist of approximately half freemartins and half fertile heifers. It is suggested that laboratory testing be carried out on the heterosexual twin heifers with normal vaginal length.

Laboratory testing includes polymerase chain reaction (PCR) analysis, karyotyping, blood typing, and the erythrocyte lysis test for the detection of blood cell chimeras. Although most female cattle that are blood cell chimeras are likely to be sterile freemartins, several fertile XX/XY animals have been described.[22–25]

PCR assay has become the most common commercially available test to diagnose freemartins. The PCR procedure demonstrates sex chromosomes exhibiting XY and XX in the same animal. The test is relatively fast and highly accurate because it can detect the presence of as little as 1 in 10,000 blood cells containing the Y chromosome.[26] A blood tube containing 5 to 8 ml of whole blood with ethylenediaminetetra-acetic acid (EDTA) or a drop of blood on a blood card from a suspected freemartin may be submitted for testing. The cost for one assay in 2005 was $US40. This test is available from several laboratories including Biogenetic Services Inc., Brookings, SD (info@biogeneticservices.com), and Veterinary Genetics Laboratory, Davis, CA (cattle@vgl.ucdavis.edu).

Karyotyping is another method for demonstrating blood cell chimerism. Blood lymphocytes are cultured and metaphase chromosome spreads are examined for XY cells. The distribution of male cell percentages in nucleated blood cells appears to be random in individual animals, and freemartins may contain a high to low percentage of XY cells.[27] False negative results can occur in animals containing a small proportion of XY cells if insufficient metaphases are counted. Karyotyping requires considerable laboratory work and is fairly expensive. Another interesting test of XX/XY chimerism is through skin grafting between heterosexual twins—freemartin heifers accept a surgically placed skin graft from their male twin.[28]

OTHER INTERSEX CONDITIONS RESEMBLING FREEMARTINISM

Intersex cattle other than freemartins are very rare. Male pseudohermaphrodites are genetic and gonadal males, but the external genitalia resemble those of a female. Male pseudohermaphrodites are more common than female or true hermaphrodites, probably because more genes are required to initiate male development (steroidogenic enzymes, 5α–reductase, and androgen receptors), with correspondingly greater opportunity for genetic

defects. Limited case reports of male pseudohermaphrodites in cattle have been published.[29–32] Classification of intersex cases requires careful anatomic (often at post mortem), chromosomal, and endocrinologic examination. It is possible that some other intersex conditions are misclassified as freemartins if the diagnosis is based solely on physical examination.[33]

Bovine male pseudohermaphroditism (often referred to as testicular feminization) results from androgen insensitivity. Affected animals are XY males with testes, paramesonephric and mesonephric (wolffian) duct regression, and female-like external genitalia. The tubular genitalia of the paramesonephric (müllerian) system are underdeveloped owing to testicular production of antimüllerian hormone (müllerian-inhibiting substance). Production of testosterone by the testes is normal, but because of intracellular androgen insensitivity, the mesonephric (wolffian) system fails to develop without androgenic support. It is possible that this disorder is inherited as an X-linked trait in cattle, as in other species.[31] Clinically, affected animals may be mistaken for heifers but fail to show estrus and exhibit bull-like behavior. On examination of the internal reproductive tract, the vagina may be short to normal in length; no cervix is present, with a very small or absent uterus and testes in the normal position of ovaries.[32]

Fig. 48-1 Segmental aplasia affecting the right uterine horn. (Courtesy of Dr. C.D. Buergelt, University of Florida.)

SEGMENTAL APLASIA OF THE PARAMESONEPHRIC (MÜLLERIAN) DUCTS

Segmental aplasia is a result of a prenatal lack of development of a portion of the paramesonephric (müllerian) duct system, resulting in various degrees of aplasia, potentially involving the vagina, cervix, uterus, and oviducts. Historically described as "white heifer disease"[34,35] owing to a high prevalence in white Shorthorn females, segmental aplasia has been reported in several other breeds of cattle including Holsteins,[1,36] Senepol,[37] German Black Pied,[38] Guernsey,[1] Jersey,[1] Angus,[39] and Ayrshire.[39] The prevalence of segmental aplasia ranges from 0.15%[1] to 0.2%[40] in slaughterhouse studies. Although rarely diagnosed in practice, segmental aplasia in cattle provides an often academic discussion of the locally acting nature of endometrial prostaglandins, the likely inheritance of the condition, and cull versus treatment options.

A range of defects of the paramesonephric (müllerian) system may be seen in animals affected by segmental aplasia. Individual cattle may present with abnormalities ranging from an imperforate hymen to complete maldevelopment of the tubular reproductive tract. The most common presentation encountered in practice is aplasia and resultant blockage affecting the caudal portion of one uterine horn, often referred to as **uterus unicornis**, resulting in accumulation of endometrial secretions in the cranial horn (Fig. 48-1). In a review of 20 cases of uterus unicornis, 14 animals had a defective right uterine horn and 6 had a defective left horn.[39] A persistent hymen usually is not present.[39] When both horns are affected, the aplasia includes the cervix and vagina.[41] Segmental aplasia of the oviducts is rare,[2] and obstruction of the oviducts may result in accumulation of secretions and hydrosalpinx. The aplastic section of the reproductive tract usually consists of a band of connective tissue and muscle with no lumen, mucosal epithelium, or glands.[36,41]

A **persistent hymen** is considered to be a form of segmental aplasia and is a result of an embryonic malunion of the paramesonephric (müllerian) ducts and the ectodermal urogenital sinus. Heifers that have a complete hymen accumulate secretions in the vagina and also may develop mucometra. Tenesmus is an occasional presentation and is due to significant fluid accumulation in the cranial vagina. A persistent hymen occurs occasionally in the cow, either as a single lesion or associated with segmental aplasia.[42]

Fluid accumulation in cases of segmental aplasia may be misdiagnosed as pregnancy, pyometra, mucometra, or cystic ovarian disease. Rarely, retained endometrial secretions become inspissated and surrounded by oily fluid and may be confused with a fetal mummy.[43] Diagnosis of segmental aplasia usually is achieved through careful rectal palpation or transrectal ultrasound examination and identification of the abnormal anatomy as indicated by the inability to pass a pipette into both uterine horns. A definitive diagnosis is achieved at necropsy examination.

In the Shorthorn breed and derivatives (e.g., Belgian Blue), inheritance appears to be linked to the roaning gene.[44] A high incidence of segmental aplasia, causing a reduction in herd fertility, has been reported[45,46] in association with the extensive use of carrier sires. In the Holstein breed, inheritance is suggested to be due to autosomal recessive genes that are linked for aplasia affecting the left and the right uterine horns.[41] Anecdotally, some Holstein cows may not pass on the trait to offspring (Strelow L: personal communication, 2005).

Segmental aplasia affecting one uterine horn provides a natural model for locally acting hormonal control by the endometrium on the ipsilateral corpus luteum. Animals with segmental aplasia affecting one uterine horn show erratic estrus intervals[47] or anestrus[36] as a result of failure of local endogenous prostaglandin F_{2a} production from minimal or damaged endometrium.

Infertility is a likely presentation in affected animals, although presentation for pregnancy diagnosis also is not uncommon. Therapy of affected animals should be tempered with the recognition of the likelihood of potentiation of the condition, particularly in breeds in which a genetic mode of transmission has been clearly defined. Treatment modalities in animals with one aplastic uterine horn have included insemination at detected estrus, palpation or ultrasound examination to detect the side of ovulation and subsequent CL formation, and short-cycling the cow with prostaglandins until the animal ovulates of the ovary on the normal horn. Ovariectomy via laparotomy or colpotomy[48] of the ovary ipsilateral to the affected horn, thereby ensuring that ovulation occurs only on the unaffected side, is another potential treatment option. Affected animals may maintain pregnancy through use of embryo transfer even if the cow ovulates on the affected side through the administration of human chorionic gonadotropin (hCG) every 10 days, starting 3 days after embryo transfer until an accessory CL is created on the unaffected horn. Some cows affected with segmental aplasia have made successful embryo donors, with unaffected offspring (Strelow L: personal communication, 2005). Heifers that have a persistent hymen as the only abnormality may be treated by creation of a cruciform incision in the hymenal tissue.

NEOPLASIA

Neoplasia affecting the reproductive tract is considered rare in cattle. Most reported cases have been diagnosed in abattoirs at postmortem meat inspection, and a clinical history is rarely available. Tumors that occupy a large amount of the uterine wall or occlude the uterine lumen may result in reduced fertility or abortion.[49,50] The most prevalent tumor type affecting the tubular reproductive tract differs among published series. Rebhun[49] reports that lymphosarcoma is the most common tumor affecting the uterus. Noakes and associates[51] and Roberts[39] suggest benign tumors of the mesenchymal tissues (e.g., leiomyoma, fibromyoma, fibroma) to be most common. In view of the high seroprevalence of BLV in North American cattle[52] and the considerable number of condemned carcasses as a result of systemic lymphosarcoma,[53] it would be expected that this tumor type would be predominant in the United States and Canada. In regions with low seroprevalence of BLV (e.g., Europe, Australasia),[54] it is likely that the benign tumor types would be more prevalent.

Considerations in the differential diagnosis for neoplastic conditions of the tubular reproductive tract include pregnancy (placentomes or fetus), abscess, adhesions, mummified/macerated fetuses, fat necrosis, and tuberculosis. Depending on the tumor type, neoplasia affecting the uterus may appear as singular discrete masses, numerous masses, or thickening of the uterine wall. Leiomyomas are smooth-surfaced, discrete, benign tumors that consist of smooth muscle fibers and collagen and resemble smooth muscle on cut surface. Leiomyosarcomas are locally invasive and may contain areas of necrosis. Fibromas are hard, white, round masses that consist of dense bundles of collagenous fibrous tissue.[55] Adenocarcinomas arise from the uterine wall and do not usually affect mucosal and serosal surfaces. When cut, this tumor type is hard (calcification) and appears white to yellow, and metastases commonly are found in the internal iliac lymph nodes and lungs.[55] Lymphosarcoma can be focal, multifocal, or diffuse, with local lymph nodes usually also affected. Cows that are pregnant and affected by uterine lymphosarcoma typically produce small, nonviable calves.[49] Lymphosarcoma, adenosarcoma, and carcinoma in the reproductive tract may be primary but often tend to be metastatic from a distant site. Definitive diagnosis may be achieved through cytologic examination after biopsy or at postmortem examination.

Partial hysterectomy via flank laparotomy may be considered for management of neoplastic conditions affecting one uterine horn. Leiomyomas and fibromas are the uterine neoplasms most amenable to surgical resection. Early leiomyosarcoma also can be successfully resected if removed before metastasis occurs. Surgical approaches through a ventral midline, caudal flank, or ventrolateral incision have been described.[56,57] The affected uterine horn is exteriorized, and the ovarian pedicle is double-ligated using absorbable suture material and then transected. The broad ligament is dissected from the uterine horn to the site that is most suited for transection (usually the base of the affected horn). The affected horn is removed, and the stump is oversewn with a double-layered inverting suture pattern. Closure of the abdomen is routine. Animals are considered to be suitable surgical candidates if the neoplastic portion of the uterine horn is located cranially, allowing adequate closure of the stump, so as not to affect the patency of the nonaffected horn. Cows have maintained pregnancy after removal of one uterine horn.[57]

INCOMPLETE FUSION OF THE PARAMESONEPHRIC (MÜLLERIAN) DUCTS

Failure of complete fusion of the paramesonephric (müllerian) ducts during reproductive tract development results in a range of abnormalities, mostly affecting the cervix. The most common presentation of this disorder is the development of a double external cervical os (Fig. 48-2). Mild cases result in a vertical band of tissue caudal to the cervix that has little effect on reproduction. Both external openings may join into a normal internal cervical os, or one side may end in a blind diverticulum. This abnormality often goes undetected but occasionally may cause difficulty in passing an artificial insemination pipette or result in dystocia when parts of the calf pass each side of the two external cervical canals. Fertility is reported as normal[39] to subfertile[58] in affected animals. Studies have reported an incidence of between 0.2%[1] and 12.8%[59] of cows with a double cervix. A high incidence

Fig. 48-2 Double external cervical os. (Courtesy of Dr. C.D. Buergelt, University of Florida.)

of this condition has been found in some herds[59] and breeds,[57] but the general prevalence is likely to be low. Inheritance is reported to be due to an autosomal dominant gene with incomplete penetrance[58] or a single autosomal recessive gene with low penetrance and variable expressivity.[59]

The most severe manifestation of the condition is **uterus didelphys**, which involves complete failure of fusion of the paramesonephric (müllerian) ducts, resulting in separation of the uterine horns and a complete double cervix, with a band of tissue extending to the vaginal vestibular junction.[60] Fertility is affected, because semen must be deposited in the cervical os that is ipsilateral to the ovulating ovary. Reports indicate that cows may become pregnant,[61] but on account of the division of the uterine horns, placental attachment in the nongravid horn is impossible, and the pregnancy may not be carried to term.[62]

CHAPTER 49

Bacterial Causes of Bovine Infertility and Abortion

MICHAEL J. YAEGER and LARRY D. HOLLER

Bacteria generally are cited as the most common agents of infection causing abortion in cattle. In large retrospective studies, bacterial infections of the fetoplacental unit were identified in 15% to 16.2% of aborted bovines and accounted for 48% to 58% of abortions caused by infectious agents. Abortion in cattle has been associated with more than 25 different species of bacteria, which vary considerably in their pathogenicity for livestock (Table 49-1). It appears that if a bacterium can survive transit in the maternal bloodstream to reach the fetoplacental unit, it has the potential to cause abortion. The fetus may be particularly susceptible to infection by a wide variety of organisms as a result of its immature immune system and suppression of the immune response at the junction of the maternal and fetal placenta.

Diagnostic laboratory data have provided valuable insight into the relative prevalence of bacterial species that contribute to the development of bovine abortion. Unfortunately, similar information is not available for bacterial causes of infertility. *Campylobacter fetus* spp. *veneralis, Leptospira*, *Mycoplasma, Ureaplasma, Chlamydia,* and *Haemophilus somnus* all have been associated with bovine infertility, but at present the relative prevalence and importance of these agents are unknown.

A number of the bacterial causes of bovine abortion and infertility are potential zoonoses. The agents of these diseases include *Leptospira, Brucella, Listeria, Chlamydia, Salmonella,* and *Campylobacter* spp. Care should be taken in handling and transporting the uterine discharge or products of abortion, to minimize or eliminate opportunities for human exposure.

BOVINE ABORTION CAUSED BY OPPORTUNISTIC BACTERIA

By far the larger portion of this chapter discusses the specific agents recognized as potential causes of bovine abortion. The vast majority of bacterial abortions in cattle (82%), however, are caused by organisms generally considered to be opportunists. These opportunistic organisms fall broadly into two overlapping categories: (1) bacteria that are part of the normal microflora of the mucosal surfaces (*Arcanobacterium pyogenes, Pasteurella multocida, Mannheimia hemolytica, Haemophilus somnus, Escherichia coli, Campylobacter* spp., *Staphylococcus* spp. *Streptococcus* spp.), and (2) common environmental bacteria (*Bacillus* spp., *Pseudomonas* sp, *E. coli*). These ubiquitous bacteria occasionally are able to enter the maternal bloodstream, survive transit to the fetoplacental unit, and cause abortion. Such agents are not considered to be contagious or transmissible causes of abortion.

The significance of isolating one of these agents from an aborted bovine conceptus depends on the incidence of abortion and the clinical signs in the herd. Recovery of any of the aforementioned organisms in isolated abortions generally is of minimal significance from a herd health standpoint. Isolation of one or more species of opportunistic bacteria from fetuses during an outbreak or ongoing abortion problem suggests that (1) access of these ubiquitous organisms to the maternal bloodstream has been enhanced or (2) abortions are a consequence of another disease process.

Although difficult to determine with certainty in retrospect, the occurrence of abortions may be a function of factors that enhance access of ubiquitous bacteria to the maternal bloodstream. Such factors could include subclinical or clinical acidosis (rumenitis), external lesions, or poor feed quality leading to microtrauma in the upper digestive tract. Anecdotal information from diagnostic laboratory submissions would support a link between subclinical or clinical acidosis and bacterial abortion in both dairy and beef cattle.

Pathogens of adult animals, such as *Salmonella, Mannheimia hemolytica, H. somnus,* and *P. multocida,* can cause abortion in one of two ways. With the exception of *Salmonella,* these organisms are ubiquitous members of the normal microflora and can behave as opportunists. They also may cause abortion as a result of disease processes in the adult, in which case abortion is a secondary consequence of the organism's ability to cause enteric or respiratory disease, with bacteremia leading to fetal infection. Although these agents can be considered contagious pathogens, they typically are not classified as contagious causes of abortion.

Diagnosis

Diagnosis is based on the isolation of a moderate to heavy and relatively pure growth of a bacterium from fetal tissues and/or placenta in conjunction with confirmatory gross and microscopic lesions. The four tissues from which bacteria are most commonly isolated are placenta, abomasal contents, lung, and liver. Culture of placenta is somewhat problematic because it often is contaminated by bacteria from the vaginal or vulvar region or the environment. Nonetheless, it is imperative to submit placenta for culture because the infectious process may be con-

Table **49-1**

Bacterial Agents Associated with Abortion or Stillbirth in Cows*

Agent	Frequency (% of total bacteria isolated)
Arcanobacterium pyogenes	29.2
Bacillus spp.	24.8
Listeria	9.4
Escherichia coli	7.6
Leptospira	6.1
Mannheimia hemolytica	2.9
Streptococcus spp.	2.1
Pasteurella multocida	2.0
Salmonella spp.	2.0
Brucella abortus	1.9
Haemophilus somnus	1.6
Staphylococcus spp.	1.6
Campylobacter fetus spp. *veneralis*	1.5
Campylobacter fetus spp. *fetus*	1.3
Pseudomonas spp.	1.2

*Bacterial species encountered in 8962 bovine abortions or stillbirths. Data from Kirkbride CA: Bacterial agents detected in a 10-year study of bovine abortions and stillbirths. *J Vet Diagn Invest* 1993;5:64.

fined to the placenta, so that the organism will not be recovered from fetal tissues or fluids. Gross lesions that may be observed in association with abortions due to opportunistic bacteria include placentitis, fine strands of fibrin covering the viscera, and occasionally epicarditis (in abortion due to *Bacillus* spp.). Microscopic lesions typically include changes characteristic of a placentitis, suppurative fetal bronchopneumonia, and occasionally inflammation of the liver.

Treatment and Control

Control of multiple abortions due to opportunistic bacteria is based on diminishing opportunities for ubiquitous organisms to gain access to the maternal bloodstream and survive transit to the fetus. This is accomplished by optimizing the health status of the cow (nutrition, stress, environment) and addressing factors associated with enhanced access of these bacteria to the maternal bloodstream, such as acidosis, poor feed quality, and presence of external lesions. Control of abortions that occur as a consequence of an infectious process in the dam is based on controlling the underlying disease process in the cow.

BOVINE ABORTION AND INFERTILITY RELATED TO INFECTION BY SPECIFIC PATHOGENS

Brucellosis

Brucellosis once was considered to be the most important reproductive disease of cattle. Today, however, the State-Federal Brucellosis Cooperative Eradication Program, launched in 1934, as well as subsequent programs, has resulted in the elimination of this disease from commercial herds in the Unites States. As of December 2000, no known commercial cattle or bison herds were infected with *Brucella* in the United States. Currently the only remaining focus of brucellosis in the United States is in the Greater Yellowstone Area, which includes Yellowstone National Park, Grand Teton National Park, the National Elk Refuge, and portions of Idaho, Montana, and Wyoming, where free-ranging bison and elk are infected. These animals pose a disease threat to cattle in surrounding brucellosis-free areas and serve as a potential source for disease reintroduction into domestic cattle and bison herds. Transmission from bison to cattle has been demonstrated when *Brucella*-infected bison were penned with unvaccinated, seronegative cattle. Documented cases of natural transmission of *Brucella* from bison or elk to cattle have not been reported, however.

Currently, 46 states, Puerto Rico, and the U.S. Virgin Islands are classified as brucellosis-free, meaning that they have had no infected cattle or domestic bison herds for at least 1 year. Four states—Florida, Missouri, Oklahoma, and Texas–are close to complete eradication of the disease and, with no known infection at this time, are now in the final 1-year countdown phase.

Continued surveillance is necessary to prevent this insidious disease from once again gaining a foothold in U.S. domestic populations. It has been estimated that if brucellosis were allowed to spread, beef and dairy production costs would increase by $80 million within 10 years.

Agent, Source, and Epidemiology

Brucella abortus is a small, nonmotile, nonsporulating, nonencapsulated, gram-negative coccobacillus. Brucellae are facultative intracellular pathogens that are able to survive and multiply within phagocytic cells and lymphoid tissues as a result of their ability to prevent fusion of lysosomes with the phagosome.

The infected cow is the principal source of *Brucella.* The aborted fetus, placenta, and uterine discharge contain large numbers of organisms. Transmission typically is the result of ingestion of the products of a *Brucella*-induced abortion (fetus, placenta, uterine discharge) or ingestion of material contaminated by these products. *Brucella* may be present in uterine discharges beginning 2 weeks before calving or abortion, and lasting 2 to 3 weeks thereafter. The incubation period is quite variable, ranging from 2 weeks to 1 year or longer. The minimum incubation period from infection to abortion is approximately 30 days.

In the bull, *B. abortus* infection may produce orchitis, epididymitis, and inflammation of the accessory reproductive organs. Orchitis may lead to reduced libido and spermatogenesis and impaired fertility. Although the organism can be transmitted in semen, the bull appears to play a minor role in the transmission of *Brucella.*

Pathogenesis

Brucella penetrates the mucosa of the nasal or oral cavities after ingestion. *B. abortus* initially localizes in lymph nodes, infects the gravid uterus during bacteremia, and multiplies to massive numbers in chorioallantoic tro-

phoblasts, leading to trophoblast necrosis and chorioallantoic ulceration. Fetal bacteremia follows replication of *Brucella* organisms in trophoblasts. Once infection is established in sexually mature animals, it tends to persist indefinitely. Not all infections result in abortion, however, and less than 20% of infected cows abort more than once.

Intracellular replication in chorioallantoic trophoblasts is responsible for the massive accumulation of *B. abortus* in the placenta. The growth of *Brucella* organisms in trophoblasts may be enhanced by their erythritol and/or hormone content, because both erythritol and progesterone augment the growth of *B. abortus* in vitro.

Clinical Signs

The primary sign of brucellosis is abortion. Abortions generally occur after the fifth month of gestation. Retained placenta and metritis are frequent sequelae to abortion. *Brucella*-infected cows also may give birth to weak calves that die shortly thereafter.

Pathology

The most consistent lesion observed in the conceptus is placentitis. In severe cases, the intercotyledonary placenta may be dry, thickened, and cracked and has been described as having the appearance of Moroccan leather. The intercotyledonary placenta may be covered by a thick, yellowish exudate. Cotyledons may demonstrate foci of necrosis and be covered by an exudate. Fetal lungs occasionally are enlarged, firm on palpation, and covered by fine strands of fibrin.

Diagnosis

A definitive diagnosis of *Brucella* abortion requires isolation of the organism from fetal tissues or uterine discharge. The organism can be readily isolated from fetal abomasal contents, lung, placenta, and uterine fluids. It also may be recovered from colostrum, milk, and meconium. In the face of suspicious lesions and negative culture results, immunohistochemistry (IHC) studies can be used to confirm *Brucella* infection. After a diagnosis of *Brucella* abortion, additional infected animals generally are identified by serologic testing. Such testing may not identify all infected animals, because up to 15% of infected cows do not seroconvert until after abortion or calving.

A new systemic vaccine for brucellosis, Strain RB51, has been approved for use in cattle. The advantage of this vaccine is that it induces a protective response without stimulating the development of antibodies that react with standard assays based on *B. abortus* LPS oligosaccharide side chains.

Treatment and Control

Control of brucellosis traditionally has been based on vaccination of calves to reduce the population at risk, control of cattle movement to diminish the spread of disease, and testing to identify reactors. Currently, treatment has no role in the control of bovine brucellosis. Brucellosis is a reportable disease, and regulations require herd quarantine and elimination of all reactors. The current focus of brucellosis control is on surveillance, with rapid elimination of new *Brucella* infections.

Campylobacter fetus spp. *veneralis* Infection

Bovine genital campylobacteriosis is a sexually transmitted disease caused by the gram-negative, microaerophilic rod *Campylobacter fetus* subsp. *veneralis*. This organism is an obligate parasite of the bovine reproductive tract. Bulls are asymptomatic carriers. The clinical effects of infection are manifested in the cow. Historically, campylobacteriosis has been one of the most important sexually transmitted diseases of cattle. Economic losses are the result of poor conception rates, increased culling due to infertility, decreased average weaning weights, and increased management costs related to prolongation of the calving season.

Agent, Source, and Epidemiology

Campylobacter fetus spp. *veneralis* is an extracellular, motile, gram-negative, microaerophilic rod. Cattle constitute the primary host and main reservoir for this organism. Reproductive tract infection in cows and young bulls typically is transient. Bulls younger than 3 years of age tend to be resistant to infection and clear the organism within a few weeks. Mature bulls (4 years of age and older) become chronic carriers.

The disease is transmitted by coitus. The transmission rate from infected bulls to susceptible cows may approach 100%. Infected bulls may carry the organism in the preputial cavity indefinitely. Bulls do not become permanent carriers until they are at least 4 years of age, however, and most not until 5 to 6 years of age. The development of epithelial crypts in the penile mucosa with advancing age provides a favorable habitat for the bacteria. Because infection in young bulls is transient, transmission by these animals relies on sexual contact with an infected cow. Bull-to-bull transmission can occur from contaminated semen collection equipment or through mounting activity when bulls are held in common areas.

Cows become infected after natural service by an infected bull or after insemination with contaminated semen. Infection may be spread from cow to cow through the use of poorly sanitized instruments used for reproductive procedures. Infected cows develop immunity and generally clear the organism within 3 to 6 months of infection, and in a majority of cows, *Campylobacter* will not survive a normal gestation. Some persistently infected cows may harbor the organism for over a year, however, and it has been recovered from cows as long as 196 days beyond the end of pregnancy initiated by infected semen. Failure to eliminate the infection may be due in part to the organism's ability to undergo substantial antigenic change during the course of natural infection. After clearance of infection, cows are resistant to reinfection for a short period of time.

Pathogenesis

The disease is transmitted by coitus. After exposure, the anterior vagina and cervix are colonized, and the infection spreads to the uterus and oviducts within 12 to 14

days. Infection typically does not interfere with fertilization and early embryonic development. Uterine infection leads to early embryonic death as a result of the inflammatory response in the uterus and oviducts. The clinical manifestations of infection in the female seem to depend on the number of organisms contained in the original infective dose and on the rate of multiplication within the uterus. Rapid replication occurs most commonly, causing death of the developing embryo or fetus on days 15 to 80. Because embryonic death typically takes place after maternal recognition of pregnancy (days 15–17), the dam's return to estrus will be delayed. Less rapid replication leads to midterm abortion. *Campylobacter fetus* spp. *veneralis* is progressively eliminated from the oviducts and uterus, and fertility returns. Frequently, however, the organism persists in the cervix and vagina for several more months, during which time the cow remains a source of infection.

Clinical Signs

Detection of clinical signs is dependent on how closely the herd is monitored. Although rarely observed, infection is associated with vaginitis, cervicitis, and endometritis. In closely monitored herds, an increased number of repeat breeders will be identified. The hallmark of *Campylobacter* infection is irregular and delayed returns to estrus. "Infertility" is actually the result of early embryonic death. Herd pregnancy rates will be low (40%–70%), and a wide range of gestational ages may be found at the time of pregnancy examination. Less than 10% of infected cows will abort a detectable fetus. Cows typically abort between the fourth and seventh months of gestation. In *Campylobacter*-endemic herds, clinical signs are most commonly seen in young cows or newly introduced animals.

Pathology

We emphasize that this organism does not cause specific gross lesions in the aborted fetus or placenta. A history of infertility accompanied by a low number of midterm abortions is more indicative of the potential for *Campylobacter* abortion than of gross lesions. Aborted fetuses typically have a placentitis, which is consistently identified microscopically, but gross evidence for a placentitis is variable and often inconspicuous. Changes characteristic of a suppurative fetal pneumonia and hepatitis often are observed on microscopic examination of fetal tissues.

Diagnosis

Diagnosis is based on (1) isolation of the organism, (2) demonstration of the agent in fetal tissues, preputial scrapings, or vaginal mucus with direct fluorescent antibody (FA) tests, or (3) detection of antibodies in vaginal mucus by an enzyme-linked immunosorbent assay (ELISA) or agglutination tests.

Infertility. A definitive diagnosis typically is based on isolation of the organism under microaerophilic conditions on selective media. Culture of preputial scrapings tends to be more productive than that of preputial washes because the organism resides deep in the preputial crypts. Culture of vaginal mucus is most useful when samples are obtained early in the course of infection and when the cows are in estrus. The recovery rate drops substantially in chronically infected cows.

Proper handling of samples is necessary to optimize organism recovery. A transport medium should be used, such as Clark's transport media or Weybridge TEM. Practitioners should contact their regional diagnostic laboratory for media and specific transport recommendations.

Serologic diagnosis of campylobacteriosis is not practical because infection does not stimulate the production of sufficient serum antibody levels to be accurately measured by commercial methods. Genital tract infection in the cow, however, stimulates local immunity, which can be detected by the vaginal mucus agglutination test or an ELISA measuring immunoglobulin A (IgA) antibodies. Both of these tests are used most appropriately on a herd rather than individual animal basis. An indirect FA assay may be used to detect the organism in preputial scrapings from bulls.

Abortion. A rapid, presumptive diagnosis can be made by the identification of small, motile organisms with rapid, darting movement on darkfield examination of stomach contents. This is a screening test for *Campylobacter* and does not differentiate *C. fetus* spp. *veneralis* from *C. fetus* spp. *fetus* or *Campylobacter jejuni*. A definitive diagnosis is based on isolation of the organism from placenta or fetal lung or stomach contents. Metabolic profiles are used to differentiate the various *Campylobacter* species that can be isolated from aborted bovines.

Treatment and Control

Control is based on the following factors: (1) transmission is venereal, (2) older bulls become permanently infected, (3) infected cows typically become immune 3 to 6 months after infection, and (4) vaccination of cows and bulls is both prophylactic and curative.

In uninfected herds, the following measures can help prevent introduction of the disease:

Avoid open range with mixing of cattle.
Avoid leasing/purchasing mature bulls unless they have been thoroughly tested for venereal diseases.
Keep fences in good repair to prevent introduction of unwanted animals.
Restrict replacement animals to virgin bulls and virgin heifers.

> Cows in the late stages of gestation or unbred cows with young calves at their sides are unlikely to be infected. Because of the financial ramifications of introducing this disease into a naive population, vaccination is recommended when the risk of disease introduction is increased.

Once the disease is diagnosed, control is based on identifying and eliminating chronic sources of infection and preventing reinfection. Bulls are the primary source of chronic infection. Blood culture for *Campylobacter* is indicated for all nonvirgin bulls 6 to 8 weeks before the breeding season, and all seropositive animals should be culled. For valuable bulls, treatment is an option. In young bulls, vaccination and sexual rest typically result in elimination of the organism within a few weeks to several months. Therapeutic immunization can extend

the age of natural resistance in young bulls and aid in eliminating infection in bulls up to 5 years of age. Older, chronically infected bulls may be treated. A topical ointment containing 10 g neomycin and 4 g erythromycin in 200 g of carbowax has been reported to be effective when applied to a thoroughly cleaned and exteriorized penis and prepuce for three treatments repeated at 24-hour intervals.

A reliable vaccine is available for campylobacteriosis, and vaccination of cows and bulls can be used for both prevention and elimination of this disease. A unique feature of immunization against *C. fetus* spp. *veneralis* is that it affords dramatic protection against an extracellular, noninvasive pathogen of the genital mucosa—an unusual feature of vaccination. Vaccination against this organism, however, results in both protection against subsequent infection and cure of chronic infection in bulls up to 5 years of age and in cows. In infected herds, all breeding stock, including bulls, should be vaccinated. Animals are initially vaccinated twice, 2 to 4 weeks apart and at least 30 days before start of the breeding season, followed by annual vaccination.

Because campylobacteriosis is a venereally transmitted disease, cessation of natural breeding and the use of artificial insemination techniques for at least two breeding seasons after infection is detected, with appropriate precautions including addition of antibiotics to semen extender and careful sanitation between animals, has been used to eliminate herd infections.

Haemophilus somnus Infection

Haemophilus somnus has been associated with a complex of diseases including thromboembolic meningoencephalitis, polyarthritis, pneumonia, myocarditis, and infections of the reproductive tract. The organism is a common inhabitant of the bovine vagina and is an important cause of vaginitis and endometritis.

H. somnus has been isolated from field cases of abortion, and abortion has been experimentally reproduced at all stages of gestation with the organism. Available evidence, however, indicates that *H. somnus* is not a major cause of abortion in cattle. *H. somnus* was not recovered from aborted fetuses in two large retrospective studies and was identified in only 0.23% of aborted bovines in a third. Documented outbreaks of *H. somnus* abortion are rare, and a majority of abortions due to this agent appear to be sporadic.

The status of *H. somnus* as a cause of infertility is controversial. Studies had demonstrated that *H. somnus* can adhere to the zona pellucida of intact embryos and cause degeneration. These studies, along with epidemiologic information, suggest that *H. somnus* may be capable of causing infertility. Conversely, additional epidemiologic investigations have discounted the ability of *H. somnus* to cause infertility, and attempts to experimentally reproduce infertility with *H. somnus* have not been successful. Because of common presence of this organism in the vaginal or vulvar region and its ability to cause vaginitis/metritis, *H. somnus* is in an ideal position to contribute to infertility. Its association with herd infertility problems, however, has been tenuous.

Agent, Source, and Epidemiology

H. somnus is a gram-negative, non–spore-forming coccobacillus. The bovine reproductive tract is the likely reservoir for this organism because it is a common component of the normal bacterial flora of the male and female genital tract. A 80% to 90% genital carrier rate has been reported in bulls. Except for infrequent reports of infertility and poor semen quality, the organism does not seem to cause significant reproductive disease in bulls. *H. somnus* has been isolated from the genital tract of up to 57% of healthy cows. The organism can remain in the vagina for long periods without clinical signs. Organisms are shed in urine or discharges to contaminate the environment.

Spread to other animals appears to be the result of contamination of the environment by respiratory or vaginal discharges and urine. Reports indicate that carrier bulls can infect cows, and the organism is readily spread by natural breeding.

Pathogenesis

Infertility probably is the result of the effect of *H. somnus* on the developing embryo. As noted earlier, *H. somnus* can adhere to the zona pellucida of intact embryos and cause degeneration. It was able to induce detrimental effects on bovine embryos without causing significant uterine lesions.

Abortion due to *H. somnus* has been experimentally reproduced by intravenous, intratracheal, and intra-amniotic inoculation of the organism. Abortion probably is secondary to hematogenous dissemination following vaginal or respiratory infection. Laboratory studies do not support ascending infection through the cervix.

Pathology

Recognizable gross lesions in the conceptus generally are confined to the placenta and consist of a necrotizing to necrosuppurative placentitis with associated placental edema. Reports indicate that *H. somnus* has the same affinity for the vascular system in the fetus as in the adult, and microscopic examination of placenta and fetus generally will reveal vasculitic changes.

Diagnosis

Infertility. Caution must be exercised when *H. somnus* is considered as a cause of infertility. Although isolation of the organism is essential to confirm a diagnosis, its mere presence in the vagina does not signify clinical disease. A consistent correlation between isolation from the vagina and inflammatory lesions has not been identified. *H. somnus* should be considered as a potential cause of infertility when a heavy growth is isolated from animals with post-breeding endometritis, vaginitis, and purulent vaginal discharge. Care should be taken to rule out other causes of infertility including trichomoniasis, ureaplasmosis, venereal campylobacteriosis, and infectious pustular vulvovaginitis.

Abortion. Diagnosis is based on recovery of the organism from the placenta or fetus. Isolation of a heavy and pure growth of the organism from fetal tissues generally is diagnostic. Isolation of a light growth from the placenta could be due to contamination in the birth canal,

however, and culture results should be interpreted in conjunction with clinical confirmation of placental lesions, particularly vasculitis.

Treatment and Control

Infertility. Antibiotic treatment has been reported to increase fertility in herds affected with *H. somnus*–induced vulvovaginitis. *H. somnus* is sensitive to most antibiotics at therapeutic levels, including second- and third-generation penicillins, florfenicol, tetracycline, and sulfas. Treatment with florfenicol or ceftiofur has lead to good clinical response. Vaccination also has been reported to result in a return to a normal reproductive schedule within several months.

Abortion. Because *H. somnus* reaches the conceptus by hematogenous dissemination, vaccination probably would be of value in preventing abortion due to this agent. Controlled studies to determine the efficacy of vaccination for the prevention of abortion have not been undertaken, however. Because *H. somnus* typically causes sporadic abortions, vaccination to specifically prevent abortion is rarely warranted.

Leptospirosis

Leptospira abortion in cattle is not a single disease with common risk factors, epidemiology, host response, or means of control. It can be separated into relatively distinct syndromes depending on whether disease is caused by host-adapted strains or whether the cow is an incidental or accidental host. Cattle are a maintenance host for hardjo. A maintenance host relationship is characterized by efficient transmission between animals, a relatively high incidence of infection, production of chronic rather than acute disease, and persistence of infection in the kidney and genital tract (BP). Diagnosis of infection in maintenance hosts often is difficult because of a relatively low antibody response and the presence of few organisms in tissues. Infection of incidental or accidental hosts leads to acute disease, sporadic transmission within the host species, and a short phase of renal infection. Incidental infections are typified by a marked antibody response, with large numbers of organisms in the tissues of infected animals.

Agent, Source, and Epidemiology

Organisms of the genus *Leptospira* are small aerobic spirochetes that can be found in a wide variety of animal species (parasitic strains) and in water (saprophytic strains). Pathogenic leptospires were formerly classified as members of the species *L. interrogans*. The genus has recently been reorganized, and pathogenic leptospires are now identified in seven different species. Greater than 200 different serovars have been identified throughout the world.

Each serovar tends to be maintained in specific maintenance hosts. Hardjo is the serovar maintained in cattle. Two major genotypes of hardjo are found in cattle: **hardjobovis** and **hardjoprajitano.** Serovar pomona is maintained in swine and a variety of free-living animals and is the most important source of incidental infection of cattle in the United States, Australia, and New Zealand.

Transmission among maintenance hosts often involves direct contact with infected urine, placental fluids, or milk. Transplacental and venereal transmission also can occur. Infection of incidental hosts typically is acquired by indirect means, such as contact with water sources or an environment contaminated by the urine of maintenance hosts. The relative importance of incidental infections is dependent on management and environmental factors, which determine the opportunity for contact and transmission of the organism from other species to cattle. Warm, moist conditions with a pH near neutral favor the survival of leptospires. Because of this, infection by incidental leptospires is most common in spring, summer, or fall in temperate regions. Environments favorable to the survival of leptospires are much less important in the epidemiology of host-maintained species.

Pathogenesis

Infection of susceptible animals occurs through the mucous membranes of the eyes, nose, vagina, and penis and through abraded or water-softened skin. A bacteremic phase follows after a 4- to 10-day incubation period. This phase typically is subclinical, but bacteremia may be associated with acute clinical disease. After leptospiremia develops, the organism localizes to and persists in a number of organs, including the kidney and the genital tract of males and females. Leptospires are shed in urine and in the postcalving uterine discharge. They also may localize in the testes and accessory glands and can be demonstrated in bull semen. Venereal transmission of hardjo in cattle is common.

Leptospires localize and multiply in the proximal tubules and are voided in the urine. With hardjo infection in cattle, the organism is shed consistently in urine for 4 to 6 weeks and intermittently for 6 to 12 months. Shedding in urine may persist for life. Urinary shedding with hardjoprajitano is of very low intensity, and the venereal route probably is more important. Localization and persistence of the organism in the uterus may result in fetal infection with subsequent abortion, stillbirth, or birth of a weak calf.

Clinical Signs

The vast majority of leptospiral infections in nonpregnant cattle are subclinical. Fetal infection will result in abortions, stillbirths, and the birth of weak calves. Hardjo and pomona are the most commonly implicated serovars. Abortion occurs 1 to 6 weeks (pomona) to 4 to 12 weeks (hardjo) after the acute phase of infection. Pomona abortions generally occur in the last trimester. Hardjo may cause infertility, or abortion from 4 months of gestation to term. The incidence of abortion on individual farms can be very high (up to 50%) after an epizootic of pomona infection. Abortion rates tend to be much lower with hardjo (3%–10%) but occasionally may approach 30%. Infertility has been a common field observation in hardjo-infected herds. Infertility apparently responds to vaccination and treatment.

Pathology

Consistent gross lesions are not identified. Occasional fetuses appear jaundiced. Microscopic lesions may be observed in the kidney and consist of foci of tubular necrosis with interstitial and perivascular infiltrates of lymphocytes and a few plasma cells. Renal inflammation is not specific for leptospirosis because other agents, including *Neospora,* may cause similar lesions. Bile plugs in canaliculi may be identified in the liver.

Diagnosis

Diagnosis of *Leptospira* abortion is based on demonstration of leptospires in fetal tissues or the identification of a serologic response in the dam or the fetus. Because isolation and identification of leptospires constitute a specialized, difficult, and time-consuming process, it is rarely undertaken as a routine diagnostic procedure. Kidney generally is the tissue of choice for diagnosing *Leptospira* infection in the fetus, and the organism can be identified by a direct FA test on fresh, minimally autolyzed kidney or with IHC studies on fixed kidney. Postmortem autolysis can limit the usefulness of both IHC and FA tests. PCR assay appears to be the most sensitive procedure to diagnose leptospiral abortion but is not widely available.

The fetus is able to mount a serologic response by 4 to 5 months of gestation. Because maternal antibody does not cross the placental barrier, the presence of leptospiral antibodies in fetal thoracic fluid is indicative of in utero infection.

Interpretation of results of *Leptospira* serologic studies in the dam is complicated by a number of factors, including cross-reactivity of antibodies, vaccination titers, and differences in response to host-adapted versus non–host-adapted serovars. Paired serum samples from aborting cows typically are of no value, because titers are either maximal (for non–host-adapted strains), falling, or static at the time of abortion (for host-adapted strains). A finding of high titer (≥1 : 1000) at the time of abortion in an individual animal that has not been recently vaccinated suggests a strong possibility of *Leptospira* abortion; high titers are common after abortion due to non–host-adapted strains. Unfortunately, the converse is not true. Approximately one third of cows that aborted *Leptospira*-infected fetuses had low titers (<1 : 100). Often, at the time of abortion, antibody titers are quite low, or antibody may even be undetectable, in maintenance hosts. Maintenance hosts may be actively infected and shedding leptospires with antibody titers of 100 or less. For chronic hardjo infections, the chance of fetal infection is approximately 60% in a recently aborting cow with a titer of 300 or greater, 80% with a titer of 1000 or greater, and 90% with a titer of 3000 or greater. A herd test approach is not very useful for the diagnosis of hardjo-associated abortion in endemically infected herds, because low titers are common after abortion. The presence of bleeding in 10 animals, or 10% of the herd, with the identification of titers to hardjo of 300 or greater indicates active infection but is not necessarily diagnostic for *Leptospira* abortion.

Treatment and Control

Control of both incidental and host-maintained leptospirosis is based on vaccination and limiting exposure. To limit exposure to non–host-adapted leptospires, it is desirable to reduce contact with wildlife, control rodents, and eliminate access to potentially contaminated water sources (such as by fencing off sloughs, ponds, and streams). Vaccination against incidental serovars generally provides good protection against challenge.

Control of host-adapted strains is more difficult. In outbreaks, antibiotics can be used to try to diminish exposure by decreasing or eliminating shedding. A variety of antibiotics, including streptomycin, tetracycline, erythromycin, tiamulin, and tylosin, have been reported to be effective against leptospires. The most effective antibiotic, streptomycin, can no longer be used in cattle in the United States, however. Antibiotics may diminish shedding but have been disappointing as a means of eliminating infection.

Annual vaccination with a polyvalent product typically is the foundation of a *Leptospira* control program. The first vaccination should be administered after the age of 6 months. Animals should initially be vaccinated twice, followed by annual vaccination. In problem herds, twice-yearly vaccination may be necessary because of the often short-duration, low-titer immunity. Because the predominant vaccine strain of hardjo is hardjoprajitano, vaccines may not provide good protection against hardjobovis.

Listeria Infection

The principal diseases caused by *Listeria monocytogenes* in ruminants include encephalitis, abortion, and neonatal septicemia. It is the exception for different conditions to occur in the same flock or herd. *Listeria* is widely distributed in nature, having been isolated from soil, vegetation, decaying vegetation, water, feces, sewage sludge, and tissues from a wide variety of vertebrate and invertebrate species. Especially in temperate regions, exposure to *L. monocytogenes* is common, although disease is not.

In pregnant animals, *Listeria* has a predilection for fetoplacental tissues. Fetal infection results in abortion, generally during the last trimester. Because of the ubiquitous nature of the organism, *Listeria* may cause sporadic, individual animal abortions. Outbreaks of *Listeria* abortion are more common in the winter and generally are the result of ingestion of *Listeria*-contaminated feed, particularly improperly cured silage. Although abortion rates of up to 50% have been reported, the abortion rate rarely exceeds 15%.

Agent, Source, and Epidemiology

L. monocytogenes is a gram-positive coccobacillus. The genus *Listeria* contains five species, of which *L. monocytogenes* is the principal pathogen. Bovine abortions are most commonly caused by serovars 1 and 4b. *Listeria ivanovii* occasionally has been associated with bovine abortion.

The natural habitat of *L. monocytogenes* appears to be the environment, and the organism is widespread. Ingestion of *L. monocytogenes* results in an animal-environmental cycle, and during an outbreak of listeriosis, the bacterium can be isolated from the feces of a large

percentage of healthy animals. The aborted fetus, placenta, and uterine discharge contain myriad *Listeria* organisms, and contamination of food or water sources with this material may be a source of infection for other animals.

Most outbreaks of listeriosis have been traced to feeding pregnant animals spoiled feeds containing massive numbers of *Listeria* organisms, most commonly improperly cured or spoiled silage. The bacteria can proliferate in rotting vegetation, in which aerobic conditions and a pH higher than 5.4 are more likely. Additional sources of *Listeria* include decayed forage at the bottom or corners of feed bunks and rotted hay at the periphery of hay bales or haystacks. The incidence of disease due to *Listeria* is increasing, possibly as a result of changes in the handling of bulk feedstuffs, which may lead to a greater degree of spoilage.

Pathogenesis

L. monocytogenes is capable of entering cells of the monocyte-macrophage series, escaping from the phagosome, multiplying within the cytoplasm, and spreading between cells. Crucial to the virulence of *L. monocytogenes* is its ability to escape intracellular killing within macrophages by lysis of the phagosomal membrane and move into the cytoplasm, which is mediated by the secretion of a hemolysin, listeriolysin.

Oral infection does not consistently produce abortion. Abortion is readily produced by the intravenous inoculation of pregnant ruminants. Fetal infection is considered to be the result of hematogenous spread from the placenta. The incubation period from infection to abortion is typically 5 to 12 days.

Clinical Signs

A majority of *Listeria* abortions occur during the last trimester, although abortion may occur as early as the fourth month of gestation. *Listeria* abortions differ from many other bacterial abortions in that clinical signs often are present in the cow before, during, and after abortion. These include weight loss, fever, an inflammatory leukogram, endometritis, and retained fetal membranes. The effect on fertility usually is transient, and aborting animals tend to resist reinfection. In herds experiencing *Listeria* abortions, encephalitis seldom occurs in conjunction with reproductive disease.

Pathology

Affected fetuses often are retained in utero for several days before expulsion and typically are autolyzed. Abortion is the result of an acute placentitis with subsequent fetal septicemia. Although often difficult to visualize owing to autolysis, placental lesions may consist of pinpoint, yellowish foci involving the tips of cotyledonary villi with focal to diffuse intercotyledonary placentitis. The fetus usually is autolyzed, and miliary foci of necrosis may be seen in the liver or spleen. These foci may be confused with necrotizing lesions associated with IBR abortion.

Diagnosis

Diagnosis is based on isolation of the organism from fetal tissues or placenta. Unlike in *Listeria* encephalitis, in which culturing the organism from brain may be difficult, *Listeria* is readily recovered from fetal tissues and placenta—the fetus typically dies as a result of a septicemia, so that bacteria are present in high numbers in all tissues and fluids, placenta, and the uterine discharge. Microscopic lesions may consist of an acute placentitis and necrotizing to necrosuppurative hepatitis. Bacterial colonies often are observed in the lumen of vessels throughout the fetus and in the center of hepatic lesions.

Gram staining of fetal fluids or tissue impression smears will reveal numerous gram-positive, pleomorphic coccobacilli. A polyvalent (serotypes 1 to 4) FA conjugate is available for the identification of organisms in impression smears. Presence of *Listeria* in fixed tissues also can be confirmed by IHC studies.

The importance of *L. monocytogenes* as a food-borne pathogen had earlier prompted the development of reliable and highly discriminating typing methods for epidemiologic purposes. These include DNA fingerprinting and pulsed-field gel electrophoresis. The use of molecular methods has enabled the discrimination of individual strains of *Listeria,* which could aid in investigating potential sources of the organism in epizootics.

Treatment and Control

The connection between *L. monocytogenes* and silage feeding is well established. The wide distribution of the organism in nature makes it unlikely that silage will be totally free of *Listeria*. Therefore, an emphasis should be put on proper curing of silage and elimination of the feeding of spoiled material to pregnant animals.

Because *Listeria* is an intracellular parasite, killed vaccines have not been effective. Modified live vaccines have shown promise in other species but at present are not available for use in cattle. If potentially contaminated material must be fed to pregnant animals, therapeutic doses of antibiotics, such as tetracycline, can be added to the feed or water. Antibiotic therapy is contraindicated in dairy herds because of the problem of residues in the milk.

Mycoplasma and *Ureaplasma* Infection

Considerable field and experimental evidence is available to support the ability of *Ureaplasma diversum* and *Mycoplasma* spp. to cause infertility and abortion in cattle. Unfortunately, a diagnosis of infertility due to these agents is complicated by the fact that they may be normal inhabitants of the urogenital tract of cows and bulls and frequently are isolated in the absence of disease.

Field studies have linked *Ureaplasma diversum* to vulvitis, infertility, and abortion, and all three syndromes have been experimentally reproduced. Apparent outbreaks of *Ureaplasma*-induced infertility have been reported, with conception rates as low as 20%. Reproductive problems may persist for up to 6 months. *Ureaplasma* also has been associated with bovine abortion. Unfortunately, few diagnostic laboratories routinely attempt to isolate *Ureaplasma* from aborted fetuses, so current understanding of the importance of this agent as a cause of abortion is based largely on information from a single laboratory. Over a 7-year period beginning in

1994, *Ureaplasma* abortion was diagnosed in 2.3% (range 0.9–3.9%) of aborted bovines at this laboratory. *Ureaplasma* was the second most common bacterial cause of abortion reported during this period, trailing only *A. pyogenes* (3.0%). The incidence of *Ureaplasma* abortion has been reported to be as high as 10%.

Mycoplasma bovigenitalium has been linked to granular vulvovaginitis, endometritis, and infertility in the cow and seminal vesiculitis in the bull. *M. bovis* infects the reproductive tract of bulls less commonly than *M. bovigenitalium*. *M. bovis* may represent a more important danger after venereal transmission, however, because of its proven pathogenicity for the cow's reproductive tract. Endometritis, salpingitis, infertility, and abortion have been produced by *M. bovis* in experimentally infected cows. Seminal vesiculitis, epididymitis, and orchitis due to *Mycoplasma* infection have been reported in bulls.

A variety of mycoplasmas have been isolated from aborted bovine fetuses. Only *M. bovis* (and *Mycoplasma mycoides*) has consistently caused abortion when inoculated into pregnant cows. *Mycoplasma* spp. appear to be an uncommon cause of abortion in cattle. In one large prospective survey, *Mycoplasma* organisms were not isolated from any of the 794 fetal samples evaluated. Reports typically associate *Mycoplasma* infection with sporadic abortions.

Agent, Source, and Epidemiology

Both *Ureaplasma diversum* and *Mycoplasma* spp. belong to the family Mycoplasmataceae and are small (0.3–0.8 μm in diameter), cell wall–deficient, pleomorphic organisms. *M. bovigenitalium* and *U. diversum* are commonly carried in the vulva and vagina of females and in the distal urethra, prepuce, and semen of males. *Ureaplasma* also is commonly carried in the nasal passages. These organisms are readily transmitted by natural breeding and contaminated insemination. Additional modes of transmission include direct contact, infection during passage through the birth canal, and environmental contamination by urine from infected animals.

Pathogenesis

Salpingitis commonly is observed in cattle with *Mycoplasma* or *Ureaplasma* infection. The induction of salpingitis, cervicitis, and endometritis after natural service or artificial insemination is the likely mechanism of infertility.

Clinical Signs

In the cow, clinical signs associated with *Ureaplasma* infection include granular vulvitis, infertility, and abortion. In utero *Ureaplasma* infection also has lead to the birth of weak calves. Direct inoculation with *Ureaplasma* organisms has produced seminal vesiculitis in bulls, and an association with posthitis has been reported. *Mycoplasma* infection of the reproductive tract may result in granular vulvovaginitis, infertility, and abortion.

Pathology

In cases of *Ureaplasma* abortion, the intercotyledonary chorioallantois is thickened, opaque, and white to brown, and the cotyledons may be cupped. Histologic examination reveals placentitis characterized by a mononuclear inflammatory cell infiltrate accompanied by fibrosis, necrosis, and mineralization with associated vasculitis of chorioallantoic and amniotic vessels. Nonsuppurative alveolitis with hyperplasia of bronchiolar-associated lymphoid tissue also is generally apparent.

Placentitis, suppurative fetal bronchopneumonia, and subacute myocarditis and epicarditis have been reported in cases of *Mycoplasma* abortion.

Diagnosis

Infertility. The first step in establishing a diagnosis of infertility due to *Mycoplasma* or *Ureaplasma* is isolation of the organism. Unfortunately, this initial step is fraught with a number of pitfalls. These organisms are fastidious, and the special procedures and expertise required for their isolation are not available at all laboratories. Because of the fragile nature of both organisms, proper collection techniques and preservation are essential. To isolate either *Mycoplasma* or *Ureaplasma* organisms, Dacron- or polyester-tipped swabs should be used to collect vulvar and vaginal samples. Areas of active vulvar inflammation tend to be the most productive. Swabs should be immediately submersed in transport medium (without charcoal) and frozen. Samples must remain frozen until arrival at a laboratory. PCR assay also has been used to detect *Ureaplasma* or *Mycoplasma* organisms but typically is not available for routine diagnostic procedures. Caution must be exercised when either *U. diversum* or *M. bovigenitalium* is under consideration as a cause of infertility, because both are commonly isolated from healthy animals, and concurrent evaluation for other causes of infertility is warranted.

Abortion. Preferred specimens for the isolation of *U. diversum* or *Mycoplasma* spp. include lung, caruncle, cotyledon, stomach contents, and amniotic fluid. These samples should be immediately refrigerated and presented to a laboratory the same day or immediately frozen and shipped frozen. Isolation of either organism from the conceptus is significant only in conjunction with clinical confirmation of characteristic lesions.

Treatment and Control

Artificial insemination may play a role in *Ureaplasma*-induced infertility. *Ureaplasma* can be carried into the uterus during artificial insemination; subsequent infection of the upper reproductive tract may lead to infertility. Use of a guarded insemination instrument is of value in preventing uterine contamination. Tetracycline (1 g), administered by intrauterine infusion 1 day after insemination, has been used to improve fertility in herds with confirmed *Ureaplasma*-related reproductive problems. Tylosin (10 mg/kg) for 5 days was reported to be an effective treatment for *Ureaplasma*-induced vulvitis and posthitis.

Fluoroquinolone antibiotics, such as enrofloxacin, have shown promise against mycoplasmas and may be useful for the treatment of reproductive disease caused by *Mycoplasma* spp. Tylosin and tetracycline also typically demonstrate good activity against *Mycoplasma* spp.

Chlamydia Infection

In cattle, chlamydial infection has been associated with keratoconjunctivitis, pneumonia, enteritis, polyarthritis-polyserositis, encephalomyelitis, mastitis, seminal vesiculitis, infertility, and abortion. Unlike in sheep and goats, in which this organism is one of the most important causes of abortion, the paucity of reports in cattle suggests that *Chlamydia* is an uncommon pathogen of the bovine reproductive tract. In one study in which more than 250 fetuses were evaluated, *Chlamydia* was not identified in a single aborted bovine.

Agent, Source, and Epidemiology

Chlamydiae are obligate, intracellular parasites that multiply within the cytoplasm of eukaryotic cells. The life cycle has two distinct forms: **elementary bodies** (200–300 nm), which are involved in attachment and penetration of susceptible host cells, and **reticulate bodies** (500–1000 nm), which are the replicating form. Reticulate bodies mature into a new generation of infectious elementary bodies, which are then released by cell lysis. Strains of *Chlamydia* associated with genital tract infections in the bovine typically are immunotype 1.

In ruminants, the intestinal epithelium appears to be an important natural habitat for *Chlamydia*. Persistent intestinal infections are common in cattle, sheep, and goats. The organism may be shed in feces, nasal, ocular, or vulvar discharges or in uterine fluids, placenta, or urine. Infection may be established by ingestion or inhalation of these materials.

Chlamydia has been identified in the testes, epididymis, accessory sex glands, kidney, semen, and urine of experimentally inoculated bulls. Infertility and repeat breeding were reported in cows bred by bulls naturally shedding chlamydiae in semen.

Pathogenesis

Infertility. *Chlamydia* does not appear to interfere with fertilization, nor does it penetrate the zona pellucida. The agent multiplies within endometrial cells, leading to endometritis. Uterine inflammation is the likely mechanism of early embryonic death.

Abortion. The placental junction is breached during chlamydemia, which results in placental and fetal infection. Cows inoculated intravenously with *Chlamydia* organisms aborted within 5 to 38 days, whereas pregnant cows inoculated by the intramuscular, subcutaneous, or intradermal route aborted or gave birth to weak calves 33 to 126 days later.

Clinical Signs

Chlamydia infection has been associated with infertility, repeat breeding, and abortion. Chlamydial abortions typically are sporadic, although in some herds as many as 20% of pregnant cows may abort. Abortion has been detected as early as the fifth month of gestation, but most occur during the last trimester. The birth of weak calves also has been reported in association with *Chlamydia* infection. Retained placentas have been observed after both experimental and natural abortions.

Pathology

The hallmark of chlamydial abortion is a placentitis, which is manifested as thickening and necrosis of the intercotyledonary placenta with necrosis of cotyledonary villi. A necrotizing vasculitis with edema often is observed in the placenta. Late-gestation fetuses also may exhibit abdominal distention due to ascites; an enlarged, swollen, mottled red-yellow liver; and diffuse lymph node enlargement.

Diagnosis

A diagnosis of chlamydial abortion relies on demonstration of the organism in fetal tissues or placenta, the detection of antibodies in fetal thoracic fluid, or the demonstration of a serologic response in the dam. Sample selection is of primary importance for the diagnosis of chlamydial infection. Preferred samples include placenta or the discharge from a recently aborting cow. *Chlamydia* is less consistently identified in fetal liver or lung. A tentative diagnosis can be based on the identification of small, intracytoplasmic organisms in Gimenez-stained placental impression smears. A definitive diagnosis is based on positive identification of *Chlamydia* with FAs on placental impression smears, or detection of the agent in uterine discharge, placenta, fetal lung, or liver by culture, antigen-capture ELISA, or PCR assay. These procedures also can be used to detect chlamydiae in semen or uterine discharges in cases of infertility. IHC studies have been used to identify chlamydiae in fixed placenta or liver.

Delivery of a *Chlamydia*-infected fetus stimulates a rapid rise in antibody titer that reaches maximum levels 14 to 21 days after the termination of pregnancy. Accordingly, paired serum samples obtained at the time of abortion and 2 to 3 weeks later should have a significant rise in titer. Because chlamydial infection typically causes late-gestation abortion after chronic infection of the fetus, seroconversion often can be demonstrated in fetal fluids and is diagnostic for chlamydial abortion.

Treatment and Control

Vaccines have been used to prevent chlamydial abortion in other species. An approved vaccine is not available for use in cattle, however. Use of vaccines intended for other species may not be effective owing to antigenic differences between strains. Chlamydiae are susceptible to tetracycline, and this antibiotic has been used both as a preventive and for treatment in other species. Because premonitory signs are absent and *Chlamydia* infection typically is associated with only sporadic abortions in cattle, however, the use of tetracycline for prevention generally is not warranted.

Viral Diseases of the Fetus

CLAYTON L. KELLING

BOVINE VIRAL DIARRHEA VIRUS INFECTIONS

Bovine viral diarrhea virus (BVDV) is one of the most commonly encountered and economically important pathogens of cattle in North America. Since the mid-20th century, BVDV has been recognized as a significant cause of disease of the gastrointestinal system. The impact of BVDV on reproduction was not perceived for another 30 years, when the occurrence of persistent infection in immunotolerant cattle was described.

BVDV infections may occur in cattle as acute illness—that is, bovine viral diarrhea (BVD)—or as a generally chronic condition—mucosal disease. When susceptible pregnant cattle are infected with BVDV, transplacental infections usually occur. Transplacental infections may lead to embryonic or fetal death and abortion, to developmental defects of organs, or to development of immunotolerance and establishment of persistent infections. Acute BVDV infections contribute, through immunosuppression, to causing multifactorial diseases, such as diseases of the respiratory and enteric tracts in susceptible calves.

Clinical Forms of Infection with Bovine Viral Diarrhea Virus

The clinical form of BVDV infection—inapparent or severe BVD, reproductive failure, persistent infection, or mucosal disease—observed within a herd is dependent on interaction of several factors at the time of infection. These determining factors include the biologic properties of the virus, the age and stage of gestation of pregnant cattle, level of immunity of the herd, and the interplay of stressors.[1]

Acute Infections

BVD is an acute postnatal infection in seronegative, immunocompetent cattle. The clinical severity of acute BVDV infections is variable, but a majority of postnatal BVDV infections are inapparent. Milder forms of BVD are characterized by high morbidity, low mortality, a normal host immune response, and minimal mucosal lesions. Usual findings include pyrexia, nasal discharge, and transient leukopenia. Viremia lasts for 3 to 10 days (acute infections with higher virulence isolates may result in viremia of longer duration) and antibody titers rise slowly

CHAPTER 50

Viral Diseases of the Fetus

CLAYTON L. KELLING

BOVINE VIRAL DIARRHEA VIRUS INFECTIONS

Bovine viral diarrhea virus (BVDV) is one of the most commonly encountered and economically important pathogens of cattle in North America. Since the mid-20th century, BVDV has been recognized as a significant cause of disease of the gastrointestinal system. The impact of BVDV on reproduction was not perceived for another 30 years, when the occurrence of persistent infection in immunotolerant cattle was described.

BVDV infections may occur in cattle as acute illness—that is, bovine viral diarrhea (BVD)—or as a generally chronic condition—mucosal disease. When susceptible pregnant cattle are infected with BVDV, transplacental infections usually occur. Transplacental infections may lead to embryonic or fetal death and abortion, to developmental defects of organs, or to development of immunotolerance and establishment of persistent infections. Acute BVDV infections contribute, through immunosuppression, to causing multifactorial diseases, such as diseases of the respiratory and enteric tracts in susceptible calves.

Clinical Forms of Infection with Bovine Viral Diarrhea Virus

The clinical form of BVDV infection—inapparent or severe BVD, reproductive failure, persistent infection, or mucosal disease—observed within a herd is dependent on interaction of several factors at the time of infection. These determining factors include the biologic properties of the virus, the age and stage of gestation of pregnant cattle, level of immunity of the herd, and the interplay of stressors.[1]

Acute Infections

BVD is an acute postnatal infection in seronegative, immunocompetent cattle. The clinical severity of acute BVDV infections is variable, but a majority of postnatal BVDV infections are inapparent. Milder forms of BVD are characterized by high morbidity, low mortality, a normal host immune response, and minimal mucosal lesions. Usual findings include pyrexia, nasal discharge, and transient leukopenia. Viremia lasts for 3 to 10 days (acute infections with higher virulence isolates may result in viremia of longer duration) and antibody titers rise slowly

for 3 months after infection.[2] Severe acute BVD outbreaks with marked thrombocytopenia, hemorrhages, and high mortality rates have been associated with infection with high-virulence BVDV isolates.

Acute BVDV infections contribute to causing multifactorial diseases through immunosuppression. Immunosuppression is mediated by suppression of immune functions through the lymphotropism of BVDV. BVDV lymphotropism results in depletion of lymphocytes from lymphoid tissues. Immunosuppression due to BVDV infection enhances the severity of bovine rotaviral enteritis in calves, in addition to directly causing enteritis.[3] BVDV-induced immunosuppression predisposes calves to development of naturally occurring bovine respiratory tract disease (BRD). Indirect effects of BVDV in causing BRD were demonstrated in experimental bovine respiratory syncytial virus (BRSV) and BVDV co-infections in which more severe respiratory tract and enteric disease occurred than in infections with either virus alone.[4] Subpopulations of lymphocytes were more markedly altered in peripheral blood and lymphoid tissues from co-infected calves than in calves infected with either BRSV or BVDV alone. Co-infected calves had a reduction in the percentage of T lymphocytes (including $CD8^+$ lymphocytes and $CD4^+$ lymphocytes) in the thymus and Peyer's patches.[5] An additional finding in these calves was more extensive pneumonia, characterized by caudodorsal as well as cranioventral interlobular edema, emphysema, and bronchopneumonia in caudal lung lobes. By contrast, calves infected with BRSV alone had only cranioventral bronchopneumonia.

Transplacental Infection

Transplacental infection is likely to occur in susceptible, pregnant cattle infected with BVDV. The outcome of transplacental infection is dependent on the biologic properties of the infecting virus, especially the biotype of the virus, and the stage of gestation at the time of infection. The potential outcomes of transplacental infections—embryonic or fetal death and abortion, developmental defects of organs, and development of immunotolerance with establishment of persistent infections—are discussed later in the chapter.

Persistent Infection

Fetal infection with noncytopathic BVDV can result in the birth of calves with persistent BVDV infection. The primary means of producing a persistently infected calf is through transplacental infection after a primary acute infection in a pregnant cow, although persistently infected cows (i.e., congenitally infected) also will give birth to persistently infected calves. Persistently infected animals shed large amounts of virus and are therefore carriers and a primary source of exposure for susceptible cattle.[6] In most instances they do not produce detectable antibodies to BVDV, because they are immunotolerant to the virus. Some calves with persistent infection are stunted or weak at birth, have poor growth rates, and die at a young age.[7] Others appear healthy and survive to maturity. The prevalence of cattle with persistent infection is variable; however, on the basis of sampling of randomly selected herds, it has been estimated that 4% of herds in the United States have persistently infected calves.[8] Such animals are at risk of developing mucosal disease.

Mucosal Disease

Mucosal disease, associated with high mortality rates, occurs sporadically (low morbidity) in cattle that usually are between 6 months and 2 years old but may be of any age. Characteristic clinical manifestations include anorexia, pyrexia, diarrhea, loss of condition, and death.[2] Gross pathologic lesions may include erosive or ulcerative lesions on the muzzle and lips, buccal mucosa, and tongue. Commonly, elongated ulcerative lesions occur in the mucosa of the esophagus. Erosions also may be found on the rumen pillars, reticulum, and abomasum. Enteritis may be evident and may vary in presentation from catarrhal to hemorrhagic to erosive/ulcerative. Peyer's patches and lymphoid tissue in the proximal colon may be hemorrhagic.[9] Thymus atrophy and enlarged peripheral lymph nodes are prominent features.

Biologic Properties of Bovine Viral Diarrhea Virus

BVDV is a member of the genus *Pestivirus,* family Flaviviridae,[10] which also includes border disease virus of sheep and hog cholera virus. Pestiviruses are small, enveloped, single-stranded, positive-sense RNA viruses that are antigenically related.

The host range for BVDV comprises domestic or wild ruminants and swine. Pestiviruses are presumed to persist in the environment for no more than two weeks, and are readily inactivated by common disinfectants. Therefore, virus transmission is primarily vertical or by inhalation or ingestion of material contaminated with infected body secretions and excretions (saliva, oculonasal discharge, urine, feces, semen, uterine secretions, placenta, and amniotic fluid) of infected animals.

Isolates of BVDV vary in their relative virulence potentials, which accounts in part for variability in severity of lesions and clinical disease among different cases.[11] BVDV isolates are divided into two biotypes (groups of viruses with the same genetic composition) based on their ability to induce microscopically visible changes (vacuolization and lysis) in host cells in vitro: cytopathic and noncytopathic. BVDV strains are divided into two genetic groups or genotypes—1 and 2—using gene sequencing techniques and cross-neutralization assays. RNA viruses, including BVDV, are prone to mutate; therefore, BVDV has high potential to mutate in response to selective immune pressure. Mutation is the putative strategy used by BVDV to escape the host's immune response and to persist in the cattle population. Antigenic diversity among field isolates has important implications for development of protective immunity.

Biotypes: Noncytopathic and Cytopathic

The two biotypes of BVDV, cytopathic and noncytopathic, have separate biologic roles[2]; biotype differences are important in disease pathogenesis. Both biotypes of BVDV infect cattle and cause disease, but only the noncytopathic isolates cause persistent infections. Isolates

that have the ability to cause microscopically visible changes in host cells (vacuolization and lysis) are assigned to the cytopathic biotype. Isolates lacking this capability are assigned to the noncytopathic biotype. Cells infected with cytopathic BVDV have an 80-kilodalton (kD) polypeptide that is distinguishable electrophoretically from cells infected with noncytopathic viruses, which do not have the polypeptide.[12] This 80-kD nonstructural viral protein apparently plays a crucial role in replication of cytopathic viruses. Diversity in antigenicity among strains is not discretely separable. No link exists between biotype and antigenicity, and strains that are antigenically distinct overlap both biotypes, so protective immunity afforded by a vaccine is not dependent on the biotype of the vaccine virus.

In the laboratory, the presence of noncytopathic BVDV constitutes a significant quality control issue for workers in diagnostic laboratories as well as for manufacturers of vaccines. This is because noncytopathic BVDV isolates commonly occur in commercial fetal calf sera used to supplement cell culture media used in cell cultures to grow viruses. In the diagnostic laboratory, when noncytopathic BVDV occurs undetected as a contaminant of cell culture, accuracy of diagnostic laboratory assays, such as virus isolation tests and serum neutralization tests, is compromised. Noncytopathic BVDV contamination of modified live virus vaccines during the manufacturing process has represented a significant risk factor since these products were introduced.[13] The potential for contamination of cell cultures with noncytopathic BVDV is a continual concern, because between 20% and 50% of commercial fetal bovine serum lots are virus positive[14] for both genotypes.[15] Fetal bovine serum quality assurance procedures applied before use in diagnostic laboratory testing or in cell culture production systems to grow vaccine virus include rigorous virus testing followed by the additional precautionary measure of irradiation or chemical treatment.[14]

Genotypes

BVDV strains are divided into two genetic groups or genotypes using gene sequencing techniques and cross-neutralization assays.[16,17] Genotype 1 isolates are primarily classic laboratory reference and vaccine strains. Genotype 2 viruses are found predominantly in fetal bovine serum, persistently infected calves born to dams vaccinated against BVDV, and the more recently described BVDV strains associated with high mortality and acute and peracute infections involving hemorrhage. Biotype, genotype, and antigenic cross-reactivity vary independently,[18] as do biotype, genotype, and pathogenicity.[19] The antigenic differences between genotype 1 and genotype 2 isolates and the clinical importance of genotype 2 BVDV isolates constitute the basis for the recognition that to be effective, vaccines must provide broad cross-protective immunity against both genotype 1 and 2 isolates.

Outcomes of Fetal Infections with Bovine Viral Diarrhea Virus

BVDV enters the susceptible host primarily by the oronasal route and replicates in tonsils, lymphoid tissues, and epithelium of the oropharynx. Phagocytic cells take up BVDV or virus-infected cells, or both, for transport to lymphoid tissues.[20] Viremia is evident 2 to 4 days after exposure. Viremia in a pregnant female is certain to lead to transplacental infection and fetal infection. The outcome of fetal infections with BVDV is determined primarily by the stage of fetal developmental at the time of infection, and by biotype and virulence of the infecting virus.[21] The stage of development of the evolving fetal immune system at the time of infection plays a major role in determining the outcome of infections.[21] Transplacental infections are particularly damaging during the first two trimesters of gestation and may result in persistent infections, fetal death and abortion, or congenital developmental defects.[22] Persistent infection in calves is the most significant outcome of fetal infection because of the negative effects such infection has on herd production. Persistently infected calves are the most important source of virus to perpetuate disease within and between herds. Moreover, persistently infected calves usually have poor growth rates and die at a young age. Reproductive failure mediated by abortion and birth of calves with congenital abnormalities also are significant outcomes of fetal BVDV infections that adversely affect herd performance.

Persistent Infections

Persistent BVDV infections may be established if infection of the fetus occurs during the third or fourth month of gestation before immunocompetence becomes established.[21,23] Viremia of the pregnant dam, stemming from either a persistent or an acute infection, is the source of the virus that infects the fetus. Before infecting the fetus, BVDV replicates in the placenta. Persistent viremia develops as a result of fetal immunotolerance and failure to develop antibodies against the persisting virus.[6] Persistently infected calves are carriers because they are viremic and shed virus continuously, and they may spread virus within and between herds. The level of viremia may decline with the development of neutralizing antibody and become undetectable as the animal ages[24] as a result of deterioration of highly specific immunotolerance to the persisting virus.[25] Deterioration of immunotolerance, eventuating in an immune response, may result from development of antigenic-variant viruses within the immunotolerant, persistently infected animal.[25] Persistently infected calves frequently are "poor doers," have reduced growth rates, are more susceptible to common calfhood infections of mucosal surfaces including pneumonia and enteritis, and are at risk of developing mucosal disease.[26,27]

Abortion

BVDV infections of fetuses during the first and second trimesters may cause fetal death and abortion. Third-trimester abortions also have been attributed to BVDV infection.[21] Individual isolates probably vary in their ability to cause abortion. The rate of abortion under field conditions is variable, but abortion rates as high as 40% have been reported after experimental infections on day 100 of gestation.[22]

Congenital Defects

Congenital defects may result if infection occurs during midgestation (100–150 days). Congenital defects associated with BVDV infections may involve the nervous system (microencephaly, cerebellar hypoplasia, hydranencephaly, hydrocephalus, and hypomyelination), eye (cataracts, retinal degeneration, optic neuritis, and microphthalmia), immune system (thymic aplasia), integumentary system (alopecia and hypotrichosis), musculoskeletal system (brachygnathism, growth retardation, and arthrogryposis), or respiratory system (pulmonary hypoplasia).[28] The pathogenetic mechanisms for development of defects are not known. Because fetal organs and immune system (inflammatory response) are developing during this stage, direct cell damage by viral infection and destruction of virus-infected cells by the evolving immune system are possible mechanisms.[21]

Late-Gestation Transplacental Infections

The outcome of BVDV infections during late gestation (last trimester) is comparable with that with acute postnatal infections of cattle. At this time the fetal immune system has developed to respond efficiently against BVDV infection. Consequently, transplacental infections during late gestation are not associated with a significant level of congenital defects. Third-trimester abortions have been attributed to BVDV infection.[21] The most common outcome of infections during this period is birth of a clinically normal calf with high levels of precolostral antibodies.[21,22]

Diagnosis of Bovine Viral Diarrhea Virus Fetal Infections

Identification of Persistently Infected Cattle

Persistently infected carrier cattle are identified in herds on the basis of tests conducted in a diagnostic laboratory. The tests include (1) the virus isolation (VI) test, (2) the immunohistochemistry (IHC) test, (3) the polymerase chain reaction (PCR) assay, and (4) the enzyme-linked immunosorbent assay (ELISA).

Virus isolation test. The standard VI test format (macrotest), a highly reliable test,[7,29] is not practical for testing a large herd. The standard VI test may be used to test mononuclear cell preparations (buffy coats) from blood samples collected in tubes with anticoagulants. The cells are washed to limit interference from antibodies, which reduce test sensitivity. An adaptation of the standard VI test is the immunoperoxidase microtiter plate VI assay, which is relatively sensitive and specific and is designed to efficiently test large numbers of serum samples, such as in herd testing programs.[30,31] Blood is collected for virus isolation from calves that are 2 months of age or older, when maternal antibody titers have declined, because maternal antibodies reduce the ability to isolate BVDV from the serum of younger persistently infected cattle.[7,29]

Immunohistochemistry test. The IHC test is conducted on skin biopsy specimens (ear notches) collected from animals of any age, fixed in formalin, and submitted to the diagnostic laboratory.[32–34] The fixed skin specimens are sectioned, stained, and examined for the presence of BVDV antigen. The IHC test, like the VI test, has excellent sensitivity and specificity.[34] Sensitivity of IHC studies is not affected by the presence of maternal antibody, so calves of any age, including newborn calves, may be tested.[34,35]

Polymerase chain reaction assay. The PCR assay may be used to test individual animals (serum, whole blood, or skin samples) or to screen entire herds by testing pooled samples such as bulk tank milk or pooled serum samples for the presence of carrier cattle.[36] The BVDV PCR assay is highly sensitive, but a potential complication with the assay is lack of test specificity, so that false positive results are possible from nonspecific reactions with contaminating viral RNA (unpublished observation). It is therefore advisable to confirm positive BVDV PCR assay results with VI tests.[35]

Enzyme-linked immunosorbent assay. The ELISA may be used to test individual blood samples for the presence of BVDV antigen. The antigen-capture ELISA compares closely with virus isolation techniques for detection of persistently infected cattle using blood samples routinely submitted for BVD diagnosis. The test format is adapted to a microtiter plate assay, which permits efficient testing of large numbers of serum samples.[31,37]

Aborted Fetuses

Diagnosis of BVDV as the cause of abortion is not unequivocal, because fetal infection may not result in abortion. Therefore, the presence of virus, viral antigen, or BVDV antibody in an aborted fetus does not confirm that BVDV was the cause of abortion.[28] The entire fetus should be submitted to a diagnostic laboratory for complete testing because of the complexity of the factors to be considered in conclusively establishing BVDV infection as the cause of abortion or, conversely, in ruling out BVDV infection as the cause of abortion. Diagnosis of BVDV as the cause of abortion is based on evidence of BVDV infection of the fetus (presence of virus, antigen, or RNA in tissues, or antibody in serum or exudates), in conjunction with clinical confirmation of microscopic lesions, most often in fetuses aborted before 4 months of gestation. Microscopic lesions attributable to fetal BVDV infection include a necrotizing inflammatory reaction with mononuclear cell infiltration in several tissues.[38] Other features may include lymphoid depletion of the cortex of the thymus, precocious development of secondary lymphoid tissue, and peribronchiolar lymphonodular hyperplasia. The cerebellum is affected with necrosis and depletion of cells and infiltration of mononuclear cells. Microfocal lesions may be seen in the oral mucosa and in the skin. Skin lesions are characterized by hyperkeratosis and parakeratosis. BVDV antigen may be deposited in lymphoid tissues and in the cerebellum.[9] Demonstration of rising BVDV antibody titers in paired serum samples from dams may be not be possible. This is because antibody titer may have already increased at the time of abortion because of the time lag from infection of the dam to abortion. Identification of BVDV in a fetus in the absence of lesions provides useful information regarding the temporal occurrence of BVDV within the herd.

Congenital Developmental Defects in Term Calves

Diagnosis of BVDV as the cause of congenital developmental defects in term calves is based on evidence of transplacental BVDV infection in combination with presence of characteristic clinical signs and gross or microscopic lesions. Evidence of transplacental BVDV infection is obtained by culture of BVDV or detection of BVDV antigen or RNA. Antibody in serum collected from a calf before it has ingested colostrum also constitutes evidence of transplacental BVDV infection. Calves born with cerebellar hypoplasia have difficulty standing and exhibit a wide-based stance, and are ataxic. Blindness may result from congenital defects of the eye. Ophthalmic examination may be performed to reveal the presence of cataracts. Calves may be born weak and undersized subsequent to fetal growth retardation due to BVDV infection.[28] Gross lesions involving the nervous system, eye, immune system, integumentary system, musculoskeletal system, or respiratory system are described in greater detail earlier in the chapter. It is prudent to exercise caution in attributing these lesions to BVDV without demonstrating virus or viral antibody, because other causes for many of these lesions exist. Unfortunately, the virus frequently is cleared by the time calves are born. Presuckle serum is useful for diagnostic applications.

Late-Gestation Transplacental Infections

The presence of BVDV antibody titers in serum collected from normal term calves before they have ingested colostrum indicates that infection occurred late in gestation after the fetus developed immunocompetence.

Screening Herds without a History of BVDV Infection

A herd that does not have a history of BVDV infection may be screened to determine if BVDV infection is active in the herd (i.e., determine if animals with either acute or persistent infections are present). One screening approach that limits the expense of testing, as well as labor requirements, is testing for the presence of antibodies to BVDV in a representative subset of nonvaccinated, sentinel cattle[39] that are at least 8 months old.[40] The presence of BVDV antibodies in any of these animals indicates that one or more acutely or persistently infected animals are present in the herd.[40,41] The absence of BVDV antibodies indicates that carrier cattle that shed virus, both acutely and persistently infected animals, are not present—the herd is BVDV-free. PCR assays of the somatic cells of bulk-tank milk is another approach that has been used in dairy herds to screen for evidence of carriers with persistent BVDV infection among lactating cows.[36]

Prevention and Control

The goal of a BVDV control program is to prevent fetal infection to eliminate BVDV-associated reproductive losses and the birth of persistently infected calves. Control of BVDV infection is best achieved by avoiding persistently infected carrier cattle and acutely infected cattle, and by maintaining sound immunization practices. Elimination of persistently infected carriers from the herd is accomplished by testing the herd and by closing the herd to incoming animals that are potentially persistently infected carriers or acutely infected, transient virus shedders. Identification and removal of persistently infected cattle require accurate herd-based diagnostic laboratory testing.[42]

Detection and Removal of Persistently Infected Carrier Cattle

Removal of persistently infected cattle from a herd and prevention of reintroduction of persistently infected cattle into a herd are essential herd management procedures because persistently infected cattle are the primary source of infection for a herd. Selection of replacement breeding cattle on the basis of performance effectively eliminates some persistently infected cattle from the herd on the basis of poor growth rates. Other persistently infected animals may be eliminated from herds because of the shortened lifespan sometimes associated with persistent infection in cattle. Some persistently infected cattle, however, may have normal growth rates[21,39] and normal lifespans and accordingly be retained in the breeding herd. Consequently, the importance of using laboratory tests to ensure detection and removal of all persistently viremic cattle from a herd is clearly evident. Seed stock producers, especially breeders of purebred cattle, should be strongly encouraged to test their animals and remove persistently infected carrier animals from their herds.[35]

The greatest proportion of persistently infected animals in BVDV-infected herds are calves younger than 6 months of age.[43] Initially, calves are tested, rather than dams, because if calves are tested, information about the persistent infection status of the calves and about that of their dams is obtained simultaneously. This is because persistently infected dams always give birth to persistently infected calves. IHC testing of skin biopsy specimens (ear notches) is recommended for this procedure. Testing and removal of persistently infected calves from the herd must be completed before the breeding season begins, to prevent contacts of persistently infected calves with pregnant cows, so as to prevent transplacental infection, production of persistently infected calves, and perpetuation of infection within the herd. In addition to testing calves, replacement heifers, cows not calving, bulls, and dams of any calves that test positive must be tested.[35]

Biosecurity

Before implementation of an extensive BVDV testing program in a herd, the potential for re-exposure of a BVDV-free herd to BVDV infection after completion of a persistently infected carrier testing and removal program must be considered. Introduction of BVDV infection into a herd may occur by contact with cattle from other herds or with addition of animals to herds. Requirements for a BVDV biosecurity program are that all purchased cattle be tested for persistent infection status or originate from a BVDV-free herd. Purchased replacement animals should be isolated and tested before being added to the herd to avoid introduction of acutely-infected animals. The offspring of purchased pregnant replacement cattle must also be tested to confirm their BVDV persistent infection–free status before being added to the herd.[40,44] Seed

stock producers are obligated to maintain a BVDV-free herd by maintaining strict biosecurity practices, including testing of all animals in their herd to warrant BVDV-free status.[35]

Vaccination and Immunity

The goal of immunization is to prevent infection of target organs such as the fetus. This is accomplished by inducing both the B and T cell arms of the immune system. Free virus is inactivated by the B cell arm of the immune response, by neutralization of BVDV infectivity by immunoglobulin, and secondarily by aggregating virions and enhancing clearance. Infected cells that have potential to release infectious virus are eliminated by T cells.[45]

Optimally, vaccines should provide broad cross-protective immunity that protects the fetus against all field strains of BVDV. Vaccines do provide significant protection against fetal infection, which will limit reproductive disease, including production of persistently infected calves. Vaccines do not provide absolute fetal protection, however. Results of experimental challenge vaccine studies have shown that no BVDV vaccine can induce complete fetal protection, and birth of persistently infected calves in vaccinated cows has been reported in the field. Consequently, vaccination should not be relied on completely to provide protection against fetal infection. Management practices also should be implemented to identify persistently infected carrier cattle and eliminate them from the herd, and to avoid exposure to BVDV infection.[35,46]

Modified live virus vaccines against BVDV activate systemic and local, humoral and cell-mediated immune responses. Immunity induced by modified live virus vaccine generally is more cross-reactive than that induced by inactivated vaccines. Cross-reactivity is important for BVDV immunity because the potential for antigenic variation exists. Other advantages of modified live virus vaccines include longer duration of immunity and a reduced requirement for repeated administration of vaccine. Disadvantages of these vaccines are immunosuppressive properties and the potential to cause severe fetal anomalies and disease attributable to vaccine contamination with adventitious BVDV. Another disadvantage is the potential for restoration of virulence of the virus during infection. Experimental challenge-exposure studies have demonstrated a reasonable degree of protection against fetal infection using a modified live virus vaccine.[47]

Inactivated vaccines are neither immunosuppressive nor fetopathogenic. Inactivated vaccines also offer the advantage of immunization with minimal risk of infection. In general, disadvantages of inactivated BVDV vaccine may be a need for increased frequency of administration due to a weaker neutralizing antibody response and shorter duration of protection.

Timing of vaccination. The best general recommendation for control of BVDV disease includes avoiding addition of replacement animals that are persistently or transiently infected, avoiding purchase of pregnant cattle, removal of carrier cattle from the herd, and adherence to a vaccination schedule based on use of both modified live virus and inactivated BVDV vaccines. It must be recognized that live, replicating vaccines (i.e., modified live virus vaccines) have certain inherent properties (see preceding discussion of benefits of modified live virus vaccines versus inactivated vaccines) that may enable them to induce more complete protection against transplacental infection. Therefore, it may be wise to recommend vaccination of unstressed, healthy heifers, isolated from pregnant cows, with modified live virus vaccine. All replacement heifers should be vaccinated twice with modified live virus before breeding. In non-vaccinated animals, modified live virus vaccines should be administered three estrous cycles (i.e., 2 months) before breeding. Administration of inactivated vaccines to heifers before breeding should be timed so that maximal responses are achieved. Booster vaccinations should be administered in accordance with the vaccine manufacturer's recommendation.

It may be difficult to time vaccination in a dairy herd to avoid use of modified live virus vaccines on premises with pregnant animals, because dairy cows typically are at various stages in their reproductive cycles. Beef calves, weaned at 5 to 7 months of age, typically are seronegative or have low titers of maternal antibody at weaning time.[7] Thus, calves should be immunized before weaning so that they are protected at weaning when they enter concentration points at which a high risk of infection exists.[46]

BOVINE HERPESVIRUS-1 (INFECTIOUS BOVINE RHINOTRACHEITIS VIRUS) INFECTION

Bovine herpesvirus-1 (BHV-1) is well recognized as a pathogen that infects the respiratory and reproductive tracts and also infects the fetus, potentially leading to abortion. BHV-1 infects cells of the upper respiratory tract, causing rhinitis, conjunctivitis, and tracheitis. Respiratory tract infections with BHV-1 also may contribute to establishment of bacterial bronchopneumonia by impairing host defenses, such as by diminishing lung clearance mechanisms and by immunosuppression. If infection occurs in nonimmune pregnant females, systemic infection, fetal infection, and abortion are the likely consequences. Genital infections may result in development of pustular vulvovaginitis in females or balanoposthitis in males. Genital infections, characterized by formation of variable numbers of small nodules, vesicles, focal erosions, or ulcers visible on inflamed mucosal membranes, occur transiently and resolve spontaneously in 1 to 2 weeks.

Important Biologic Properties of the Virus

BHV-1 is a member of the family Herpesviridae, subfamily Alphaherpesvirinae. In addition to causing a range of clinical diseases, it also can establish latent infections localized in trigeminal and sacral ganglia.[48] Latent BHV-1 can become reactivated under certain circumstances such as stress or after corticosteroid treatment.[48] Vaccination with most modified live virus vaccines has the potential to produce latent infections. Because of viral latency and reactivation, cattle that recover from BHV-1 infec-

tions may serve as a source for future infection of unexposed cattle. BHV-1 is fairly resistant to environmental influences and can survive for 5 to 13 days in warmer environments, but because the virion is enveloped, it is susceptible to most disinfectants.[49] Only one serotype of BHV-1 is recognized.

Infection by BHV-1 is transmitted by direct contact with upper respiratory, conjunctival, or genital tract mucous membranes. Infected animals shed virus from respiratory mucous membranes and secretions, or genital mucous membranes and secretions, for 8 to 16 days after exposure.[49] The virus is present in all fetuses aborted as the result of BHV-1 infection, and these fetuses can serve as a source for transmission of disease.[50,51] Venereal transmission and the use of contaminated semen or instruments during artificial insemination are the primary means for transmission of these genital infections. BHV-1 can be isolated from the semen of exposed but clinically normal bulls, and this should be considered when exposed bulls are used either for natural breeding of unexposed cows or as semen donors.[48]

Fetal Infection and Abortions

When BHV-1 respiratory tract infections occur in nonimmune pregnant females, the likely outcomes are viremia and subsequent fetal infection and abortion.[50] Exposure of multiple susceptible animals in a herd can result in abortion storms, with as many as 25% to 60% of cows in a herd aborting.[51–53] Sporadic abortions also may be seen, particularly in herds with a previous history of vaccination or exposure. Abortions also can occur when pregnant cattle are vaccinated with conventional modified live virus vaccines.[54]

BHV-1 abortions may occur at any gestational stage, but naturally occurring abortions are most common between 4 and 8 months of gestation.[51–53,55] Aborting cattle may be subclinically infected or exhibit overt clinical disease. When clinical signs are present in aborting cows, they usually manifest as respiratory tract disease or conjunctivitis.[55] Abortions are rarely seen in conjunction with infectious pustular vulvovaginitis.[50] Abortions often do not occur for several weeks after appearance of clinical signs in the dam. The incubation period in one group of pregnant heifers, experimentally infected intravenously, ranged from 17 to 85 days.[56] The mechanism for this latent period between maternal exposure and abortion is unknown, although some evidence suggests that the virus may reside in the placenta for extended periods before infecting the fetus proper, without causing abortion.[51]

Diagnosis of Abortion

BHV-1 infection of the fetus results in rapid fetal death (24–48 hours), but expulsion is delayed for up to 7 days, with consequent autolysis of tissue of variable degree. The placenta often is retained. Gross changes in the aborted fetuses often are obscured by autolysis, but tiny (1- to 3-mm-diameter) white-tan foci may be evident on the surface of liver and lung. Red-tinged serous fluid in body cavities and red color of fetal tissues reflecting the autolysis usually are evident. The placenta may be edematous.[52]

BHV-1 abortions can be confirmed by immunohistochemical tests and microscopic examination of fetal tissues. Microscopically, scattered foci of necrosis in several organs may be present, which can lead to a presumptive diagnosis of BHV-1 abortion. In particular, foci of necrosis may be found in the liver, spleen, adrenal glands, lung, kidneys, and placental cotyledons. Herpesviral intranuclear inclusions may be present in cells adjacent to necrotic foci but usually are masked because of autolysis. Little or no inflammatory cell infiltrate is found in fetal tissues, reflecting the rapidly lethal effects of BHV-1 fetal infection. The diagnosis can be confirmed either by detection of BHV-1 viral antigen or viral nucleic acid or by isolation of the virus from fetal tissues. Viral isolation may be difficult, depending on the degree of fetal autolysis; placental cotyledons are the preferred tissue for virus isolation attempts if autolysis of fetal tissue is extensive.[51]

The BHV-1 antigen can be detected in cryostat tissue section–fluorescent antibody tests (especially kidney and adrenal) and from paraffin-embedded formalin-fixed tissues (especially liver, lung, kidney, adrenal, and placenta) by immunohistochemistry studies.[57] Viral nucleic acid has been detected in aborted fetuses by in situ hybridization[58] and by PCR assay.[59] Determination of BHV-1 antibody titers on paired maternal serum samples is of little help in diagnosing BHV-1 abortions. Most abortions occur several weeks after infection of the dam, so increases in antibody titers will have occurred before abortion. Maternal antibody titers indicate exposure, but without demonstration of rising antibody titers, it is not possible to confirm recent BHV-1 infection.

Prevention and Control

Prevention and control of BHV-1–induced abortion in herds are achieved primarily by implementation of sound biosecurity practices and by vaccination. Biosecurity practices should include control of movement of new stock into a breeding herd to eliminate the possible introduction of BHV-1 into a susceptible herd. Screening of semen used in artificial insemination for BHV-1 contamination and selection of seronegative donor bulls are recommended measures to prevent venereal transmission.[60] Eradication programs have been established in certain European countries, such as Switzerland, Denmark, and the Netherlands.[61]

Vaccination commonly is practiced to prevent and control BHV-1 infection because of the high prevalence of BHV-1.[51] Numerous BHV-1 vaccines are commercially available and include both modified live virus and inactivated vaccines. Manufacturers' recommendations should be followed to achieve optimal immune responses and to avoid potential adverse effects associated with their use. Most modified live virus vaccines can cause all of the manifestations of BHV-1 infection in the bovine reproductive tract.[62] Because of the risk of vaccine-induced abortions and exposure of susceptible dams, most modified live virus vaccines are not recommended for use in pregnant cattle or calves suckling pregnant

cows. Inactivated vaccines are safe for use in pregnant cattle. If modified live viruses are routinely employed, the timing of injections can be scheduled to reduce the risk of vaccine virus–induced abortion or transmission of virus to susceptible animals. In beef herds, heifers may be vaccinated before the beginning of breeding season. In dairy cattle, the simplest means of reducing such risk is to vaccinate heifers only before breeding (4–6 months of age, and again at 8–12 months) and to vaccinate postpartum heifers and cows at the time of routine postpartum examinations. These animals are not pregnant and tend to be housed with like animals. Furthermore, routine vaccination should result in development of a "herd immunity," so that likelihood of transmission of vaccine virus to susceptible cattle is reduced.[63]

BLUETONGUE VIRUS INFECTION

Bluetongue virus is an orbivirus that infects cattle and sheep; in North America, it is transmitted by the biting midge, *Culicoides variipennis*.[64] The midge becomes persistently infected with bluetongue virus and may transmit virus for several weeks.[65] Bluetongue virus infection of cattle is common in endemic areas of the world, which correspond to the geographic distribution of the vector. Bluetongue virus is not contagious, and vertical transmission is not important, so perpetuation of the virus in nature is dependent on continuous cycling of virus between the insect vector and susceptible ruminant animals.[66] Cattle are considered to be natural reservoir hosts of bluetongue virus. Although bluetongue virus is common in cattle in endemic areas, bluetongue disease is rare.[67] After onset of infection, cattle may be viremic for up to several weeks, during which time infected animals may act as viral amplifiers and reservoirs for the transmitting *Culicoides* vector.[65] Although viremias may be prolonged, they are not persistent, nor does this agent cause immunotolerance.[67] Prolongation of viremia in cattle, which facilitates infection of the insect vector, probably is the result of the strong association of bluetongue virus with erythrocytes, which may protect virus from elimination by neutralizing antibody.[65]

Fetal Infection and Abortions

Bluetongue virus fetal infection of cattle and sheep can occasionally result in abortion, but teratogenesis is more common.[68] Naturally occurring bluetongue virus fetal infection and abortion have been reported in cattle, but only in countries in which modified live virus vaccines have been used. Vaccine strains of bluetongue virus are the likely cause of naturally occurring fetal infection, because studies in pregnant sheep have shown that bluetongue virus crosses the placenta and produces fetal malformation only after the virus has been altered by adaptation to cell culture.[68]

When rare fetal infections with bluetongue virus do occur, they mimic results from experimental infections. Infection of susceptible heifers or cows during early gestation (during the first 90–100 days of gestation) may result in fetal death (by either resorption or abortion). Fetal infection between 75 and 100 days of gestation results in stillborn fetuses or in the birth of weak calves or calves with cerebral malformations.[69] Central nervous system abnormalities due to bluetongue virus infection in term calves may include hydranencephaly or cerebral cysts.[67–69] Cerebral malformations do not occur in fetuses infected after 150 days of gestation. These late-term fetal infections may have no effect on gestation or may result in premature births. The infected calves may have no visible lesions or a mild nonsuppurative encephalitis.

Diagnostic and Control Considerations

In most instances, infected fetuses surviving beyond midgestation have detectable fetal or precolostral antibodies to the bluetongue virus, but the virus is no longer present.[67–69] The virus is difficult to isolate, and freezing of infected tissue destroys the virus. The virus is rarely if ever isolated from term fetuses if infection occurred before 150 days.[69] Virus may be present in the semen of seropositive bulls, but only when they are viremic. Bluetongue virus in semen is associated with the presence of contaminating erythrocytes or mononuclear cells that carry virus; the virus is not found in spermatozoa.[67] International regulations prohibit movement of livestock and germplasm from countries harboring animals with bluetongue viruses to countries considered virus-free.[67] U.S. livestock industries incur significant losses each year because of these trade restrictions, even though supporting evidence for transmission of bluetongue virus between countries, by either semen or embryos, is lacking.[67]

Vaccines are available, but owing to the rare occurrence of fetal infection or clinical disease in cattle, their use even in endemic regions seems unwarranted. Cows develop immunity to the infecting serotype but remain susceptible to infection by other serotypes.[69] Because bluetongue virus is transmitted by *Culicoides* spp., the modified live virus in the vaccine also may be transmitted among animals by the insect vector; thus, if vaccines are used, administration of vaccines should be limited to times of the year when vectors are inactive.[67]

CHAPTER 51

Protozoal Abortion in Cattle

BRUCE ABBITT and D. OWEN RAE

Ruminant protozoal abortifacients include *Tritrichomonas foetus* and *Neospora, Toxoplasma,* and *Sarcocystis* spp. The latter three genera all are members of the family Sarcocystidae. The genus *Sarcocystis* is composed of 130 species of cyst-forming coccidians with differences in life cycle and pathogenicity.[1] All Sarcocystidae species with known life cycles exploit natural predator-prey relationships. Sexual reproduction takes place in the intestine of the predator, resulting in fecal passage of oocysts that are orally infective for the prey species (intermediate host); asexual reproduction takes place in tissues of the prey species, which are then orally infective for the predator species (definitive host). For example, the several *Sarcocystis* species that infect the bovine—*Sarcocystis cruzi, Sarcocystis hirsuti,* and *Sarcocystis hominis*—have raccoons and canids (dog, wolf, coyote, fox), felids, and primates (humans, monkey), respectively, as definitive hosts. Felids act as the definitive hosts for *Toxoplasma gondii,* with almost all warm-blooded animals potentially serving as intermediate hosts. Infection by *T. gondii* also can be maintained in successive generations of two common intermediate hosts (rats and mice) by congenital (dam-to-daughter) transmission.[2,3]

The life cycle of *Neospora* has only recently been determined but has been shown to follow a pattern similar to that for other species of Sarcocystidae (Fig. 51-1). Oocysts were found in dog feces,[4] and it appears that the dog can play the role of both an intermediate and a definitive host. Other intermediate hosts include ruminants and canids.[5] This agent is maintained in successive cattle generations by congenital (dam-to-daughter) transmission. It also is increasingly clear that *Neospora caninum* is the most important abortifacient agent in this group.

NEOSPORA CANINUM

N. caninum was discovered in 1984 as the cause of congenital infection of the central nervous system in dogs, and in 1988 the organism was isolated and named.[6] Slight ultrastructural and antigenic differences exist between tissue phases of *T. gondii* and *N. caninum*.[7,8] Comparison of ribosomal RNA or DNA sequences indicates a close phylogenetic relationship but distinct species in analysis by random amplified polymorphic DNA–polymerase chain reaction.[9–11] The definitive host of *N. caninum* is the dog[4]; wild canids are intermediate hosts and may be implicated as definitive hosts with further study.[12,13] Researchers have found antibodies in naturally exposed water buffalo, coyotes, red foxes, and camels, suggesting that these animals are natural intermediate hosts.[5] Congenital infection by *N. caninum* has been documented in many species. Naturally occurring congenital infections were first documented in dogs[14] and cattle.[6] Further study suggests that natural and experimental congenital infection occurs in horses, sheep,[15] goats,[16] deer,[17] and mice.[18] As has been proved for *T. gondii,* it is possible that infection is acquired congenitally, by ingestion of oocysts (fecal contamination of feed), or by contact (nasal, ocular, or oral) with cysts or tachyzoites.[19]

Since the 1960s, there have been many reports of abortion in cattle due to unidentified protozoa, often tentatively assumed to be either *Sarcocystis* spp. or *T. gondii*.[20] Retrospectively, most cases involved microscopic lesions that are now recognized as virtually diagnostic for fetal infection by *N. caninum.* These microscopic lesions are most consistently nonsuppurative encephalitis with foci of necrosis and gliosis, and nonsuppurative myositis, hepatitis, and myocarditis. Protozoa are rarely found by microscopic evaluation of hematoxylin-eosin (H&E)-stained sections from affected fetuses.[21] With use of immunohistochemistry studies,[22] however, protozoa can be visualized in most fetuses with lesions typical of protozoal abortion.[7]

Reported cases indicate worldwide distribution of this abortifacient in cattle. Cases have been documented in Canada,[23,24] the United States,[25,26] the Netherlands,[27] New Zealand,[28] South Africa,[29] Australia,[30,31] Mexico,[32] England and Wales,[33] and Japan.[34] Continued investigation during the past decade validates the worldwide distribution of infection in dairy and beef cattle globally.[5] In California[21,35] and similarly in New Zealand,[28] *Neospora* has been diagnosed as the cause of abortion in approximately 20% of fetuses from dairy cattle submitted to diagnostic laboratories and the cause of abortion in approximately 44% of all fetuses originating from California dairy herds with a prior history of *Neospora* abortions.[36] In the midwestern United States, a survey of 655 aborted bovine fetuses submitted to a state diagnostic laboratory revealed 2.7% to be the result of *Neospora* infection; of interest, 19 of 20 of the *Neospora*-infected fetuses represented dairy breeds and 12% of submitted fetuses from dairy cows were diagnosed with *Neospora* infections.[37]

The dog, as the definitive host of *Neospora,* contributes to the horizontal transmission of the agent and thereby the establishment of infection.[4,38–42] Infection can then be propagated by vertical transmission in the bovine through multiple generations.[41–43] This horizontal introduction by a definitive host combined with vertical propagation from the infected intermediate host helps to explain the high prevalence and worldwide distribution of *Neospora* abortion. Because the dog generally has both worldwide distribution and a common association with

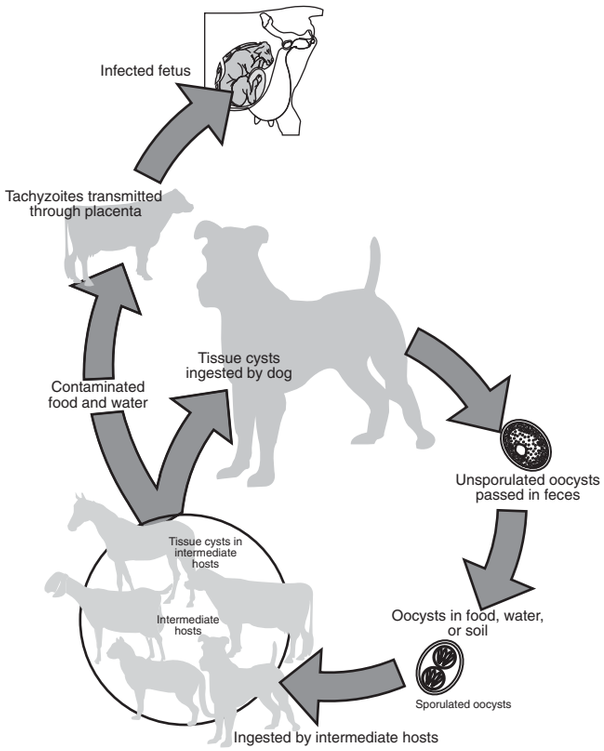

Fig. 51-1 The life cycle of *Neospora caninum*.

dairies and livestock enterprises, the likelihood of cattle exposure to infection may be increased. Of interest, naturally occurring abortions and congenital infection with *Neospora* also have been documented in sheep,[44] goats,[16] horses,[45] and black-tailed deer.[17]

Neospora-induced abortions typically occur during the early second trimester[25,26,28,35–37] but can occur throughout gestation.[28,32,35] On gross examination, aborted fetuses often are moderately or severely autolyzed, but microscopic diagnosis usually is possible because of persistence of both characteristic lesions and protozoa.[28,32,33,43] Desirable samples for submission to the diagnostic laboratory include the entire fetus and placenta or samples from the brain, heart and liver, as well as body fluids or blood serum.[5] Although autolysis may present some difficulties in preparation of samples, semiliquid brain tissue should be fixed in 10% buffered neutral formalin for histologic and immunohistochemistry examination.[5] Cows aborting *Neospora*-infected fetuses are not clinically sick, and in one report, conception rates to artificial insemination were not adversely affected by a history of *Neospora* abortion.[32]

A sensitive and specific serologic test is available,[46] and serum from congenitally infected calves is positive before intake of colostrum.[6,46] Term calves with serologic and/or microscopic evidence, or both, of *Neospora* infection have been reported to have enhanced survivorship during the preweaning period, to be essentially clinically normal, or to have various degrees of central nervous system impairment.[6,30,47–50] Serologic studies in California drylot dairies reveal that herd infection rates can be estimated by serologic testing of calves before colostral intake, because congenital infection occurs in 78% to 80% of seropositive cows.[47] Repeated serologic testing of individual cows from these dairies reveals an apparent lack of new infections (i.e., serologically positive cows remain positive and serologically negative cows remain negative). Furthermore, the percentage of serologically positive cows that abort is approximately twice that of seronegative herdmates.[47] The absence of seroconversion (from seronegative to seropositive status in adult animals) in these herds strongly indicates maintenance of herd infection by the primary means of placental or congenital transmission.

Congenital transmission may explain the endemic pattern of abortion observed in herds suffering annual abortion rates exceeding 5% for several years.[51] Epidemic patterns of abortion, however, also may be seen—that is, a high percentage of abortions may occur during a relatively short period of time.[25,52] Several studies have shown a three- to fourfold increase in abortion risk for seropositive cows compared with that for seronegative herdmates.[53,54] Repeat abortion in the same cow has been observed in an infected herd[32] and was proved in four cows in a California dairy herd.[6] Furthermore, the cow with a history of previous abortion as a result of *N. caninum* infection has up to a 5.7 times greater risk of abortion in the subsequent pregnancy.[55] The serologic findings in California drylot dairies suggest that repeat abortions are caused by recrudescence of latent infection, although acquisition of a new infection also is possible.

TOXOPLASMA GONDII

T. gondii is a significant, well-documented cause of abortion and congenital infection in sheep and goats; the clinical manifestations are very similar to those of *Neospora* infection in cattle.[56–61] This similarity is not surprising in view of the close phylogenetic relationship between these organisms.[10,11] *T. gondii* previously has been suspected as a cause of congenital infection with associated neurologic effects or abortion in cattle,[20] but the cause in such cases is now disputed or proved to have been *Neospora*.[49,62] Additionally, *T. gondii* has rarely been isolated from bovine tissues, and experimental infection of pregnant cows by oral administration of *T. gondii* oocysts does not result in abortion.[62]

SARCOCYSTIS

The clinical signs of acute sarcocystosis in cattle include pyrexia, ptyalism, enlarged lymph nodes, anemia, and abortion; these have been reproduced by oral administration of *S. cruzi* oocysts.[63–66] Experimentally induced abortions were characterized by a general absence of protozoa within aborted fetuses. By contrast, protozoal schizonts are readily found in endothelial cells in multiple organs of the dam, indicating that abortion is due to systemic illness of the dam and not protozoal infection of

the fetus.[65,66] Regardless, the paucity of clinical reports of acute bovine sarcocystosis suggests this to be a rare clinical occurrence. In the few published case reports, *Sarcocystis*-induced abortion was characterized by an absence of illness in the dam and presence of protozoa in multiple organs of the fetus. The location of protozoal schizonts within endothelial cells and immunoreaction of the schizonts confirm *Sarcocystis*.[67,68] In surveys in England and Wales[33] and in California,[7] however, either 0 (England and Wales) or 4% (California) of aborted bovine fetuses with microscopic lesions typical of protozoal abortion were infected by *Sarcocystis;* the remainder were infected by *Neospora*. In summary, *Sarcocystis* is a proven, but rare, bovine abortifacient.

Prevention and Control

The ruminant protozoal abortifacients discussed in this chapter all are members of the family Sarcocystidae. Prevention should include measures that disrupt the predator-prey life cycle of these protozoa, thereby interrupting horizontal transmission. Carcasses and placentas should be disposed of in a manner to prevent consumption by the definitive host animals, and feed and water should be handled, stored, and supplied in a manner to prevent or minimize fecal contamination. The vertical transmission of *N. caninum* through chronically infected cows requires that these be identified and removed from the herd and that introduction of infected replacement heifers be prevented or limited. The ability to screen cattle for presence of *Neospora* by serologic tests (both adults and newborn calves before intake of colostrum) provides a means of selecting noncarriers for replacements and eliminating carriers from within a herd.

Treatment of carriers in vivo has not been shown to be effective at present[69]; various drugs have been shown to inhibit growth of *N. caninum* in vitro,[70] and some treatment regimens have been evaluated in *N. caninum*–infected puppies.[71] Management of these agents should focus on prevention and control, not treatment.

Research directed at producing an effective immunizing agent has had limited success to date. Killed *N. caninum* or its products have been injected into prepartal mice and shown to block transplacental transfer of the agent,[72,73] but in cattle, clear evidence of vaccinal prevention of *N. caninum* abortion is lacking.[74] Protective immunity seems to develop after primary exposure, reducing or potentially preventing subsequent abortion.[44,75,76] Particular challenges, however, arise in conferring protective immunity to animals already infected naturally,[77,78] and in preventing vertical transmission.[75] Although investigation of biologic, pathophysiologic, and immunologic properties of *N. caninum* continues, rudimentary products are being employed in cattle populations to reduce the impact of the agent. For example, a recent field trial showed a 50% reduction in abortions of dairy cows given commercial *N. caninum* vaccine, as compared with cohort control cows (11% and 21%, respectively).[79]

A clearer understanding of protozoal abortion is speedily emerging—specifically, *N. caninum* abortion. Continued investigation is anticipated to reward us with a better understanding of its pathophysiology, control, and prevention.

CHAPTER 52

Epizootic Bovine Abortion (Foothill Abortion)

ROBERT H. BONDURANT, MARK L. ANDERSON, JEFFREY L. STOTT, and PETER C. KENNEDY

HISTORY AND ETIOLOGY

Epizootic bovine abortion (EBA), also known as **foothill abortion**, is a distinct, tick-transmitted disease of pregnant cattle that graze foothill and mountain pastures of California and adjacent states.[1] Endemic areas often are bushy or wooded regions, typically dry chaparral or oak-studded environments from 500 to 7000 feet above sea level, and are the habitat of the argasid tick vector *Ornithodoros coriaceus*[2] (Fig. 52-1). Heifers confined to permanent (irrigated) pastures within endemic areas rarely if ever experience EBA.

A causative agent for EBA has been sought for more than 50 years.[3] Research through the mid 1980s suggested several different agents, including chlamydiae *(Chlamydophila),* viruses, and spirochetes; however, recent breakthroughs, using molecular techniques, chemical and immunohistologic stains, and other methods, have implicated a bacterial agent.[3–6] Although the disease has a limited geographic distribution, it is a major cause of abortion, neonatal mortality, and economic losses in endemic areas. It also is of interest to the veterinary scientist because of its unusual presentation, long latent period, and pathologic features.

NATURAL HISTORY

Typically, only heifers, or adult cows brought for the first time into endemic areas during or after the breeding season, are susceptible to the disease. Abortions, which usually occur sporadically but may come in dramatic "storms," result in the loss of late-term fetuses (6 to 9 months of gestation). Birth of live but unthrifty calves also may occur as part of an EBA outbreak. If the herd is not moved from one calving season to the next, heifers and cows that abort an EBA fetus in one season tend not to suffer EBA again in the following year.

In the 1960s, the geographic distribution of the soft-bodied tick, *O. coriaceus* (see Fig. 52-1), was shown to

CHAPTER 52

Epizootic Bovine Abortion (Foothill Abortion)

ROBERT H. BONDURANT, MARK L. ANDERSON, JEFFREY L. STOTT, and PETER C. KENNEDY

HISTORY AND ETIOLOGY

Epizootic bovine abortion (EBA), also known as **foothill abortion**, is a distinct, tick-transmitted disease of pregnant cattle that graze foothill and mountain pastures of California and adjacent states.[1] Endemic areas often are bushy or wooded regions, typically dry chaparral or oak-studded environments from 500 to 7000 feet above sea level, and are the habitat of the argasid tick vector *Ornithodoros coriaceus*[2] (Fig. 52-1). Heifers confined to permanent (irrigated) pastures within endemic areas rarely if ever experience EBA.

A causative agent for EBA has been sought for more than 50 years.[3] Research through the mid 1980s suggested several different agents, including chlamydiae *(Chlamydophila),* viruses, and spirochetes; however, recent breakthroughs, using molecular techniques, chemical and immunohistologic stains, and other methods, have implicated a bacterial agent.[3–6] Although the disease has a limited geographic distribution, it is a major cause of abortion, neonatal mortality, and economic losses in endemic areas. It also is of interest to the veterinary scientist because of its unusual presentation, long latent period, and pathologic features.

NATURAL HISTORY

Typically, only heifers, or adult cows brought for the first time into endemic areas during or after the breeding season, are susceptible to the disease. Abortions, which usually occur sporadically but may come in dramatic "storms," result in the loss of late-term fetuses (6 to 9 months of gestation). Birth of live but unthrifty calves also may occur as part of an EBA outbreak. If the herd is not moved from one calving season to the next, heifers and cows that abort an EBA fetus in one season tend not to suffer EBA again in the following year.

In the 1960s, the geographic distribution of the soft-bodied tick, *O. coriaceus* (see Fig. 52-1), was shown to

Fig. 52-1 Adult engorged *Ornithodoros coriaceus* tick, the vector of epizootic bovine abortion. (Courtesy of M. Oliver.)

Fig. 52-2 Epizootic bovine abortion fetus, with petechiae on the ventral surface of the tongue and oral mucosa. (Courtesy of Dr. P. C. Kennedy.)

coincide with the known areas in which EBA had been reported.[2] The most common hosts of this ectoparasite are deer and cattle. Experimental feeding of the tick on susceptible pregnant heifers was shown to reproduce the disease.[2,7] On the basis of this and other work, the role of *O. coriaceus* as a vector of the EBA agents has been accepted. Various agents have been isolated from this tick, but none of these agents has reliably reproduced EBA.[3] Experimental work has shown that the thymus of EBA-aborted fetuses reliably transmits the disease when extracts are inoculated into susceptible pregnant heifers. In recent studies, the "thymic agent" was shown to be nonfilterable (e.g., infectivity was removed by filtration); it also was destroyed by sonication, and its pathogenicity was ablated by antibiotic treatment.[4] Although no agent has been reliably cultivated from the thymus, molecular techniques that amplify microbial nucleic acids (polymerase chain reaction [PCR] assays) identified a deltaproteobacterial agent, specifically of the Myxococcales order.[5] This order is notorious for failure of organisms to grow in in vitro culture. So, although the demands of classic Koch's postulates have not been met, a majority of guidelines that have been suggested for DNA sequence–based determination and incrimination of a presumptive microorganism in disease have been satisfied.[8]

CLINICAL SIGNS AND FINDINGS

Heifers or cows that have been either naturally or experimentally exposed to EBA show no overt signs of illness at any time after exposure. Minor elevations in total leukocyte counts about 1 week following tick feedings have been noted. The interval from exposure to abortion is unusually long, typically 3 to 4 months, with nearly all abortions coming in the third trimester. When fetuses are expelled, they usually are in a relatively fresh (i.e., nonautolytic) state. Serum from aborted EBA fetuses shows markedly elevated immunoglobulin concentrations, especially immunoglobulin G (IgG) (150–800 mg/dl; geometric mean, approximately 300 mg/dl), and in some instances, the immunoglobulin levels can approach those of colostrum-fed neonates (>1 g/dl).[7,9] We are not aware of another disease entity that routinely stimulates such high levels of bovine fetal immunoglobulin.

The chronic nature of the disease process in the fetus and the late stage of gestation suggest that the heavily stressed fetus secures its own delivery through cortisol release, and that some calves may survive parturition yet succumb in the neonatal period. Often, heifers or cows in which abortion has occurred commence lactation; in any case, they tend to show few lasting effects of the infection, and they generally are able to conceive during the following breeding season, provided that the abortive delivery proceeded without complications.

PATHOLOGY

The agent of EBA establishes a chronic fetal infection with widespread gross and histologic lesions. The lesions develop progressively over a period of 3 months or more, with abortion typically occurring in the last trimester. As mentioned, the fetus is almost always fresh, fetal death having occurred from shortly before to shortly after delivery. Petechial hemorrhages are common in the mucosa of the conjunctiva and oral cavity and are especially distinctive along the ventral surface of the tongue (Fig. 52-2). Generalized enlargement of lymph nodes is usual. Some superficial nodes, such as the prescapular lymph nodes, can be readily palpated through the skin (Fig. 52-3). Whereas the prescapular lymph nodes of normal term fetuses weigh between 3.5 and 7.0 g, EBA fetuses may have prescapular lymph nodes that weigh 16 g or more.[10,11] Abdominal distention due to severe ascites is a variable feature, although some degree of ascites, often with strains of clotted fibrin, usually is present. An impressive but inconsistent gross lesion of EBA is an enlarged congested liver with a nodular capsule (Fig. 52-4). A more consistent gross change is splenic enlargement accompanied by enlargement of internal lymph nodes. The thymus may be reduced in size, with interlobular to diffuse hemorrhage and edema in the cervical portion. The lungs may be partially inflated. Other gross

Fig. 52-3 Epizootic bovine abortion fetus, with an easily palpable, enlarged prescapular lymph node.

Fig. 52-4 Enlarged liver of an epizootic bovine abortion fetus, with a coarsely nodular capsular surface.

findings may include small gray inflammatory foci in the heart, kidney, or other organs.

Histologic examination of fetal tissues, particularly the lymphoid organs, is required to confirm a diagnosis of EBA.[10,11] The thymic lesions that develop late in the course of the disease apparently are unique to EBA (Fig. 52-5, *middle panel*), although not always present. Other features include loss of cortical thymocytes and infiltration of the medullary region with macrophages. Frequently, the interlobular septum is distended with fibrin and hemorrhage and is infiltrated by macrophages. The grossly evident enlargement of the lymph nodes is caused by lymphoid follicular hyperplasia with widespread macrophage infiltration in the sinuses and medulla. Lymphoid hyperplasia with macrophage infiltration also is present in the splenic white pulp. Late in the course of the disease, after the proliferative response, a common finding is acute necrosis in lymphoid organs, which may trigger the abortion. Also seen are widespread inflammatory lesions, which tend to have a vascular orientation in most organs, including the brain, the lungs, and the liver.

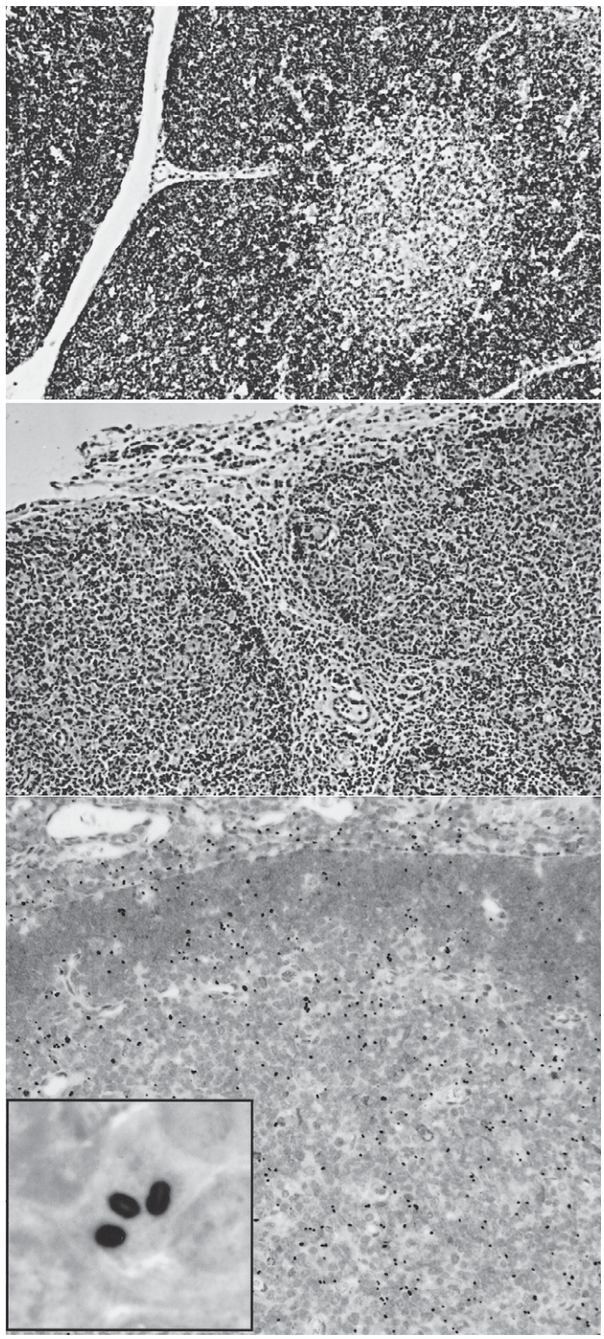

Fig. 52-5 Three photomicrographs of thymus from a normal *(top panel)* and two epizootic bovine abortion (EBA) fetuses *(middle and bottom panels).* In the normal fetus, a dense cortical mantle of thymocytes surrounds the medullary region. The interlobular septa are narrow and sparsely populated. In the EBA-affected thymus, the hematoxylin-eosin stain *(middle panel)* reveals thymic lobules that are reduced in size with loss of cortical thymocytes and macrophage infiltration. The interlobular septa are expanded by mixed cellular infiltrate. Immunohistochemical staining of an EBA thymus, using serum from an EBA fetus with high levels of immunoglobulin *(bottom panel),* reveals numerous short bacterial rods in the medullary zone, in the narrow cortical mantle, and in the septa. *Inset,* High-magnification view (oil immersion, approximately 1000×) of three bacterial rods within a cell in the medullary region.

In the brain, abnormalities include granulomatous meningitis with focal gliosis and vasculitis. The alveolar septa of the lung are thickened, with mononuclear cell infiltration and focal granulomatous infiltration in the interlobular septa. A consistent although less specific feature is granulomatous portal hepatitis with variable centrilobular congestion and hepatic cord atrophy.

DIAGNOSIS

The diagnosis of EBA is based on compatible pathologic findings and herd history with the elimination of other likely infectious causes. In some situations, however, when fetuses are extensively autolyzed and/or usable samples are limited, additional diagnostic procedures can be employed to demonstrate the bacterial agent associated with this disease. Modified Steiner silver stains may reveal small intracytoplasmic bacterial rods in the lymphoid tissues. Furthermore, an immunohistochemistry stain using serum from affected fetuses with elevated immunoglobulin levels provides improved identification of the bacteria (see Fig. 52-5, *bottom panel*).[6] The bacterial rods are widely disseminated in the lymphoid tissues. Although not yet being routinely applied to diagnosis, an EBA-specific PCR assay has been developed and validated for identification of the etiologic agent in both fetal necropsy tissues and the salivary gland of the tick vector.[5]

TREATMENT AND PREVENTION

Because the etiologic agent of EBA is not definitively identified and cannot yet be propagated in vitro, neither treatment nor vaccine is currently available. Rather, the cattle industry currently "manages around" EBA by manipulating the exposure of susceptible females. In areas in which the vector season is well defined and relatively limited (e.g., in the tick's northern ranges), some success has been achieved by those ranchers who have changed to fall calving. This tactic delays tick exposure of the pregnant cows until much later in gestation (e.g., at 7 months or later), with the result that exposure apparently occurs too late to destroy the fetus. Theoretically, such fetuses should mount an effective immune response to the agents of EBA. The apparent success of this "fall calving" strategy has lent strength to the hypothesis that fetuses must be exposed to the agents of EBA before the sixth month of gestation to manifest actual abortion.

In areas in which the vector season is prolonged (e.g., in the southern ranges of the tick), less benefit is derived from changing the calving season. That is, it is difficult to find a "window" of time during which animals can reach an advanced stage of gestation without also being exposed to ticks. Preventive efforts in these locales have involved the introduction of replacement heifers to endemic areas before their first breeding season, in order to induce immunity.

The apparent antibiotic susceptibility of the putative agent makes it tempting to recommend antimicrobial therapy to heifers at the time of or before exposure. Exposure can occur over such an excessive interval, however, that any treatment would have to be administered over a very long term. No recent data exist to support such an approach, although older anecdotal information suggested that feeding chlortetracycline during the tick season imparted some benefit. Well-controlled clinical trials are needed before such a strategy can be recommended.

Currently, researchers are making vigorous efforts to isolate and/or purify the causative agent from the fetal thymus in an attempt to develop a specific immunogen, and perhaps to formulate a rational treatment strategy.

CHAPTER 53

Mycotic Bovine Abortion

RICHARD L. WALKER

ETIOLOGIC AGENTS

Various molds and yeasts have been implicated in mycotic bovine abortion. Most of these agents are saprophytic fungi found in moist organic environments such as soil, hay, and poor-quality silage.

Aspergillus fumigatus is the most commonly isolated fungus, accounting for 60% to 80% of mycotic abortions.[1] Other *Aspergillus* species, including *Aspergillus flavus, Aspergillus terreus,* and *Aspergillus nidulans,* are encountered less frequently. The Zygomycetes compose the second most commonly encountered group; these include *Absidia corymbifera, Absidia ramosa, Mortierella wolfii, Rhizomucor pusillus,* and *Rhizopus arrhizus*.[1] *Pseudallescheria boydii* is another prevalent agent, albeit less commonly encountered. Species of *Penicillium;* dematiaceous fungi such as *Curvularia geniculata, Exophiala jeanselmei,* and *Wangiella dermatitidis;* and yeasts, usually of the genus *Candida* or *Torulopsis,* account for most of the remaining mycotic organisms encountered.[1] The relative frequency with which different fungi occur varies according to the geographic region. In northern New Zealand, for example, *M. wolfii* rather than *A. fumigatus* is the most common cause of mycotic abortion.[2]

EPIDEMIOLOGY

The incidence of bovine mycotic abortion varies widely, ranging from 2% to 20%.[3,4] Some surveys found mycotic agents to be the most commonly diagnosed cause of bovine abortion.[5] Mycotic abortions occur sporadically. Rarely are more than 10% of pregnant cows affected in a herd.[6] The age of the cow does not appear to be a factor predisposing to mycotic abortion.[7]

In the Northern Hemisphere, most mycotic abortions occur in the winter and spring months. Increased confinement of cattle during this period and feeding of hay or poor-quality silage are risk factors.[4] Confined housing in conjunction with feeding hay poses the greatest risk.[4] Some evidence suggests that abortions associated with *M. wolfii* are linked to nonstandard methods of silage preparation, particularly inadequate wilt-time before storage or inadequate silage compaction or storage due to incomplete sealing of the container.[5]

The relationship between frequency and amount of rainfall during the previous hay or silage-making season and the annual incidence of mycotic abortion remains unresolved. Some studies demonstrate a positive correlation; others have found no significant relationship.[4,8,9]

The suggestion that mycotic abortion is associated with the use of artificial insemination has not been substantiated.[5]

CLINICAL FINDINGS

Generally, mycotic abortions occur late in pregnancy, most often between 6 and 8 months of gestation, although they can occur as early as 2 months of gestation. Prodromal signs usually are not noted. The fetus is expelled soon after death in abortions caused by *Aspergillus* spp; however, it may be retained for up to 24 hours when a zygomycetous fungus is the etiologic agent.[1] The placenta frequently is retained and remains firmly attached. A secondary infection also may ensue.[10] Maternal caruncles may rupture at the peduncle and be expelled still attached to the cotyledons. This is most often observed when abortions are caused by zygomycetes.[6] Unless severe endometrial damage occurs, most cows recover sufficiently to have normal subsequent pregnancies.[4,10]

In approximately 25% of cows with *M. wolfii*–associated abortions, a fulminating, postabortion pneumonia occurs.[1] Cows exhibit rapid, shallow respiration with forced expiration.[11] Death usually occurs within 72 hours of onset of clinical signs.[2] Infrequently, signs of pneumonia are observed before the abortion.

PATHOGENESIS

The portal of entry of fungal agents is unknown; however, the respiratory and gastrointestinal tracts are the most likely routes of exposure. Although most fungal conidia that reach the lower respiratory tract remain there or are eliminated, it is speculated that some may enter blood vessels in alveolar septa and reach the placenta through the systemic circulation. Rumen infections, omasal ulcers, and intestinal lesions also may be factors predisposing to hematogenous spread to the gravid uterus, perhaps by facilitating penetration of mucosal barriers.[10] The hematogenous route is believed to be the primary route of infection because the lesion develops initially in the placentomes.[10] Once established, the infection spreads from the initial focus to the arcade zone of the placentome and advances laterally. Infection subsequently spreads to the interplacental space between cotyledons. Fetal tissues may be involved, primarily skin and lungs. Brain or liver involvement occurs occasionally.[10]

Mycotic abortions have been induced experimentally by intravenous administration of fungal conidia; however, intratracheal and oral administration have not successfully reproduced disease. Ascending infections in the genital tract are not thought to be a common route for infection. Attempts to experimentally induce abortion

with intrauterine inoculation of *Aspergillus* conidia have been unsuccessful.[12]

The pneumonia that develops in cows after *M. wolfii*–associated abortions is thought to result from a lung-uterus-lung cycle. Although the initial site of entry is unknown, spores most likely enter through the alimentary tract and pass by the venous or lymphatic system through the pulmonary vasculature, with subsequent localization in caruncles of the placenta. After abortion, a large number of fungal elements are absorbed from the uterus, causing an acute, fulminating, embolic pneumonia in the cow. This typically occurs 2 to 4 days after abortion.[13]

DIAGNOSIS

Samples for Examination

The placenta is the most useful sample for accurate diagnosis of mycotic abortion. If possible, the entire placenta should be submitted for examination, because infection may be restricted to only a portion of the placenta. Cotyledons with uterine caruncular tissue are the specimens of choice. The fetus or fetal tissues, particularly skin, lungs, and abomasal contents, also are useful diagnostic samples. Because the fetus is not involved consistently, however, submitting only the fetus or fetal tissues may lead to a false negative diagnosis. In *M. wolfii*–infected fetuses, liver and brain are the most commonly involved tissues.[13]

Gross Examination

Severe placentitis with necrosis of the cotyledons and leathery thickening of the intercotyledonary space is the most consistent finding in mycotic abortion. The cotyledons may have a coffee-bean or cup-shaped appearance due to the thickened margins of the cotyledons surrounding the attached necrotic caruncular tissue. Although the gross lesions in the placenta in mycotic abortions are quite distinctive, the lesions of other infectious causes of abortion, such as brucellosis and campylobacteriosis, can have a similar appearance.[6]

In approximately 25% of cases, the fetal skin has lesions. The lesions appear as raised, circumscribed plaques with a tendency to coalesce, somewhat resembling ringworm lesions. Areas around the eyes and on the head, shoulders, back, and sides are preferentially affected sites.[10] The skin lesions appear dry and wrinkled in infections with *Aspergillus* spp. but have a moist appearance when Zygomycetes are the inciting agents. The fetus may appear emaciated and dehydrated, exhibiting an overall wrinkled appearance to the skin.

Direct Microscopic Examination

Scrapings from placenta and affected skin, as well as abomasal contents, should be examined for fungal hyphae after the samples are digested with a 10% potassium hydroxide solution. Most organic substances are cleared with this treatment; however, fungal hyphae are unaffected and are readily visualized microscopically. Methods using calcofluor white or chlorazol black E also can be used to enhance visualization of fungal hyphae.

Finding hyphae in placental or fetal skin scrapings in conjunction with compatible gross lesions provides a rapid presumptive diagnosis of mycotic abortion. The presence of fungal hyphae in the abomasal fluid correlates well with mycotic abortions; occasionally, however, fungal hyphae are found in the abomasal fluid as an incidental finding.

The microscopic appearance of the hyphae can be a clue to the particular fungal agent involved. *Aspergillus* hyphae are 3 to 6 μm in diameter, with parallel sides and frequent septation; typically, hyphae branch in a dichotomous pattern. The hyphae of *P. boydii* are similar to those of *Aspergillus* organisms except that the branching pattern is more irregular. The hyphae of the Zygomycetes are broad (5 to 20 μm), thin-walled, and pleomorphic. The hyphae tend to branch irregularly, sometimes at right angles, and are nonseptate, although occasional septa are detected.[14] It is not possible to distinguish among genera of the Zygomycetes on the basis of hyphae in tissue digestions or histologic sections. The presence of budding yeasts and pseudomycelia or brown-pigmented hyphae may suggest an infection caused by a yeast or one of the dematiaceous fungi, respectively.

Histopathologic Examination

The placenta is the most severely affected tissue in mycotic abortions. Typically, wedge-shaped areas of necrosis or hemorrhage, or both, occur in the caruncle as a result of necrotizing vasculitis and thrombosis. Cotyledonary villi and placental stroma often are secondarily involved by local or hematogenous spread. Fungal hyphae can be found in vascular structures, thrombi, necrotic tissue, and adjacent viable tissue. The zygomycetous fungi are more easily visualized than *Aspergillus* organisms in hematoxylin-eosin–stained tissue sections. In general, fungal elements are best visualized in tissue using the Gridley fungus stain or Gomori's methenamine silver nitrate stain or by the periodic acid–Schiff reaction. Microscopic fungal morphologic characteristics, as previously described, can be used to suggest the group of agents involved.

The skin lesions of mycotic abortions involve predominantly the epidermis and dermis, with a parakeratosis, necrosis, and neutrophilic infiltration. In some instances, dermal vessels are thrombosed, and fungal elements can be seen invading the dermis. When the lungs are involved, a purulent bronchopneumonia with hyphae in the bronchioles can be observed. Focal hepatic necrosis can occur and is a relatively common finding with *M. wolfii*–associated abortions.[13] Occasionally, encephalitis with perivascular cuffing, neutrophilic infiltration, and necrosis of the neuropil is observed.

Mycologic Examination

Culture results alone should be interpreted with caution. Because the placenta may be contaminated, the morphologic characteristics of fungi recovered should be consistent with the morphologic appearance of fungal

hyphae observed by direct, microscopic, or histopathologic examination before the fungus is designated as the etiologic agent. Cultures from the abomasal contents are less prone to contamination.

For isolation, fungal media with antibiotics should be used to suppress bacterial contamination. Sabouraud's dextrose agar and potato-dextrose agar are commonly used media. Cultures are routinely incubated at 25° to 30°C for up to 4 weeks.

Isolation of zygomycetous fungi can be difficult.[2] They do not remain viable in tissues as long as other fungi do. Toxic effects from tissue autolysis are thought to be responsible, in part, for the failure to recover organisms when they are observed in tissue sections.

Molds isolated from the placental or fetal tissues are identified on the basis of colonial and microscopic morphology. Speciation can be difficult, especially with the zygomycetous fungi, and may require mating studies, which is beyond the capability of most clinical laboratories.

Yeasts are most easily identified with the use of commercially available assimilation systems.

MANAGEMENT AND TREATMENT

Because of the sporadic nature of mycotic abortions and differing management and feeding practices, specific control efforts should be tailored to the scenario at hand. When warranted, changes in housing to decrease confinement and cow density, as well as improving ventilation, will limit exposure to fungal conidia. Limiting the feeding of moldy hay or poor-quality silage, particularly to pregnant animals, is important in minimizing the potential for abortion.

Specific antimycotic treatments for cows that abort usually are not required. Instead, efforts should be directed at minimizing endometrial damage resulting from retained placenta or subsequent secondary infection.

CHAPTER 54
Reproductive Toxicants

STAN W. CASTEEL

Reproductive toxicology is the study of toxicant exposures that adversely affect sexual behavior, gametogenesis, conception, development, parturition, or healthy maturation of progeny. Even under normal physiologic conditions, reproductive function is subject to failure. It is therefore not surprising that exposure of this system to toxic insult interferes with the complex biologic processes that culminate in healthy offspring. The true incidence of toxin-induced reproductive dysfunction is unknown but presumably is well below that due to infectious and management-related causes.

The incidence of malformed calves has historically been underreported because of the negative impact on the sale of breeding stock, or malformations have been undiagnosed because the death of offspring was not associated with easily identifiable anomalies.[1] Experimental evidence, however, confirms that poisonous plants can induce livestock losses as a result of embryonic death, abortion, and teratogenesis. The relationship between exposure and reproductive dysfunction is complex because exposure of the dam, the sire, or both may influence reproductive outcome. In addition, exposures may have occurred in the distant past, immediately before conception, or during gestation. The timing of toxin exposure before or during gestation can be identified for some specific dysfunction, and for others it cannot. Examples include chromosomal abnormalities detected in the embryo that arise from mutations in the germ cells of either parent before conception, or from direct exposure of the embryo/fetus during gestation. Malformations usually occur with exposure during a discrete period of gestation, extending from about day 40 to day 90 of bovine fetal development.

POISONOUS PLANTS

Bovine reproductive toxins are derived primarily from plants. The importance of the contribution made by poisonous plants is best appreciated by considering the pervasive exposure of cattle on rangelands and pastures. Experimental evidence has substantiated the reproductive toxicity of a number of range and cultivated plants.

Poison Hemlock

Poison hemlock is most likely to be ingested in the spring, because it often is one of the first green forages to appear. Ingestion of poison hemlock *(Conium maculatum)* by pregnant cows during the gestation interval of days 50 to 75 induces multiple congenital contractures (MCCs) in calves, a condition commonly referred to as "crooked calf disease."[2] Pregnant cows gavaged with the fresh green plant during days 50 to 75 of gestation had calves with arthrogryposis and spinal curvature, defects similar to those induced by administration of the isolated teratogenic principle coniine. Dams gavaged with the dry plant had either normal or equivocally deformed offspring, whereas those fed 410 to 840 g of fresh green plant daily from day 50 to 75 of gestation either aborted or delivered calves with limb deformities. Periodic ultrasound scanning during the treatment period revealed severe inhibition of fetal movement in goats.[3] Suppression of fetal movement during the critical gestational window is thought to be the cause of the plant-induced cleft palate (suppression of tongue thrusting) and skeletal contractures. A similar mechanism is likely in cattle.

Lupines

Certain species of the *Lupinus* genera cause MCCs in calves exposed in utero during days 40 to 70 of gestation.[4] Certain *Lupinus* species, such as *Lupinus sericeus* or *Lupinus caudatus,* contain anagyrine as the principal alkaloid and are teratogenic in cattle, but not in sheep and goats. The teratogen in *Lupinus formosus* is thought to be ammodendrine.[5] This plant species has induced severe limb and spinal deformities together with cleft palate in calves. These defects were induced in calves when dams were dosed with 2.33 to 3.16 g of fresh plant/kg of body weight twice daily during days 40 to 70 of gestation. More recent data from epidemiologic studies suggest that the gestational period of teratogenic susceptibility may extend to day 100.[6] The MCCs are similar to those induced by *Conium* and *Nicotiana* genera and include arthrogryposis, torticollis, kyphosis, scoliosis, rib cage deformities, and extension or flexure of the carpal or tarsal joints.

Tobacco

Nicotiana glauca (tree tobacco) is a small tree commonly found at lower elevations of California and Arizona. Seven cows dosed with dried, ground *N. glauca* daily from the 50th to 75th day of gestation produced seven calves with arthrogryposis of the forelimbs and curvature of the spine.[7] Other abnormalities included general malpositioning and misalignment of the distal ends of the radius and ulna and the proximal ends of the metacarpal bones. Carpal joints were severely affected, fetlock and pastern joints less so, with lateral rotation of forelimbs common.

One of four calves had moderate torticollis and scoliosis. Anabasine, not nicotine, is thought to be the teratogen. *Nicotiana tabacum* (common tobacco) is a known teratogen in swine,[8] but such effects have not been documented in cattle.

Locoweeds

From an economic standpoint, the locoweeds—certain *Astragalus* and *Oxytropis* species—have more of an adverse impact on bovine reproduction than any other group of poisonous plants. Of the almost 400 species of *Astragalus* and 22 of *Oxytropis,* fewer than 20 have been verified to cause true locoism and the associated reproductive dysfunction. Undoubtedly, many more species will be found to contain swainsonine, the active toxic principle in locoweed. The multiple reproductive problems induced by chronic locoweed consumption include abortion, teratogenesis, fetal death, delayed placentation, deficient uterine and placental vascular development, hydrops amnii, hydrops allantois, abnormal cotyledonary development, decreased conception rate, reduced libido, and diminished sperm production.[9] Enlarged ovaries with extensive follicular-type development have been observed in prepubertal calves intoxicated with locoweed.[10] Cytoplasmic vacuolation is seen in luteal cells and in atretic follicles, which may affect normal progesterone and estrogen levels.[11] Cytoplasmic vacuolation of the pituitary may affect normal gonadotropin levels in both sexes, thereby influencing reproductive performance.[12]

Locoweed poisoning is a chronic condition requiring continuous ingestion for 4 to 6 weeks. Initially, cattle may be reluctant to graze locoweed, but once started, they become habituated, often seeking it out while excluding appropriate forage from their diet. Recovery is possible if cattle are removed from infested ranges and supplied with suitable feed before they become too emaciated. Some *Astragalus* locoweeds are perennials that thrive only during favorable environmental conditions.[13] Flourishing and declining locoweed populations on western ranges are associated with the waxing and waning of reproductive and other acute and chronic disorders in indigenous cattle. *Oxytropis* locoweeds cause more consistent annual losses, coincident with more stable plant populations.

The toxic principle of locoweeds and the *Swainsona* genus of Australia is the indolizidine alkaloid swainsonine. Swainsonine interferes with oligosaccharide degradation and glycoprotein processing by inhibiting lysosomal α-mannosidase and mannosidase II. Resulting lesions are characterized microscopically by cytoplasmic vacuolation of cells in a variety of tissues.[14] Because locoweed poisoning is an induced storage disease, postmitotic cells such as neurons and cardiac myocytes are most vulnerable. Involvement of these cells leads to clinical signs of central nervous system derangement (locoism) and heart failure. Vacuolar degeneration also is observed in other tissues, including the gonads, thyroid gland, pancreas, lymph nodes, and placenta. Lesions in the fetus are similar to those in the dam, presumably because swainsonine traverses the placental barrier.

In pregnant animals, both dam and fetus are affected, with abortion and teratogenic effects recorded. Locoweeds are unique in possessing a broad gestational window for the induction of toxic effects on the fetus. Abortion, the most common untoward effect, can occur at any stage of gestation after ingestion of locoweed for several weeks. Two cows dosed with *Astragalus lentiginosus* through a rumen fistula at 0.6 kg for the first 120 days of gestation aborted deformed fetuses by day 173.[15] Skeletal malformations commonly include limb and joint abnormalities. The fetus normally is hypoxic and hypertensive relative to the dam because of fluid-filled lungs, with the fetus receiving oxygen from the placenta. Locoweed is thought to induce increased vascular resistance in the fetus, an effect similar to that in cattle at high elevations.[1] The increased workload on the fetal heart results in hypertrophy, dilatation, cardiac insufficiency, fluid accumulation, fetal death, and subsequent abortion. In ewes fed *A. lentiginosus,* serum progesterone and cotyledonary prostaglandin concentrations were altered[16]; presumably, cattle are affected in similar fashion. A dose-dependent reduction in serum progesterone concentration and a significant increase in cotyledonary prostaglandins were observed.

Real-time ultrasound imaging was used in the pregnant ewe model to demonstrate the adverse effects of locoweed on fetal growth and development.[17] Ewes fed locoweed during gestational days 60 to 100 developed irregularly shaped cotyledons, with many of these structures becoming atretic. Excessive fluid accumulated in the placenta, leading to fetal heart arrhythmias. During dosing from days 60 to 70 of gestation, the heart rate in affected fetuses initially exceeded 200 beats per minute. With continued exposure to locoweed, fetal heart rate slowed to 60 beats per minute, and 3 days later fetal cardiac arrest occurred, followed by abortion in 40 to 72 hours. Fetal heart arrhythmias occurred concomitantly with cotyledon atrophy and hydrops allantois. Necropsy revealed fetal cardiomegaly. Similar fetal effects are thought to occur in cattle.

Effects of locoweed on the male reproductive tract have been studied in the ram; however, the effects can be extrapolated to other ruminant species. Spermatogenesis was decreased, and numerous cytoplasmic vacuoles have been reported in Sertoli cells, spermatogonia, and primary and secondary spermatocytes.[18] Epithelium lining the epididymis, vas deferens, and seminal vesicles was severely hypertrophied and vacuolated. The lumen of the epididymis was practically devoid of sperm. Glandular tissue of the bulbourethral glands was mildly vacuolated.

Pine Needle Abortion

Needles from the Ponderosa pine tree *(Pinus ponderosa),* lodgepole pine *(P. contorta),* and common juniper *(Juniperus communis)* cause abortion primarily when consumed during the last trimester.[19] Consumption by pregnant cows induces a premature parturition or abortion usually in 1 to 3 days but may be delayed for 2 to 3 weeks.[20] The greatest response from ingestion of pine needles occurs when ingested for a period of 3 days or more

and at a relatively high level (>2 kg/day). Severe winter weather often leads to conditions in which cattle mingle under trees to escape wind and snow. Some calves from affected dams are born weak but may survive with adequate care. Common sequelae include retained fetal membranes and metritis. A study examining the effects of dietary variables on consumption of pine needles and parturition concluded that (1) feeding high levels of protein increased pine needle consumption but not abortion rate, (2) weathered or aged pine needles had activity equivalent to or greater than that of fresh needles, and (3) feeding corn silage to cows prevented pine needle consumption.

Isocupressic acid (ICA) is the abortifacient principle in Ponderosa and lodgepole pines, as well as in common juniper.[19] It is contained in green or dry needles, bark, and branch tips. Isocupressic acid, like acetyl-ICA and succinyl-ICA, is classified as a labdane resin acid. All of these resin acids have induced abortions in cattle. The rumen microbes rapidly hydrolyze acetyl- and succinyl-ICA to ICA, the direct abortifacient. Isocupressic acid levels were 0.8% and 2.0% (dry weight) in lodgepole pine and common juniper, respectively.

The mechanism of pine needle abortion involves a profound constriction of the caruncular arterial bed.[21] Furthermore, pine needle extracts and plasma from fed cows increased uterine arterial tone in vitro. After consumption of pine needles by beef cows in late gestation, uterine arterial blood flow progressively decreased to less than 50% of prefeeding rates before premature delivery of live weak calves. In another study, uterine blood flow in cows fed pine needles decreased progressively, declining to 25.5% of baseline by the day of premature parturition.[22] The evidence suggests that consumption of pine needles induces a progressive reduction in uterine blood flow to the gravid horn and that this reduction causes the onset of premature parturition accompanied by normal prepartal changes in steroid secretion.

Broomweed

Perennial broomweeds or snakeweeds (*Gutierrezia microcephala* or *Gutierrezia sarothrae*) infest vast expanses of arid western rangelands. Although unpalatable, broomweed is one of the first green plants to emerge in the spring. Broomweed causes abortion or premature birth of weak calves. In affected herds, 10% to 60% of calves typically are involved. Of 52 cows fed *G. microcephala,* 23 cows delivered normal calves and 27 cows delivered premature, weak, or dead calves weighing 7.5 to 50 pounds. Broad gestational susceptibility of the fetus to broomweed is apparent from these early experiments. Thirty-four cows had placentas retained for 3 to 10 days after calving. Several cows had signs of systemic illness, and four either died or were euthanized. The toxicity of the broomweed varies according to growing conditions from year to year, stage of growth, and soil type.[23] Broomweed grown on sandy soil is more toxic than that grown on hard soils. The toxic principles in broomweed include mono- and diterpenes, saponins, oxygenated flavonol methyl esters, and yet-to-be-characterized saponins.[24] Specific abortifacients have not been identified.

Fescue

Fescue *(Festuca arundinacea)* toxicosis is caused by ingestion of fungus-infected *(Neotyphodium coenophialum)* tall fescue, mostly the Kentucky-31 cultivar. *N. coenophialum* is a seed-borne, intercellular, systemic fungus that resides in the leaf, sheaths, and flower of the grass host.[25] With 35 million (mostly fungus-infected) acres in the eastern and midwestern United States, the impact on bovine performance is enormous. Newer varieties of fescue have been developed that are free of the endophyte fungus. Unfortunately, the hardiness of this cool-season grass is considerably diminished in the absence of the fungus. Clearly, although it is toxic to cattle and other livestock, the fungus confers stress tolerance to the grass. Fungus-free fescue is less tolerant to weather-related and other stressors, including overgrazing. Cattle seem to like it more, but so do insects, nematodes, and plant pathogens.

The most critical consequence of feeding infected fescue in cow-calf operations is diminished reproductive efficiency. This condition usually is associated with a syndrome commonly referred to as "summer slump" and is pronounced when ambient temperature exceeds 32°C (89°F).[26] Toxic fescue forage fed to steers during the winter months did not cause health problems or reduction in performance; however, it did depress circulating PRL in a dose-dependent manner.[27] Clinical signs of summer fescue toxicosis are exacerbated by elevated environmental temperatures because of a decreased ability to dissipate excess body heat.[26] This is due largely to the peripheral vasoconstrictive effects of the toxic ergot peptide alkaloids (primarily ergovaline) produced by the endophyte fungus *N. coenophialum.* Adverse effects were recorded in two groups of cattle exposed to fescue containing 285 and 381 parts per billion (ppb), respectively, of ergovaline. The vasoconstrictive effects of another endophyte-produced compound, *N*-acetylloline, on the bovine lateral saphenous vein may contribute to fescue-associated problems.[28] These studies suggest possible additive effects of *N*-acetylloline and ergovaline and support the concept that a redistribution of blood flow to internal organs somehow compromises reproduction. Other signs associated with the summer toxicosis syndrome in general include slobbering, open-mouth breathing, reduced average daily gain, and a propensity to spend daytime hours in water or shade, rather than grazing. Fescue-induced hyperthermia also appears to be partly responsible for the decreased intensity of estrus and an increased embryolethality. This is consistent with the finding that bovine embryos incubated at 40°C for 48 to 60 hours suffer a dramatic increase in mortality.[29]

Reduced calving rates are attributed to feeding endophyte-infected fescue.[30] Ninety-six percent of beef heifers raised on low-endophyte fescue (0% to 5% plants infected) conceived, compared with 55% of those raised on high-endophyte fescue (80% to 90% plants infected). Of primiparous cows grazing highly infected pastures, 33% conceived, versus 93% on low-endophyte pastures. Conception rates decreased 3.5% for each 10% increase in fungal infection. In a 3-year study, 39% of animals on

high-endophyte fescue raised a calf, versus 65% of those on low-endophyte fescue pasture.[31] The proportion of heifers with surviving calves was 11% with high-endophyte fescue versus 58% with low-endophyte fescue in the first-year, 63% versus 84% in the second year, and 42% versus 53% in the third year. First-service artificial insemination (AI) conception rates for the high-endophyte–exposed heifers were reduced for the first 2 years of the study (45% versus 74%)[32]; however, the overall first-service conception rates among those cows inseminated for the 3-year period were 74% and 78% for the high- and low-endophyte groups, respectively.

Alterations in the hormonal milieu of cattle also are associated with infected fescue ingestion. Circulating prolactin (PRL) levels are depressed in cattle consuming infected fescue.[33] Dopamine is a known inhibitor of PRL secretion, and elevated circulating dopamine is associated with decreased serum PRL.[34] The dopamine-like activity of a toxic fescue diet is reflected by the significant depression in serum PRL within 48 hours after ingestion commences.[26] This biomarker of exposure is sustained regardless of ambient temperature effects, indicating that certain hormone levels are altered even in the absence of high environmental temperatures. Heat stress does appear to potentiate the adverse effects of infected fescue on reproductive function, however. McKenzie and Erickson[35] reported a 23% reduction in basal luteinizing hormone (LH) concentrations in heifers fed fescue hay. Other investigators, however, found no effect of endophyte-infected fescue on serum LH despite ergovaline intake at least 50% greater than the typical field exposure.[36] Altered luteal function was reported in 62% of heifers in which a corpus luteum was detected by ultrasonography.[37] Serum progesterone level was depressed and was unrelated to decreased average daily gain; however, it was prevented by high-energy supplementation. Puberty, as detected by the first sustained increase in serum progesterone, was delayed in Angus heifers raised on endophyte-infected fescue.[31]

These reports substantiate the adverse effects of toxic fescue on bovine reproductive function. Treatment of intoxicated cattle is neither practical nor economically feasible, and it is not particularly efficacious. Several mineral supplements have been touted as alleviating the clinical signs of fescue toxicosis. To date, little scientific evidence is available to support their efficacy. Slow-release formulations of thiabendazole[38] and ivermectin[39] obviate some of the adverse effects of the endophyte toxins. Thiabendazole has been shown to reduce some of the vasoconstrictive activity of toxic fescue. Enhanced reproductive performance, however, has not been demonstrated. Internal parasites do reduce forage intake in cattle, which translates into a reduction in gain. Work done by Dr. George Garner at the University of Missouri with cattle in environmental chambers indicates that parasites tend to lower the temperature threshold at which animals show signs of fescue toxicosis. The decreased sensitivity to summer fescue toxicosis, together with increased intake, may partially explain why dewormers improve performance. Metoclopramide, a dopamine receptor antagonist, was shown to increase the concentration of serum PRL, prolong grazing time, and maximize daily gain in steers ingesting toxic fescue.[40] Further research in these areas is necessary to demonstrate an effective cost-benefit ratio.

Toxic fescue pastures can be either renovated or managed; the decision is an economic one. To remove endophyte-infected fescue, the application of an effective herbicide is followed by a smother crop such as wheat or sudan grass, harvesting of the smother crop, and another application of herbicide if necessary.[41] Cattle can be rotated off fescue during the hot summer months to increase gains. Toxic pastures also can be interseeded with legumes such as red clover, lespedeza, and birdsfoot trefoil for the dilution effect. Supplementation with corn at approximately 0.6% of body weight will allow efficient forage digestion and reduce the toxic effects of fescue. Avoiding the excessive application of nitrogen fertilizer reduces the concentration of ergovaline in toxic fescue. Application and type of fertilizer can be selected to encourage the growth of legumes. Cattle should not be permitted to graze the most toxic portion of infected fescue, the seedheads. Clipping or heavy grazing will prevent this from occurring. Finally, the ammoniation of toxic fescue hay is highly recommended to increase digestibility, reduce the toxic effects of ergovaline, and increase daily gains by 50% or more.

Gossypol

Gossypol is the primary toxic principle found in whole cottonseed and cottonseed meal. It is a yellow, polyphenolic pigment produced in high concentrations in the seeds of the cotton plant (genus *Gossypium*). Being toxic, gossypol imparts insect resistance to cotton, making low-gossypol varieties subject to considerable damage. In a different way, gossypol has a cumulative toxic effect in monogastric and ruminant animals. During processing the seeds are sliced into flakes to facilitate extraction of oil for use in salad oil, margarine, and shortening. The remaining cottonseed flakes, together with some free gossypol, are ground into cottonseed meal for use as a protein supplement for livestock.[42] Gossypol poisoning rarely occurs and usually can be traced to situations in which gossypol concentrations in the ration were unknown or recommended safe levels were exceeded.

Gossypol content of whole cottonseed and cottonseed meal varies according to the species of cotton, environmental conditions during the growing season, and the method of oil extraction.[42] It exists in two forms: the free, toxicologically active form and the inactive, protein-bound form. Gossypol in unprocessed seed exists exclusively in the toxic unbound form and is readily absorbed from the gut of monogastrics. Mature ruminants, however, are relatively resistant to free gossypol because of their ability to detoxify it by binding to rumen proteins. High free gossypol intake can overwhelm this detoxifying mechanism, leading to obvious clinical intoxication[43] or insidious effects on reproduction.[44,45] Mature ruminants can tolerate large quantities of free gossypol without apparent adverse effects; however, reduced performance was detected in dairy cows fed rations containing 2250 parts per million (ppm) for several weeks.[46]

The adverse effects of gossypol on reproduction were first recognized in humans in China during the 1930s and 1940s.[47] Not a single childbirth was reported in an area of China where out of economic necessity, crude cottonseed oil was substituted for soybean oil in cooking. Afflicted women suffered from amenorrhea, and the men were impotent. Subsequent studies of gossypol as a birth control agent in humans received widespread attention.

To assess the adverse effects of gossypol on bovine reproduction, different levels of gossypol in rations have been studied. Brangus heifers fed diets containing either 5 g of free gossypol/day from direct solvent–extracted cottonseed meal or 15 g free gossypol/day from cottonseed for 70 days were evaluated, after follicle-stimulating hormone (FSH) treatment, for adverse effects on embryo development, grade, and viability[48] and follicular development and function.[49] The number of follicles and follicular size were reduced in heifers receiving 5 g of free gossypol/day from direct solvent cottonseed meal but not in heifers receiving 15 g of free gossypol from cottonseed. Embryo quality, developmental stage, and viability indexes were not significantly different for heifers fed the control diet and those fed the gossypol diets; however, a higher percentage of degenerative embryos were found in heifers receiving 5 g free gossypol from cottonseed meal than in those fed either of the other regimens. By contrast, another study in which direct solvent cottonseed meal and cottonseed were used to provide free gossypol intakes of 0, 0.4, 1.7, 3.3, and 8.2 g/day for 62 days to postpubertal beef heifers showed no treatment-related difference in 30-day pregnancy rates after removal of gossypol from the diet.[50] Heifers consuming 10 to 20 g/day of dietary free gossypol for 1 to 2 months exhibited increased red blood cell fragility but no detrimental effects on growth rates or reproduction.[51] Lactating cows fed 20 mg free gossypol/kg of body weight for 33 weeks did not have significant differences from control animals in preovulatory LH surge, luteal phase concentrations of progesterone, follicular fluid concentrations of estradiol and progesterone, and 60-day pregnancy rates.[51] Gossypol interferes with normal in vitro development of embryos and synthesis of progesterone by luteal cells.[52] These findings have not been corroborated in vivo. Current evidence indicates that rations containing reasonable concentrations of gossypol are unlikely to adversely affect reproductive performance in heifers and cows.

Gossypol impairs reproduction in laboratory animal and human males at concentrations sometimes encountered in commercial livestock rations.[44] In bovine males fed gossypol-containing rations, histologic evaluation revealed an increased seminiferous tubule lumen diameter, thinner germinal epithelium wall, and a decreased number of germ cell layers.[53,54] Spermatocytes were present in the lumen of seminiferous tubules of bulls fed gossypol but not in control animals. The cellular damage is confined mainly to the intraluminal cell layers. Brahman bulls fed a ration of cottonseed meal and corn in a formulation to deliver 8.2 g of free gossypol per bull per day had a lower percentage of normal spermatozoa compared with control animals (49% ± 9.8% versus 83% ± 3.2%) by week 5. The abnormality was restricted primarily to midpiece morphology.[55] Sperm motility also was depressed in gossypol-fed bulls by week 9. These studies reveal the relative insensitivity of ruminant females to dietary gossypol. By contrast, bulls show marked testicular damage, implying that free gossypol intake should be restricted.

Poisonous Plants of Lesser Importance

Consumption of *Iva angustifolia* (narrowleaf sumpweed) has been associated with mid- to late-gestation bovine abortion, lactogenesis, vaginal mucous discharge, and placental mineralization.[56] Similarly, *Cupressus macrocarpa* (cypress tree) ingestion has been associated with abortion in cattle and cerebral leukomalacia in the aborted fetus.[57]

PHYTOESTROGENS

Phytoestrogens are estrogen mimics produced in relatively large amounts by certain legumes. The quantity of phytoestrogens is rarely sufficient to cause total reproductive failure, but subclinical impairment is common in sheep.[58] Ingestion of excessive forage estrogens by ruminants can cause hyperestrogenism, with nymphomania, cystic ovaries, and swollen genitalia, or antiestrogenic effects of gonadal hypoplasia and anestrus, depending on the action of the compound on estrogenic receptors.[59]

The contribution of phytoestrogens to reproductive failure in cattle is largely anecdotal, with limited documentation by controlled studies. In a herd of 700 cows, the pregnancy rate dropped to 45% in cattle pastured on burr medic (*Medicago* spp.), known to contain the proestrogens formononetin and coumestrol.[60] In another herd of 100 cows, the pregnancy rate dropped to 10%, with shortened estrous cycles in cattle pastured on subterranean clover *(Trifolium),* which contains the proestrogens isoflavone biochanin A and genistein. The influence of phytoestrogens was studied in three ovariectomized heifers, each fed 20 kg of 100% red clover silage daily for 14 days.[61] Behavior, reproductive organs, and pituitary response to exogenous gonadotropin-releasing hormone (GnRH) injections were monitored. Clinical effects included development of edema and mucous discharge from the vulva, presence of milky fluid in the mammae, and increases in teat size and cross-sectional area of the uterus. The red clover silage diet appeared to attenuate the pituitary response to GnRH. The concentration of phytoestrogens in forage depends on the time of harvest and methods for preservation. Field-curing hay reduces estrogenic activity by approximately 70%, whereas ensiling preserves it.[62]

NITRATE-INDUCED ABORTION

Many species of animals are susceptible to nitrate (NO_3^-) poisoning, with cattle being the most frequently affected. Ruminants are especially vulnerable to nitrate intoxica-

tion because of the nitrate-reducing potential of rumen microbes. Cattle are therefore susceptible to both preformed nitrite, such as from a fertilizer source, and nitrate from nitrate-accumulating plants or fertilizer. The reduction of NO_3^- to the more toxic nitrite (NO_2^-) is an intermediate step in the bacterially mediated biochemical sequence of the formation of fully reduced ammonia (NH_3). The relatively toxic nitrite ion can be absorbed into the bloodstream, where it oxidizes normal ferrous iron (Fe^{2+}) in hemoglobin to the ferric state (Fe^{3+}), forming methemoglobin. Methemoglobin is unable to carry oxygen, resulting in hypoxemic stress in supplied tissues. Excessive maternal exposure to nitrate or nitrite may be a cause of late-gestation abortion in cattle. Forage nitrate concentrations of approximately 1% are considered potentially toxic to cattle. Field cases of bovine abortion have been associated with forage containing as little as 0.52% nitrate, and abortion usually is reported to occur with feeds containing 0.61% to 1.0% nitrate.[63] Common examples of nitrate-accumulating plants include Sudan grass, oat, wheat, corn, pigweed, and Johnson grass. Heavy fertilization associated with cool, cloudy growing conditions is conducive to nitrate accumulation.

Placental transfer of oxygen may be greatly reduced, with consequent hypoxia and intrauterine death of the fetus, in nitrate-poisoned cows. Further adverse effects of nitrite include its vasodilatory action and the consequent reduction in mean arterial blood pressure and oxygen tension.[64] Hypoxemia in late-gestation fetuses results in increased cortisol[65] and ACTH concentrations in fetal plasma.[66] Nitrite-induced fetal hypoxemia could result in abortion as a result of anoxic death of the fetus, as well as activation of the fetal adrenals. Sodium nitrite given intravenously to pregnant cows at a dosage of 20 mg/kg of body weight was fatal to two of eight fetuses within 24 hours.[67] Nitrate concentration in fetal ocular fluid of casarean-delivered fetuses equaled or exceeded the perinatal concentrations of 20 µg NO_3^-/ml (20 ppm) found in specimens diagnostic for excessive nitrate exposure.

MYCOTOXINS

Reproductive failure in livestock often is thought to be a feed-associated problem when an infectious cause cannot be diagnosed. Evidence to support such claims frequently hinges on the chemical identification of mycotoxins in representative feed samples. Unfortunately, few experimental studies provide definitive proof of the role of mycotoxins in bovine reproductive disease. Empirical and anecdotal evidence demonstrating a cause-and-effect role for mycotoxins involved mycotoxin concentrations rarely found in naturally contaminated rations.

The estrogenic mycotoxin **zearalenone** has a potent effect in female swine at concentrations of 1 to 2 ppm in complete rations. The relative resistance of cattle to zearalenone is illustrated by the following studies. Cycling, virgin Holstein heifers given daily oral doses of 250 mg zearalenone (equivalent to 62.5 ppm in the dairy ration fed these heifers) for one nonbreeding estrous cycle and the following two estrous cycles during which the heifers were artificially inseminated had a 62% conception rate, versus 87% in control animals.[68] Serum progesterone was unaffected. Doses up to 500 mg of 99% pure zearalenone given once per day to 18 nonpregnant, multiparous dairy cows for two consecutive estrous cycles had no effect on serum progesterone or estrous cycle length.[69] An estrogenic mycotoxicosis induced by consumption of moldy forage was observed in three Friesian cows and four buffaloes.[70] Similar changes were induced in mouse reproductive tracts when the animals were injected with the moldy hay extract.

Ergot alkaloids, produced by the *Claviceps* genus, have been incriminated in various reproductive diseases. *Claviceps* fungi invade the ovary of various grasses and small grains, replacing these structures with dense fungal masses referred to as **ergot bodies** or sclerotia. Ergot bodies are the source of physiologically active ergot alkaloids found in contaminated grains such as rye, barley, oat, wheat, fescue, and bromegrass. The ergotamine group of ergot alkaloids (i.e., ergopeptine alkaloids, which cause myometrial contraction in late pregnancy) induce a marked peripheral vasoconstriction, resulting in gangrene of the distal extremities.[71] The natural alkaloids of ergot also are potent stimulants of uterine muscle.[72] Small doses stimulate increased force and frequency of contraction. The sensitivity of the uterus to ergot alkaloids varies with maturity and the stage of gestation. Exposure of the gravid uterus during late gestation elicits forceful, prolonged contractions with a marked increase in tone. In sheep, supplementary feeding of a ration containing 0.1%, 0.5%, or 0.7% ergot bodies by weight decreased the number of ewes lambing by 20%[73]; by extrapolation, similar results could be expected in cattle. Abortion occurred in 11 of 36 cows in late gestation 7 days after being placed on a ryegrass pasture.[74] At least 25% of the seedheads of ryegrass contained ergot bodies. Aside from the adverse effects on reproduction, ergotism promotes agalactia in several livestock species including cattle.[75]

Bovine abortion has been associated with consumption of aflatoxin-contaminated peanuts.[76] Eleven of 14 cows in late gestation aborted after consumption of aflatoxin-tainted peanuts for 4 days. Eight of the cows died as a result of acute aflatoxicosis. A subsample of the peanuts contained 77 ppm aflatoxin. More than a few parts per million of aflatoxin are seldom found in nature. Clearly, abortion in these cows was secondary to acute toxicant-induced alteration in maternal homeostasis. No empirical evidence is available to suggest that aflatoxin doses below the acute maternally toxic threshold are capable of a direct abortifacient effect.

POLYBROMINATED BIPHENYLS

The appearance of polybrominated biphenyls (PBBs) in 1973 in cattle feed was a dramatic event receiving widespread media attention. The source of these compounds was from accidental incorporation of a flame retardant into cattle rations.[77] Adverse effects on reproduction included prolonged gestation and the resulting dystocia, poor udder development, septic metritis, and death of newborn calves.

CHAPTER 55

Dropsical Conditions Affecting Pregnancy

SIMON F. PEEK

Hydrallantois and **hydramnios**, hydrops of the allantois and the amnion, respectively, are the two most common causes of dropsy of the fetal membranes and fetus in cattle. Other, less common causes include edema of the chorioallantois, fetal anasarca, and fetal edema with ascites and hydrothorax.[1] In the largest published retrospective study of hydrops to date, Vandeplassche and associates documented that of a total of 60 cases, hydroallantois accounted for 88%, 5% of the cases were hydramnios, and 7% involved both compartments.[2]

HYDRALLANTOIS

Hydrallantois is the single pathologic factor present in 85% to 90% of dropsical conditions in the bovine.[1,2] Placental dysfunction is thought to be the cause of hydrallantois, although this condition is observed with both uterine and placental disease. Adventitious placentation commonly is present (Fig. 55-1), and the number of caruncles also may be deficient. This deficiency may be due to a congenital lack of development or to uterine disease acquired later in life. A reduction in the number of caruncles also has been noted with hydrallantois, and those that are present tend to be hypertrophied.[3] The condition is seen sporadically in both dairy and beef cows, and dams carrying multiple fetuses are at greater risk for hydrallantois. An increased prevalence of hydrallantois has been noted in recipient cattle carrying fetuses produced by in vitro fertilization and by transgenic and cloning technologies.[4,5]

The structural and functional changes in the chorioallantois that lead to hydrallantois result in the excessive production of a transudative fluid that resembles plasma.[1] In severe hydrallantois, the accumulated fluid volume may reach 150 to 250 L, and the combined weight of the dropsical fluids, membranes, and fetus can exceed 225 kg.[3] Fluid composition studies comparing allantoic fluid from normal cows in late gestation and from those suffering from hydrallantois have demonstrated marked differences in sodium, potassium, chloride, and creatinine levels.[2,6,7] In hydrallantois, the levels of these electrolytes are much higher, more closely resembling plasma levels.[8] In addition, lower peripheral plasma concentrations of estradiol have been observed in cows suffering from hydrallantois.[7] The exact role of estrogen deficiency in the maintenance of fetal membrane permeability and its effect on allantoic and amniotic fluid volume in the cow remains uncertain. Studies in pigs and ovariectomized sheep, however, point to a link between the estrogen-to-progesterone ratio and fetal fluid volume.[8,9]

The clinical signs associated with hydrallantois vary with the volume of fluid at presentation. Abdominal distention rarely has been noted as early as the fifth month of gestation.[3] The typical case of hydrallantois, however, is characterized by a larger than normal accumulation of allantoic fluid during a 5- to 20-day period in the last trimester of pregnancy[3] (Fig. 55-2). Mild cases may remain undiagnosed or may be suspected only at parturition when an abnormally large volume of fetal fluids is expelled. In such instances, the producer may have assumed that the dam was carrying twins. In the more severe cases, progressive abdominal distention during the last 4 to 6 weeks of pregnancy worsens to such an extent as to decrease appetite and cause difficulty moving or rising.[10] Progressive maternal tachycardia, anxiety, reduced appetite, and dehydration should be anticipated with untreated hydrallantois. Recumbency and metabolic problems, particularly ketosis, are therefore potential complications associated with advanced cases of hydrallantois, and these will be even more likely should the condition be associated with multiple fetuses. The combined weight of the fetus(es) and allantoic fluid also may result in either prepubic tendon rupture or secondary ventral abdominal muscle herniation.

A definitive diagnosis of hydrallantois can be obtained by rectal palpation. The external appearance of the cow may suggest the presence of vagal indigestion, but rectal palpation will quickly distinguish between the two conditions. In hydrallantois, the abdominal cavity will be dominated by the fluid-filled uterus, frequently precluding palpation of other structures, whereas vagal indigestion will be characterized by a prominent, enlarged L- or V-shaped rumen. The fetus and placentomes usually are not palpable in cases of hydrallantois, and it is therefore difficult to ascertain the viability of the fetus without fetal heart rate measurement. Evaluation of fetal number and viability is best performed by transabdominal ultrasound examination with a 2.5- or 5-MHz sector scanner.

HYDRAMNIOS

Hydramnios causes approximately 10% of the cases of hydrops of the fetal membranes in cows.[1] The condition is characterized by gradual accumulation of excessive amniotic fluid, with progressive abdominal enlargement in the dam during the last trimester of pregnancy. The abdominal distention typically is slower to develop than

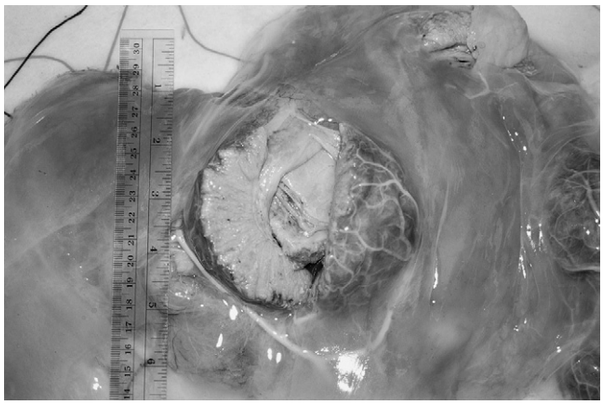

Fig. 55-1 Abnormal cotyledon from the placenta of a cow with hydrallantois (8 months of gestation). The cotyledon, measuring 5 inches in diameter, has been sectioned; note the excessive edema within the intercotyledonary placenta.

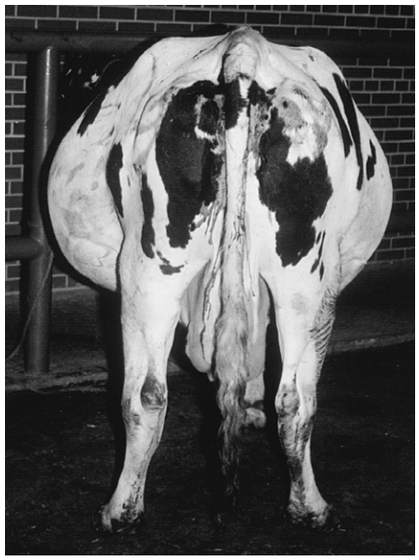

Fig. 55-2 Severe bilateral abdominal distention secondary to hydrallantois is evident when this adult Holstein cow is viewed from the rear. (Courtesy of Dr. W. C. Rebhun.)

in hydrallantois.[3] Hydrops of the amnion usually is the result of an abnormal fetus and is therefore considered a fetal problem, whereas hydrallantois is due to maternal abnormalities of placentation. From midgestation to term, amniotic fluid normally is swallowed or inhaled into the large bronchi of the fetus and subsequently absorbed.[11] Hydramnios results from fetal abnormalities that prevent swallowing or intestinal transport of amniotic fluids.[1] During late gestation, the volume of normal amniotic fluid reaches between 3.8 and 7.6 L; however, in hydramnios, the volume will increase to 19 to 114 L. The fluid is viscous and syrupy in consistency.[1]

Hydramnios can be associated with both genetic and nongenetic fetal abnormalities. Certain fetal anomalies inherited as autosomal recessive traits have been associated with hydramnios in specific breeds of cattle:

- Dexter cattle pregnant with bulldog calves. These fetuses usually are aborted between 5 and 8 months of gestation.
- Angus cattle pregnant with brachygnathic calves whose skeletons also lack marrow cavities. Affected cows demonstrate abdominal enlargement in the last month of pregnancy.
- Red Danish cattle pregnant with muscle contracture monsters
- Guernsey cattle pregnant with calves suffering from pituitary hypoplasia or aplasia. Prolonged gestational length also is seen in this condition owing to the abnormal fetal pituitary-adrenal axis.
- Hereford cattle pregnant with hydrocephalic calves.[1]

The nongenetic causes of hydramnios in cattle include those anomalies that impair the ability of the fetus to swallow amniotic fluid, such as schistosomus reflexus. Hydramnios also has been reported in hybrid crosses between American bison and domestic cattle.[11]

TREATMENT OF HYDRALLANTOIS AND HYDRAMNIOS

The decision whether to treat a cow suffering from hydrallantois or hydramnios should always be tempered by practical considerations regarding the likelihood of success and the etiology of the specific condition. Salvaging the cow for slaughter should be considered in all cases of hydrops in the cow.[1,3,11] The cause of hydrallantois is uterine or placental disease, or both, so the likelihood of recurrence should be considered.[3] In cases of hydramnios, an inherited etiology should be considered and the fact that the fetus most likely will be anomalous should be borne in mind. If the fetal anomaly is due to an established autosomal recessive disorder, both the dam and the sire will be carriers.[1,3]

The severity of the condition at presentation also should play an important role in decision making. In severe cases of hydrallantois in which the patient is already recumbent and unable to rise, or prepubic tendon or abdominal wall rupture has already occurred, the prognosis becomes increasingly grave, and immediate slaughter should be considered. In dairy cattle, because individual animals are in negative energy balance and often within the last trimester at the time of diagnosis, they may never obtain projected production levels despite successful termination of a pathologic pregnancy. For the aforementioned reasons, salvage usually is considered unless the cow or the fetus is particularly valuable and the pregnancy is within 2 to 3 weeks of term.[10]

If the decision is made to treat the condition, several options exist. Most clinicians agree that elective cesarean section is rarely as successful as induced parturition.[3,10,11] Uterine atony due to overdistention, retained fetal membranes, and severe metritis are complications that should always be anticipated after either induced parturition or elective surgery. Debate exists among different authors about whether hydrops patients are markedly dehydrated

or not; some sources support the hypothesis,[1,10] whereas others refute it.[11] The induction of parturition, however, will result in a slower release of uterine fluids than the rapid decompression that occurs after surgery. The rapid release of up to 250 L of allantoic fluid would certainly seem to predispose the patient to hypovolemic shock subsequent to compartmental shifting into the splanchnic pool.[11] Some clinicians advocate the use of a trocar or plastic tube inserted percutaneously through the abdominal and uterine walls to draw off fluid gradually during a 24-hour period before elective cesarean.[6] This procedure will predispose the cow to the development of peritonitis and/or metritis, however, and whether this maneuver actually allows a significant volume of fluid to drain is uncertain.[3] Drainage also can be attempted transcervically if the cervix is relaxed enough to permit passage of a suitable catheter. In cases of hydrallantois treated by cesarean section, some authors have observed that the uterus may continue to fill with a significant volume of transudative fluid for up to 48 hours after surgery.[1]

To induce either abortion or calving, 25 to 35 mg of prostaglandin $F_{2\alpha}$ can be injected intramuscularly either alone or in combination with dexamethasone.[3] An alternative regimen involves the administration of 10 to 20 mg of flumethasone intramuscularly. Some clinicians advocate the use of 6 to 8 mg of estradiol cypionate intramuscularly once daily until parturition to relax the cervix and caudal reproductive tract. The combination of a prostaglandin and an abortifacient steroid reliably induces parturition in late gestation in a normal cow within 24 to 48 hours, but the response can be rather more unpredictable in cases of hydrops.

After induction of parturition, the cow should be carefully monitored and regularly examined for signs of labor. Periodic vaginal examination is important to ascertain the progress of cervical dilation and to rupture the fetal membranes as soon as possible.[3] Once the fetus can be palpated per vagina, it should be assessed for size, position, and the presence of any anomalies that may hinder vaginal delivery. In many cases of hydrallantois, parturition may not progress beyond this point as a result of uterine atony, and assistance will be required to complete delivery.

After induction, the cow should be kept in a deeply bedded stall with good footing, to limit the chances of catastrophic musculoskeletal injury associated with parturition. If dehydration is suspected or if the cow has evidence of other metabolic complications (ketosis, hypocalcemia), then supportive polyionic intravenous fluids augmented with dextrose and calcium are indicated. In a field situation, acute hypovolemic shock can be addressed with smaller volumes of hypertonic saline (2–3 L of 7% sodium chloride given intravenously, followed by access to water and electrolyte solutions). In dairy cows, milking should be initiated as soon as the calf is delivered, although it often can be challenging to achieve projected production levels in cows that have experienced a dropsical pregnancy. A majority of fetuses will be small, nonviable, or anomalous, but in the rare case of an apparently viable calf, colostrum must be provided from an alternative source, because the dam rarely has normal colostrum. With exceptionally valuable calves it is wise to consider plasma administration, because colostrum absorption may be compromised by precocious gut closure induced by chronic in utero swallowing of excessive fetal fluid.

The prognosis for individual animals suffering from hydrallantois, particularly if the condition is advanced at the time of diagnosis, is much poorer for life and future fertility than is the case with hydramnios. Retained fetal membranes and potentially severe metritis should be anticipated with both conditions, but especially with hydrallantois, particularly if parturition is induced or the cervix is still significantly closed at the time of elective cesarean section. Prophylactic antibiotics should be instituted if the cow is not being sold for slaughter.

OTHER DROPSICAL CONDITIONS OF CATTLE

Dropsical conditions other than hydrallantois and hydramnios are very rare but include the following:

Fetal ascites. This condition has been associated with both infectious and noninfectious fetal pathology. Fetal ascites and fetal and placental edema can be seen with intrauterine fetal death and autolysis from whatever cause, and the degree of fetal enlargement dictates whether or not dystocia results.[1]

Edema of the chorioallantois. Excessive edema of the chorioallantois has been classically associated with *Brucella abortus* infection.[1]

Fetal anasarca or excessive fetal edema. Both of these conditions can be seen in isolation or in combination with hydrallantois or hydramnios.[1] Fetal anasarca can be an inherited condition in the Ayrshire breed as an autosomal recessive disorder.[12]

In all of these conditions, with the possible exception of edema of the chorioallantois, abdominal enlargement usually is not noted.[1]

CHAPTER 56

Effects of Environment on Bovine Reproduction

PETER JAMES HANSEN

> Whoever would study medicine aright must first learn of the following subjects. First, he must consider the effect of each of the seasons of the year and the differences between them.
>
> HIPPOCRATES (c. 400 BC), *Airs, Waters, Places*

Originally domesticated in the Near East around 8000 years ago, domestic cattle have become distributed throughout most of the world. The rate of geographic dispersion of cattle has been slow until recently, and distinct genetic populations of cattle have arisen that are adapted to specific environments. Beginning in the latter half of the 19th century, and progressing rapidly in the 20th century to the present, however, technologic advances in transportation and management practices have led to rapid changes in the environment in which cattle are reared and in the genetic composition of cattle. These advances involved geographic change in location of specific breeds, management practices that confer environmental stress, and alterations in the genetics and physiology of cattle that have reduced adaptation to the local environment. As a result, cattle often are placed in environments in which physiologic and productive functions are not optimal. Cattle, like most mammals, are very adaptable animals and possess many homeokinetic mechanisms to maintain critical body functions at the expense of changes in other physiologic functions. Unfortunately, reproduction is one of the physiologic functions that often is most expendable in homeokinetic control systems. In fact, reproductive function is dictated in large part by the environment, and heritability estimates for reproductive traits are low.

At least four general approaches can be taken to manipulate environmental effects on reproduction. First, the environment can be altered to provide cows with conditions more conducive to reproduction. Second, it also is possible to change the cow genetically so that it is more adapted to local environmental conditions. Third, it often is possible to schedule reproductive activity so it occurs when climatic conditions are optimal. Finally, it sometimes is possible to alter the physiology of the cow to modify the effects of environment on reproduction. Successful development of any of these schemes will depend on knowledge of the magnitude of environmental effects and of the physiologic alterations mediating environmental effects. This chapter discusses in detail what is known about these subjects for two environmental inputs—heat stress and photoperiod—and suggests management approaches to enhance reproductive function of cattle through manipulation of these environmental influences. Also provided is some information about other environmental regulators of reproduction.

EFFECTS OF HEAT STRESS ON REPRODUCTIVE FUNCTION

Among the highest physiologic priorities of all homeotherms is maintenance of body temperature. The cow maintains a constant core body temperature of approximately 38.5°C by matching internal heat production with net loss of heat to the environment. In situations leading to hyperthermia (internal heat

This chapter discusses in detail what is known about these subjects for two environmental inputs—heat stress and photoperiod—and suggests management approaches to enhance reproductive function of cattle through manipulation of these environmental influences. Also provided is some information about other environmental regulators of reproduction.

EFFECTS OF HEAT STRESS ON REPRODUCTIVE FUNCTION

Among the highest physiologic priorities of all homeotherms is maintenance of body temperature. The cow maintains a constant core body temperature of approximately 38.5°C by matching internal heat production with net loss of heat to the environment. In situations leading to hyperthermia (internal heat

production greater than net loss of heat), thermoregulatory regions of the central nervous system engage physiologic systems to reduce internal heat production and increase net heat flow from the body. Several physiologic changes that stabilize body temperature are deleterious to reproduction. In addition, the hyperthermia experienced by heat-stressed cows can itself compromise reproductive function. Taken together, these effects lead to a severe reduction in reproductive performance of cattle.

All cattle are at risk of becoming hyperthermic, but the problem of heat stress is greatest in lactating dairy cattle populations. Genetic selection for milk yield has produced an animal with high internal heat production, thus increasing susceptibility to hyperthermia. In lactating cows, the upper critical temperature (the ambient temperature at which hyperthermia occurs) is as low as 24° to 27° C. Effects of heat stress are therefore not limited to the tropics but sometimes occur during the summer in temperate zones. By contrast, many beef breeds are adapted for tropical or semitropical conditions. Indeed, some reports indicate that reproductive function of Zebu cattle is highest in summer and lowest in winter.

Detection of Estrus

As shown in Figure 56-1, ability to detect estrus in *Bos taurus* declines during periods of heat stress. This decline occurs in large part because of a reduction in duration of estrous behavior. In contrast with *B. taurus*, evidence for decreased duration of estrus in *Bos indicus* by heat stress is scarce. Under Florida conditions, estrus in Brahman heifers averaged 8.6 ± 2.3 hours in spring, 5.5 ± 1.2 hours

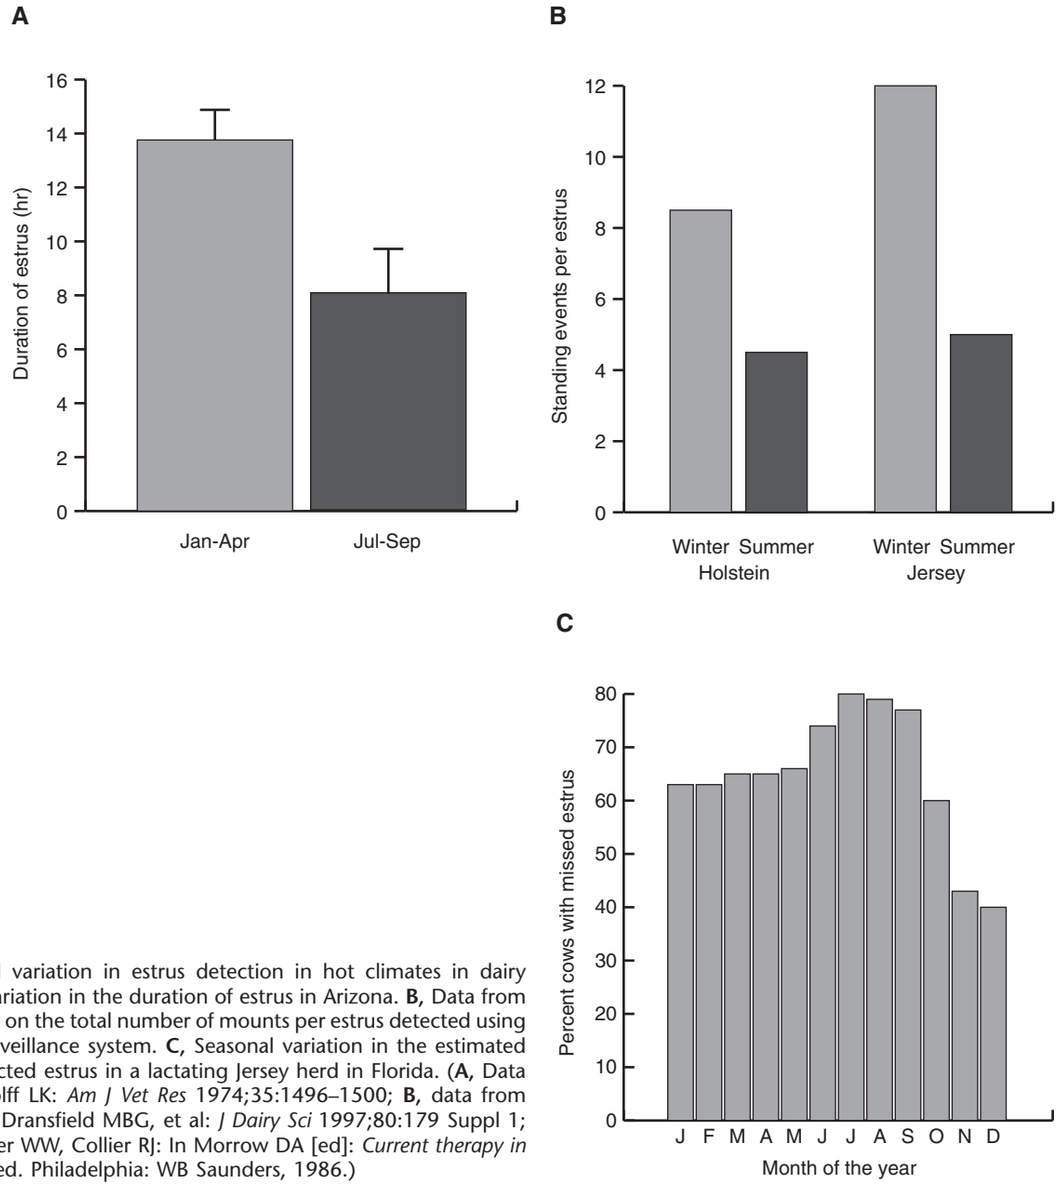

Fig. 56-1 Seasonal variation in estrus detection in hot climates in dairy cattle. **A,** Seasonal variation in the duration of estrus in Arizona. **B,** Data from dairy cows in Virginia on the total number of mounts per estrus detected using a radiotelemetric surveillance system. **C,** Seasonal variation in the estimated frequency of undetected estrus in a lactating Jersey herd in Florida. (**A,** Data from Monty DE, Wolff LK: *Am J Vet Res* 1974;35:1496–1500; **B,** data from Nebel RL, Jobst SM, Dransfield MBG, et al: *J Dairy Sci* 1997;80:179 Suppl 1; **C,** data from Thatcher WW, Collier RJ: In Morrow DA [ed]: *Current therapy in theriogenology*, 2nd ed. Philadelphia: WB Saunders, 1986.)

in summer and 5.4 ± 0.5 hours in fall and 6.8 ± 1.6 hours in winter.[1] In this same study, under conditions in which variation in feed availability was minimal, the proportion of ovulations without detected estrus was greater in winter (59.7%) than in summer (40.3%).

Reduced estrous behavior probably is related, at least in part, to reduced locomotor activity experienced by heat-stressed animals. An endocrine cause also is possible, because heat stress has been reported to reduce peripheral concentrations of estradiol-17β around the time of estrus in some studies. Heat stress also has been observed to decrease gonadotropin responses to injection of gonadotropin-releasing hormone (GnRH) in cows with low circulating concentrations of estradiol-17β.

Effects of Heat Stress on Establishment of Pregnancy

Data in Figure 56-2 illustrate the marked seasonal depression in pregnancy rates per insemination of artificially inseminated dairy cattle in warm months of the year. This depression is most apparent in regions of the world with hot climates but can occur in more temperate areas also. Heat stress is the major environmental factor responsible for lowered pregnancy rates in the summer. Experimental exposure of cattle to heat stress reduced pregnancy rate and embryonic survival, whereas provision of cooling during the summer improved the frequency of cows' becoming pregnant after insemination (Table 56-1). Moreover, the magnitude of the depression in pregnancy rate is proportional to the degree of hyperthermia; this has been demonstrated for both dairy and beef cows.

It is important to define the phases of the reproductive process leading to fertilization and embryonic development that are sensitive to maternal hyperthermia, because together these phases dictate the critical windows in which cows must be kept homeothermic to maintain high pregnancy rates. Disruption of the reproductive process can occur quite early—during oocyte growth or maturation. Although little seasonal effect on fertilization rate for oocytes subjected to in vitro fertilization (IVF) has been observed, fertilized oocytes collected from cows during the summer are less likely to give rise to an embryo capable of development to the blastocyst stage than are embryos collected during the winter. Seasonal variation in performance of embryo production systems based on

NS, not significant.

IVF has been observed even in a relatively cool region like Wisconsin. Additional evidence from Israel suggests that oocyte quality gradually improves as season progresses from early to late autumn, as supported by data from studies in which cows were subjected to multiple oocyte recoveries.

The periovulatory period represents another period during which the establishment of pregnancy can be disrupted by heat stress. For example, heat stress of superovulated cows for 10 hours beginning at the onset of estrus had no effect on fertilization rate but reduced the proportion of normal embryos recovered on day 7 after estrus. This effect of heat stress was not caused by effects on spermatozoa within the reproductive tract, because insemination was not performed until body temperatures of heat-stressed cows had returned to normal. Rather, heat stress altered the oocyte or the reproductive tract so that normal embryonic development was compromised.

In another study, it was demonstrated that heat stress of superovulated cows reduced development and viability of embryos if cows were exposed to heat stress at day 1 after estrus but not if heat stress was given on day 3, 5, or 7 after estrus (Fig. 56-3). Moreover, the reduction in development to the blastocyst stage caused by exposure of cultured embryos to elevated temperature declined as embryos proceeded through development (see Fig. 56-3). Thus, embryos become more resistant to effects of heat stress as pregnancy proceeds. Nonetheless, the embryo can still be damaged by severe heat stress even late in development. For example, heat stress of beef cows from days 8 to 16 of pregnancy reduced conceptus size at day 17.

Causes of Heat Stress–Associated Pregnancy Failure

Potentially, heat stress could cause pregnancy loss by exerting actions on either the oocyte, embryo, or reproductive tract. Furthermore, disruption of pregnancy could occur because of direct effects of elevated temperature on cellular function or as an indirect consequence of physiologic changes for regulation of body temperature.

Heat stress could compromise oocyte competence by at least three possible mechanisms: (1) Disruption in patterns of folliculogenesis could lead to ovulation of an aged oocyte with lowered potential for fertilization. Consistent with this idea is the finding that heat stress beginning at day 1 of the estrous cycle caused earlier emergence of the dominant follicle of the second follicular wave. Such an effect could conceivably alter the quality of the oocyte ovulated at the subsequent estrus, because oocytes from persistent dominant follicles have reduced competence. This mechanism must not be the only one operational, however, because it does not explain why season (and presumably heat stress) adversely affects multiple oocytes in the cohort of follicles ovulated after superovulation, collected by transvaginal ultrasound–guided recovery, or aspirated from excised ovaries. (2) Heat stress also has been reported to affect follicular steroidogenesis.

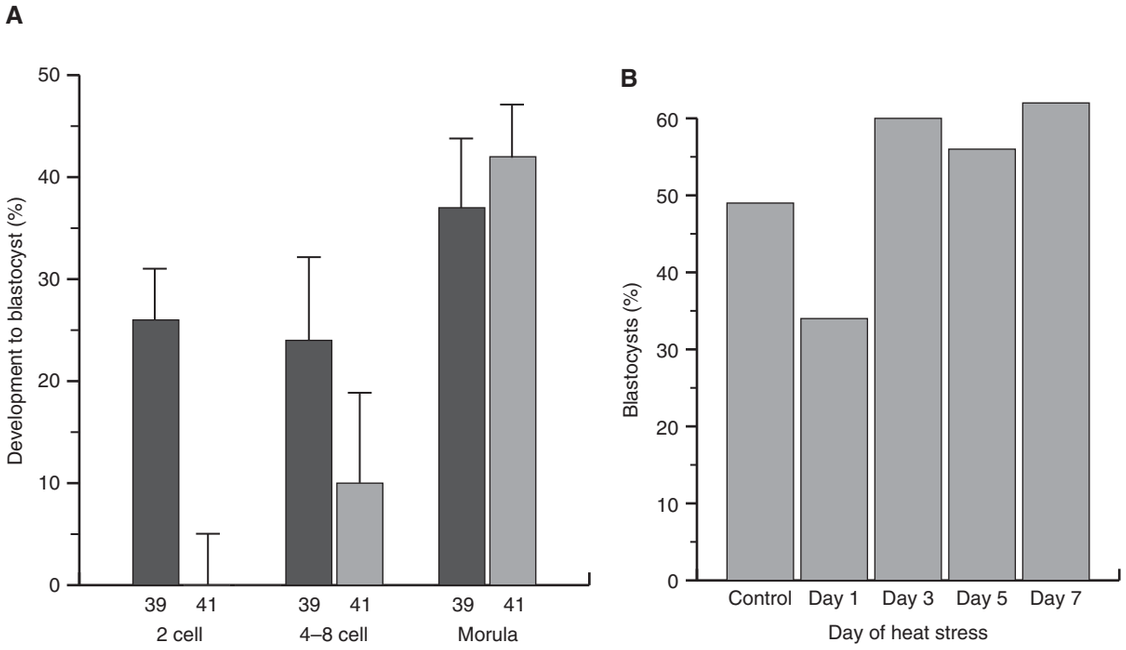

Fig. 56-3 Developmental changes in resistance of bovine embryos to heat shock. **A,** *Left panel*: Effect of heat stress on day 1, 3, 5, and 7 of pregnancy (day 0 = estrus) in superovulated cows on the proportion of embryos recovered as blastocysts. **B,** *Left panel*: Data illustrating how stage of embryonic development affects response of embryos to an elevated temperature of 41°C for 12 hours, compared with control conditions of 39°C. (**A,** *Left panel*: Data from Ealy AD, Drost M, Hansen PJ: *J Dairy Sci* 1993;76:2899–2905; **B,** *left panel*: data from Edwards JL, Hansen PJ: *Mol Reprod Dev* 1997;46:138–145, 1997.)

Perhaps alterations in the steroidal environment disrupt oocyte development. (3) Finally, oocytes may be similar to male germ cells in that they have heightened sensitivity to elevated temperature. Unlike most cells, the oocyte in developing follicles is transcriptionally inactive after it reaches a diameter of approximately 110μm (i.e., at about the 3-mm follicle stage). This means that the range of cellular adjustments to elevated temperature that are possible in the oocyte are limited to those not involving transcription. For example, bovine oocytes cannot undergo increased synthesis of heat shock protein 70 (HSP70) in response to elevated temperature.

Sensitivity to elevated temperature persists for several cleavage divisions after fertilization, with the embryo acquiring increased resistance to heat shock as it proceeds through development. Thus, the increased resistance of cows to heat stress as pregnancy proceeds may reflect developmental changes in the embryo that lead to greater cellular resistance to elevated temperatures (see Fig. 56-3). The molecular basis for increased embryonic thermotolerance is not known. Heat shock protein synthesis in embryos exposed to elevated temperature occurs as early as the four-cell stage, and other biochemical changes may therefore also be important.

Hyperthermia also may disrupt endometrial function directly, as has been reported for cultured endometrial and oviductal explants. Although protein secretion by endometrium is more resistant to the disruptive effects of heat shock than conceptus tissue, endometrial synthesis of two heat shock proteins, HSP90 and HSP70, is induced by heat shock. These proteins are components of the progesterone receptor complex, and increased synthesis of HSP70 and HSP90 in endometrium could conceivably inhibit endometrial responsiveness to progesterone. Evidence that progesterone support of the uterus is reduced by heat stress as a result of decreased circulating concentrations of progesterone is highly equivocal and may depend on the duration and severity of stress, as well as the nature of concomitant changes in blood volume. Heat stress has been reported to reduce uterine blood flow, and such an effect could reduce delivery of nutrients and hormones to the uterus.

The process by which the embryo causes maintenance of the corpus luteum also is potentially sensitive to disruption by heat stress. Culture at 43° C reduced secretion of the antiluteolytic hormone interferon-τ by day 17 conceptuses. Heat shock also increased release of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) and prostaglandin E_2 from endometrial explants and uterine production of $PGF_{2\alpha}$ in response to oxytocin.

Effects of Heat Stress in Late Pregnancy and the Postpartum Period

Abortion caused by heat stress is rare, but placental function is compromised by heat stress in the last third of pregnancy. Thus, in one study, secretion of the placental hormone estrone sulfate, placental size, and calf birth weight were reduced in the summer or by experimental heat stress (Table 56-2). These effects of heat stress probably are caused primarily by the reduction in blood flow to the placenta that occurs with heat stress. In one study in California, calf mortality in the summer increased as environmental temperature increased. This relationship could reflect the lower calf birth weights caused by heat stress, as well as reduced immunoglobulin transfer to the neonate.

Mammogenesis is dependent on placental function, so it would be expected that heat stress during late pregnancy compromises subsequent milk yield. Indeed,

[c]From June to October, Israeli-Holstein cows were either given access to shade (control) or given shade or cooled with fans and sprinklers during the dry period. Data from Wolfenson D, Flamenbaum I, Berman A: *J Dairy Sci* 1988;71:809–818.
FCM, fat-corrected milk yield; NS, not significant.

cooling heat-stressed cows during the dry period can sometimes increase subsequent milk yield (see Table 56-2).

Consequences of heat stress for reproductive function in the cow during the postpartum period have not been extensively studied. The incidence of retained placenta was higher in the summer in a study in Georgia. Heat stress during late pregnancy increased postpartum uterine output of $PGF_{2\alpha}$ but had no effect on resumption of estrous cycles. Similar studies have not examined this effect in beef cattle, although suckling could change the relationship between heat stress and postpartum endocrine function.

Effects of Heat Stress on the Bull

Many mammals have evolved so that male gametogenesis is unable to occur at temperatures characteristic of the body core—heat stress for as little as 12 hours disrupts spermatogenesis in the bull. The stage of spermatogenesis that is most susceptible to elevated temperature is the primary spermatocyte, although damage to B spermatogonia can occur in bulls and prolonged exposure to heat damage can damage dividing spermatocytes and spermatids. Mammals have evolved an intricate anatomic and physiologic system for local thermoregulation of the testis that involves placement of the testis outside the body cavity, exchange of heat between the body core and testis through countercurrent mechanisms in the pampiniform plexus, and regulation of heat loss to the surrounding air by means of muscular control of the placement of the testis relative to the body and the surface area of the scrotum and by sweating. As a result, testicular temperature is approximately 5°C below core body temperature. Spermatogenesis is disrupted when either the thermoregulatory system that maintains testicular temperature is disrupted or an elevation in body temperature caused by fever or heat stress raises the temperature of the blood reaching the testis. Effects of disruption in sperm production include decreased sperm numbers, decreased sperm motility, and increased numbers of abnormal sperm. Some reports have suggested that spermatozoa from heat-stressed bulls are less able to withstand freezing and to bind heparin.

The timing of changes in sperm production after the onset and termination of heat stress is illustrated in Figure 56-4. There is a delay of about 2 weeks between heat stress and the onset of the first alterations in sperm output, because the primary spermatocyte is the most susceptible germ cell. The process of spermatogenesis takes approximately 54 days in bulls, and effects of heat stress on sperm output persist for 7 to 8 weeks after the end of heat stress.

Alterations in endocrine function caused by heat stress are much less severe than effects on spermatogenesis. Transferring bulls from 21° to 35.5°C caused a decrease in testosterone concentrations in one study, whereas heat stress of 34°C caused a transitory decrease in luteinizing hormone (LH) secretion without any effect on testosterone concentrations in another study.

Although artificial insemination bypasses many of the effects of heat stress on the bull, the possibility remains that spermatozoa become heat shocked when they are placed in the reproductive tract of a hyperthermic female. Exposure of frozen thawed spermatozoa to 41° to 42°C had little effect on motility and no effect on fertilizing ability. It is possible, however, that embryos formed by fertilization of heat-shocked sperm are compromised in ability to develop, as was concluded from studies in the rabbit.

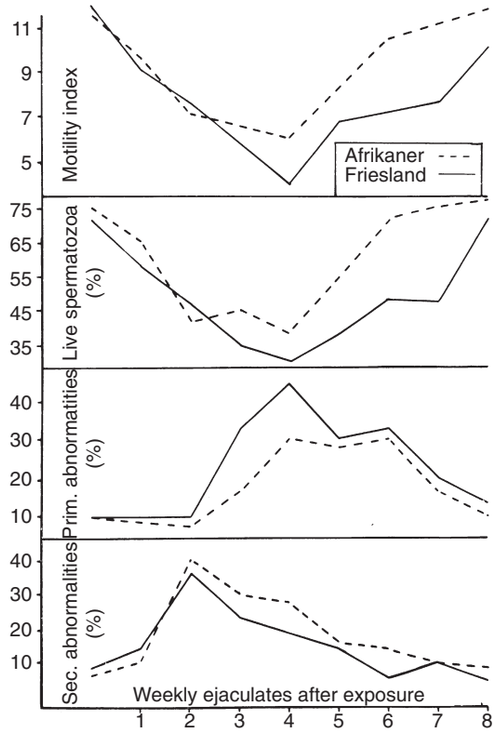

Fig. 56-4 Time-dependent changes in characteristics of ejaculates collected from bulls exposed to a 6-day period of heat stress (40°C for 12 hours per day). Ejaculates were collected after completion of heat stress and at weekly intervals thereafter. MEASURING THE MAGNITUDE OF HEAT STRESS

Successful animal thermoregulation involves the balance of heat production and heat loss. Environmental variables determining the degree to which thermoregulation is possible include air temperature, humidity, wind speed, and solar radiation. The degree of heat stress depends on all of these variables. The best way to determine the magnitude of heat stress in a simple and accurate manner is through use of the black globe thermometer. This is a device in which a thermometer is placed inside a round black vessel—it can be as simple as a toilet bowl float painted black. The thermometer does not undergo evaporative cooling (unless wetted), but otherwise the temperature inside the float depends on the same environmental factors that determine the degree of heat stress that cows experience—air temperature, solar radiation, and wind speed. Effect of humidity on thermal balance

of the cow can be considered through use of temperature-humidity indexes or black globe temperature-humidity indexes. One black globe temperature-humidity index (BGTHI) used by Buffington and co-workers[2] is as follows:

$$BGTHI = BGT + 0.36T_{dp} + 41.5$$

where T_{dp} is dewpoint temperature and all temperatures are in degrees centigrade.

Meteorologic measurements are useful in assessing heat stress but do not always reflect the change in body temperature experienced by a cow in response to heat stress. This is because the body temperature change depends on resistance to heat flow and internal heat production. Effects of heat stress on cattle are modified by breed, coat color, lactation, drugs such as xylazine and bovine somatotropin, and exposure to flies. Accordingly, direct measurements of body temperature probably are the best indicator of the degree to which physiologic functions of the cow are depressed by heat stress. In lactating dairy cows, a rise in uterine temperature by 0.5°C above normal on the day of insemination was associated with a 12.8% decline in pregnancy rate.[3] The genetic correlation between rectal temperature and calving rate in beef cattle in Queensland was 0.76.[4]

SCHEMES TO PREVENT EFFECTS OF HEAT STRESS ON REPRODUCTION

Estrus Detection

Cooling cows around the time of anticipated estrus can increase estrus detection. Using such an approach, Her and colleagues[5] observed that the proportion of cows detected in estrus was higher for cooled cows (88%) than for noncooled cows (66%), and Ealy and associates[6] reported that 47% of cows cooled with fans and sprinklers were detected in estrus, versus 37% for cows receiving shade alone.

It also is expected that use of estrus detection aids will improve detection of estrus during hot weather. Such systems range from the simple to the complex. Simple systems include application of paint to the tailhead, whereas more complex systems include the HeatWatch system, in which a radiotelemetric pressure transducer is affixed to the cow to transmit information regarding number of times an animal is mounted, and pedometers that measure increased locomotor activity associated with estrus. In a study conducted during the summer in Florida, the proportion of cows detected in estrus within 96 hours after injection of $PGF_{2\alpha}$ was increased by the use of tail chalk from 24% to 43%.[6]

One method for completely eliminating problems of estrus detection is to use an ovulation synchronization protocol that allows timed artificial insemination without the need for estrus detection. The most common system, called the OvSynch method, involves injection of 100 μg GnRH at day 0, 35 mg $PGF_{2\alpha}$ on day 7, and 100 μg GnRH on day 9 and insemination on day 10. Effectiveness of timed artificial insemination during the summer is illustrated in Table 56-3. Timed artificial insemination protocols do not reduce the effect of heat stress on fertility—rates of pregnancy per insemination generally are similar in cows inseminated at a fixed time and in those inseminated at estrus. Because all cows eligible for breeding are inseminated, however, the herd pregnancy rate (the proportion of cows eligible for breeding that become pregnant, calculated as estrus detection rate ×

pregnancy rate per insemination) increases at fixed times postpartum.

Cooling of Cows to Improve Fertility

Data in Table 56-1 illustrate that altering the environment to reduce the magnitude of heat stress improves fertility in lactating cows. A good review on the design of dairy cattle housing in hot climates is available.[7] The most effective housing systems for cooling lactating cows are those that are designed to maximize the time that cows spend in a cooled environment, achieved through the combined use of shade, fans, and an evaporative cooling system of sprinklers or misters (Fig. 56-5). Although continuous cooling of cattle during hot months provides greatest relief from effects of heat stress, some improvement in pregnancy rates has been achieved by cooling cows during periods when establishment of pregnancy is most susceptible to disruption by heat stress. This approach to improving fertility in the summer has been termed **strategic cooling** and depends on estrous synchronization to control when cows are placed in the cooled environment. In practice, strategic cooling systems have been effective in some experiments but not in others. Averaged across multiple studies, application of strategic cooling from a variable period of 4 to 16 days around the time of estrus increased pregnancy rate from 19% in control animals to 28% in cooled cows.

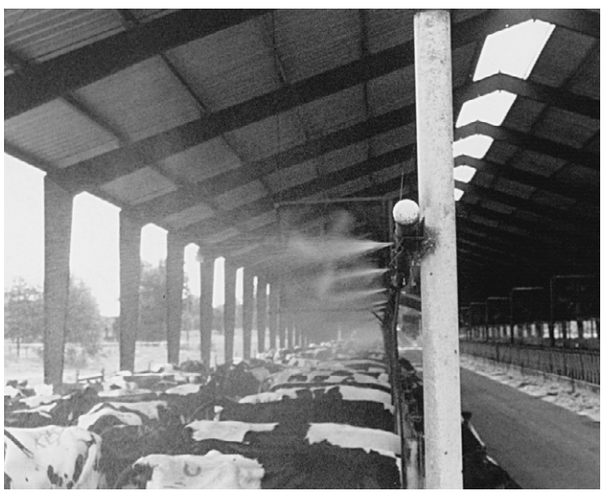

Fig. 56-5 A freestall barn modified to provide evaporative cooling. Facilities such as the one shown here are becoming increasingly common in hot regions. The barn itself provides shade, and additional cooling is provided by sprinklers and fans. The sprinklers are designed to apply water at a rate and drop size sufficient to allow water penetration to reach the skin. Typically, sprinklers are programmed to turn on for 3 minutes on a 15-minute cycle. The fans, which operate continuously, promote evaporation of water from cows and also provide convective cooling. (Courtesy of David Bray, University of Florida.)

Use of Artificial Insemination and Embryo Transfer

Artificial insemination can eliminate infertility caused by heat stress in bulls because semen collected in cool environments can be stored frozen until later use in hot weather. Similarly, embryo transfer can be used to reduce effects of heat stress on the cow. This is so because only embryos that develop to the blastocyst stage and have acceptable morphologic characteristics are transferred. Moreover, embryos subjected to maternal hyperthermia at day 7 (and presumably later) are more resistant to maternal hyperthermia than are embryos at very early stages of development. Several studies conducted in Florida have demonstrated the efficacy of embryo transfer for improving fertility during heat stress (Table 56-4).

One potential limitation to the routine use of embryo transfer in summer is the fact that heat stress can reduce the rate of production of embryos from superovulation and IVF. This limitation can be bypassed by the use of frozen embryos collected at cool periods of the year or in geographic regions where cattle are not susceptible to heat stress. Unfortunately, IVF-derived embryos exhibit poor survival after cryopreservation. Thus, although transfer of fresh embryos produced by superovulation or IVF increased pregnancy rate in summer as compared with artificial insemination, such was not the case when frozen or vitrified IVF-derived embryos were used (see Table 56-4). Production of IVF-derived embryos using oocytes recovered from slaughterhouse ovaries is an inexpensive way of producing large numbers of embryos for transfer into heat-stressed recipients. Widespread use of such embryos, however, probably will depend on improvements in culture systems or cryopreservation protocols that allow high survival rates after freezing.

Genetic Improvement

Distinct breed differences are recognized in effects of heat stress on reproductive function, with reproductive function in *B. indicus* and other thermotolerant breeds being less affected by heat stress than in breeds that evolved in Northern climates. Differences between *B. taurus* and *B. indicus* in thermotolerance are due largely to differences in thermoregulation. In one study, the change in calving rate for each unit increase in rectal temperature was the same for *B. taurus* and *B. indicus* × *B. taurus* crossbreds. Some evidence, however, indicates that breed differences in thermotolerance also exist at the cellular level. Most strikingly, Brahman embryos were found to be more resistant to culture at elevated temperatures than Holstein or Angus embryos. This finding raises the possibility that it may be possible to identify genes that confer cellular thermotolerance and transfer these to breeds of cattle susceptible to heat stress so as to reduce infertility during heat stress.

The relative advantages and disadvantages of crossbreeding between thermotolerant and nontolerant breeds depends on a host of conditions and is beyond the scope of this chapter. Genetic selection to increase thermotolerance also can be practiced but may have undesirable consequences. One trait that contributes to thermotolerance

is low metabolic heat production. Therefore, selection for thermotolerance could indirectly lead to selection for reduced feed intake, milk production, or growth. It also is possible to select for specific traits conferring resistance to heat stress (including coat color and the *slick* gene controlling hair length in cattle), but potential advantages of such an approach are diminished by reduced selection for traits of economic importance such as milk production. A better approach may be to select for production in the hot climate itself; data from beef cattle suggest that this approach results in indirect selection for thermotolerance.

PHOTOPERIOD AND REPRODUCTION

Although cattle are not seasonally anestrous animals, photoperiod modifies reproductive processes controlling the establishment of estrous cycles at puberty and during the postpartum period. Photoperiod also may affect fertility. The pineal gland appears to be the mediator for many actions of photoperiod.

Puberty

Two studies indicate that exposure to short photoperiods early in life hasten puberty. In Wisconsin, heifers born in autumn attained puberty sooner than those born in spring, regardless of photoperiodic and temperature environments experienced in the second 6 months of life. Furthermore, puberty was hastened in heifers born in February-March and given a melatonin ear implant at approximately 100 days of age for 5 weeks, to simulate short days. In contrast with the situation existing until 3 to 5 months of age, long photoperiods are the stimulatory photoperiod in older calves. Exposure of calves to artificial days of 16 to 18 hours of light per day (for a pattern of hours of light–hours of darkness [L:D] of 16L:8D or 18L:6D) reduced age and weight at puberty (i.e., first ovulation) in heifers and increased circulating concentrations of testosterone at 14 to 20 weeks of age in bulls. An example of the magnitude of photoperiodic effects on puberty is shown in Figure 56-6.

The prepubertal period in cattle occurs over a long time span that ranges from 6 to 24 months or longer. Consequently, the influence of season of birth on onset of puberty depends on other genetic and environmental factors that determine the length of the prepubertal period. For example, heifers in Wisconsin born in the spring reached puberty earlier than winter-born heifers if fed a diet high in energy, whereas the opposite was true if heifers were fed a diet low in energy.

The Postpartum Anestrus

In Northern latitudes, the duration of the postpartum anestrus often is shorter for cows calving in the summer or autumn than for cows calving in the winter or spring. The magnitude of the seasonal effect is greater for cows that have other factors that dispose them to a long postpartum anestrus, such as primiparity, suckling, low energy intake, and genetic capability for high milk production. Seasonal differences in the resumption of estrous cycles after calving probably result from variation in many factors, such as nutrition and housing. Photoperiod is one of these inputs, because exposure of suckled beef cows that calved in the winter to 18L:6D reduced the duration of postpartum anestrus. The magnitude of the beneficial effect of supplemental lighting also was greatest for cows with the longest postpartum anestrous periods.

Other Effects of Photoperiod

Several reports indicate that supplemental lighting during the winter increases pregnancy rates. In other reports, long photoperiods increased sperm motility and decreased sperm abnormalities in bulls and reduced interval to uterine involution. Effects of photoperiod extend to *B. indicus*, even though these cattle evolved in an environment with little seasonal variation in day length. Brahman cows subjected in the winter to 14L:8D experienced higher pregnancy rates and reduced frequency of "silent" ovulations, compared with cows exposed to natural photoperiods.

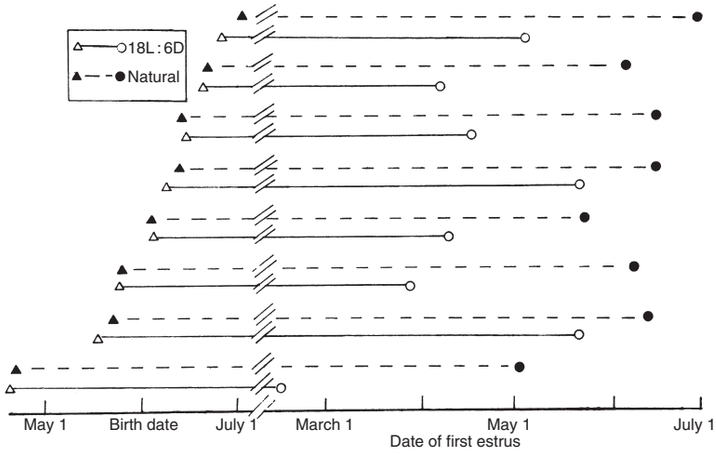

Fig. 56-6 Effect of photoperiod on puberty in heifers reared in Wisconsin. Beginning at 5 months of age, heifers either continued exposure to natural photoperiods or were exposed to a daily pattern of 18 hours of light and 6 hours of darkness (18L:6D). Shown are individual dates of birth (*triangles*) and first estrus (*circles*). (From Hansen Kamwanja LA, Hauser ER: *J Anim Sci* 1983;57:985–992, with permission of *Journal of Animal Science*.)

Mechanism of Action of Photoperiod

In seasonally breeding species, the pineal plays a central role in mediating effects of photoperiod on the hypothalamic-pituitary axis through secretion of the hormone melatonin. As in seasonally breeding species, secretion of melatonin in cattle exhibits a diurnal pattern, with highest concentrations during darkness. The duration of elevated melatonin secretion is proportional to the length of darkness, although the two periods are not identical. Involvement of the pineal in photoperiodic regulation of reproduction in cattle is indicated by the finding that administration of a melatonin implant hastened onset of puberty when administered at approximately 100 days of age and slightly lengthened the postpartum anestrus in beef cows.

Some evidence indicates that photoperiodic modulation of reproduction is exerted at the level of the hypothalamic-pituitary axis. LH secretion early in life was greater for heifers born in September than for those born in March. Also, circulating concentrations of LH and follicle-stimulating hormone (FSH) were greater in ovariectomized heifers exposed to days of increasing length than in those exposed to days of decreasing length. Supplemental lighting in the winter also increased the magnitude of estradiol-induced LH secretion. In contrast with these findings, exposure to 18L:6D had no effect on LH secretion in postpartum cows, prepubertal bulls, or ovariectomized heifers, compared with natural winter photoperiods. Furthermore, long days or afternoon injections of melatonin inhibited LH and FSH secretion in ovariectomized heifers given an estradiol implant.

Secretion of prolactin is markedly increased by photoperiod, but it is unlikely that alterations in secretion of this hormone are responsible for changes in reproductive activity. Exposure to 16L:8D hastened onset of puberty in heifers, even though prolactin secretion became refractory to photic influences. Additionally, treatment of postpartum cows with dopamine agonists to lower prolactin secretion did not affect length of the postpartum anestrus. Effects of photoperiod on reproduction also are not mediated by changes in body weight. Some component of photoperiodic effects may be mediated by metabolic changes, however, because treatment of heifers with growth hormone–releasing hormone reduced beneficial effects of a 16L:8D photoperiod on age at puberty.

Schemes to Improve Reproduction through Manipulation of Photoperiodic Signals

Practical advantages accruing from manipulation of photoperiod are likely to be greater in the postpartum period than in the prepuberium. The magnitude of the influence of photoperiod on age at puberty is small, and earlier puberty does not necessarily lead to earlier establishment of pregnancy. By contrast, seasonal and photoperiodic effects on duration of the postpartum anestrus and calving interval sometimes are large. Supplemental lighting during short days also increases milk yield.

The minimum photoperiod necessary to enhance postpartum reproduction is not known. The only photoperiod that has been tested experimentally for postpartum cows is 18L:6D. A 14L:10D photoperiod, however, was found to enhance other aspects of reproductive function in Brahman cattle and probably is adequate. Work from studies on photic regulation of hormone secretion can be used to estimate some of the other characteristics of supplemental lighting required to affect postpartum reproduction. One economical way to manipulate photoperiod may be through use of "skeleton" lighting, in which animals are exposed to a short period of light during darkness to entrain them to a long photoperiod. Exposure of bulls and cows to 2 hours of light beginning 13 to 20 hours after dawn in animals otherwise receiving 6 hours of light per day increased secretion of prolactin. The intensity of light necessary to suppress melatonin secretion was as little as 400 lux, whereas light levels as low as 200 lux increased prolactin secretion. The spectrum of wavelengths of light that are effective evidently is broad, because supplemental lighting from fluorescent, incandescent, mercury vapor, red, or blue lamps has been shown to increase prolactin secretion.

OTHER STRESSES

As mentioned earlier, the low heritability associated with reproductive traits in cattle constitutes a testament to the

importance of environment on reproductive function. This chapter has emphasized the importance of heat stress and photoperiod, but many other environmental inputs contribute to variation in reproductive function of cattle. A brief review of some of these factors is presented next.

Cold Stress

Having evolved in cold and wet climates, adult cattle of European origin seem to be little affected by cold stress. Exposure to cold increases metabolic rate and energy balance, but the environmental temperatures at which this occurs are very low. Cold stress has the greatest consequence for the newborn calf, which has a poorly developed thermoregulatory system. *B. indicus* calves are particularly susceptible to the development of hypothermia. Exposure to cold stress also can cause scrotal frostbite of bulls, and the resultant edema of the scrotum results in increased scrotal temperature and infertility.

Social Factors

Abundant evidence indicates that interval from calving to first estrus in postpartum beef cows is reduced by the presence of bulls or androgenized cows. It is equivocal, however, whether a similar effect occurs in prepubertal heifers. Also, libido and mating ability of young bulls were not affected by exposure to heifers during rearing. In adults, temporary isolation has been reported to decrease libido of bulls, and maintenance of cows in tie stalls delayed resumption of ovarian activity after calving, as compared with untethered cows. Social status also can affect reproductive function: In one report, interval from calving to conception was shorter in cows experiencing an increase in dominance rank than in cows experiencing a decrease in dominance rank.

The extent to which estrous activity occurs is dependent on social factors. Mounting activity per cow increases if several cows are in estrus together, because cows that are under the influence of estrogen are more likely to mount cows in estrus than are cows under the influence of progesterone. Number of mounts and accuracy of estrus detection also increase if androgenized cows are present in a herd. Some evidence also indicates that mounting activity is stimulated if cows in estrus are unfamiliar to detector animals.

Shipping Stress and Emotional Stress

Data are equivocal regarding whether reproductive activity is susceptible to stress associated with rough handling or fear. For example, characteristics of estrus in ovariectomized heifers and cows treated with estradiol cypionate were not affected by a variety of stresses including acute starvation and being chased by a dog, soaked with water, or worked in a chute while receiving a drench and insecticide spray. In addition, repeated handling stress during the follicular phase of the estrous cycle had no effect on estrous behavior, although two of seven stressed cows did not undergo detectable preovulatory surges of LH. In another study, however, the stress of transportation reduced superovulation response. In still another report, transportation reduced induction of LH surges induced by estradiol benzoate treatment in noncycling cows (but not in cyclic cows).

Confinement

Confinement represents the most recent example of large-scale, manmade alterations in the environment in which cattle exist. It is reasonable to assume that, as with any environmental change, confinement has increased the stress imposed on cattle. Very little is known about the effects of confinement on reproduction, even though increasing numbers of cattle are managed in such environments. Concrete flooring reduces the expression of estrous intensity, and lameness, which is one of the consequences of housing cattle on inadequate flooring, is associated with lower pregnancy rates per insemination. Other effects of footing surface (including the effects of mud) on reproduction are unknown.

Flies often are abundant in confinement housing, and some data indicate that exposure to flies exacerbates problems of heat stress. Little is known about the potential for exposure to environmental pollutants associated with confinement. This is a potentially important topic because manure gases have been reported to delay onset of puberty in gilts.

CHAPTER 57

Effects of Nutrition on Reproduction in Dairy Cattle

JAMES N. SPAIN, MATTHEW C. LUCY, and DAVID K. HARDIN

Walton, as cited by Coppock,[1] predicted that individual cow yields of more than 31,000 kg of milk per year were attainable, with the potential for herd averages of 16,000 kg of milk per year. Breed averages for milk yield increased 40% to 60% for first-lactation cows between 1960 and 1988.[2] With continued genetic progress and improvements in management systems, Walton's predicted levels of milk production are reasonable and achievable goals.

As milk production increases, fertility of lactating dairy cattle, as a general rule, decreases. A survey of commercial herds in North Carolina showed a decrease in conception rate from 52% to 32% in a comparison of the lowest-producing (n = 425) and the highest-producing (n = 53) herds.[3] Days open and days to first service were similar for both groups. More recently, Washburn and associates[4] summarized Dairy Herd Improvement Association (DHIA) data from 10 states in the southeastern United States. In the period 1976 to 1999, annual milk yield per cow increased 1800 kg, while days open increased from 112 to 152 during the same time period. The herds also experienced an increase in services per conception (from a mean of 1.9 to 2.9). Lucy[5] completed an extensive review and suggested that high levels of milk production are not the sole cause of reduced reproductive performance. Indeed, overall management including housing, health, and nutrition practices also affects fertility of lactating dairy cattle. These findings emphasize the importance of management in maintaining reproductive efficiency as herds achieve higher levels of milk production.

Nutritional status and nutritional management are essential components of overall herd management. The nutritional status of the herd also affects the reproductive soundness and efficiency of the herd. Bauman and Currie[6] described the hierarchy of nutrient utilization by the lactating dairy cow. Within this ranking, reproduction lists below maintenance (necessary for survival), production (milk produced for the young), and growth. Royal and co-workers[7] summarized strategies to improve fertility in dairy cattle, including genetic, endocrine, and nutritional approaches. Ferguson[8] categorized nutritionally associated reproductive problems as primary or secondary. **Primary** conditions of malnutrition affecting reproduction include clinical deficiency and excessive intake of a particular nutrient. **Secondary** conditions comprise those in which other constraints result in a nutritional imbalance. Therefore, a suboptimal plane of nutrition can result in impaired reproductive performance. This observation holds true for both the developing replacement dairy heifer and the lactating dairy cow.

This chapter reviews the effects of nutrition on the reproductive biology of the dairy cow, with regard to both onset of puberty and lactation.

PUBERTY

Gill and Allaire[9] analyzed DHIA records from Ohio and concluded that the optimal age for Holstein heifers at first calving for total lifetime production was between 23 and 24 months. More recent research demonstrated that heifers calving early (22.9 months of age) produced more milk than those calving at an older age (26.5 months).[10] To achieve an average age at first calving of 24 months, heifers must reach puberty by 8 to 9 months of age. This timing would allow heifers to establish cyclicity before

Walton, as cited by Coppock,[1] predicted that individual cow yields of more than 31,000 kg of milk per year were attainable, with the potential for herd averages of 16,000 kg of milk per year. Breed averages for milk yield increased 40% to 60% for first-lactation cows between 1960 and 1988.[2] With continued genetic progress and improvements in management systems, Walton's predicted levels of milk production are reasonable and achievable goals.

As milk production increases, fertility of lactating dairy cattle, as a general rule, decreases. A survey of commercial herds in North Carolina showed a decrease in conception rate from 52% to 32% in a comparison of the lowest-producing (n = 425) and the highest-producing (n = 53) herds.[3] Days open and days to first service were similar for both groups. More recently, Washburn and associates[4] summarized Dairy Herd Improvement Association (DHIA) data from 10 states in the southeastern United States. In the period 1976 to 1999, annual milk yield per cow increased 1800 kg, while days open increased from 112 to 152 during the same time period. The herds also experienced an increase in services per conception (from a mean of 1.9 to 2.9). Lucy[5] completed an extensive review and suggested that high levels of milk production are not the sole cause of reduced reproductive performance. Indeed, overall management including housing, health, and nutrition practices also affects fertility of lactating dairy cattle. These findings emphasize the importance of management in maintaining reproductive efficiency as herds achieve higher levels of milk production.

Nutritional status and nutritional management are essential components of overall herd management. The nutritional status of the herd also affects the reproductive soundness and efficiency of the herd. Bauman and Currie[6] described the hierarchy of nutrient utilization by the lactating dairy cow. Within this ranking, reproduction lists below maintenance (necessary for survival), production (milk produced for the young), and growth. Royal and co-workers[7] summarized strategies to improve fertility in dairy cattle, including genetic, endocrine, and nutritional approaches. Ferguson[8] categorized nutritionally associated reproductive problems as primary or secondary. **Primary** conditions of malnutrition affecting reproduction include clinical deficiency and excessive intake of a particular nutrient. **Secondary** conditions comprise those in which other constraints result in a nutritional imbalance. Therefore, a suboptimal plane of nutrition can result in impaired reproductive performance. This observation holds true for both the developing replacement dairy heifer and the lactating dairy cow.

This chapter reviews the effects of nutrition on the reproductive biology of the dairy cow, with regard to both onset of puberty and lactation.

PUBERTY

Gill and Allaire[9] analyzed DHIA records from Ohio and concluded that the optimal age for Holstein heifers at first calving for total lifetime production was between 23 and 24 months. More recent research demonstrated that heifers calving early (22.9 months of age) produced more milk than those calving at an older age (26.5 months).[10] To achieve an average age at first calving of 24 months, heifers must reach puberty by 8 to 9 months of age. This timing would allow heifers to establish cyclicity before

the breeding period. Establishing cyclicity before breeding has been shown to improve fertility. For example, the conception rate for heifers at pubertal estrus was 21% lower than at their third estrus.[11] An excellent plane of nutrition is critical for heifers to reach puberty and first calving at 9 months and 24 months of age, respectively. Lammers and colleagues reported that heifers needed to gain 820 g/day (average daily gain from birth to calving) to achieve body weight and age targets at first calving.[12]

A number of factors that include body weight, body size, plane of nutrition, breed, and season influence age at onset of puberty. Social environment and phase of the moon also have been reported to alter onset of puberty.[13] Nutrition, because it influences body weight and size, contributes to the onset of puberty. The age at which a heifer begins regular estrous cycles also is correlated with the rate of gain from birth to puberty. Bortone and colleagues[14] reported that heifers fed 115% of National Research Council (NRC) recommendations from 3 to 12 months of age were 22 days younger at the onset of puberty than control animals fed 100% of NRC levels. The correlation between gains in body weight and age at puberty indicates that an increased growth rate in heifers reduces the age at puberty.[15,16] The study of Bortone and colleagues[14] also found that the body weight of heifers at the onset of puberty was the same for faster-growing heifers as for controls. These data indicate that body weight can be used to predict the onset of puberty and establish rate of gain.

Feeding heifers to reach target weight at a selected age for a given genotype is a practical management tool to ensure high potential fertility. Nutrient intake that supports growth and development is essential to achieve a target weight by 9 months of age. Nutrient intake is controlled by growth rate, fiber and energy concentration (or density) of the diet, and the dry matter content of the diet. Tomlinson and associates,[17] using prepubertal and pubertal heifers, found maximal dry matter intake at a neutral detergent fiber level of 41% and an acid detergent fiber level of 20% of the dietary dry matter. Quigley and co-workers[18] reported that intake could be limited by diets containing greater than 23% acid detergent fiber. Intake with high-fiber diets may be limited by the physical constrictions of rumen fill and distention. A decreased rate of fermentation and rate of passage of high-fiber diets also can limit dry matter intake.[19] Nutrient density and fiber content of the diet should be evaluated when animals do not reach the production goals of puberty, breeding, and first calving.

The ration should provide adequate amounts of required nutrients in a form that stimulates intake. Excessive grain (or starch) supplementation should be avoided. Excessive starch feeding can predispose the animal to ruminal acidosis and laminitis. This disorder can limit performance of the animal by decreasing eating time and obviously will slow the rate of gain. Fibrous feeds have been used as substitutes for cereal grains. These feedstuffs can support optimal growth while minimizing the potential effects of supplementation with high-starch grain mixes.

Feed additives also have been used in the diet of developing heifers. Sodium bicarbonate and yeast have been studied for use in the diet of young calves. Observed effects on intake, ruminal fermentation, and health have been variable and nonconclusive.[20] The use of ionophores generally improves growth rates, as well as feed efficiency, of ruminants. Two compounds commonly used are lasalocid and monensin. Feeding ionophores has been shown to decrease age at first breeding and calving, primarily because the growth rate to adequate body size and weight is accelerated. It has been hypothesized that monensin decreases age at puberty by a mechanism independent of weight gain.[21] Estradiol implants also have been found to improve feed efficiency in prepubertal Holstein heifers.[11]

Plane of nutrition also can influence the onset of puberty. Plane of nutrition can inhibit the onset of puberty in heifers at an adequate body weight, size, and age. Gonzalez-Padilla and associates[22] demonstrated that 14-month-old heifers could be maintained in a prepubertal state and then suddenly made to ovulate by increasing nutrient intake. It generally is accepted that the physiologic cause of the delay is the result of inhibition in pulsatile release of gonadotropin-releasing hormone (GnRH) from the hypothalamus and the subsequent release of luteinizing hormone (LH) from the pituitary gland. It also has been demonstrated that GnRH secretion is extremely sensitive to the nutritional status of the animal. Furthermore, insulin may play a role for energy-yielding nutrients, as it binds receptors in the region of the brain thought to regulate GnRH secretion.[23] Conditions such as disease and parasitism can influence nutritional status by altering intake or absorption of nutrients. Bumgarner and coworkers[24] reported that calves treated with anthelmintics in both mid-June and mid-July had a reduction in fecal oocyte counts and increased daily gain. Numerous other studies demonstrated improved weight gains from the use of anthelmintics.[25] Respiratory disease that results in severe lung damage can also result in poor performance of growing dairy heifers. A sudden onset of disease can result in a transient period of anestrus.

LACTATING COW

As discussed earlier, Bauman and Currie[6] described the need of lactating cows to prioritize nutrient utilization. In general, energy is the nutrient of primary concern relative to supporting maintenance, lactation, and reproduction. Imbalances or deficiencies of protein, minerals, or vitamins also have been reported to adversely affect the reproductive function of lactating dairy cows. Nutritional imbalances or deficiencies are most important during the period immediately preceding parturition through conception. This section focuses on the influence of nutritional status at critical points throughout lactation.

The nutritional balance of a dairy cow during the periparturient period can have a tremendous influence on fertility and reproductive efficiency. During the final 30 days of gestation, lactation is initiated, with production of colostrum and final growth of the fetus. At day 270 of gestation, the uterus and fetus require greater than 1600 kcal per day.[26] Concurrent with increased nutrient

requirements, the prepartal cow experiences a marked decrease in dry matter intake. Severe anorexia or an imbalance of nutrient intake can predispose the animal to a number of metabolic diseases that constitute the **parturition disease complex.**[27] These diseases are not independent but can increase the risk of subsequent problems. For example, Curtis and coworkers[28] reported that cows with hypocalcemia were at increased risk of suffering dystocia, retained fetal membranes, and ketosis. Dystocia and retained fetal membranes are predisposing factors for postparturient uterine disease. Markusfeld[27] documented that cows experiencing postparturient uterine disease had a decreased milk yield for the lactation and increased number of days open. Retained fetal membranes also have been influenced by selenium and vitamin E supplementation. Cows that experienced retained fetal membranes may have had a lower plane of nutrition. Disrupted intake accompanied by disrupted energy metabolism can result in an increased level of circulating ketone bodies. Miettinen[29] reported that cows with higher concentrations of circulating ketone bodies had more days to first service, decreased first service conception rates, and more days open. More recently, cows with serum beta-hydroxyl butyrate concentrations of 1100 μmol/L in weeks 1 and 2 of lactation were found to have increased risk of conception failure.[30] These studies make a significant statement regarding the importance of periparturient health and metabolism on fertility and reproductive efficiency during subsequent lactation. The primary modulator of reproductive function appears to be energy intake and the energy status of the animal.

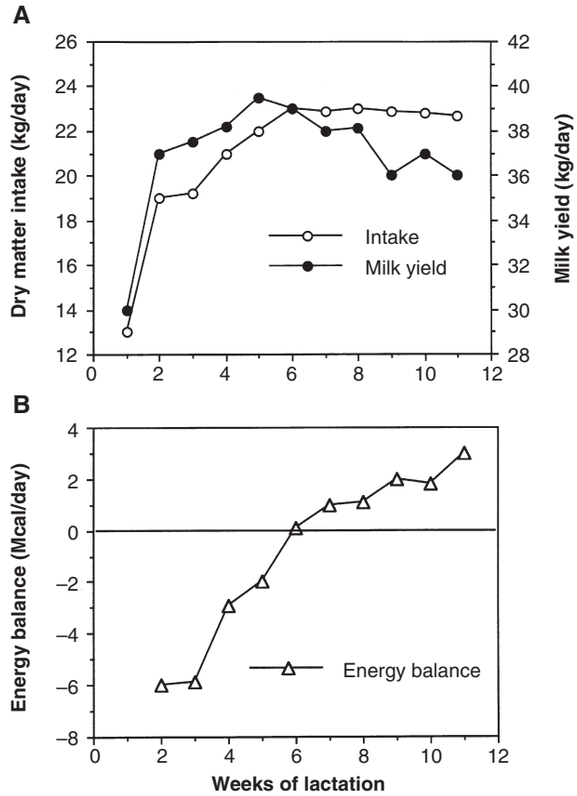

Fig. 57-1 Average daily dry matter intake and daily fat corrected milk yield **(A)** and daily energy balance **(B)** for lactating Holstein cows ($N = 17$). (From Lucy MC, Staples CR, Thatcher WW, et al: Influence of diet composition, dry-matter intake, milk production and energy balance on time of post-partum ovulation and fertility in dairy cows. *Anim Prod* 1992;54:323.)

Energy

Energy or energy balance is considered the primary nutrient relative to nutritional modulation of reproductive function of the dairy cow. The energy balance of the animal is most simply expressed by the equation

Energy balance
= energy intake (milk energy secreted
maintenance energy)

With initiation of lactation, the acceleration in milk production exceeds the increases in dry matter intake. Kertz and colleagues[31] showed that dry matter intake increased gradually, to peak at week 10 after calving. Lactating cows consume inadequate dietary energy to meet peak milk production. As a result, early-lactation cows experience a negative energy balance (Fig. 57-1). On the basis of energy calculations, cows in early lactation can experience as much as a 20-Mcal deficit of net energy. Cows compensate during this delay in energy intake by mobilizing stored body energy. For the early postpartum cow, this energy is generated primarily from stored adipose tissue. One kilogram of body fat contains 6 Mcal of stored energy.[31] Therefore, early-postpartum dairy cows must rely on oxidation of body fat for energy to compensate for inadequate energy intake.

The nutritional challenge of negative energy balance is significant and can adversely affect the reproductive performance of the dairy cow (Fig. 57-2). A similar effect is recognized in most species. This response by the animal may represent a mechanism to conserve energy during periods of starvation. This same mechanism, however, allows the animal to synchronize reproductive events with periods of positive nutritional status. The timing of these nutritional challenges is an important consideration in management, in view of the need to have high fertility and conception rate during early lactation. The inhibitory factors that prevent pregnancy are only partially understood. Negative energy balance can increase the period of postpartum anestrus and decrease fertility at first and subsequent inseminations, depending on the severity of the imbalance.

Cows should experience the first postpartum ovulation by 30 days after calving. Cows are not inseminated at this time because of incomplete involution of the uterine tissues. It is important, however, to minimize the length of postpartum anestrus for two reasons. First, cows with long intervals to first ovulation will be anestrous during the breeding period. Conception will therefore not occur because the cow does not express estrus and does not ovulate. Second, a shorter time to estrus will enable the cow to have multiple ovulations before the first insemination. The estrous cycle has a cleansing effect on the

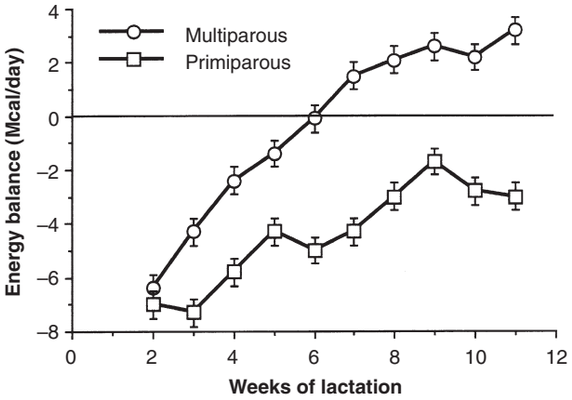

Fig. 57-2 Average daily energy balance for multiparous (n = 35) and primiparous (n = 15) Holstein cows. (From Lucy MC, Staples CR, Thatcher WW, et al: Influence of diet composition, dry-matter intake, milk production and energy balance on time of post-partum ovulation and fertility in dairy cows. *Anim Prod* 1992;54:323.)

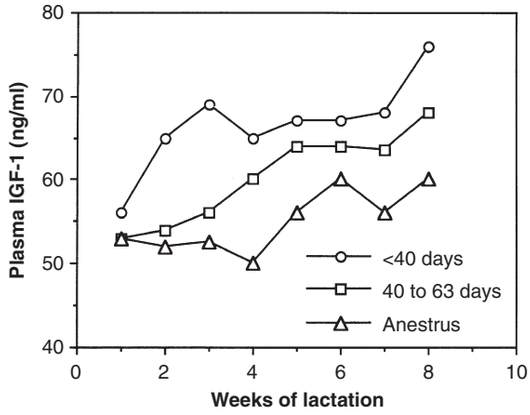

Fig. 57-3 Concentrations of insulin-like growth factor-I (IGF-I) in Holstein cows with different intervals to first ovulation. Interval to first ovulation was less than 40 days (n = 25), 40 to 63 days (n = 14), or more than 63 days (anestrus, n = 15). (From Thatcher WW, de la Sota RL, Schmitt EJ, et al: *Reprod Fertil Dev* 1996;8:203.)

uterus, with increased uterine contractility and relaxation of the cervix. Therefore, as shown in a large study conducted in Florida,[32] cows with prebreeding estrus had higher first-service conception rates (47%) compared with cows with no prebreeding estrus (34%).

To achieve the maximum number of estrous cycles before breeding, cows must ovulate during the early postpartum period (<21 days in milk). Research has shown that cows will ovulate approximately 10 days after reaching the lowest point of negative energy balance, the nadir.[33] Growth of follicles and ovulation are dependent on the pulsatile secretion of LH.[34] In cattle in severe negative energy balance, the secretion of LH is inhibited.[35] Disrupted or decreased LH secretion slows the growth and development of the follicle, which delays ovulation.[36] Insulin and insulin-like growth factor-I (IGF-I) also are required for normal follicular growth and ovulation. Cows in negative energy balance have reduced levels of IGF-I. This is an important relationship, given that IGF-I amplifies the effects of LH on the ovary through potentiating the signaling mechanism for LH.[37] Therefore, the actions of LH are decreased in cows in negative energy balance because lower IGF-I leads to reduced effectiveness of LH. Consequently, follicles in cows with extremely low IGF-I do not develop normally, and ovulation is delayed because LH is less active. This effect was demonstrated in a study by Thatcher and co-workers[38] (Fig. 57-3). Cows that had first ovulation before 40 days post partum had the highest concentrations of plasma IGF-I.

In accordance with these findings, the interval to first ovulation is controlled primarily by energy balance.[39] One of the most important factors that determine when the nadir will occur is postpartum feed intake. Postpartum dairy cattle that have the greatest increase in dry matter intake after calving are most likely to pass their energy nadir early and have the shortest interval to first ovulation (Fig. 57-4). In a study in Illinois, cows that consumed the most feed had the shortest interval to first ovulation.[40] Anestrous cows (>42-day interval to first

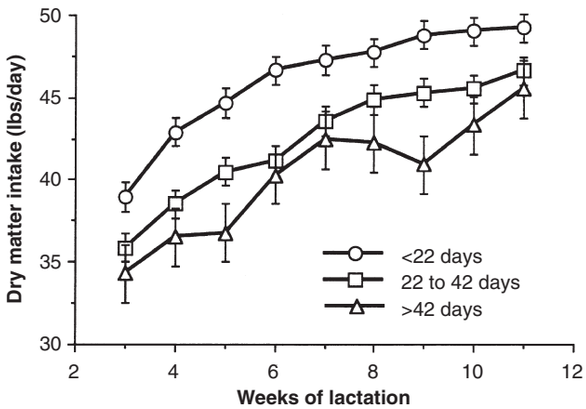

Fig. 57-4 Average daily dry matter intake for Holstein cows with different intervals to first ovulation. Interval to first ovulation was either less than 22 days (n = 17), 22 to 42 days (n = 18), or more than 42 days (n = 5). (From Lucy MC, Staples CR, Thatcher WW, et al: Influence of diet composition, dry-matter intake, milk production and energy balance on time of post-partum ovulation and fertility in dairy cows. *Anim Prod* 1992;54:323.)

ovulation) had the lowest dry matter intake. On the basis of these results, high-quality diets must be fed during the early postpartum period. In addition, postpartum metabolic disorders must be prevented so that cows can resume the maximal rate of recovery of dry matter intake after calving. These conditions not only maximize milk production but also improve feed intake and decrease the interval to first ovulation.

In addition to decreased interval to first ovulation, improved energy balance during early lactation can decrease the incidence of other ovarian diseases. For example, cystic ovaries are most prevalent in high-producing dairy cows that are in negative energy balance. Although this phenomenon is not fully understood, a

common link between this disease and negative energy balance is the abnormal secretion of LH.[41] Cystic ovaries are associated with increased LH secretion but an inhibition of the preovulatory LH surge. The cumulative effect of these conditions is development of a large cystic follicle that fails to ovulate in the absence of the ovulatory surge of LH. This relationship further strengthens the relationship among energy balance, LH, and early postpartum reproductive performance of the dairy cow.

Energy status at the time of breeding also can affect reproduction. Several reviews summarized by Weaver[42] conclude that cows that lose weight at the time of breeding have lower fertility. This decrease in fertility may be related to decreased progesterone secretion by the corpus luteum. Progesterone concentrations before and after insemination have been positively correlated with fertility.[43] The exact relationship between low progesterone and fertility has not been described; however, several reports have related low progesterone concentrations in cows that are losing weight.[44,45] In addition, cows in good body condition (body condition score [BCS] of 2 or 3 on a scale of 1 to 5) had better conception rates when receiving a transplanted embryo than did thin cows.[46] This study demonstrates the importance of uterine function in fertility and the possible role of progesterone in fertility in thin cows. Inadequate uterine function may be related to lower progesterone concentrations in cows in poor body condition. Furthermore, progesterone release in response to LH is severely diminished in the absence of IGF-I.

Thus, the effects of negative energy balance can be multiple and related. First, severe negative energy balance at calving can predispose the animal to increased days to first ovulation. This relationship appears to be hormonally modulated by insulin, LH, IGF-I, and progesterone. Insulin, LH, and IGF-I appear to influence the function of the ovary. In addition, the decreased pulsatility of LH decreases progesterone. Decreased progesterone has been shown to decrease fertility, possibly owing to poor uterine function. Therefore, energy balance or feed intake does affect reproductive performance of dairy cows.

Protein

Protein nutrition of the lactating dairy cow is confounded by energy balance. These animals have very limited labile protein stores, so diet is the primary source of nitrogen. Because of extensive pregastric fermentation by ruminal microorganisms, protein presented for absorption in the small intestine is altered considerably relative to the dietary protein actually consumed. Dietary protein and protein digestion have been categorized by location and rate of digestion of the protein.[47] As a result of the presence of rumen microflora, ruminants can use nonprotein nitrogen sources to produce a high-quality microbial protein for digestion in the small intestine. Dietary crude protein (CP) that is fermented by rumen microflora is defined as **rumen-degradable protein** (RDP). This protein is degraded to ammonia, single amino acids, and peptides. Ammonia produced in excess of that which the microbial population can utilize is absorbed from the rumen and transported in the circulatory system. A major portion is converted to urea in the liver. Feeding diets high in total CP or diets containing an excess of RDP or soluble CP can predispose lactating cows to elevated blood urea nitrogen (BUN) levels. Butler[48] completed an extensive review on the effects of protein nutrition on reproductive function and suggested several potential modes of action, including altered uterine environment, altered endocrine profiles, and indirect effects from altered energy partitioning during periods of negative energy balance.

A number of studies have been conducted to evaluate the relationship between dietary protein level and source with BUN level and conception rates in dairy cattle. Ferguson and Chalupa[49] summarized published data and used logistic regression to generate a predictive model. The model estimated the effects of RDP and undegraded intake protein on fertility in dairy cows. These workers concluded that a serum urea nitrogen level of greater than 20 mg/dL resulted in a lower conception rate. Hutjens and Jordan[50] summarized eight studies that evaluated BUN and conception rate. Cows fed 19% to 21% CP diets had higher BUN (21.3 versus 13.8 mg/dL) and lower conception rate (62% versus 48%) compared with cows fed diets containing 15% to 16% CP. Guo and associates[51] studied the relationship between milk urea nitrogen (MUN) using DHIA data representing 10,000 cows in more than 700 herds. These scientists reported that MUN was related to decreased fertility within the herd, but the effect was inconsistent across herds. What has not been clearly defined are the mechanisms involved in this relationship. Elevated blood levels of ammonia or urea or both could alter secretions produced in the reproductive tract itself and affect viability of the ova, sperm, or embryo. In addition, the hormonal balance required for normal function also may be involved.[48] These two areas have been the focus of much published research.

A series of studies has shown increased urea nitrogen levels in blood and in oviductal and vaginal fluids.[52] Williams and coworkers[53] also found that high-protein diets increased the urea nitrogen content of uterine secretions but found no differences in fertility or in vitro embryo development. Jordan and coworkers[54] found that high-CP diets changed the concentrations of magnesium, potassium, phosphorus, and zinc in uterine secretions. Overall, high-protein diets increase the nitrogen content of uterine secretions, in addition to shifting mineral composition; however, a direct effect of these changes in utero on fertility and embryo viability is less clear. Blanchard and others[55] evaluated the effects of a high-RDP diet on fertilization and embryo quality. Cows fed high-RDP diets had similar numbers of fertilized, unfertilized, transferable, and nontransferable ova compared with cows fed low-RDP diets. Elrod and Butler[56] proposed that the products of excessive protein degradation in the rumen decreased uterine pH, which may reduce fertility. Garcia-Bojalil and associates,[57] however, reported no difference in ovarian follicle development or number and quality of recovered embryos due to protein level (12.3% versus 27.4% CP). These data suggest that other mechanisms are involved.

Altered hormonal balance caused by elevated BUN levels also may decrease fertility and reproductive

performance. Visek[58] reviewed the effects of ammonia on metabolic hormones and reproduction. Excessive ammonia or chronically elevated ammonia may alter hormonal status and thus performance of the animal. The metabolic signals have not been established, but intermediates of the urea cycle such as arginine may potentially cause shifts in insulin and alter glucose metabolism. Fernandez and associates[59] showed that subclinical ammonia toxicity decreased insulin concentrations in the plasma of steers. Decreased insulin may suggest a disruption in fertility similar to that described earlier for periods of negative energy balance and low circulating insulin concentrations. The shift in hormonal balance also was associated with reduced glucose utilization by insulin-sensitive extrahepatic tissue. Therefore, excess ammonia absorbed from the rumen of cows fed high-RDP or soluble-CP diets could down-regulate a hormonal or metabolic signal to the ovary.

In addition to metabolic hormones, studies also have evaluated the effects of reproductive hormones. Two studies[60,61] showed that the amplitude of the LH peak was higher for cows fed high-protein diets. Progesterone was more variable, with one study showing lower progesterone[60] and the other showing no differences.[61] These studies did not establish an endocrine mechanism through which high-CP diets might alter reproduction.

A confounding factor is the milk production response often observed with high-protein diets. Carroll and associates[62] fed cows diets containing 13% or 20% CP. Cows fed a high-CP diet produced more milk (2.7 kg) during peak lactation; however, the reproductive parameters monitored exhibited few differences due to diet. Howard and colleagues[63] reported similar results in a larger study conducted in Oklahoma. No differences were observed in conception rate or days open due to level of protein in the diet. In both studies, reproductive efficiency was excellent, as indicated by fewer than 1.8 services per conception and average days open less than 85. Therefore, excellent reproductive management of high-producing cows can maintain reproductive efficiency.

Minerals and Vitamins

Several excellent reviews on the effects of mineral nutrition and status on reproductive function of dairy cattle are available.[64–68] These surveys discuss the impact of mineral and vitamin status on reproductive function and performance.

Calcium as an individual nutrient has been associated with poor reproduction when severely deficient. Calcium, the relationship of calcium to phosphorus, and the balance of calcium with vitamin D also have been linked to altered reproductive performance. Ward and coworkers[69] reported that cows fed high-calcium and high–vitamin D diets ante partum had more rapid uterine involution, fewer days to first service, and fewer days open. Hignett and Hignett[70] often are cited for their work with the calcium-phosphorus balance and vitamin D to support normal reproduction. From their results, a minimum calcium-to-phosphorus ratio of 1.5:1 and a minimum daily P intake of 30 g were suggested. As Wiess[68] notes, current NRC recommendations agree with these data, but data relating recommended levels to fertility and reproductive performance have not been reported.

Macromineral and vitamin nutrition also can indirectly affect reproductive health and performance. Curtis and associates[28] described the relationships between hypocalcemia and periparturient disorders. Parturient hypocalcemia significantly increased the odds ratio for dystocia and retained placenta. These investigators concluded that the loss of muscle tone associated with hypocalcemia could reduce normal uterine function. Early research found that feeding low-calcium diets prevented parturient paresis.[71] Practical dry cow diets often are low in calcium, but cattle suffer from hypocalcemia. Block[72] reported the advantage of shifting the dietary cation-anion balance on calcium status. Manipulation of the anionic content of the diet has been used to lower the incidence of hypocalcemia and clinical milk fever. As discussed earlier, decreasing these metabolic disorders probably would improve reproduction. Morrow[73] reported that dairy heifers suffering from phosphorus deficiency had high rates of infertility as measured by services per conception. Increasing phosphorus in the diet returned blood levels to normal, with improved fertility.

Several trace minerals have been found to be important for reproduction.[65] Selenium and vitamin E are the two most often considered for change in herds suffering from reproduction problems; however, other microminerals also have been recognized to be important. Ingraham and colleagues[74] found that copper supplementation increased fertility when combined with increased phosphorus. Manganese also has been shown to influence reproduction. Wilson[75] improved the conception rate among cows in 12 cooperating dairies by feeding supplemental manganese. Zinc is recognized as an essential nutrient required for normal growth. Zinc also has been identified as a component of or cofactor for more than 200 proteins and enzymes. Although zinc's role in metabolism has been defined, including the growth and repair of normal epithelial tissue, the role in reproduction is not fully understood. Two reviewers have examined the importance of zinc for testosterone biosynthesis and spermatogenesis.[65,76] Little work has been completed for the mature cow. Apgar[77] reviewed zinc's influence on reproduction for all species. Zinc deficiency increased the length of labor and bleeding time in the rat. This relationship also has been reported for the ewe. In all species, the possible influence of zinc on endocrine changes has not yet been adequately described.

Selenium and vitamin E have been the two trace minerals most extensively researched. Trinder and coworkers[78] reported that supplemental selenium and vitamin E 30 days ante partum reduced the incidence of retained placenta. Supplemental selenium and vitamin E also reduced delay in delivery of the fetal membranes. Similar reports have been published from other laboratories[79,80]; others, however, have reported no benefits of selenium or vitamin E.[81,82] Segerson and associates[83] noted that only marginally deficient cows responded and that cows with adequate selenium or those with severe deficiency did not respond to the diet. In summary, selenium and vitamin E are necessary in the diet of the dry cow

and the milking cow to maintain normal reproductive function. Supplementation above recommendations or in severely deficient animals will not provide reproductive benefits.

Beta-carotene (carotene) also has been investigated as a nutrient having special requirements for reproduction. Hemken and Bremel[84] reviewed this topic in 1982 and concluded that adequate evidence did not exist to support the establishment of a requirement for carotene above that for vitamin A. Chew and co-workers[85] reported high levels of carotene in the blood, corpus luteum, and follicular fluid, but effects on ovarian functions were not described. Additional studies also have failed to establish a requirement for carotene.[86–89]

IMPLICATIONS FOR MANAGEMENT

Research has established that the nutritional status of the animal alters the reproductive function of the animal. In fact, the current question is how and to what level nutrition alters the reproductive function of the high-producing dairy cow. Poor nutrition can result from inadequate nutrient density in the diet, inadequate amounts of the diet fed, and insufficient access to the diet. Prepartum metabolic disorders have a carryover effect that can impede reproductive function because of the residual effects of severe negative energy balance. This phenomenon emphasizes the importance of nutritional management, as well as overall management of the herd. This aspect of farm management will become increasingly critical as the genetic base of the dairy cow population continues to improve. As noted by Norman and Powell,[2] tremendous potential exists in the current gene pool of dairy cattle. The long-range challenge will be maximization of this genetic potential to its fullest extent.

CHAPTER 58

Effects of Nutrition on Reproductive Performance of Beef Cattle

WILLIAM S. SWECKER, Jr., and RAMANATHAN KASIMANICKAM

"If you feed them, you can breed them. If you don't, you won't."

Bill McDonald, seventh-generation beef producer, Montgomery County, Virginia

The relationship between nutrition and reproduction is bidirectional—that is, reproductive status alters nutrient requirements, but the nutrients assimilated by the cow also alter reproductive function. A beef cow must conceive, carry a fetus to term, give birth, and wean a calf in a 12-month period; thus, she is either pregnant or lactating at any given time. The fetus becomes a high priority for nutrient repartitioning in the dam, which can increase nutrient requirements by 75% at the end of pregnancy to support a weight gain of up to 70 kg for the fetus, the placenta, and fetal fluids.[1] Likewise, nutrients are repartitioned again at calving to support lactation, which can increase requirements by 50% to 100% above maintenance.[2] Hormonal changes associated with pregnancy and lactation aid in the prioritization of nutrients; however, a negative energy balance during early lactation modifies the signals that initiate ovarian cyclic activity.

The beef cow utilizes tissue energy, which results in loss of body condition, to counter the negative energy balance of early lactation. The challenge to meet nutrient requirements becomes more difficult with the addition of environmental influences such as cold, rain, heat, and mud. This chapter reviews the requirements of beef cattle relative to their reproductive status and defines abnormalities of reproduction and related nutrient risk factors in beef cows. Nutrition and reproduction in the bull are discussed briefly.

CHAPTER 58

Effects of Nutrition on Reproductive Performance of Beef Cattle

WILLIAM S. SWECKER, Jr., and RAMANATHAN KASIMANICKAM

"If you feed them, you can breed them. If you don't, you won't."

Bill McDonald, seventh-generation beef producer, Montgomery County, Virginia

The relationship between nutrition and reproduction is bidirectional—that is, reproductive status alters nutrient requirements, but the nutrients assimilated by the cow also alter reproductive function. A beef cow must conceive, carry a fetus to term, give birth, and wean a calf in a 12-month period; thus, she is either pregnant or lactating at any given time. The fetus becomes a high priority for nutrient repartitioning in the dam, which can increase nutrient requirements by 75% at the end of pregnancy to support a weight gain of up to 70 kg for the fetus, the placenta, and fetal fluids.[1] Likewise, nutrients are repartitioned again at calving to support lactation, which can increase requirements by 50% to 100% above maintenance.[2] Hormonal changes associated with pregnancy and lactation aid in the prioritization of nutrients; however, a negative energy balance during early lactation modifies the signals that initiate ovarian cyclic activity.

The beef cow utilizes tissue energy, which results in loss of body condition, to counter the negative energy balance of early lactation. The challenge to meet nutrient requirements becomes more difficult with the addition of environmental influences such as cold, rain, heat, and mud. This chapter reviews the requirements of beef cattle relative to their reproductive status and defines abnormalities of reproduction and related nutrient risk factors in beef cows. Nutrition and reproduction in the bull are discussed briefly.

NUTRITION AND FEMALE REPRODUCTION

Nutrient Requirements of the Beef Cow

Abnormalities in reproductive function may not be detected by the producer or the veterinarian until weeks or months after the causative insult, which may be infectious, toxic, or nutritional. The nutrient demands of the cow relative to the feed supply available can be evaluated historically or prospectively. The nutritional requirements of beef cows vary with their reproductive status[3]:

- *Calving to conception* (82 days): Reproductive functions during this period include uterine involution, resumption of normal estrous cycles, and lactation. Nutrient requirements are greatest during this period, and in most instances the cow must utilize tissue energy to meet these requirements because she cannot consume enough nutrients. Clinically, this is represented by loss of body condition.
- *Pregnant and lactating* (123 days): The primary demand for nutrients during this stage is lactation, and cows should gain weight during this period. Increased nutrient intake supports lactation, which also results in calf weight gain.
- *Midgestation* (140 days): Nutritional requirements are lowest, and cows can be maintained on low-quality feeds during this period. This is an excellent time to increase the body weight of thin cows.
- *Precalving* (50 days): Nutrient requirements rapidly increase during this phase, and body condition should be maintained, in addition to the weight gain caused by an increase in the weight of fetal tissues, placenta, and uterine fluid. Inadequate nutrition, especially during this period, can result in decreased calf survival, lower milk production and slower calf growth, and delayed resumption of ovarian activity.

Energy and protein requirements during each of these four periods are listed in Table 58-1.

Table **58-1**

Protein and Energy Requirements for an 1100-lb Beef Cow during the Reproductive Cycle

Reproductive Period	Net Energy (Mcal/day)	Protein (kg/day)
Calving to conception (85 days)	14.9	1.05
Conception to weaning (125 days)	12.2	0.86
Weaning to late gestation (110 days)	9.2	0.64
Late gestation (50 days)	10.3	0.73

Data from Corah LR: Nutrition of beef cows for optimizing reproductive efficiency. *Compend Contin Educ Pract Vet* 1988;10:659; and Corah LR: Body condition: an indicator of the nutritional status. *Agric Pract* 1989;10:25.

Abnormalities in Female Reproduction

Veterinarians or producers commonly recognize reproductive abnormalities when cows do not calve or when a large percentage of cows are found to be open when examined for pregnancy. The nutritional events that result in failure of cows to become pregnant may have occurred 4 to 18 months previously. Although overlap among diagnostic groups will be inevitable, the practitioner can attempt to categorize the nonpregnant cows as those that failed to have normal estrous cycles, those that failed to conceive, or those that conceived but did not remain pregnant; each category suggests different causes. A thorough review of the diagnosis of nutritional infertility has been published.[4]

Failure to Cycle: Heifers

Most production systems require that heifers calve at 23 to 24 months of age. Heifers that calve early in the calving season wean more and heavier calves during their lives.[5] Heifers, therefore, should reach puberty at 12 to 13 months of age to allow one or two estrous cycles before breeding at 14 months. Age at puberty is influenced by breed, by season, and by plane of nutrition.[5,6] Growth rates during the preweaning and postweaning periods are inversely related to age at puberty, and the postweaning growth rate is associated with plane of nutrition.[5] The onset of puberty appears to be associated with increased frequency of luteinizing hormone (LH) secretion. Increased pulsatile LH secretion is associated with increased energy intake, whereas reduced energy intake suppresses LH secretion in heifers.[7] Delayed puberty also is associated with low concentrations of insulin-like growth factor-I (IGF-I). Proliferation of steroidogenic capacity of thecal[8] and or granulosa cells[9] is associated with decreased concentration of IGF-I. Recent research has focused on leptin as a regulator for reproductive function and particularly as a mediator for nutritional cues. Short-term fasting of peripubertal heifers decreased leptin gene expression, and circulating leptin concentrations were coincident with reductions in circulating concentrations of insulin and IGF-I and in LH pulse frequency, resulting in delayed puberty.[10] Conversely, serum leptin concentration was positively correlated with changes in increasing body weight in prepubertal heifers.[11] Addition of ionophores to the ration increases growth rate but also tends to decrease age at onset of puberty, independent of weight.[12,13]

Historical recommendations have been that heifers should be fed to reach a target weight of 65% to 70% of their mature weight at breeding. Brahma-cross heifers fed to a target weight of 318 kg showed estrus earlier and had increased rates of pregnancy after 20 days of breeding (39% versus 9%) and at the end of the breeding season (82% versus 66%) compared with heifers fed to a target weight of 272 kg.[14] Conversely, spring-born, weaned beef heifers (213 kg) were fed over winter to achieve either 55% or 60% of mature weight at breeding. Heifers fed for 60% mature weight were heavier at breeding (313 versus 289 kg) and had increased condition scores (6.0 versus 5.6), and more were cycling before the breeding season (85% versus 74%). Pregnancy rates at the end of the

45-day breeding season, however, were similar between groups (88% versus 92%) The heifers were then followed through three calvings; production did not differ between groups except for higher 205-day adjusted weaning weights after the second calving for the heifers fed to achieve 55% of mature weight at breeding.[15]

Decreased Reproductive Rates in Mature Cows

Breed, suckling stimulus, and plane of nutrition affect return to estrus in postpartum cows.[16] Body condition score (BCS) at calving and nutrient supply during the early postpartum period affect the return of ovarian cyclic activity and subsequent pregnancy rates (Table 58-2).

Alterations in plane of nutrition and BCS alter hormonal status. For example, pulse frequency of LH was increased 3 weeks post partum in cows that calved in moderate body condition compared with cows that calved in poor body condition.[17] Postpartum LH secretion is less responsive to dietary protein. LH release at 20, 40, and 60 days after calving did not differ between cows fed adequate crude protein before calving (0.96 kg/day) and cows fed restricted crude protein (0.32 kg/day) starting at 90, 60, and 30 days before calving.[18]

Several studies have shown that body condition at calving alters the time between calving and conception and pregnancy rates. Pregnancy rates for cows with BCS of 4 and 5 at calving were lower than pregnancy rates for cows with BCS of 6 and 7 at calving (64.9% and 71.4% versus 87.0% and 90.7%, respectively).[19] In a similar study, cows with BCS of 4 at calving had a pregnancy rate of 50%, whereas cows that calved with BCS of 5, 6, and 7 had pregnancy rates of 81%, 88%, and 90%, respectively.[20] BCS at calving also affects calving interval. Cows with BCS greater than 5 had 10 to 18 fewer days open than cows with BCS of 4.[19] Investigators using a 5-point condition score scale demonstrated a decrease in calving interval of 11.2 days for each unit increase in body condition at calving.[21] This is approximately equivalent to a change of 5 to 6 days in calving interval for a unit change in condition score when a 9-point scale is used. Cows with BCS greater than 5 displayed estrus 12 days earlier after calving and had 14 fewer days open than cows calving with BCS less than 4.[18] A cubic relationship between condition score at calving and pregnancy rate has been described: The effect of a 1-unit change in BCS on pregnancy rate was found to be greater for cows with BCS between 4 and 6 than for fatter or thinner cows.[23]

One study demonstrated that BCS at the beginning of the breeding season influenced pregnancy rate and calving interval; however, changes in live weight from calving to the beginning of the breeding season and BCS at the end of the breeding season had no effect on reproductive performance.[21] Changes in postpartum nutrient intake may benefit thin (BCS <4) more than adequately nourished cows. Pregnancy rates were evaluated in cows whose calves were removed for 48 hours at initiation of breeding. Cows with BCS less than 4 at calving that were fed to lose weight after calving had decreased pregnancy rates at 40 and 60 days after breeding compared with cows fed to gain weight after calving, cows fed to maintain their weight after calving, or cows fed to lose weight but with 2 weeks of increased energy intake before breeding (flushing). The ration fed after calving did not alter the pregnancy rate in cows that calved with BCS greater than 5.[22] Conversely, cows fed to gain 0.9 kg/day after calving had higher first-estrus pregnancy rates and higher serum IGF-I, leptin, and glucose concentrations post partum than cows fed to gain 0.5 kg/day. Condition score at calving (group means 4.4 versus 5.1) did not influence hormonal status after calving.[24]

The timing of the calving season may modify the influence of nutrition on reproductive performance. BCS at calving may be more critical in spring-calving herds, whereas changes in BCS from calving to breeding may be more important in fall-calving cows owing to differences in availability of feed.[25]

All increases in nutrient supply before and after calving should be evaluated relative to cost of added feed versus potential increase in reproductive performance.

Table **58-2**

Body Condition at Calving and Return to Estrus after Calving in Beef Cows

		% OF COWS CYCLING	
BCS at Calving	No. of Cows	60 Days after Calving	90 Days after Calving
Thin (1–4)	272	46	66
Moderate (5–6)	364	61	92
Good (7–9)	50	91	100

BCS, body condition score.
Data from Whitman, Colorado State University, 1975.

Body Condition Scores

Body condition scoring is a visual and tactile appraisal of muscle and adipose tissue. Condition scores allow more precise ration assessment or formulation and predict reproductive performance. Body condition may more accurately estimate tissue reserves than body weight. Weight loss during the periparturient period is associated with loss of fetus, fetal fluids, and placenta, whereas increases in weight are associated with digestive tract fill needed to support lactation and an increase in udder size. Most beef cattle condition scoring systems use a 9-point scale, with BCS 1 being extremely thin and BCS 9 being extremely obese.[22] Body condition and weight were evaluated in 11,301 Angus cows at weaning, and a positive correlation was found between BCS and body weight. BCS accounted for only 16% of the total variation in weight, however.[26] Herd, year-month, and cow age also influenced body weight. Body weight changes among condition scores were not constant; 50- to 70-pound differences were found between condition scores lower than 5, and 85- to 100-pound differences were found between condition scores greater than 5 (Table 58-3). Descriptions of BCS 3 through 6 from several published studies are presented in Table 58-4.

Table **58-3**

Body Condition and Associated Weight in Angus Cows at Weaning

BCS	Body Weight (kg)	Change from Previous BCS (kg)
2	448	—
3	473	25
4	495	22
5	525	30
6	564	39
7	604	40
8	650	46

BCS, body condition score.

Protein

The effect of protein on reproductive function is less clear than is the effect of energy. An association between increased protein intake, especially rumen-degradable protein, and increased early embryonic death has been reported. Energy deficiency or protein-energy imbalance, however, may be as critical as the protein excess.[4] Supplementation with 50% rumen-undegradable or bypass protein after calving did not alter pregnancy rates in cows, compared with pregnancy rates in cows fed 25% bypass protein (88% and 86%, respectively).[27] Supplementation with 250 g of bypass protein (blood meal, corn gluten meal, and soybean meal) after calving increased the percentage of first-calf heifers that conceived during the first estrous cycle compared with heifers supplemented with 250 g of degradable protein (wheat mill run, soybean meal, and urea). Supplementation with bypass protein, however, did not affect the pregnancy rate for the breeding season.[28] Pregnant beef heifers on winter range and hay were supplemented to meet either metabolizable protein requirements or crude protein requirements during gestation. Supplementation to meet metabolizable protein improved 2-year-old pregnancy rates (91% versus 86%) over the 2-year study. The authors suggested that the response to MP supplementation on reproduction was not by improved weight or BCS change before calving and the response may involve endocrine mechanism.[29]

Fat Supplementation

Fat supplements provide an energy-dense source of calories or may provide specific fatty acids that influence reproductive function. Willams and Stanko[30] reported multiple reproductive benefits of fat supplementation of beef cows. Supplemental fat fed during the early postpartum period enhanced luteal function by reducing the incidence of short cycles and prevented a postpartum decline in growth hormone. Linoleic acid inhibits the production of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) by the uterus. Higher dietary fat levels may increase the concentration of cholesterol—which is a precursor for progesterone—in the blood.[30]

Fat supplementation also may play a role in the development of prepubertal heifers. Prepubertal heifers fed safflower seeds as a supplemental fat source from 254 days of age until puberty or breeding season (control diet 1.9% fat, supplemented diet 4.4% fat) had increased serum cholesterol on days 84 and 162 and increased serum progesterone concentrations 7 to 10 days after observed estrus. Heifers in this study were sired by bulls from three breeds: Hereford, Limousin, and Piedmontese. Sire breed was a factor in percentage of heifers that were pubertal at the beginning of breeding and puberty age during the entire study. Sire breed–diet interaction was significant for percentage of heifers pubertal at the beginning of breeding. Of interest, an increased number of Piedmontese-sired heifers on high-fat diets were pubertal at the beginning of breeding (97.6% versus 76.2%), whereas a decreased number of Limousin-sired heifers on high-fat diets were pubertal at the beginning of breeding (60.5% versus 69.8%). The authors concluded that the effects of supplemental dietary fat may be breed-dependent.[31]

Role of Minerals and Vitamins

Deficiencies of almost all nutrients have been thought to cause infertility, yet few have been proved to do so in cattle.[4] Dietary deficiencies of cobalt, copper, iodine, manganese, phosphorus, and selenium, as well as excesses of molybdenum, have been reported to cause infertility by one of three mechanisms: (1) decreased activity of rumen microorganisms with depression in digestibility; (2) alteration of enzymatic action, which involves energy or protein metabolism or alteration of hormone synthesis; or (3) inability to maintain the integrity of the cells of the reproductive system.[4] In addition, trace element deficiencies decrease immunocompetence, which potentially increases the risk of infectious causes of infertility.

Deficiencies of copper, selenium, and manganese have been reported to reduce fertility through altered embryonic survival and to delay estrus or puberty.[32] Cows in one herd supplemented with trace element and vitamin boluses that provided an estimated 2 mg selenium, 2 mg cobalt, 138 mg copper, 113 mg zinc, 71 mg manganese, 2.1 mg iodine, 4644 IU vitamin A, 929 IU vitamin D, and 9 IU vitamin E per day had a calving rate of 93%, compared with 64% for unsupplemented cows. In a second herd, duration of calving season was reduced from 105 days to 49 days in supplemented cows.[33] Vitamin E supplementation for 6 months in heifers was reported to increase the pregnancy rate from 33% to 58% to 83%.[34] Trace element deficiencies often manifest as nonspecific disorders with impaired reproduction as one component. Thorough analysis of feeding programs and analysis of biologic samples for trace elements should allow the practitioner to evaluate the role of trace elements in infertility.

Table **58-4**

Clinical Features with Body Condition Scores (BCSs) in Beef Cattle

	CLINICAL FEATURES			
Study	**BCS 3**	**BCS 4**	**BCS 5**	**BCS 6**
Richards et al.[22]	*Thin:* Ribs are still individually identifiable but not quite as sharp to the touch. There is obvious palpable fat along spine and over tailhead with some tissue cover over dorsal portion of ribs.	*Borderline:* Individual ribs are no longer visually obvious. The spinous processes can be identified individually on palpation but feel rounded rather than sharp. Some fat cover over ribs, transverse processes, and hip bones.	*Moderate:* Cow has generally good overall appearance. On palpation, fat cover over ribs feels spongy, and areas on either side of the tailhead now have fat cover.	*High moderate:* Firm pressure now needs to be applied to feel spinous processes. A high degree of fat is palpable over ribs and around tailhead.
Westendorf et al.[43]	*Thin:* Ribs still identifiable but not as sharp to the touch. Some fat along the spine and over the tailhead.	*Borderline:* Individual ribs are no longer obvious. The spine still feels rounded rather than sharp. There is some fat cover over the ribs and hip bones.	*Moderate:* Good overall appearance. Fat cover over the ribs feels spongy, and areas on either side of the tailhead have fat cover.	*High moderate:* Firm pressure must be applied to feel the spine. A large amount of fat is present over the ribs and around the tailhead.
Corah[44]	Beginning of fat cover is seen over the loin, back, and foreribs. Backbone is still highly visible. Process of the spine can be identified individually by touch and may still be visible. Spaces between the processes are less pronounced.	Foreribs are not noticeable; 12th and 13th ribs are still noticeable to the eye, particularly in cattle with a large spring of rib and ribs wide apart. The transverse spinous processes can be identified only by palpation (with slight pressure) to feel rounded rather than sharp. Full but straightness of muscling in hindquarters.	12th and 13th ribs are not visible to the eye unless the animal has been shrunk. The transverse spinous processes are rounded, though this can be felt only with firm pressure; the roundness is not visually apparent. Spaces between the processes are not visible and distinguishable only with firm pressure. Areas on each side of the tailhead are fairly well filled but not rounded.	Ribs are fully covered, not noticeable to the eye. Hindquarters are plump and full. Noticeable sponginess to covering of foreribs, and on each side of the tailhead, can be felt. Firm pressure is required to feel transverse processes.
Pruitt and Momont[45]	Outlines of all ribs are visible.	Outlines of 3–5 ribs are visible.	Outlines of 1–2 ribs are visible.	No ribs are visible.
Wiltbank[46]	*Thin:* Fat along backbone and slight amount of fat cover are present over ribs.	*Borderline:* Some fat cover over ribs is present.	*Moderate:* Fat cover over ribs feels spongy.	*Moderate to good:* Spongy fat over ribs, and fat is beginning to be palpable around tailhead.

Endophyte-Infected Tall Fescue

Pregnancy rates reported for cows grazing endophyte-infected *(Acremonium coenophialum)* tall fescue are 67%, 55%, 33%, 80%, 55.4%, and 39%, whereas pregnancy rates for control cows grazing uninfected or low-endophyte fescue pastures are 86%, 96%, 93%, 90%, 94.6%, and 65%, respectively.[35] Plasma prolactin concentrations are decreased in cows that consume endophyte-infected fescue, yet LH concentrations are normal. The endophyte generates toxins such as ergovaline, which may affect the cow's ability to maintain pregnancy.[35]

NUTRITION AND MALE REPRODUCTION

The associations between bull fertility and nutrition have been reviewed.[36] Rate of gain after weaning and level of nutrition influence the weight and age at which bulls reach puberty. Young bulls maintained on low planes of nutrition had reduced testicular growth, ejaculate volume, sperm production, and seminal vesicle development. Conversely, overfeeding energy to young bulls can decrease reproductive performance as a result of increased fat deposition in the scrotum or the pampiniform plexus. Severe reduction of protein in rations fed to young bulls decreased sperm production capacity. Refeeding of nutritionally stressed growing bulls has improved reproductive performance in some trials but not in others. Mature bulls appear more resistant to dietary stressors; however, overfeeding and severe protein restriction have resulted in decreased libido.[36]

Zinc deficiency in ruminants impairs fertility in males, as evidenced by reduced testis size in zinc-deficient calves.[37] Selenium is present as glutathione peroxidase in seminal plasma. Semen from bulls with low selenium concentrations had lower motility after thawing than did semen from bulls with higher selenium concentrations.[38] Yearling beef bulls treated with sustained-release selenium boluses had increased sperm motility when compared with untreated bulls.[39]

Gossypol, a compound found in cottonseed that reduces fertility in male rats and humans, immobilizes bull spermatozoa in vitro.[40] Gossypol fed at rates of 6 and 30 mg/kg of body weight for 60 and 42 days, respectively, did not affect seminal quality, quantity, or spermatogenesis in yearling Holstein bulls when compared with control animals fed soybean meal rations.[41] Rations containing 60 mg of gossypol per kilogram of body weight (whole cottonseed), 6 mg/kg (cottonseed meal), and 0 mg/kg (soybean meal) were fed to Brahma bulls from weaning to puberty. Age at puberty was increased and 196-day weight gain was decreased in bulls fed whole cottonseed compared with bulls fed cottonseed meal. The age at puberty and 196-day weight gain were intermediate in the group fed soybean meal; therefore, gossypol did not express its effects in a dose-dependent manner. Electroejaculated semen quality and quantity at puberty did not differ among treatment groups; however, luminal diameters of the seminiferous tubules were larger, germinal epithelium was thinner, and germ cell layers were fewer in bulls fed gossypol.[42] Gossypol, therefore, alters microanatomy of the testes but seems to have minimal influence on the quantity and quality of semen from young Holstein or Brahma bulls.

SUMMARY

Research trials that investigate the relationship between nutrition and reproduction may be inadvertently biased to give false negative results because of the number of cows needed to detect small differences in pregnancy rates. An investigator needs 335 cows in each group to detect a difference between an 85% pregnancy rate and a 90% rate at $P < 0.05$. Conversely, a trial with 50 cows per treatment group can detect only a difference between a 75% pregnancy rate and a 90% pregnancy rate at $P < 0.05$. Studies with small numbers per group, therefore, should be evaluated carefully.

In simple terms, the developing fetus has a high priority for nutrients, lactation is a secondary priority that will decrease with decreased intake, and conception has a low priority and tends not to occur until other requirements such as maintenance, growth, and lactation are satisfied. In addition, suckling inhibits resumption of the estrous cycle. Nutrient supply to the cow before parturition and the resulting BCS at calving appear to be the most important factors in determining reproductive performance. Postpartum energy intake above maintenance can increase reproductive success in thin cows. Thus, the management decisions of when to place the bull with the cows and when to wean the calves are critical and should match the available nutrient supplies to the demands of the cows.

CHAPTER 59

Heifer Development: Nutrition, Health, and Reproduction

ROBERT L. LARSON and RICHARD F. RANDLE

Replacement heifer development is a critically important area of beef production in which veterinarians can provide valuable production medicine advice to their clients. Development costs for preparing a heifer to calve at 24 months of age average about 31% of her lifetime expenses, whereas delaying first calving to 30 or 36 months increases the cost of development to 42% or 46% of her lifetime costs, even if her lifetime productivity is extended by 6 to 12 months.[1]

Not only does the group of replacement heifers need to calve at a mean of 24 months, but the distribution of calving should result in most if not all of the heifers calving early in the calving season.[1] In order to reach this goal, the heifer development program should ensure that most heifers in the replacement pool reach puberty at least 42 days before the start of breeding, because the conception rate to first service is lower on the pubertal estrus than on the third estrus.[2,3]

Many producers put additional pressure on heifers to reach puberty at a young age by breeding them 3 to 4 weeks earlier than the mature cowherd. The stress of calving is greater on heifers than on older cows and calving difficulty is more likely in this group. Thus, breeding replacement heifers essentially one heat cycle earlier than the mature cows allows the producer to concentrate on the heifers at calving. In addition, the length of time from calving to the resumption of cycling is longer in heifers than in cows.[2] Therefore, calving heifers earlier than mature cows gives the heifers the extra time they need to return to estrus and be cycling at the start of the subsequent breeding season.

A heifer development program that is designed to start breeding replacements 28 days earlier than the mature herd, and that strives to have a high percentage of heifers reaching puberty 42 days before the start of breeding, needs to have the group reaching puberty by $12\frac{1}{2}$ months of age.

The beef heifer has reached puberty when she is able to express estrous behavior and ovulate a fertile oocyte. The onset of puberty is influenced primarily by genetic factors governing age and weight at onset specific to the breed.[2,3] The age at puberty can be decreased by selecting for breeds with a younger age at puberty, selecting within a breed for younger age at puberty, or crossbreeding with another breed that has a similar or younger age at puberty. Other factors also can have some influence on the onset of puberty and include exposure to bulls, time of year, and exposure to progestogens.[2–4]

A SYSTEMATIC APPROACH TO HEIFER DEVELOPMENT

The primary objectives for successful heifer development are for the heifer to calve early, give birth to a healthy, vigorous calf, and rebreed. A comprehensive set of guidelines for replacement heifer development that coordinates established management practices known to be beneficial to appropriate heifer development can be developed using a total quality management approach.

A comprehensive health and vaccination program starting at or before weaning should be administered under the advice and guidance of the veterinarian to ensure proper use of health products according to label directions. The health program is focused on maintaining good health and providing adequate protection against the major diseases that cause reproductive losses and reduced reproductive performance in cattle.

Prebreeding examinations serve as a monitoring point to evaluate the postweaning to prebreeding phase of heifer development. These examinations are scheduled in advance of the breeding season to identify deficiencies and determine readiness of heifers for breeding. These examinations should include determination of weight assessment of body condition, assignment of reproductive tract score (RTS), pelvic measurements, and visual observations for structural soundness.

Early-pregnancy examinations should be scheduled to determine the success of the breeding program and to determine fetal age. This can be especially useful in herds in which artificial insemination (AI) is used. Allowing a minimum of 2 weeks between the AI period and natural service permits the examiner to distinguish AI-bred heifers from natural service–bred heifers.

Each client should receive individual and summary data from the pregnancy examinations. These data include stage of gestation (in days) for each heifer and a projected calving date based on the observation. Producers utilizing synchronization and AI can be provided with synchronization response and AI conception rates. The summary data also should include total pregnancy rates and pregnancy rates by 20-day intervals.

Ration Formulation

For heifers to reach puberty by 12 to 13 months of age, they must receive adequate nutritional intake to signal the body that the "luxury" of reproduction is attainable. Once puberty is attained, nutrition must be at a level that allows the heifer to continue cycling, ovulate a viable oocyte, and establish pregnancy. Nutritional demands of heifers during pregnancy exceed those of mature cows because the heifer is partitioning nutrients for her own growth, as well as for fetal growth and development. This increased demand for nutrients continues through early lactation, when the beef female has her highest nutritional requirements. Deficiency of energy or protein for extended periods during the first $2\frac{1}{2}$ years of life will have a negative impact on fetal development, calf viability, milk production, and rebreeding for the next pregnancy.

Social interaction within beef herds dictates a lower status for smaller, younger animals such as replacement heifers. If harvested forage or supplements are fed to groups that contain both mature cows and replacement heifers, the intake of heifers is negatively affected by dominance aggression displayed by mature cows. Because of this social constraint, heifers must be fed separately from the mature cows in order to obtain necessary nutrients.

Weaning to Breeding Nutrition

The target weight concept is based on the fact that *Bos taurus* breed heifers such as Angus, Hereford, Charolais, and Limousin are expected to reach puberty at approximately 60% of mature weight.[2] Dual-purpose breed heifers such as Braunvieh, Gelbvieh, and Red Poll (selected for both meat and milk production) tend to reach puberty at about 55% of mature weight. *Bos indicus* heifers, most commonly Brahma or Brahma-cross, are older and heavier at puberty than the other beef breeds, reaching puberty at about 65% of mature weight.[3] The target weight for heifers can be based on the average mature weight for the herd, or it can be determined by using the frame score to predict mature weight[4] (Table 59-1). Once the target weight is known and the number of days until the start of the breeding season (or until a mid-development ration change) is determined, the rate of gain needed is a simple calculation.

Meeting the target weight, but not grossly exceeding it, is important for heifer fertility and production. Developing heifers on a high plane of nutrition (both energy and protein) from weaning to breeding results in earlier puberty,[3] improved udder development,[3] and increased conception rates[4] compared with a low plane.

Although hitting the target weight at the start of the breeding season is important for fertility and future productivity, weight gains do not need to be consistent throughout the weaning to breeding period. Freetly and associates showed that so long as replacement heifers grow to meet a minimal body weight before mating, a period of limit feeding, followed by full feeding to capture compensatory gain, may be used to decrease the amount of feed required for heifer development without a decrease in the ability of the heifer to conceive, or a decrease in her calf's growth potential; however, first-calf survival may be affected.[3]

To ensure that the target weights and body condition scores are being met, a subgroup of the heifers should be weighed and scored for body condition at reasonable intervals (such as monthly), to confirm that targeted gains are being reached. If gains are not near target levels, the ration should be adjusted accordingly.

Breeding through Midgestation Nutrition

The target weight concept can be integrated into planning the nutritional requirements through pregnancy. A heifer should weigh 80% to 85% of her mature weight at the time of calving as a 2-year-old. Energy and protein requirements (National Research Council [NRC] estimates) for growing heifers during mid-gestation should be used to formulate rations that allow heifers to maintain body condition and progress toward target calving weight. Economic considerations may favor limited weight gain or even weight loss during mid-gestation in mature beef cows, but because of higher nutrient demands of heifers, little or no decrease in body condition should occur during the first pregnancy.

Last 60 Days of Gestation Nutrition

The nutritional demands of pregnancy increase as gestation progresses. These demands increase not only as a

TABLE **59-1**

Mature and Puberty Target Weights for Heifers of Different Frame Sizes

Frame Score	Expected Mature Weight (lb)*	55% of Mature Weight (lb)	60% of Mature Weight (lb)	65% of Mature Weight (lb)
2	953	524	572	619
3	1027	565	616	668
4	1100	605	660	715
5	1173	645	704	762
6	1247	686	748	811
7	1320	726	792	858

result of fetal growth but also because of uterine/placental growth and metabolism involved with the fetal-maternal interaction and the exchange of nutrients and waste.

In one study, heifers calving in body condition scores (BCSs) of 4, 5, or 6, respectively, had calves with progressively heavier birth weights, but dystocia score was not influenced by BCS at calving.[4] Heifers with greater weight gains ante partum had calves with heavier actual and 205-day adjusted weaning weights than did heifers with moderate weight gains.[18] Greater BCS at calving resulted in more heifers in estrus and more heifers pregnant by 40 and 60 days of the subsequent breeding season.[18] Thin females should be fed levels during the last third of pregnancy to achieve a targeted BCS of 6 or higher at calving, whereas those in moderate-high to high body condition at 90 days before calving should be fed levels to maintain body reserves.

First 80 Days of Lactation Nutrition

During the first 80 to 100 days after parturition, the heifer must continue to grow at about 0.5 lb per day, support lactation for a suckling calf, resume estrous cyclicity, and conceive for her second pregnancy. The maintenance requirement for lactating heifers averages about 20% higher than that for nonlactating heifers, with actual maintenance requirements being greatly affected by level of milk production. Marston and colleagues[3] illustrate the importance of adequate body condition at calving in that supplementation of energy or protein after calving had little effect on subsequent pregnancy rate. The period of time between calving and rebreeding is fairly short, only 82 days to maintain a 365-day calving interval, and during this time the cow has her highest nutritional demand due to lactation. Because of these factors, weight gain or body condition increase is difficult in the early postpartum cow. Lalman and co-workers[4] found that feeding high-energy diets post partum to thin heifers reduces the negative effects of prepartal nutrient restriction but does not completely reverse those effects.

Use of Progestogens

Progesterone and synthetic progestogens induce puberty in heifers, and management systems that capitalize on this result have been developed. Short and colleagues showed that more prepubertal heifers (8.5 months of age and weighing 249 kg) given a progesterone implant for 6 days plus an injection of estradiol-17β 24 hours after implant removal showed estrous behavior and ovulated within 4 days than heifers treated with estradiol-17β alone.[5] A commercially available synthetic progestogen is melengestrol acetate* (MGA). Studies have demonstrated the ability of MGA to induce puberty in heifers, especially heifers near the age and weight requirements for spontaneous induction of puberty. Conception rate at first service for heifers that attained puberty while being treated with MGA administered orally for 14 days, followed by prostaglandin $F_{2\alpha}$ given as an intramuscular injection 17 days after the final day of MGA feeding, was not different from that for control heifers that attained puberty during the same period.[5]

*The Upjohn Co., Kalamazoo, MI.

Use of Ionophores

Ionophores originally were cleared for use to improve the feed efficiency of feedlot cattle on high-concentrate diets[2] and to improve pasture cattle gains.[6] Now, ionophores also are cleared for use in replacement heifers. Inclusion of ionophores in heifer diets has been shown to increase the number of heifers that had reached puberty by the start of the breeding season, decrease the age at puberty, decrease the weight at puberty, increase the corpus luteum weight, and increase the amount of progesterone produced.[6–8] The decrease in age at puberty was independent of improved average daily gain and increased body weight.

Effect of Growth Implants

Implanting suckling calves with anabolic growth promotants is a highly profitable practice used by cow-calf operators to increase weaning weights of calves intended for slaughter. Research on the effect of implanting heifers that are later saved for replacements on percentage cycling and conception rates has been somewhat inconsistent, with results ranging from negative[6,7] to positive.[2] When nutritional levels are adequate to sustain the anabolic effects on weight gain, implants have been reported to have no negative effects.[7] Negative results were most likely to occur when implants were placed at birth, or when heifers were implanted with anabolic agents three times between birth and puberty.[28,29]

Numerous studies have shown that heifers implanted with anabolic growth promotants at 2 to 3 months of age have a larger pelvic area as yearlings than do controls without implants.[7,8,31] This increase ranged from 10 to 29 cm^2. A few studies have followed the heifers to calving at 2 years of age to determine whether the larger pelvic areas were maintained. These studies showed that much of the advantage for implanted heifers seen as yearlings was lost by the time they were ready to calve; the advantage was only 3 to 9 cm^2, compared with controls with no implants.[31,32]

Use of Anthelmintic Treatment

Internal parasites can have a negative impact on virtually all production characteristics of beef cattle, including gains from weaning through the first pregnancy.[7,8] Minimizing the negative impact of internal parasites improves the efficiency of gain for replacement heifers. Improved gain increases body weight and hence the number of heifers cycling at the beginning of the breeding season.[27,29] It is interesting to note, however, that improvements in reproductive response in replacement heifers treated with anthelmintics may not be due solely to reaching target weights faster than nontreated heifers. It is noteworthy that Larson and associates found the correlations between weight gain or prebreeding heifer weight and puberty in ivermectin-treated heifers

approached zero, indicating that the gain response does not fully explain the earlier onset of puberty.[35] Purvis and Whittier also showed that decreased age and weight at puberty in ivermectin-treated heifers compared with controls was not due to improved average daily gains.[27] Therefore, other pathways affecting onset of puberty, besides weight gain, are being stimulated due to treatment with ivermectin and possibly other anthelmintics.

Assessment of Growth and Maturity

Body Weight

Yearling weight should approach or exceed the target weight in order to have a high percentage of a group of heifers pubertal by the start of the breeding season.

Reproductive Tract Scores

The reproductive tract scoring system was developed as a practical method for determining onset of puberty in production herds. This system subjectively classifies pubertal status using size of the uterus and ovaries estimated by palpation per rectum.[4] A reproductive tract score (RTS) is assigned to each heifer using a 5-point scale on which a score of 1 is considered to indicate an immature tract and scores of 4 and 5 are considered to indicate a cycling tract (Table 59-2).

An RTS of 1 is used to describe heifers with infantile reproductive tracts that are not near the time of puberty when palpated. These heifers have small, flaccid tracts and small ovaries with no significant structures. Heifers assigned an RTS of 2 have slightly larger uterine diameter, but tone is still lacking and the ovaries have very small follicles. Heifers described as having an RTS of 3 have some uterine tone and larger uterine diameter than heifers with more immature scores. These heifers are subjectively evaluated as being close to cycling (within 6 weeks). Heifers assigned either a score of 4 or 5 are considered to be cycling, as indicated by good uterine tone and size and easily palpable ovarian structures. RTS 4 is assigned to heifers that do not have a palpable corpus luteum (CL), despite the presence of large follicles, either because they are in their pubertal cycle or because they are in a stage of the estrous cycle in which a CL is absent. Heifers with an RTS of 5 are similar to RTS 4 heifers in uterine and ovarian size, tone, and structure when palpated per rectum, except that a CL is present in RTS 5 heifers.

Pregnancy rates subsequent to AI after estrous synchronization differed between RTSs, with higher pregnancy rates found with progressively higher tract scores.[8] Because of the myriad variables affecting conception and pregnancy rate, however, simply having a high percentage of a group of replacement heifers assigned an RTS of 4 or 5 did not ensure a high AI pregnancy rate.

Heifers should be evaluated for RTS about 6 to 8 weeks before the start of the breeding season. If deficiencies are found, management changes instituted this far ahead of the breeding season can result in an increased number of heifers reaching puberty by the start of the breeding season. If the heifers are evaluated too far ahead of the breeding season (>8 weeks), the heifers are likely to be young and to have lower RTSs that do not constitute a true reflection of their potential to reach puberty before the breeding season.

Pelvic Area Measurement

The use of pelvic measurement at 1 year of age as a tool to decrease the incidence of dystocia has been described extensively since the late 1970s.[9] Veterinarians have used pelvic area measurements in yearlings because the major cause of dystocia is a disproportionately large calf relative to the heifer's pelvic area. The correlation between yearling and 2-year-old pelvic areas is 0.70; therefore, measuring the heifer's pelvic area as a yearling is beneficial for predicting pelvic size at the time of parturition.[38] Pelvic area is moderately to highly heritable (0.44 to 0.61), so after a few years of measuring replacement heifers and bulls used to produce replacements, producers can increase average pelvic size of the herd.[10,11]

Critics of using pelvic area measurements to decrease dystocia point out that pelvic area is also positively

TABLE **59-2**

Reproductive Tract Scores (RTSs)

		APPROXIMATE OVARIAN SIZE			
RTS	**Uterine Horn Size/Tone**	**Length (mm)**	**Height (mm)**	**Width (mm)**	**Ovarian Structures**
1	<20 mm diameter No tone (immature)	15	10	8	No palpable follicles
2	20–25 mm diameter No tone	18	12	10	8-mm follicles
3	25–30 mm diameter Slight tone	22	15	10	8- to 10-mm follicles
4	30 mm diameter Good tone	30	16	12	>10-mm follicles CL possible
5	>30 mm diameter Good tone	>32	20	15	>10-mm follicles CL present

CL, corpus luteum.

correlated to mature cow size and calf birth weight.[10,11] If producers place selection pressure on heifers for pelvic area by selecting for increasingly larger pelvic area, calf birth weight also will increase, so that the rate of dystocia is not likely to decrease.[10] A number of researchers have shown that selection based on pelvic area alone did not significantly reduce the incidence of dystocia in groups of heifers.[11,12]

Rather than using pelvic area measurement to select for maximum pelvic size, this tool should be used to set a minimum pelvic size as a culling criterion (such as 150 cm^2 at 1 year of age) without assigning preference for heifers that exceed the minimum.

Evaluation of Reproductive Soundness of Heifers Based on Weight, Reproductive Tract Score, and Pelvic Area

An effective way to evaluate the reproductive soundness of yearling heifers in a ranch setting is by using yearling weights, RTS, and pelvic area measurements together to describe the maturity and reproductive soundness of the heifer group. These three criteria are closely correlated in that within a group of heifers with similar genetic makeup, both higher tract scores and greater pelvic areas can be expected in heifers that have heavier yearling weights.

Because yearling weight, RTS, and pelvic area normally are well correlated, the practitioner or the producer should make note of heifers or groups of heifers for which that relationship is not strong. Heifers that have reached their target weight and have a high RTS but that have small pelvic areas may have a genetic predisposition for a small pelvis. This genetic input may have come from the male or the female component of the genetic makeup. As another example of lack of correlation of these normally well-correlated criteria, heifers that were implanted with a growth promotant near the time of birth may have very adequate yearling weights and pelvic areas but RTSs that indicate tract immaturity.

Pelvic area tends to increase more rapidly near the time of puberty than during the prepubertal period.[10] This knowledge is useful in evaluating pelvic area data in that a heifer that has an RTS of 5 and is of adequate yearling weight but has a small pelvis has a high probability of having a small pelvis at the time of calving as a 2-year-old, whereas a heifer with the same pelvic area that has an RTS of 2 and has not reached her target weight may very well have an adequate pelvis at calving if management changes are made so that she reaches puberty and becomes pregnant.

Biosecurity

Biosecurity is the attempt to keep infectious agents (e.g., bacteria, virus, fungi, parasites) away from a herd. One aspect of biosecurity is a vaccination program that improves the immunity of cattle against the infectious agents that they may contact. Not all diseases of cattle have commercial vaccines available, and no vaccine is completely effective at preventing disease in all situations. Therefore, other aspects of disease prevention and biosecurity are at least as important as a vaccination program. A vaccination program should be tailored to address specific risk factors and then rigorously applied to the herd. For most beef herds, the potential list of diseases in a vaccination program include brucellosis, infectious bovine rhinotracheitis (IBR), bovine viral diarrhea (BVD), vibriosis (campylobacteriosis), and leptospirosis. Other diseases for which vaccines are available are *Haemophilus somnus* infection and trichomoniasis.

Because most infectious agents cannot live very long outside or off an animal, and because most do not travel great distances through the air, a method to keep other animals and people away from a herd will be almost entirely effective in accomplishing the goal of keeping infectious agents away. Keeping a closed herd is one method of maintaining biosecurity. A **closed herd** is one in which no cattle enter the farm and no cattle on the farm have contact with cattle from other farms. A herd is not closed if cattle share a fence with cattle from a different farm, if cattle are purchased (bulls, replacement heifers, replacement cows, stocker cattle), if cattle return to the herd after being at a performance evaluation (i.e., bull test station) or show, if bulls are borrowed or loaned, or if cattle are transported in a vehicle that transports other cattle. Using this definition, it is obviously difficult (and perhaps not desirable from a production standpoint) to maintain a completely closed herd. Including as many closed-herd protocols as possible within a farm's or ranch's management practices, however, will minimize exposure to infectious agents.

In **open herds**, additions (replacement females and bulls) should be purchased only from herds managed with a known and effective vaccination and disease testing and diagnosis program. Producers should avoid purchasing animals from unknown sources or that have been mixed with other cattle before sale. Also, additions to the herd should be isolated from the resident herd for at least 1 month before introduction to the herd. Isolated cattle should not share feeders, waterers, or air space (the optimal distance will depend on wind velocity and direction and is not well defined). During the isolation period, animals should be vaccinated with the same program as that used on the farm and screened to identify those replacements persistently infected with BVD virus using an immunohistochemistry (immunoperoxidase) test on a skin biopsy sample, or by polymerase chain reaction assay, virus isolation test, or enzyme-linked immunosorbent assay (ELISA) of serum or blood. The practitioner should work with the diagnostic laboratory to accurately interpret the tests. Some beef operations also may screen for Johne's and bovine leukosis virus (BLV).

Equipment and animals other than cattle can carry infectious diseases. Exposure of cattle to rodents, birds, cats, and dogs should be limited. Rodents and birds are a problem primarily when cattle are confined, and professional exterminators may be needed to devise an effective control plan. Salmonellosis, cryptosporidiosis, and other diseases can be transmitted by dogs and cats; therefore, keeping pet animals away from cattle is an important aspect of biosecurity.

Humans can carry infectious diseases; therefore, producers should limit access to the herd and ensure that

visitors wear clean boots and coveralls if they have recently visited other cattle operations. Trucks that deliver animals and feed, or that pick up animals (alive or dead), should remain away from the herd and away from normal traffic areas.

SUMMARY

A systematic approach to heifer development that encompasses nutritional development to ensure heifers will reach target weights, periodic assessment of growth and maturity by measuring body weight and reproductive tract maturity, and a herd biosecurity program that includes stringent vaccination and quarantine protocols will improve pregnancy rates and optimize development costs per pregnant heifer.

CHAPTER 60

Surgical Correction of Abnormalities of Genital Organs of Cows

RICHARD M. HOPPER

Many urogenital problems in the cow mandate culling because of economic considerations and unfavorable prognosis; however in some situations the value of the animal dictates an attempt at treatment, with restoration of fertility the goal. Because most urogenital accidents or injuries occur in conjunction with pregnancy or parturition, the goal of surgical intervention may be simply to allow for delivery of the calf, or if parturition has occurred, allow for increased weight gain of the calf or cow for sale at a later date. Thus, although restoration of fertility may not always be achieved, a salvage procedure is often an economically viable option.

ANESTHETIC CONSIDERATIONS

Most procedures described here can be performed while the animal is standing, with good restraint and well-utilized local anesthesia; minimal sedation is required. Although it is understood that tranquilization does not provide analgesia, it is important to remember that with cattle, controlling anxiety is just as important. Alternatively, it is also important to consider the side effects of most sedatives. Xylazine, for example, increases uterine contractions and decreases uterine profusion and oxygenation.[1] Also, most cows have a tendency to lie down when sedated. Therefore, light sedation with properly administered regional anesthesia is preferred for standing procedures. Additionally, it is typically beneficial to administer nonsteroidal anti-inflammatory drugs (NSAIDs) to minimize postsurgical inflammation and discomfort.

The regional anesthetic blocks most commonly employed are the epidural for most procedures involving the vulva, vagina, or perineum and either the inverted-L

CHAPTER 60

Surgical Correction of Abnormalities of Genital Organs of Cows

RICHARD M. HOPPER

Many urogenital problems in the cow mandate culling because of economic considerations and unfavorable prognosis; however in some situations the value of the animal dictates an attempt at treatment, with restoration of fertility the goal. Because most urogenital accidents or injuries occur in conjunction with pregnancy or parturition, the goal of surgical intervention may be simply to allow for delivery of the calf, or if parturition has occurred, allow for increased weight gain of the calf or cow for sale at a later date. Thus, although restoration of fertility may not always be achieved, a salvage procedure is often an economically viable option.

ANESTHETIC CONSIDERATIONS

Most procedures described here can be performed while the animal is standing, with good restraint and well-utilized local anesthesia; minimal sedation is required. Although it is understood that tranquilization does not provide analgesia, it is important to remember that with cattle, controlling anxiety is just as important. Alternatively, it is also important to consider the side effects of most sedatives. Xylazine, for example, increases uterine contractions and decreases uterine profusion and oxygenation.[1] Also, most cows have a tendency to lie down when sedated. Therefore, light sedation with properly administered regional anesthesia is preferred for standing procedures. Additionally, it is typically beneficial to administer nonsteroidal anti-inflammatory drugs (NSAIDs) to minimize postsurgical inflammation and discomfort.

The regional anesthetic blocks most commonly employed are the epidural for most procedures involving the vulva, vagina, or perineum and either the inverted-L

or paravertebral block for the flank approach celiotomy. Additional regional anesthetic techniques that may be of value are discussed as well.

Proximal Paravertebral Block

Indications
Flank abdominal approaches, whether for a hysterotomy or for gastrointestinal procedures, are the major reason this block is utilized.

Procedure
This block anesthetizes T13, L1, and L2 as they exit the intervertebral foramen. The pertinent anatomic landmarks are the head of the 13th rib and the transverse processes of the lumbar vertebrae.[2] The lumbar area is surgically prepped. Then the skin at the three injection sites is desensitized with 1 to 2 ml of 2% lidocaine. The first site (T13 block) is about 2 to 5 cm lateral to the midline, caudal to the head of the 13th rib, and cranial to the transverse process of L1. The second site (L1 block) and third site (L2 block) are also 2 to 5 cm off the midline and cranial to the transverse processes of L2 and L3, respectively. Next, a 14-gauge needle is inserted (at a 90-degree angle) into the site to facilitate passage of an 18-gauge needle for the actual deposition of the lidocaine. At each site an 18-gauge needle that is at least 10 cm in length is inserted through the 14-gauge needle to a depth of about 9 to 10 cm ("walking" off the transverse process to a depth 1 cm beyond the process) injecting 10 ml of lidocaine there and another 8 to 10 ml as the needle is removed.

The main disadvantage of this procedure is that it can be difficult in fat cattle.

Inverted-L Block

Indications
Indications are the same as for the paravertebral block. However, this block can be performed more quickly and easily.

Procedure
This is simply a "line block" that follows the pattern of an upside-down L along the dorsal and cranial borders of the paralumbar fossa. Utilizing either a 20- or 18-gauge needle, 2% lidocaine is deposited every 3 to 5 cm along the aforementioned line. A total volume of 70 to 150 ml is typically utilized. The main disadvantages are the large volume of lidocaine required and inconsistent analgesia.

Pudendal Nerve Block

Indications
This block is most commonly used in preputial surgery in the bull, but it has applications for the cow as well. It can be helpful in chronic prolapse cases in which the bladder is also prolapsed. It is also indicated in any caudal urogenital procedure in which there is extreme tenesmus and an epidural does not seem adequate.[3]

Procedure
To perform this block, first prep the area of the ischiorectal fossa. Then by rectal palpation locate the lesser sciatic foramen. This is wrist deep and lateral. The lesser sciatic foramen is formed by the sacrosciatic ligament dorsally and the lesser sciatic notch ventrally. Following the intradermal injection of a small amount of lidocaine, a 14-gauge needle is placed through the skin in the ischiorectal fossa. Then a 6- to 8-inch 18-gauge needle is passed within the 14-gauge needle and with guidance from the hand within the rectum, the tip of the needle is placed in close approximation to the internal pudendal nerve. Then 20 to 75 ml of lidocaine is injected. Because these are paired nerves, swap hands and sides and repeat.

Sacral Paravertebral Nerve Block

Indication
The sacral paravertebral nerve block provides longer "semipermanent" analgesia following caudal urogenital tract procedures in which other regional blocks do not adequately control tenesmus and avoids the potential negative side effects of the "alcohol" epidural.

Procedure
Because blocking the pudendal, middle hemorrhoidal, and caudal hemorrhoidal nerves is most easily facilitated by blocking S3, S4, and S5 as they branch off the spinal cord, the important anatomic landmarks are the foramina that are located lateral to the dorsal midline. Any lateral movement increases the difficulty, so squeeze chute restraint and tranquilization are recommended. A caudal epidural may be beneficial in the flighty or hypersensitive individual. Clip and perform a surgical prep of the skin over the dorsal sacrum. This completed, the S3, S4, and S5 foramina are located. This is best accomplished by first identifying the sacral-coccygeal joint (the most cranial of the joints movable when the tail is raised and lowered); 1 to 2 cm lateral to this are the paired S5 foramina. The S4 foramina are about 3 to 4 cm cranial, but more lateral and the S3 foramina are an additional 3 to 4 cm cranial. A stab incision dorsal to each foramen will facilitate the introduction of a 5- to 7-cm, 18-gauge needle. When the osseous ring is entered inject the 2 to 3 ml of the alcohol or alcohol/lidocaine mixture. An effective mixture is 1 ml of 2% lidocaine and 2 ml of 95% ethyl alcohol. This should effectively decrease tenesmus, while maintaining tail viability.

High Epidural Block

Indication
This block can be utilized when the cow is to be in ventral recumbency, maximum control of the hind limbs is desired, and facilities allow for a period of recumbency following the surgery.

Procedure
This procedure is the same as that for a routine caudal epidural except that the dosage of 2% lidocaine is 60 to 100 ml. The primary advantage, immobility of the rear

legs, is also one of the prime disadvantages. Additionally, it is crucial that the head, shoulders, and thorax be elevated so that analgesia to respiratory centers does not occur.

SURGERY OF THE VULVA AND PERINEUM

Episiotomy

Indications

This procedure is performed most commonly during the management of a dystocia, when the vulva has not fully dilated or there is a fetal-maternal size disproportion, and typically in heifers. Although an episiotomy helps to facilitate fetal passage during an assisted delivery, it is also performed to prevent tearing. Surgical closure is more effectively performed following an incision than with tearing, and undue trauma is avoided.

Surgical Technique

Typically the calf's head is well into the vagina and is stretching the vulva when a decision is made to perform an episiotomy. Because the vulva is stretched so tightly even if epidural anesthesia has not already been employed, local anesthesia is rarely administered prior to the incision. Utilizing a scalpel, an 8- to 10-cm incision is made at the 10:00 or 2:00 position of the vulva, with the goal being to avoid the tearing of the vulva and perineum toward the rectum.

Following the delivery of the calf, the incision can be closed with a suture and pattern of your preference. Absorbable suture with a deep vertical mattress pattern is recommended. Absorbable suture eliminates the need for removal, although re-examination prior to breeding is recommended and the vertical mattress provides good apposition of both the submucosal and cutaneous layers. A surprisingly modest defect is created when the incision is left to heal by second intention, but because of the possibility that it may predispose the patient to pneumovagina, this is not recommended.

Aftercare

Complications, although rare, can usually be prevented by the administration of an antibiotic alone or with nonsteroidal anti-inflammatory drugs.

Caslick's Procedure

Indications

This procedure is performed primarily to correct pneumovagina. It is also performed sometimes following a colpotomy (see surgery of the uterus or surgery of the ovaries) to reduce the likelihood of postsurgical complications from an iatrogenic pneumovagina or eventration. Additionally it can be utilized with very mild cases of vaginal prolapse.

Anesthesia and Restraint

This procedure is performed with the cow standing, ideally restrained in a chute utilizing epidural anesthesia or a local infusion of lidocaine in the vulvar lips in the areas to be incised.

Surgical Technique

Utilizing scissors, a thin strip of tissue is removed from the dorsal one third to one half of the mucocutaneous junction of each vulvar lip. This can be facilitated by the injection of the lidocaine described previously. The lips of the vulva are then sutured together with a suture and pattern of the surgeon's choice. Complications can result from overly aggressive closure, specifically causing a urine "backsplash" effect, but the procedure usually achieves its intended purpose.

Repair of Perineal Lacerations and Rectovaginal Tears

Indications

Perineal lacerations in cattle most frequently result from excessive traction or an attempt to deliver a fetus through a nondilated birth canal. Unlike the mare, spontaneous perineal lacerations are uncommon in cows. First-degree lacerations involve only the mucosa of the vulva or vestibule and heal in many cases without treatment. Deeper lacerations may be complicated by prolapse of perivaginal fat and by bacterial infection of the genital organs or the urinary bladder. Treatment with systemic and local antibiotics is indicated in cases of infection.

Second-degree lacerations are deeper than first-degree lacerations and involve the entire wall of the vestibule and rectum and a portion of the perineal body but do not compromise the rectum or anus. The tissues are usually devitalized and contaminated by bacteria; thus, a period of 6 to 8 weeks should be allowed for healing before surgical closure of the defect. If second-degree lacerations are not corrected, incompetence of the vestibular sphincter allows aspiration of air and feces into the vaginal canal, which commonly leads to infertility.

Third-degree lacerations involve the vagina and the rectum as well as the perineal body and the anal sphincter and leave the patient with a common opening for the digestive and reproductive tracts. This is also termed as a rectovaginal tear. Considerable tissue damage and bacterial contamination accompany this injury, and most surgeons recommend that 6 to 8 weeks be allowed before attempting to correct the damage. Fecal contamination of the vagina, the cervix, and the uterus frequently, but not always, results in infertility until the defect is repaired.

Anesthesia and Restraint

Perineal lacerations can be repaired with the patient restrained in a stanchion or squeeze chute under epidural anesthesia in most cases. Light sedation may be needed in some cases to minimize movement by the patient.

Surgical Technique

Second-degree lacerations can be repaired by débriding the margins of the wound and bringing the dorsal portion of the vulvar labia into apposition with nonabsorbable suture material.

Several operative techniques have been described for surgical repair of third-degree perineal lacerations. The objective common to all procedures is to rebuild the shelf

of tissue between the rectum and the vestibule and restore the integrity of the perineal body.

In contrast to mares, the feces of cows are soft, and most surgeons do not withhold feed and water prior to surgery. After the rectum is manually emptied of feces, the tail is tied away from the surgical field and the area prepared for aseptic surgery. A tampon made of a 4-inch stockinette filled with cotton can be placed deep in the rectum and tied to the tail with umbilical tape to assist in control of fecal soiling of the surgical site. Exposure of the surgical area can be achieved by placing retraction sutures on both sides of the anal sphincter and in both vulvar lips. Tension can be exerted on the sutures by assistants, or the sutures can be anchored to the skin.

A technique originally developed in mares has been modified and successfully used to repair third-degree perineal lacerations in cows. A horizontal incision is initiated along the junction between the rectal and vestibular mucosa from the dorsal commissure of the vulva to the shelf that lies between the intact rectum and the vestibule. The rectal and vestibular tissues are separated and the incision continued caudally at the same level to the dorsal vulvar commissure on the opposite side. Flaps of tissue, which will be used to separate the rectum and vestibule, are then formed by dissecting the vestibular mucosa on both sides ventrally for a distance of 3 cm. At the cranial limit of the laceration, the rectum and vestibule are separated for a distance of 4 to 6 cm.

Closure of the laceration is begun by the placement of two or three Lembert sutures of number 3 absorbable suture material transversely in the vestibular submucosa in the area of separation between the vestibule and rectum. Modified Lembert sutures are then placed at 1-cm intervals to appose and invert the vestibular flaps. The needle is first introduced into the perivestibular tissue, then into the vestibular submucosa in the dissected flap. The suture is then carried across the laceration and reintroduced into the vestibular submucosa of the opposite flap and finally continued into the perivestibular tissue on the opposite side and tied. The suture line is continued until the defect is closed to the level of the dorsal commissure of the vulva. The rectal mucosa is avoided in placement of the modified Lembert sutures. Concurrently, a continuous horizontal mattress suture is used to appose and seal the vestibular mucosa. Two or three modified Lembert sutures are placed, followed by two or three bites of the horizontal mattress suture until the shelf between the rectum and vestibule is re-established. The perineal body and dorsal portion of the vulvar labia are then débrided and apposed with interrupted sutures to restore their integrity and prevent aspiration of air and contaminants into the reproductive tract.

Aftercare

Procaine penicillin G (22,000 IU/kg, IM or SC, every 12 hours) is administered for 4 to 5 days after surgery. NSAIDs can be used for a short time after surgery to minimize dyschezia. A gentle digital examination of the vaginal side of the surgical site can be performed to assess healing after 2 weeks. Palpation per rectum should be avoided for at least 30 days. Uterine infections secondary to fecal contamination should be treated as indicated. Natural mating should not be permitted for at least 6 weeks after surgery or, because manipulation of the rectum is required, artificial insemination for at least 8 weeks.

The prognosis for successful repair and restoration of reproductive function is good, but rectovestibular fistulae may form in some cases. Less commonly, wound dehiscence results in partial or complete failure of the closure. Small rectovestibular fistulae may not result in infertility in all cases. Perineal lacerations do not commonly recur at the subsequent calving.

SURGERY OF THE VAGINA AND CERVIX

Urethral Extension

Indications

Urovagina or urine pooling is encountered less commonly in cows than in mares and is frequently a sequela to obstetric trauma. The cervix falls below the pelvic floor, which allows urine to flow forward and pool in the cranial vagina rather than flow caudally through the vulvar cleft. Infertility due to the spermicidal action of urine and chronic endometritis may follow. A procedure for creating an extension of the urethra in mares has been modified and adapted for use in cows.

Anesthesia and Restraint

Extension of the urethra is performed in standing animals under epidural anesthesia.

Surgical Technique

After preparation of the perineum and vagina for aseptic surgery, a Foley catheter is passed through the urethra into the urinary bladder and the bulb inflated. The vulvar labia are retracted and separated by tension on a stay suture on each side. The vaginal mucosa is then incised in an elongated U, with the apex 1 cm cranial to the urethral orifice and continued caudally along the floor of the vagina to terminate approximately 2 cm cranial to the vulvar labia. The edges of the incision are then undermined to create two flaps, which can be apposed without tension. The ventral flaps are apposed over the Foley catheter to create a shelf using 2-0 absorbable material in a continuous Lembert pattern. Some surgeons appose the submucosa with a simple continuous suture pattern of the same material, while others omit this layer. The dorsal flaps are apposed and everted into the vaginal lumen with a continuous horizontal mattress suture. The tube created to extend the urethra should be of sufficient size to allow unobstructed flow of urine. The catheter can be left in place for several days postoperatively if the patient experiences difficulty urinating, but this increases the likelihood of an ascending urinary tract infection. Fistulae are most likely to form at the cranial aspect of the newly created tube and result in continued backflow of urine; therefore, care must be taken to ensure adequate closure.

Aftercare

The patient should be observed frequently for ability to urinate normally for several days following surgery.

Endometritis secondary to urine pooling should be treated appropriately.

Replacement and Retention of the Vaginal/Cervical Prolapse

Numerous techniques have been described for both temporary and permanent repair of vaginal/cervical prolapse. This illustrates the fact that there is no "perfect procedure." Instead we have several techniques that have advantages over the others for the specific prolapse presented. Most practitioners select a technique that they feel most comfortable with and employ it the vast majority of the time but should become proficient with at least one other technique that can be employed when dictated by the case presentation.

Indications by Case Presentation

Because this is a heritable condition, repair is considered with the goal being to maximize the salvage opportunity for the client; a single exception will be discussed later. Because economics plays a role, the easiest and least costly repair is usually employed. Other considerations are severity, pregnancy status, management ability of the client, chronicity of the condition, and tissue damage from previous attempts at repair. The Bühner technique is the most commonly used procedure because it can be easily and quickly performed and because of its retention strength. A disadvantage is that when used for the cow that is pregnant the suture must be removed prior to calving.[4] Because the Bühner technique is basically a purse-string type suture, it can impair circulation and induce edema, which in turn may result in cellulitis and infection. This is often problematic in cows with *Bos indicus* genetics because they tend to have larger, more pendulous vulvas. Vulvar "prolapse pins" can be used to avoid this inflammation, but as with the Bühner method, if the cow is pregnant they must be removed prior to calving. The Minchev procedure or a modification that employs the "Johnson Button" is indicated when the cow is pregnant and management does not allow for close observation or in the case in which a Bühner suture has or might cause cellulitis and infection of the vulva. Finally in the case in which permanent retention is desired, the Winkler technique, in which the cervix is sutured to the prepubic tendon, can be employed.

Anesthesia and Restraint

Regardless of which procedure is utilized for retention of the vagina (+/– cervix and bladder) proper restraint is important. Sedation may be indicated for the extremely fractious cow. Epidural anesthesia is always indicated and a pudendal block may be helpful when the bladder is also prolapsed. Following the epidural, confirm the suspected pregnancy status of the cow by rectal palpation. Then tie the tail out of the way and clean the perineal area and the prolapsed tissues with a surgical scrub. If the bladder has been prolapsed, it is better to evacuate it by catheterization or draining via a 14-gauge (or smaller) needle. Following replacement of the prolapse it may be necessary to "re-prep" the area prior to performing your chosen retention procedure.

Bühner Technique

Surgical Technique

Stab incisions are made 1 to 3 cm dorsal and ventral to the vulva to facilitate entry and passage of a specially designed needle (Bühner needle). The needle is introduced into the ventral incision and forced dorsolaterally to the vulva and at a depth that will provide strength, until it comes out the dorsal incision. At that time the needle is "threaded" with umbilical tape and the needle is drawn back ventrally to pull the tape through. The procedure is repeated on the other side of the vulva. The suture tape is then tied at the area of the ventral incision. Although most texts describe the use of either a square or surgeon's knot, an alternative is to place a slip or bow. This allows the owner to "untie" the suture tape, check the cow to see if she is in labor and then retighten and retie it if the examination was precipitated by a "false alarm."

Prolapse Pins

Surgical Technique

These are small pins (about the diameter of a 20 penny nail and 10 cm long) with wooden pegs on the ends. These are placed transversely through and across the vulva. Typically 3, but sometimes 2 pins will provide adequate retention. Advantages are that it is external, does not cause the swelling that a Bühner will, and provides good retention. The disadvantages are that the pins must be removed prior to calving and that one must keep a supply of the pins as well as a specialized needle that facilitates passage of the pins on hand.

Minchev Procedure

Surgical Technique

This procedure provides for retention of the vagina and cervix by fixing the cranial vagina with a suture out to the external gluteal region. A modification utilizes a prolapse pin that is marketed by Jorgensen Laboratories under the name Jorvet Prolapse Kit and by Kane Enterprises as the Pro-Fix Button. Either technique can be used in the pregnant cow and allow calving without removal. After replacing the vagina or cervix, introduce the prolapse needle (this is a sharpened metal pin housed inside a rigid plastic fixture) vaginally to a point in the cranial vagina close to the cervix. This is important because pins or sutures placed midway in the vagina will allow a "partial" prolapse of the vagina, and with the straining that is stimulated by that, tearing and complete prolapse can follow. With an appreciation for the location of the rectum as well as the iliac artery and vein, place the needle through the vaginal wall and direct it out through the sacrosciatic ligament toward the skin over the gluteal area. These products have "buttons" that are fixed to the outer area and facilitate retention. The old Minchev procedure simply utilizes umbilical tape rather than a rigid pin. The tape is passed using a long needle and then fastened to the outside with a gauze stint. It is fixed on the inside vaginal wall with a button (a top from a syringe case can be used). Again, the

advantage to this procedure is that because it does not restrict the vagina, calving can proceed. Also, because adhesions often result, it sometimes provides a "permanent" repair.

Winkler Cervicopexy

Indication

Because the goal of this procedure is to provide permanent retention and the condition it corrects is known to be hereditable, case selection is important so that one avoids an actual or perceived ethical violation. The case presentation that can be determined to not be hereditable is the cow that has had multiple and continued superovulation treatments for embryo transfer. A history that reveals that none of the cows from the dam line or her heifer offspring have prolapsed offers reasonable proof that the condition was iatrogenic.

Surgical Technique

The Winkler cervicopexy in which the cervix is sutured down to the prepubic tendon provides permanent retention. Using a nonabsorbable (8 mm Braunamid) with a long S-shaped needle (13 cm long) that has been bent into a U-shape, take a transverse bite through the cervix. This can be most easily done with the cervix retracted (prolapsed cervix prior to replacement). Then after replacing the cervix pass the needle through the vagina ventrally 4 to 5 cm off the midline (placement of a urinary catheter is recommended to prevent its entrapment). Engaging the prepubic tendon, return the needle through the vagina and tie the suture ends. A modification of this procedure has been described that utilizes a second surgeon who from a lateral flank approach assists by placing and passing the needle through the prepubic tendon and back to the primary surgeon through the vagina. In the author's opinion the main difficulty in performing this procedure without assistance is not in engaging the prepubic tendon, but in the reintroduction through the vagina. If one attempts this without assistance and has trouble passing the needle back into the vagina, a colpotomy approach can be used. This will also help to better assure proper suture placement with respect to the urethra and bladder. This incision must be closed, however, as evisceration would be a possible (likely) complication due to the fact that most prolapsed cows continue to strain following prolapse repair.

Cervical Injury Repair

Indications

Cervical lacerations are frequently the result of excessive traction applied to relieve dystocia. Infertility due to incomplete closure of the cervix and subsequent bacterial contamination of the uterine cavity may follow. Lacerations that involve no more than one third of the circumference of the cervix are amenable to surgical correction.

Anesthesia and Restraint

Cervical lacerations can be repaired in standing patients under epidural anesthesia.

Operative Procedure

Surgery is delayed for 6 to 8 weeks after the inciting injury to allow swelling and inflammation to subside. The perineal area is prepared for aseptic surgery and a tampon is placed in the rectum to control fecal contamination during surgery. The cervix is retracted caudally by use of a cervical forceps or traction sutures. The edges of the defect are débrided by careful dissection and granulation tissue removed. After devitalized tissue has been removed, the cervical defect is closed in three layers. The cervical mucosa is everted into the cervical lumen using a continuous horizontal mattress pattern. The muscularis is apposed with a simple continuous pattern and the vaginal mucosa is everted into the vaginal lumen with a second layer of continuous horizontal mattress sutures.

Aftercare

Infusion of a lanolin-based antibacterial ointment into the cervical lumen for several days may reduce the formation of postoperative adhesions.

SURGERY OF THE UTERUS

Cesarean Section

Indications

Cesarean section is typically utilized when there is a dystocia caused by a fetopelvic disproportion or extreme malposture and the calf is alive. Some veterinarians choose to perform a cesarean section rather than perform a complete fetotomy, so dead calves and fetal monsters can be added as optional indications. Additionally uterine torsion, malformation of the maternal pelvis, incomplete cervical dilatation, stricture of the birth canal, and uterine rupture can often be best managed by cesarean delivery. Also if the cow has a history of dystocia or the calf is valuable, an appointment cesarean section can be scheduled a few days before term.

Anesthesia and Restraint

Cesarean section can be performed with the dam standing or in dorsal or lateral recumbency; the choice depends on the demeanor of the patient, the condition of the fetus, the facilities available, and the surgeon's preference. In general and in most cases a left flank approach with the patient restrained in a squeeze chute is the best choice.

Caudal epidural anesthesia is often used in conjunction with other forms of anesthesia and sedation for standing flank approaches. Alternatively, a high epidural can be utilized when the cow is to be placed in dorsal recumbency for a ventral midline approach. Remember that following the high epidural the cow will be ataxic following the surgery for a period of time (see earlier discussion under Anesthetic Considerations).

Paravertebral, inverted-L, and line block anesthesia are all useful to desensitize the paralumbar fossa for the flank approach in the standing patient (see Anesthetic Considerations).

Choices for sedation include acepromazine (0.044 mg/kg), xylazine 0.02 mg/kg), butorphanol (0.05 mg/kg), and combinations of these drugs. Low doses that provide

relief from anxiety, rather than deep sedation, which may encourage recumbency, are obviously preferred.

Surgical Technique

Many surgical approaches have been described for performing cesarean section in cattle. The two most commonly employed are the left flank approach, which can be performed with the patient standing or in right lateral recumbency, and the ventral midline approach.

Left flank approach. After the skin surrounding the incision site has been prepared for aseptic surgery, an incision is begun 10 to 15 cm ventral to the transverse processes of the lumbar vertebrae midway between the last rib and the tuber coxae and extended sufficiently to allow extraction of the fetus. After incising the abdominal muscles, the peritoneum is identified and incised. Opening of the abdominal cavity is usually accompanied by the sound of air entering the potential space. The rumen is displaced cranially to allow access to the other abdominal organs and can be used to advantage to block escape of the intestines through the incision. A left oblique celiotomy approach for cesarean section in standing cows has been described. The incision in the abdominal wall is begun 8 to 10 cm cranial and 8 to 10 cm ventral to the cranial aspect of the tuber coxae and is extended cranioventrally at a 45-degree angle to end 3 cm caudal to the last rib. This surgical approach permits easier access to the gravid uterus than the more traditional vertical incision in the paralumbar fossa.

One of the fetal limbs (hind limb in the case of cranial presentation of the fetus) is identified and used as a handle to deliver the uterus to the abdominal incision. It is best to exteriorize the part of the uterus that encases the distal limb, "hooking" the hock outside the incision. This will allow an incision extending from the hock down to and over the foot, which is generally sufficient to deliver the calf without tearing. When the incision is not long enough, delivery of the calf results in uncontrolled tears that complicate closure. Exteriorization of a portion of the uterus may be difficult in cases of large fetuses or uterine torsion and the practitioner may be forced to make the uterine incision intra-abdominally. Contamination of the abdomen with uterine fluids is virtually impossible to prevent if the uterus is not completely exteriorized and may occur even if it is. This is usually of little consequence when the calf is fresh (alive or recent death), but if a calf is decomposing, a potentially fatal peritonitis may result. Additionally, intra-abdominal exposure to the commonly used obstetric lubricant, J-Lube has been shown to be fatal in cattle, horses, and mice.[5] Therefore, it is recommended that because contamination of the abdomen with uterine contents is so hard to avoid during cesarean sections, that J-Lube should not be used during obstetric procedures that might ultimately result in a cesarean section. Conversely, carboxymethylcellulose, another commonly used obstetric lubricant, has been shown to be safe and to actually decrease adhesion formation.[6]

After the uterus has been incised, the fetal limbs are identified and obstetric chains are attached to facilitate delivery. The uterus is then closed with absorbable suture material. Recommended patterns are the Cushing or a modified Cushing pattern known as the Utrecht uterine suture. A single layer is sufficient if the uterine wall is healthy. Two layers can be placed if the uterine wall is friable or if leakage of uterine contents is a potential problem. Care is taken to avoid inclusion of the placenta in the suture line. Should the placenta complicate closure of the wound, it can be trimmed away from the incised edges. Do not remove the placenta unless it detaches easily.

After the uterine incision has been closed, the uterus and abdominal cavity are lavaged with large volumes of saline (with or without heparin and antibiotics) to remove or dilute clotted blood and debris. Irrigation of the uterus and the abdominal cavity with 3% glycerol in saline or a 1% solution of carboxymethylcellulose in water has been used to reduce abdominal adhesions following surgery. Administration of oxytocin into the wall of the uterus (20 units) or intravenously (100 units) after the uterine incision has been closed will hasten uterine involution and expulsion of the placenta.

Routine closure of the peritoneum and muscle layers in a continuous pattern with an absorbable suture and apposition of the skin with a nonabsorbable suture material in a pattern of the surgeon's choice completes the procedure.

Ventral midline approach. Patients can be positioned in dorsal recumbency with the head and limbs secured to maintain the patient in position. After suitable anesthesia has been applied, the skin is prepared for aseptic surgery. The incision is initiated at the level of the umbilicus and extended caudally to the cranial border of the mammary gland. An approach through the ventral body wall has the advantage of providing excellent exposure of the uterus. Exteriorization of the uterus is facilitated, and contamination of the abdominal cavity with septic uterine contents is reduced. Surgeons may find it easier to extract the fetus from dams in dorsal recumbency. Respiratory function of cattle is compromised while in dorsal recumbency; thus, surgery should be completed with dispatch. An additional disadvantage of positioning the patient in dorsal recumbency is that the surgeon is forced to perform the procedure while in an uncomfortable position.

Incisions in the ventral body wall are more likely than those in the paralumbar fossa to be complicated by postoperative hernias. Strict attention to the fundamental principles of surgery is indicated to prevent or reduce the incidence of postoperative eventration.

Hysterotomy via Colpotomy

Indication

The primary indication for this procedure is the removal of a mummified fetus from a cow that was unresponsive to medical therapy. A mummified fetus is rarely encountered and often the cow is culled. First, differentiate this from the macerated fetus, which has a poorer prognosis. If treatment is elected, first try prostaglandins. If this is not effective, try priming the cervix with estrogen followed in a few days with serial prostaglandin injections. In cases in which there is no response to these treatments a surgical remedy may be effective. Although it is possi-

ble that some of these could be removed via a hysterotomy utilizing a flank or midline approach, most "mummies" are so small that it is hard to get good exposure. A hysterotomy via a colpotomy approach can be performed[7] easier and in less time.

Anesthesia and Restraint

The cow is restrained in a chute. If possible, fast the cow, removing feed for 24 hours and water overnight. Sedation or tranquilization is dependent on the patient's personality. Administer an epidural and evacuate the rectum as effectively as possible. Then place a length of 3-inch stockinette packed with cotton within the rectum.

Surgical Technique

Clean the vulva and prepare the vagina by lavaging with a dilute disinfectant. Using dampened cotton pledgets dry or at least remove water from the vaginal vault. Creating a pneumovagina by introducing or allowing air in will facilitate the procedure. With a blade carefully guarded between finger and thumb, introduce the hand into the vagina and at a location in the anterior vagina that is dorsolateral (at 10 o'clock) to the cervix make a small stab incision. Then remove the hand and re-enter the vagina without the blade. Enlarge the incision bluntly first with the fingers and then hand until the hand can be introduced into the abdomen. At this time the surgeon can easily palpate the uterus and when the horn with the mummy is located can grasp and retract it out through the rent created in the vagina. Once it is exposed make an incision into the uterus, extract the mummy, and suture the uterus with a continuous suture pattern as for a cesarean section hysterotomy. Replace the uterus. Although suturing the vagina is considered optional and the author does not attempt to close colpotomy incisions on mares, the author does close it in cows. This can be done with a continuous pattern (the suture technique described later for uterine tears can be utilized). Fertility should be the same as in those that respond to prostaglandins.

Management of the Uterine Prolapse

Treatment of this condition begins with phone consultation when the client calls. Instruct the client to restrain the cow, as movement risks injury. If the cow is down, instruct the client to tie the cow in a way as to keep it from getting up. Then the client can either soak the prolapsed uterus in cold, salty water or wrap the prolapse with a towel that has been soaked in cold, salty water. Covering the prolapse with sugar has been recommended for its osmotic effect on the edematous uterus, but the grainy sugar crystals have the negative effect of irritating the endometrium as the uterus is being manipulated to replace it. However, it can obviously be utilized and then rinsed off after the desired effect has occurred.

Procedure

If the cow is down, place her in dorsal recumbency with her hind limbs pulled back so that she is resting, tilted forward, stifle down, and hocks up. Regardless of whether or not she is down or standing, a towel or preferably a coated mesh tray (small animal cage floor rack) can be placed under the prolapse by assistants and then raised to help you as you attempt to replace the uterus. Rinse the prolapse with a cold, hypertonic saline mixture with dilute povidone to remove dirt, hay, and other debris. This should not be excessive and in fact it is probably better to not remove placenta that is attached. Begin efforts at replacement by gently pushing the tissue closest to the vulva back in while supporting the body of the uterus at a level dorsal to the vulva. The uterus could be placed inside a garbage bag if attempts at replacement seem like they may take more than 8 to 10 minutes, as this will decrease damage to the caruncles and endometrial lining. When the uterus is replaced, fill the uterus with as much warm saline (dilute povidone) as possible to facilitate a complete straightening out of the uterine horns. Then siphon off the fluid to decrease the chance of uterine rupture. Although wine bottles, Frick speculums, and batons have all been used to accomplish this, the lavage is safer. This along with getting the cow standing is crucial, as any invagination of the tips of the uterus can result in re-prolapse or an ischemic necrosis of the uterine tip. Oxytocin (20–40 IU IM) can be administered if there is complete confidence that the uterus is in normal anatomic position. The placement of retention sutures or other retention devices is controversial as they are not necessary if replacement is complete and uterine contraction is occurring and can cause a serious complication when there is uterine invagination and attempted re-prolapse. If retention devices are in place, the uterus will not completely prolapse, but will fill the vagina within the pelvis, resulting in uterine necrosis. If retention devices are placed, and they may be indicated in the recumbent cow with an atonic uterus, then the cow must be monitored closely. Uterine boluses should not be used and uterine lavage is preferable to antibiotic infusion in the contaminated uterus. Also remember that many of these cows are also hypocalcemic, so oral or intravenous calcium may be indicated.

Uterine Tearing or Rupture

Most injures to the uterus are iatrogenic and occur during efforts to relieve dystocia. With few exceptions they occur on the dorsal aspect of the uterus (cranial to the cervix) when the obstetrician is attempting to repel a breech presentation or during the forced extraction of a large fetus. In the case of the first situation repair is secondary to removal of the calf, and so a flank cesarean section is performed, and after the calf is delivered, the uterine defect may be approached and repaired through the flank incision. In the second scenario there are several treatment options.

The etiology for each tear is different. In the case of the tear caused by "excessive" force during mutation of the calf, the uterine wall was probably already weakened by some level of pressure (ischemic) necrosis. In the second situation, a large calf, a "dry" birth canal, and forced extraction combine to create an overfolding and subsequent shearing of the uterine wall. These tears are usually 5 to 30 cm in length, although some seem almost circumferential.

Regardless of the etiology of the tear, repair may not be necessary if it is small and dorsal. Because of rapid uterine involution tears smaller than the width of a hand will usually not need repair. Treatment for these can be limited to repeated oxytocin injections for the first 24 to 48 hours and 7 to 10 days of antibiotics. If the tear is larger and must be closed, the uterus can be prolapsed to facilitate closure or repaired with a "blind" suture technique. To prolapse a uterus, administer 10 ml of epinephrine in 250 ml of saline while tugging on a uterine caruncle. It is important to monitor the heart while this is done. After the uterus is prolapsed the tear can be closed with an absorbable suture of the surgeon's preference and the uterus is replaced. An alternative is a one-handed blind suture closure.[8] Thread an atraumatic needle (size and shape is determined by preference) with a 150-cm length of No. 2 or 3 catgut. With the needle at the halfway point of the suture (doubled) make a knot at the end (knot 1) and about 25 cm from the end (knot 2). Next introduce the needle into the vagina guarding the point with the fingers until reaching the tear. At one end of the tear begin closure. After going through the uterine wall (about 1 cm lateral to the tear) run the needle between the doubled suture and cinch at knot 2. (The only purpose of knot 1 is to keep the two loose ends together.) Then close the tear with a continuous pattern until the last bite is made 1 cm lateral to the end. It is important to pull the suture tight with each throw. Then reverse and continue the closure back to the original site and tie to the tail. Uterine involution serves to cover small appositional problems. Recommended treatment following either closure includes antibiotics and oxytocin.

SURGERY OF THE OVARIES

Ovariectomy

Indications

This procedure is performed on heifers destined for grazing or feeding to suppress estrus, prevent pregnancy, and induce abortion. It has also been utilized in brucellosis control programs. A unilateral ovariectomy may be indicated to remove an ovary affected by neoplasia or surrounded by adhesions. Also removal of the ovaries prior to the death of a valuable animal and shipment to a facility that can harvest ova for in vitro maturation and fertilization is an increasing possibility.[9]

Anesthesia and Restraint

An ovariectomy is usually performed with the animal standing in stocks or a squeeze chute after feed has been withheld for 24 hours. If the ovaries are to be removed via colpotomy, an epidural is useful; if an incision in the paralumbar fossa is to be used, an inverted-L or paravertebral anesthesia can be used (see Anesthetic Considerations).

Colpotomy

Two techniques for removal of the ovaries using an incision in the cranial vaginal wall have been utilized. In patients of sufficient size, the operator's hand and arm encased in a lubricated sterile sleeve are introduced into the vagina. A scalpel handle is held in the palm, the blade guarded by the index and middle fingers and used to make a stab incision through the vaginal wall near the cervix at the 10 or 2 o'clock position. The scalpel is removed and the operator's fingers are used to bluntly enlarge the incision sufficiently to permit the hand to enter the abdominal cavity. Care should be taken to make the incision completely through the vaginal wall; if the peritoneum is not incised, it will stretch away from the operator's hand and make entry into the abdominal cavity difficult. An instrument designed to cut cloth has been found to be a useful and safe alternative to a scalpel. The blade can be guarded until the incision site has been reached and then the guard retracted. The ovaries are located in succession and withdrawn into the vaginal canal where the ovarian attachments can be severed with a spaying shears or with an écraseur and the ovary removed. The blood supply to an ovary containing a corpus luteum is substantial and hemostasis is essential. The vaginal incision is usually left to heal by second intention.

Specialized instruments have been designed for spaying heifers that are used to enter the abdominal cavity through a puncture in the vaginal wall and are manipulated by the operator's hand and arm inserted in the patient's rectum. The K-R spay instrument is a tubular device with a trocar point used to puncture the vaginal wall and enter the abdominal cavity. The ovaries are located by manipulation per rectum and placed one at a time into the instrument's cutting chamber and severed from their attachment by rotating the inner tube. Care must be taken to avoid accidental incision of the intestine. After both ovaries have been excised, the instrument is withdrawn and the ovaries removed from the chamber and discarded.

The Willis spay instrument is a stainless steel rod 48 cm long. One end is bent to form a handle while the other is flattened and has a teardrop-shaped eye with a sharpened apex used to sever the ovarian attachment. The instrument is introduced into the vagina and the vaginal wall punctured. By rectal manipulation, an ovary is placed through the eye of the instrument and the attachment severed by withdrawing the instrument with steady pressure. After the ovarian pedicle has been cut, the ovaries are allowed to drop into the abdominal cavity.

Both the K-R and Willis spay instruments are most applicable to use in prepubertal animals because enlargement of the ovary caused by the presence of a corpus luteum makes the procedure more difficult. Death following use of spay instruments has been attributed to hemorrhage and to peritonitis resulting from intestinal damage.

Celiotomy

Unilateral or bilateral ovariectomy can be performed using an incision in the paralumbar fossa. Although access can be gained from either side, the left flank is usually chosen, as the rumen reduces the possibility of prolapse of the small intestine through the incision. An

incision through the abdominal wall is centered in the paralumbar fossa halfway between the last rib and the tuber coxae. The operator's hand and arm are introduced into the abdominal cavity and the ovary is located by palpation. If a bilateral ovariectomy is to be performed, the far ovary is usually removed first and the near ovary last. Hemostasis is crucial, especially if an ovarian neoplasm or ovary containing a corpus luteum is to be removed and can be accomplished by crushing the ovarian pedicle with an écraseur or by applying an umbilical cord clamp. Ligatures can be used but are difficult to apply securely because the length of the mesovarium usually does not permit the ovary to be exteriorized through an incision in the paralumbar fossa. After the ovarian pedicle has been ligated or clamped, the ovary is excised with surgical scissors. The abdominal incision is closed using the suture material and pattern of the surgeon's choice.

Aftercare

The degree of aftercare following ovariectomy varies with the type of patient. In the case of feedlot heifers, recommended aftercare ranges from observation only to administration of antibiotics parenterally or in feed for several days following surgery. Treatment for 5 to 7 days with an appropriate antibiotic usually is recommended following therapeutic unilateral ovariectomy in adult animals. Postoperative analgesics may be indicated in selected cases.

Sequelae to ovariectomy include excessive hemorrhage and peritonitis. In cases of unilateral ovariectomy, adhesions between the remaining reproductive organs and the surrounding tissue may interfere with future fertility. Methods that minimize hemorrhage and fibrous tissue formation should be chosen if the patient is to be used for breeding.

CHAPTER 61

Reproductive Health Programs for Dairy Herds: Analysis of Records for Assessment of Reproductive Performance

JOHN FETROW, STEVEN STEWART, STEVE EICKER, and PAUL RAPNICKI

RECORDS AND MONITORING

The effective use of records is a cornerstone of modern dairy production medicine. Records provide access to the performance results of a dairy's management and serve as a major source of diagnostic information when problems arise. As veterinary service to dairy farms has matured, practitioners have become more involved in herd-level analysis, management consulting, and problem solving. Monitoring is an essential component of any system that must respond to external influences (Fig. 61-1).[1–3] A parameter of the system is measured and compared with standards, goals, or past performance. If the parameter does not meet the goal, then plans are made and actions are taken (usually including collection of more diagnostic information). Because of both the action taken and the external influences on the system, a result is achieved. The result becomes the new status and the cycle begins again. Even though this activity is routine in most veterinary reproductive programs, in many cases it is not as fully developed or deliberately documented as might be most useful to the client.

Although the general scheme described is consistent across all types of monitoring, it is useful to distinguish between the following four general classes of monitoring.

1. **Surveillance.** Surveillance is a monitoring system designed to generate action at the first detection of a parameter. *Brucella* testing for reproductive disease control and public health is an example. The monitoring system (milk ring test or herd serology) is set such that a predetermined course of action will be taken if any indication of brucellosis is detected. These sort of monitoring systems typically play a minor role in day-to-day dairy farm management.
2. **Status monitoring.** This form of monitoring involves the measurement of a parameter and the comparison of its absolute value to a goal figure. Services per conception might be set at 3.0, with the intent that performance worse than that number will initiate further diagnostic effort or management changes. In outbreak investigation, this is the typical starting point for the veterinarian. Status monitoring simply asks, "Are things as they should be?"

   Although attempts have been made to arrive at a single "index" that will assess the performance of a dairy's reproductive program, none are adequate alone.[2] Evaluating reproduction involves a complex set of issues that are to some degree unique to the particular dairy. Attempts have been made to develop expert computerized systems to evaluate reproduction,[4] but none are in widespread use at the current time.
3. **Trend monitoring.** Typically more robust than status monitoring, tracking the trend in a parameter over time provides an added dimension of understanding to the analysis. Services per conception of 3.0 may be a problem in a herd that had been at 2.5, whereas it may be cause for celebration in a hot climate herd whose historical average has been nearer to 3.5. Trends allow for graphic display of the data and improve both client understanding and motivation.
4. **Exception monitoring.** Here, the trend of the herd as a whole is not the emphasis; instead attention is focused on displaying the individuals whose performance is substandard. In a sense, this is status monitoring within the herd, applied to individuals. Generally, this sort of detailed monitoring can be accomplished conveniently only with computerized record systems. Exception monitoring results are generally in the form of counts, graphic distributions, or action lists.

Viewed from another perspective, monitoring can be applied to two classes of information:

1. **Outcomes:** Traditionally, monitoring focused on measuring and evaluating the results of some system in operation on the dairy. Most of the measures used to monitor reproduction on dairies still fall into this class (e.g., days open, conceptions, pregnancies). These outcomes can be seen as the "objectives" of the system in operation, that is, its output. If the system is inadequate (in design or in operation or because

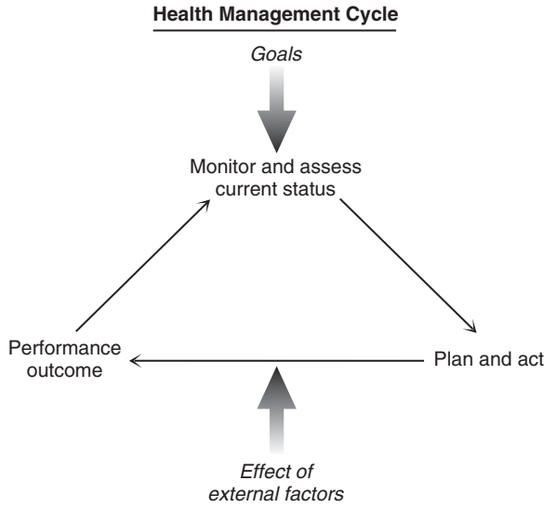

Fig. 61-1 Role of monitoring in farm management feedback cycle. (Adapted from Radostits O, Leslie K, Fetrow J: *Herd health: food animal production medicine,* 2nd ed. Philadelphia: WB Saunders, 1994.)

of unanticipated external influences), the objectives are not reached.

2. **Processes:** Monitoring can also be applied to systems in operation to discover whether the prescribed activities of the system are being done and being done properly. To be effective, this presupposes that a specific operating system is defined and the person(s) responsible are aware and properly trained. For example, in a dairy reproduction program based on estrus detection, are personnel actually taking the time to observe the breeding population of cows? Do they know what to watch for? Do they report observations to the right person in a timely manner? Are they accurate in their observations? Are enough cows bred within a specified period? The distinction between these two classes of monitoring sometimes is indistinct (e.g., are enough cows bred?), but the conceptual difference is valuable. Real beneficial changes on the dairy happen at the process level, and problems can often be most quickly detected as undesirable changes in processes. Economic impact largely happens at the outcome level. Process monitoring (oversight) is a major part of a manager's responsibilities and is key to assuring that the right things are done in the right way. Veterinary involvement in reproductive programs may include such process monitoring, either as a trouble-shooting activity or as part of the dairy's operating management. To be effective in the latter role, the veterinarian must be on the dairy on a consistent basis and sufficient time has to be committed to the task. Typically, such process monitoring by the veterinarian includes a training component.

As dairies become more rationalized and as science and process development advances, the connection between processes and outcomes becomes tighter and more predictable. As that development continues, more and more time and attention will be committed to process monitoring, with less focus on outcomes because they will follow more reliably (but not necessarily perfectly) from proper processes.

PITFALLS OF MONITORING PARAMETERS

The practitioner should be aware of several pitfalls in status and trend monitoring that can lead to inappropriate inaction (real problems escape notice) or inappropriate action (situations are misdiagnosed as problems and the wrong action is taken). Of the two, inappropriate inaction is probably the more common in reproductive production medicine and the more costly. The major pitfalls are as follows.

1. **Variation in methods of calculation:** There are many sources of reproductive indices and each has arrived at its own (often undocumented) approaches to calculating reproductive indices.[2] Recommendations regarding calculation have been put forth, but remain inconsistently implemented.[5] Furthermore, new approaches have become more appropriate since the last time a committee met to consider standardization. Care is necessary in interpreting numbers as presented, particularly when comparing results between various recording and summarizing programs.[2,5,6]
2. **The dangers of averages.** Reproductive herd records, and therefore reproductive herd monitoring, are rife with averages (means). Average days open, average services per conception, average annual culling rate as a percent of the herd (which is neither an average nor a rate)—these and others are used daily by veterinarians as they try to track the reproductive performance of their client herds. Averages measure one type of central tendency of a distribution of individual observations. Alone, they do not describe the spread of the distribution, nor do they call attention to failures of opportunities. Average days open, for example, can be the same in different herds, but with very different distributions. One herd can have a well-managed, tightly clustered distribution around the mean, while in another herd some cows might become pregnant very early while others are extremely delayed. Both herds might have the same average number of days open.

   Herd size can have a dramatic effect on the variation and computation of averages. In a 50-cow herd with 25 confirmed pregnant animals, a single cow with 350 days open increases the average days open of the currently pregnant cows by 10 days. If this cow is then sold, the average of the remaining 24 will drop by 10 days (example assumes average days open of 100 days). If the dairy farmer is unaware of this, false credit for a positive result may be given to an irrelevant intervention. Conversely, two animals conceiving

at 37 days would drop the average of the 27 pregnant animals by 5 days. At the other extreme of herd size, in very large herds with many cows contributing to the parameter, the average in any time period will tend to regress toward the long-term mean, obscuring problem cows that as individuals can be quite costly. Herd size effects cannot be avoided when averages are calculated; the practitioner must be aware of the possible pitfalls and use judgment when analyzing reproductive records.

3. **Percentages.** Percentages, like averages, can be misleading. In small herds or with small subsets of large herds (e.g., first-lactation animals bred by Joe Smith in June), one must be very careful not to overinterpret deviations from proportions used as standards. As an example, the 95% confidence interval (i.e., the true mean likely falls within this range) for services per conception when 13 pregnancies result from 40 breedings (a 33% conception rate) extends from 17% to 48%. One end of that range is a conception rate disaster, the other would be considered outstanding on modern commercial dairies. For many smaller Midwestern dairies, 40 breedings would take 6 months to accumulate, making tracking conception rates a problematic process. The practitioner must use judgment about when to intervene. Dairy managers are rarely willing to wait until something is statistically proved before they intervene. The burden of "proof" necessary to motivate management action can be quite different than the proof needed to establish scientific "truth." Not doing something when it is needed can be just as costly (or more so) than doing something unnecessary.
4. **Momentum.** Momentum in a parameter occurs whenever the events from the distant past are included in the current calculation of a parameter. For the parameter to change appreciably, given the weight added by events that are long past, then either the current status must change radically or significant time must pass. Either way, momentum tends to dampen change in a parameter, obscuring the actual status and recent trend. Both average days open and calving interval include a great deal of momentum.
5. **Lag.** Lag or delay occurs when the outcome of an event or intervention cannot be measured for some extended period of time. Lag is inherent, for example, in the calculation of conception rates, because conception (pregnancy) cannot be confirmed until at least several weeks after breeding. Lag becomes more severe when an inappropriate parameter is chosen to monitor a management program's results. An example might be the use of age at first calving to monitor the results of a prostaglandin synchronization program in heifers. The lag period is nearly a year before the effect of the program can be measured. A parameter such as the number (and identification) of heifers older than 13 months and not bred would have far less lag and thus would be more valuable as a monitoring tool for this prostaglandin program.
6. **Bias.** Bias can be introduced in many ways into the calculation of parameters that monitor status and trends on dairy farms. Bias exists when a systematic error is made in the selection of animals used in the calculation, the information used is incomplete or inaccurate, or the assumptions made about the biology are wrong. Bias distorts the parameter's true representation of reality. Some of the causes of such bias in reproductive parameters are as follows.
   - **Effect of culls and "do not breed" cows.** In many record systems, animals that have left the herd are not included in the calculation of some reproductive parameters. For example, the average days in milk at first breeding for the past 6 months should logically include any animal that was inseminated for the first time in the past 6 months, whether she is currently in the herd or is no longer present. Similarly, cows designated as "do not breed" cows may also be excluded. These animals are commonly those with the worst reproductive performance. Their exclusion from the data set would make the reported parameter better than reality in the herd.
   - **Presumption of reproductive outcome.** Reproductive calculations often may make optimistic assumptions about the outcome or status of some animals. These compromise-approaches to calculating parameters are legitimately necessary in some cases, but the practitioner needs to understand that the parameter may represent the best-case scenario. As an example, some record systems may assume that all cows that are bred and not checked for pregnancy are pregnant for the purpose of calculating average days open.
   - **Exclusion of subpopulations.** Some measures report on the performance of individuals with a positive (or otherwise known outcome), but ignore (or do not reflect) the current numbers of animals either pending status confirmation or past a management cutoff with no action. As an example, average days open in pregnant cows excludes cows from the calculation that are not yet confirmed pregnant. These may be the most important cows from a reproductive program perspective.
   - **Synchronization programs.** The routine use of prostaglandin or other hormone interventions for estrus induction, although often cost-effective management strategies, wreaks havoc with the calculation of many reproductive parameters. Apparent estrus detection rates are often calculated based on the assumption of 21-day estrous cycles. Inducing estrous cycles obviously makes this assumption false. Similarly, calculation of the interestrous interval and the expected pattern of estrous cyclicity are

severely confounded in herds in which estrus synchronization is used.
- **Use of bulls.** The calculated reproductive parameters can be severely distorted by the use of bull breeding, especially in herds in which the use of bulls is poorly recorded. For example, pregnancy to the bull may be calculated as resulting from an artificial insemination (AI) breeding, influencing the apparent services per conception rates.

Although the preceding list of pitfalls may seem long, it should not deter practitioners from working with records to analyze a herd's reproductive performance. Instead, knowing these pitfalls should lead to a healthy skepticism about the number presented, a determination to increase accuracy and completeness of the underlying data, and a fuller understanding of the conditions under which parameters may not truly represent herd status.

Inadequacies of the Calving Interval

The classic parameter for monitoring the status of a reproductive program has been calving interval. Although a short calving interval might be the *goal* of a reproductive program, it is totally inadequate as a *monitoring parameter.* Calving interval has severe momentum. It requires two consecutive calving dates, so on a herd calculation basis, events from as much as 2 years before still enter into the current calculation. Similarly, it suffers from severe lag, because the outcome from reproductive management efforts must wait through at least one entire gestation before the results can be calculated. Calving interval introduces bias by excluding populations (culled cows, first-lactation animals, animals pregnant but not yet calved, "do not breed" cows). Last, by being an average, calving interval has all of the computational pitfalls described for averages. Veterinarians, as a profession, must stop using calving interval as a monitoring parameter.

Terminology Issues

There are many terms used in describing reproductive programs, terms that have survived and become part of the everyday lexicon of dairying. Unfortunately, some of these terms are not consistent with standard meanings of words. Although it is likely that many terms will go on being used even though improper, it would serve the industry and profession if everyone could be a bit more precise in how words are used. Specifically, rate is a term often misapplied to reproductive parameters. A rate is formally a measure of an event or statistic *per time period*. Thus, miles per hour or deaths per 1000 cows per year are rates. Unfortunately, many parameters associated with reproduction are discussed as rates but in fact are not rates. For example, conception rate is not a rate (no dimension of time). Conception rate (pregnancies per insemination) is a risk (proportion of a population with some particular characteristic[7]). Older terms with widely accepted meanings are probably best left as is. New terms should be more carefully chosen.

GENERAL GOALS OF A REPRODUCTIVE PROGRAM

It has long been known that there is an important economic advantage to be gained by efficient reproduction in dairy herds.[8–12] The economic effects of a sound reproductive program include increased milk by returning cows sooner to the earlier, more profitable phase of their lactation, increased numbers of replacement heifers and bull calves born, reduced costs of reproductive disease and reduced costs from culling, reduced nonproductive days due to extended dry periods, and increased rate of genetic gain.

On a biologic basis, the goal of a reproductive health program on a commercial dairy can be summarized as follows: Throughout her herd life, a cow should calve without difficulty and deliver a live calf, experience little or no postpartum reproductive disease, begin to cycle soon after calving, be inseminated soon after the voluntary waiting period, conceive to a high genetics bull within an optimal time period (or conceive at the right age as a heifer), and carry each fetus to term. This is not to imply that the goal is elimination of all pathologic events; to do so would be biologically impossible and economically inefficient. Rather, the goal is to have a minimum of pathologic events and a maximum of productivity within the constraints of practical biologic and economic reality. This general goal can be subdivided into sections, as follows.

1. **Prompt rebreeding** (appropriate voluntary wait period). After calving, uterine involution should occur promptly and cows should be reproductively sound by 45 days in milk (DIM). Once past the farm's voluntary wait period (VWP; usually 45–60 days), cows should be seen or induced in estrus, be inseminated, and conceive in an efficient manner. If both estrus detection and conception rates are adequate, then only a small percentage of cows should have extended days open.
2. **Genetic return.** Genetic return on the investment in semen or bulls should be optimized. Some computer packages can calculate optimal bull profiles for selection for artificial insemination, given the farmer's goals for genetic gain and variability.[13] It is worth noting that the genetic return on the investment in semen occurs only if the insemination results in a live *female* calf that subsequently conceives, calves, and has a productive lactation. Genetic improvement on a dairy farm is a long-term and somewhat risky investment. Assuming a 40% conception rate, 44% of females not born co-twin to a bull, a 10% abortion rate after pregnancy diagnosis, and a 20% loss of replacements from parturition until the end of a productive first lactation (includes stillbirths), only 13% of inseminations actually return any appreciable value in genetic gain to the producer. This means it takes at least 7 straws of semen just to produce a first lactation animal. On many farms, they need to purchase

well over 10 straws to produce a complete first lactation.

3. **Pregnancy wastage.** Pregnancy wastage should be at a practical, economic minimum (early embryonic death, abortion, stillbirths). Recent adoption of pregnancy diagnostic tests that can detect conception at an earlier stage is changing how pregnancy wastage is defined and the proportion of lost "conceptions" that are expected.
4. **Disease.** Peripartum disease morbidity should be minimized, enhancing animal welfare, avoiding impacts on later reproductive performance, lessening loss of cows either by death or culling, and minimizing therapy and labor costs.

MONITORING STATUS AND HERD REPRODUCTIVE TRENDS

Many parameters are used to monitor reproductive status and trends on the dairy farm. Some of these goals are shown in Table 61-1. For the most part, these are the traditional monitoring parameters for dairy reproduction. These herd goal levels must be applied with caution and may not be the appropriate alerting levels for management intervention on an individual cow basis. Several reviews of these parameters and their application have been written, so what follows is only a brief outline of the major parameters.[5,14–20]

Overall Reproductive Efficiency

Herd Distribution of Cows by Reproductive Status

Perhaps the best starting place for evaluating a dairy's reproductive status is simply a breakdown of cows by reproductive status and lactation (see Table 61-1[21]). Cows are split into the following groups:

1. *"Do not breed" cows:* cows for which management has decided to stop inseminations
2. *Fresh cows:* typically cows less than the voluntary wait period; on some dairies those cows not yet confirmed to have completed their normal involution post partum
3. *Cows OK to breed and known to be open:* includes cows previously bred but determined to be open
4. Cows bred and awaiting pregnancy diagnosis
5. Pregnant cows still milking
6. Dry (nonlactating), pregnant cows
7. Animals that have exited the dairy in the time frame of interest (whether sold or died)

Note that the principal focus of a dairy's reproductive program should be on cows in preceding groups 2 and 3, that is, those that can either be seen in estrus or synchronized to come into estrus and be inseminated and those transition cows that need careful attention, with lesser focus on early postpartum cows for uterine pathology (part of group 2) and bred cows that need a pregnancy diagnosis (part of group 4). This breakdown of cows in the herd may help focus management attention on those cows that can be usefully affected by management action.

Pregnancy Risk (Pregnancy Rate)

Pregnancy risk is probably the single most telling parameter to evaluate the reproductive performance of a dairy (although pregnancy risk alone is not sufficient, as noted earlier). Pregnancy risk is the proportion of open cows that become pregnant during a specified period of time. It is the proportion of cows that make the transition from open to pregnant (as a percentage of eligible cows) over a 21-day period. Thus, it estimates the "risk" that an eligible open cow will become pregnant on the dairy in the next 21 days. The definition of pregnancy risk is the total number of cows that become pregnant during a period of time (typically 21 days) out of the total number of cows eligible to become pregnant during the same period.

To be eligible, each cow should meet the following criteria:

- The cow should be past the voluntary wait period at the beginning of the period.
- The cow is known to be open at the start of the period.

TABLE **61-1**

Breakdown of Cows in a Dairy Herd by Reproductive Status (RPRO)

COMMAND: SUM BY RPRO LCTGP FOR LACT>0 RC>0\B

RPRO	%COW	#COW	LCTGP=1	LCTGP=2	LCTGP=3
NO BRED	0	3	0	1	2
OK/OPEN	17	158	54	46	58
BRED	19	182	81	48	53
PREG	27	256	24	78	54
DRY	6	64	25	17	22
SLD/DIE	27	252	49	63	140
Total	96	915	233	253	329

NO BRED, do not breed cows; fresh, cows not ready to breed; OK/OPEN, cows available to breed; BRED, cows bred, not checked for pregnancy; PREG, pregnant, milking cows; DRY, pregnant, dry cows; SLD/DIE, sold or dead cows. LCTGP, lactation groups are first, second, and third or later lactations.

- The cow is not flagged as a "do not breed" cow in the period.
- The outcome of any insemination during the period is known—pregnant or open.
- Additionally, if both AI and bull pens are used on the dairy, the AI pregnancy risk should not include any animal that was not inseminated in the AI pen but was moved into the bull pen during the period.
- **Note:** for computational purposes, cows that meet these criteria for at least half of the 21-day interval are eligible.

Pregnancy risk has been estimated by multiplying estrus detection rate (or insemination risk) times the conception rate in a herd, but this estimate is fraught with potential errors. Estrus detection rate may not include cows not yet bred, estrus events may be detected but the cow not inseminated,, and estrus may be recorded more than once in a 21-day period. This may bias the estimate of estrus detection in terms of a cow's single chance of getting pregnant in a 21-day period. Conception rate calculations may only include pregnant cows, and again, cows can be bred more than once in a 21-day period. Finally, the time periods over which estrus and conception rates are calculated are often not the same. It is far better that pregnancy risk be calculated directly from cow level data, not computed from estrus and conception rate parameters.

Pregnancy risks may be calculated for a single cycle, but one must be careful not to extrapolate too freely from single cycle results to overall herd performance. Particularly for programs that synchronize estrus, the first cycle of a program may achieve relatively high pregnancy risks (essentially equal to conception rate as all cows are inseminated), but the following cycle may experience much lower pregnancy risks, as cows awaiting pregnancy examination are not detected as they return to estrus. In synchronization programs in which cows have different risks of pregnancy in alternating cycles, any calculation of pregnancy risk across an odd number of cycles will distort the herd's real reproductive performance. Similarly, one should be careful of only calculating pregnancy risk for a set number of days of lactation which may only include an odd number of cycles.

Pregnancy risks have the advantage that the only lag in their calculation is the period until pregnancy status can be determined after breeding. Because all eligible cows are included, bias is not introduced in the parameter. If the risk is calculated for each successive 21-day period, there is little momentum in each number and trends in the parameter can be observed (Table 61-2). Pregnancy risks vary widely across dairies, with typical average pregnancy risks of about 12% to 14% (Fig. 61-2[21]). If a dairy could reliably and accurately submit 60% of eligible cows for insemination at least once in a 21-day period and achieve 40% conception for animals submitted for insemination in this 21-day period, the pregnancy risk would be 24%. Clearly, there is a great deal of opportunity to improve overall reproductive performance on most dairies.

The data that were used in generating Figure 61-2 were mostly based on pregnancy confirmation by rectal palpation, typically at day 35 after breeding or later. These

are the numbers routinely used by dairy veterinarians and for which the profession has a sense for what is acceptable and what is not. The advent of earlier pregnancy diagnosis (e.g., ultrasound and possibly immunologic tests) will tend to shift expectations. Ultrasound at day 26 will detect pregnancies that may no longer be there at day 42 after insemination. If these earlier "pregnancies" are considered real, the computational result will be higher pregnancy risks, but also higher abortion risks, as some of those early embryos are lost. There is not a consensus within the industry yet about how to handle this issue. Perhaps agreement could be reached that would continue to refer to pregnancy losses after pregnancy confirmation at 45 days (or 60) of gestation as abortions, and losses earlier as embryonic deaths. However, most dairies cannot reliably identify when a cow actually aborted.

Number of Pregnancies per Time Period

A pragmatic, but not particularly diagnostic approach to monitoring reproductive function on a dairy is to simply monitor the number of confirmed pregnancies per period of time. The logic is approximately as follows: If a dairy intends to calve 120 animals per year (as an example), then on average it must achieve somewhat more than 10 pregnancies per month in cows and heifers (more than 10 to allow for some abortions and cow culling) in order to have enough calvings 9 months hence. Given the average conception rate, one can also use this approach to monitor the number of breedings needed each month as well. This approach may be crudely useful for a quick managerial scan of reproduction (very little lag, no momentum), but it cannot detect the sector of the reproductive program in which a breakdown may have occurred.

Days Open

Better described as the calving-to-conception interval, in the past this was the most widely used parameter to assess "overall" reproductive performance in a herd.[22] As calculated by many DHIA record programs, it tends to estimate the minimum projected days open, and in some cases is named just that. Calculated on an annual basis, days open has significant momentum and lag and is distorted by exclusions, culling, "do not breed" cows, and assumed outcomes. Different record systems deal with these issues in different ways.[22] Nonetheless, it is a readily available and understandable parameter and so remains in widespread use. In addition to the difficulties inherent in calculating average days open, depending too much on this single number may mask serious reproductive inefficiency from a wide distribution of individual cow performance. Suffice it to say, although some veterinarians will continue to use average days open as a historical assessment of reproductive efficiency, prudent practitioners will do so with care.

Calving Interval

Although maintaining a short calving interval is the conceptual goal of reproductive management, the parameter itself is fraught with problems. As noted earlier, calculating an actual calving interval requires that a cow has calved twice. The parameter has severe momentum and excludes first-lactation animals and culled cows. It is the weakest monitor of a herd's reproductive performance, and should not be used.

Survival Curves

Survival curves are the graphic presentation of the change in a population from one "state" to another over time,

for example, from being open to being pregnant or being not yet bred to bred for the first time. Ideally these curves could provide some information about the trajectory of transition, about what proportion of the population is pregnant or bred by a given time, and about what portion ultimately does not become pregnant or get bred. The slope of the survival curve is *not* the rate of conversion (the "risk") because the denominator population changes at the same time as the numerator changes. There are significant and troubling problems in the construction of these curves in all but deliberate prospective studies (e.g., in defining what the population at "risk" is for a survival curve, what to do with a cow bred 34 days ago but not declared pregnant, what to do with a cow that was pregnant, lost the fetus and is pregnant again). Survival curves are perhaps most useful when two different beginning populations are compared on the same curve. Differences in the experiences of the two populations are often rapidly apparent but may be confounded by differing time periods for the two populations, culling rates in early lactation, etc. (Fig. 61-3[21]). Although survival analysis is a valuable research evaluation tool, it is a problematic herd monitoring tool.

Breaking Days Open into Components

In a pivotal 1975 paper, Barr[23] laid out a conceptual framework for allocating the total days open to several components. That conceptual framework remains a cornerstone of the production medicine approach to addressing reproductive efficiency on dairy farms. As stated by Ferguson and Galligan, "most variations in herd performance result from pathology of management and not pathophysiology."[24,25] Barr's conceptual framework allows the practitioner to dissect the influences of management to localize the subsystem that is responsible for poor reproductive performance. Figure 61-4 provides a schema for this framework, as well as identifying typical problems by subsystem.

Barr's concept is that days open (in normal, fertile cows) comes from four sources:

1. Farm policy for the voluntary wait period (VWP).
2. One half of an estrous cycle past the VWP for the first estrus to occur. Some cows may be in estrus the day after the VWP and others 20 days after the VWP, but on average, it will take one half of a cycle. This is physiologically dictated, in the absence of synchronization programs.
3. Failure to detect estrus. Again, each missed estrus requires another 21 days of waiting (in the absence of synchronization programs).
4. Failure to conceive when bred. Each failure to conceive adds another 21-day estrous cycle to the tally of days open.

The effects of estrus detection and conception rate are not independent. For example, if it takes two services per conception and if every other estrus goes undetected,

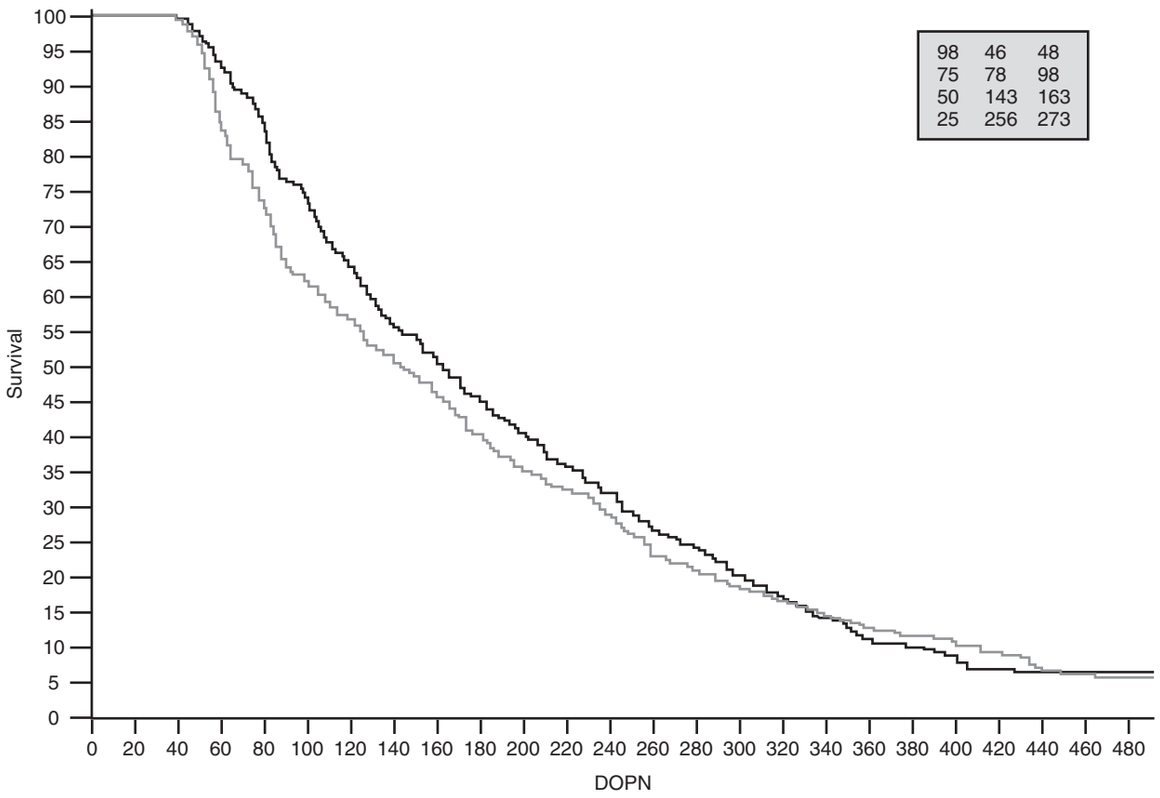

Fig. 61-3 Survival curve for days open for first lactation with second and older lactation.

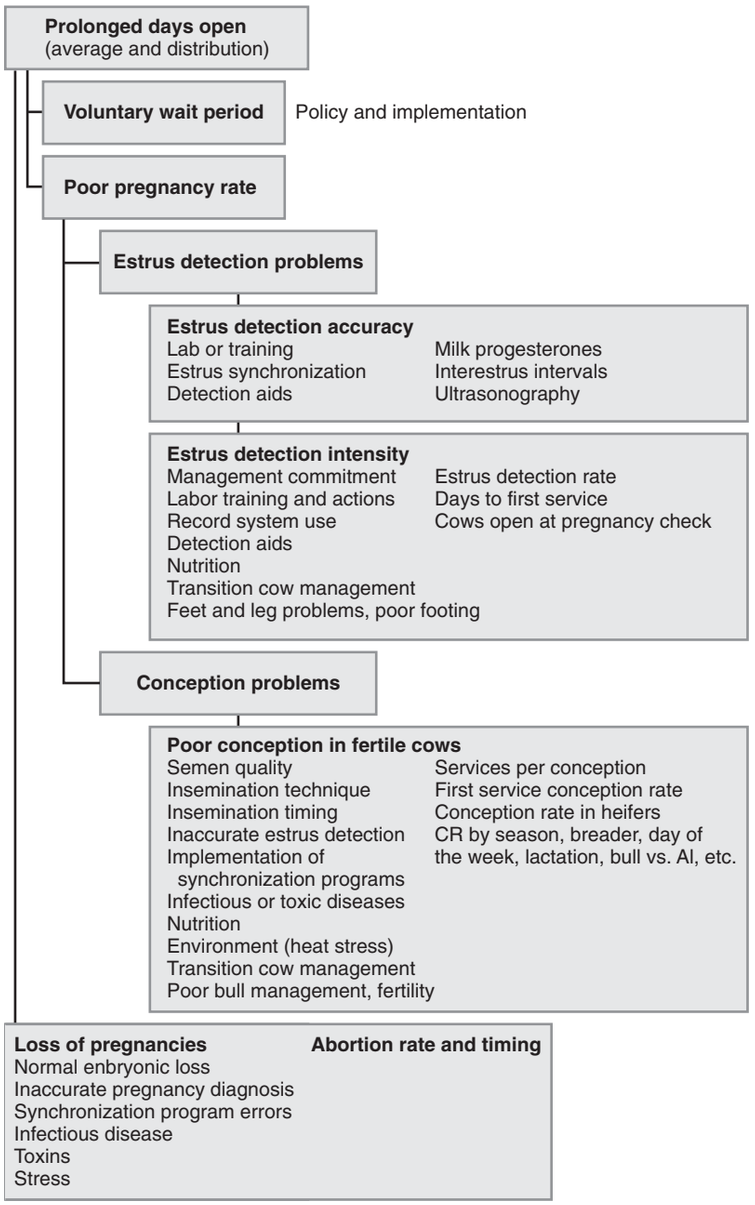

Fig. 61-4 Conceptual framework for evaluating dairy herd reproduction. (Adapted from Radostits D, Leslie K, Fetrow J, eds: *Herd Health: Food Animal Production Medicine*, ed 2, Philadelphia, WB Saunders, 1994.)

then it will take four estrous cycles to detect the two estruses that are needed to achieve two breedings and one pregnancy.

Consider the example of a herd with the following reproductive performance: 50-day VWP, 33% conception, 50% of estruses detected. (DIM = days in milk, or days since calving):

50 DIM: voluntary wait period
60 DIM: average cow has her first estrus in the breeding cycle, which goes undetected
81 DIM: second estrus, detected, inseminated, does not conceive
102 DIM: third estrus, not detected
123 DIM: fourth estrus, detected, inseminated, does not conceive
144 DIM: fifth estrus, not detected
165 DIM: sixth estrus, detected, inseminated, conceives

With no disease, no abortion, and normal management, the average cow has 165 days open. A tally of the 165 days by cause shows:

50 days: VWP
10 days: one half of an estrous cycle
42 days: failure to conceive on the two unsuccessful breedings
63 days: failure to detect three estruses

165 days total

This estimate of 165 days is based on performance in conception and estrus detection that is better than the average U.S. herd (note: this example would have a pregnancy risk of 17%), but it also assumes that all cows in the herd are fertile and are bred until they finally conceive. In reality, dairy managers give up at some point trying to get the final few percentages of cows pregnant and those cows are culled. As a practical example, given the aforementioned assumptions and accepting that no cow will be bred past 300 days in milk, the result would be approximately 134 days open for the average pregnant cow in the herd and roughly 11% of cows culled as not pregnant (Table 61-3[26]). These numbers do not account for the effects of abortion. This means that more than half of all herds are doing more poorly than 135 days open (accepting a 10% culling proportion for open cows), many substantially so. For most herds, achieving the oft extolled average days open number of 115 days (a 13-month calving interval) is an unreasonable starting goal under traditional management. It should be remembered, too, that in this example herd case, 11% of cows remain open after 300 DIM, in the absence of any reproductive disease.

A critique of Barr's concept lies in the assumption of no reproductive disease. The issues of infertile cows, chronic infections, and scarring of the reproductive tract should be taken into account. Although certainly operative on an individual cow basis, the effect of disease (absent herd level nutritional, toxic, venereal or contagious reproductive pathogens) seems to be small in most herds. In particular, there seems to be little reproductive "memory" from one lactation to the next, at least for cows that remain in the herd for a subsequent lactation. Current herd average days open seems to be the best predictor for an individual cow's days open, if that prediction must be made near the time she calves. When studied across a large population, a cow's reproductive history in the previous lactation had little or no effect on her reproductive performance in the current lactation.

Given the conceptual breakdown of the source of days open in a herd, the question is how one can monitor each of these critical controllable components.

Voluntary Wait Period

The obvious first step to determining the dairy's policy regarding voluntary wait period (VWP) is to ask. Unfortunately, stated policy and actual behavior are often not the same. The minimum wait period can be determined by finding the unusual cow with the fewest DIM at first breeding, but this is seldom a reasonable description of true management behavior of the herd. An estimate of actual VWP can be better derived from the DIM, where first breedings begin to cluster. Scatter plot distributions of days in milk at first breeding will give an impression of what is actually happening (Fig. 61-5[21]).

These types of graphic displays have the advantage of little or no lag or momentum. They are sensitive to the herd's status and help identify individuals with unacceptable performance. They seldom fail to illustrate real problems, although they may flag problems in individuals that are not indicative of a general herd mismanagement problem. They also allow action to proceed

TABLE 61-3

From John Fetrow, VMD.

*This dairy reproduction model assumes that only one estrus and one insemination per cycle. It does not account for abortions, and it assumes all cows are fertile.

†Reproductive culls if breeding stops at this point.

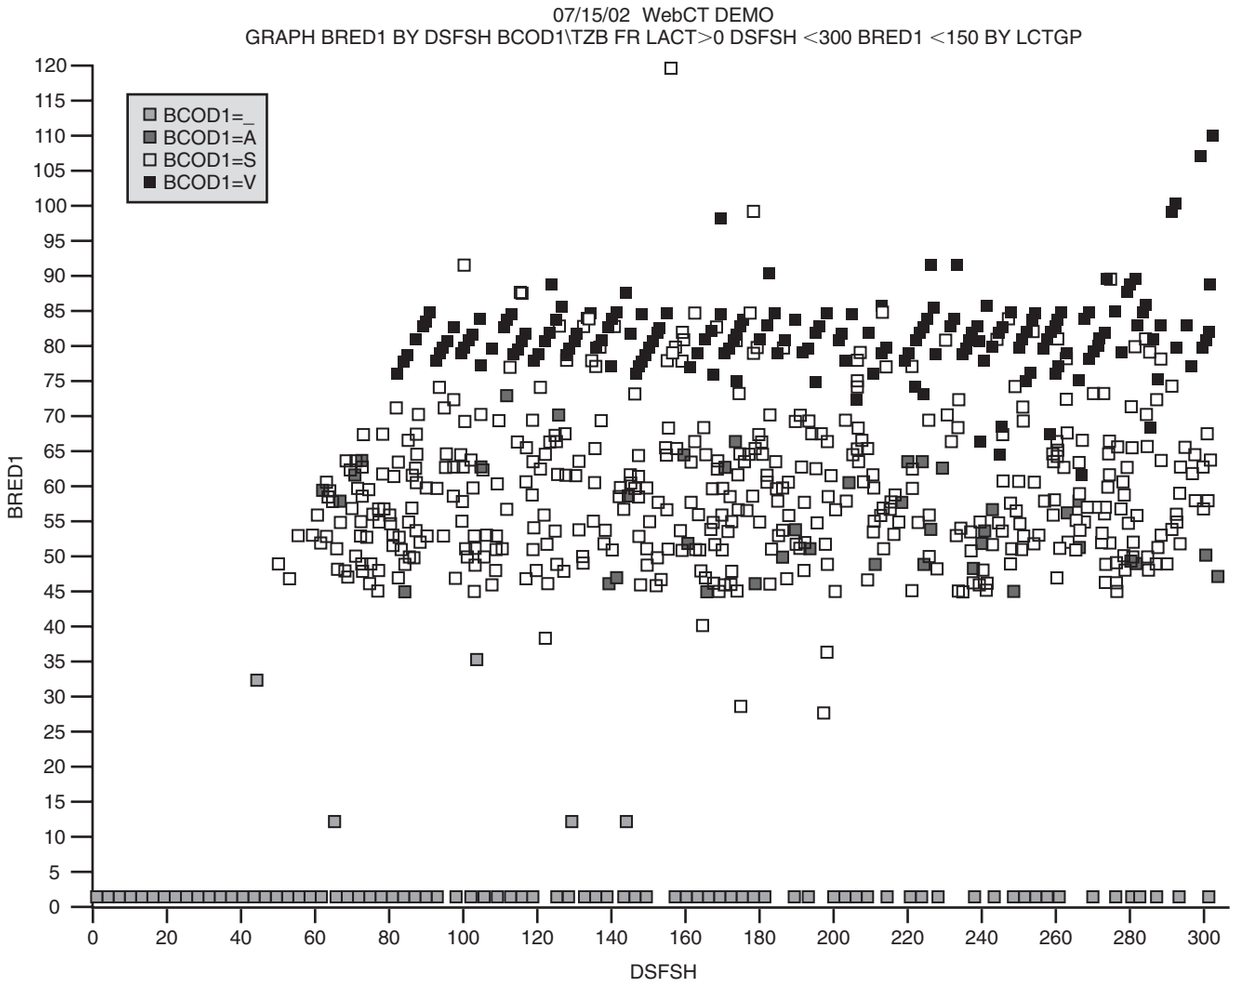

Fig. 61-5 Scatter graph of days at first breeding (BRED1) by current days in milk. This graph provides a reliable impression of the dairy's voluntary wait period before starting routine breeding (in this example about 50 days in milk). Note the use of routine synchronization in cows not bred by 75 days in milk.

without the need for precise quantification of overall herd parameters. Most important, they typically initiate a discussion.

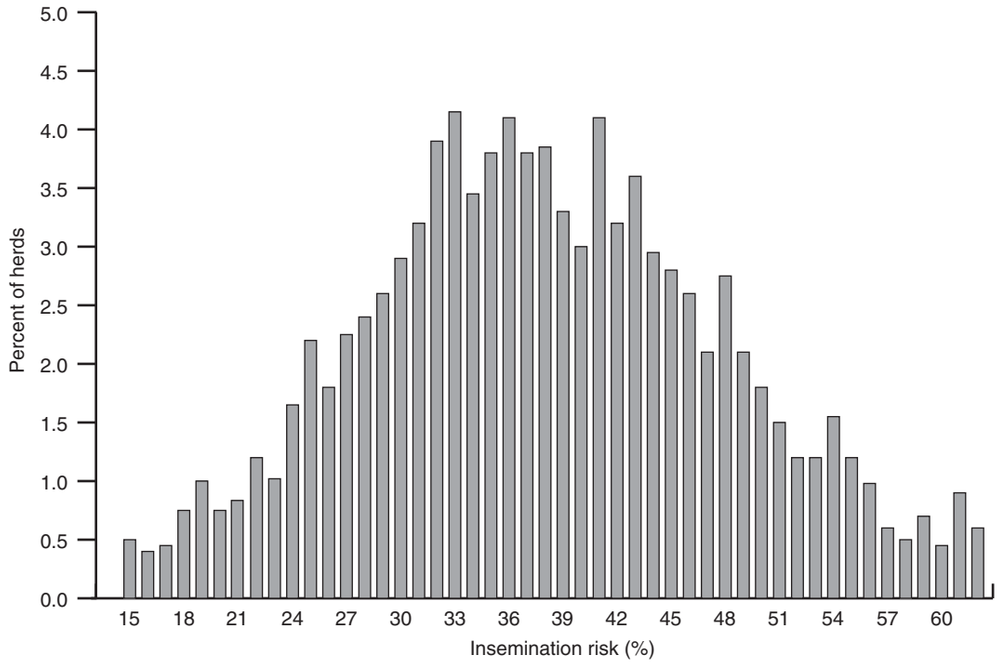
Estrus Detection

The two components of estrus detection are intensity (what proportion of cows are seen in estrus?) and accuracy (of those identified in estrus, what proportion really is in estrus?).

Estrus detection intensity. Percentage of estruses detected (estrus detection rate; actually a risk) is the usual parameter used to monitor estrus detection intensity. It is calculated based on the number of estruses detected over a period of time divided by the expected number of estruses in the breeding population (see Table 61-2[21]). Its calculation can have bias, depending on how cows are qualified as being eligible to come into estrus; it tells nothing about accuracy and is confounded by the use of synchronization programs.

Insemination risk is the chance that a cow will be inseminated at least once within a defined 21-day period. The difference between estrus detection rate and insemination risk lies in the point of view of the evaluation. Estrus detection rate measures how well the dairy identifies or induces cows to be in estrus, that is, the focus is on the cow and her behavior, heat detection aids, and labor on the dairy. Thus, a detected but noninseminated estrus counts in the calculation. In contrast, insemination risk focuses more on the herd dynamic: how effectively management is acting to get cows inseminated in a 21-day period. With insemination risk, cows bred twice in a 21-day period serve no better purpose than cows bred once, and cows detected in estrus but not inseminated do not count in the calculation. Insemination risk varies widely across herds, with the average rate centered at around 35% (Fig. 61-6).

Days to first estrus or days to first breeding is an indirect measure of prebreeding estrus detection intensity. If



Minnesota DHIA Data
1532 Herds Nov&Dec2003

	Ins_Risk	Preg_Risk	Conc_Risk
Mean	38.06%	13.92%	37.66%
Median	37.55%	13.56%	36.65%

Data provided by Dr. Steve Stewart based on 1,532 Minnesota DHIA herds, November and December 2003

Fig. 61-6 Insemination risk in Minnesota DHIA herds: risk that an insemination eligible cow will be inseminated at least once in a 21 day period. (Data provided by Dr. Steve Stewart based on 1,532 Minnesota DHIA herds, November and December 2003.)

the average is near to the VWP policy of the dairy (within 18 days or so in the absence of a synchronization program), then estrus detection intensity is probably acceptable. If the gap is longer, either estrus detection intensity is low, or the actual VWP is not the same as stated policy. Remember that this is a average, and calculation may suffer from lag, momentum, and bias. The scatter graph mentioned earlier will be far more useful.

The number of cows pregnant at pregnancy examination is a more indirect measure of estrus detection intensity. The logic of expecting more than about 80% of cows to be pregnant when examined is that if estrus detection is intense, then most cows that did not conceive when bred will be detected in estrus before pregnancy examination, leaving mostly pregnant cows to be examined. However, the expected percentage varies, depending on how long after breeding cows are examined for pregnancy, and there are formulae to calculate an estimate of estrus detection rate.[27] This measure of estrus detection intensity is confounded by conception rate as well; high proportions of open cows found at the pregnancy check can result from very poor conception as well as from poor estrus detection.[27]

A form of Q Sum graph can also be used to assess estrus detection intensity (Table 61-4[21]). The computer calculates each expected estrus for each cow, typically assuming a first estrus at day 50 and a 21-day estrous cycle (and adjusting for prostaglandin use, if recorded). Given the expected estrus, the program then records the actual outcome and displays the result. In the graph in Table 61-4, O would mean bred and open, P would mean bred and known pregnant, B would mean bred and outcome unknown, and M would mean estrus missed. If an expected estrus is detected, the observation moves one character to the right. If missed, the observation moves one character to the left. For a 50% estrus detection rate, the line of observations would tend to fall vertically on the page. Although crude in some ways, this sort of graphic approach is a valuable monitoring, educational, and motivational tool. Because the data are sorted on a chronologic basis by day, Q Sum graphs are much less useful in large herds than in smaller herds.

Estrus detection accuracy

Milk progesterone. Cows truly in estrus should have low milk progesterone concentration. For reliable interpretation, 15 to 20 cows should be sampled, with milk taken at the same time as insemination or the first milking after insemination. Samples should be frozen until a cohort has been collected for testing. Care must be taken to conduct the tests properly. In practical application, fewer

Estrus events are projected for each eligible cow. If an estrus is detected, the graph moves to the right (B means bred; O means bred but open). If the projected estrus is missed, the graph moves to the left (M means missed). In this example, estrus detection efficiency is less than 50% (a vertical progression downward is 50%).

than 10% of cows bred should have luteal levels of milk progesterone at the time of breeding.[28]

Interestrous intervals. With classic breeding programs, an argument can be made that estrus detection accuracy can be evaluated by monitoring the interval between breedings for cows (Table 61-5[21]). In theory, the intervals should be some integer multiple of 19 to 23 days; that is, they should follow a normal estrous cycle. The widespread use of synchronization programs on dairies often renders this approach unworkable.

Conception Rates

Various measures of conception efficiency are available: services per conception in pregnant cows (ignores repeat breeders), in all bred cows, stratified by lactation, by season, by artificial insemination technician, and so on. These analyses depend on accurate recording of the necessary information by the breeding staff of the dairy. Conception rates (again, really risks) on dairies range widely, with the median conception rate in a large sample of Minnesota dairies at 38% (Fig. 61-7). Table 61-6 shows one such stratification, in this case for conception by breeding type.[21] By their nature, conception parameters always have lag and momentum. Each parameter provides a window onto conception efficiency, and a combination of parameters can focus on the possible problem area if there is a serious conception problem in the herd. Q sum graphs can also be applied to conception in smaller herds, with the graph moving right when a breeding is successful and left when a breeding is unsuccessful.

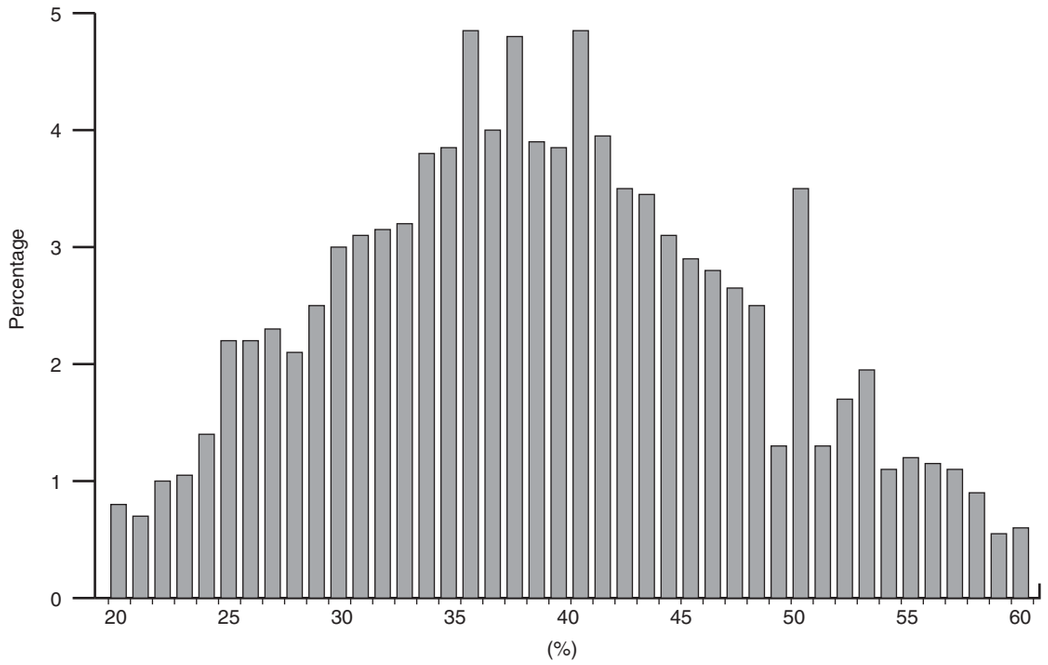
25–35 days	45	28	34	1	63	11	2.2
36–48 days	32	61	127	11	199	36	3.1
Over 48 days	35	54	100	8	162	29	2.9
Totals	36	189	331	30	550	100	2.8

Ideally, most inseminations should fall between days 19–23, or multiples thereof. This approach provides one measure of estrus detection accuracy. This is distinctly confounded by the use of synchronization programs that can return cows to estrus at other than 21-day intervals. Conc, conception rate; SPC, services per conception.



DC305 Conception *Rates: MN DHIA Jan–Mar 2004*
38.9 Mean (20–60 CR)
38.0 Median (20–60 CR)

Fig. 61-7 Conception rates in Minnesota DHIA herds 2004. (Data provided by Dr. Steve Stewart based on 2,193 Minnesota DHIA herds, 2004; only herds with conception rates of 20–60 percent are included.)

Bull Performance

There are many aspects involved in bull performance on dairies. Typically bulls are used as "clean up" breedings, with cows not pregnant to a series of AI inseminations turned into bull pens for breeding. Bulls are often poorly managed on dairies (poor feet, overused, not rested, etc.) and the result is that bull performance is commonly far below optimum. Dairymen may have a belief that the bull is naturally more efficient at getting cows pregnant than AI programs, but hard data often show this is not the case. If dairies reliably designate bull pens, record when cows are moved into those pens, and confirm pregnancy such that AI and bull pregnancies are distinguished, then pregnancy risks for bulls can be calculated in the same way as AI breedings (Table 61-7). It is not

TABLE **61-6**

Example Breakdown of Conception Rates for a Dairy

COMMAND: BREDSUM\O

Breeding	Code	%Conc	#Preg	#Open	Other	Total %	Tot SPC
Luteal heat	34	51	97	2	150	8	2.9
Ov-Synch heat	29	245	580	36	861	48	3.4
Standing heat	41	300	425	47	772	43	2.4
Totals	35	596	1102	85	1783	100	2.8

In this case the breakdown is by type of breeding, but many other breakdowns are possible and may be useful in characterizing conception problems (e.g., by day of week, by technician, by season, by insemination number). Conc, conception rate; SPC, services per conception.

The bull pregnancy risk (8%) was substantially below the pregnancy risk for AI breedings in this herd.

uncommon for bull pregnancy risks to be poorer than AI rates in the same herd.

Reproductive Disease

Monitoring the incidence of reproductive disease can be useful as an indicator of underlying problems with management. It is important that the dairy settle on a consistent case definition so that everyone involved understands what and when to record as an event. Typically, retained placentas, metritis, dystocia, and stillbirths are monitored as indicators of dry cow and transition feeding program management (particularly mineral and energy balances), calving area hygiene, and calving supervision. Cystic ovarian disease incidence may be an indicator of early postpartum energy status, but care should be exercised to distinguish true high incidence from overzealous diagnosis. As a rough guide, no reproductive disease should have an incidence higher than 10% of cows per lactation, although this may be too stringent a standard for metritis, depending on the case definition used. The trend in incidence over time is a more useful indicator of problems than the specific level in any period.

Abortion

There are two scenarios in which abortion becomes a herd problem. The first is a herd in which there is an increased incidence of abortion over a long time frame (endemic abortion). The second is when a clustering of abortions occurs in a short time frame (an abortion outbreak). Determining when a herd has had an "abnormal" number of abortions is a difficult and controversial question and requires knowledge of what a "normal" abortion rate is and what level above the normal rate is acceptable to that particular dairy. Estimates of abortion are also

confounded by the time of pregnancy diagnosis. Increased use of ultrasound for early pregnancy diagnosis will tend to elevate early pregnancy loss estimates compared to diagnosis based on rectal palpation 10 to 14 days later. The stages of pregnancy may be conveniently broken down into specific stages:

Gestation days 1 to 42: embryonic period (growth of embryo, no or limited placental attachment)
Gestation days 42 to 120: early fetal stage (placental attachment having taken place by about 45 days,[29] no or limited fetal immune function)
Gestation days 120 to 180: middle fetal stage (development of immune function)
Gestation days 180 to 260: late fetal stage (beginning of rapid increase of fetal weight)
Gestation days 260 to 280: premature birth stage (calf may be viable if born; stillbirth common if delivered prematurely)[30]

Estimates of the normal abortion rate for dairies range from 0.4% to about 10%.[31,32] Findings as low as 0.4% almost certainly reflect failure of diagnosis. One large study in 10 northwestern U.S. dairies found that 11% (range 7.6–13% by herd) of pregnancies diagnosed by rectal palpation after 31 days' gestation were lost between day 42 and day 260, during the fetal stage.[33] The range of reported abortion rates may be due to the definition of what constitutes an abortion (time in gestation), completeness of detection of lost pregnancies, the accuracy of the original diagnosis of pregnancy, and the population of cows that are used as the denominator in the calculation. Most loss of pregnancy does not lead to an observation of the aborted fetus or membranes; cows simply return to estrus or are found nonpregnant at a subsequent examination.[33] Taking these issues into account, normal abortion rates appear to be about 2% to 5% when only observed abortions are considered, approximately 8% to 10% or perhaps higher if one considers both unobserved and observed abortions based on pregnancy status determined by traditional rectal palpation programs.[34] As a rule of thumb, abortion rates in excess of 10% of pregnancies confirmed at 42 days of gestation or greater should be considered increased rates. More data are needed to clarify what constitutes "normal" loss of embryos prior to 42 days of gestation. Computer record programs must grapple with these definitions. Because the definition of an abortion is a pregnancy that is later determined to be open, then early pregnancy diagnosis will result in what appears to be a sharp increase in abortion rates in a herd where no biologic change has occurred. One approach is this issue is to accept a pregnancy as "confirmed" only if diagnosed after day 42. Earlier pregnancies, if lost by day 42, would fall back into the category of nonconception (or maybe as early embryonic death), rather than abortion. This compromise serves to reserve the term "abortion" for the fetal period of gestation, but combines two sources of reproductive failure (true conception failure and early embryonic death) together in one category. As diagnostic abilities increase, it seems very likely that what were once considered simple failures of conception are in large part really loss of early embryos.

Determining what constitutes a significant clustering of abortion remains problematic. In practice, waiting for statistical proof of an outbreak may not be prudent; practical importance may be established and action probably warranted well before statistical significance is reached. It is increasingly clear, however, that pregnancy diagnoses made in the first 2 months of gestation need to be reconfirmed so that lost pregnancies are identified in a timely manner and open cows are dealt with appropriately. Diagnosing the cause of abortion continues to be a challenge. There is a bias toward submitting fetuses aborted in later stages of gestation rather than younger ones, which may lead to inaccurate assessment of the major causes of fetal losses on dairies.[35] Fetal losses in earlier stages of gestation are far less likely to be observed, despite the fact that cows are more likely to lose their pregnancy in these early stages (particularly up to about day 60).[33] Serologic status of cows that abort may be similarly misleading, unless seroconversion can be demonstrated.[36]

Culling

As a reproductive monitoring tool, culling has very significant lag and momentum. By the time a cow is culled, the fundamental management problem that led to the cull (e.g., poor transition cow management, poor estrus detection) is probably distant history. Another difficulty lies in the definition of the reason an animal was culled.[37] If a low-producing cow with poor feet and legs and one blind quarter is open at 150 days post partum and the dairy manager decides to stop breeding her, is she a reproductive cull (open when culled at the end of lactation)? Thus "reproductive culling" is a very poor monitor of a herd's reproductive program. The tools described here remove all justification for ever attempting to use "reproductive culling rate" as a monitor of the reproductive program on a dairy.

MANAGING REPRODUCTION ON A DAY-TO-DAY BASIS

Monitoring for status and trends provides valuable insight into the herd's current and historical situation, but it often stops short of answering the question of what needs to be done on the dairy. As noted earlier, at any given time most cows on a dairy are not eligible for management intervention for reproduction. Record systems need to reach past the general herd status and target those cows for which action can be taken. What is often needed is not a measurement of the performance of those animals whose outcome (positive or negative) has already been resolved, but rather the identity and status of those animals for which positive management action is possible. Such cows might be past the VWP and not bred, bred but not confirmed pregnant, and so on. Given that estrus detection is the major opportunity area in the reproductive program on most dairy farms, much of the focus should be on cows that have not been detected in estrus and bred. Effective record systems allow these cows to be identified easily, often leading to efforts to induce a fertile estrus.

Data from dairy management software or downloaded DHIA records afford a significant opportunity for veterinarians to participate in this sort of "action list management" in their clients' reproductive programs. Care is necessary to be sure that lists correctly isolate those cows that are eligible for a particular intervention and that no cows are missed or incorrectly included. Many systems fail because of fundamental errors of management or implementation. It cannot be assumed on all dairies that cows have unique identification or that data are correctly entered. These basics are necessary before sophisticated programs can be implemented.

CONCLUSION

Reproduction has a central role in the management of a dairy farm. Veterinarians need to be fully involved in the reproductive management of their client herds. To do so most effectively, veterinarians must learn to routinely assess the herd's status and trends and identify both individual cows and general areas of management where intervention is possible and the client's welfare served.

CHAPTER 62

Reproductive Health Programs for Beef Herds: Analysis of Records for Assessment of Reproductive Performance

TERRY J. ENGELKEN, CHE TREJO, and KYLE VOSS

Those operations that emphasize decreased cost of production and the optimization of production efficiency should remain competitive in the years to come. However, certain external factors outside the "farm gate" will continue to have a dramatic effect on how cow and calf producers conduct their business. The continued consolidation in the packer and retail segments, the move from commodity beef production toward branded retail products, and the globalization of world markets will certainly help shape the face of the beef industry. The need for producers to develop record systems that can track individual animals from conception to consumption will be driven by consumer demands for a safe and wholesome product, legislation that mandates country of origin labeling (COOL), and the threat of foreign animal disease outbreaks. It is a certainty that an identification system will become federally mandated in the United States in the near future.

Recent survey data in Mississippi would indicate that over 50% of cow/calf producers do not use individual animal records to make management decisions.[1] This same survey suggests that nearly 40% of these producers do not use financial records. Larger operations were more likely to use the information provided by records (both animal and financial) when making decisions compared to smaller operations. However, even in the largest herds (over 500 head), nearly one third did not use animal records in the decision-making process. Although these findings may be surprising, they represent a real opportunity for practitioners to increase their involvement in the overall reproductive management of these operations.

Most indices currently used to evaluate herd performance are directly tied to reproduction efficiency. Measures such as pregnancy rate, calving percentage, calving distribution, and percent calf crop all affect pounds of calf produced per exposed female. If reproductive performance falls below targeted levels, the practitioner is often asked to provide a plan to improve efficiency. This process requires that the producer provide or the practitioner construct adequate herd records to facilitate the evaluation process. This process will ensure that needed changes in herd management can be identified and that cost-effective solutions can be documented and evaluated over time.

DATA COLLECTION

The usefulness of available herd information is totally dependent on its accuracy and its relationship to meaningful reproductive performance measures. Data not meeting these criteria are irrelevant and only serve to make the veterinarian's task more difficult. In those situations in which records are incomplete or inaccurate, the practitioner would be better off taking time to design a system of data collection to fit the operation. This system could be as simple as an index card for each cow. It could also involve a customized spreadsheet or database application or utilize one of the currently available software packages on a laptop or PDA. Regardless of the collection system used, data are only useful if they facilitate decision making.

The minimum data required to begin any analysis[2] include factors such as cow identification, age, breed, body condition score, pasture location, and estimated days pregnant, all of which can be captured chuteside as each group of breeding females is processed. Female weights and frame score are also useful parameters to track if those numbers can be conveniently collected.

Pregnancy evaluation should be done as soon as possible after the end of the breeding season. This allows a more accurate dating of the pregnancies and an earlier indication of reproductive performance. Performance of individual breeding groups as well as the whole herd can then be compared to established targets for operations in a particular geographic region.[3] This type of reproductive information is critical in evaluating the success of the breeding program.

The bull battery represents the other half of the reproductive equation. Information concerning the day the bulls entered and left the pasture, bull breed and identification, and pasture assignment should also be collected.[3] Purchased bulls that have been added to the herd since the last breeding season should have their breeding soundness examination forms, registration papers with EPD values, and health certificates examined by the prac-

titioner. The producer should retain these records at least through the following calving season and preferably for as long as the bull remains in the herd. This information can be very useful when trying to track down the cause of reproductive losses or increased calf morbidity.

Detailed herd surveys can also be used to build an initial database.[4] Herd surveys not only give the veterinarian an overview of the operation, but also require the producer to take time and review the production practices currently in use. These surveys come in many formats; they should cover areas such as the animal health program, feeding practices, supplemental feeding, land allocation, grazing and fertilization practices, genetic selection, and physical facilities. Financial information should also be considered. Once accurate information is obtained, the veterinary clinic can act as a central data procession point to compile and analyze individual cow data and overall herd performance.

RECORD ANALYSIS

When evaluating the success of the breeding program, the traditional measure that has been most often used is percent pregnant. Taking the number of animals pregnant in the individual group or herd and dividing it by the number of exposed females will calculate this measure. Although this measure has some value, it gives no insight into important factors such as the length of the breeding season, bull-to-female ratios, grazing conditions, or cow characteristics (age, body condition score [BCS], or frame score) that have an impact on reproductive performance. A more complete analysis of herd performance would enable the veterinarian to judge when individual cows become pregnant and the percentage by each estrous cycle. A complete evaluation allows the practitioner and client to track cow and bull reproductive performance, replacement heifer development, and the herd's nutritional status.[2,3,5,6] This type of analysis leads to a better understanding of production problems, intervention strategies, and lines of communication between the producer and practitioner.

If accurate production records already exist, variations in female reproductive performance can be assessed by cow age, breed, frame score, and body condition score. However, in many cases the first opportunity to access this information occurs at the time of pregnancy examination. Although this evaluation should determine pregnancy status first and foremost, the analysis should also consider the costs involved in getting cows pregnant and the value of the weaned calf. Cost centers such as the nutritional program, heifer replacement, and grazing costs can then be related to overall profitability. Also, the timing of herd management events should be evaluated and clearly defined.[3]

Once all data are collected, this information can be summarized in tabular form as a starting point for the herd analysis (Table 62-1). As this is done, individual group and herd factors that affect reproductive performance will begin to emerge. The fall-calving herd profiled in Table 62-1 shows excellent reproductive performance across all age groups. With the exception of the expected decrease in performance of the oldest set of cows, there was no real difference in percent pregnant, average days pregnant, or body condition score. Typically, the 3-year-old females are the most difficult group to get rebred because they are nursing their first calf. In our experience, it is not unusual to see the pregnancy rate in this group of females drop 5% to 10% below the herd average, while taking 10 to 14 days longer to conceive. Because of the capital invested in the replacement heifer program, it is critical that these young females be monitored and managed to ensure acceptable reproductive performance through their first two breeding seasons.

Nutritional management can have a dramatic impact on reproductive performance.[7] Also, the supplemental feeding program typically represents the largest cash cost associated with the cow/calf operation. The nutritional status of the herd can be monitored by using a body condition scoring system to evaluate the success of the feeding program.[2] By dividing the herd into groups based on body condition, the practitioner can evaluate reproductive performance and communicate those findings to the producer. Table 62-2 details the relationship for another fall-calving herd. This particular operation was successful in managing the forage base and supplemental feeding program so that less than 10% of the herd was in borderline condition (BCS = 4) at the time of pregnancy examination. Because of the expense associated with feeding the cow herd and the critical role that nutrition plays in productivity, it is critical that this relationship be evaluated on an annual basis.

Calving histograms can be used to further define the conception pattern of the herd and the expected calving distribution.[5,6] The histogram shows the percentage of

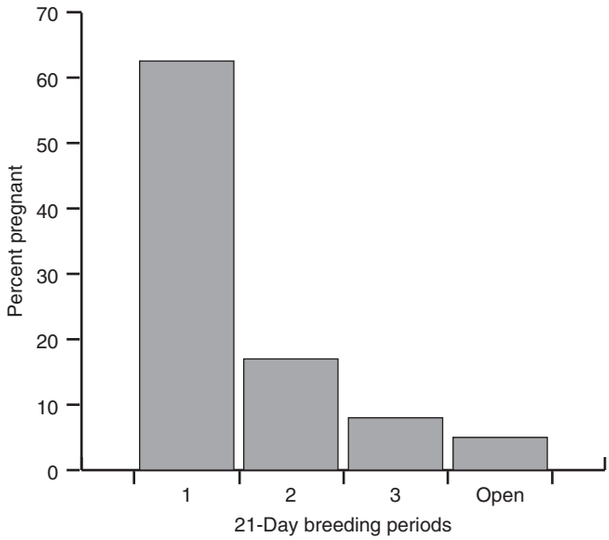

Fig. 62-1 Breeding histogram showing the percentage pregnant by 21-day periods.

females bred in each 21-day period (Fig. 62-1). This process should be done for the entire herd and then broken down into specific breeds, ages, body condition scores, or pasture locations, as deemed necessary by the practitioner. Reasonable targets for mature cows (4–8 years old), using a limited breeding season (45–75 days) include having 60% of the females conceive in the first 21-day period and less than 10% open. These targets will vary for different female groups and environmental conditions.

Pregnancy examination data and the calving histogram can be utilized to determine the median pregnancy date (MPD) for the herd.[2,6] If calving information is available, median calving date (MCD) can be used as well. A discussion on how to calculate these measures was included in the first edition of this text.[2] These measures can be used to manipulate the beginning of the breeding season to produce a more concentrated breeding and calving season. These parameters are particularly useful in herds with prolonged breeding seasons, poor conception rates in the first 21-day period, and a large number of late-calving cows. Once the MPD is calculated, the following breeding season can be "pushed back" as needed in order to give the females more time to gain condition between calving and breeding or to make sure that the breeding season better matches the forage base of the ranch. This should help producers avoid the economic penalties associated with high culling and replacement rates.

The major income-producing component of the cow/calf enterprise is the weaned calf. Therefore, it is imperative that factors affecting pounds of calf produced per exposed female be routinely monitored.[8] Factors such as dystocia, enteric disease, and respiratory pathogens lead to increased death loss of calves. Lower than expected suckling calf performance (growth rate) also contributes to poor weaning weights. Calf age and weaning weight are directly related, with early born calves being heavier at weaning (Table 62-3). Calf weaning weights are also affected by age of the dam; cows 4 to 8 years of age typically wean heavier calves than younger or older females (Table 62-4). A prolonged breeding and calving season not only results in younger and lighter calves being weaned, but also makes postweaning management of the replacement heifers more difficult. The age distribution of the females should also be evaluated over time if weaning weights are not meeting expectations.

With an annual replacement rate of 10% to 20%, the sale of cull animals represents another significant source of income for producers.[9] Besides serving as a source of income, these cows can also be used to judge how well the female selection criteria match the ranch environment. Culling rate, cow age, reason for culling, and sale price need to be monitored over time (Table 62-5). Physical abnormalities, such as ocular neoplasia and lameness, need to be addressed as part of the producer's beef quality assurance program. Disease monitoring programs can also be instituted in culled cows to evaluate the incidence of reproductive disease and the effectiveness of the herd health program.[10]

An evaluation of the financial health of the cow/calf enterprise enables the producer to quantify cost of production and owner equity status. This also gives the practitioner an opportunity to show the client how veterinary input has affected herd profitability. Information concerning only the costs and returns of the cow herd is considered.[11] Fixed inputs being used in more than one ranch enterprise (such as machinery and buildings) are charged to the cow herd based on the percentage of their use. Pounds of calf produced per exposed female is a good indicator of overall productivity. The accuracy of this type

TABLE **62-3**

Relationship of Calving Distribution to Calf Performance in a Mississippi Cow/Calf Operation

of analysis depends on the investigator's ability to select and monitor consistent input and output parameters.

If the producer is currently using an accountant to generate tax information, it should be possible to obtain the needed financial statements for an enterprise analysis. A beginning and ending balance sheet, income statement, depreciation schedule, and tax return for the fiscal year are needed. The fiscal year is determined according to when the calves are weaned. Production efficiency and financial return should be evaluated to facilitate the comparison of an operation's performance over the years and with other operations in the veterinarian's practice area (Tables 62-6 and 62-7).

INTERPRETATION

Once the needed information is available and the production and financial goals of the operation are established, the veterinarian begins the task of trend recognition, identification of inefficiencies, and instituting needed management changes.[2,3,11] Trends associated with reproductive efficiency, calf performance, and production costs must be identified. Because the effect of a disease process may actually mimic managerial or environmental effects, identifying the cause of these trends may be difficult. The practitioner, in conjunction with a diagnostic laboratory, is best suited to evaluate potential herd conditions to form a logical diagnostic plan of action. This ensures that the proper diagnostic samples are collected and the needed resource people contracted.

Management recommendations are then instituted to correct the situation.

In herds with established herd health programs, a marked decrease in total pregnancy rate or a shift toward increasing late-period breeding percentages from the previous year indicates reproductive management problems.[5,10,11] This may be a reflection of reduced bull fertility, inadequate group nutrition, the introduction of a disease-causing organism, or any combination of these. Nonpregnant cows serve as a potential resource for providing clues as to the reason for the reduced reproductive performance.[10] Reproductive tracts should be carefully palpated and diagnostic samples collected to rule out a disease process. Cervical mucus samples and uterine biopsies can be submitted for culture and histopathologic examination. The development of new diagnostic technologies, such as polymerase chain reaction (DNA probes), holds great promise in enabling the practitioner to identify infectious agents with much greater accuracy. If needed, culled cows can be followed to slaughter and their reproductive tracts examined post mortem. When this type of diagnostic work-up is combined with serologic testing, bull evaluation, body condition scoring, and nutritional evaluation, the cause of the problem is much more likely to be identified.

In herds not on a routine reproductive management program, poor reproductive efficiency often accompanies a prolonged breeding season.[2,3,5,6,11] In an evaluation of these herds, emphasis should be placed on those factors that influence the first 21-day breeding period (Fig. 62-2). The number of females cycling at the beginning of the breeding season has the greatest impact on early conception rate. This number may vary according to cow age, postpartum interval, and body condition score. By comparing the number of females found pregnant with the calving percentage, the practitioner can determine the timing of reproductive losses. This allows for the targeting of specific pathogenic organisms that are most commonly associated with pregnancy wastage in the early, middle, or late gestation.[10] Once the cause is determined, specific recommendations can be made for changes in bull battery management, herd vaccination protocols, or the herd's nutritional management.

The pregnancy distribution illustrated in Figure 62-2 could result from a disease process affecting conception or early gestation. However, it is more likely the result of having the cow herd enter the breeding season in poor body condition. This lengthens the postpartum interval and delays the onset of the estrous cycle. Then as the grazing conditions improve and the females increase body condition (periods 3 and 4), cycling resumes, and conception occurs. To prevent this pattern from recurring in subsequent years, the producer must decide if it is more economical to deliver additional supplemental feed or delay the start of the following breeding season. If the breeding season is moved back, it should be based on the median pregnancy date in this herd. The practitioner should also perform a detailed review of the operation's heifer development program. A long-term objective may require the producer to change the genetic base of the cow herd to better fit the ranch environment.

	AMOUNT	
Financial Parameter	***1998***	***2001***
Raised/purchased feed cost ($/cow)	$213.40	$123.34
Pre-tax ranch expense/cow	$362.40	$282.23
Unit cost of production (breakeven/cwt)	$106.79	$73.04
Net income/cow	–$125.16	$73.33
Percent equity	66.2 %	90.7 %
Percent return on assets	–2.77%	7.01%

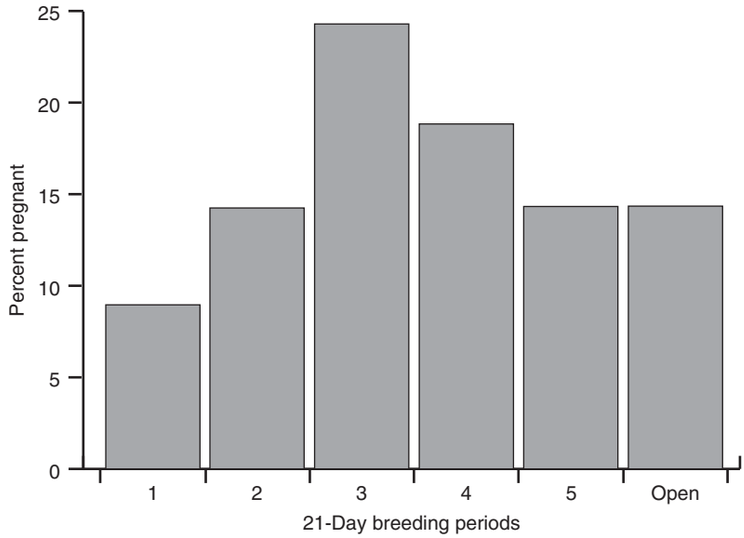

Fig. 62-2 Breeding histogram depicting a prolonged breeding season, poor conception rate per 21-day period, and a large number of open cows.

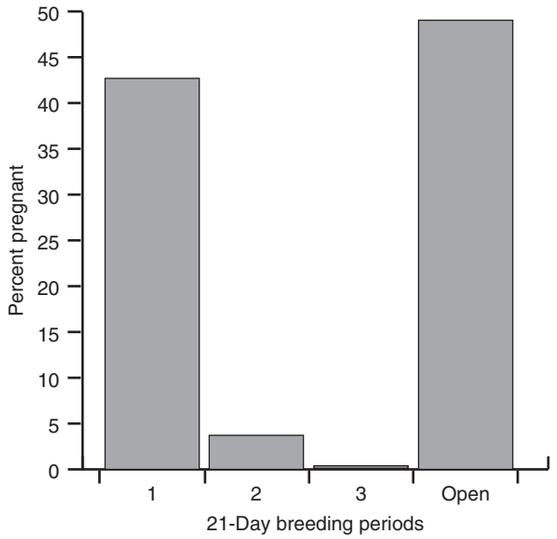

Fig. 62-3 Pregnancy distribution in a spring-calving herd following multiple bull failure.

The pregnancy distribution depicted in Figure 62-3 is not uncommon in smaller operations. The breeding season began well, but conception ended abruptly. This type of distribution most commonly occurs in breeding groups where the only bull in the pasture has been injured. The injury may be musculoskeletal in origin, but in our experience, it is most likely a preputial laceration or a penile hematoma. Often times the breeding season is lost by the time the injury is detected and a new bull turned out. This type of distribution may also occur with unseasonably hot temperatures that coincide with the spring breeding season in the southeastern United States. This effect is amplified in those situations that rely on fungus-infected fescue pastures as the dominant forage. This combination of prolonged, high ambient temperatures and increased body temperature associated with fescue intake tends to decrease semen quality and breeding activity in bulls. Producers will often comment that the bulls are spending more time under the shade or standing in ponds than "working" the breeding herd.

Mismatches between the cow and her environment can negatively affect calf performance as well. Prolonged postpartum intervals lead to younger and lighter calves at weaning. Females calving in poor body condition experience more dystocia and produce less milk. The prolonged breeding season depicted in Figure 62-2 also complicates the postweaning management of both cows and calves.[6] Owing to the wide variation in date of conception, supplemental feed budgeting for the pregnant cows is difficult. The calves are extremely uneven in size and body weight, which decreases their total value. There is also a wide range in heifer weights, making replacement selection and management more difficult. By relating the calving histogram and median calving date to a producer's production practices, the practitioner is in a position to recommend cost-effective management changes and to document their impact on ranch profitability.

Using records to periodically review herd performance is a critical component of the production medicine program. This review should focus on those management issues that were originally identified as causing production or financial inefficiency for the operation. This process may deal with the reproductive performance of the entire herd or one of the specific components (mature cows, replacement heifers, young cows, bull management, etc.) that has caused problems in the past. Key production and financial parameters should also undergo periodic evaluation to make sure that progress is being maintained.

The data in Table 62-4 represents calf weaning weight as a function of cow age. In the initial year (1992), it was noted that weaning weights were generally lower than expected and the 3-year old cows were especially affected. It was felt that the decrease in production in the young cows was due to an increase in their postpartum interval following first calving. Another concern was that the majority of the mature cows (ages 6 years and older) were weaning calves that were no heavier than those from the 2-year-old females raising their first calf.

In this situation, factors affecting weaning weight were evaluated and changes in the supplemental feeding program, replacement heifer development, and the genetic base of the cow herd were employed. Over the following 7 years, there was an overall increase in the herd's weaning weight and better production from the mature cows. However, it appears that work still needs to be done in the postpartum management of the replacement heifers to ensure timely conception during the second breeding season. This will ensure adequate production as 3-year olds. This periodic analysis of historical ranch data enables the practitioner to evaluate the success of the management program and justify its cost to the producer.

SUMMARY

The reproductive performance of the breeding herd is critical to the operation's ability to produce income. Income generation is affected not only by the absolute number of females that conceive, but also by the timing and distribution of the pregnancies. The success or failure of the breeding season can be affected by a wide range of disease and management factors. Complete and accurate record systems offer the practitioner an opportunity to recognize trends, identify problems, and implement cost-effective management changes. These record systems also document the effect of these management changes on subsequent productivity. The use of data collection and expert analysis as a means of tracking herd efficiency will become very important in these operations. Veterinarians have a unique opportunity to position themselves to take a leading role in providing cow/calf producers with this type of service.

CHAPTER 63

Assisted Reproductive Technologies in Cattle

PETER W. FARIN, KAREN MOORE, and MAARTEN DROST

Assisted reproductive technologies (ART) have made tremendous advances, especially during the past 15 years. Artificial insemination (AI) remains the most effective method for achieving genetic progress in populations of cattle. The global market remains strong for frozen semen and embryos. Millions of cattle are bred by AI, and more than a half million embryos are transferred annually world wide. Most of the top dairy sires used for AI were derived from embryo transfer (ET). Improvements in methods of controlling the estrous cycle and ovulation have resulted in more effective programs for AI, superovulation of donor cows, and the management of ET recipients. The recent introductions of in vitro embryo production, cloning, and sexed semen have added to the ART "toolbox."

In this chapter we discuss current reproductive technologies in cattle, with particular emphasis on procedures used in the practice of ET. Our goal is to provide the reader with information and guidelines for applying ET and related technologies. The newer technologies of in vitro embryo production and cloning are also addressed. The chapter concludes with a discussion of the use of sexed sperm and embryos to preselect calf gender.

ARTIFICIAL INSEMINATION

Artificial insemination was the first assisted reproductive technology to be applied commercially for the genetic improvement of animals in the mid-1900s. The advantages of AI in terms of disease control, the import and export of frozen semen, the availability of accurate breeding records, and the elimination of dangerous bulls on farms are well established. AI has become the foundation for expanded breeding schemes such as estrus synchronization programs (synchronized breeding, including timed AI), embryo transfer, in vitro embryo production (IVP), the use of sexed semen, cloning, and transgenics. The use of AI, especially in dairy cattle, has become so routine that most of it is practiced by the producers or herd managers themselves. The main disadvantage is that the latter do not always develop sufficient skills to maintain acceptable conception rates in their herds.

EMBRYO TRANSFER

The next major commercial advancement in reproductive biotechnology was embryo transfer in the late 1970s. ET

CHAPTER 63

Assisted Reproductive Technologies in Cattle

PETER W. FARIN, KAREN MOORE, and MAARTEN DROST

Assisted reproductive technologies (ART) have made tremendous advances, especially during the past 15 years. Artificial insemination (AI) remains the most effective method for achieving genetic progress in populations of cattle. The global market remains strong for frozen semen and embryos. Millions of cattle are bred by AI, and more than a half million embryos are transferred annually world wide. Most of the top dairy sires used for AI were derived from embryo transfer (ET). Improvements in methods of controlling the estrous cycle and ovulation have resulted in more effective programs for AI, superovulation of donor cows, and the management of ET recipients. The recent introductions of in vitro embryo production, cloning, and sexed semen have added to the ART "toolbox."

In this chapter we discuss current reproductive technologies in cattle, with particular emphasis on procedures used in the practice of ET. Our goal is to provide the reader with information and guidelines for applying ET and related technologies. The newer technologies of in vitro embryo production and cloning are also addressed. The chapter concludes with a discussion of the use of sexed sperm and embryos to preselect calf gender.

ARTIFICIAL INSEMINATION

Artificial insemination was the first assisted reproductive technology to be applied commercially for the genetic improvement of animals in the mid-1900s. The advantages of AI in terms of disease control, the import and export of frozen semen, the availability of accurate breeding records, and the elimination of dangerous bulls on farms are well established. AI has become the foundation for expanded breeding schemes such as estrus synchronization programs (synchronized breeding, including timed AI), embryo transfer, in vitro embryo production (IVP), the use of sexed semen, cloning, and transgenics. The use of AI, especially in dairy cattle, has become so routine that most of it is practiced by the producers or herd managers themselves. The main disadvantage is that the latter do not always develop sufficient skills to maintain acceptable conception rates in their herds.

EMBRYO TRANSFER

The next major commercial advancement in reproductive biotechnology was embryo transfer in the late 1970s. ET

enabled the acceleration of the proliferation of genetic material from the dam as well as of the sire. The ability to freeze and transport bovine embryos around the world has made ET an extremely useful technology for disease control and biosecurity programs, genetic salvage of valuable individuals, and development of new lines or breeds of cattle. ET is a factorial process that depends on a series of carefully orchestrated sequential steps. Poor performance in any of the steps directly affects the success rate and the final outcome, the number of calves weaned.

Donor Selection

Selection of the donor is based on two major criteria: (1) genetic merit, generally determined by the owner and based on performance, and (2) reproductive soundness, as assessed by the veterinarian. The donor must be in good body condition and preferably gaining weight. She should be free from underlying diseases, a minimum of 50 to 60 days post partum, and cycling regularly. Generally, cows with a history of reproductive problems do not make good donor animals.

Donors are further evaluated by examination of the cervix, uterus, and ovaries per rectum to determine that they are free from adhesions or other palpable lesions. It is prudent to test the patency of the cervical canal with a cervical dilator for sufficient internal diameter to permit passage of a collection catheter, especially if the prospective donor is a heifer or of *Bos indicus* breeding. This prevents the occasional frustration of being unable to negotiate the cervix after a series of costly hormonal injections.

Vaccinations should be current for local diseases. Blood typing of both donor and sire prior to or at the time of embryo transfer for subsequent identification of offspring is highly recommended and is generally required prior to export.

Donor Management

Single embryos or multiple embryos may be collected from naturally ovulating or superovulated cows, respectively. For optimal efficiency 2 to 4 donors should be treated and synchronized with their recipients for each attempt; this allows sharing of the recommended potential 8 to 10 recipients per donor.

Superovulation remains the least predictable step in the process of embryo production. In the bovine tremendous variation in response occurs with age, breed, lactational status, nutritional status, season, and stage of the cycle at which treatment is initiated. Follicle stimulating hormone (FSH), which has a short half-life, necessitates twice-daily injections over a period of 4 to 5 days. Treatment is begun during the mid-luteal phase (day 8 to 12) of the donor's cycle and employs the use of prostaglandins (PG) to synchronize the cycles of the donors and the recipients. Alternatively, treatment may be initiated on day 16 or 17 (day 0 = estrus) of the donor's natural estrous cycle. Currently the most commonly used source of FSH in the United States is Folltropin-V.*

†PGF2α, Prostaglandin F2α; Lutalyse, Pfizer Animal Health, New York; IM injections.
‡FSH, Follicle stimulating hormone; Folltropin-V, Bioniche Animal Health USA, Inc., Athens, GA; IM injections.
§FSH treatment is discontinued when the donor comes into estrus early. If the donor does not come into estrus, FSH treatment may be continued 1 additional day at the dosage level of the last scheduled day. Artificial insemination (AI) of donor at 4 to 6 hours after onset of estrus, repeated once 10 to 12 hours later.

Twice daily intramuscular injections of FSH are recommended (Table 63-1). Prostaglandins (25–35 mg $PGF_{2\alpha}$ or 500 µg PG-analogue IM) are routinely given at the time of the fifth and sixth FSH injections of a 4-day regimen, which is then followed by estrus in 2 days and ovulation in 3 days. This interval from PG to the onset of estrus is 12 to 24 hours shorter in superovulated animals than in naturally ovulating cows or heifers. Consequently, recipients should be injected with PG 24 hours before the donors if this method of synchronization is used. The response to the FSH regimen ranges from zero to 20 or more ovulations with an average of 8 to 10. There appears to be no difference in response between a 4-day and a 5-day regimen. Generally, heifers require a smaller total dose and older animals a higher total dose.

Many embryo transfer practitioners use exogenous progesterone or intravaginal controlled drug (progesterone) release devices (controlled internal drug release, CIDR)† as part of the superovulation protocol. This approach may be used simply to synchronize a group of donors in order to start the FSH treatment approximately 10 days after their synchronized heat. Alternatively, the

donors may be superovulated with the CIDR in place according to the treatment schedule in Table 63-2. The advantage of the latter approach is that the donors may be implanted at any time during their cycle. However, it is critical that the donor is a reproductively normal, cycling animal.

It is difficult to accurately assess the number of ovulations by palpation of ovarian structures per rectum on the day of embryo recovery when the number of corpora lutea (CL) exceeds 4 to 6 per ovary or when several anovulatory follicles are also present. An excessive number of anovulatory follicles in the presence of corpora lutea appears to adversely influence the percentage of recovered embryos because of an unfavorable estrogen-to-progesterone ratio, which affects gamete and embryo transport through the tubular reproductive tract.

Ultrasonography

Donor management can be enhanced by the use of real-time ultrasonography. In addition to accurate assessment of the normalcy of the reproductive tract, including ovarian status, the presence of a dominant follicle (DF) can be ascertained. The presence of an active DF can suppress ovulation rate by as much as 40%. Ablation of the DF prior to FSH treatment allows donors to be scheduled based primarily by the calendar rather than their follicular wave patterns.

Ultrasonography is helpful in assessing the potential superovulatory response on the day prior to ovulation or at the time of AI. When only one or a few follicles are observed a back-up sire can be selected rather than semen from an extremely expensive bull.

Ultrasonography and palpation of the ovaries per rectum have been shown to have similar accuracy for determination of the number of CL at the time of embryo recovery. However, the number of anovulatory follicles can be counted more accurately by ultrasonography, and this information may aid in explaining a poor response to the owner.

Estrus Detection and Insemination

Accurate estrus detection is of great importance not only for timely insemination of the donor, but also for the determination of the degree of synchronization of estrus and ovulation between the donor and her recipients. The age of the embryo is calculated from the time of onset of standing heat.

Donors should be artificially inseminated twice with a 10- to 12-hour interval, beginning 4 to 6 hours after the onset of estrus, to cover the range of time over which the ovulations may occur. Depending on the quality of the frozen semen, a double inseminating dose may be used at each insemination. A double inseminating dose should be used in cows with a large pendulous uterus.

Embryo Recovery

Bovine embryos descend into the uterus around day 4.5 (estrus = day 0) and shed their zona pellucida ("hatch") between days 8 and 10. Consequently, most nonsurgical recoveries are made between days 6 and 8.

A two-way round tip balloon catheter (French size 16 to 24) with a 30 ml inflatable balloon is used. The two-way catheter has one channel for inflation of the balloon plus a single channel for alternate inflow and outflow of flushing medium. A sterile stylet (such as the plunger of an insemination gun) is inserted the full length of the device to render it sufficiently rigid to allow introduction into the uterus under guidance per rectum.

The donor is restrained in a chute or in stocks. Nervous animals may be given 5 to 10 mg of acepromazine or another suitable tranquilizer. Feces are carefully removed from the rectum to avoid aspiration of air, and an estimate is made of the number of ovulations (CL). Epidural anesthesia is administered (4 to 6 ml of 2% lidocaine hydrochloride) to prevent defecation and straining. Fractious animals may be given epidural anesthesia with a combination of xylazine (30 mg) and sterile saline or sterile water (7 ml or sufficient quantity). *Bos indicus* breeds are more sensitive to the action of xylazine and should receive 20 mg of xylazine in a sufficient quantity, usually 7 ml, of sterile saline. Inadvertent air can be removed from the rectum with a small stomach tube attached to a wet vacuum cleaner. The vulva and perineal region are thoroughly washed with plain water and blotted dry. The tail is tied out of the way. If the cervix feels small or tortuous, a cervical dilator may gently be used to expand and straighten the cervical canal. The dilator and subsequent catheters may be covered with a sanitary sleeve before they are introduced into the vagina. This protective cover is perforated just before the instrument enters the external os of the cervix. *The rigid, relatively sharp-pointed dilator should be used with extreme caution as it can readily perforate the uterine wall when it is*

forced through the tight cervical canal. The lips of the vulva are again parted and the balloon catheter, with the stylet in place, is inserted into the vagina and advanced into the lumen of the cervix. It is then manipulated into the appropriate horn until the inflatable balloon is situated at the base of the uterine horn. The balloon is slowly inflated with 15 to 20 ml of air or flushing medium in adult cows and 10 to 15 ml of air in heifers. The endometrium can easily be split by overdistention, resulting in hemorrhage and escape of the flushing solution into the mesometrium, from which it cannot be recovered.

After the catheter is in position, the stylet is removed and the catheter is connected via a Y junction by sterile tubing to a 1000 ml bottle or bag of flushing medium. The remaining arm of the Y junction is connected to a free piece of tubing. The flow of medium in both pieces of tubing is controlled by quick-release clamps. While the outlet tubing is occluded, the flushing solution enters the uterus by gravity flow with the bottle suspended approximately 1 meter above the level of the uterus. The horn of the uterus is extended by elevating the tubouterine junction and by carrying it anteriorly. When the inflow stops, the inlet tubing is clamped off and the clamp on the outlet tubing is released. The fluid is channeled directly through an embryo filter (75 µm pore size).

In older animals with long pendulous tracts, manipulation of the cervix and uterus can be facilitated by retracting the cervix into the vagina with cervical forceps. If the returning fluid is blood-tinged, the red blood cells may be washed directly through the filter by opening both clamps between the bottle of flushing solution and the filter. The filter should never be allowed to run completely dry, leaving the embryos on the filter disk exposed to the air.

In superovulated animals the procedure is repeated for the opposite horn, using a separate sterile catheter. It is hazardous to reinsert the stylet into the balloon catheter while it is in the uterus because the sharp tip might exit through one of the side openings. Some operators prefer placement of the catheter with the balloon just anterior to the internal os of the cervix, in the body of the uterus, which enables them to flush both horns simultaneously. In older animals the balloon is frequently displaced to this body location during the filling and stretching of the uterus even though the balloon was initially placed in one of the horns. When this happens, both horns are simply flushed at the same time (body flush).

Flushing and Holding Media

The most commonly used medium for nonsurgical embryo recovery is Dulbecco's phosphate buffered saline (PBS). One percent heat-treated bovine serum (10 ml) is added to each individual 1 L bottle of flushing medium, which may be used at room temperature. Serum acts as a protein source for embryo growth and membrane stabilization, and renders embryos less sticky. In lieu of serum, 0.04% bovine serum albumin (BSA) may be used for the recovery medium and 0.4% for the holding medium.

Ten to 20% serum is added to the flushing medium to make a holding medium that can also be used for short-term (less than 24 hours) culture. Holding medium should be sterilized by filtration through a 22 µm Millipore filter attached to an all-plastic syringe. The rubber plungers of some syringes have been shown to be coated by an embryotoxic lubricant; hence it is recommended that all-plastic syringes be used.

Holding dishes should be kept covered to minimize contamination and evaporation. The latter will increase the osmolarity of the medium. Changing the embryos to a fresh dish of holding medium periodically (every 2 hours) further minimizes the effects of contamination and evaporation.

By the very nature of the procedure, it is vital that all aspects of **quality control** of media and equipment that come in contact with the embryos are strictly adhered to. It is also advisable to use commercially prepared media and sterile disposable supplies.[1]

Embryo Handling and Evaluation

Identification and evaluation of embryos is one of the most challenging aspects that confronts the embryo transfer practitioner, especially the beginner. Embryo quality and poor handling techniques can directly affect pregnancy rates. A stepwise procedure for embryo searching is presented at the end of this section.

Environment

Once removed from the stable protective environment of the uterus the embryo should be handled with respect regarding its temperature, pH, osmolarity, and contaminants, factors that may affect viability. Embryos depend on the ambient fluid to maintain their physiologic integrity and as a source of nutrients.

Embryos may be maintained at room temperature for several hours without decreasing pregnancy rates significantly, provided the embryos are transferred to fresh holding medium every 2 hours. Storing embryos in a temperature-controlled portable incubator is recommended for long distance transportation. There is no obvious decrease in pregnancy rates after storage at these temperatures for 12 to 24 hours. On the other hand, embryos do not tolerate temperatures above body temperature (39°C) very well.

The physiologic range of proper pH for embryos is from 7.1 to 7.5. Thus, the pH of flushing and holding media needs to be within this range. Even a slight change in the salt concentration (osmolarity) of the medium can effectively reduce the viability of embryos. If the salt concentration of the flushing or holding media is below that of the uterine environment, embryos will absorb water and swell to reach osmotic equilibrium, which sometimes results in rupture of the cell membrane. Conversely, if the salt concentration is above that of the uterus, the embryo will shrink in size (dehydration), causing a reduction in metabolic activity. In comparing the two situations, although both are detrimental to embryos, shrinkage would be less detrimental. If PBS is prepared from a powdered mixture, care should be taken that the correct amount and quality of water is added. The normal osmolarity of uterine fluid is 270 to 300 milliosmoles.

Exposing the embryos to ultraviolet rays for a prolonged period may cause cellular death. The use of insecticide sprays in the embryology room should be avoided. Insufficient time of aeration after using ethylene oxide gas for sterilization of equipment is detrimental to live cells. Storage period, different suppliers, and batches (lot number) of sera all affect embryo growth differently.

Identification of Embryos

Evaluation of the embryo in the uterine effluent is based on identification of several morphologic features of the embryo using light microscopy. This is the only practical method to determine suitability of the embryo for transfer and freezing. These methods are subjective and depend on experience.

The embryo is **spherical** and is composed of cells (blastomeres) surrounded by a gelatin-like shell and acellular matrix known as the **zona pellucida.** The zona pellucida performs a variety of functions until the embryo hatches, and is a nice landmark for embryo identification. The zona is spherical and translucent; thus, it is clearly distinguishable from cellular debris. Because of its shape the embryo tends to roll on the bottom of the searching dish.

The overall **diameter** of the bovine embryo is 150 to 180 μm including a zona pellucida thickness of 12 to 15 μm. The diameter remains constant until expansion of the blastocele begins. The color of the morula and (early) blastocyst also facilitates identification because the embryo is usually darker than other uterine debris. Knowing the age of the embryo (days after onset of estrus) is also important in locating the embryo in the searching dish. The fully expanded blastocyst possesses a thinner zona pellucida and is pale (translucent) in color. A spontaneously hatched embryo is very hard to identify because the embryonic mass, without the zona pellucida, is morphologically similar to uterine debris. If the hatched embryo has collapsed, it may still be identifiable but with considerable difficulty. In summary, the important criteria in identifying embryos are (1) shape of the embryo, (2) presence of a zona pellucida, (3) size, (4) color, and (5) knowledge of the age of the embryo.

During embryonic development, cell numbers increase by geometric progression. Synchronous cell division is generally maintained up to the 16-cell stage in embryos. After that, cell division becomes asynchronous and finally individual cells possess their own cell cycle. These cells composing the embryos are termed blastomeres and are easily identified up to the 16-cell stage as spherical cells. After the 32-cell stage (morula stage), embryos undergo **compaction.** As a result, individual cells in the embryo are difficult to identify beyond this stage. The most obvious morphologic manifestation during compaction is the loss of a concise cellular outline. The embryo proper develops from the **inner cell mass,** whereas the surrounding **trophectoderm** primarily gives rise to the chorionic ectoderm of the placenta.

Handling the Embryos

Once an embryo is identified in the searching dish, it is immediately transferred to a small Petri dish (35 × 10 mm) containing fresh, filtered (0.22 μm pore size), sterile holding medium. Embryos are tentatively classified simply as good or bad, and may be recorded on the cover of the holding dish. This allows for a quick account of the total number of embryos found. Embryos are then serially rinsed through at least three different dishes containing fresh sterile medium using a new sterile pipet for each step. Finally, they are placed into a dish awaiting transfer or cryopreservation. Under some circumstances (e.g. for export of embryos) they *must be* rinsed through 10 different dishes containing sterile media and exposed to trypsin.[1] All dishes must be kept covered between searches to avoid contamination, and particularly evaporation, when placed in the incubator. Evaporation of the small volume of medium in a flat dish rapidly leads to hypertonic solutions.

Classification of Embryos

Embryos recovered 5 to 8 days after estrus are **classified morphologically** into the following groups, based on their stage of development. Proper evaluation requires rolling of the embryos along the bottom of the dish.

Morula: Blastomeres are round in shape and are not tightly connected to each other. Individual blastomeres are difficult to discern from one another. The cellular mass of the embryo occupies most of the perivitelline space.

Compact morula (tight morula): The shape of a tight morula is similar to a golf ball, in that the outer edge is slightly undulated (scalloped) in appearance because of compaction. Individual blastomeres are no longer distinguishable. Cells on the surface of the mass are polygonal in shape. The embryo mass occupies 60% to 70% of the perivitelline space.

Early blastocyst: A tiny transparent (clear) space that contains fluid is visible. This area is the beginning of the blastocele. The embryo occupies 70% to 80% of the perivitelline space.

Blastocyst: The prominent blastocele cavity accounts for more than 70% of the volume of the embryo. Two groups of cells are present and clearly recognizable as the trophoblastic layer beneath the zona pellucida and the darker inner cell mass occupying one side of the embryo. The perivitelline space may still be visible but is very small.

Expanding or expanded blastocyst: There is no perivitelline space between the layer of trophoblastic cells and the inside of the zona. The zona pellucida becomes thinner as the blastocyst expands. A small well compacted inner cell mass positioned on one side of the embryo is observed. The color of the embryo is pale to clear because of the large amount of fluid present inside.

Collapsed blastocyst: There is perivitelline space along with a very thin zona pellucida. The blastocyst may be partially collapsed, with a smaller blastocele cavity, or completely collapsed and having the appearance of a compact morula.

Hatched blastocyst: Ultimately the blastocyst expands to the point of rupture and the embryo escapes from the disrupted zona. Hatched blastocysts may be spherical with a well-defined blastocele or they may be collapsed, resembling debris. Identification of embryos at this stage can be difficult for the inexperienced operator.

When zona-free, or hatched, blastocysts are collected, there is a greater risk of damage due to handling. Furthermore, hatched blastocysts are sticky and may adhere to tubing and glassware. Embryo filters should not be used when there is a possibility that hatched embryos will be recovered (>day 7.5).

Embryos are then classified according to **quality** based on morphologic appearance. Excellent/good, fair, and poor quality embryos are considered transferable into recipients. Excellent or good quality embryos (Code 1) are freezable.

Codes for Embryo Quality[1]

Code 1: Excellent or good. Symmetrical and spherical embryo mass with individual blastomeres (cells) that are uniform in size, color, and density. The embryo is consistent with its expected stage of development. Irregularities should be relatively minor and at least 85% of the cellular material should be an intact, viable embryo mass. This judgment should be based on the percentage of embryo cells represented by the extruded material in the perivitelline space. The zona pellucida should be smooth and have no concave or flat surfaces that might cause the embryo to adhere to a Petri dish or a straw.

Code 2: Fair. Moderate irregularities in overall shape of the embryo mass or size, color, and density of the individual cells. At least 50% of the cellular material should be an intact, viable embryo mass.

Code 3: Poor. Major irregularities in shape of the embryo mass, or size, color, and density of individual cells. At least 25% of the cellular material should be an intact, viable embryo mass.

Code 4: Dead or degenerating. Degenerating embryos, oocytes, or 1-cell embryos are nonviable.

Loading the Straw

Immediately prior to nonsurgical transfer, embryos are loaded individually in sterile 0.25 ml French straws. The embryo is aspirated from the holding dish into the straw with the aid of a 1 ml tuberculin syringe attached to the plug end of the straw. First a 3 cm column of medium is aspirated into the straw, followed by a 0.5 cm column of air, then a 3-cm column of medium containing the embryo, followed by another air bubble. The remainder of the straw is filled with medium until the initial column of medium wets and solidifies the plug.

Recipient Selection and Synchronization

1. Recipients should be large-framed, healthy, mature young cows or heifers in good body condition. A minimum of two normal cycles should ideally have been recorded before use, whether they will be synchronized with prostaglandins or selected from a pool of cycling animals. It has been common in embryo transfer programs to overlook the quality of the recipients. Recipients and their maintenance represent the greatest single cost of running a commercial bovine embryo transfer program. Culls from a breeding program, animals in poor condition, and early postpartum animals do not make suitable recipients. Recipients should not be fat and should preferably be gaining 0.1 to 0.2 kg per day. They should be vaccinated for the common abortion diseases.
2. Synchronous recipients can be produced in three ways: (1) Selection from a large pool of cycling females. This strategy limits the number of embryos and time when embryos can be collected. Approximately five percent of the herd will be in heat on any given day. (2) Estrous cycles of any number of recipients can be synchronized with $PGF_{2\alpha}$ or its analogues, or with CIDR devices, to exhibit heat the same day as or just ahead of the donor. (3) Timed ET, analogous to timed AI (Ov-Sync), can also be used. The importance of close synchrony between the age and the stage of development of the embryo, and the endocrine status of the endometrium of the recipient must be emphasized. Pregnancy rates following embryo transfer are best when the recipient is in estrus from 36 hours before to 12 hours after the donor.
3. The average bovine donor yields 6 to 8 transferable embryos. Therefore, 8 recipients per donor is a reasonable number to prepare. When recipients are palpated for corpora lutea, about 12 need to be palpated in order to definitely identify 8 with active corpora lutea. Not all donors will respond to the superovulatory treatment or yield transferable embryos. For optimal efficiency, two to four donors should be superovulated at the same time, which permits sharing of the prepared recipients and avoids the expensive disappointment encountered too frequently when only one donor is prepared at a time.
4. It is sometimes difficult for the embryo transfer practitioner to locate and identify a CL at the time of transfer to a synchronized recipient. Ultrasonography can identify a solid CL (>12 mm) or a fluid-filled CL with at least 3 mm of luteal tissue surrounding the central cavity. Not every recipient needs to be examined by ultrasonography, but if there is a reason for doubt, the presence of a suitable CL can be confirmed with ultrasound.
5. Embryos are routinely transferred about 7 days after the onset of estrus. Nonpregnant recipients and occasional pregnant recipients will show estrus 14 days after transfer. These animals may be examined by palpation, milk progesterone determination, or ultrasound to confirm the occurrence of true heat and the absence of a CL.
6. Early identification of nonpregnant recipients allows efficient and economical re-use of suitable animals. Of cows diagnosed pregnant using ultrasonography at 28 days after AI, 13.5% experienced early embryonic death by 56 days after AI in one study. Therefore, cows diagnosed

pregnant at 28 days of gestation by ultrasound should be re-examined around 60 days of gestation. This is also a good time (55 to 70 days) to use ultrasonography for gender determination of fetuses with unique genetic merit.

Embryo Transfer Procedure

Bovine embryos are transferred directly via the cervix, analogous to artificial insemination. It is important to minimize contamination of the uterus because it is more susceptible to infection during the luteal phase. Feces are evacuated from the rectum and the ovary containing the corpus luteum is determined. Epidural anesthesia is induced to prevent straining and defecation. The perineal area is washed, and the vulva is blotted dry.

In the laboratory, the embryo is aspirated into the 0.25 ml French straw between two air pockets and two columns of culture medium as described above. The straw is inserted into the transfer syringe and shortened to fit even with the end of the gun. A sterilized sheath is fitted over the transfer gun. A second, larger plastic sleeve, which is closed at the distal end, is fitted over the first to serve as a protective cover and permits passage of the gun through the vagina without coming into contact with the vaginal flora. The tip is placed into the external os of the cervix and is then pushed through the outer plastic sleeve before it is guided through the cervical canal and as gently as possible into the uterine horn on the side of the corpus luteum. The embryo is then gently deposited approximately one third of the way into the uterine horn ipsilateral to the CL and the gun is slowly withdrawn. A negative correlation has been demonstrated between the time spent manipulating the cervix and the uterine horn, and the pregnancy rate. Trauma to the delicate endometrium causes bleeding, and blood (complement in the serum) is embryocidal. Success is related to dexterity and practice, and pregnancy rates achieved by most operators improve with experience.

Donor and Recipient Aftercare

It is common practice to treat the donor with prostaglandins after the collection of embryos. The ovaries are generally greatly enlarged by the excessive number of corpora lutea. This treatment will not only rapidly reduce the size of the ovaries, but also terminates any unwanted pregnancies should an occasional embryo not have been flushed out. It is best not to breed the donor on this induced heat 3 to 5 days later. Furthermore, like a spontaneous heat, the induced heat will have a salutary effect on uterine health should any contamination have been introduced at the time of the collection.

Cows can be superovulated at 2-month intervals for three treatments without an appreciable decrease in embryo recovery rate. Single embryo collections may be made when the animals come into estrus and are inseminated between these superovulatory treatments.

Pregnant recipients should basically be managed like other pregnant cows. Overly fat recipients are undesirable. When the recipients have reached day 21 to 24 of their cycle (14 to 17 days after transfer on day 7), a presumptive diagnosis of pregnancy can be made based on palpation of a CL, or indirectly by determining an elevated concentration of progesterone in the milk or plasma. The conceptus may also be identified by ultrasonography at about day 26 or 27. Definitive pregnancy examinations are made at 5 weeks after transfer and confirmed at 3 months by palpation per rectum.

CRYOPRESERVATION

Cryopreservation of embryos offers several important logistical and economic advantages. First, since generally two or more donors are superovulated and flushed at the same time, there may be an excess of embryos for the number of available, synchronized recipients. Second, when the number of prepared recipients exceeds the number of fresh embryos, previously frozen-thawed embryos may be used, for the cost of maintaining large numbers of nonpregnant recipients over an extended period of time is high. Third, frozen embryos can be marketed directly by the owner of the donor, eliminating the need for shipment of pregnant recipients. Fourth, importation and exportation of frozen embryos can be an important method of disease control.

The major physical and chemical consequences of cryopreservation are the removal of pure water from the solution, which results in the formation of ice crystals and an increase in the concentration of solutes. These processes are influenced by the type of freezing medium, the osmolarity and pH of the fluid, and the rate of cooling. Damage to the embryos (cells) is caused by internal ice crystal formation, the ion concentration, and the interaction between these two physical factors. Cryoprotectants are used to protect the cells during the freezing and thawing procedures by changing the size and shape of the crystals. Both penetrating cryoprotectants, which are small molecules such as glycerol or ethylene glycol, and nonpenetrating large molecules, such as sucrose, are used.

The first prerequisite for success with any of the cryopreservation methods is to select only the best quality embryos (Code 1) for freezing. Advanced morula to blastocyst stage embryos have the highest survival rate. Some of the cells comprising the embryo will be killed/damaged by freezing and thawing. Lower grade embryos usually already have a number of dead cells and hence an insufficient number of cells to survive the freezing process, which results in unsatisfactory pregnancy rates. Embryos should be frozen within 3 to 4 hours after recovery.

It is critical to follow freezing protocols carefully and with attention to detail to minimize prolonged exposure to the cryoprotectant, which is toxic to the embryo. Freezing machines must be calibrated accurately to avoid seeding at temperatures above –5° C. Seeding is the process of induction of the formation of small ice crystals by touching the straw containing the embryo with a supercooled instrument. The small ice crystals subsequently spread throughout the solution and prevent the sudden formation of large ice crystals, which might injure the cells of the embryo. Other prerequisites include proper sealing of the straws to keep liquid nitrogen from entering the straw, which results in explosion of straws

upon thawing, and again avoiding prolonged exposure to the cryoprotectant during thawing.

Slow Cool Freezing Protocols

Currently bovine embryos are frozen by slow cool freezing methods using either ethylene glycol or glycerol. Ethylene glycol has the advantage that embryos can later be thawed and transferred directly, but glycerol has to be removed in stepwise fashion upon thawing and this procedure requires the use of a microscope and time. Freezing protocols are basically the same for ethylene glycol and glycerol. Ethylene glycol is a much smaller molecule and hence penetrates more rapidly but is much more toxic to the embryo than glycerol. To freeze for **direct transfer**, embryos are equilibrated for 5 to 10 minutes in 1.5 M ethylene glycol in PBS, part of which can be done while loaded in the straw at room temperature. At this temperature (–6 to –7° C) the straw is held for an additional 5 minutes, after which it is cooled at a rate of 0.5° C per minute to –33° C. After holding for 15 minutes at –33° C the straws are plunged directly into liquid nitrogen.

When freezing with glycerol, it is simplest to use a commercially prepared liquid embryo freezing medium, which contains PBS + 0.4% BSA + 10% glycerol. To freeze, embryos are equilibrated for 10 to 15 minutes in the 10% glycerol freezing medium. The remaining steps are the same as the preceding steps for ethylene glycol (in the freezing unit at –6 to –7° C for 5 minutes, seeded, held for an additional 5 minutes, and cooled at a rate of 0.5° C per minute to –33 C).

Each embryo is aspirated into an individual 0.25 ml straw by inserting the straw, plug end first, into the tip of a tuberculin syringe. The straw should first have been rinsed with freezing medium (up to, but not including, the cotton plug) to remove any toxic residues.

The 0.25 ml straw is loaded in the following order: a column of freezing medium, a bubble of air, the embryo in a column of freezing medium, a bubble of air, a column of freezing medium, so that the straw is full when the initial column wets the cotton plug. Both ends are then sealed with a small plug.

The Manual of the International Embryo Transfer Society provides detailed guidelines for labeling straws.[1] Half-length 0.50 ml straws are labeled beforehand. Accurate identification of the embryo(s) in each straw is imperative and should include identification of the donor registration number and the semen code.

Identification of Embryos for Direct Transfer (with Ethylene Glycol)

The *Manual of the International Embryo Transfer Society* stipulates the following for all embryos frozen for *direct* transfer[1]:

1. They must be frozen in a yellow translucent straw. This means that the straw, though yellow, is sufficiently transparent so that the embryo and the air locks are clearly visible. Such straws are available from vendors.
2. The letters DT precede the straw number on the label and the vendors will preprint this on yellow translucent straws if requested. The individual straw number may drop to the second line of the label when necessary but not separate from DT that precedes it.
3. If the label is on the plug extended from the end of the straw in which the embryo is frozen or if the label is on or within an extension of the straw in which the embryo is frozen, such plug or extension must be yellow.
4. The goblet in which embryos frozen for direct transfer are stored must be yellow.
5. The head of the cane that holds a yellow goblet that holds embryos frozen for direct transfer must be yellow.
6. Yellow should not be used for any other straws, goblets, labels or cane heads.

Thawing Protocol for Embryos Frozen in Glycerol

1. Remove the straw from the liquid nitrogen and hold it in the air for 15 seconds followed by 15 seconds in 37° C water.
2. Dry the straw and recover the embryo by cutting the heat-sealed end of the straw with clean scissors or by removing the plastic plug, and expelling the embryo by using the cotton plug as a plunger.
3. Glycerol is removed from the embryo by dilution in four steps lasting 6 minutes each: (1) 6% glycerol plus 10% sucrose in PBS plus 0.4% BSA; (2) 3% glycerol plus 10% sucrose in PBS plus 0.4% BSA; (3) 10% sucrose in PBS plus 0.4% BSA; (4) PBS plus 0.4% BSA. Instead of 0.4% BSA, 10% heat-inactivated serum may be used. Thawing media may also be purchased commercially.
4. The embryos should be evaluated as soon as possible after removal of the cryoprotectant. The embryos are frequently slightly darker in appearance, and the inner cell mass is smaller than that of fresh embryos. Occasionally the zona pellucida is cracked. If procedures are done properly, less than 5% of the embryos will have degenerated. Degenerated embryos should generally be discarded; however, if recipients are available they may be transferred anyway; a few will turn into calves.
5. Embryos should be aspirated from the final dilution medium into a rinsed, new 0.25-ml straw and immediately transferred to synchronized recipients.

If procedures are carried out correctly, pregnancy rates will be about 80% of those for unfrozen embryos transferred under similar circumstances.

Protocol for Direct Transfer

1. Line up recipients: (a) verify heat date, which should be 7 days earlier in most cases; (b) palpate for the presence of a corpus luteum and mark the appropriate side of the recipient with a crayon; (c) clip/scrub/disinfect for epidural anesthesia; (d) inject 5 ml 2% lidocaine to cows, 4 ml into heifers.

2. Prepare DT straw: (a) place liquid nitrogen tank and thawing unit side by side; thawing unit temperature should be 30°C (90°F) or less; (b) identify cane and straw; (c) remove straw, hold in air for 5 seconds, then place in thawing unit for 20 seconds while swirling; (d) dry straw, cut straw, and load straw in transfer syringe; (e) cover syringe with sanitary sheath.
3. Transfer immediately by placing the embryo one third of the way into the horn ipsilateral to the CL.

Vitrification Freezing Protocols

Vitrification is a newer alternative for freezing embryos that uses a higher concentration of cryoprotectants, avoids ice crystal formation, and places embryos in a glasslike state. It is very fast, requires less sophisticated equipment, and is thought to reduce the chilling and osmotic injury seen in slow cooling methods. The high toxicity produced by increased concentrations of cryoprotectants is avoided by quickly loading embryos into special straws, cryoloops, or droplets and directly plunging them into liquid nitrogen. One drawback to vitrification, however, is that direct embryo transfer results are not optimal, so embryos must first be rehydrated in a stepwise fashion before transfer.

Currently, there are several protocols for embryo vitrification. The most commonly used method[2] involves pre-equilibrating embryos in 7.5% ethylene glycol (EG): 7.5% DMSO in M199/20% FBS for 3 minutes, followed by quickly transferring embryos into vitrification medium (16.5% EG:16.5% DMSO in M199/20% FBS), loading them into open pulled straws and rapidly plunging them into liquid nitrogen. Vitrified embryos are thawed by immersing them in 0.25 M sucrose in holding medium for 1 minute and then transferring them to 0.15 M sucrose in holding medium for 5 minutes, followed by two 5-minute incubations in holding medium. Embryos can then be placed into culture or transferred to synchronized recipients, as described above. This method results in 7% to 95% viability after thawing, and pregnancy rates of 33% are common.

IN VITRO PRODUCTION OF EMBRYOS

In vitro production of embryos (IVP) refers to the use of laboratory procedures to generate embryos for transfer, freezing, and other biotechnologies including cloning and transgenesis. In vitro production systems offer additional options to conventional ET for obtaining embryos from donor cattle of superior genetic merit. The first calf resulting from the transfer of an embryo derived from an in vivo–matured oocyte, fertilized in vitro was reported by Brackett and colleagues in 1982.[3] Currently, embryos are routinely produced in laboratories world wide using a variety of embryo culture systems. In cattle, IVP typically consists of the following four components: retrieval of oocytes from ovarian follicles, in vitro maturation of oocytes (IVM), in vitro fertilization (IVF), and in vitro culture (IVC) of presumptive zygotes to the morula or blastocyst stage of development. This section will address the applications of IVP in cattle, as well as provide an overview of IVP procedures and expected results.

Applications of IVP

The development of effective methods for retrieving oocytes from donor cows and the concurrent refinement of in vitro culture systems to produce large numbers of embryos have resulted in creative applications of IVP in cattle. In vitro embryo production systems are used in the cattle industry, the biotechnology industry, the conservation of rare or endangered breeds, and research. Furthermore, IVP is an integral part of cloning, as discussed below. In the cattle industry, production of embryos in vitro is an alternative technology to conventional ET for generating embryos using sexed or unsexed sperm, and ultimately calves from the transfer of these embryos. Embryos produced in vitro may be transferred into recipients on day 7 or 8 of the estrous cycle or frozen for future transfers.

Oocyte retrieval and in vitro embryo production may be practiced in nonpregnant cows and heifers, pregnant cows up to about 110 days of pregnancy, and postpartum cows not responsive to FSH treatment for superovulation. Additional candidates for IVP include cows with a history of poor response to superovulation treatments, cows with reproductive problems such as acquired blockage of the uterine tubes, cows with terminal illness, and cows at slaughter. Large numbers of embryos may be generated using oocytes obtained from ovaries at an abattoir. In vitro embryo production may also be used to make half-sib embryos for transfer by fertilizing in vitro–matured oocytes with semen from different sires. Cattle producers will often alternate between conventional superovulation and IVP in attempt to increase embryo yield from valuable donor cows. In vitro embryo production services are commercially available at several embryo transfer companies and universities.

Oocyte Recovery and Transport

The first step in the IVP procedure is to obtain potentially competent oocytes from ovarian follicles of the donor cow. Ovarian follicles may be aspirated using laparoscopy, or more commonly by using ultrasound-guided **transvaginal oocyte retrieval** (TVOR). In cases of genetic salvage, the ovaries may be surgically removed using colpotomy in mature cows or by standard flank approach ovariectomy in heifers or cows.[4,5] Oocytes can also be harvested from ovaries obtained at an abattoir.

The skilled practitioner can learn to harvest oocytes from the ovaries of cows on the farm using ultrasound-guided TVOR. Briefly, the cow is restrained in a squeeze chute, and the external genitalia and perineal area are cleaned with a Betadine scrub, rinsed, and dried. A standard epidural block of 2% lidocaine hydrochloride is administered to the donor cow, and a sedative may also be administered as needed. The transvaginal aspiration system consists of a good quality ultrasound unit fitted with a 7.5 MHz probe, a vacuum pump and regulator, a probe handle for housing the ultrasound probe, and aspiration needle. The hub of the aspiration needle is attached by tubing to an oocyte collection container, such as a 50 ml conical centrifuge tube or an embryo

collection filter. An additional piece of tubing connects the oocyte collection container to the vacuum pump. The aspiration needle and tubing are first flushed with medium containing heparin. The probe handle containing the ultrasound probe and aspiration needle is then inserted into the vaginal vault. The operator's opposite hand stabilizes the ovary near the cranial vagina using per rectum palpation technique. As ovarian follicles are visualized on the ultrasound screen, the operator carefully advances the aspiration needle through the vaginal wall and pierces follicles to be aspirated with the needle. Follicular fluid and oocytes are aspirated into the collection tube or filter using a vacuum pressure of about 75 mmHg.

Oocyte retrieval can begin in cows at approximately 30 days post partum, a time when cows are not usually responsive to superovulation treatment. The TVOR procedure can be repeated as often as twice weekly until the desired number of oocytes is obtained from the cow. Each TVOR procedure takes approximately 30 minutes to perform. Oocyte yield following TVOR attempts is variable between donor cows; however, 4 to 6 oocytes suitable for IVP are commonly obtained from a healthy donor cow.[6,7] In a large study at a commercial ET facility, the mean number of oocytes per TVOR attempt in Holstein donor cows ranged from 1.5 to 10.9 oocytes with 7.2% of oocyte collections yielding no oocytes.[6]

Recovered oocytes in follicular fluid and medium should be maintained at 39° C. Bovine oocytes may be shipped to an IVP facility using counter-to-counter or overnight services. Oocytes may be shipped in oocyte maturation medium held in a temperature-controlled portable incubator. Ovaries for shipment should be held in physiological saline with 0.75 μg/ml penicillin in a sealed thermos bottle, and shipped in a cooler or Styrofoam box containing warm packs as needed. After arrival at the IVP facility, oocytes are aspirated from follicles and placed in oocyte maturation medium. Frozen semen to be used for IVP should be shipped to the facility either prior to or at the same time as shipment of the donor's oocytes or ovaries. Ideally, the semen should first be tested in the IVP system using oocytes obtained at a slaughterhouse.

In Vitro Procedures and Results

In the laboratory, immature oocytes with their cumulus cells (cumulus oocyte complexes, COC) are washed in modified Tyrodes medium (TL-Hepes), and matured for approximately 22 hours in vitro using tissue culture medium-199 (TCM199) with supplements. At the end of the maturation period, COC are placed in fertilization medium (TALP medium with supplements) with thawed frozen spermatozoa selected for high motility using swim-up or Percoll sperm separation procedures. Gametes are co-incubated for 18 to 20 hours after which time presumptive zygotes are washed in TL-Hepes and placed into culture medium. Bovine embryos have been successfully cultured to the blastocyst stage using undefined media (commonly, TCM199 plus co-culture cells, serum, and other components), semidefined media (e.g., modified synthetic oviductal fluid, SOF with BSA), and fully defined media (e.g., SOF with polyvinyl pyrrolidone, PVP).

The yield of transferable quality embryos after IVP varies from about 20% to 40% or greater. Embryo yield from cows in poor body condition, terminally ill, or infertile is often low and more unpredictable than that from healthy cows. The consistent production of good to excellent quality morulae and blastocysts from an IVP system requires meticulous attention to detail. A number of factors can influence the survival of embryos produced using in vitro systems including medium composition, atmosphere, oocyte quality, and embryo genotype.

Acceptable pregnancy rates can be achieved following transfer of in vitro–produced embryos; however, these pregnancy rates are often lower than those seen after transfer of in vivo–produced embryos.[6,7] Pregnancy rates of recipients following transfer of in vitro–produced embryos of grade 1 (good/excellent) were greater than those for embryos of grade 2 (46.9% versus 35.6%; 60% versus 46%). In addition to embryo quality, pregnancy rates after transfer of embryos produced in vitro are influenced by embryo culture medium, stage of embryo development, fresh versus frozen embryos, and synchrony of embryo development and recipient's day of the estrous cycle.

CLONING

Cloning is the production of a copy or copies of an individual and occurs in animals either naturally or artificially, when an embryo is split to produce identical twins. The word "clone" has also been used to describe animals produced by nuclear transfer for the production of an unlimited number of genetically identical offspring. The first successes in cloning livestock were with sheep, by fusing a cell from a 16-cell embryo to an oocyte that had its chromosomes removed (enucleated oocyte). From that time through the early 1990s several groups began developing this technology for the commercial production of cloned beef and dairy cattle. However, the biggest breakthrough in nuclear transfer came when it was demonstrated that a viable offspring could be produced by fusing cultured adult somatic cells with enucleated oocytes to produce Dolly the sheep in 1997. Cloning with adult cells offers the advantages of cloning from genetically proven animals, and production from cultured cells ensures an unlimited supply from which to clone. Somatic cell cloning has now been successful for cloning cattle, sheep, horses, mules, goats, pigs, many laboratory animals, as well as dogs and cats. This topic is covered in greater detail in our review.[8]

Applications of Cloning

The main application of cloning to the livestock industry is for expanding superior genetics. Animals of high genetic merit, male or female, can be selected for cloning based on any desirable trait, including growth, feed efficiency, and disease resistance. Production of numerous animals of exceptional genetic merit would allow for more rapid genetic progress and the associated economic benefits. The nutrition, reproduction, and health of these animals should be more easily managed because of animal uniformity.

Nuclear transplantation has also been useful for salvaging old genetics and exotic breeds. Germ plasm from a breed of cattle on Enderby Island that had essentially gone extinct was preserved using somatic cell nuclear transfer from the only remaining cow. Additionally, this technology can be used to import and propagate new or exotic breeds of cattle that may offer other desirable genetic traits not currently available for use in cross breeding schemes. Moreover, tissues can be harvested from recently deceased animals and propagated for use in cloning. This also has a tremendous advantage in the slaughterhouse, where superior carcasses can be selected and tissues taken for future cloning.

Another way in which cloning will impact the livestock industry is with genetically engineered donor cells. Through the various genome projects, the genomes of different organisms are being sequenced and the genes that impact different traits are being identified. As this information is made available, we will be able to add, remove, or modify genes of economic importance to the livestock industries in donor cells prior to cloning.

Research communities are also interested in producing cloned livestock. Using a uniform set of identical animals is ideal for conducting certain types of experiments. It removes genetic variability so that only the effects of the treatments or environment are measured. Therefore, it would be faster and easier to test, for example, new vaccines to determine the best treatment, reducing the number of animals needed to come to these conclusions. Additionally, researchers have found that livestock in some cases are better models for studying disease. Clones could be genetically engineered to mimic particular genetic disorders and compared to nonengineered clones so that only the gene causing the disease would be different. New treatments for the disease would then be more easily tested to determine which is the most effective.

Current Methods

Cloning first requires a supply of cells from the donor animal to be cloned. It is not yet clear which cells are the most effective for producing live cloned offspring. Currently, biopsies are taken either from fetuses or adults, essentially from any tissue in the body, and then propagated in culture to generate fibroblasts. It is critical for the practitioner to ensure that the area to be biopsied be thoroughly cleaned with disinfectant, and the tissue be collected using sterile technique in order to remove any chances of contamination, which could render the sample unusable. Tissue biopsies are transported to the lab, where they are minced and/or treated with enzymes and cultured to obtain cell lines. These cell lines can be expanded in large quantities and frozen in liquid nitrogen for future use. At the time of cloning, cells are removed from tissue culture plates by trypsin treatment and held in suspension until transfer.

Nuclear transfer involves removing the chromosomal DNA from mature oocytes and transferring the genetic material from a cell of the donor animal to be cloned through a process of fusion and reprogramming (Fig. 63-1). Briefly, immature oocytes are collected either from slaughterhouse ovaries or by transvaginal oocyte retrieval (TVOR) and matured in vitro as described above. After 18 to 22 hours, oocytes are stripped of their surrounding cumulus cells, and those with visible polar bodies (mature metaphase II oocytes) are selected for further manipulations. Using micromanipulators, each oocyte is enucleated by piercing the zona pellucida with a glass needle and removing the polar body with a small amount of the adjacent cytoplasm, containing the oocyte's chromosomal material, which is then discarded. A donor cell from the animal to be cloned is then transferred through the same hole in the zona of each enucleated oocyte. The donor cell is then fused to the enucleated oocyte by alignment in a fusion chamber and applying one or two DC pulses of 2.25 KV/cm, 15 μsec each, although voltage and timing may vary. Fused couplets are activated by either chemical or electrical stimulation in order to mimic sperm penetration and finish the reprogramming and maturation process. Reconstructed cloned embryos are then cultured in vitro for 6 to 9 days and evaluated for development. Viable compact morula and blastocyst-stage embryos are transferred to synchronized recipients

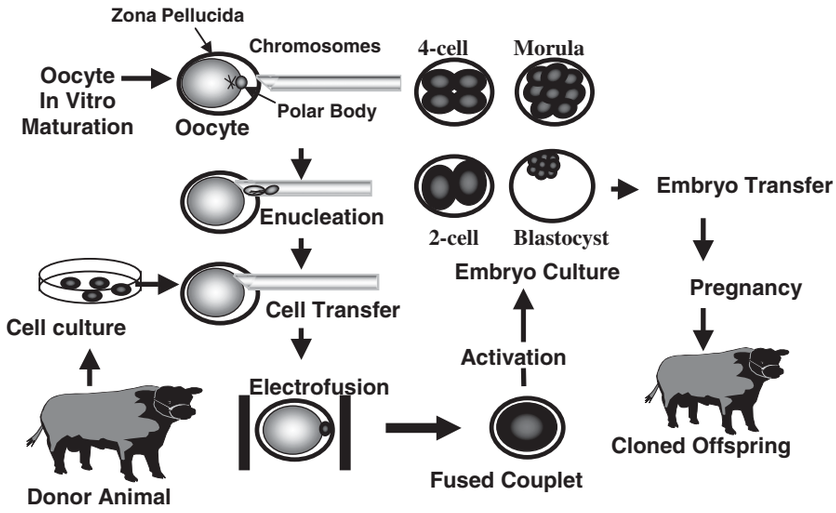

Fig. 63-1 General overview of procedures for producing a cloned calf.

as described above and carried to term in order to produce live cloned offspring. Additional care is required for recipients receiving cloned embryos and is addressed below. Cloning is now commercially available through several companies and universities.

Challenges in Cloning

Currently, the technology of nuclear transfer is quite inefficient. It is apparent that the inefficiencies of micromanipulation, with an average fusion rate of 64%, and an average blastocyst development rate of 33%, production of cloned embryos can still be improved upon. It is not clear yet which donor cell types give the best results; however, it is well established that younger passage cell lines yield more favorable results. Furthermore culture conditions of donor cell lines can greatly impact the survival rates of cloned embryos produced from them. There are additional factors that have an impact on the production of a live offspring that need to be addressed. These include early embryonic and fetal losses, which can occur any time during gestation. Losses occur most often between days 30 and 90 of gestation, and can be as high as 80%. On average, only 10% of cloned embryos transferred are carried to term, or less than 1% of the cloned embryos originally constructed. These issues are addressed below.

Another concern for nuclear transfer is the potential loss of genetic diversity. Although unlimited numbers of identical cattle can be produced with cloning, it should not replace natural breeding. If it did, it could result in loss of genetic variation and inbreeding, which are not desirable. This same concern was addressed when artificial insemination first became popular. Producers should be aware of these possibilities, and with proper guidance and management of breeding schemes, problems such as these will not occur.

CALVES FROM IVP AND CLONED EMBRYOS

The use of in vitro embryo production and cloning has stimulated considerable interest in the effects of reproductive biotechnologies on the offspring. The sex ratio of calves from conventional ET is not significantly different from that of calves resulting from AI. However, the selection and transfer of advanced stage embryos produced in vitro often results in slightly more bull calves. This may be attributed to the intriguing finding that male embryos tend to develop more rapidly in vitro than female embryos.

The birth weight of calves resulting from routine ET is not significantly different from that of calves resulting from AI. However, the transfer of embryos produced either in vitro using a variety of culture systems or by cloning has resulted in calves with normal to altered birth weight and development. An increase in calf birth weight of 15% or greater is often the most striking observation to a producer— hence, the term large offspring syndrome (LOS).[7,9-11] However, these calves can have other distinct developmental abnormalities involving the placenta, fetus, and/or calf, with or without an increase in birth weight.[12] Thus the term abnormal offspring syndrome (AOS) has been proposed to more accurately describe this syndrome.[12]

Commonly reported abnormalities associated with AOS include increased calf birth weight, hydrops of the allantois, reduced placental vascular development, increased abortions and dystocia, and increased perinatal death. For calves produced from cloned embryos, the increase in calf birth weight and other physical and biochemical abnormalities are often extreme. This condition has been reported in cattle, sheep, and mice. The biologic mechanisms that underlie this important condition remain to be uncovered. However, alterations in the expression of imprinted genes (e.g., IGF2 and IGF2 receptor), as well as nonimprinted genes (e.g., myostatin) most likely play a role.[10, 12]

Veterinarians attending to recipients carrying fetuses from in vitro–produced or cloned embryos need to regularly monitor the pregnancies by palpation and ultrasonography. Recipients carrying pregnancies from the transfer of these embryos should be given special attention at the time of calving because they may require obstetric assistance including cesarean section. Furthermore, neonatal calves may exhibit hypoxia, hypothermia, hypoglycemia, metabolic acidosis, and weakness.[9,12] Intensive neonatal care including administration of intravenous fluids and supplemental oxygen may be necessary to enhance calf survival rates.

In summary, in vitro production and cloning systems are effective for producing additional embryos and calves from donor cows and heifers. However, the practitioner should be prepared to monitor the pregnant recipient and address the problems that may occur in the recipient and the newborn calf. An important challenge facing IVP and cloning biotechnologies in cattle is the development of culture media that will consistently result in a higher percentage of viable blastocysts, normal pregnancies, and calves.

CONTROLLING SEX OF CALF

Embryo and semen technologies can be used alone or together to produce calves of the desired sex. This can be accomplished by determining the sex of the embryo before transfer, AI of single- or multiple-ovulated females with sexed sperm, using sexed sperm in in vitro embryo production systems, and by cloning.

Procedures for determining the sex of an embryo recovered from a donor cow or produced in vitro are well established. Briefly, a biopsy is obtained from the embryo mass using micromanipulation equipment, and then Y-chromosome-specific DNA within blastomeres is amplified using polymerase chain reaction (PCR). The sex of an individual embryo can be determined within hours with greater than 95% accuracy.[13] However, procedures for sexing embryos are expensive and require a high level of laboratory skill to perform. Biopsy of an embryo also can decrease the embryo's viability. In addition to determining sex of the embryo, biopsy and PCR may be used to detect specific traits of importance to health and production. For example, bovine leukocyte adhesion

deficiency (BLAD) can be detected in an embryo biopsy by PCR assay.[14]

Sexed bovine sperm is now commercially available and is an appealing technology for selectively producing heifer or bull calves. Sperm cells can be separated using a high-speed flow cytometer cell sorter into X- and Y-chromosome bearing populations. Spermatozoa are sorted through the equipment based on slight difference in DNA content; sperm cells containing X-chromosomes have about 4% more DNA. Approximately 10 million live sperm cells can be sorted by the equipment per hour with about 90% accuracy.[15] Insemination with sorted spermatozoa has resulted in the production of calves of the desired sex with about 90% accuracy (87.8% female calves from X-sorted sperm, and 92.1% male calves from Y-sorted sperm).[16] Thus, breeding programs can be targeted to produce calves with a wide array of specific purposes such as replacement heifers, bull calves for steer/beef production, and bull calves as potential AI sires. Field trials conducted with heifers inseminated with sexed semen demonstrated that pregnancy rates were 70% to 80% of that seen with unsexed semen. As with other reproductive technologies, breeding programs with sexed semen are more successful in well-managed herds. Based on data from more than 1000 calves, AI with sexed semen resulted in calves that did not differ in physical, health, or growth characteristics compared to calves from AI with unsexed semen.

Sexed semen can also be used to produce sexed embryos by insemination of superovulated cows or by in vitro fertilization of oocytes. The sexed embryos can then be transferred into synchronized recipients, as previously discussed. The production and transfer of embryos of known sex could potentially reduce the costs associated with conventional ET using unsorted semen. Currently, the limitations of sexed sperm technology in cattle are that expensive equipment is needed to sort sperm cells, lower efficiency of production per straw of semen, limited number of bulls available for selection as sires, higher cost per straw of sexed semen, and decreased fertility compared to unsorted sperm. Improvements in production efficiency and fertility of sexed semen could result in huge potential benefits for the dairy and beef industries.

CHAPTER 64

Clinical Reproductive Anatomy and Physiology of the Buck

HARI O. GOYAL and MUSHTAQ A. MEMON

ANATOMY OF THE REPRODUCTIVE TRACT

The male reproductive organs include a pair of testes, which produce sperm and hormones; a pair of excurrent ducts (rete testis, ductuli efferentes, epididymis, and ductus deferens) where sperm mature and then are stored (in the tail of the epididymis) until ejaculated; a penis, which serves as a copulatory organ; and a set of accessory sex glands whose secretions (seminal plasma) form the bulk of the semen (Fig. 64-1).

The testes, although developed in the abdomen, migrate prenatally through the inguinal canal into the scrotum. The mature testes are ovoid in shape and positioned vertically in the scrotum; each testis can weigh 90 to 100 g in a 2- to 3-year-old Nubian buck with a 28 to 30 cm scrotal circumference.[1] The rete testis, a network of intercommunicating channels, occupies almost two thirds of the central axis of the testis. The ductuli efferentes, a group of 15 to 20 tubules, connect the rete testis with the epididymis, which, although a single tube about 60 to 80 m long, can be divided into three main regions: head, body, and tail. The head lies on the dorsocaudal border of the testis, the body is a thin strip-like structure attached on the caudomedial border of the testis, and the tail is an enlarged promontory structure located on the ventromedial border of the testis that can be palpated through the scrotum in mature goats. The ductus deferens connects the tail of the epididymis to the pelvic part of the urethra. Enwrapped by its own peritoneal fold, the ductus deferens ascends through the inguinal canal to enter the abdominal cavity at the vaginal ring. It then separates from the other parts of the spermatic cord and pursues a course via the genital fold to the caudal part of the bladder. The distal part of the ductus deferens enlarges to form the ampulla, which is 6 to 7 cm long and 4 to 5 mm in diameter, and dips under the prostate to open with the excretory duct of the seminal vesicle on the side of the colliculus seminalis.[2]

Seminal vesicles, the largest of the accessory sex glands, are elongated saccular organs with a lobulated surface. They lie on each side of the caudal part of the dorsal surface of the bladder. Each gland in a 2- to 3-year-old Nubian buck is about 4 cm long, 2.5 cm wide, and 1.5 cm thick.[2] Although they lie in close contact with the rectum, it is difficult to palpate them through the rectal wall. Each excretory duct passes through the prostate gland and opens on the colliculus seminalis. The entire prostate gland is disseminated and completely surrounds the wall of the pelvic urethra. Numerous small ducts carry the prostatic secretion into the urethra. The paired bulbourethral glands lie on the dorsal surface of the urethra opposite the ischial arch and are covered by a thick layer of dense connective tissue and by the proximal part of the thick bulbospongiosus muscle. The excretory duct of each gland opens into the urethra under a blind fold of mucous membrane, which makes it difficult to pass a catheter into the bladder.

The penis is classified as fibroelastic because it is covered by thick fibrous tissue with relatively poorly developed venous sinuses. It is rigid even in the quiescent stage. Its body forms a sigmoid flexure, which is located caudal to the spermatic cord. During erection, the sigmoid flexure straightens and the elongated penis becomes rigid without the erectile tissue undergoing much engorgement. The glans penis is a somewhat rounded cushion of erectile tissue. The urethral process is peculiar because it projects beyond the glans penis by about 2 to 3 cm.

SPERMATOGENESIS AND TRANSPORT, MATURATION, AND STORAGE OF SPERM

Spermatogenesis

Spermatogenesis is a highly synchronized and hormonally controlled sequence of events wherein the germ cells undergo a series of divisions and differentiation (spermatogonia, primary spermatocytes, secondary spermatocytes, early spermatids, and late spermatids) resulting in the formation of haploid sperm. Mathematically, 64 sperm cells can result from one spermatogonium, and in sheep, the entire cycle of spermatogenesis, from the first spermatogonial division to the release of sperm into the lumen of the seminiferous tubule, is completed in 49 days.[3] The cycle is expected to be similar in goats. Spermatogenic cycling begins with the onset of puberty and is repeated at a fixed interval throughout the life of the animal.

The differentiation of spermatogonia to sperm is closely regulated by Sertoli cells, which form close junc-

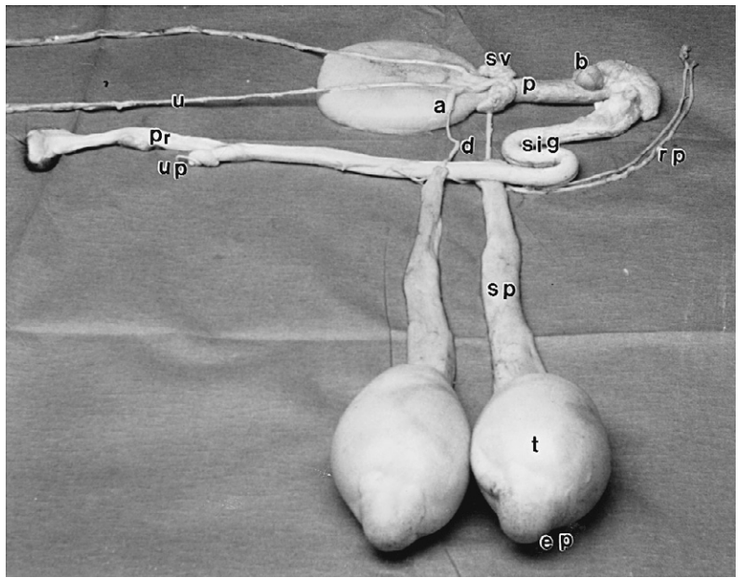

Fig. 64-1 Genital organs of a normal buck. a, ampulla; b, bulbourethral glands; d, ductus deferens; ep, tail of the epididymis; p, prostate gland; pr, prepuce; rp, retractor penis muscle; sig, sigmoid flexure; sp, spermatic cord; sv, seminal vesicle glands; t, testis; u, ureter; up, urethral process.

tional contacts with germ cells. In addition to Sertoli cell secretions, testosterone is essential for spermatogenesis in all mammalian species, including goats. In fact, spermatogenesis requires a 50 to 100 times higher level of testosterone surrounding the germ cells than in the systemic circulation.[4] Testosterone is also essential for production of seminal plasma, epididymal maturation of sperm, and development and maintenance of secondary sex characteristics and libido. More than 90% of the body's testosterone is secreted by the Leydig cells, whose structure and function depend on the functional maturity of the hypothalamus-pituitary–Leydig cell axis. The hypothalamus secretes luteinizing hormone–releasing factor, which stimulates the pituitary to secrete luteinizing hormone, which, in turn, stimulates the Leydig cells to secrete testosterone. The body maintains a homeostatic level of testosterone through the negative feedback effects of testosterone on the pituitary gland or the hypothalamus or both.[4]

Transport

After leaving the seminiferous tubules, the maturing sperm pass through the rete testis, the ductuli efferentes, the head of the epididymis, the body of the epididymis, and into the tail of the epididymis, which serves primarily as a storage site until ejaculation. Sperm passing through these ducts are immotile, so their transport is accomplished primarily by peristaltic contractions of smooth muscle cells surrounding the ducts. Transport is completed within 10 to 15 days.[5]

Maturation

While passing through the excurrent ducts, especially the epididymis, sperm undergo maturational changes that enable them to acquire the abilities to move in a forward direction and to enter and fertilize an ovum. Although the mechanisms responsible for sperm maturation are not fully understood, it is generally believed that certain epididymal secretions, principally glycoproteins, coat the cell surfaces of immature sperm and thus cause them to undergo a functional change.[6,7] The secretion of epididymal proteins is androgen-dependent, and any long-term disturbance in their synthesis or secretion can affect fertility.

Storage

Sperm are stored in the tail of the epididymis and can stay there without losing motility or fertility for 5 to 14 days in primates[8] and substantially longer in other species of domestic animals.[5] The epididymal capacity to store sperm has a direct effect on sperm concentration per ejaculate and on sperm depletion. In our experience, semen from 2- to 3-year-old Nubian bucks can be collected every other day for several weeks without any significant decrease in total number of sperm per ejaculate. According to Amann and Schanbacher[9] the number of sperm stored in the tail of the epididymis is maximal in rams that have not ejaculated for at least 7 to 10 days but is reduced by at least 25% in males ejaculating daily or every other day.

REPRODUCTIVE PHYSIOLOGY

Puberty

The onset of puberty can be defined as a gradual progression of a number of biologic events, such as the onset of spermatogenesis, appearance of sperm in the ejaculate, and capability of intromission. The pubertal age is breed-

dependent, varying from 2 to 3 months in Milch bucks[10] to 4 to 5 months in Nubian, Moxoto, and Boer bucks,[11–13] to 12 to 48 months in Damascus bucks.[14] Most breeds of goats raised in the temperate environment of the Northern Hemisphere possess sperm in the ejaculate at 4 to 5 months. However, at this age, their semen quality is poor, and therefore, they should not be used for breeding. Nubian bucks start producing quality semen at about 8 months of age and begin exhibiting libido, characterized by the desire of young bucks to mount other animals, at 10 to 12 weeks.[13]

Whether kidding season (winter versus summer) can influence puberty remains unknown, but poor management, such as overcrowding, early weaning, and low-quality feed, and multiple births (double or triplet versus single) can delay the onset of puberty. One common feature that is noticed in all prepubertal bucks is the presence of attachments between the prepuce and penis. In Nubian bucks, these attachments begin to separate at 3 months. The urethral process is separate at 3.5 months and the glans penis is completely free of the preputial mucosa by 4.5 months. Because fertile matings are possible in 4- to 5-month-old bucks, males should be separated from does by 4 months of age, or earlier for fast-growing kids, especially those born as singlets, to prevent accidental breeding.

Sexual Behavior

Sexual behavior of bucks can be described as a pattern of well-defined steps, including actively seeking estrous females, courtship, mounting, intromission, and ejaculation. After detecting an estrous female, the buck enters into courtship behavior, which entails kicking, pawing, and nuzzling the female, grunting, and displaying the flehman response (curling of the upper lip). Once the female stands motionless, the buck attempts one or two false mounts, which are followed by mounting with intromission of the penis into the vagina. Ejaculation occurs spontaneously and is characterized by a strong pelvic thrust with a rapid backward movement of the head. After ejaculation, the buck dismounts and displays refractoriness (no sexual arousal) for a few minutes to a few hours. Sexual behavior is androgen-dependent and its onset in prepubertal animals coincides with a rise in testosterone levels.[15] Other factors that may influence sexual behavior are season, social contact (presence of a dominant buck), nutrition, disease, and stress.

FACTORS AFFECTING SEMEN PRODUCTION

Age

Immature bucks of all breeds produce poor-quality semen. Nubian bucks by 8 months of age begin to produce high-quality semen with sperm motility and morphology as good as that of 1- to 5-year-old bucks. However, the semen volume, sperm concentration per milliliter, and total number of sperm per ejaculate increase gradually up to 2 years of age.[1] Similarly, in Alpine and Poitevine bucks, the number of sperm produced in the first breeding year represents only 60% of that produced in the second breeding year.[16] Whether old age (5 years and after) has any effect on some or all of the seminal attributes has not been adequately studied.

Photoperiod (Season)

Whether bucks are truly seasonal breeders remains controversial. Semen from Nubian bucks raised in a temperate environment and trained at an early age can be collected with an artificial vagina throughout the year without any noticeable change in sexual behavior or seminal characteristics.[13] On the other hand, studies conducted in different parts of the world have found varying degrees of seasonal effects on some or all seminal attributes.[17,18]

Temperature

Spermatogenesis in most mammals (except the elephant and whale) requires a temperature 3° to 5°C lower than body temperature. The body's failure to maintain lower testicular temperature such as that resulting from high ambient temperature, high fever, frostbite of the scrotum, and retention of testes within the abdominal cavity invariably affects seminal quality, depending on the duration and intensity of the heat. However, if the causative influence is corrected in time, normal semen production can be restored.

Nutrition

Poor nutrition in general, and protein deficiency in particular, are known to have a deleterious effect on the general health of animals of all age groups. Noteworthy effects on reproduction might include delayed puberty and sexual maturity, diminished libido, and decreased or even complete loss of spermatogenesis. Generally these effects are mediated through the central nervous system, and more specifically through the hypothalamic-pituitary-testicular axis. Conversely, the deficiency of certain vitamins (A, B, and E), amino acids (arginine, lysine, tryptophan, phenylalanine, and histidine), and minerals (zinc) affects the testes directly and can cause variable impairment of spermatogenesis.

Disease

Certain common diseases that are known to have a deleterious effect on seminal quality are varicocele, unilateral or bilateral cryptorchidism, epididymitis, and spermatocele. In addition, genetic disorders such as XXY syndrome, intersex or hermaphroditism, and hypospadias (incomplete development of the prepuce) have been reported to occur in bucks of some breeds.[19] Interestingly, genetically related sperm abnormalities including the Dag defect, the diadem defect, the corkscrew defect, and the pseudodroplet defect, which have been related to subfertility in bulls, have not yet been reported in goats.

CHAPTER 65

Examination of the Reproductive Tract and Evaluation of Potential Breeding Soundness in the Buck

MUSHTAQ A. MEMON, W. DUANE MICKELSEN, and HARI O. GOYAL

PHYSICAL EXAMINATION

A physical examination must include a general examination for health with special consideration of the reproductive organs. To be a satisfactory potential breeder, a buck should be in good flesh. Thin or excessively fat animals should be avoided. A little reserve flesh is desirable, since bucks can be expected to lose weight during the breeding period. Bucks with severe structural faults or diseases of hindlimbs will be less inclined to serve females. One common structural fault is the postlegged condition, in which the hindlimbs are too straight. The result is usually increased pressure on the pasterns and abnormal growth of the hooves, which require frequent trimming. Arthritic conditions can occur. Bucks should be examined for foot rot and foot abscesses.

EXAMINATION OF THE REPRODUCTIVE TRACT

The testes should be examined for size, symmetry, and consistency (Fig. 65-1). Seasonal variations and breed differences must be kept in mind. A sound buck during the breeding season should have large oval testes that are firm to the touch and of equal size. Soft, nonresilient testes are usually seen during the nonbreeding season or may be associated with poor health. Scrotal thermography and ultrasonography are techniques that may be useful in aiding detection or confirmation of abnormalities of the scrotum and its contents. These recently developed diagnostic methods are not yet economical or practical in field situations. The epididymis consists of three anatomic parts: the head, the body, and the tail. Attention should be given to alterations in their size, form, and consistency. Gross alterations in the epididymis are fairly rare in the goat.

The penis should be extended and examined. This is usually accomplished while collecting a semen sample when an electroejaculator is used. Otherwise, the penis must be manually extended from the sheath so that a careful examination can be made. The urethra extends beyond the tip of the penis about 2 to 3 cm, forming the urethral process. The urethral process is thought to aid in spraying semen around the os of the cervix. When bucks have urinary calculi, the urethral process is the common area of obstruction. The urethral process is usually removed during treatment of urolithiasis with no apparent detrimental effect on fertility.[1]

SCROTAL CIRCUMFERENCE AND ITS CORRELATION WITH SPERM PRODUCTION

Scrotal circumference measurements, because of their high correlation with testicular size and capacity for sperm production, have become an integral part of the breeding soundness evaluation of bulls. Information on similar relationships is limited in bucks, however. Using a nonstretchable tape, the examiner measures the scrotum at the point of its greatest diameter, pulling the tape snugly and applying moderate tension so that the testes are pulled together and the tape is in contact with the entire circumference (Fig. 65-2). There is a positive correlation between scrotal circumference and body weight in bucks (Table 65-1).[2] Based on data collected in young growing and mature Nubian bucks, the mean scrotal circumference measurements at 5, 8, 21, and 36 months of age are 14, 20, 26, and 30 cm, respectively. In mature bucks, scrotal circumference is positively ($P < 0.01$) correlated with both sperm concentration per milliliter and total sperm per ejaculate, but the correlation is significantly higher in the latter (r, 0.66 versus 0.36).[3]

LIBIDO

Libido is an essential component of breeding performance but is difficult to measure during a routine breeding soundness examination. When semen samples are collected with an artificial vagina, libido can be assessed to some degree. A carefully obtained history may reveal

whether does are being covered and whether intromission and ejaculation (indicated by a sudden backward motion of the head) occur.

SEMEN COLLECTION

Semen can be satisfactorily collected from bucks using an artificial vagina (AV), an electroejaculator, or a Bailey ejaculator* (Fig. 65-3). The AV consists of the following parts: (1) a rubber tube that is 8 inches long and 2 inches in diameter and is equipped with an air and water valve, (2) a rubber pressure bulb, (3) a latex inner liner, (4) a latex semen collection funnel, (5) two wide rubber bands, (6) a 15-ml graduated Pyrex collection vial, and (7) a nondrying, nonspermicidal lubricant.† No exogenous stimulus is needed when semen is collected with an AV; however, the buck must be trained to serve the AV using a mount animal. A doe in estrus is an ideal mount animal; however, a doe in diestrus injected intramuscularly with 5 to 10 mg prostaglandin F_2 alpha,* or an ovariectomized doe injected intramuscularly on alternate days with 1 mg of estradiol cypionate† could be used as a mount animal.[4] The casing of the AV is filled with warm water to provide an internal temperature of approximately 39° C at the time of collection. Air is added to create pressure and the AV is lubricated immediately before collection. After two false mounts, the buck is allowed to serve the AV. The penis is never handled directly, but is directed by grasping the sheath or the prepuce. The buck will seek the AV, then thrust into it. The AV should never be slipped onto the penis.

Bucks are restrained in a chute or held against a wall for semen collection with the Bailey ejaculator or electroejaculator. The electroejaculator rectal probe with

three electrodes (19 × 3.5 cm, length × diameter) is lubricated and inserted into the rectum. Intermittent stimulation is obtained by rotating the variable power knob to up to three and then back to zero at a frequency of once every 2 to 3 seconds. During and after collection, semen should be protected from direct sunlight and temperature shock, and sperm motility should be evaluated within 10 minutes of collection.

The use of an electroejaculator or a Bailey ejaculator has one disadvantage—libido cannot be assessed because of the forced ejaculation. In our experience a greater volume of semen but a lower concentration of spermatozoa was collected with the electroejaculator and Bailey ejaculator methods than with the AV method.[4] Also, the use of the electroejaculator, and especially the Bailey ejaculator, resulted in increased vocalization and excessive muscular contraction of the hind limbs. Owing to this undesirable response, the Bailey ejaculator in the present form (11.2 volts), is not recommended for semen collection in goats.[4] A technique used successfully and with very little trauma to the buck is massage of the rectum for 30 seconds with the rectal probe of the electroejaculator and then use of direct stimulation for 8 to 10 seconds. Usually, the semen sample is collected with one stimulus, but if the buck fails to ejaculate, one must wait an additional 30 to 60 seconds and then repeat the stimulus one more time.

SEMEN EVALUATION

Many factors including semen volume, motility, concentration, and morphology of spermatozoa have been used for assessing the quality of semen. No single test has been developed that is an accurate predictor of fertility of individual ejaculates. Both semen quantity and quality can vary with age, season, temperature, breed, and even between individuals within the same breed. Generally, semen from goats has a low volume and a high concentration of spermatozoa (Table 65-2).

Semen evaluation for the purpose of breeding soundness examination should include the following parameters.[5]

TABLE **65-2**

Normal Values for Semen of Adult Bucks*

Measurement Parameter	Normal Value
Volume, ml	1.0 (0.5–1.5)
Motile sperm, %	80 (70–90)
Sperm concentration, 10^9/ml	4 (2–5)
Morphologically normal sperm, %	80 (70–90)

*Values given as mean (range).
Adapted from Memon MA: Male infertility. *Vet Clin North Am Large Anim Pract* 1983;5:539; and Skalet LH: Effects of age and season on the spermiogram of Nubian male goats. MSc Thesis, Tuskegee University, Tuskegee, AL, 1986.

Volume

The volume is measured in milliliters directly from the graduated collection vial. This parameter is reliable only for ejaculates collected with an AV.

Color

The color of semen depends on the number of sperm per milliliter and can vary from whey-like ($<0.1 \times 10^9$/ml) to milky ($0.5–1.5 \times 10^9$/ml) to creamy ($2.5–\geq 4 \times 10^9$/ml).

Gross or Mass Motility

A small (~10 µl) drop of fresh, undiluted semen is placed on a prewarmed (37°C) glass slide without a coverslip, and the wave motion is observed using a 10× phase-contrast objective (magnification ×100). An estimate of the vigor of the wave is graded as follows: very good (++++, vigorous swirls), good (+++, slow swirls), fair (++, no swirls, but generalized oscillation), or poor (+, sporadic swirls).

Progressive Motility

The percentage of progressively motile spermatozoa is one of the most widely used tests for semen quality. A drop of fresh semen is diluted with prewarmed, phosphate-buffered saline or 2.9% sodium citrate solution (pH 7.4). A small (~10 µl) drop of the diluted semen is placed on a prewarmed slide, covered with a prewarmed coverslip, and then examined with a 40× phase-contrast objective (magnification ×400) using a microscope equipped with a thermocontrolled heating stage set at 37°C. Five fields are randomly observed and the number of spermatozoa moving in a forward direction are subjectively estimated (nearest 5%) in each field. Circular or reverse motion is often a sign of cold shock or chemical shock. However, a reverse motion may also be seen if there is a high percentage of midpiece abnormalities.

Concentration

Concentration is not routinely measured in field conditions. In laboratory situations, concentration is calculated by use of a hemocytometer for occasional samples and by use of a calibrated spectrophotometer for large numbers of samples. The concentration of sperm is expressed as the number of sperm per milliliter and total number of sperm per ejaculate. The latter is calculated by multiplying the former with the volume of the semen. Sperm concentration can be measured by a commercial Unopette system.* The semen sample is stirred gently to create a uniform suspension. The semen is drawn up into the capillary pipette (20 µl) provided with the kit and dispensed into the second diluent container according to the kit instructions. The diluted semen is loaded into the two counting chambers of a hemocytometer, and sperm are counted at ×100 magnification. The number of sperm in the large center square equals the number of million sperm per milliliter in the ejaculate. The total number of sperm in the ejaculate equals the concentration (sperm per milliliter) multiplied by the ejaculate volume.

Morphology

Semen from bucks contains some abnormal spermatozoa, but this is not usually associated with lower fertility until the percentage of abnormal spermatozoa is greater than 20%. The types of abnormalities can be counted by examining stained or unstained (air-dried) semen smears. The commonly used stains are eosin-nigrosin, Wright's, and Williams' stains. Staining with new methylene blue is frequently used to detect white blood cells, which are indicative of infections.

Generally, sperm abnormalities are evaluated in an eosin-nigrosin–stained smear with a bright field microscope or in an unstained smear with a phase-contrast microscope. A small droplet of fresh undiluted or diluted semen (1:10), depending on the concentration of sperm, is placed on a glass slide and mixed with a drop of eosin-nigrosin stain (if a stained smear is to be used); the smear is prepared by drawing a coverslip across the slide. The smear is air-dried, and 200 sperm per slide are examined using a 100× objective (magnification ×1000) and classified as normal or as primary or secondary abnormalities. Primary abnormalities include (1) misshapen heads (microcephalic, macrocephalic, round, elongated, pyriform, swollen, missing), (2) abnormal acrosomes (missing, swollen, folded), (3) abnormal middle pieces (abaxial, double, swollen, coiled, kinked, bent, looped), (4) abnormal principal pieces (coiled, looped), (5) fractured necks, and (6) proximal protoplasmic droplets. Secondary abnormalities are (1) distal protoplasmic droplets, (2) bent principal pieces, and (3) detached normal heads.

*Becton-Dickinson, Rutherford, NJ.

CONCLUSIONS

A satisfactory potential breeder is a buck that can be expected to produce a high conception rate in a group of sound, disease-free, eligible does. The following minimum values for semen collected with an AV from a satisfactory potential breeder are suggested: semen volume 0.5 ml, motile sperm 70%, sperm concentration 2 10^9/ml, morphologically normal sperm 80%. A questionable potential breeder may require re-examination at a later date. A buck declared questionable would not make an acceptable candidate for purchase or sale. Unsatisfactory potential breeders are not necessarily infertile or subfertile, but they may be rejected for reasons other than semen quality. Examples are a buck with a unilateral cryptorchid testis or a buck with hindlimb impairment.

The rating given as a result of the examination is a scientific opinion or a judgment of the veterinarian. The results of a breeding examination are valid only for the day of the examination and do not ensure continued fertility. Owners, of course, will be interested in a judgment of prior and potential reproductive performance of the buck and information concerning the etiology of any discovered malady. Testicular degeneration and hypoplasia are not uncommon in bucks, but assessment of causative factors and prognosis is difficult. With testicular degeneration, the prognosis is grave; however, animals afflicted with a transient disease or environmental stress exhibit poor semen quality for variable periods of time and may recover full breeding soundness. Therefore, bucks classified as questionable or unsatisfactory breeders should be re-evaluated after an 8-week interval. Only those bucks that are consistently classified as unsatisfactory potential breeders should be culled.

CHAPTER 66

Infertility and Diseases of the Reproductive Organs of Bucks

W. DUANE MICKELSEN and MUSHTAQ A. MEMON

Reproductive efficiency is important in dairy goat herds, and selection of highly fertile buck goats is absolutely essential. Many problems exist that may cause infertility in bucks; they are discussed here in some detail. Hand-mating is the usual practice in dairy goat herds, for it is not desirable to allow odorous bucks to run free with lactating does. The duration of estrus in does is 32 to 40 hours, and does are usually mated at 12-hour intervals until estrus subsides. Does actively seek the presence of the buck when in estrus and, when given a choice, usually prefer a scented buck to a deodorized one. Bucks can initiate and even synchronize cyclic activity in does at the beginning of the breeding season. Detection of estrus in does is best accomplished with the use of the buck. An intact buck should be penned in an area where does in estrus can be observed congregating near the pen.

LIBIDO

Mounting and thrusting behavior, sniffing the urogenital region, and exhibiting the flehman response are common behaviors of adult bucks. As in sheep, during the nonbreeding season (in the Northern Hemisphere, autumn is the breeding season), it may be difficult to obtain an ejaculate with an artificial vagina or the buck may be very slow to serve a doe in heat.[1] Out of the breeding season the buck may rest his head on the doe's hindquarters but fail to align himself with the longitudinal axis of the doe.[2] With the onset of the breeding season, bucks properly align, and mounting, thrusting, and ejaculation occur.

One of the most common reasons for a buck to come to the end of his breeding career is arthritis. Painful hips, stifles, or hocks cause reluctance or inability to mount. If several bucks are run together with does, a dominant but arthritic male may prevent breeding by another fertile buck. Lame bucks also tend to lose body condition because they do not get up to eat as much as they should. The cause of lameness may be trauma (degenerative) or infectious. Bucks with degenerative arthritis, which is often caused by congenitally poor conformation, or with other anatomic defects, should not be used for breeding.

Infectious causes of arthritis may result from caprine arthritis encephalitis (CAE) virus. With the CAE virus, the clinical disease is more common in some families than in others, suggesting an inherited susceptibility to effects of the virus. Research has shown that clinical CAE is associated with certain histocompatibility antigens, again suggesting a hereditary component.[3] Transmission of CAE infection by breeding appears to occur infrequently, if at all.[4] Detection of antibodies against CAE virus at the Washington Animal Disease Diagnostic Laboratory is performed with the use of a kinetic enzyme-linked immunosorbent assay. The antigen used in this assay is prepared from purified CAE virus with a technique designed to enhance the dominant antigens against which goats infected with CAE develop antibodies.[5]

INTERSEXES

Abnormal sexual differentiation leading to the intersex condition is relatively common in goats. It is more prevalent in dairy goats of the Saanen, Toggenburg, and Alpine breeds than in any other breeds of animals.[6] Intersexes exhibit phenotypic variations ranging from nearly normal females to nearly normal males. Generally they are female-like at birth, but as they reach the age of sexual maturity, they become larger than normal females, with a masculine head and erect hair on their neck. They exhibit small teats and a bulbous clitoris or a shortened penis. At puberty the clitoris becomes enlarged enough to be externally visible.[7]

The intersex acts like a female at birth but later, usually at puberty, starts to butt like a buck and become aggressive toward other goats and people. These animals also develop the odor characteristic of bucks. A majority of intersexes show pronounced male libido in the presence of a doe. Some of the more female-like intersexes lactate.[6] Intersexes are named with reference to the gonads they carry. The term "true hermaphrodite" is used to distinguish an animal that carries both gonads from those that carry either one or the other type of gonads (pseudohermaphrodites). Male pseudohermaphrodites have testes and female pseudohermaphrodites have ovaries. Most intersexes, however, have testes. Usually the testes are abdominal or they may be partially or totally descended (Fig. 66-1). The principal hormone produced by the gonads in caprine intersexes is usually testosterone.[6] Intersexes are frequently seen in polled dairy goats. The most accepted hypothesis is that hermaphroditism and horned traits are controlled by recessive genes and that these two loci are close to each other on the same chromosome (linked). The polled condition is the result of a mutation at the horn locus. The polled trait (P) is domi-

Fig 66-1 Hermaphrodite goat, on its dorsum, showing testes, vulva, and enlarged clitoris.

nant to the horned trait (p) and appears together with hermaphroditism (h) in PPhh or Pphh goats because the two loci are linked.[8] Therefore, intersexes will be seen mainly among polled goats and only rarely among horned animals (pp) because of the occasional crossing over between the two loci, which results in a pphh genotype. Cytogenetic evaluations of caprine intersexes clearly show that most polled intersexes are karyotypically female (XX) and the breeding histories of the parents indicate that intersexes are homozygous for the polled trait.[9] The presence of male gonads in these homozygous polled (PP) intersexes of XX makeup suggests that they are sex-reversed females. In the female caprine fetus, which is homozygous for the polled gene, two doses of the P gene divert the process of sexual differentiation toward the male despite the presence of two X chromosomes.[10]

Intersex goats have been found to have the H-Y antigen. The H-Y antigen is a male-specific transplantation antigen and is reportedly lower in intersexes than in normal XY males.[11] The suggestion has been made that animals of the same genotype and sex may differ in the density of H-Y antigen on their cell surface, which might explain the variability in primary sex determination among goats.

The gene for the polled trait has an impact on the reproduction performance of bucks. Bucks that are homozygous for the polled gene tend to become sterile. Although the testes of these bucks are of normal size and the seminiferous tubules display active spermatogenesis, there are no sperm detectable in the ejaculates because of blockage in the caput epididymidis. These trapped sperm form hard masses of variable size that are palpable near the head of the epididymis. In older bucks, the seminiferous tubules are closed, causing degeneration or rupture, releasing sperm into the interstitium (extravasation), which often leads to sperm granuloma formation.[12] Thus, the homozygous state for the polled gene is disadvantageous to both sexes. In males, it causes poor differentiation of the duct system, resulting in sterility, and in genetic females it causes gonadal reversal leading to masculinization of the gonads and external genitalia.

Freemartinism

The incidence of twins or triplets is higher than that of single births in goats. Perinatal mortality rate is lowest in twins compared with singlets or triplets. However, the incidence of intersexes is higher in twins and triplets than in singlets. A prerequisite for caprine freemartinism is birth as a twin to a male kid or as one of heterosexual multiples. Sometimes birth as a twin may not be recognized if one of the twins dies in utero. In these cases, confirmation of freemartinism can be obtained from chromosome analysis, which reveals the coexistence of male and female cells in the blood and other hematopoietic tissues. In caprine freemartins, the proportion of male cells in leukocyte culture could be as low as 1%, which necessitates careful examination of a number of cells for an accurate diagnosis of the freemartin condition.[13] Because twinning occurs in horned and polled goats, freemartin intersexes can be seen among both types of goats. Approximately 6% of intersexes can be expected to be freemartins. It is believed that in a majority of twin pregnancies in goats, vascular anastomosis does not occur similar to that in the bovine species. The external and internal genitalia of caprine freemartins are similar to those of polled intersexes. However, the masculine features are generally more exaggerated, and the gonads are partially descended testes devoid of germ cells.[13] Intersexes and freemartins do not produce sperm, even during the breeding season, and generally are less odoriferous than normal bucks.

Total Chimeras

Chimerism may result from fusion or cellular admixture of male and female embryos at an early stage in embryogenesis or from fertilization of the second polar body and ootid by X- and Y-bearing spermatozoa prior to fusion of the polar body with the ootid.[13] Although the occurrence of this type of intersex is rare in goats, approximately 1% of caprine intersexes belong to this category. Some of these are true hermaphrodites with a nearly normal ovary on one side and a testis or ovotestis on the other. Karyotypic analysis shows that they are whole-body chimeras.

TESTICULAR AND EPIDIDYMAL ABNORMALITIES

Testicular Degeneration

On digital palpation, normal testes feel resilient, with a consistency as firm as muscle. The ultrasonographic

appearance of a normal testis is one of uniform homogenicity with a central hyperechoic line representing the mediastinum testis. The testicular tunic and capsule are also distinct hyperechoic lines, whereas fluid around the testes (hydrocele) is hypoechoic.[14] The tail of the epididymis is more heterogeneous and less echogenic than the testis.[15] Testicular degeneration, or atrophy, of unknown etiology but accompanied by abnormal spermatozoa appears to be common in some goat populations. Often the testes are more elongated and smaller than normal. The head of the epididymis may undergo a palpable loss of lobulation. Multiple foci of calcinosis are grossly visible on the cut surface of the testis.[16] Ultrasonographically, testicular degeneration and mineralization are hyperechoic.[17] Firm, mineralized parenchyma, detectable by ultrasonography, has been observed in older or infertile bucks.[18] Testicular degeneration or atrophy has been found in a number of clinical conditions including systemic disease, epididymitis, debility from various causes such as poor nutrition and parasitism, aging, and higher or lower than normal environmental temperatures.[19]

Testicular Hypoplasia

Abnormally small testes may be found in animals suffering severe malnutrition or in animals that are intersexes. Hypoplasia is often difficult to distinguish from atrophy, but with either, testicular size and function should improve with proper feeding if malnutrition is responsible.[19] Hypothyroidism and severe zinc deficiency compounded by reduced feed intake have resulted in decreased weight of the testis and epididymis, a reduction in spermatogenesis, and degenerative changes in the testes and accessory sex glands.[20,21] Intersexes and freemartins often do not undergo the testicular size increase that normally occurs at puberty, or else the testes may atrophy at that time. One case of testicular hypoplasia has been reported in a horned buck with chromosomal mosaicism (XXY and XY).[22]

Cryptorchidism

Cryptorchidism is a developmental abnormality in which one or both testes fail to descend from the abdominal cavity into the scrotum. The retained testis may stop along the normal path of descent, or it may divert to an ectopic location. Unilateral cryptorchidism may or may not adversely affect semen quality, whereas bilateral cryptorchidism results in sterility. Among unilateral cryptorchids the right testis is retained in the abdomen in about 90% of the animals.[23]

A higher incidence has been reported in intersexes, which is related to the polled characteristic. However, in Angora goats, cryptorchidism is not related to the polled intersex condition, which does not occur in this breed. Affected Angoras are genetic males.[23] The cryptorchid trait is recessive but controlled by a few pairs of genes.[24,25] Other possible etiologic factors of cryptorchidism include hormonal imbalances, mechanical obstruction such as fibrous adhesions, and focal infections along the course of descent, especially near the inguinal ring where many cryptorchid testes are located.[19] Normal abdominal temperature is about 5°C higher than scrotal temperature. Under the influence of abdominal temperature, the seminiferous tubules are not active and spermatogonia do not develop into spermatozoa. The Leydig cells are not affected and produce androgens; therefore, libido of cryptorchid animals is normal and physical features are masculine.[23] To prevent this condition, cryptorchid bucks should not be used for breeding and their sires and dams should also be culled. Even stricter selection would involve culling all offspring of known carriers.

Orchitis and Epididymitis

Bacterial orchitis and epididymitis are far less common in goats than in sheep. During the acute stage, orchitis usually presents with a typical clinical picture. The affected testes are hot, swollen, and painful. Affected bucks show systemic signs including pyrexia, depressed appetite, loss of libido, and inability to walk long distances. The testes usually swell rapidly and sometimes become twice their normal size within 24 hours after early signs are noticed. In chronic orchitis, there may be marked loss of testicular mobility within the scrotum due to extensive fibrous adhesions. The testes become indurated and fibrous as the changes result in atrophy. Coliform bacteria and *Pseudomonas* have been cultured from ejaculates of young bucks. Coliforms have caused both orchitis and epididymitis when injected into the testis.[26] *Actinobacillus seminis* was isolated from 4 of 40 Angora bucks examined in South Africa, but details related to clinical presentation were not given.[27]

Sperm Granulomas

Sperm granulomas are common causes of sterility in bucks. They are frequently associated with the polled condition but have been observed in horned bucks. This condition is believed to be heritable and recessive, with incomplete penetrance (estimated in one study as 0.55).[28] The normal head of the epididymis forms from the union of approximately 16 to 19 efferent ductules.[29] The direct cause of obstruction is believed to be one or more of these ductules that end blindly.[28] The ducts become distended with inspissated sperm until rupture occurs and sperm are released into the stroma of the epididymis. A severe inflammatory reaction with lymphocytes and giant cells occurs in response to the sperm cells and eventually a granuloma forms, which may calcify. Back pressure from granuloma formation eventually leads to degeneration and even mineralization of the testicular stroma.[28,30] Some animals are sterile because all of the efferent ducts are affected. Others may be initially fertile but become infertile if bilateral granulomas form. Normal libido persists. The firm granulomas in the head of the epididymis and reduced size of the testes will be palpable. Less commonly, granulomas form in the body or the tail of the epididymis. On ultrasonographic evaluation, appearance of sperm granulomas has been described as fluid-filled structures with a ring of echogenic tissue.[18] Ultrasonography is also useful for demonstrating testicular mineralization, the end stage of degeneration induced by back

pressure. Correction of the defect is not possible. The diagnosis can be confirmed by gross and histologic examination after castration or slaughter.

Scrotal Hernia

Scrotal and inguinal hernias have not been described in goats but have been observed by the authors in sheep and are presumed to be hereditary in that species. Clinical signs include distention of one side of the scrotum with a freely movable, fluctuant loop of intestine. If a hernia is identified and surgical correction is desired, the buck should be castrated bilaterally at the same time.

PENILE AND PREPUTIAL ABNORMALITIES

Hypospadias

Hypospadias and failure of preputial closure are diagnosed by inspection of the external genitalia and by catheterization of the urethra. The external urethral orifice opens on the ventral aspect of the penis (rather than at the tip) or in the perineum when hypospadias is present. Affected animals may be asymptomatic or may have urine scalds and infection of regional mucocutaneous surfaces. This condition usually is a part of the intersex condition commonly seen in goats.[23] Evaluation of the karyotype and gonadal histologic features may further characterize this disorder as an abnormality of sexual differentiation.

Posthitis

Posthitis, also termed "pizzle rot," is a chronic condition characterized by scabs and ulcers of the skin and mucosa of the prepuce and is caused by an interaction of a high-protein diet and *Corynebacterium renale*. Free ammonia scalds the preputial and penile mucosa. Wethers appear to be more susceptible than intact bucks. Pustules and ulcers on the prepuce and penis of bucks have been described as caused by a herpesvirus that is associated with vulvovaginitis in does.[31] The gross appearance varies with the extent of secondary bacterial infection. Histologically, findings of acidophilic intranuclear inclusion bodies and chromatin margination in epithelial cells adjacent to ulcers are considered highly suggestive of herpesvirus infection.[32] It is also reported that bucks that spread the infection to does during mating may remain free of clinical signs.[33]

Phimosis

Phimosis is suspected in bucks when the penis cannot be extruded, when there is decreased libido or inability to copulate when females return to service. The exact cause of the condition is not known. Adhesions of the penis in the region of the sigmoid flexure may be due to trauma from horn injuries. Phimosis in younger animals without evidence of trauma is considered to be a congenital condition that causes permanent unsoundness.[34] It must be differentiated from the normal inability of the prepubertal buck to extrude the penis owing to the presence of adhesions between the penis and prepuce.

Paraphimosis

Inability to withdraw the penis into the prepuce results in edema, swelling, and balanoposthitis. The prognosis is guarded and depends on the diligence of treatment and degree of trauma or necrosis present.[19] Treatment includes cleaning of the prolapsed penis with mild antiseptic solution and removal of necrotic tissue. Attempts should be made to get the penis back into the prepuce as soon as possible. Penile edema may be reduced by frequent hydrotherapy, use of diuretics, and application of ointments or Epsom salt packs. Treatment may be warranted only in valuable bucks. In most cases, culling of affected animals is recommended.

Urinary Calculosis

Urolithiasis is a common problem in castrated bucks (wethers) but also occurs occasionally in intact males. Various management factors, including deprivation of water and increased feeding of excessive minerals (particularly phosphate), contribute to urinary calculosis.[19] Urolithiasis is usually diagnosed on the basis of typical signs that begin with uneasiness, arched back, straining, and attempts to urinate accompanied by rapid side-to-side movement of the tail. In some bucks, small amounts of urine leak from the prepuce and, after evaporating, leave deposits of crystals on preputial hair. Later, the affected animals may kick at the belly, refuse food and water, prefer to lie down, become rather dull, and isolate themselves from the flock.

If the obstruction is at the base of the urethral process, urethrostomy can be performed by simply placing the patient on its rump and flexing its back to prolapse the penis through the preputial orifice. The penis is manually grasped and the urethral process is cut at the junction of the glans penis with scissors. If urination is normal following the operation, fertility is not usually impaired.

DISEASES TRANSMITTED BY SEMEN

Agents known to be transmitted in semen include foot and mouth disease virus, bluetongue virus, leptospiras, mycoplasmas, and toxoplasmas. Agents that are probably transmitted include *Brucella melitensis* and *Mycobacterium paratuberculosis*.[6] Most infectious agents can survive the semen freezing process. However, extended semen may contain less than the minimum infective dose. If bucks are kept in artificial insemination centers, they can be routinely screened for most of these diseases. Custom semen freezing centers have reported poor semen quality and freezability when semen is processed from bucks with severe CAE that have received phenylbutazone.[6] This might be because of effects of the virus on testicular function or decreasing body condition as the disease advances rather than because of a toxic effect of anti-inflammatory drugs.

CHAPTER 67

Urogenital Surgery in Goats

A. M. HEATH, DAVID GARTRELL PUGH, and M. S. EDENS

The most common urogenital surgery that will be performed by most practitioners is castration of young bucks. However, as the goat is becoming a preferred pet animal in many households, knowledge of some common urogenital emergency procedures is becoming vital. Two of the most common reasons for veterinarians to see individual goats are for the relief of dystocia in the female and urolithiasis in the male. Both of these conditions often result in emergency surgery. The preparation of teaser animals for detecting females in estrus for artificial insemination programs is also discussed in this chapter.

MALE UROGENITAL SURGERY

Surgical Castration

The most common surgical procedure performed on goats is castration. Complications include excessive hemorrhage, evisceration, infection, rupture or tearing of the ureter, and tetanus.[1] Tetanus prophylaxis should include the use of toxoids and antitoxins. Evisceration appears more common in young goats, and possibly has some breed predisposition (pygmy[1]). Routine castration of kids is usually done the first week of life. However, if the kid is to be a pet, it is advisable to wait until at least 5 to 6 months of age in order to allow for maturation of the penis, urethra, and detachment of penile adhesions.[1]

Animals may be sedated, anesthetized, or restrained by an assistant. Young lambs or kids 2 to 4 days old are often surgically castrated without anesthesia. Light sedation of pet goats can be beneficial owing to their propensity for vocalization. Local anesthesia can be achieved by local infiltration of a 1% lidocaine hydrochloride solution in the scrotum and around the spermatic cord. Large, adult bucks should be sedated (xylazine hydrochloride, 0.05–0.3 mg/kg IM) as they may be very susceptible to shock associated with the stress and pain of castration.[1] The lower one third of the scrotum is removed by a scalpel blade to expose both testicles. The scrotal fascia is stripped away and testicle is identified and pulled by steady traction ventrally while the cremaster muscle and the remaining scrotal fascia are torn away from the spermatic cord. Completely tearing away the cremaster muscle and the scrotal fascia will allow more of the spermatic cord to be exposed to ensure it is broken above the pampiniform plexus. The cord is broken by applying constant downward pressure on the testicle with one hand to expose as much of the spermatic cord as possible and then breaking the cord as dorsally as possible by applying pressure on the cord with the other hand.[1] Breaking the cord above the pampiniform plexus will generally result in less hemorrhage than breaking the cord at or below the plexus.

In bucks older than 4 months of age and during the breeding season, it may be necessary to place an emasculator or transfixation ligature dorsal to the pampiniform plexus, in order to control hemorrhage. If hemorrhage appears to be clinically significant, the bleeding vessels should be ligated. If bleeding vessels cannot be identified, the scrotum can be packed with sterile gauze (soaked in antiseptic iodine or epinephrine) and the scrotum sutured closed. An alternative would be to close the scrotum with purse-string or a through-and-through suture pattern in order to reduce dead space within the scrotum. The day after surgery the scrotum should be reopened and the gauze removed. If the scrotum is packed, the animal should be placed on antibiotics for 1 to 4 days. On rare occasions when the testicles are pulled, the testicular artery may be avulsed from the aorta, which can result in fatal hemorrhage.[2] Animals need exercise after castration in order to reduce postoperative swelling.[1]

Elastrator Band Technique

The use of the elastrator band is the most commonly used technique by many producers on animals under 3 to 4 weeks of age. A heavy rubber band is placed around the neck of the scrotum. The entire scrotum is included within the bands.[1] Pulling the testicles as far ventrally as possible away from the abdominal wall before placing the bands will prevent trapping penile structures (sigmoid flexure) within the band. Elastrator band methods are considered inhumane by some if performed on animals over 1 to 3 weeks of age.[2] The scrotal sac and the trapped testicles undergo ischemic necrosis and slough within 2 weeks. It has an advantage of no open wounds or hemorrhage, but is associated with an increased risk of tetanus.[2] Occasionally the blood supply to one or both testicles will not be occluded, and the testicles will remain and continue to function.[2]

Burdizzo Emasculatome

Another method for castrating sheep and goats involves using the emasculatome. There are no open wounds and compared to elastrator bands there is a decreased risk of tetanus. Anesthesia is not required. The testicle is pushed to the ventralmost part of the scrotum and each cord is held tightly against the lateral aspect of the scrotum with one hand while the Burdizzo emasculatome instrument is applied twice to each cord.[1] Clamping each cord sepa-

rately increases the likelihood of interrupting the testicular blood supply and decreases the incidence of scrotal sloughing. The complications of this method include testicular survival, scrotal sloughing, scrotal swelling, and tetanus. Some consider this an inhumane method of castration in older animals.[1]

Hemicastration

In cases of unilateral testicular disease, the decision may be made to remove the involved testicle in order to prevent heat-induced testicular degeneration of a normal testicle that may occur as a result of inflammation in the diseased testicle. General anesthesia is recommended. The male is anesthetized, placed in right lateral recumbency, and the entire scrotum and the surrounding area are clipped and aseptically prepared. Starting near the base of the affected testicle and extending to near the apex, an elliptical incision is made through the skin and tunica dartos on the lateral aspect on the scrotum. The incision should not be extended into the normal hemiscrotum. The affected testicle and its associated tunics are bluntly dissected away from the scrotum. The vaginal tunics are excised in order to expose the testicle and the spermatic cord. The spermatic artery and vein are ligated with a transfixation suture above the pampiniform plexus, and the cremaster muscle is ligated at a point proximal to the vascular ligature. A separate ligature is then placed around the entire spermatic cord. The cord is clamped approximately 5 to 6 cm distal to the vasculature suture, and the cord transected. The remaining vaginal tunic is transected far enough distally to allow the tunics to be closed over the remaining cord with an inverting suture pattern. Excess skin should be trimmed so that no dead space is present. The tunica dartos muscle and the longitudinal skin incision are closed separately. If excess hemorrhage is expected, the scrotum may be bandaged following surgery. The bandage should be removed within 12 hours after surgery to minimize thermal damage to the remaining testicle. Routine postoperative antibiotics (penicillin or tetracycline) should be continued for 4–5 days. Nonsteroidal anti-inflammatory drugs may be indicated for control of pain, swelling, and other signs of inflammation.[1]

Teaser Preparation

Teaser bucks greatly facilitate estrus detection for artificial insemination and embryo transfer programs, particularly if used in conjunction with marking harnesses. A young, healthy, postpubertal male with good libido would be the best choice. The male should be incapable of intromission in order to minimize the spread of venereal disease or contamination of the vagina prior to artificial insemination. He should also be rendered infertile in order to guarantee no offspring are produced.

Vasectomy

A properly performed vasectomy will render the male incapable of fertilization, but will not prevent intromission. The animal is mildly sedated (xylazine 0.05 mg/kg IM) and the area proximal to the scrotum is infiltrated with lidocaine and prepared for aseptic surgery. The spermatic cord is identified and the overlying skin is incised. A combination of blunt and sharp dissection is used to carefully isolate the vas deferens from surrounding structures of the spermatic cord. Two ligatures are placed 4 cm apart on the vas deferens and a 2-cm section of the vas deferens is removed. The skin is closed with sutures, staples, or by a subcuticular pattern.[3] The procedure is repeated on the remaining vas deferens. Alternatively, the procedure can be performed through a single incision over the spermatic cord. The buck should not be used for estrus detection for 30 days.[1]

Epididymectomy

Like the vasectomy, an epididymectomy will not prevent intromission but will prevent emission of sperm. Bilateral caudal epididymectomy is a simple surgical procedure and easier to perform than a vasectomy.[4] The distal scrotum is aseptically prepared. A local anesthetic is infiltrated in the skin over the tail of the epididymis. The testis is forced distally in the scrotum until the tail of the epididymis is easily identified through the scrotal skin. A skin incision is made over the epididymal tail and continued through the common vaginal tunic until the tail of the epididymis is exposed. The tail of the epididymis is grasped with a pair of towel forceps, and dissected away from the testicle. The epididymis should be isolated and sutures placed proximal and distal to the tail of the epididymis. A portion of the epididymis is removed. In an alternative method, a pair of forceps are clamped across a loop of epididymis and this portion of the epididymis removed. The authors suggest the loop of epididymis be stored in a container with formalin labeled with the owner's name and the goat's identification. This can later be used as evidence that the surgery was performed correctly. If the epididymis is sutured and the procedure is performed under aseptic conditions, the scrotal skin may be sutured. In less than sterile conditions, the skin is left open to granulate. A minimum of 30 days of sexual rest should be enforced before use in a teasing program.[1,3]

Penile Translocation

A surgical procedure useful to prevent intromission is translocation of the penis to the left flank. A vasectomy or epididymectomy should also be performed in conjunction with this surgery in order to ensure sterility. The buck should be given a systemic antimicrobial 2 to 4 hours prior to surgery. With the buck standing, an area 1 cm cranial to the flank fold is marked.[1,4] The buck should then be either heavily sedated, anesthetized with injectable anesthetics, intubated and maintained on gas anesthesia, or given a lumbosacral epidural. The goat is placed in right lateral recumbency and the ventral abdomen and left flank are clipped and prepared for aseptic surgery.[4,5] A 4-cm circle of skin and cutaneus trunci muscle is excised 1 cm above the flank fold, just cranial to the mark made on the left flank. This area is covered with saline moistened gauze.[1] A 4-cm circumfer-

ential skin incision is made around the preputial orifice. A single skin suture is placed at the dorsal aspect of the preputial orifice.[4] The skin incision is extended longitudinally along the penile shaft, two thirds of the way to the scrotum.[1] The penis and nonhaired prepuce are freed of the subcutaneous tissue. A tunnel under the cutaneus trunci muscle is created by scissors or blunt dissection from the circular incision in the flank to the caudalmost aspect of the longitudinal incision over the penis. A towel forceps is now passed through the tunnel starting at the circular incision and exiting near the penis. The penis, with a sterile glove covering the preputial orifice to prevent contamination, is then repositioned through the tunnel by using the towel forceps to grasp the skin of the preputial orifice. The penis is then pulled dorsally so that it is at a 45-degree angle to the long axis of the body and the orifice is positioned within the circumferential skin incision.[4] Care should be taken to prevent twisting the penis or prepuce. The suture at the orifice should be used to align the dorsal aspect of the preputial orifice with the dorsalmost point in the circular incision. The subcutaneous tissue of the preputial orifice is sutured to the cutaneus trunci muscle. One absorbable simple interrupted suture is place at each quadrant, and then additional sutures are placed within each quadrant to completely oppose the tissue. The skin of the preputial orifice is then sutured to the skin of the flank incision in a similar manner using nonabsorbable suture. The subcutaneous tissue along the ventral longitudinal incision into the prepuce is closed. The skin can be closed using either simple interrupted sutures or a continuous pattern. The cranial aspect of the incision (where the preputial orifice was located) is left open to allow for drainage.[1,4,5] Tetanus prophylaxis (tetanus toxoid or tetanus antitoxin) and fly control should be instituted. A bilateral epididymectomy or vasectomy is performed, and antibiotics continued for 5 to 7 days (Procaine penicillin 22,000 IU/kg twice a day). The sutures are removed in 14 days. The male will be ready for use in a teasing program within 1 month.

Surgical Treatment for Urolithiasis

Clinical signs of urolithiasis include straining to urinate, continuous dribbling of urine, colic, vocalization, and flagging of the tail. Small mineralized crystals can sometimes be found on the preputial hairs of the goat. These goats are often presented with numerous acid-base imbalances and electrolyte abnormalities. Increased blood urea nitrogen (BUN) and creatinine concentrations are sometimes noted. These abnormalities should be addressed in the course of preparation for surgical intervention.

Several surgical techniques are used to manage cases of urolithiasis. Whenever treating urolithiasis, the clinician should evaluate the diet of the affected animal, analyze any stones encountered, and include medical therapy where appropriate. Risk factors that have been associated with urolithiasis include high concentrate rations, low roughage rations, a low Ca:P ratio, high magnesium diets, and alkaline urine. High-protein diets may also contribute to the formation of mucoproteins that tend to coalesce with mineral crystals. In general, the treatment of most cases of urolithiasis will include some form of surgical intervention in combination with dietary management. Urine acidifiers (ammonium chloride, 2–4 g daily per os) are used to try to maintain the urine at a pH of between 6 and 6.5.[6,7]

Amputation of the Urethral Process

The first step that is taken when a goat is presented with the inability to urinate is to amputate the urethral process. The urethral process is identified as a slender appendage at the distal end of the penis and is simply cut off with a pair of surgical scissors. Although this will often result in immediate relief of the blockage, the problem may recur with subsequent calculi production blocking the flow of urine at other sites. Future stenosis of the excision site is also a possibility. The goat should be monitored closely for reobstruction and the diet appropriately modified.

Perineal Urethrotomy

Perineal urethrotomy is a commonly performed procedure in male goats, but surgical failure, poor long-term survival rates (strictures), and loss of reproductive function decrease the usefulness of this procedure.[6,8,9] Either general anesthesia or epidural anesthesia may be employed for the procedure. The perineal area is scrubbed and a 10-cm midline skin incision is made below the ischial arch. Careful sharp dissection is used to expose the retractor penis muscles, the bulbospongiosus muscle, and the underlying penis. An incision is made through the median raphe of the bulbospongiosus muscle and into the underlying urethra. Palpating the distinct urethral groove on the ventral surface of the penis identifies the urethra. The urethra can be irrigated in both an anterograde and a retrograde fashion to help dislodge any calculi. This should be done with extreme caution so as not to rupture the urethra that may already be compromised. A Foley catheter can be placed into the bladder through the incision to allow easy flow of urine and to divert urine flow away from the surgical wound. The incision can be allowed to heal by granulation. Alternatively, a more ventral approach can be made and the urethral mucosa and the tunica albuginea may be sutured to the skin to create a urethrostomy.[6,10–12] The remaining incision dorsal and ventral to the urethrostomy site should be closed. The Foley catheter is maintained for 3 to 4 days in either procedure.[10] Antibiotics may be used at the surgeon's discretion. A cystotomy should be considered if there is the potential for substantial calculi to be retained in the bladder.

Penile Amputation

Amputation of the penis provides a simple approach to relieving urethral obstructions. However, this procedure may not be as cosmetically appealing and strictures may occur after surgery. It should, however, be considered as the treatment of choice for long-term survival when the urethra has already ruptured and there is significant damage to the distal portion of the penis and surrounding tissues due to urine accumulation. The surgery can be accomplished under either general or epidural anesthesia. A midline incision is made in the perineum dorsal to the

sigmoid flexure at the point where the perineum turns ventrocranially. Careful sharp dissection is made to expose the penis. The distal sigmoid flexure is identified and pulled to the incision site. If there has been significant urine damage to the preputial tissues due to urine leakage, the entire distal penis can often be extracted from the wound with moderate pressure. The penis is avulsed from its preputial attachment. A point on the penis 4 to 6 cm distal to the dorsal edge of the skin incision is chosen for the amputation site. The dorsal penile vessels are ligated dorsal to this point and the retractor penis muscles are ligated and transected as far proximally as possible. If the distal penis is not removed, the dorsal penile vessels should be reflected off the penis and left intact. The penile stump is sutured to the skin by placing a suture near the dorsal edge of one side of the incision, going through the body of the penis, exiting through to skin on the opposite side and returning the suture in the same manner to the starting side to form a horizontal mattress suture. The skin incision is closed above and below the penis. The urethra is split to spatulate the opening in order to prevent stricture formation. The corpus cavernosum (CCP) is sutured closed to prevent bleeding that will occur when intact bucks are sexually stimulated. A wedge-shaped piece of tunica albuginea is removed from each side of the penis in order to facilitate closure. Castration at the same time as the penile amputation is prudent.[13]

Cystotomy or Tube Cystotomy

Cystotomy provides the best long-term survival and the return to normal breeding of bucks with urolithiasis because the urethra is not surgically invaded. It should also be considered as an option for the therapy of pet animals to ensure the health of the urethra and ultimately a more cosmetically appealing cure. The buck is placed under general anesthesia and placed in dorsal recumbency. A right paramedian incision is made (2.0 to 3.0 cm off midline) extending cranially 8.0 cm from the teats.[6,9–12] The urinary bladder is retracted out of the abdomen and stay sutures are placed at either end of a proposed cystotomy site (dorsal aspect of the bladder) in order to allow for stabilization of the bladder. The bladder is incised, lavaged, and massaged in order to remove all calculi.[6] Mild normograde urethral flushing with an isotonic solution or combining normograde and retrograde flushing can help remove urethral calculi.[1,6] If normal flow through the urethra can be established, the bladder should be closed in an inverting pattern avoiding penetration into the lumen of the bladder.

If any doubt remains about the function of the urethra, a Foley or mushroom (16–24 F) catheter is placed into the bladder. This procedure should allow for a decrease in urethral inflammation and urethral spasms and will subsequently allow normal urine flow through the urethra.[9] A small skin incision is made lateral to the abdominal incision and the catheter is then tunneled subcutaneously prior to penetrating the abdomen lateral to and separate from the original paramedian incision. This is placed in the same manner as one would place a chest drainage tube. Layers of omentum are pleated over the end of the catheter. After the Foley catheter is positioned in the abdominal wall, a purse-string suture is placed in the ventrolateral bladder wall. A stab incision is made in the middle of the purse string, the balloon end of the Foley catheter threaded into the bladder, and the purse string suture is tightened around the catheter and the bulb is inflated.[6,9] The catheter is pulled outward so that the bladder is positioned near the lateral body wall. The catheter is secured to the skin on the lateral body wall and the original abdominal incision closed. A valve should be placed over the end of the catheter to help in the prevention of an ascending infection. The finger of a latex glove taped over the end of the catheter will provide this valve effect.[6,9,11,12]

Bandages and Elizabethan collars should be used to prevent the goat from damaging the tube.[6] Animals should be closely monitored for signs of depression, anorexia, or abdominal pain.[6] A clamp is placed over the catheter 4 days after surgery to impede urine flow. This will allow the clinician to access the goat's ability to urinate normally. If the goat is still unable to urinate normally, the catheter clamp should be released and the goat evaluated again the next day. Goats should be able to urinate normally for 2 days before deflating and removing the catheter. The Foley catheter should not be removed prior to day 7 postoperatively.[9] The bladder defect is allowed to heal spontaneously.

Bladder Marsupialization

When other surgical corrections have failed to provide a normal urine flow, a salvage technique such as bladder marsupialization may be considered.[6,11,13] Complications from this procedure include urinary incontinence, urine scald, and cystitis.

An 8- to 12-cm paramedian incision is made lateral to the prepuce. The bladder apex is exteriorized, stay sutures placed 4 to 5 cm apart, and a cystotomy incision made between the sutures. A second abdominal incision is made on the opposite side of the prepuce in a location far enough cranial to prevent urine scalding. The bladder apex should be positioned with minimal tension into the second abdominal incision by the stay sutures. The bladder is tacked to the abdominal wall with four evenly spaced sutures. The serosal and muscular layers are sutured to the abdominal fascia to form a circular stoma. The bladder mucosa is then sutured to the skin. The original abdominal incision is closed in a routine fashion.[11,13] The surgical stoma should be large enough to allow urine flow, but not too large as to allow bladder eversion. Short-term complications of marsupialization are bladder prolapse and cystitis, and long-term complications are closure of the stomal site.[6,13]

FEMALE UROGENITAL SURGERY

Cesarean Section

Often due to the small size of the patient, the clinician may find it more difficult to vaginally manipulate the fetuses in goats than in other domestic animals. Therefore, cesarean sections are recommended when vaginal delivery cannot be accomplished and the animal's value will allow this procedure.[1] Mild sedation with acepro-

mazine, in conjunction with leg restraints and an inverted-L block with 10 to 20 ml 2% lidocaine provides good anesthesia. Deeper sedation is attainable with a mixture of Telazol (6.6 mg/kg IV) and ketamine (6.6 mg/kg IV). Although other approaches are possible, a recumbent, left flank approach has the advantage of easy restraint.[1] The front and rear legs are restrained in extension with soft cotton ropes. A rolled towel is placed under the spine to tilt the doe to a 30-degree angle toward the surgeon. The paralumbar fossa is clipped and prepped aseptically. A skin incision is made near the center of the left paralumbar fossa. Depending on the size of the doe, the incision should start 5 cm ventral to the lateral processes of the lumbar vertebrae and continue in a slight ventrocranial direction for approximately 15 cm.[1]

The external and internal abdominal oblique muscles can be excised in the same plane as the skin incision. An incision is carefully made through the transverse abdominal muscle and the peritoneum. This incision can be extended by inserting fingers into the incision and pulling both dorsally and ventrally to separate the muscle along the direction of its fibers.[1]

The uterus is located and partially exteriorized. Sterile pads are packed around the exposed uterus to decrease abdominal contamination. The uterus should be incised longitudinally over the greater curvature of the horn in a relatively avascular area.[1] The incision should be long enough to allow easy removal of the fetus without risking uterine tears. Multiple incisions may be needed in the case of twins or triplets. After removal of the fetuses, the incision should be closed with an inverting suture pattern (e.g., Utrecht pattern). If a good closure is not obtained, the entire incision can be oversewn with a second inverting closure. The transverse abdominal wall is closed along with the peritoneum with a simple continuous pattern. The internal and external abdominal obliques may be closed together and the skin closed in a routine fashion.

Ovariectomy

Bilateral ovariectomy is performed to produce females for use in semen collection and libido testing of males. These ovariectomized females should be given estradiol (100 mg) 24 to 48 hours prior to use.[1,14] Other indications are for the treatment of ovarian tumors and for sterilizing pet animals. A flank or a midline approach is acceptable to perform ovariectomies. The animal should be heavily sedated and the incision site blocked with a local anesthetic or general anesthesia may be used. Animals should be given antibiotics up to 4 hours preoperatively and the clinician should adhere to aseptic technique. The abdomen should be entered as far caudally as possible and the ovaries are located. The ovarian pedicle should be identified and the ovary gently exteriorized. A crushing forceps is placed on the ovarian pedicle and a transfixation ligature is placed around the pedicle. The ovarian pedicle is transected. The hemostat is released and the pedicle examined for hemorrhage. The abdominal incision is closed in a routine manner. The procedure may also be performed through a ventral midline incision. This may be more appropriate for larger goats and primiparous goats.

CHAPTER 68

Techniques for Artificial Insemination of Goats

LOU NUTI

Artificial insemination (AI) involves placement of semen from a male into the reproductive tract of a female by mechanical means rather than by natural mating. A thorough understanding of the various components of an AI program is very important to goat breeders if the herd is to be handled effectively and efficiently. This chapter is designed to provide readers with a foundation to build a sound AI program.

ADVANTAGES OF ARTIFICIAL INSEMINATION

The contribution of AI to the genetic makeup of highly productive strains and breeds of cattle during the past 40 years has made AI a desirable tool for genetic improvement in other species. AI offers goat breeders the potential for use of genetically superior sires. It enables the small herd owner to obtain breeding services at a reasonable cost. By means of AI, breeders are able to identify superior animals that possess desirable traits. The mating of outstanding sires and dams, even miles apart, may be effectively performed by AI using frozen semen. Such matings have the potential to create desirable new lines, reduce inbreeding, and reduce spread of disease by minimizing animal movement. When used correctly, AI has a number of benefits, including maximal use of outstanding sires, increased herd uniformity, elimination of bucks on the farm, relatively inexpensive semen costs, decreased potential for venereally transmitted diseases, and improved herd management.

DISADVANTAGES OF ARTIFICIAL INSEMINATION

The disadvantages of using AI should also be understood and carefully examined before the herd manager decides on this program for a herd. These include initial costs for AI equipment and nitrogen refrigerator, increased labor for heat detection and insemination, lack of standardized procedures for packaging and quality control for goat semen, lack of suitable sire proofs for production traits, requirement for specialized training because of anatomic constraints associated with the size of the goat, and potential for spread of less desirable traits.

SIGNS AND DURATION OF ESTRUS

The signs of estrus are primarily changes in behavior, one or more of which may be exhibited by most does. It is important to become familiar with and to record these signs for individual does, including time of onset, duration, and intensity. These signs are valuable pieces of information that can be used to determine optimal time for natural mating or AI. Signs include increased frequency of bleating, frequent urination, obvious restlessness or an increase in doe interaction, tail flagging, increased curiosity and attentiveness to the herd handler, noticeable change in milk volume in lactating animals, exhibition of male behavior by does (mounting, snorting), receptivity to mounting (standing heat), and anatomic changes including swelling of the vulva, discharge of vaginal mucus, and hyperemia of the vulva.

ESTRUS DETECTION AND ARTIFICIAL INSEMINATION

One of the most important, if not the most important, aspects of goat breeding when hand mating or AI is used is proper detection of estrus. Because the noticeable signs of estrus are primarily changes in behavior, familiarity with the normal behavior of individual does is required. These behavioral changes along with anatomic changes are the best tools to use to time mating either by natural service or by AI.

When bucks are available, does actively seek males when they are in estrus. The odor of bucks seems to have a stimulatory effect on does. The most dependable sign of estrus is the doe's response to a buck. A doe will remain immobile for breeding only during this period of standing heat, which lasts from 12 to 48 hours. Successful AI requires that human judgment be substituted for a buck's instinct and libido. If a person is less diligent or conscientious in the task of detecting heat than the buck, then some does in estrus will be missed and not mated.

Herd management conditions determine the exact procedures to be followed in observing for signs of heat. Does should be observed at least twice a day when the animals are free from distractions. Lactating animals can be observed shortly after each milking. Open, nonlactating does in loose housing or at pasture must be observed carefully. These animals may have to be confined twice daily. Choosing the right time of day (early morning and late night when it is cool) and location (shade, water source, near buck pens) will help tremendously.

Nothing helps detection of does in heat as much as accurate animal identification such as tags with large numbers or clear brands, and a record-keeping system

that indicates when particular animals require observation. Individual doe cards and large calendars are often used to keep simple "heat due" dates.

IMPORTANCE OF TIMING IN ARTIFICIAL INSEMINATION

It must be understood that a doe is fertile only when an ovum is present that can be fertilized. Likewise, it must be understood that ova are viable for only a short time after being ovulated unless they are fertilized. Does do not ovulate until late estrus or shortly after the end of standing estrus. Therefore, for optimal results does should be inseminated during the latter half of standing heat or shortly after the end of standing heat.

The accuracy of recognizing the signs of standing heat is at best fair and is generally reflected in the success of AI. Quite often, goat breeders follow the AM:PM rule used in breeding cattle; animals first noticed in heat in the morning are bred in the afternoon and animals first noticed in heat in the afternoon are bred the following morning. Although this system works moderately well, it is no substitute for exact information regarding individual estrous behavior and length. The author's personal preference is to inseminate at least 12 hours after the first observation of heat, with preference for late rather than early insemination, provided that animals are checked regularly at least twice a day at 12-hour intervals. This preference is based on information available regarding the time of ovulation, duration of sperm transport in the female reproductive tract, and time of survival of male and female gametes.

AIDS FOR SUCCESSFUL HEAT DETECTION

A number of aids have been developed to assist with the task of detecting does in estrus. These include the use of a "buck rag," which is a cloth that has been wiped over the scent glands of a male in rut, stored in a closed jar, and warmed before opening in the presence of the does; a sturdy and secure buck pen with a breeding window in an area where does are brought in for heat detection; the use of sexually altered (by penile deviation or vasectomy) males fitted with a marking harness; use of wethers or intact females treated with testosterone; and the use of intersex goats or hermaphrodites.

HANDLING OF SEMEN

The procedures used for handling semen, beginning from the time it is shipped from the supplier until it has been deposited in the doe, have a tremendous influence on fertility. Low temperature enables semen to be stored for extended periods of time once it has been frozen, but the fact that semen remains frozen does not ensure that fertility has been maintained. Damage can be expected any time the temperature of frozen semen rises above –130°C, and the rate at which semen deteriorates increases as the temperature rises. Although liquid nitrogen has a temperature of –196°C, the potential for damage due to elevated temperatures is present when semen is transferred between tanks and when semen is elevated into the neck of a tank so that some can be removed for thawing. A current inventory of the location of semen within a storage tank and use of procedures to minimize both the extent of warming and length of time semen is exposed to elevated temperatures during routine handling are essential to maintenance of high fertility. Thawing techniques differ between ampules and straws, and among various types of straws. Research on thawing semen in ampules or straws has concluded that semen in ampules should be thawed in ice water while semen in straws should be thawed in water at about 35°C.

Although most researchers now recommend that semen in straws be thawed in water at about 35°C, controversy exists as to whether the semen should remain in the thaw bath until its temperature has reached the temperature of the water or whether thawing should be timed so that the semen temperature does not rise above 5°C. Recent work on cattle semen in a large trial concluded that thawing need not be timed to prevent semen temperature from rising above 5°C, and that fertility may actually be improved by allowing semen temperature to rise to 35°C.

Another controversial issue, with respect to semen in straws, is the importance of using the semen immediately upon thawing. Although most cattle AI organizations recommend that thawed semen be used as soon as possible, they have expressed little concern at allowing semen to remain in the thawing bath for several minutes. In goats, however, it is recommended that semen be thawed for 30 to 60 seconds at 35°C because of the likelihood that the semen will spend several minutes in the doe's tract while the inseminator tries to penetrate the cervix.

NUMBER OF SPERM PER INSEMINATE

The number of sperm per inseminate is an important factor influencing the fertility of frozen semen. The optimal number of sperm per inseminate depends on the fertility of the sire, inseminator competence, and the timing of insemination relative to ovulation. Goat semen processors are best qualified to determine the optimal numbers of sperm cells based on client feedback. Few field trials titrating sperm numbers against conception rates have been conducted for goats. As a result, most goat semen processors package goat semen in concentrations that yield 50 to 100 million progressively motile sperm cells after freezing and thawing. With suitable processing and careful handling and thawing, at least 50% of the cells survive and are progressively motile. Thus, initial prefreeze concentrations should be between 200 and 400 million per milliliter of extended semen. Semen from certain sires survives freezing, storage, and thawing better than semen from others, for unknown reasons. Thus, knowledge of individual freezing ability of semen is essential for deciding how many sperm are necessary for each breeding unit.

Another important consideration with respect to sperm numbers has to do with the site of semen deposition. Laparoscopic insemination directly into the uterine horns requires fewer sperm than does transcervical insemination into the uterine body. Greater numbers of sperm are required for either cervical or vaginal

TABLE **68-1**

Minimum Safe Numbers* of Motile Spermatozoa for Insemination at Different Sites

	TYPE OF SEMEN		
Site	***Fresh***	***Liquid-Stored***	***Frozen-Thawed***
Vaginal insemination	300	Not effective	Not effective
Cervical insemination	100	150	180
Intrauterine insemination (total in two horns)			
Via cervix	60	60	60
Laparoscopically	20	20	20

*In millions.
Data from Evans G, Maxwell WMC: *Salamon's artificial insemination of sheep and goats.* Sydney: Butterworths Publishers, 1987.

insemination. Whatever the site of insemination, the number of motile spermatozoa in the inseminate affects fertility. Generally, less fresh extended semen will be needed than frozen-thawed semen. A recommended safe limit for the number of motile spermatozoa is shown in Table 68-1.

SITE OF SEMEN DEPOSITION

The site of sperm deposition within the reproductive tract of the doe has a marked effect on pregnancy rates. Semen should be deposited in the body of the uterus, although cranial cervical deposition has yielded satisfactory results (Fig. 68-1). In cattle, the reproductive tract can be palpated, but experienced inseminators deposit dye correctly into extirpated reproductive tracts only 24% of the time. Thus, it is likely that many failures in goat AI are the result of misplaced semen. In the author's experience, attempts to pass an AI gun have resulted in placement of the tip of the gun in one of the uterine horns or puncture of the cervix and placement of the tip of the gun in the abdominal cavity. Gauging the depth of AI gun penetration by marking the gun as well as developing the proper "feel" when applying pressure to pass the AI gun past the cervical rings should improve AI success rates.

Laparoscopic uterine insemination procedures have the advantage of depositing semen directly into the lumen of the uterine horns at a point closer to the site of fertilization than transcervical insemination. This also eliminates one of the primary barriers to semen deposition, namely, the cervix. Two stab incisions are made in the ventral abdominal wall approximately 2 cm on either side of the midline about 10 cm cranial to the udder. One is for insertion of the trocar-cannula (7 mm), through which the laparoscope is introduced. The second incision is for the secondary trocar-cannula through which the inseminating instrument (5 mm) is introduced. Several types of inseminating instruments have been developed. The inseminating gun with aspic needles* is a very useful and precise instrument. The needle is sharp and long enough to go through the uterine wall so that semen can be deposited within the uterine lumen (Fig. 68-2). If difficulty is encountered during injection or if swelling of the uterine wall occurs, the semen is not being injected into the uterine lumen. To ensure correct semen deposition, the inseminating needle must be perpendicular to the uterine horn and the needle must be introduced completely through the uterine wall. Alternatively, a Pasteur pipette can be used for this purpose.

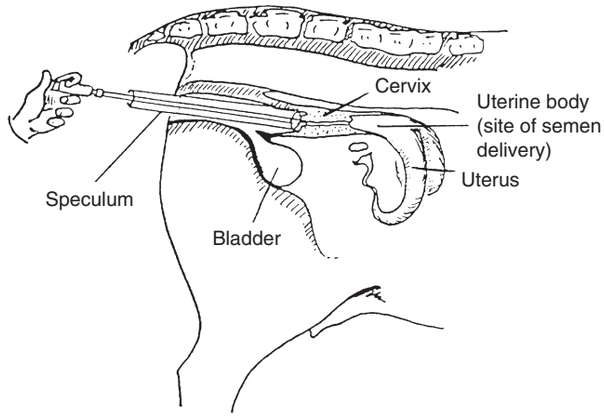

Fig. 68-1 Optimal site of semen deposition.

EXPULSION OF SEMEN

Because most ampules or straws contain no more than the minimum number of sperm needed for maximum fertility, care must be taken to prevent loss of sperm in straws, ampules, or insemination equipment. It has been shown that rapid expulsion (2–3 seconds or less) of semen from the catheter that was used to aspirate semen from ampules together with the use of high-viscosity extenders (e.g., 50% egg yolk/citrate) resulted in 27% semen residue remaining in the rod, which translates to loss. Although the inseminator has little control over the extender used, he or she can increase the number of sperm delivered significantly by expelling the semen over a 5- to 7-second interval. Losses are not as pronounced when straws are

*IMV International Corp, Minneapolis, MN.

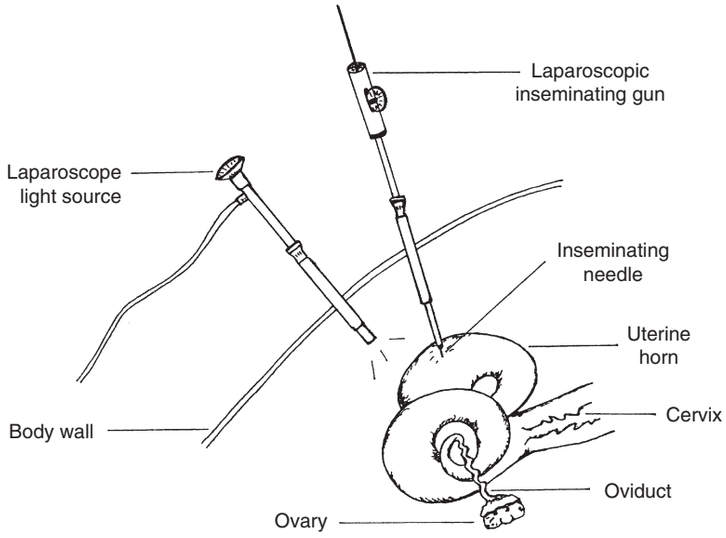

Fig. 68-2 Laparoscopic artificial insemination of goats.

used because semen is expelled directly from the straw by means of a metal plunger that forces a solid plug through the straw. Nonetheless, several seconds should be allowed when expelling semen from straws, because rapid expulsion may increase the chance for leakage of semen within the insemination device due to straw damage or improper seating of the straw.

INSEMINATOR COMPETENCE AND TRAINING

Inseminator errors in handling and placement of semen within the reproductive tract of does and the importance of proper timing of insemination have been discussed. It is suspected that these errors are the most common cause of low fertility when AI programs are unsuccessful in herds in which does are free of disease and have normal reproductive cycles. It should be clear that although frozen semen may be of excellent quality when it leaves a buck stud or AI facility, fertility will be poor if semen is improperly handled or deposited in the wrong place at the wrong time.

Experience per se does not ensure competence. Differences in success among "experienced" cattle inseminators, even among those closely supervised, have been reported. One would suspect that differences in conception rates may be even greater with owner-inseminators, probably because close supervision is generally lacking and proper techniques are forgotten and skills are lost during long nonbreeding periods. Retraining prior to the breeding season should be considered by such individuals. When large numbers of animals are to be inseminated in a short period of time, such as in an estrus synchronization program, inseminators should make certain that they are sufficiently conditioned against fatigue. If AI training workshops are not available, inseminators could try to spend time with someone who has had a consistently high success rate and watch closely for the step-by-step procedure used.

ARTIFICIAL INSEMINATION EQUIPMENT BOX

This box should be large enough to accommodate all the AI equipment. Insemination boxes can be acquired from an AI equipment supplier. These boxes are usually of a durable material or metal. The box should have a lid to keep the equipment clean and in order. The AI box generally contains an insulated thaw box, insemination gun (for 0.25- or 0.5-ml straws), sheaths, lubricating jelly, speculum, light source, thermometer, straw cutter, tweezers, paper towels, and a speculum brush. Anything that comes into contact with the internal reproductive tract of the doe should be sterile. Thus, special precautions should be taken in cleaning, handling, and storing the speculum, AI gun, light, and sheaths. The sheaths are usually prepacked in sterile bags. Once the sheath is removed from the bag, care must be exercised in handling to avoid possible contamination. Specula should be soaked immediately after use in warm, soapy water until they can be thoroughly washed in hot soapy water, using a test tube brush. Specula are then rinsed thoroughly and sterilized in boiling water, alcohol, or chlorhexidine disinfectant or by baking in a hot oven. Once cleaned, rinsed, and dried, each speculum is wrapped in a clean paper towel until its next use. All other equipment should be cleaned in a like manner. The insemination gun should be cleaned by taking the plunger out of the barrel and wiping each part thoroughly. All AI equipment should be stored in a dust-free container until use.

RECORD KEEPING FOR ARTIFICIAL INSEMINATION

A system for recording complete and accurate insemination data is an integral part of a successful AI program. The more detailed the observation of each insemination attempted, the more likely important clues will be noted that will improve future attempts. A 3-by-5–inch index

card kept in a recipe file box works well. Information usually noted includes the date of breeding; the number of straws used; the date of last service or AI; the name and number of the doe; the name and address of the doe's owner; the complete name and registration number of the sire; the date of semen collection and the processor; the appearance of the cervix; the quantity, appearance, and consistency of mucus at time of AI; the depth of transcervical insemination and degree of difficulty; the interval from thaw to insertion of semen into the doe; the time required for insemination; the time from first detection of heat to AI; the length of estrus after AI; and record of the semen processor's evaluation of the semen unit used.

REBREEDING FOLLOWING ARTIFICIAL INSEMINATION

If a doe is still in standing heat 12 to 24 hours after insemination, a decision must be made about whether to reinseminate. Most processors recommend a second insemination, but proper trials have not been conducted to justify the added cost. Until credible evidence is available, the decision must rest with the owner of the female. The cost and availability of semen and labor must be weighed against the likelihood of enhancing conception.

If the female appears to be in heat again 3 weeks subsequent to insemination, she should be examined with a vaginal speculum and an AI light. The cervical opening is located and inspected for evidence of a grayish mucus plug. If this plug is present, the doe is most likely pregnant. If the plug is disturbed, the doe may abort. Therefore, it is not recommended that AI be repeated on what appears to be a subsequent heat. If there is doubt that the doe is pregnant and rebreeding is desired, natural service is recommended.

TRANSCERVICAL ARTIFICIAL INSEMINATION

If a clean, comfortable site has been selected ahead of time, breedings have been planned, and insemination equipment has been kept in a clean, dust-proof container, then insemination of the doe should require only a few minutes. Tools and supplies should be assembled within easy reach of where the doe will be inseminated. Two clean specula (in case one should be dropped and broken), a package of disposable sheaths, lubricant, paper towels, tweezers, straw cutter or scissors, and inseminating gun should be laid out. The thaw container should be filled with water at 35° to 37.8°C. A thermometer should be used to make sure the water stays at this temperature. Some hotter water should be kept nearby and added if the water temperature falls below 35°C before the straw of semen is thawed.

A bucket of warm soapy water and a bucket of clear water should be prepared. The doe is restrained and the perineal area washed thoroughly with soapy water, rinsed, and dried with a paper towel. Next, the inseminator's hands are washed and dried. It is helpful to have an assistant restrain the doe and hold the tail to one side. The speculum is lubricated and inserted into the doe's vagina. If resistance is encountered, the speculum should be directed first dorsally and then slightly ventrally to pass over the ischial arch. After placing the breeding lamp inside the speculum, the entire speculum is rotated 180 degrees. The cervical opening should be located somewhere between the 5 and 7 o'clock positions. Once the cervix has been located, pressure is placed on the speculum to "lock" the cervix into the lumen of the speculum. If the doe is healthy and in standing heat, the cervix should be bright red and the external os relaxed, giving the appearance of a small black dot. If the cervix and cervical mucus appear typical of mid- to late heat, the AI procedure can be continued. If the mucus is thin and watery and the cervix is closed, the speculum should be removed and the doe checked again 6 to 12 hours later.

The assistant holds the tail and speculum in the doe while the inseminator proceeds. The semen storage tank is opened and the canister containing semen from the sire of choice is located. That canister is elevated up to the frost line in the neck of the tank. The desired cane is lifted out just far enough for the practitioner to reach into the goblet with the straw tweezers and remove one straw of semen. The identification on the straw is quickly checked and it is noted whether the straw is plugged at both ends. If it is plugged on both ends, the straw is placed in 35°C water for a minimum of 30 seconds. The straw can be left in the water bath for up to 4 to 5 minutes. If a straw is being used that is not plugged at both ends, a finger must be held over the unplugged end while the semen is thawing, as water is spermicidal. While the straw is thawing, the practitioner or assistant warms the insemination gun by rubbing it in a clean paper towel to create friction. This should be done immediately before loading the gun with the straw of semen. Warming the gun is a very important step, especially if the ambient temperature is low. The straw is removed from the thaw box and dried thoroughly with a paper towel, and the identification on the straw is rechecked. If an error has been made, refreezing the thawed straw should not be attempted. If the thawed semen cannot be used in the next few moments, it should be discarded. One end of the straw is plugged with white, cotton-like substance about 13 mm long. The opposite end is placed in the straw cutter and cut off. The cut end of the straw is placed into the open (nontapered) end of the sterile sheath. The warmed insemination gun is slid into the sheath with the plunger drawn out about 200 mm. Care should be taken to check that the cut end of the straw is seated squarely into the sheath adapter or the base of the tapered end of the sheath. The plunger is pushed gently until the air is expelled. The sheath is locked to the gun and kept warm but not hot.

When the cervix is located, the breeding gun is inserted through the speculum into the opening of the cervix. Then, using moderate pressure and a rotating motion, the breeding gun is manipulated through the rings of the cervix. A slight amount of forward progress should be felt each time one of the cervical rings is passed. Before proceeding too far through the cervix, a second sheath (one that has been marked 38 mm from the end) is inserted into the speculum until it touches the outside of the cervix. This sheath is used as a "yardstick" to

measure the actual depth of penetration that has been achieved. In no instance should penetration be greater than 38 mm to avoid perforation of the uterine wall or entry into one of the uterine horns. If a depth of at least 32 mm has been achieved, the semen should be deposited. If this depth has not been reached, the sheath can be rotated with forward pressure, but attempts to pass the insemination gun should not be prolonged. Continued efforts for more than 10 minutes are counterproductive. If the cervix has been penetrated at least 13 mm, there is a good chance that the sperm can negotiate the remainder of the cervical canal. If optimal penetration has been achieved, the insemination gun is slightly withdrawn so that the tip of the sheath is not pushed tightly against any tissue. The plunger of the breeding gun is then depressed very slowly and gently to deposit half the semen (about 50 mm on the plunger). The gun is then withdrawn to the midpoint of the cervix and the remaining semen slowly deposited. The inseminator removes the equipment from the doe by withdrawing the speculum about 50 mm and then gently and slowly withdrawing the speculum and insemination gun simultaneously.

When the insemination gun is removed and semen is seen between the sheath and the straw in any quantity, it is likely that "blow back" has occurred and instead of the semen entering the cervix, it flowed back into the sheath. If there is concern that insufficient semen was deposited, another straw may be thawed and the procedure repeated after ensuring that the straw is seated securely in the tapered end of the sheath. After insemination is complete, the doe is allowed to stand and relax for a few minutes while notes concerning the insemination are completed.

LAPAROSCOPIC ARTIFICIAL INSEMINATION

Feed and water should be withheld from does for at least 12 hours prior to laparoscopic AI. Sterile insemination equipment should be used and needles should be rinsed with sterile physiologic saline before use. Insemination equipment that comes into contact with semen should be kept at 30° C. All equipment should be checked for proper function, including the laparoscope light source. The trocar-cannula assemblies and body of the laparoscope should be placed in an appropriate sterilizing solution between inseminations. Does are prepared for insemination by light sedation. Does are placed in dorsal recumbency in a suitable cradle and the abdomen cranial to the udder is shaved and scrubbed. Local anesthetic is injected subcutaneously at two sites 5 to 7 cm cranial to the udder and 3 to 4 cm lateral to the ventral midline.

The cradle is raised to position the doe head down at an angle of 40 degrees or more from horizontal. Each trocar-cannula is inserted into the peritoneal cavity at the anesthetized sites. The laparoscope is inserted through the appropriate cannula. The peritoneal cavity is inflated with a small amount of gas if necessary. The uterus is located and visualized through the laparoscope. The insemination pipette is loaded with 0.3 ml of air and then the required volume of semen. Fresh semen should be stored in a water bath at 30°C until it is used. Frozen semen should be thawed just prior to use. The insemination pipette is inserted through the cannula. An avascular area of the uterine horn is identified and a stab incision is made with the pipette at a right angle to the uterine wall. The inseminator must be certain that the tip of the pipette is in the lumen of the uterus. The plunger of the insemination gun is depressed and one half of the semen is expelled. The procedure is repeated on the opposite uterine horn, and the balance of the semen is deposited. The process should be observed to determine that semen flows from the insemination gun freely without resistance and without enlargement of the tissue surrounding the stab incision. If there is any resistance to flow or if there is any indication that semen is not deposited within the uterine lumen, the position of the gun should be adjusted. After semen has been deposited in both uterine horns, the insemination gun is removed from cannula. The laparoscope and cannulae are removed and placed in the sterilizing solution in preparation for the next animal. An antibiotic spray can be applied to the wounds and a long-acting antibiotic can be injected. Does are removed to a recovery area and left undisturbed for 1 to 2 hours after insemination.

CONCLUSION

The key to success in any breeding program is sound management. Because of the many factors involved, functional and current records are essential for adequate planning and sound management decisions. Unless each factor that contributes to the percentage of does cycling and the conception rate is optimized, fertility will be reduced. Few producers can afford animals of low fertility. Any doe that fails to become pregnant under proper management conditions should be culled.

CHAPTER 69

Clinical Reproductive Physiology and Endocrinology of Does

MARY C. SMITH

PUBERTY

Well-fed females of the European breeds commonly reach sexual maturity and begin to show signs of estrus at 6 to 8 months of age, during the autumn of their first year. If Angora doelings are small, the onset of puberty may be delayed until the second autumn. In pygmy goats, puberty may occur as early as 3 months, and occasionally even doelings of the larger breeds cycle at this young age. Introduction of a buck synchronizes puberty in a group of doelings during the breeding season. Generally, breeding should be delayed until the animal has attained 60% or more of its adult weight. Angora goats should weigh a minimum of 27 kg; larger dairy goat breeds should weigh 32 to 41 kg before being bred. If these guidelines are followed, higher conception rates and kidding percentages as well as safer parturitions will be achieved.

ESTROUS CYCLE

During the normal breeding season, August to March and especially October to December in temperate northern latitudes, goats are polyestrous. Near the equator, native breeds cycle year round but cyclicity is influenced by feed availability. Photoperiod (via secretion of melatonin from the pineal gland during hours of darkness) is an important signal for the onset of cyclicity in autumn. The end of the breeding season (transition to the anestrous period) is believed to occur because goats have become refractory to short days rather than because of a small increase in day length after the winter solstice.[1] A 60-day exposure to long days (16 hours) will end the goat's refractoriness to short days. Introduction of a buck can advance the breeding season, as most seasonally anestrous does come into estrus and ovulate within 8 days.

The normal estrous cycle of dairy goats is approximately 20 to 21 days, while pygmy goats are variously reported as having average cycles of 18 to 24 days.[2] Estrous cycles are usually more erratic at the beginning and the end of the breeding season. Short cycles of less than 12 days, and often of only 5 to 7 days, are quite common, especially in young does. Short cycles are often associated with premature regression of the corpus luteum. Estrus is occasionally observed during pregnancy.

Proestrus often lasts about 1 day. It is a period when the buck or teaser closely follows the doe, but she will not stand to be mounted. Estrus, or standing heat, lasts a variable time, often 12 to 24 hours. The doe is restless, bleats frequently, and wags her tail. Metestrus is the time from refusal to mate until formation of one or more corpora lutea. Ovulation is spontaneous and is variously reported to occur 12 to 36 hours after the onset of standing heat and may be hastened by the presence of a male goat. Diestrus, the period of corpus luteum function, is the longest portion of the cycle.

Studies in the cycling Boer doe have shown that follicular waves appear, usually with 4 waves per cycle. Follicles exceeding 3 mm in diameter emerge on days 2, 7, 12, and 17 of the 21-day cycle. There are no statistical differences between waves in number of follicles or diameter of the largest follicles.[3] Improved nutrition increases ovulation rate.

Endocrinology of the Estrous Cycle

The frequency and amplitude of luteinizing hormone (LH) pulses increase progressively as the first estrous cycle of the season approaches. Exogenous melatonin also increases LH pulse frequency. With the onset of puberty or the arrival of the breeding season, high-frequency LH pulses stimulate follicle development, there is a sustained increase in estradiol, and a preovulatory LH surge occurs, followed by ovulation. During estrus, as during seasonal anestrus, the plasma progesterone concentration is less than 1 ng/ml. Progesterone values reported during the luteal phase (typically 4 to 8 ng/ml) are variable and depend on the number of corpora lutea present and the assay procedure used. The progesterone concentration is also reduced under conditions of higher nutrition because of higher clearance rates of the hormone by the liver. The progesterone concentration drops off precipitously 3 days before the next estrus. During the last 2 days of the cycle, 17β-estradiol rises from a baseline of about 8 to 10 pg/ml to a maximum of about 32 pg/ml at the beginning of standing estrus, only to fall to baseline again 12 hours later. Peak plasma levels of LH, follicle-

stimulating hormone (FSH), and prolactin are observed during estrus, within a few hours after the estradiol peak. A second FSH peak has been detected 48 hours after the first.[4] This sequence of hormonal events is quite similar to that reported for the ewe and the cow. Inhibin is a glycoprotein hormone produced by granulosa cells that inhibits the release of FSH from the anterior pituitary. Immunization against inhibin increases the ovulation rate in goats.[5]

Estrus Detection

A teaser or breeding buck is best able to elicit and detect signs of estrus in the doe. If a buck is introduced into the herd at the beginning of the breeding season, the does will show heat in an average of 5 to 8 days. Standing and riding behavior among does is not as common as with cows. Many does will not cycle visibly unless a buck or another source of the buck odor, such as a cloth that has been rubbed all over the buck, is present in the environs. A common method of heat detection for small herds is to rub a rag on the rank buck's scent glands, caudomedial to his horns, and store this rag in a tightly covered container. The buck jar is opened and presented warm to the doe each day; when in estrus, she will be very interested in the jar. If the buck himself is present, the two animals will stay close together. If separated, they will restlessly search the perimeter of their enclosures for a means of escape.

The external genitalia may be more swollen, reddened, and more moist during estrus, but these signs are not dependable with all does. Rapid side-to-side or up-and-down tail flagging is a good sign of heat that can often be detected in the absence of a buck. The behavior probably serves to spread pheromones from the doe's vulva to any nearby males. Restlessness and a tendency to be more vocal than usual are also commonly observed. Urination may increase in frequency. Milk production and appetite may decrease and somatic cell counts in the milk increase.

Vaginal smears have been used to identify the stage of the estrous cycle with only partial success. The period of standing heat corresponds fairly well with the appearance of greater than 50% desquamated, eosinophilic, polyhedral epithelial cells in the vaginal smear. These cells decline rapidly and are replaced by more basophilic and spherical epithelial cells, which continue to be present until just before the next estrous period. Numerous metestrous leukocytes with compact nuclei appear in the smear at the time of ovulation.

A speculum examination of the cervix may be more helpful in detecting estrus. At the beginning of heat, the vaginal mucosa is reddened and moist, but little mucus is present. As heat progresses, a variable amount of transparent mucus is visible in the cervix and on the floor of the vagina. This mucus later turns cloudy and finally is cheesy white at the end of heat. Conception is best when the doe is bred at the stage at which her cervical mucus is cloudy and the cervical os is relaxed. Metestrous hemorrhage, as seen in the cow, is rarely observed in goats.

GESTATION

The placenta of the goat is cotyledonary and syndesmochorial. The caruncles are concave. The fetal trophectoderm consists of binucleate and uninucleate cells. The fetal binucleate cells migrate to and fuse with the uterine epithelium to form syncytial plaques.[6] This migration continues throughout pregnancy.

The percentage of multiple births seems to vary with the population under study, including its nutritional status. Twins or triplets are usually more common than single kids, except in primiparous animals. Quadruplets are not rare. In Angora goats, at least, the ovulation rate is 20% higher on the second heat than on the first heat of the breeding season. Fertilized ova commonly migrate to the opposite horn in multiple births, allowing better spacing of conceptuses. Transuterine migration of embryos is also common in singleton pregnancies. Implantation occurs at approximately 18 days after breeding.

Although slight breed differences do exist, the average duration of gestation is generally reported as 5 months, or 150 days (varying from 147 to 155 days). There is little effect of litter size on gestation length; quadruplets are born only 3 days earlier than single kids. Births are much more apt to occur during daylight hours than at night and are most frequent around midday.[7] If parturition occurs during the breeding season, the doe will resume ovarian activity and can conceive again.

Endocrinology of Gestation

The plasma level of progesterone, which is produced almost entirely by the corpora lutea of the pregnant goat and not by the placenta, remains high until about 4 days before parturition. Ovariectomy at any stage of gestation will cause abortion. Prostaglandin E_2 is produced in large amounts by the caprine placenta and is believed to be luteotropic in this species.[8] Several pregnancy-associated glycoproteins (PAGs) including pregnancy-specific protein B are produced by trophoblastic binucleate cells and are detectable in the peripheral circulation of the dam from 21 days after insemination and continuing throughout gestation.[9,10] Goats with two or more conceptuses tend to have higher concentrations of PAGs than goats carrying single fetuses. PAG concentrations may drop several days or weeks before abortion in conditions where placental function is disturbed.[11]

Estrone sulfate (from the fetus or placenta) begins to rise at 40 to 50 days of gestation, and can be used for pregnancy diagnosis after this time. Peak estrogen levels are reached at parturition; a very low level is found 1 day after parturition. Placental lactogen, which is also produced by the placenta and thus can be used for pregnancy diagnosis and prediction of litter size, follows a similar pattern.[12] Placental lactogen is first detectable at about 60 days of gestation and stimulates mammary gland development. Goats with false pregnancies/hydrometra will have a prolonged elevation in progesterone but will not show increases in PAGs, placental lactogen, or estrone sulfate.

CHAPTER 70

Clinical Examination of the Female Reproductive Tract

LIONEL J. DAWSON

Goats are usually seasonal breeders. With respect to reproduction, the single most important regulating factor is the day length, or photoperiod. This influence is more pronounced the further north or south of the Equator the animal is located.

The length of the breeding season is most influenced by the following:

- Photoperiod
- Breed
- Nutrition

HOW PHOTOPERIOD INFLUENCES THE REPRODUCTIVE PROCESS IN DOES

The underlying influence of photoperiod affecting cyclicity is mediated through the secretion of luteinizing hormone (LH) from the anterior pituitary. In making the transition from anestrus to cyclicity, serum concentration of LH begins to increase.[1–9] The reason for this increase has been attributed to an increase in the frequency and magnitude of the LH pulses.[8] Final maturation and ovulation of ovarian follicles depend on sufficient LH release.[8–10]

A currently accepted hypothesis referred to as the "gonadostat hypothesis," maintains that in prepubertal and seasonally anestrus does, estrogen secretion from the follicles strongly inhibit the release of LH.[9,10] As the animal matures or is exposed to decrease in day length (late summer and fall), this inhibitory effect is lost, and there is increased LH release leading to ovulation and cyclicity.[8–10]

This change in sensitivity or alternating inhibitory influence of estrogen remains unclear. It may be due to changes in melatonin production from the pineal gland, mediated through the light perceived by the eye.[9–15]

European goat breeds (Saanen, Toggenburg, and French Alpine), Spanish, Angoras, and Kikos have a more

CHAPTER 70

Clinical Examination of the Female Reproductive Tract

LIONEL J. DAWSON

Goats are usually seasonal breeders. With respect to reproduction, the single most important regulating factor is the day length, or photoperiod. This influence is more pronounced the further north or south of the Equator the animal is located.

The length of the breeding season is most influenced by the following:

- Photoperiod
- Breed
- Nutrition

HOW PHOTOPERIOD INFLUENCES THE REPRODUCTIVE PROCESS IN DOES

The underlying influence of photoperiod affecting cyclicity is mediated through the secretion of luteinizing hormone (LH) from the anterior pituitary. In making the transition from anestrus to cyclicity, serum concentration of LH begins to increase.[1–9] The reason for this increase has been attributed to an increase in the frequency and magnitude of the LH pulses.[8] Final maturation and ovulation of ovarian follicles depend on sufficient LH release.[8–10]

A currently accepted hypothesis referred to as the "gonadostat hypothesis," maintains that in prepubertal and seasonally anestrus does, estrogen secretion from the follicles strongly inhibit the release of LH.[9,10] As the animal matures or is exposed to decrease in day length (late summer and fall), this inhibitory effect is lost, and there is increased LH release leading to ovulation and cyclicity.[8–10]

This change in sensitivity or alternating inhibitory influence of estrogen remains unclear. It may be due to changes in melatonin production from the pineal gland, mediated through the light perceived by the eye.[9–15]

European goat breeds (Saanen, Toggenburg, and French Alpine), Spanish, Angoras, and Kikos have a more

restricted breeding season (September to February). Whereas Nubian, Nubian crosses, Boer, pygmy, and Tennessee stiff-legged goats have a longer or extended breeding season.[16] There is not only great variation among breeds regarding the length of the breeding season, but there are significant variations within a breed. Selection for long breeding season should be utilized as a management tool.

Nutrition and body size play an important role when doelings reach puberty. In general, doelings born in late winter or early spring will reach puberty that fall. Breeding should be delayed till animals reach 65% of their mature weight, approximately 70 lb in meat goats and 70 to 90 lb in dairy goats.[16]

Reproductive problems in goats are usually management problems associated with confinement, attempts to breed them outside their natural breeding season, improper heat detection, poor breeding management, or improper artificial insemination.[17]

CLINICAL EXAMINATION OF THE DOE

History

A complete history should be an important part of the breeding soundness examination (BSE) because of the inaccessibility to the majority of the reproductive tract to palpation or visual inspection.[16,17] Information regarding the intention of the owner in utilization of these goats for production (meat, milk, and fiber), brush control, or as a companion animal should be gathered.

Housing

Goats may be housed in a pasture, dry lot, backyard, or barn.

Nutrition

- Pasture (Bermuda, native grass)
- Supplements (concentrate, hay, silage)
- Trace minerals

Breeding Management

- Natural or artificial insemination (AI)
- Time of the year (season)
- Hormonal manipulation of the does
- Bred on natural heat or time breeding

Natural Breeding

- Buck-to-doe ratio
- Number of bucks in a pen or pasture
- Fertility of the buck used (BSE done on the bucks before the breeding season)
- Bucks' libido
- Prior history of urethral obstruction in the buck

Artificial Insemination

- Source of the semen
- Evaluation of the frozen semen
- Heat detection
- Experience and success of the inseminator
- Bred once or twice during estrus
- Evaluation of the vagina and cervix on speculum examination at the time of AI
- Presence or absence of mucus at the time of AI

Estrous Cycle (Breeding Season)

- Length of estrous cycle
- Interestrous interval
- Duration of estrus
- Reaction of the female to the male

Detection of Estrus

- Epididymectomized or vasectomized bucks with marking harnesses
- Number of does to a teaser buck
- Frequency of changing the marking crayon on the harnesses
- Number of teaser bucks checking estrous behavior among does.
- Frequency of heat detection (markings on the doe)

Other Reproductive History of the Doe

- Prior kidding history (dystocia, uterine infection, discharge, etc.)
- Average age of the flock
- Age of the doe with the reproduction problem
- Prior abortions (herd or the doe)

Other Factors

- Milking history of the dairy does
  - Milk production (305 days)
  - Daily milk production
  - Whether they are milked during the breeding season
  - Mastitis
- Any chronic infection to the doe (parasitism, caseous lymphadenitis, Johne's disease, etc.)
- Diagnosis of other diseases in the herd
- Vaccination history

Physical Examination

- Current body condition
- Conformation
- Lameness
- Polled or horned
- Eyes

External and Internal Genitalia Examination

Visual examination of the perineal area should include evaluation of the anogenital distance.

In dairy breeds, especially in Alpines, Saanens and Toggenburgs, there is a strong association between intersex and polled conditions.[18] The polled trait (P) is autosomal dominant, and the horned trait (p) is recessive;

thus, PP and Pp are polled, and pp goats are horned.[18] Current thinking is that the same or a closely linked autosomal gene controls sexual developments, but in a recessive fashion; when homozygous, this gene causes expression on the Y chromosome.[18] Thus, Pp polled goats and pp horned goats are unaffected. PP polled male goats are always sterile; PP polled female goats are genetically female (XX), become intersexes, and have impaired fertility. They often develop buck-like head and neck, buck odors, buck behavior, shortened vagina, enlarged clitoris, and an increased genital distance.[18]

Vulva

Examine the lips of the vulva, then part the lips of the vulva and evaluate the clitoris. Any lesions on the vulva (scabs, ulcers, pustules, etc.) should be noted.

Vagina

Speculum examination is made of the walls of the vagina, vestibule, and cervix. Rule out any urine pooling in the vagina and also discharge. If discharge is present, determine the source (vagina, cervix, or through the external os of the cervix).

Cervix

Examine the external os and area around the opening (fornix).

Digital examination along with speculum/endoscopic evaluation could be done to evaluate the vagina, vestibule, and cervix and to rule out persistent hymen, lacerations, and adhesions. During the period of estrus in a doe, there is clear mucus discharge seen in the anterior vagina, later turning to cloudy (milky) toward the end. This is normal discharge and does not require treatment.[17]

Reproductive Ultrasonography

Ultrasonography has been used for evaluating the reproductive tract in small ruminants.[17,19,20] Goats are scanned transabdominally either at the right or left inguinal region or may be scanned transrectally using a probe adapter to a 7.5-MHz linear transducer.

Goats are usually scanned standing, and they tolerate it better than being tipped over in a dorsal recumbency posture. Transabdominal scanning is done on the right side, slightly cranial to the mammary gland, and about 3 to 4 inches from the midline (paramedian), because the reproductive tract is pushed toward the right side by the rumen. For transabdominal scanning, 3- to 5-MHz curvilinear or sector scanning transducers are superior to linear-array transducers; 5- to 7.5-MHz linear transducers have been used transrectally[17,19,20] (Table 70-1).

Earlier pregnancies around 20 to 25 days may be seen best with a transrectal approach, preferably in a dorsal recumbency position.[22–24]

Laparoscopy and Laparotomy

Laparoscopy or laparotomy may be done in certain infertility cases in does, especially to rule out oviductal blockage, ovarian disease (cysts and tumors), and adhesions to the reproductive tract due to dystocia or surgical embryo transfers.[17]

TABLE **70-1**

Reproductive Ultrasonography in Goats[16,17,19,21–24]

Conditions	Ultrasonographic Finding
Pregnancy, 35 days to term	
30–35 days	Multiple anechoic circular areas (fluid in the coiled uterine horns); embryo and amniotic membranes could be detected in the fluid
>40 days	c- or o-shaped placentomes seen
>45 days	Fetal skeletal hyperechoic and fluid anechoic; estimating the stage of gestation could be done by measuring crown—rump, crown—nose, or fetal biparietal diameter
Pseudopregnancy	Hypoechoic uterine fluid but no embryo or placentomes
Pyometra	Hyperechoic uterine conditions but no fetal skeleton
Fetal death or mummification	No heartbeat, fluid loss or none around the fetus, +/– placentomes
Fetal maceration	Fetal parts seen, no placentomes, and less fetal fluid in the uterus; doe may have vaginal discharge and may be septicemic

CHAPTER 71

Manipulating the Estrous Cycle in a Doe

LIONEL J. DAWSON

Goats are generally classified as "seasonally polyestrous" or short-day breeders in a temperate region. The degree of seasonality varies among breeds and their locations (latitude). Thus, the length of the breeding season is most influenced by photoperiod, breed, and nutritional status of the doe.

Native breeds near the equator generally cycle throughout the year.[1–3] In a temperate climate, goats are usually short-day breeders and have regular estrous cycles or heat cycles between August and March. But in the Northern Hemisphere in a temperate zone, the breeding season is much shorter, usually from October to December.[1,3,4]

Photoperiod and its influence on the secretion of melatonin from the pineal gland during the hours of darkness are important signals for cyclicity in the fall. The underlying influence of photoperiod, and its effects on cyclicity, is mediated through changes in pulsatile release of gonadotropin-releasing hormone (GnRH) from the hypothalamus, and the release of luteinizing hormone (LH) from the anterior pituitary gland.[5–19]

Estrus synchronization in animals that cycle throughout the year (polyestrous) focuses on manipulating either the luteal or follicular phase of their cycle. In does (seasonally polyestrous) during the breeding season, the opportunity to control their cycle is greater during the

CHAPTER 71

Manipulating the Estrous Cycle in a Doe

LIONEL J. DAWSON

Goats are generally classified as "seasonally polyestrous" or short-day breeders in a temperate region. The degree of seasonality varies among breeds and their locations (latitude). Thus, the length of the breeding season is most influenced by photoperiod, breed, and nutritional status of the doe.

Native breeds near the equator generally cycle throughout the year.[1–3] In a temperate climate, goats are usually short-day breeders and have regular estrous cycles or heat cycles between August and March. But in the Northern Hemisphere in a temperate zone, the breeding season is much shorter, usually from October to December.[1,3,4]

Photoperiod and its influence on the secretion of melatonin from the pineal gland during the hours of darkness are important signals for cyclicity in the fall. The underlying influence of photoperiod, and its effects on cyclicity, is mediated through changes in pulsatile release of gonadotropin-releasing hormone (GnRH) from the hypothalamus, and the release of luteinizing hormone (LH) from the anterior pituitary gland.[5–19]

Estrus synchronization in animals that cycle throughout the year (polyestrous) focuses on manipulating either the luteal or follicular phase of their cycle. In does (seasonally polyestrous) during the breeding season, the opportunity to control their cycle is greater during the

luteal phase, which is of longer duration and is more responsive to manipulation.[22] Strategies can be employed to extend the luteal phase by supplying exogenous progesterone or to shorten this phase by prematurely regressing existing corporal lutea (CL).[20–27] Different protocols have been established for effective synchrony of the estrous cycle, and also to provide an acceptable level of fertility, when utilizing artificial insemination or natural mating. Hormones have been used in goats to manipulate the estrous cycle, but none have been approved for use on goats in the United States.

The annual reproductive cycle of goats in a temperate region can be divided into (a) breeding season, (b) nonbreeding season or physiologic anestrous period, and (c) transitional period or season.

Under natural circumstances the breeding season begins when the onset of estrus activity within a group of does is increasing, and a majority of them are exhibiting estrus. The time of the year over 90% of the group will be cycling regularly is dependent largely on the breed, location, and nutritional status of the doe. This period usually begins late August to October, and may extend up to March.

During the nonbreeding season the majority of the does are not spontaneously cycling. The time of the year depends on the breed, location, and nutritional status of the does. Blood progesterone levels are low (less than 1 ng/ml), and there is very little ovarian activity on ultrasonography. This period is usually between April and July.

The transition period is between the nonbreeding and breeding season. Does are not spontaneously cycling but can be induced to initiate estrous cycles with buck exposure or hormonal therapy. It is usually between July and August, and it depends upon the location, breed, and nutritional status of the doe. At the end of the breeding season a transitional period is believed to occur before the nonbreeding or anestrus period (March and April), when the does' breeding activity declines.[1,20,21]

During the breeding season, estrus synchronization is best done utilizing hormones either by extending the luteal phase by supplying exogenous progesterone (Table 71-1), or by shortening the diestrus phase by prematurely regressing the existing corpus luteum (Table 71-2).[20–27] Extending the luteal phase by supplying exogenous progesterone is best done by utilizing intravaginal sponges, controlled internal drug release devices (CIDR), and feed supplements.[21,22,25,26] For better synchrony of estrus and ovulation, gonadotropins and prostaglandins are used at or near the end of the progestin treatment (Tables 71-3 and 71-4). Gonadotropins commonly used are follicle-stimulating hormone (FSH) and equine chorionic gonadotropin (eCG). Equine chorionic gonadotropin is commonly used because of its longer half-life than FSH.

Table **71-1**

Extending the Luteal Phase: Progesterone or Progestagen Products Used to Synchronize Estrus in Goats[20–24,26,27,39,54]

Product	Drug	Period	Estrus
Intravaginal Sponges			
Veramix Repromap Sincrocel	60 mg medroxyprogesterone acetate (MAP)	12–14 days	24–96 hours
Cronolone Chronogest	30–40 mg flurogesterone acetate (FGA)	12–14 days	24–96 hours
Controlled Internal Drug Release Devices (CIDR)			
CIDR-G	330 mg progesterone	12–14 days	24–96 hours
Feed Supplement			
MGA	0.125 mg melengestrol	8–14 days (twice a day)	24–96 hours
	0.25 mg melengestrol	8–14 days (once a day)	24–96 hours

Note: None of these drugs are approved for use in goats in the United States.

Table **71-2**

Shortening the Luteal Phase[20–27,39–42,53]

Product	Dosage	Treatment	Route	Estrus
Lutalyse (Dinoprost tromethamine)	10 mg	Two injections, 11 to 12 days apart	IM	24–72 hours (48–60 hours)
Estrumate (Cloprostenol)	50–150 μg	Two injections, 11 to 12 days apart	IM	24–72 hours (48–60 hours)

Note: None of these drugs are approved for use in goats in the United States.

Table **71-3**

Gonadotropin Products[23,26]

Product	Dosage	Route
PG 600 5 ml contains 400 IU eCG, 200 IU hCG	Full dose, 5 ml (off season, transition, and breeding seasons)	Intramuscular
Equinex, Stimukron, Fostim, Folligon (equine chorionic gonadotropin, eCG)	400–500 IU off season and transition period 200–300 IU, breeding season	Intramuscular

Note: None of these agents has been approved for use in goats in the United States. Equine chorionic gonadotropin (eCG) mainly has FSH-like activity. Human chorionic gonadotropin (hCG) has LH-like activity.
Data in this table have been derived from Keisler DH: Endocrine control of reproduction in the ewe and ram. Proceedings of Small Ruminant Short Course (ACT and SFT), Kansas City, Mo, August 1994, pp 2–31 and Keisler DH, Buckrell BC: Breeding strategies in ewes. In Youngquist RS (ed): *Current therapy in large animal theriogenology.* St. Louis: Elsevier, 1997, pp 603–611.

The drawbacks of using eCG are as follows: higher doses many result in large numbers of anovulated follicles, and repeated usage can cause declining fertility due to the presence of antibodies against eCG.[20,21,28,33] eCG is not commercially available in the United States, but a product containing both eCG and human gonadotropin, which is labeled for use in gilts (PG600), has been tried and used successfully in goats.

TRANSITIONAL PERIOD

The buck effect is a powerful tool to enhance induction of estrus in does. Sudden introduction of previously isolated bucks to does will stimulate a surge of LH followed by ovulation in majority of does (97%) within 48 to 72 hours.[29,30,31] The initial ovulation in these animals is accompanied by estrus in 60% of the does.[29] From 30% to 60% (75%[29]) of the does will short cycle and ovulate again in 3 to 8 days or 7 to 12 days after the introduction of the buck.[20,21,27,29–31,34] Two peaks of conception have been observed after the introduction of bucks; the first one is at 7 to 12 days and the second one is about 28 to 35 days.[2,21,29] In Creole goats, which are less seasonal breeders, three peaks of conception have been observed. The first peak occurred at 3 to 5 days, the second at 8 to11 days, and the third at 27 to 29 days after the introduction of the buck.[29] This phenomenon of short cycling in late transition in does may be due to lack of prior exposure of the reproductive tract to progesterone, and the corpora lutea that form initially are short lived due to early luteal regression (ELR).[21,27,29–34] In sheep the current thinking is that early luteal regression may be due to lack of progesterone priming and the positive effects of estradiol on the uterus. Estrogen increases the availability of oxytocin receptors, leading to the release of PGF_2 alpha from these receptors, and thus lysing the corpus luteum.[32,33,34]

Does that were supplemented with progesterone (45 mg of FGA [flurogesterone acetate]) in late transition, with the sponges removed on the day the bucks were introduced, had a higher percentage of does showing estrus and reducing the number of short cycles (ELR).[31] Buck effect and exogenous hormones are methods commonly employed to induce estrus in the transitional period (Table 71-5).

NONBREEDING SEASON

Out-of-season breeding in does could be done mainly by using hormones and manipulating the photoperiod to hasten the onset of estrus. This will enable the producer to have kids from does bred out of season, take their kid crop to market when prices are high, have year-round milk production, and also increase the number of kids born to the doe during her lifetime.

A number of methods have been tried to induce estrus in this period:

1. Administering hormones (Tables 71-4 and 71-6) progesterone, eCG, and prostaglandin
2. Altering the amount of daylight the does receive during the late winter or spring (Table 71-6)
3. Treating the does with melatonin (Table 71-6)

Photoperiod manipulation is done by altering the day length. Decreasing the day length will trigger the secretion of melatonin from the pineal gland. Melatonin production may influence the secretion of LH from the anterior pituitary gland, and hasten cyclicity.[4–18] Regulating photoperiod involves the availability of lightproof barns so that the amount of light perceived by the does can be controlled. Changes in light exposure require at least 60 days to induce change or cyclicity.[35–38] Gradual change is not necessary; the amount of change that is perceived by the eye is important. A reduction from 18 to 14 hours of light per day is as effective as a reduction from 13 to 9 hours per day. It is possible to expose does to additional light in the barn, and use the outside natural light as the perceived change. For example, does are exposed to additional lights when they are brought to the barn every evening from the beginning of December. These does are exposed to about 18 to 20 hours of light (natural and artificial), and this practice is continued to the beginning of February (60 days). Then the does are not exposed to artificial lights from the beginning of February, and are exposed only to natural daylight. This will result in the perception of marked reduction in day length in February and March and will enable a large percentage of does to cycle in 6 to 8 weeks under natural light. (late March to early April).

Exogenous melatonin can be administered to supplement the endogenous release and thereby mimic short

Table **71-4**

Progesterone in Combination with Prostaglandin and Gonadotropin

Product	Dosage	Location	Duration	eCG	Prostaglandin	Season	Estrus	Breeding	Pregnancy Rate
Chronogest	20 to 45 mg FGA	Vagina	12 days	+ [48 hours prior]	+ [48 hours prior]	Breeding and nonbreeding season	24 ± 6 hours	AI 43 hours after sponge removal	70%[43]
Repromap	60 mg MAP	Vagina	16 days	+ [Removal]	—	Breeding season	32.2 ± 0.5 hours	AI 48 and 60 hours after sponge removal	52%[44]
Chronogest	40 mg FGA	Vagina	16 days	+ [Removal]	—	Breeding season	30.9 ± 0.4 hours	AI 48 and 60 hours after sponge removal	60%[44]
CIDR-G	330 mg progesterone	Vagina	16 days	+ [Removal]	—	Breeding season	27.2 ± 0.4 hours	AI 48 and 60 hours after sponge removal	47%[44]
Chronogest	30 mg FGA	Vagina	12–14 days	—	+ [Day of removal]	Breeding season	42 ± 8 hours	AI 12 and 24 hours after the onset of estrus	67%[45]
Sincrocel	60 mg MAP	Vagina	12–14 days	—	+ [Day of removal]	Breeding season	53 ± 15 hours	AI 12 and 24 hours after the onset of estrus	75%[45]
Chronogest	45 mg FGA	Vagina	11 days	+ [48 hours prior]	+ [48 hours prior]	Breeding season	33 ± 6.6 hours	Not available	Not available[46]
Chronogest	45 mg FGA	Vagina	11 days	+ [48 hours prior]	+ [48 hours prior]	Nonbreeding season	23.4 ± 7.3 hours	AI 24 hours after the beginning of estrus	75%[46,50]

Continued

Table **71-4**

Progesterone in Combination with Prostaglandin and Gonadotropin—cont'd

Product	Dosage	Location	Duration	eCG	Prostaglandin	Season	Estrus	Breeding	Pregnancy Rate
Chronogest	45 mg FGA	Vagina	11 days	+ [48 days prior]	+ [48 hours prior]	Nonbreeding season	24-72 hours [90%] in estrus	AI 45 hours after sponge removal	65%[47] if <30 hours in estrus after sponge removal; 33% if >30 hours in estrus after sponge removal
Repromap	60 mg MAP	Vagina	17 days	+ [Removal]	—	Breeding season	<48 hours 72% in estrus <72 hours 85% in estrus	Natural 24 to 96 hours after sponge removal. AI every 24 hours after the onset of estrus	71%[48] 81%[48]
CIDR-G	330 mg progesterone	Vagina	9 days	+ [Removal]	+ [Removal]	Breeding season	24–36 hours	Natural service	95%[49]
CIDR-G	330 mg progesterone	Vagina	9 days	—	+ [Removal]	Breeding season	24–72 hours	Natural service	65%[49]
Chronogest	30 mg FGA	Vagina	13 days	—	+ [Removal]	Breeding season	32.9 ± 9.7 hours	AI 12 and 24 hours after the onset	63%[51]
Sincrocel	60 mg MAP	Vagina	13 days	—	+ [Removal]	Breeding season	48.8 ± 12.0 hours	AI after the onset	65%[51]
CIDR-G	330 mg progesterone	Vagina	13 days	—	+ [Removal]	Breeding season	40.2 ± 10.5 hours	AI after the onset	63%[51]
MAP	60 mg MAP	Vagina	18 days	+ [Removal]	—	Nonbreeding season	44.6 ± 8.2 hours	Natural 24–120 hours	66%[52]

Note: Prostaglandins are not usually used during the nonbreeding season or anestrus period, because the does are not cycling.
AI, artificial insemination; CIDR, controlled internal drug release device; eCG, equine chorionic gonadotropin.

Table **71-5**

Different Methods Employed to Hasten Cyclicity During the Transition Period

Method	Duration	Estrous
1. Buck effect	Late transition	24–96 hours[2,21,29–31]
2. Progesterone (12–14 days) + equine chorionic gonadotropin (eCG) on the day or 24 to 48 hours prior to removal	Early transition	24–72 hours[54]
3. Progesterone (12–14 days) + eCG on the day or 24 to 48 hours prior to removal	Late transition	24–48 hours
4. Progesterone sponges (10 days) + eCG (removal) + prostaglandin 48 hours prior to removal	Late transition	40.9 ± 3.2 hours[55]

Note: Prostaglandins are rarely used during this period, because the does are not cycling.

Table **71-6**

Different Methods Employed During the Nonbreeding Season

Method	Duration	Estrus
1. Progesterone + equine chorionic gonadotropin (eCG) + prostaglandin	12–14 days	24–96 hours
	On the day of removal or 24 to 48 hours before	44.6 ± 8.2 hours[52]
	On the day of removal or 24 to 48 hours before	25 ± 5 hours[43,46,47,50] <72 hours = 90% estrus
2. Artificial lights	Mimic long days for 60 days followed by short days for 60 days or natural light	40–70 days[35]
3. Melatonin (implant, oral, or injection)	60–100 days	30–60 days
4. Artificial lights + melatonin	Mimic long days for 60 days followed by melatonin for 60–100 days	Buck exposure 60 days into melatonin treatment; estrus 2–3 days[36]

days associated with the onset of the breeding season.[35–38] Melatonin can be administered daily in feed, drench, injection, or a slow-release implant.[20] Melatonin is more effective in advancing the breeding season than in inducing estrus during the anestrous period.[35–38] It is more effective if its application has been preceded by long days. Thus, a combination of extra lighting for 60 days, followed by 60 to 90 days of melatonin administration, has been effective in inducing estrus.[36–38]

In a study, does receiving extra light followed by melatonin treatment for 90 days had more consistent ovulation when exposed to bucks.[36] Suggesting buck exposure was an essential component of the successful treatment (Table 71-6).

CONCLUSION

Progress has been made during the last decade toward manipulating and controlling the estrus cycle during the breeding season, nonbreeding season, and also during the transitional period. By improving the reproductive efficiency during their annual or yearly reproductive cycle, we can increase the number of kids per doe during her lifetime, producing kids out of season; kids could be sold when the prices are high; and year-round milk production in dairy animals is possible. In the United States there is limited availability of pharmaceutical products to manipulate or control the estrus cycle in does. Prostaglandins and other hormones are used in some animals to manipulate their annual cycle, but none are approved to be used in goats, although they are used in an extralabel manner (ELUD). The practitioner should be aware that under the AMDUCA regulations, nontherapeutic extralabel use is not permitted. Thus, regulatory guidance should be requested for use of these products in goats.

CHAPTER 72

Pregnancy Diagnosis in Goats

DAVID MATSAS

Caprine pregnancy can be diagnosed over a wide range of times during gestation. Demand for pregnancy diagnosis, however, varies with herd type. Owners may simply want to know if their goats are pregnant. Commercial milk producers may justify examination costs with costs of keeping open does and the need to maintain production. Intensively managed herds benefit from early diagnosis by maximizing the number of pregnancies during a defined period. Goats bred out of season have variable pregnancy rates and diagnosis allows planning for winter milk supplies. Pregnancy diagnosis also helps monitor the success of artificial insemination.

PITFALLS TO CLINICAL DIAGNOSIS

An accurate caprine pregnancy test must distinguish hydrometra from pregnancy. Hydrometra occurs commonly in goats and may cause false positive results. Annual herd incidence varied between 3% and 21% in one study, with considerable variation among herds and within herds during different years.[1] The prevalence of hydrometra is perhaps the most important reason for pregnancy diagnosis in commercial dairy herds. The test must also be highly sensitive (few false negatives). Pregnant goats given prostaglandin usually abort. A false negative test in a doe given prostaglandin will become readily apparent.

Estrous Behavior and Physical Appearance

Goat owners frequently use clinical signs such as estrous behavior following breeding and abdominal contour to make a presumptive diagnosis of pregnancy. Failure to return to estrus after breeding during the ovulatory season suggests pregnancy, but does with hydrometra or pathologic ovarian conditions may also fail to exhibit estrus. Failure to return to estrus cannot be relied upon when does are bred late in the breeding season or during the anovulatory season. Pregnant does may show standing estrous behavior, further making this an unreliable sign. Goats with hydrometra may have large, pendulous abdomens and look pregnant. Goats with permanent stretching of the abdominal muscles (dropped stomach) have distended, pendulous abdomens and could be mistaken for pregnant.[2]

Abdominal Palpation and Ballottement

During the last half of pregnancy, the gravid uterus or fetus can sometimes be palpated through the abdominal

CHAPTER 72

Pregnancy Diagnosis in Goats

DAVID MATSAS

Caprine pregnancy can be diagnosed over a wide range of times during gestation. Demand for pregnancy diagnosis, however, varies with herd type. Owners may simply want to know if their goats are pregnant. Commercial milk producers may justify examination costs with costs of keeping open does and the need to maintain production. Intensively managed herds benefit from early diagnosis by maximizing the number of pregnancies during a defined period. Goats bred out of season have variable pregnancy rates and diagnosis allows planning for winter milk supplies. Pregnancy diagnosis also helps monitor the success of artificial insemination.

PITFALLS TO CLINICAL DIAGNOSIS

An accurate caprine pregnancy test must distinguish hydrometra from pregnancy. Hydrometra occurs commonly in goats and may cause false positive results. Annual herd incidence varied between 3% and 21% in one study, with considerable variation among herds and within herds during different years.[1] The prevalence of hydrometra is perhaps the most important reason for pregnancy diagnosis in commercial dairy herds. The test must also be highly sensitive (few false negatives). Pregnant goats given prostaglandin usually abort. A false negative test in a doe given prostaglandin will become readily apparent.

Estrous Behavior and Physical Appearance

Goat owners frequently use clinical signs such as estrous behavior following breeding and abdominal contour to make a presumptive diagnosis of pregnancy. Failure to return to estrus after breeding during the ovulatory season suggests pregnancy, but does with hydrometra or pathologic ovarian conditions may also fail to exhibit estrus. Failure to return to estrus cannot be relied upon when does are bred late in the breeding season or during the anovulatory season. Pregnant does may show standing estrous behavior, further making this an unreliable sign. Goats with hydrometra may have large, pendulous abdomens and look pregnant. Goats with permanent stretching of the abdominal muscles (dropped stomach) have distended, pendulous abdomens and could be mistaken for pregnant.[2]

Abdominal Palpation and Ballottement

During the last half of pregnancy, the gravid uterus or fetus can sometimes be palpated through the abdominal

wall. This is difficult in does that tense their abdominal muscles. Ballottement of the fetus low in the right flank, as performed in cattle, may be attempted in late pregnancy, but one is often left wondering if the "bump" felt was the ventral sac of the rumen or a fetus. Rectal-abdominal palpation with a rod has been done in goats but was too traumatic to be safely recommended.[3]

A bimanual palpation technique was recently described wherein the reproductive tract is examined per rectum by the index finger of one hand while the fingertips of the other hand are pushed upward into the ventral floor of the posterior abdomen.[4] Pregnancy was diagnosed from day 28 onward with this method. At an early stage, hydrometra cannot be distinguished from pregnancy with this technique.

Recent technologic advances have replaced many of the previously described caprine pregnancy tests.[5] Real-time ultrasonography and biologic tests are now the most sensitive and specific methods. Tests specific for pregnancy in the goat and their application relative to the day of breeding are summarized in Table 72-1.

ULTRASONOGRAPHY

A-Mode Ultrasonography

Ultrasound waves emitted by amplitude-depth units are reflected from tissue interfaces and converted to audible or visual signals. These units detect fluid-filled organs at a depth of 10 to 20 cm. Pregnancy diagnosis is based on finding fluid within the uterus, so hydrometra or pyometra will give false positive results. False negatives are possible during late pregnancy when the volume of uterine fluid relative to fetal size has diminished. Accu-

Table **72-1**

Comparison of Tests Specific for Pregnancy in Goats

Days Since Breeding	B-Mode Ultrasonography	Doppler Ultrasonography	Estrone Sulfate Test	PSPB Test	Radiography
20–25	Transrectal scan, embryo visible after day 24	NA	NA	After day 24, positive = pregnant or recent fetal death, negative = open or fetal death; high sensitivity and specificity	NA
26–35	Transabdominal scan may reveal uterus/fetus, if negative, do transrectal	Intrarectal scan may give false negative	NA		NA
36–50	Transabdominal scan: fetus, placentomes visible	Intrarectal scan	NA		NA
51–75	Same as above, may estimate age from biparietal diameter	External scan may give false negatives	After day 50, positive = live fetus, negative = open or fetal death; high sensitivity and specificity		May see fetal skeleton day 65+ but false negative possible
76–90	Same as above	External scan			Fetal skeleton visible but false negative possible
91–term	Same as above, biparietal diameter not accurate after 100 days	External scan			Fetal skeleton visible, false negative unlikely

NA, not applicable; PSPB, pregnancy-specific protein B.

racy is affected by the prevalence of hydrometra in the herd. Lack of specificity for pregnancy makes A-mode ultrasonography unreliable for pregnancy diagnosis in goats.

Doppler Ultrasonography

Ultrasound waves emitted by Doppler units are reflected from stationary and moving organs at different frequencies and converted to audible signals. Pregnancy is diagnosed by detection of the fetal heartbeat, fetal movement, umbilical blood flow, or blood flow in the maternal middle uterine arteries. Increased flow in the uterine arteries may accompany hydrometra, so pregnancy should be diagnosed on the basis of fetal sounds.

Transabdominal scans are done by placing the transducer low on the right flank. Transrectal scans are done by inserting a specially designed rectal probe into the rectum and slowly rotating it in the area of the pelvic inlet and caudal abdomen. Fetal sounds include pounding of the fetal heart, sharp fetal movements, and the swishing sound of blood flow in the umbilical arteries.[6,7] Maternal sounds include swishing blood flow in the middle uterine artery and rumbling intestinal movement.[6,7]

During the first half of gestation, transrectal Doppler was more accurate than the external approach.[6] Transrectal scans can be attempted at 25 to 30 days after breeding, but false negative results are a problem.[7] It is preferable to wait until day 35 to 40. Accuracy of transrectal Doppler was 94% to 100% for detecting pregnancy and 25% to 75% for detecting nonpregnancy in goats 55 or more days after breeding.[3] During the last half of gestation, external Doppler was nearly 100% accurate for detecting pregnancy.[6] A 2.25-MHz transducer is suggested for near-term pregnancies and a 5-MHz transducer for earlier pregnancies.[6] B-mode ultrasonography has largely replaced Doppler for pregnancy diagnosis.

B-Mode Ultrasonography

B-mode ultrasound units produce a real-time, two-dimensional image on a screen, allowing direct visualization of the uterus, fetal fluids, fetus, fetal heartbeat, and placentomes. A 5-MHz linear-array transducer is the most versatile for reproductive work in livestock. It can be used externally or intrarectally over a wide range of gestational ages. Lower frequency linear-array, sector, or curvilinear probes are also suitable for external use in goats. B-mode scanning for pregnancy can be rapidly learned, and experienced examiners achieve an accuracy of 91% to 100%.[8,9]

A transabdominal approach is generally used for examinations made more than 35 days after breeding. The standing doe is restrained against a wall or on an elevated stand or milking stanchion. The transducer is placed low on the right flank in the inguinal region. A higher quality image is obtained by clipping a small area of hair so that the probe makes direct contact with the skin. In late pregnancy, more cranial portions of the ventral abdomen may need to be shaved. An ultrasonic coupling agent is applied to the transducer head or skin to eliminate air spaces. The examiner systematically searches the caudal abdomen by slowly moving and rotating the probe in the inguinal region.

Transrectal scanning is done by inserting the lubricated probe into the rectum and slowly rotating it from side to side. Transrectal scanning is usually reserved for diagnosis at less than 30 to 35 days after breeding. Some does object at first but most acquiesce in a short time. The anechoic urinary bladder serves as a good point of orientation and is recognized by its triangular neck as the probe is moved caudally. A poor quality image or no image is usually due to feces trapped under the probe, in which case it should be removed, wiped clean, and reinserted. Limited maneuverability of the probe allows effective imaging only of the pelvic canal and an area just cranial to the pelvic brim. Alternatively, a transvaginal approach using a cylindrical sectoral probe with a variable angle head can be used to scan the reproductive tract from the cranial vagina.[10]

Pregnancy can be detected transrectally in most does by about 20 days after breeding.[9] The embryo is often visible by 24 days and is seen more consistently as gestation advances.[9] The ideal time for transabdominal scanning is roughly from 40 to 75 days of gestation when the pregnant uterus lies against the right body wall. Before day 40, the probe may have to be placed higher in the inguinal region and aimed toward the pelvic brim. Diagnosis of nonpregnancy less than 30 days after breeding is probably best achieved by the transrectal approach. Transabdominal scanning during the third trimester may require moving the probe cranially along the ventral abdomen to image the gravid uterus that has descended well into the abdominal cavity.

A positive diagnosis of pregnancy is made when the embryo, fetus, or placentomes are seen. A presumptive diagnosis of early pregnancy can be made when multiple fluid-filled sections of uterine lumen are seen cranial to the bladder (Fig. 72-1); however, hydrometra causes a false positive test. Hydrometra occurs commonly enough to advise cautious positive diagnoses until the embryo, fetus, or placentomes are seen.

During the first trimester, the embryo appears as an echogenic mass surrounded by anechoic fluid within the uterine lumen (Fig. 72-2). Seeing fetal movements or the fetal heartbeat assures viability. During the second trimester, the fetal head, thorax, and limbs become more discernible. As pregnancy advances, only portions of the fetus such as the thorax or skull may be imaged at a time. As the ratio of uterine fluid to fetus decreases during late pregnancy, it may be difficult to distinguish the fetus from the rest of the dam's abdomen. The fetal skull and beating heart are good points of orientation when scanning during late pregnancy.

Placentomes are seen by 35 to 40 days as echogenic densities in the uterine wall. By 45 to 50 days, they are more easily seen as C-shaped densities with the concave surface directed toward the uterine lumen. As pregnancy advances, numerous placentomes appear as distinct donut-shaped and C-shaped echodensities surrounded by anechoic fluid when imaged in the longitudinal and cross-sectional planes, respectively (Fig. 72-3). During the second and third trimesters, these large placentomes are

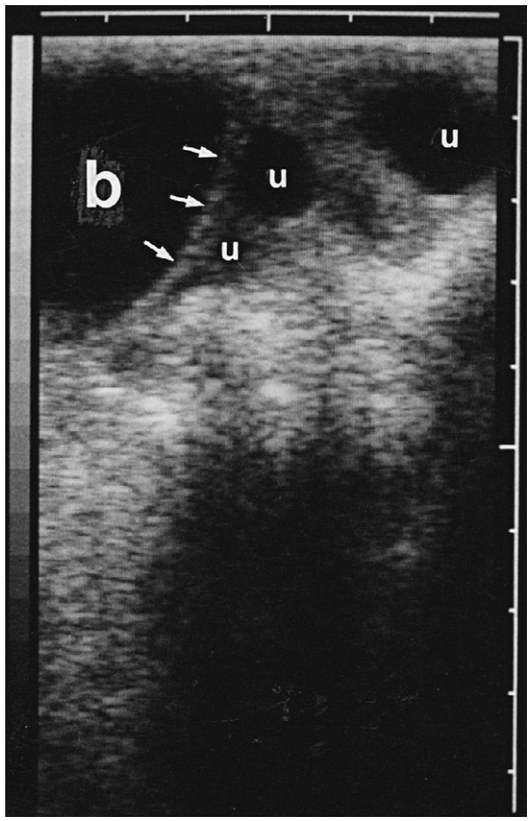

Fig. 72-1 Transrectal B-mode ultrasonographic image (produced with 5-MHz linear-array transducer) characteristic of early pregnancy (day 25). Multiple anechoic sections of uterine lumen *(u)* are present cranial to the urinary bladder *(b)* separated by the bladder wall *(arrows).* This image might also represent low-volume hydrometra, because an embryo is not seen.

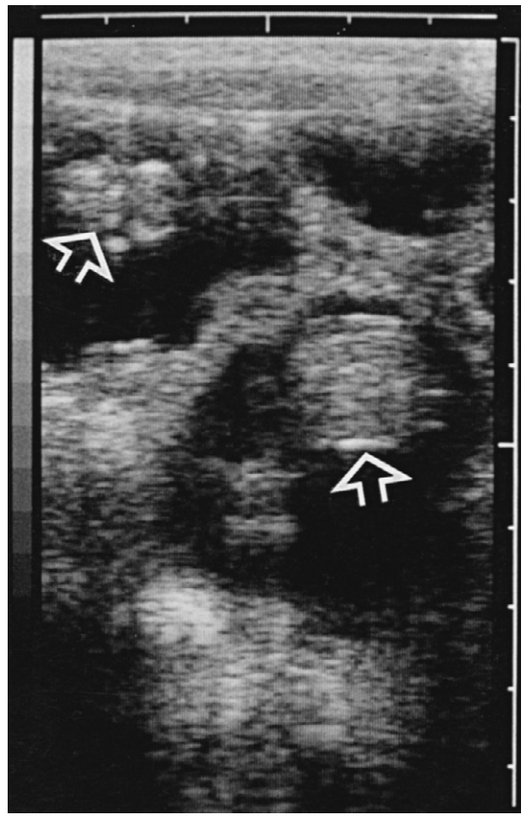

Fig. 72-2 Transabdominal B-mode ultrasonographic image (produced with 5-MHz linear-array transducer) of a 45-day twin caprine pregnancy. The embryos are seen as echogenic masses *(arrows)* within the uterine lumen. The heartbeat and movement can be seen in real time, which confirms viability.

often seen immediately after the probe is placed on the skin and allow for a rapid diagnosis of pregnancy.

Multiple fetuses can be detected to adjust feeding management. The optimal time for counting fetal numbers is between 40 and 70 days for linear-array transducers and 45 to 90 days for sector scanners.[9,11] At more than 70 days, additional fetuses may lie beyond the depth penetrated by a 5-MHz linear-array transducer. Triplets are more difficult to diagnose than twins and fetal numbers are often underestimated.

Fetal age can be estimated by measuring the width of the fetal head between 40 and 100 days of gestation.[11–14] A symmetrical image of the fetal head showing the greatest width between the parietal bones is frozen on the screen (Fig. 72-4). Symmetry is assured when both orbits are in the same image.[11] The distance between the uppermost edge of the deep and superficial parietal bones is measured with electronic calipers. Table 72-2 shows equations for estimating fetal age in various breeds based on biparietal diameter.[12–14] This technique is helpful for estimating kidding dates when breeding dates are unknown, but it requires time, patience, and practice to obtain images suitable for measurement.

Rough estimates of gestational age can be made simpler if based on uterine diameter, appearance of placentomes, and fetal size.[9,11] Placentome diameter in dairy goat breeds were correlated with gestational age up to day 90.[15] Goats were restrained over a bale of hay and transrectal measurements of placentomes in the vicinity of the bladder were made. The relationship between gestational age (GA) in days and placentome diameter (PD) in millimeters reported in this study was GA = 28.74 + 1.80(PD). Estimates of fetal age using this technique were accurate within 14 days in most of the goats studied.[15] This method was not reliable after day 90. Crown-rump length can also be used to estimate gestational age up to day 40.[9,16] A study on embryonic growth in 11 nubian goats reported a mean crown-rump length of 5.3 ± 0.3 mm on the day of first detection of an embryo (around day 20).[16] Crown-rump length increased an average of 1.4 mm per day, reaching 34.2 ± 0.6 mm on day 40.

A clear advantage of B-mode ultrasonography is the ability to distinguish a viable pregnancy from hydrometra, pyometra, or fetal mummification.[11] In hydrometra, the uterus appears distended with anechoic fluid, and no fetus or placentomes are identified (Fig. 72-5).

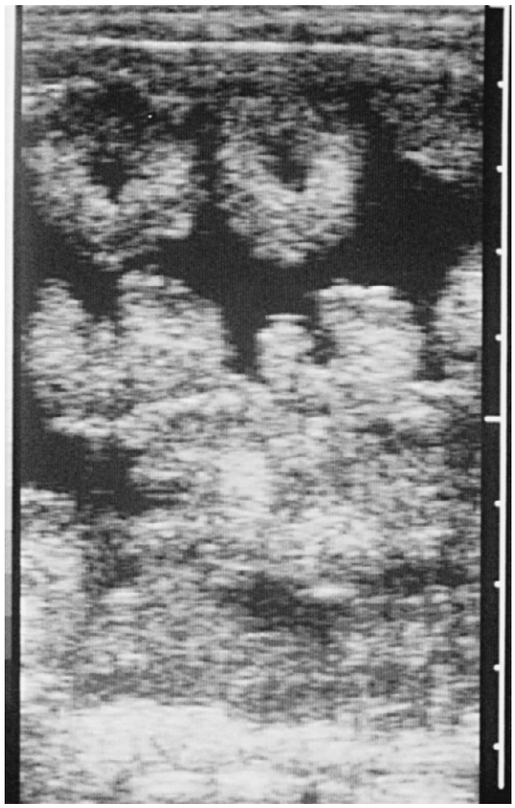

Fig. 72-3 Transabdominal B-mode ultrasonographic image (produced with 5-MHz linear-array transducer) of a 90-day caprine pregnancy. Distinct placentomes appear as donut-shaped (longitudinal plane) and C-shaped (cross-sectional plane) echodensities surrounded by anechoic fluid.

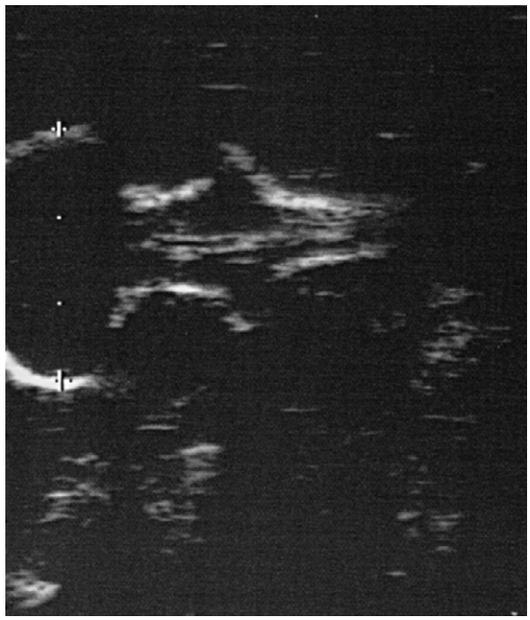

Fig. 72-4 Symmetrical transabdominal B-mode ultrasonographic image (produced with 5-MHz linear-array transducer) of a fetal head. Biparietal diameter measured with electronic calipers was 29 mm. Gestational age in this Nubian doe was estimated to be 77 days using the equation shown in Table 73-2.

Table **72-2**

Relationship Between Gestational Age and Fetal Biparietal Diameter*

Breed	Gestational Age (Days)
Toggenburg	27.9 + (1.64 × BPD)
Nubian	26.8 + (1.74 × BPD)
Angora	28.6 + (1.77 × BPD)
Pygmy	23.2 + (2.08 × BPD)

*Biparietal diameter (BPD) is measured (in mm) transabdominally using real-time ultrasonography with a 5-MHz linear-array transducer.
Data from Haibel GK, Perkins NR, Lidl GM: Breed differences in biparietal diameters of second trimester Toggenburg, Nubian, and Angora goat fetuses. *Theriogenology* 1989;32:287; and Reichle JK, Haibel GK: Ultrasonic biparietal diameter of second trimester pygmy goat fetuses. *Theriogenology* 1991;35:689.

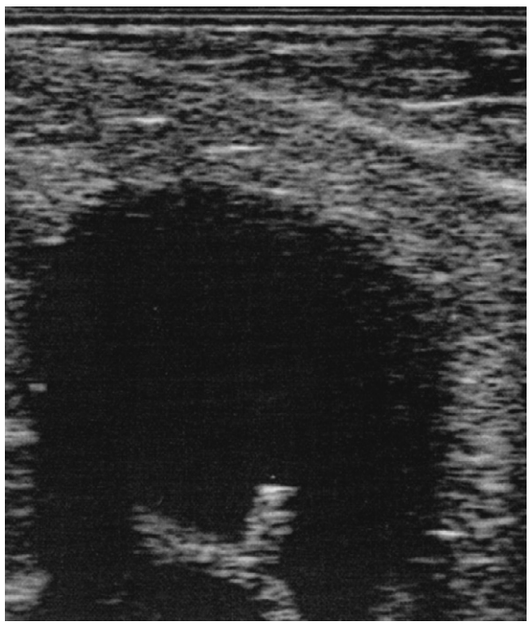

Fig. 72-5 B-mode ultrasonographic image (produced with 5-MHz linear-array transducer) of a hydrometra in a doe. The anechoic fluid-filled uterus is void of placentomes. The Y-shaped echodense lines at the bottom of the image represent the folded uterine wall.

Intersecting echodense lines representing the folded uterine wall are usually seen in the image. In pyometra, the uterus appears distended with a gray to white echoic fluid, and no fetus or placentomes are visualized. A mummified fetus appears as a dense, hyperechoic image lacking surrounding fluid with no heartbeat or placentomes.

BIOLOGIC TESTS

Estrone Sulfate Test

Estrone sulfate is a pregnancy-specific hormone produced by the fetoplacental unit in increasing amounts as pregnancy advances. After day 50 after breeding, there is a significant difference in serum and milk estrone sulfate concentrations between pregnant and nonpregnant does.[17–19] Accuracy for detection of pregnancy and nonpregnancy is high any time after 50 days after breeding. A positive test suggests that the fetus was alive at the time of sampling. A positive correlation between estrone sulfate concentration and fetal numbers was found between 51 and 65 days and after 90 days of gestation, but the concentrations were too variable to be of practical value.[19] Hydrometra will not cause false positive results with this test. False positives may occur with hemolyzed serum samples.[17] False negative tests may occur if samples are collected before 50 days of gestation. False negatives are theoretically possible in correctly timed samples, so cautious prostaglandin use is advised following a negative test.

Estrone sulfate can be measured in blood, milk, or urine by radioimmunoassay.[7,17–19] A urine test that measures total estrogens is available as a goat pregnancy test.*

Pregnancy-Specific Proteins

Pregnancy-specific protein B (PSPB) and pregnancy-associated glycoproteins (PAG) have been identified in various ruminant species including cattle, sheep, and goats.[20,21] They are produced by the placenta throughout gestation and can be measured in plasma by radioimmunoassay. Plasma PSPB and PAG concentrations were significantly different between pregnant and nonpregnant goats by day 24 and day 21, respectively.[20,21] Low levels of PSPB (<1.1 ng/ml) were found in nonpregnant goats, possibly due to cross-reactivity of antiserum with serum proteins.[20]

PSPB and PAG tests are highly specific for pregnancy. Blood levels of these proteins may remain elevated for a short time after embryonic or fetal death, which could explain apparent false positive results. Hydrometra will not cause false positives. As with all biologic tests, false negative results are possible, so cautious prostaglandin use following a negative test is warranted. A laboratory serum PSPB pregnancy test is available that is greater than 95% accurate when goats are tested after day 25 after breeding.† Future possible development of either of these tests into an on-farm test kit would offer a practical alternative to ultrasound diagnosis.

Progesterone Test

Progesterone tests more accurately detect nonpregnancy than pregnancy. Goats depend on progesterone from the corpus luteum to maintain pregnancy throughout gestation. Plasma progesterone concentrations above 1 ng/ml suggest functional luteal tissue and remain elevated throughout pregnancy. Progesterone is not pregnancy-specific, however, and elevated concentrations may accompany hydrometra, pyometra, early embryonic death, and fetal mummification, causing false positive results. Plasma progesterone concentrations below 1 ng/ml suggest nonpregnancy.

The best use of progesterone tests is to identify nonpregnant does 3 weeks after breeding. Does with low progesterone concentrations are considered open and are scheduled for rebreeding. This is particularly useful for does bred out of season, which do not reliably exhibit estrus after an infertile service. Accuracy of diagnosis from blood or milk progesterone levels, 20 to 24 days after breeding, varied from 80% to 100% for nonpregnancy and 67% to 100% for pregnancy.[22–25] Concentrations of progesterone in blood used for classifying nonpregnancy varied from less than 1.5 to less than 2.5 ng/ml.[22,23] Concentrations of progesterone in milk varied considerably among pregnant goats and among herds.[22] Nonpregnant does returning to estrus may have high milk progesterone concentrations for 1 to 2 days following lysis of the corpus luteum.[26] Plasma progesterone concentrations more accurately reflect the true endocrine status of does and were more accurate than milk progesterone concentrations for pregnancy diagnosis.[22] Does with blood progesterone concentrations between 1 and 2 ng/ml are difficult to classify accurately.

Progesterone testing has been simplified by on-farm enzyme immunoassay kits, although none are currently marketed for goats. Use of these kits with caprine blood and milk has generally given accurate results.[24,25] The accuracy of kits marketed for other species should be validated for goats before use.

In summary, progesterone testing for pregnancy diagnosis is plagued by the problem of false positive results. High progesterone concentrations only indicate the presence of functional luteal tissue. Low concentrations any time after days 4 to 6 after breeding suggest nonpregnancy.

RADIOGRAPHY

Abdominal radiography is useful for detection of pregnancy and determination of fetal numbers from the latter part of the second trimester until term. Diagnosis is based on detecting the fetal skeleton. The fetal skeleton may be seen by 58 days after breeding but is more consistently radiopaque after the 65th day.[27] Uterine enlargement suggestive of pregnancy may be seen earlier but cannot be differentiated from hydrometra or pyometra. It is recommended to wait 90 days after breeding to make a radiographic diagnosis of nonpregnancy.[7] The limits of small

*BET Reproductive Laboratory, Lexington, KY.
†BioTracking, Moscow, ID.

animal radiographic equipment may be exceeded or nearly exceeded by large does. Waiting until 90 days will make false negatives due to suboptimal technique less likely and avoid the need for repeated examinations. Hydrometra can also be diagnosed at this time if no fetal skeleton is seen.

ERRORS IN DIAGNOSIS

Understanding the common sources of error for each test will reduce the number of false positive and false negative results. False negatives (negative result in a pregnant doe) can have the most serious consequences if prostaglandin is administered. False positives (positive result in a nonpregnant doe), besides causing owner disappointment, delay the time to rebreeding or culling and so are economically unsound. With all tests, apparent false positives (true positive result but doe never kids) could be explained by unobserved abortions or embryonic or fetal death after the test was done.

Ultrasonographic Errors

A-Mode

The inherent problem with A-mode is the inability to distinguish pregnancy from hydrometra, pyometra, or the urinary bladder. False negatives are possible during late pregnancy when the volume ratio of uterine fluid to fetus is diminished. Other tests are recommended for accurate pregnancy diagnosis in goats.

Doppler

Accuracy for classifying nonpregnancy (specificity) is difficult to define because of the small number of open does included in previous studies.[3,6] Positive pregnancy diagnoses based only on fetal sounds (heartbeat or umbilical artery blood flow) should eliminate false positive errors. Correct interpretation of fetal sounds could be a problem for operators inexperienced with Doppler units. Fetal pulses in the umbilical arteries are faster than maternal pulses. Increased blood flow in the maternal uterine arteries does not necessarily indicate pregnancy.

After day 75, transabdominal Doppler is a highly sensitive pregnancy test. False negatives may occur under day 75 with the transabdominal approach. The transrectal approach is probably more accurate under day 75. Under day 40, false negatives may be a problem.[7] False negatives may also occur when feces around the rectal probe interfere with wave transmission. This should be suspected when no sounds at all are heard.[7]

B-Mode

False positive errors can be eliminated by making a positive pregnancy diagnosis only after seeing placentomes or the embryo or fetus surrounded by anechoic uterine fluid. Adherence to this rule should preclude misdiagnosis of hydrometra as pregnancy, especially during early examinations. The urinary bladder should not be misinterpreted as a fluid-filled uterus. The bladder is differentiated by its triangular neck. Intestinal loops imaged in cross section may appear as rows of C-shaped echodensities and should not be misinterpreted as placentomes. Placentomes produce a discrete echoic image surrounded by anechoic fluid.

False negatives result from failure to image an early pregnancy, an incomplete scan of the abdomen, failure to distinguish a near-term fetus from the rest of the dam's abdomen, or operator inexperience. In a transabdominal scan of a doe bred less than 40 days, the area just cranial to the pelvis must be thoroughly imaged. A transrectal scan during this time should lessen the likelihood of missing an early pregnancy.

Biologic Test Errors

Estrone Sulfate and Pregnancy-Specific Proteins

These tests are highly sensitive and specific for pregnancy in the goat, but it must be recognized that no biologic test is 100% accurate. In this regard, there is nothing like visualizing a pregnancy in real-time with B-mode ultrasonography. Errors may arise from the test methodology itself, improper handling of samples, or improper timing of sample collection. Inaccurate or unknown breeding dates may cause erroneous interpretation of results. If an exact breeding date is unknown or continuous buck exposure has occurred, a negative estrone sulfate or PSPB test has little meaning. The possibility of prostaglandin-induced abortion caused by a false negative must be considered.

Progesterone

A positive pregnancy diagnosis cannot be made solely from a high progesterone concentration. Accuracy for detecting nonpregnancy depends on the absolute concentration chosen to distinguish pregnancy from nonpregnancy. Discriminating blood concentrations are generally in the 1 to 2 ng/ml range. Results between 1 and 2 ng/ml progesterone are equivocal and such goats may be pregnant or open. Milk progesterone concentrations are even more variable and may differ among herds, as previously discussed. Errors could also result from the test methodology itself.

Radiographic Errors

Observation of the fetal skeleton will eliminate false positives. Hydrometra and pyometra cause false positives if diagnosis is based on uterine enlargement alone. False negatives are due to poor technique or examination before 90 days after breeding. Poor technique is exacerbated by doing the examination too early. Unknown or inaccurate breeding dates could account for false negatives if only a single examination is performed. If the breeding date is questionable and a negative radiographic result is obtained, re-examination at a later date is indicated.

SUMMARY

B-mode, real-time ultrasonography is the best overall method of pregnancy diagnosis in goats. Externally applied Doppler ultrasonography is a highly sensitive pregnancy test after day 75 of gestation. If ultrasonography is unavailable or impractical, the best alternative is

the estrone sulfate or PSPB test. Progesterone testing may aid early detection of nonpregnancy. Abdominal radiography performed 90 or more days after breeding is an accurate test for individual does.

CHAPTER 73

Parturition and Dystocia in the Goat

WILLIAM BRAUN, JR.

PARTURITION

Parturition is signaled by a series of events in pregnant does that alert the owner to impending kidding. Relaxation of the pelvic ligaments, as a result of an increase in circulating estrogen levels in late gestation, warns the owner that kidding is imminent. At about the same time, the vulva enlarges and may become slightly longer. In most goats there is a rapid enlargement and engorgement of the udder as well, although udder enlargement may not be an accurate indicator of impending parturition, as first fresheners may initiate udder enlargement as early as the third or fourth month of gestation. Some does have early engorgement of the udder to the point that milking is required. Other does do not show udder enlargement until the point of, or just shortly after, parturition.

As in other species, parturition is divided into three stages. The first stage is the initiation of myometrial contractions as progesterone levels drop and estrogen levels increase. In first fresheners, this stage may last from 2 to 12 hours. Pluriparous does may show very little discomfort, and the first stage may last only a few hours. The doe is restless and most signs are reflective of abdominal discomfort. She will lie down and rise, paw at the bedding, and maybe urinate or defecate in frequent, short bouts. During this period, the cervix relaxes and releases the cervical seal that is seen at the vulva as thick, tenacious, yellowish brown mucus. The contracting uterus pushes the placenta, fetus, and fetal fluids toward the cervix, further dilating it.

When the placenta and its contents fully dilate the cervix and come into contact with the vagina, second stage labor is initiated with the concomitant abdominal press that is characteristic of active labor. Depending on the number of fetuses present, this stage will last from 1 to 3 hours, with most does delivering all fetuses within 2 hours. Does typically are in lateral recumbency during this stage, but some older, more experienced does may remain standing for delivery. After the placenta reaches the vagina, the chorioallantois ruptures, lubricating the vaginal canal, and the amnion, or water bag, is partially delivered through the vulvar opening. This also ruptures and the kid is delivered. In multiple births, the doe may rest between deliveries, or they may occur one after the other.

Third stage parturition is characterized by delivery of the placenta or placentas and involution of the uterus. In the goat, the placenta is usually delivered within 1 hour of kidding and is considered retained if not expelled by 12 hours. In some multiple births, placental expulsion may be intermingled with delivery of kids. The mass and volume of the postpartum uterus decline drastically from delivery until about day 12 post partum.[1,2] Involution is macroscopically complete by day 28 post partum. The rapid decline in mass and volume of the uterus is ascribed to contraction of the myometrium together with vasoconstriction and loss of tissue fluids.[2] Lochia is normally discharged for up to 3 weeks. This is a nonodorous, reddish brown discharge that represents the debris remaining in the uterine lumen from parturition as well as some of the residual tissue and fluid from uterine involution.

DYSTOCIA

Normally, delivery is uneventful in goats. Dystocia exists when delivery is prolonged or some event occurs that makes delivery difficult or impossible. The number of cases that require obstetric assistance is low, with only 3% to 5% of births requiring help.[3] Most birthing problems are handled by owners and only the more difficult cases are submitted for veterinary assistance. Dystocia is considered to exist if the doe has been in active labor for 30 minutes or longer and is not making progress toward delivery of the kids.[4]

Most kids are born in cranial, longitudinal presentation, dorsosacral position with extremities extended, like cattle. Some 3% to 9% of kids are born in caudal, longitudinal presentation, almost all in sets of twins or multiples.[3] The incidence of dystocia is higher, on a percentage basis, for births in caudal presentation in goats.[3] In caudal presentations, 80% of the single births had one or both hindlimbs flexed.[5]

The most common dystocia arises when more than one fetus tries to exit the vaginal canal at the same time.[4] This tangle of kids is often separated by skilled owners. Other causes of dystocia are deviations from normal presentation, position, or posture, fetomaternal disproportion, failure of cervical dilation (ringwomb), vaginal prolapse, uterine torsion, and uterine inertia. Dystocias are commonly seen in Nubians because of multiple births; in first freshener Saanens that often have a single, large fetus[6]; and in pygmy goats that are too short-coupled to allow the fetus to properly position itself. One study reported that of 43 cases of fetal dystocia, 3 were caused by fetal oversize, 29 by disposition errors, and 11 by simultaneous presentations.[7]

Case Management

The diagnosis of dystocia is based on the owner's observation of the kidding process. This observation may include failure of active labor to be initiated after an appropriate time span, prolonged labor without producing kids, abrupt cessation of parturition, prolapse of portions of the reproductive tract, delivery of the placenta without delivery of kids, or a sense of anxiety that all is not going well. The veterinarian should supplement the owner's observations with historical information such as expected due date, problems during previous kiddings, parity of the doe, assistance already rendered, and any other information that the circumstances may warrant. Many owners have more experience in handling caprine dystocias than the veterinarian, and if assistance is requested, it is often in cases that require cesarean section. The length of time that the doe has been in labor is important. The cervical canal appears to remain dilated for a much shorter time period in goats than in sheep.[3] If delivery has not been accomplished within 2 to 3 hours, the cervix starts to close.

Examination of the doe and all manipulative procedures should always follow the general principles of veterinary obstetrics: cleanliness, lubrication, and gentleness. Does can be restrained in a stanchion or by a halter, or held by the owner. The perineal area is cleansed with soap and water, as are the hands and arms of the obstetrician. Examination of the reproductive tract in goats can be difficult because of the small size of the animal. Epidural anesthesia may be beneficial to prevent straining during examination or the subsequent manipulations. Some large breeds of goats will accommodate manual exploration of their tract all the way into the uterus, if the obstetrician has hands and arms of an appropriate size and plenty of lubrication is employed. Pygmy goats are more problematic and may only allow digital exploration of the vagina. In some cases in which no fetus or placenta is presented, a speculum examination of the vagina is in order. In any event, extreme care must be exercised, as the uterus and vagina are fragile and can be easily ruptured. After physical and visual examination, a diagnosis of the cause of dystocia can be made and a plan formulated for relief. The relief of dystocia includes untangling multiple kids, mutation of maldispositions, traction, partial fetotomy, and cesarean section.

Mutation and Traction

Most cases of simultaneous presentation are corrected by the goat's owner without veterinary assistance. Some novice owners will, however, present these cases for delivery. Patience in determining which extremities belong to which kid and untangling them is usually all that is required. A leg or head snare that permits a better grasp of the extremities is a useful item in these cases. Once the extremities of the first kid are identified, the second fetus is gently repelled back into the uterus and the first kid delivered by traction.

Flexion of the neck, carpus, and shoulder are the most common maldispositions in goats.[7] Not all cases of abnormal fetal presentation, position, or posture result in dystocia. Some does may kid normally if only one forelimb is presented with the head.[6] In dystocias caused by a relatively large head blocking the vaginal canal, one of the forelimbs may be repositioned into shoulder flexion, allowing room for passage of the head and remaining forelimb, and the kid delivered by traction. In any case in which the vagina contains fetal parts, more room can be created for mutation by gently repelling the fetus back into the uterus. This may also be accomplished by elevating the rear quarters of the doe and letting gravity assist in repositioning.

A kid in cranial presentation should never be delivered by traction if the neck is flexed and the head retained, as this may cause rupture of the birth canal. If sufficient room is available, the fetus can be repelled back into the uterus and the head repositioned by hand or with the aid of a head snare. In some cases, just the head is presented and both shoulders are in a flexed position. In small fetuses, traction on the head with a snare may be sufficient for delivery after the vaginal canal has been well lubricated. Dystocia after delivery of the head through the vulva may result in passive congestion of the head from pressure placed on the vessels of the neck by the vulva and vagina. Passive congestion will quickly resolve following delivery.

Carpal and shoulder flexion are corrected similarly. Carpal flexion is corrected digitally by hooking a finger around the distal forelimb below the flexed carpus and straightening the limb. Care is exercised to prevent laceration of the vaginal canal during repositioning. For shoulder flexion, the operator's hand is passed along the affected side of the head and neck until the shoulder joint is reached. A finger is hooked around the upper forelimb and the limb mutated into carpal flexion position. The carpal flexion is then corrected. It may be necessary to repel the fetus slightly into the uterus to accomplish this task. Hip and hock flexion in fetuses in caudal presentation are handled similar to shoulder and carpal flexion.

Fetotomy

A complete fetotomy, as in cows, is rarely attempted in goats. Partial fetotomy of the extremities is successful for relief of some dystocias. Fetotomy instruments for goats usually consist of a finger knife or scalpel blade and handle. Of prime concern when performing a fetotomy is that the fetus is already dead or the owner is willing to sacrifice a poorly viable fetus.

The most common reason for a partial fetotomy is amputation of the head to allow more room in the vagina for further manipulations or space for passage of the remaining fetal parts. When the head has been delivered through the vulva, it is relatively simple to amputate the head and as much of the neck as possible. In cases of head or neck flexion, it may be necessary to apply some traction to the fetus in order to get a scalpel blade in proper position to amputate the head.

Forelimbs are usually removed by subcutaneous fetotomy. A scalpel is used to circumferentially incise the skin around the carpus and then the incision is extended

medially along the leg as far as possible. The skin is bluntly dissected from the limb and the limb rotated to separate it from the body. The other forelimb is removed in a similar manner. To remove the thorax, the operator's hand is passed beneath the fetal skin to a point where the ribs can be manually crushed. The thorax is then rotated, causing the lumbar vertebrae to separate, and the cranial portion of the fetus is removed. The hindlimbs can then be removed.

Fetomaternal Disproportion

Fetomaternal disproportion may be of either fetal or maternal origin. Fetal disproportion results when a fetus is relatively too large to pass easily through the maternal pelvis or vaginal canal. This is most often encountered in does carrying a single fetus. Only parts of the fetus are capable of being delivered into the vaginal canal. If a live birth is expected, cesarean section is the preferred method of delivery. With adequate lubrication and judicious application of traction, some large fetuses can be delivered vaginally. Other less common causes of fetal oversize include anasarca or fetal hydrops and dead emphysematous fetuses. Both of these conditions can be relieved by incising the fetus to release some of the accumulated fluid or gas, by partial fetotomy, or by cesarean section.

Disproportion of maternal origin is most common in small first fresheners that have not adequately grown by the time of parturition. The pelvis is not large enough to allow easy passage of the fetus, which may be a large singleton. Other conditions that cause a relatively small pelvis or birth canal in does include injuries involving pelvic fractures, ankylosis of the tail, and soft tissue enlargements around the vagina such as abscesses or tumors. If lubrication and traction will not relieve this type of dystocia, a cesarean section will be needed for live deliveries.

Cervical Dilation Failure

Incomplete cervical dilation, or ringwomb, is a relatively common cause of caprine dystocia, accounting for 23.5% of all dystocia cases in one study.[8] Some predisposing factors include hypocalcemia, hormonal or mineral imbalances, twinning, season, and breed. Prolonged dystocia often results in the previously dilated cervix closing, further complicating the dystocia. Partial dilation of the cervix results in the cervical canal opening only a few centimeters instead of complete dilation. The myometrium pushes the fetus against the partially open cervix and then fatigues. Secondary uterine inertia is a common sequela to ringwomb.

Does are presented to the veterinarian because no kids have been delivered or only the placenta has been partially delivered. Digital examination reveals a partially dilated cervix with the cervical rings palpable. Often the canal is open only enough to allow a couple of fingers to be introduced. Attempts at manual dilation are unrewarding in most cases, with tearing of the cervix or uterus as possible sequelae. If attempts are made at manual dilation, patience and great quantities of lubricant should be employed. Treatment is typically by cesarean section. If hypocalcemia is suspected as the underlying cause, supplementation with calcium borogluconate (60–100 ml IV) may be beneficial.

Uterine Torsion

Torsion of the uterus is an occasional cause of dystocia in goats. In one report, uterine torsion accounted for 41.5% of the cesarean sections performed at a referral center.[9] Torsion typically occurs in does carrying a single fetus. Presenting signs in does with uterine torsion may mimic cervical dilation failure. Diagnosis is complicated by the inability to perform rectal palpation. Vaginal examination may reveal the typical folds in the vaginal wall or may reveal a cervix that is only partially dilated. Often diagnosis and treatment are performed at the same time with a cesarean section. If torsion can be diagnosed, rolling the goat, as in cows, may correct the torsion, but then time must be allowed for the cervix to dilate to achieve a vaginal delivery.

Uterine Inertia

Uterine inertia may be the cause or the result of dystocia. Primary uterine inertia results from failure of the uterus to properly contract during parturition. The cause is suspected to be hypocalcemia, a hormonal imbalance at parturition, or an inability of the myometrium to properly respond to contraction signals. Secondary uterine inertia is the result of failure of contractions to empty the uterus, causing fatigue of the myometrium. This may be caused by incomplete cervical dilation, maldispositions, or conditions that block the birth canal. Depending on the underlying cause, relief is by mutation and traction, supplementation with calcium, or cesarean section. Oxytocin (10–20 IU) may be given in an attempt to stimulate contractions of the uterus, but response is usually poor in cases of uterine inertia.

Aftercare

Aftercare following dystocia depends on the type of assistance rendered. If only additional traction was needed for delivery without invasion of the reproductive tract, little or no special care need be provided. In cases in which the reproductive tract has been invaded, systemic antibiotics may be warranted. Most commonly this consists of procaine penicillin G (22,000 IU/kg twice a day, IM or SQ) or oxytetracycline (11 mg/kg twice a day, IV, IM, or SQ) for 3 to 5 days post partum, with penicillin being the preferred choice. Because goats are susceptible to tetanus, a tetanus toxoid booster or tetanus antitoxin may be warranted. Oxytocin (10–20 IU IM, SQ, or IV) is administered to stimulate uterine contractions to help evacuate the uterus or to control reproductive tract hemorrhage.

In cases of fetotomy or when gross contamination of the uterus is suspected, uterine lavage with warm saline or water to which a mild antiseptic has been added may be necessary. A clean stomach tube and funnel or calf esophageal feeder can be used to lavage the uterus. Lavage

flushes debris from the uterus and stimulates uterine contractions. Antibiotic boluses can also be inserted into the uterus at this time.

CHAPTER 74

Postpartum Care of the Doe and Kid

JOAN DEAN ROWE and NANCY E. EAST

PREPARTUM PREVENTION OF POSTPARTUM PROBLEMS

Prevention of postpartum problems in does and kids begins long before parturition. Does should be examined with ultrasonography to confirm pregnancy status and stage of gestation, their body condition score (1 to 5) should be determined, and lactating does should be dried off 60 days before the expected due date. Failure to observe a 60-day dry period results in modest to marked decreases in milk production during the ensuing lactation period. An inadequate dry period may also result in decreased colostrum quality.

Some does are difficult to dry off without damage to the udder when the traditional method is used of sudden cessation of milking, withholding of water for 12 to 24 hours, decreasing of forage quality, withholding of concentrates, and isolation from the environmental stimuli that does associate with the milking procedure. The producer can dry these does off more slowly by reducing them to once-daily milking for 2 to 3 weeks prior to the expected dry-off date and decreasing concentrate consumption, followed by traditional methods of ending the lactation. An additional complication in drying off does is the inability to switch them to low-quality forage early in their dry period, for they often remain in their normal social and parity group. Removal and reintroduction of does into milking strings may lead to prolonged social aggression, resulting in significant loss of milk production and occasionally injury to does. An alternative is to breed and dry off does as a string so that feed adjustments commensurate with the varying nutritional needs of the production cycle can be made. During the last 2 to 4 weeks of the dry period, does should be fed according to body condition score, with thin does (<3.0 on a 5-point scale) receiving increased concentrate for 4 weeks over the basic 0.45 to 0.90 kg offered to does in good to overconditioned state. Ideally, does should freshen with a body condition score of 3.5 to 3.75 (on a 5-point scale). Concentrate feeding during the latter part of the dry period allows for a smooth transition from pregnancy to lactation during which high-energy feeds are required to optimize production and maintain an acceptable calcium–to-phosphorus ratio of not more than 1.5:1. Does should be closely watched during the last 4 to 6 weeks of the dry period for signs of ketosis, hypocalcemia, or abortion. Vaccination of does during late gestation for enterotoxemia and tetanus will optimize the specific immunoglobulins present in colostrum.

Maintenance of a clean, draft-free kidding area is critical for optimal doe and kid health. Kids are born agam-

flushes debris from the uterus and stimulates uterine contractions. Antibiotic boluses can also be inserted into the uterus at this time.

CHAPTER 74

Postpartum Care of the Doe and Kid

JOAN DEAN ROWE and NANCY E. EAST

PREPARTUM PREVENTION OF POSTPARTUM PROBLEMS

Prevention of postpartum problems in does and kids begins long before parturition. Does should be examined with ultrasonography to confirm pregnancy status and stage of gestation, their body condition score (1 to 5) should be determined, and lactating does should be dried off 60 days before the expected due date. Failure to observe a 60-day dry period results in modest to marked decreases in milk production during the ensuing lactation period. An inadequate dry period may also result in decreased colostrum quality.

Some does are difficult to dry off without damage to the udder when the traditional method is used of sudden cessation of milking, withholding of water for 12 to 24 hours, decreasing of forage quality, withholding of concentrates, and isolation from the environmental stimuli that does associate with the milking procedure. The producer can dry these does off more slowly by reducing them to once-daily milking for 2 to 3 weeks prior to the expected dry-off date and decreasing concentrate consumption, followed by traditional methods of ending the lactation. An additional complication in drying off does is the inability to switch them to low-quality forage early in their dry period, for they often remain in their normal social and parity group. Removal and reintroduction of does into milking strings may lead to prolonged social aggression, resulting in significant loss of milk production and occasionally injury to does. An alternative is to breed and dry off does as a string so that feed adjustments commensurate with the varying nutritional needs of the production cycle can be made. During the last 2 to 4 weeks of the dry period, does should be fed according to body condition score, with thin does (<3.0 on a 5-point scale) receiving increased concentrate for 4 weeks over the basic 0.45 to 0.90 kg offered to does in good to overconditioned state. Ideally, does should freshen with a body condition score of 3.5 to 3.75 (on a 5-point scale). Concentrate feeding during the latter part of the dry period allows for a smooth transition from pregnancy to lactation during which high-energy feeds are required to optimize production and maintain an acceptable calcium–to-phosphorus ratio of not more than 1.5:1. Does should be closely watched during the last 4 to 6 weeks of the dry period for signs of ketosis, hypocalcemia, or abortion. Vaccination of does during late gestation for enterotoxemia and tetanus will optimize the specific immunoglobulins present in colostrum.

Maintenance of a clean, draft-free kidding area is critical for optimal doe and kid health. Kids are born agam-

maglobulinemic, so the magnitude of initial pathogen challenge will influence neonatal morbidity and mortality. Incidence of postpartum metritis and mastitis in does is minimized if build-up of environmental organisms is avoided. Factors affecting environmental challenge (persistence and replication of pathogens in the environment) include population density, ventilation, and maintenance of clean, dry bedding areas. Overcrowding in the maternity area and in the area housing neonatal kids increases the build-up of fecal organisms. Environmental pathogens proliferate under warm, moist conditions. Soiled bedding in the maternity area should be removed and replaced frequently. Adequate ventilation and exposure to sunlight will reduce pathogen numbers. Inadequate drainage promotes moist conditions. Shelter from wind, rain, and other inclement weather reduces stress on the doe and is critical for kid survival. Kids exposed to extremely hot or cold weather conditions, particularly during the first 72 hours of life, have increased mortality rates.

PARTURIENT DOE MANAGEMENT

Does should be observed closely as they near kidding. Clipping hair from the udder, tail, and perineal area helps prevent contamination of the reproductive tract during parturition and assists in milking hygiene (or hygiene during nursing of kids) after kidding. Ketosis, hypocalcemia, abortion, stillbirth, and dystocia are conditions that can be expected. Prevention of postpartum complications and success of a pasteurization and pathogen-control program depend on detecting the onset of parturition and attending the birth of kids. Rapid detection and assistance with dystocia and immediate removal of kids before they nurse for pasteurized rearing programs can be aided by frequent observation of does near term. Induction of parturition with prostaglandin can be used as an aid to disease control programs that require removal of kids at birth. Some producers use infant room monitors to remotely detect the onset of second stage labor (does usually vocalize during second stage labor). Dystocia in does is usually due either to the presence of a large single fetus or to malpresentation of multiple kids that become tangled. Additionally, does that give birth to multiple kids may exhibit uterine inertia, which requires that the kids be delivered manually and that the doe be treated for hypocalcemia. Most malpresentations are easily corrected and the kids delivered. Occasionally a cesarean section is required to deliver a large kid or, more commonly, is required when the cervix fails to dilate. Natural births occur rapidly, particularly in multiparous does, which may deliver multiple kids in 30 to 60 minutes. Does attempting to deliver kids without success for more than 30 minutes of second stage labor should be examined.

POSTPARTUM CARE OF THE DOE

Does should be carefully examined for the presence of additional fetuses. The veterinarian can perform routine abdominal ballottement by standing over the doe, reaching around the caudal abdomen and joining hands, then lifting up sharply. A retained fetus may be detected as a firm mass. Ultrasonographic examination confirms this finding, but greater care must be taken to visualize the fetus once the fluid contrast is lost after the chorioallantoic membrane has ruptured. Does should also be examined for trauma or hemorrhage. Assessment of the doe's vital signs and muscle tone after parturition is useful in detecting hypocalcemia. Hypocalcemia may predispose does to uterine prolapse.

After kidding, the doe passes the placenta rapidly—often within 1 hour of the last kid's birth—but the placenta is not considered retained until 8 to 12 hours post partum. At this time, light manual traction, oxytocin (if within 48 hours post partum), and systemic or local antibiotics can be administered. In normal does, lochia can be discharged for up to 4 weeks. Lochia should be carefully cleaned from the udder before milking. Lochia from normal births may contain *Chlamydia psittaci, Coxiella burnetii,* or other pathogens that are infectious to humans and other goats. Normal reddish brown lochia must be distinguished from the brownish, watery, malodorous discharge that accompanies postpartum metritis. Does with metritis are usually febrile and partially anorectic and have depressed milk production. These does should be treated with local or systemic antibiotics and nonsteroidal anti-inflammatory drugs, and may require supportive therapy.

Dairy does should be milked soon after parturition. Even in herds in which the manager does not elect to feed heat-treated colostrum, milking the doe and hand-feeding the kids ensures maximum first feeding ingestion of colostrum by all kids. In meat and fiber production herds, does' udders should be palpated for evidence of mastitis and to evaluate sufficiency of milk production, and milk should be expressed from each teat to assess the patency of the teat and to detect abnormal secretions. Does with good milk production that give birth to a single kid should be considered as candidates for cross-fostering another kid.

In meat, fiber, or other goat herds in which does nurse their kids or otherwise are unaccustomed to frequent handling, penning the doe with her litter for several days allows close observation without having to gather does and potentially disrupting maternal bonding. This allows the caretaker to assure that both udder halves are being nursed and to monitor for the presence of mastitis and adequacy of milk production (and milk intake by her kids). This also facilitates the doe bonding with all members of the litter and aids in decision-making as to whether a doe can raise her entire litter or whether one or more kids should be hand-reared or fostered to another dam. Does and their litters may more smoothly transition into the main herd if moved from maternal pens into small group pens (with does/litters from the same kidding period) for several days before returning to the larger herd.

Postpartum does should be watched closely for signs of hypocalcemia or ketosis. Maximizing dry matter intake of fresh does will help to prevent metabolic disease and ensure maximal peak milk production. Does should be monitored for their ability to compete at feeders (and moved if needed), and fresh supplies of water and high-

quality forage should be provided immediately to encourage early return to normal feed intake.

POSTNATAL CARE OF KIDS

At the time of birth, kids should be observed for normal respiration, evidence of respiratory acidosis, and other evidence of fetal distress such as meconium staining. Mucus and fluids should be immediately removed from the nose and mouth of newborn kids. Aspiration of meconium should be suspected in kids with extensive meconium staining that demonstrate respiratory difficulty. For cases under intensive clinical management, oxygen or doxapram hydrochloride, or both, may be needed to support or stimulate respiration, especially in premature kids. Mild to moderate acidosis can be treated with intravenous HCO_3 at 1.0 mEq/kg or as determined after the base deficit is analyzed. Kids and placentas are examined for abnormalities that would suggest placentitis or other signs of in utero infection that might warrant submission for necropsy.

If the owner plans to rear kids using pasteurized colostrum methods to prevent transmission of pathogens such as caprine arthritis-encephalitis virus (CAEV) or *Mycoplasma* spp., the kids should be removed from the doe at birth, before the doe has been allowed to lick them. In meat or fiber production herds, disruption of bonding between the doe and kids should be minimized. However, the umbilicus of all kids should be inspected for hemorrhage or herniation, and the umbilical stump disinfected with tincture of iodine or chlorhexidine solution. Although chlorhexidine (1:4 dilution of concentrate) is preferred over 2% or 7% iodine for foals, similar studies have not yet been conducted in ruminants. Continued treatment of the umbilicus for several days is preferred. Kids should be examined for the presence of congenital defects such as pseudohermaphroditism, teat anomalies, cryptorchidism, atresia ani, cleft palate, brachygnathia, prognathia, and congenital goiter.[1]

In herds using pasteurized kid-rearing methods, kids are removed at birth and hand-fed heat-treated goat colostrum or cow colostrum (heat-treated preferred) by nipple bottle. A sucking reflex can be stimulated by stroking the kid's face behind its muzzle. Weak kids can be given colostrum with the use of a soft rubber catheter as a stomach tube and the barrel of a 60-ml catheter-tip syringe as a reservoir for gravity flow. Depression caused by respiratory acidosis may reduce suckling and result in decreased colostrum intake. Delayed colostrum intake, inadequate colostrum ingestion, and ingestion of poor-quality colostrum are common reasons for failure of passive transfer.

In meat and fiber production herds and other herds using dam-rearing of kids, adequate colostrum intake should be assessed. Kids nursing from a dam that has been determined to have adequate colostrum and palpation of kids' abdomens after nursing serve as indicators of colostrum consumption. However, hand-feeding of colostrum to all kids is the most definitive means of ensuring adequate colostral intake. Failure of passive transfer can be confirmed by screening serum immunoglobulins using zinc sulfate turbidity, sodium sulfite precipitation, and other screening techniques.[2] Serum immunoglobulin G levels greater than 1600 mg/dl are most desirable. Serum immunoglobulin G levels less than 600 mg/dl indicate failure of passive transfer, and partial failure of passive transfer is suggested by serum immunoglobulin G levels between 600 and 1600 mg/dl.[2] Transfusion of 20 to 40 ml/kg caprine plasma intravenously may be indicated for valuable neonatal kids with failure of passive transfer.[2]

If the use of goat colostrum is planned, or if the cow colostrum is from a predictable source, vaccination of the donor dam 1 month before parturition against *Clostridium perfringens* types C and D, tetanus, and other appropriate pathogens will maximize specific immunoglobulin concentration in colostrum. Regardless of source, colostrum must be of high immunoglobulin concentration and have good nutritional quality. Does that leaked colostrum or were milked because of premature distention of the udder will have colostrum of low immunoglobulin, vitamin, and fat content. Colostrum with an immunoglobulin content greater than 6 g/dl and specific gravity of at least 1.050 is most desirable.[2,3] Microbial contamination can be minimized by the use of hygienic milking practices. Clipping the doe's udder and thighs before parturition and cleaning the teats before milking or allowing kids to nurse will minimize bacterial contamination of colostrum and prevent ingestion of environmental organisms by kids. The bacterial counts of colostrum that is allowed to sit for long periods, especially in warm environments or where flies are present in large numbers, may exceed 250,000 colonies per milliliter. If stored, colostrum should be refrigerated or frozen in small containers to allow rapid cooling and to minimize bacterial growth.

Pasteurized-rearing programs are recommended to prevent transmission of CAEV, mycoplasma, and other pathogens. Removal of kids at birth may also reduce their likelihood of exposure to Johne's disease and other organisms. Heat treatment of colostrum for 1 hour at 56° C has been demonstrated to prevent CAEV transmission in colostrum.[4] Colostrum is heated in a double boiler to 56° C and is either held for 1 hour while being stirred or is transferred to a preheated vacuum flask for 1 hour. Monitoring the temperature of colostrum or milk at the end of the heat treatment period is critical to ensuring the success of the heat treatment. Colostrum that drops below 55° C at the end of the treatment period should be discarded or reheated. Care must be taken to avoid overheating colostrum. Heating of colostrum above 58.9° C causes denaturation of immunoglobulins and other proteins and results in clumping. Feeding heat-damaged colostrum, even if filtered, usually results in osmotic diarrhea. Heat-treating colostrum in a microwave oven is not recommended because of unequal heating properties that could result in denaturing some of the colostrum while inadequately heating other portions.

High-quality, first-milking colostrum can be heat-treated and banked for later use. Heat-treated colostrum is often frozen in small containers and thawed as needed. Frozen colostrum is best thawed in a warm water bath. Microwave thaw techniques have been used but may result in unequal heating with accompanying denatura-

tion of portions of the colostrum. Repeated freezing of thawed colostrum and storage of frozen colostrum for longer than 1 year are not recommended.

Cow colostrum can be used instead of goat colostrum; however, goat owners must take steps to ensure that the colostrum quality and freedom from *Mycobacterium paratuberculosis* or other enteric pathogens meet the same standards that they would demand from goat colostrum. Neonatal isoerythrolysis has been reported following ingestion of cow colostrum, but appears to be quite rare. Artificial colostrum substitutes have been used with mixed results. Higher serum immunoglobulin G levels are obtained in kids after ingestion of goat or cow colostrum than after colostrum substitutes.[5,6] Colostrum substitutes prepared from concentrated serum immunoglobulins appear to have more promise than those prepared from whey concentrate.

After the initial colostrum feeding, kids can be fed pasteurized milk or additional heat-treated colostrum if available. Milk for pasteurized-reared kids should be heated to a minimum of 73.9°C for 15 seconds to destroy *Coxiella burnetii*. Lower temperature and longer time schemes control other pathogens. Home pasteurization devices are widely available, but producers must monitor the exit temperatures frequently to ensure proper adjustment of the pasteurizer unit. Also, a system for identification of pasteurized milk—for example, using food coloring—may aid in avoiding the accidental feeding of raw milk. Assignment of a single person to feed kids helps to minimize errors in a pasteurized-rearing program.

Large cardboard boxes with clean bedding material work well for housing newborn dairy goat kids, especially in large herds. A doe's kids can be placed in one box, and the dam's identification written on the box as a means of identifying kids until they can be labeled with paper collars and permanently identified by tattoo. Disposable boxes are a useful means of preventing build-up and spread of enteric pathogens. Kids can be kept in these boxes for about 2 weeks, after which the box can be destroyed and kids housed in larger groups.

In herds in which kids are dam-reared, the doe and kids must have access to draft-free shelter from environmental extremes to minimize risk of hypothermia, heat-stress, or pneumonia. Young kids naturally seek out protected "hiding" places where they spend many hours sleeping away from their dam, with the dam returning to nurse her kids for brief periods. Herd owners can provide small boxes in pastures for kids to use. Restricting does to a small pasture or paddock during kidding and for a few days may be helpful in ensuring strong maternal bonding. Regardless of rearing method, kids must be raised in a clean, uncrowded environment.

Dairy kids are generally fed from nipple bottles or buckets with multiple nipples. Weaning is recommended at 2 to 3 months of age. Dam-reared kids raised for meat can be weaned at a later age. Pasteurized goat milk or cow milk should be fed for at least the first 2 to 4 weeks of life. The use of milk replacers for growing kids has met with mixed success. High-fat, low-lactose, high-protein, and low-fiber milk replacers are preferred. High-lactose milk replacers in particular may be associated with digestive upsets, including bloating and death. High-quality calf and lamb milk replacers, and some goat milk replacers, have been used successfully by producers. Mixing milk replacers (one half reconstituted milk replacer, one half whole milk) seems to minimize problems associated with milk replacers and increases their palatability. Further information on kid nutrition and management is available elsewhere.[7,8]

Horned dairy kids should be disbudded as soon as the horn bud can be distinctly palpated, usually at 5 to 7 days of age. Swiss breed kids may have palpable horn buds at a few days of age, while Nubian kids may take up to 2 weeks to develop distinctly palpable horn buds. Identification of the characteristic swirls of hair and visualization of the differentiated germinal epithelium of the horn bud before disbudding will help to avoid accidental "disbudding" of naturally polled kids. Early disbudding of kids with a disbudding iron is much less stressful and far more humane than surgical removal of scurs or horns at a later age.

During the first few days of life, kids are at greatest risk of hypothermia, hypoglycemia, and colibacillosis. Hypoglycemic kids can be treated with intraperitoneal administration of up to 50 ml of warmed 10% to 25% glucose solution, diluted with up to 100 ml isotonic sodium chloride or lactated Ringer's solution. Cryptosporidiosis and floppy kid syndrome are most commonly seen in kids from 3 to 10 days of age. Clinical signs of white muscle disease, copper deficiency, *Pasteurella haemolytica* pneumonia, mycoplasmosis, and coccidiosis frequently begin to occur at between 2 and 4 weeks of age. Additional information on kid diseases is available elsewhere.[7,8]

CHAPTER 75

Puerperal Nutrition and Metabolic Diseases

ROBERT J. VAN SAUN

The time around parturition is the single most stressful event in a doe's reproductive life cycle. Metabolic and nutritional insults before and following parturition can result in exacerbation of key metabolic changes necessary to make the physiologic transition from pregnancy to lactation, resulting in a myriad of metabolic diseases. Current perceptions tend to focus attention on the lactating doe and nutritional support of milk production; however, nutrition and management of the late pregnant doe has more significant impact on her productive efficiency, both reproductive and lactational. The focus of this chapter will be to highlight the impact of prepartum nutrition and management on periparturient metabolic disease and reproduction.

METABOLIC ADAPTATIONS AROUND KIDDING

An appreciation of the exquisite metabolic adaptations the doe must undergo to achieve a successful transition from pregnancy into lactation is key to understanding the critical role of nutrition on metabolic disease and reproductive performance. Minimal data are available regarding pregnant doe metabolism and nutrition. Given the similarity in metabolic responses observed with dairy cattle and sheep, current research concepts regarding physiologic alterations associated with the transition from pregnancy to lactation will be extrapolated from these species to the pregnant doe. Fetal metabolism and maternal metabolic adaptations over the periparturient period were detailed in Chapter 58. Important concepts as they relate to induction of metabolic disease or influencing reproductive performance are summarized here.

Fetal Metabolism

Metabolic activity of the fetus is nearly twice that of the dam, and fetus, placenta, and uterus combined (conceptus) consume nearly 50% and 80% of maternal glucose and amino acid supply, respectively.[1] The conceptus oxidizes glucose and its placental derivative, lactate, as its primary metabolic fuel; however, glucose and lactate oxidation only account for 50% to 60% of fetal caloric needs.[2] Amino acids, even in a well-fed dam, account for 30% to 40% of total conceptus caloric requirement.[2] Fetal utilization of glucose is dependent upon maternal glucose availability and with maternal undernutrition, utilization is markedly decreased. Amino acid delivery to the conceptus is independent of maternal dietary adequacy, and thus, amino acids become a primary fetal energy substance when glucose is unavailable.[3] Placental active transport and catabolism of maternal skeletal protein account for the ability of the dam to maintain consistent amino acid delivery to the conceptus.[1,2] In spite of their ready availability in maternal circulation, nonesterified fatty acids (NEFAs) and ketone bodies are not significant energy substrates for the gravid uterus as they do not efficiently cross the placenta.[2] This metabolic milieu provides a buffering system to maintain fetal growth in the face of inadequate maternal nutrition, yet not facilitate excessive fetal growth at the expense of maternal energy reserves (fat).

All macro- and microminerals are efficiently transferred from maternal circulation to the conceptus. Within the fetus, minerals are concentrated in the fetal liver as well as being utilized to meet their specific metabolic or structural physiologic roles.[4] Concentration of mineral elements within the fetal liver provides a mineral reserve in support of the neonate's higher metabolic rate and in the face of consuming a trace mineral–deficient diet (e.g., milk). Fat-soluble vitamins A, D, and E do not efficiently cross the placenta, but are concentrated in colostrum.[5–7] With the transfer of minerals and vitamins from maternal circulation to fetus and colostrum, adequacy of the late gestation maternal diet will ultimately dictate nutrient status of dam and neonate and mediate disease susceptibility potential, especially susceptibility to infectious diseases, given the important role trace minerals and fat-soluble vitamins play in immune function.

Maternal Adaptations

The goal of maternal metabolic adaptations is to increase glucose availability in support of pregnancy or subsequently lactation. To meet glucose needs during the transition from late pregnancy to lactation, maternal tissues reduce their use of glucose as an energy source, increase rate of hepatic gluconeogenesis, and provide sufficient endogenous glucogenic substrate (i.e., amino acids, glycerol, lactate) to account for lower nutrient intake.[8] Glucose is replaced by fatty acids and their derivative, ketone bodies, as alternative maternal metabolic fuels. To facilitate fatty acid availability, adipose tissue becomes sensitized to signals mediating reduced lipogenesis and increased lipolysis, hence increasing blood NEFA concentration. Reduced glucose uptake and increased NEFA

oxidation by skeletal muscle accounts for a significant savings of glucose; however, skeletal muscle also contributes amino acids in support of gluconeogenesis. Coordinated adaptation of adipose tissue, skeletal muscle, and liver function is mediated through changes in insulin concentration and tissue insulin resistance.[8]

Elevation of blood NEFA concentration metabolically is a double-edged sword. As described, elevation of blood NEFA in late pregnancy provides an alternative fuel for maternal nonuterine tissues. However, the liver absorbs NEFAs in direct proportion to their blood concentration. Hepatocytes have limited ability to completely oxidize influx of NEFAs, and they are partially oxidized into ketone bodies, which can be metabolized for energy by other nonuterine maternal tissues.[9] Available NEFAs can also be re-esterified into triacylglycerol (TAG) and packaged into very low density lipoprotein (VLDL) particles and exported from the liver.[9] If not exported in VLDL, then TAG is packaged into hepatocytes, resulting in increasing amounts of fatty infiltration. Ruminant animals in general are not efficient at exporting VLDL particles[10] and thus experience variable degrees of hepatic fatty infiltration around the time of parturition.[9]

Similar to cattle and sheep, blood NEFA concentration in goats is a metabolic marker of energy balance and degree of fat mobilization.[11] Excessive elevation of blood NEFA concentration can result from factors inducing a stress response (β-adrenergic agents stimulate lipolysis), prolonged or severe negative energy balance, or both. Dry matter intake typically declines just before, and slowly increases following parturition, placing the animal in a state of negative energy balance. Errors in feeding management, poor quality feeds, adverse environmental conditions, and number of fetuses, among other factors, can exacerbate severity and duration of negative energy balance. Hepatic uptake of blood NEFA beyond its metabolic capacity to process will result in maladaptive responses leading to ketosis and increasing fatty infiltration, which compromise hepatic function and initiate a deteriorating metabolic cycle of hypoglycemia, fat mobilization, and severe fatty infiltration.

Although hypocalcemia is not as prevalent in goats compared to dairy cattle, the doe's calcium homeostatic system must adapt to the challenges of calcium outflows associated with fetal growth and initiation of lactation. Limited studies have specifically addressed regulation of calcium metabolism in the goat, but evidence suggests similar controlling mechanisms compared to cattle.[12] Maternal adaptations to trace mineral and fat-soluble vitamin losses to fetus(es) and colostrum are limited to mobilization of reserves and replenishment from adequate dietary supplementation.

PREPARTUM NUTRITION AND REPRODUCTION

Nutrient requirements of the late pregnant, nonlactating doe are only slightly higher than maintenance, approximately equivalent to the energy and protein required to produce 2 to 4 lb of 4% milk per day.[13] However, providing sufficient quantities of essential nutrients is just as critical for the late pregnant doe as the lactating doe to maintain optimal performance. Recognition of a substantial increase in nutrient requirements for the late pregnant and lactating animal compared to maintenance has been the focus of nutritional investigations in dairy cattle and ewes. Dietary recommendations for digestible energy (DE), crude protein (CP), calcium (Ca), and phosphorus (P) for the late gestation doe are 1.5 to 1.8 times greater compared to maintenance at the same level of activity.[13] The transition from late gestation into lactation requires a similar or much greater increase in dietary nutrient intake. These differences in nutrient requirements require appropriate modifications in the feeding program as well as metabolic alterations by the doe to adequately support late gestation and lactation. If these metabolic changes are not effectively enacted, metabolic disease, reduced milk production, and impaired reproductive performance may result.

Kid Viability and Survival

Data from cattle and sheep suggest that nutrition of the dam at all stages of gestation can influence neonate viability and productivity. In reviewing factors responsible for contributing to prepartum and partum calf[14] or lamb[15,16] losses, nutritional deficiencies and toxicities influenced all factors. Similar contributing factors can be reasonably assumed for goats. Maternal undernutrition during mid- to late gestation has been implicated in an abortion syndrome observed in yearling Angora goats.[17]

Birth weight is the single most important factor determining postnatal survival. Extremely heavy birth weight is more associated with dystocia, and lighter birth weight kids, typical of twins and triplets, have higher mortality rates.[18] Dynamic in vivo measures of fetal sheep crown-to-rump length found fetal growth to be deterred or completely stopped during periods of induced maternal hypoglycemia during late pregnancy.[19] Ditocous ewes fed an 8% CP diet gave birth to lambs that were 20% lighter than lambs born to similar ewes fed isocaloric diets with either 11% or 15% CP.[20] Ewes fed 11% CP diets, however, mobilized maternal protein in support of fetal growth, whereas maternal protein accretion occurred in ewes fed 15% CP diets. In contrast, singleton-bearing ewes fed 1.4 times their estimated protein requirement (165 g CP; 11.8% CP) delivered larger lambs (4.9 versus 4.3 kg) with greater lambing difficulty and higher mortality rate compared to ewes fed to requirement (117 g CP; 8.7% CP).[21] Besides differing in using twin or singleton pregnant ewes, dietary treatments were initiated at 110 days[20] and 85 days[21] of gestation for these two studies.

Maternal dietary influence on fetal growth is more complicated than simply addressing under- or overfeeding relative to requirement. Maternal body condition score and dietary nutrient status relative to period of fetal and placental growth are confounding variables.[1] Fat ewes partition more nutrients to the gravid uterus, maintaining fetal growth during periods of moderate undernutrition in late pregnancy compared to lean ewes.[22] Lean or moderately fat ewes fed ad libitum in late pregnancy had similar placental and fetal birth weights despite different intake amounts (29% higher for lean ewes), suggesting placental mitigation of available nutrients in

controlling fetal growth.[23] West African dwarf does fed a higher level of concentrate throughout gestation had heavier birth weight kids and greater problems with dystocia, whereas does fed the same rate of concentrate for only the third trimester (>120 days) had low birth weight kids with higher mortality rate.[24] Does fed a higher and moderate amount of concentrates in second (60 to 120 days) and third trimester, respectively, had moderate birth weights and minimal health problems. High rate of energy supplementation during first and third trimester in does was suggested to be avoided.[25] Twin-bearing Tswana does supplemented throughout pregnancy had greater total kid birth weight compared to does not supplemented or supplemented before or after 103 days of gestation.[26] Although placental mass was not influenced by dietary treatment, nonsupplemented does had the lowest placental (390 versus 580 g) and total fetal (5.1 versus 5.8 kg) weights.[26]

In primigravid, singleton-bearing ewes, placental growth and, ultimately, lamb birth weight were restricted when fed for rapid growth after the first trimester.[27] Rapid maternal growth during the first trimester followed by moderate growth stimulated compensatory placental growth and moderate birth weight lamb.[27] Placental weight is the primary determinant of fetal weight.[28] Fetal cotyledon number was influenced by first trimester nutritional status, whereas cotyledon weight was mediated by second trimester nutrition.[27] Fetal number and placement within uterine horns further mitigate the relationship between gestational nutrition and fetal growth.[28]

Beyond birth weight, maternal milk production will affect growth and survival of the neonate. Inadequate nutrition during late pregnancy influences milk production and composition,[29] possibly as a result of compromised mammary gland development.[30] Dietary protein content of 11% CP (9.8 g/kg body weight × 0.75), slightly higher than the National Research Council (NRC) recommendations,[13] is recommended for adequate late gestation nutrition to meet fetal and subsequent lactational needs.[31] Current NRC pregnancy energy requirements were considered adequate;[29] however, a new NRC publication for goat nutrient requirements is under development.

Colostrum Quality and Quantity

Following birth weight concerns, adequate consumption of good quality colostrum is essential to neonatal survival. With selection for higher milk production in dairy goat breeds, potential exists for selecting against colostrum quality, as a result of increased colostrum volume, similar to what has been experienced in the dairy industry. Limited studies, with equivocal results, have addressed nutritional effects on colostrum quality in sheep and goats. Contrary to what might be expected, feeding greater amounts of prepartum protein (117 versus 165 g/day) resulted in reduced colostrum yield in sheep, but immunoglobulin concentration was not reported.[21] Energy and protein content of the prepartum diet for pregnant ewes influenced the amount of colostrum produced at 3 and 24 hours after lambing.[32] Colostrum volume increased with increasing supply of energy and protein (Table 75-1). In ewes, increasing prepartum energy intake increased colostrum yield, and increasing prepartum protein intake improved lamb colostral immunoglobin absorption efficiency.[33] Although feeding supplemental concentrate increased colostrum yield, immunoglobulin concentration was decreased even with increasing undegradable protein supplementation.[34] It would seem that beyond severe undernutrition, colostrum quality is not greatly influenced by additional energy or protein supplementation and may adversely affect quality by increasing volume. Further work is needed to fully explore prepartum diet effects on colostrum production and quality.

Table **75-1**

Effect of Prepartum Dietary Metabolizable Energy (ME) and Crude Protein (CP) Intake on Colostrum Production in Sheep

	Low Energy		High Energy	
ME intake, Mcal/d	1.94	1.94	3.46	3.46
CP intake, g/d	80	128	128	185
ME:CP	24	15	27	19
	Colostrum Volume, ml			
First 3 hours	150	320	380	640
24 hours	1020	1580	1890	2100

Adapted from Robinson JJ: Energy and protein requirements of the ewe. In Haresign W, Cole DJA (eds): *Recent advances in animal nutrition.* London: Butterworths: 1988, pp 187–204.

Fetal Reproductive Development

Adequacy of the prepartum diet has been shown to influence embryonic and fetal ovarian development and subsequent reproductive performance in the adult ewe.[35] Gunn and colleagues[36] observed a reduction in lambing percentage from ewe lambs born to ewes exposed to undernutrition during their fetal development compared to ewe lambs born to well-fed pregnant ewes. Increased numbers of high-quality embryos were collected from lambs born to ewes fed a higher level of nutrition (1.5 times maintenance) during mid-gestation (71–100 days), late gestation (101–126 days), or both.[37] Whether this nutritional effect is influencing ovarian growth, follicular development, or embryo survival is not well defined, but given the lifetime ramifications, further study to elucidate mechanisms is warranted.

Periparturient Disease

Unlike the situation for cattle given the difference in time frame between parturition and subsequent mating, periparturient disease of goats plays a lesser role in mitigating reproductive performance than recognized for dairy cattle. If the periparturient disease process induces severe body condition loss and an inability to regain condition before breeding, then reproductive performance may be adversely affected. The most significant reproductive effect of periparturient disease is reduced survival of off-

spring and dam rather than specific impact on subsequent reproductive efficiency. Role of prepartum nutrition in the pathogenesis of periparturient diseases is discussed in the following sections.

DERANGEMENTS OF ENERGY BALANCE (PREGNANCY TOXEMIA, KETOSIS, AND FATTY LIVER SYNDROME)

An inability of the pregnant or lactating doe to maintain glucose homeostasis characterizes a state of negative energy balance whereby glucogenic precursors from diet or endogenous sources are insufficient to meet the doe's total energy requirement. Metabolic signals recognizing glucose insufficiency initiate fat mobilization in proportion to degree of negative energy balance to compensate. If magnitude or duration of the negative energy balance insult is severe enough, release of NEFA may overwhelm the liver's capacity, culminating in maladaptive metabolic responses generating large quantities of ketone bodies and allowing severe fatty infiltration of hepatocytes. Ability to maintain functional insulin concentration and maternal tissue responsiveness seems pivotal to appropriate metabolic adaptation to negative energy balance.[9,38] Inherent metabolic differences among individuals (genetic variation) may account for observed disparity in individual susceptibility to clinical manifestations.[39]

Pregnancy ketosis (pregnancy toxemia) can occur during the last 6 weeks of pregnancy, concurrent with the period of rapid fetal growth, although it is most often recognized in the last 2 to 4 weeks of gestation. The last few weeks of gestation are often associated with declining intake, and when in combination with a pregnancy of multiple fetuses, place the doe in a precarious ketosis-prone metabolic position energetically. Lactational ketosis occurs most frequently within the first 4 weeks of lactation, a period associated with rapidly increasing milk production with slowly increasing feed intake. Pregnancy toxemia is the more common problem seen in goats; however, lactational ketosis is of concern with high-producing dairy goat breeds.

Any animal, management, or environmental factors that adversely affect the doe's net energy intake increases the risk of metabolic maladaptation leading to ketosis and fatty liver infiltration. Overconditioned does (>4.0 body condition score [1 to 5 scale]) are at high risk for ketosis and fatty liver as they experience reduced feed intake compared to leaner does and have abundant fat reserves to mobilize. Feed availability and quality, sudden feed changes, water availability, transportation of late gravid does (>100 days), concurrent disease, and heat or cold stress conditions are some of the factors that, singly or in combination, may initiate an episode of reduced feed intake potentially leading to a ketotic response.[39,40] Pregnancy toxemia or lactational ketosis induced by a concurrent disease is often categorized as secondary ketosis, as typically the underlying disease was responsible for reduced intake and inducing the ketotic state.

Most often, pregnancy toxemia or lactational ketosis is a sporadic occurrence of low morbidity (<3%) within a goat herd. Individual variation in the metabolic response to herd nutrition and management accounts for the sporadic nature of the disease. In contrast, factors influencing a large percentage of the herd, namely nutritional and feeding management factors, can result in a herd outbreak with morbidity rates exceeding 10% of the does. Timely recognition of individual cases and underlying etiology are important in heading off potential herd problems as mortality rates often exceed 80% in affected animals.[39]

Clinical Signs and Diagnosis

Clinical presentation of an affected doe will vary with associated metabolic derangements. Initially with pregnancy toxemia clinical signs will be vague, primarily behavioral and attitude changes. Does will generally isolate themselves and appear listless, dull, and depressed. As hypoglycemia and ketonemia progress, neurologic manifestations become evident. Does may appear blind, become disoriented and ataxic, and have reduced feed intake. Metabolic acidosis develops from excessive ketone body production. Breathing may become more rapid, neurologic signs continue to progress, and the doe is less likely to rise or respond to stimuli. Chewing, teeth grinding, and vigorous licking movements may be seen. In the final stages the doe becomes recumbent with severe neurologic signs and coma. Death is usually the result of renal failure or toxemia following fetal death. Does may show slight signs of recovery following fetal death but may ultimately succumb as a result of toxin release. Progression of clinical signs ranges from 12 hours to 7 days, a more typical time course being 3 to 4 days.[39,40] Differential diagnoses should include hypocalcemia, polioencephalomalacia, listeriosis, and ruminal acidosis (grain overload).

Lactational ketosis does may misbehave in the milking parlor, exhibiting irritability; have a poor appetite; or intermittently consume feed, especially concentrates. The most obvious sign is markedly reduced milk production and excessive weight loss. Clinical signs generally do not progress like that observed in pregnancy toxemia, as the reduction in milk production reduces negative energy balance and mitigates disease progression. More often milkers readily recognize reduced milk production and initiate treatment.

Ketosis is definitively diagnosed by identifying excessive positive ketone reaction in urine. Dipsticks and ketone powder both use the nitroprusside test to semi-quantify acetoacetate concentration. Serum or plasma β-hydroxybutyrate (BHB) concentrations can also be determined for diagnosis. Expected BHB concentration is below 8 mg/dl (0.76 mmol/L), whereas concentrations above 15 mg/dl (1.4 mmol/L) indicate moderate ketogenesis and subclinical disease. Clinical ketosis is often associated with BHB concentrations in excess of 25 mg/dl (2.4 mmol/L) and may exceed 40 mg/dl (3.8 mmol/L). Other laboratory findings suggestive of ketosis include elevated NEFA (>0.4 mEq/L) and hypoglycemia (<30 mg/dl). Depending upon the degree of associated fatty liver, elevation of some liver enzymes and lower total cholesterol concentration may be present. Degree of fatty liver infiltration is most often diagnosed on necropsy. In the

later stage of the disease, hyperglycemia, hypokalemia, hypocalcemia, and elevated creatinine and urea nitrogen may be evident. Hyperglycemia may occur following fetal death. Anorexia may account for hypokalemia and hypocalcemia. Associated dehydration results in elevated creatinine and urea nitrogen concentrations.

Treatment

Treatment and prognosis for recovery of pregnancy ketosis is dependent upon the stage of the disease when recognized and treatment initiated. If the doe is still responsive and willing to eat, dietary modification and supplementation with glucogenic precursors may be adequate. Ensure that high-quality forage is provided and consumed and fermentable energy sources (cereal grains) are appropriately supplemented. Potential glucogenic precursors to be administered orally might include propylene glycol (60 ml twice daily), glycerol (45–60 ml twice daily), or calcium propionate (40–50 g diluted in water and tubed for up to three treatments).[39–41] A number of commercial products based on these glucogenic compounds are now available. Alternatively, use of oral calf scours products containing electrolytes, glucose (40–55 g), and glycine have been administered orally every 4 to 8 hours.[39,42] If the doe is in a more advanced stage of the disease, more aggressive therapy is needed and prognosis becomes progressively guarded. Given economic issues, owners need to be well appraised of the situation and potential outcome before initiating therapy.

Hypoglycemia should be corrected with the administration of glucose via intravenous or oral administration. Bolus intravenous glucose (50 g) can be administered once daily or distributed out in multiple treatments (10 g every 4 hours) depending upon practicality, owner capabilities, and economic considerations.[42] For valuable animals, a constant 5% dextrose infusion may be used. The doe's glucose status before administering therapy should be evaluated, as late-stage disease is often associated with hyperglycemia.[42] Additionally, insulin (10–25 U Ultralente subcutaneously every other day for three treatments) can be administered along with dextrose to facilitate tissue glucose uptake and inhibit fatty acid mobilization.[39,42] Acid-base status, degree of dehydration, associated electrolyte abnormalities (typically hypokalemia and hypocalcemia), and renal function should be evaluated and appropriately balanced fluid therapy administered.[40,41] Fluids with electrolytes can be therapeutically effective either intravenously or orally, depending upon the doe's status. Hypocalcemia is often associated with pregnancy toxemia and has been implicated in blunting endogenous glucose production.[43] Crystalline amino acid solutions (8.5%, 0.6–1.2 g/kg body weight) can be combined with intravenous replacement fluids. Amino acid supplementation may provide additional glucogenic substrate and may be beneficial in augmenting hepatic synthesis and export of VLDL, thus minimizing further hepatic fatty infiltration.[44]

To reduce glucose demand and improve potential response to therapy, induction of parturition is recommended if the doe is less than 2 weeks from her due date. Continued metabolic derangement is as harmful to unborn kids as is the risk of premature birth. Does that experience pregnancy toxemia and do not succumb are at higher risk for dystocia and kid death.[40] Real-time ultrasonography can be used to evaluate fetal viability in making a decision on fetal removal. Parturition can be induced with prostaglandin injection, and does can be pretreated with dexamethasone to facilitate fetal lung development if the due date is uncertain.[41] Does that fail to kid within 72 hours after parturition induction should undergo cesarean section unless they are eating well and fetal viability is confirmed by ultrasonographic examination. Does that are down, are obtunded, have neurologic signs, or have renal failure have a very poor prognosis for recovery, and fetal viability is likely compromised.

Beyond initial therapeutic procedures, ketosis and fatty liver cases can benefit from various supportive therapy modalities. With various degrees of inappetence a common presentation, stimulation of appetite is critical. Often B-complex vitamin solutions, or more specifically, vitamin B_{12}, are administered to nonspecifically stimulate appetite. Offering fresh cut grasses or a variety of feeds may help stimulate intake in some goats. If rumen function is compromised, rumen transfaunation may be required to stimulate intake. Alfalfa meal and commercial concentrate pellets can be soaked and administered through a stomach tube as gruel to provide supportive enteral nutrition.

Lactation ketosis can be treated with any one or a combination of intravenous glucose (250–400 ml, 10% solution), oral glucose (oral calf electrolyte solutions), or propylene glycol (30–60 ml twice daily). Often one or two treatments are adequate as long as an acceptable diet is available and consumed by the doe. Glucocorticoid therapy should be used cautiously if there is evidence of an infectious process. Failure to respond to treatment requires does be examined for possible concurrent disease.

Prevention

Ketosis and fatty liver are best prevented by proper nutrition and management during late pregnancy. Late pregnancy diets should be properly balanced to provide adequate rumen-fermentable carbohydrate and degradable protein to support rumen microbial growth. Current recommendations suggest a minimum of 11% CP in the late pregnant diet.[31] Fermentable carbohydrate sources, primarily cereal grains (a minimum of 0.5 to 1 lb per day up to 2 lb per day), should be increased to meet energy needs, based on fetal numbers. Sufficient effective fiber needs to be consumed to meet the minimal rumen microbial needs. Goats, being highly selective eaters, often can select out poorer quality stems of alfalfa and not receive sufficient dietary effective fiber. Wheat straw, bean straw, beet or citrus pulp, wheat middlings, or wheat bran are suitable fiber sources. Ideally, late pregnant does should be identified by number of fetuses and fed an appropriate diet. If fetal numbers are not known, then diets sufficient to support twins should be fed.

A primary management concern in preventing ketosis problems is body condition of the does. Overconditioned does are often the result of overfeeding during the dry

period when they are maintained in their normal cohort because of social problems encountered in regrouping. Body condition should be monitored and appropriate dietary changes made to ensure all does maintain an appropriate amount of body condition throughout late pregnancy. Other management issues such as feed bunk space, feed availability or abrupt changes in diet, transport, or weather-related stressors must be addressed.

Based on dairy cattle research, feed supplements of niacin (1–2 g) or rumen-protected choline (2–5 g choline) can provide lipotrophic effects in helping the liver better process fatty acids as well as reduce fat mobilization. Dairy cattle studies have shown a reduction in ketosis prevalence, lower NEFA concentration at parturition, and reduced liver fat content when supplemented before and following parturition. However, most positive responses were reported in studies in which the cows were of high body condition scores (>4.0/5.0). Evidence is lacking to support the use of these supplements in a therapeutic, rather than a preventive, mode.

DERANGEMENT OF CALCIUM HOMEOSTASIS (HYPOCALCEMIA, MILK FEVER)

Dairy goats may develop hypocalcemia in late gestation, around the time of parturition, or during early lactation.[45,46] High-producing, older (>3 years) dairy does are more predisposed to hypocalcemia following kidding, similar to the syndrome observed in dairy cattle. However, most goats have a relatively large fetoplacental unit, which predisposes them to development of prepartum hypocalcemia. Although often discussed as an important clinical concern, prevalence of hypocalcemia in goats is much lower than the incidence observed in dairy cattle. A common presentation of hypocalcemia in goats is secondary to pregnancy toxemia or other disease process that markedly reduces feed intake.

Hypocalcemia results from the inability of the calcium homeostatic system to maintain blood Ca in the face of Ca outflow to fetus, colostrum, or milk. Parathormone, calcitonin, and vitamin D are the primary mediators of Ca homeostasis in the goat, similar to other species.[12] Parathormone responds to low blood Ca^{2+} by stimulating activation of vitamin D, which facilitates intestinal Ca absorption efficiency, and promoting Ca resorption from bone and reabsorption from renal tubules. Calcitonin has opposing effects to parathormone, resulting in reduction of blood Ca^{2+} concentration. Pathogenesis of primary hypocalcemia in sheep and goats is not well defined, but most likely follows that of dairy cattle when sensitivity of target organs to parathormone stimulation is blunted.[47] High prepartum dietary Ca has previously been implicated, but research with dairy cattle suggests that dietary effects on acid-base status, defined as dietary cation-anion difference (DCAD), is the primary inciting problem.[47]

Clinical Signs and Diagnosis

Initially the doe is ataxic, nervous, and hyperactive. The doe is hyperirritable and may show fine muscle twitching of the lips, eyelids, and ears. Trembling or twitching of other muscles of the body may also occur. Convulsions may develop. As hypocalcemia progresses, clinical signs may include anorexia, ruminal stasis, constipation, cold ears and extremities, and flaccid paralysis. The doe quickly becomes sternally recumbent and laterally recumbent in the final stages. The head may be turned back to the flank. Body temperature usually remains normal, but will decline to subnormal in a short period of time.[46] Heart sounds are muffled with tachycardia and weak pulse. Death follows bloat, regurgitation of rumen contents, and aspiration. Less severely affected does (subclinical hypocalcemia) show lethargy, poor appetite, and uterine inertia or poor milk production, depending upon time frame of presentation.

The disease course can be as short as a few hours or can occur over a couple of days. Occasionally it may occur as "sudden death". Diagnosis is made based on history, presenting clinical signs, and rapid response to therapy. Diagnosis confirmation is accomplished by determining blood Ca concentration. Serum total Ca concentrations are decreased, usually to less than 6 mg/dl (normal, 8–12 mg/dl). More severe clinical signs are correlated with lower serum total Ca concentrations (<4.0 mg/dl). Hypophosphatemia and either hypermagnesemia or hypomagnesemia often occur concurrently.[46] To help in diagnosing hypocalcemia in a sudden death case, fluid from eye chambers obtained during a postmortem examination can be analyzed for Ca concentration up to 48 hours after death. Hypocalcemia may look like other diseases and must be differentiated from polioencephalomalacia, advanced grain overload, toxic mastitis, lead poisoning, and listeriosis.

Treatment

Recommended treatment for hypocalcemia is slow intravenous administration of 50 to 100 ml of Ca gluconate (9.3% Ca) or borogluconate (8.3% Ca) solution to effect.[46] A suggested starting dosage is 1 g Ca^{2+} per 45 kg body weight.[48] Cardiac rate and rhythm should be monitored during Ca infusion. Initially, poor peripheral perfusion limits absorption of subcutaneous Ca solutions, but it can be used following intravenous treatment to help prevent relapse (20–60 ml, 20 ml/site). Soft tissue edema occasionally occurs following subcutaneous administration of Ca solutions, especially those containing dextrose. Caution should be exercised in administering both subcutaneous and intravenous Ca solutions together, as the total dose may reach a toxic level.[48] Response to intravenous treatment should be dramatic, with the doe usually starting to shiver and brighten up by the time treatment is completed. Early treatment usually results in positive responses, and does not treated will die. A rapid progression to an obtunded state is indicative of a poor prognosis. Oral calcium gel preparations designed to correct hypocalcemia in dairy cattle can be used in goats at an appropriate body weight–based dose. However, many of these gel products are caustic and can induce pharyngeal or esophageal lesions. Following intravenous or subcutaneous injections, dietary intake of Ca should be increased with use of alfalfa hay or Ca-based mineral

supplements. Does in late gestation with hypocalcemia should be evaluated or monitored for pregnancy ketosis and treated accordingly.

Prevention

Without good scientific evidence describing the mechanism responsible for hypocalcemia in dairy goats, it is difficult to define specific feeding recommendations. It would seem prudent to maintain appropriate dietary Ca and P content in late pregnancy to support fetal bone development, but not to supplement to excess. Dietary potassium (K) should be monitored in an attempt to maintain a level below 2%. Dietary magnesium (Mg) should also be monitored and maintained according to dietary K (see next section on hypomagnesemia). Once into lactation, dietary Ca and P content should be increased to a level to support milk production capacity, which can be achieved by feeding alfalfa or other legume hay. Grass forages contain moderate to low Ca content and cereal crop forages such as wheat or oat hay are very low in Ca. If these feeds make up the forage portion of the diet, additional Ca sources, primarily from mineral supplements, should be provided.

Use of anionic salts (minerals high in chloride and sulfur) has been advocated for dairy cattle in preventing milk fever.[47] For anionic diets to be effective, they need to be properly balanced relative to dietary sodium (Na), K, chloride (Cl), and sulfur (S) to achieve a cation-anion difference ([Na + K] – [Cl – S], all values in mEq) of –10 to –15 mEq/100 g diet dry matter. In using anionic salts, the goal is to induce a state of compensated metabolic acidosis, which stimulates Ca absorption and mobilization. Work with sheep[49,50] and goats[51] has shown a similar dose-response effect of DCAD on Ca homeostasis, suggesting possible applicability. To achieve the desired effect, one must ensure the animal is appropriately acidified. This requires specialized feed ingredients to be fed and close monitoring as well as controlling dietary K content. Use of buffers such as sodium bicarbonate may increase susceptibility to hypocalcemia by contributing to diet alkalinity. For this reason, buffers are best not fed during the dry period. Urine pH measurements can be used to monitor effectiveness and titrate the required amount of anionic supplement.

In general, anionic salt feeds are not very palatable and can reduce feed intake. This is an undesirable effect, but newer, more palatable products are now available. Anionic salt products need only to be fed for a brief period of 10 to 14 days immediately before parturition to prevent hypocalcemia.

HYPOMAGNESEMIA (MILK TETANY, GRASS TETANY)

Magnesium is inefficiently absorbed from the rumen, and high dietary K content can interfere with Mg absorption. Potassium poisons the ruminal Na-K ATPase-mediated active transport system for Mg.[53] Magnesium also plays a role in maintenance of blood Ca concentrations, and hypomagnesemia can induce hypocalcemia.[47] Besides mineral interactions, differences exist between grasses and legumes as to Mg content. Grasses contain less Mg than legumes and when growing rapidly in cooler conditions (lush spring pasture), Mg availability is greatly reduced. Sheep and goats, like other ruminants, have little ability to manage blood Mg concentrations if dietary or absorption levels are depressed. The combination of low intake coupled with greater losses during early lactation result in the clinical syndrome.

Hypomagnesemia is a common problem in beef cattle on spring pasture, but sporadically is seen in dairy cattle and small ruminants. Many clinical syndromes have been identified relative to disease circumstances, but all have hypomagnesemia in common. Lactating does on spring pasture are susceptible (grass tetany or lactation tetany) as well as growing kids on milk replacer (milk tetany).[46] Animals fed low-quality winter forages that are also low in Mg content can have chronic forms of hypomagnesemia, and any stressors will precipitate a tetanic syndrome (winter tetany).

Clinical Signs and Diagnosis

Hypomagnesemia (<1.2 mg/dl) usually occurs within the first 2 to 4 weeks of lactation and results in a life-threatening disease process characterized by severe tetanic muscle spasms. Some affected animals may be found dead in the pasture. Initial clinical signs include ataxia, muscle stiffness, and hyperexcitability. All muscles are overstimulated, resulting in extreme leg stiffness and observed muscle spasms. This is very different from the paralytic muscle weakness of hypocalcemia. With declining serum Mg concentration, clinical signs progress into recumbency and paddling. Convulsions may be triggered by some stimuli including predator attacks, severe weather changes, transportation, and other stressors.

Similar to hypocalcemia, diagnosis of hypomagnesemia is based on history and signalment and secondarily confirmed with blood tests. Serum Mg concentrations below 1.5 mg/dl are indicative of potential problems, and values below 1 mg/dl are diagnostic. Magnesium concentrations can be measured in eye fluid (48 hours), urine (24 hours), or cerebrospinal fluid (12 hours) from samples collected for a limited time following death.[46]

Treatment

Slow intravenous administration (50–75 ml) of combined Mg and Ca solution is required for a positive response to therapy.[46] As with any Ca therapy, heart rate and rhythm should be monitored. Response to intravenous therapy is rapid, but may be short-lived. Repeat treatments may be necessary. Subcutaneous injection of Mg sulfate (25–50 ml, 50%) solution can help ensure blood Mg concentration over a longer period of time following intravenous therapy. Oral Mg supplementation should follow treatment to also help prevent relapse as well as ensure continuing adequate intake.

Prevention

Agronomic practices from modifying fertilization practices, applying dolomitic limestone, or seeding legumes

into grass pastures are all beneficial in preventing hypomagnesemia, but may not be economically practical. Appropriate dietary supplementation of Mg from late pregnancy through early lactation is needed. Dietary Mg should be increased to account for high dietary K, up to a point. Dietary Mg should not exceed 0.4% of dry matter. A ratio of dietary K to Mg of 4 : 1 is suggested. Magnesium can be supplemented in mineral mixes, but it is unpalatable. Molasses-based mineral blocks or licks should contain at least 5% Mg to meet requirements. Mixing 1 part magnesium oxide, 1 part trace mineral salt, and 1 part soybean meal or other palatable feed has been shown to be effective in maintaining good magnesium intakes and preventing disease problems.[46]

RUMINAL ACIDOSIS

Ingestion of large amounts of readily fermented sugars and starch, often in conjunction with reduced dietary effective fiber intake, results in excessive production of volatile fatty acids (VFAs) and lactic acid, overwhelming ruminal buffering systems, culminating in severely depressed rumen pH. Cereal grains are often implicated, but readily fermentable carbohydrates capable of inducing acidosis can be found in many byproduct feeds including bakery or candy waste, fruit pomace, beets, or potatoes.[41] Sugar and starch fermentability is related to the physical and chemical form of the compound and degree of processing. Corn starch, primarily amylase, is relatively less undegradable compared to wheat or barley starch, but if ground, ensiled, extruded, or flaked, rate of degradation increases markedly.

Clinical lactic acidosis may occur at any time, but is most common in early lactation in does not accustomed to high carbohydrate rations. Changing grain source or using processed grains may also predispose to acidosis if degradability properties of the concentrate have been increased. Many lactating does consume concentrate mixes free-choice during milking, and any event that increases the time spent in the milking barn may result in acidosis in some individuals. Subclinical acidosis is also likely to be common in dairy goats that are fed to maximize milk production.

Clinical forms of ruminal acidosis can present as peracute, acute, subacute, or chronic disease processes. Lactic acid is one of many potential fermentation end products generated by sugar and starch fermenting bacteria. Under normal rumen conditions, production of lactic acid is counterbalanced with its consumption by lactate fermenting bacteria. Lactic acid is a potentially deleterious product in the rumen, as it will reduce pH to a point of suppressing bacteria responsible for fiber fermentation. Most bacteria in the rumen are pH sensitive, not being able to survive below pH of 6.0. As the rumen pH declines, *Lactobacillus* bacteria will start to proliferate, generating d-lactic acid, which is more slowly metabolized by the host animal, creating a destructive downward pH spiral. The host animal succumbs to metabolic acidosis and hypovolemic shock as a result of fluid losses to hyperosmotic rumen contents.[41]

Clinical Signs and Diagnosis

Clinical signs are dependent upon acidosis severity and duration, which is a function of type and amount of feeds consumed, particle size and degradability of carbohydrates, and degree of adaptation to the diet. In subacute acidosis, clinical signs may be vague and include some or all of the following: feed refusal, especially grain; cyclic feed intake ("slug feeding"); reduction in milk fat composition; paste-like fecal pellets to mild diarrhea; and abnormal hoof growth (hardship rings). With peracute or acute acidosis, clinical signs may be recognized within hours to 1 day of consuming the inciting diet. Animals may present with anorexia, depression, ataxia, or weakness and appear "drunk." More severe peracute cases may present as recumbent with severe systemic signs of circulatory collapse and toxemia. Fluid accumulates in a static rumen, distending the abdomen and giving the rumen a "splashy" consistency on ballottement and induces various degrees of dehydration (sunken eyes, dry mouth, elevated packed cell volume, and total protein). Colic, teeth grinding, and diarrhea may be observed with some cases. Neurologic signs consistent with polioencephalomalacia—blindness, opisthotonos, head pressing, and seizures—may be present, depending upon the severity of dehydration, metabolic acidosis and toxemia present.[41] Bacterial endotoxemia results from rumen bacterial death and may lead to secondary hypocalcemia. Body temperature initially is elevated, but declines with disease progression. In severe cases, death occurs within 24 to 72 hours.

Diagnosis is confirmed by rumen fluid examination (pH and examination of flora) collected by ruminocentesis.[40,41] Subacute acidosis will have ruminal pH values below 5.5, whereas more severe cases may reach pH 4.0 or lower. Rumen contents will be milky gray in appearance and contain no or reduced numbers of protozoa and overwhelming numbers of gram-positive rods.[40,41] Urine and blood pH will also be low with high concentrations of lactate (>30 mg/dl). On necropsy, rumen contents will have a thin oatmeal consistency and particles of the offending feed consumed can be visualized. Rumen pH will decline continuously following death as a result of ongoing microbial fermentation; therefore, postmortem ruminal pH cannot be used to diagnose an antemortem condition.

Treatment

With mild to moderate cases, symptomatic therapy with rumen alkalizing agents (magnesium oxide [10–20 g] or hydroxide [50 g], sodium bicarbonate [20 g]),[40] oral fluids, and supportive care along with a reduction in grain feeding may suffice. Treatment for acute acidosis cases is more heroic, aimed at correcting acid-base imbalances, dehydration, and toxemia. On clinical presentation, a decision must be made as to whether or not emptying of rumen contents will impact clinical progression. Rumenotomy should be undertaken if significant amounts of the offending feed are still available for fermentation within the rumen. If rumen contents are liquid, siphoning off the fluid with an orogastric tube

may be sufficient, followed by rumen alkalizing agents. Rumen transfaunation should be used to re-establish microbial floral population. Intensive supportive therapy includes intravenous fluids with Na bicarbonate (5% or calculated to need), correction of electrolyte abnormalities, systemic antibiotics, and nonsteroidal anti-inflammatory agents. Sodium bicarbonate (1 g equals 12 mEq bicarbonate) required is calculated by multiplying measured base deficit times 0.3 and body weight (kg).[40] Systemic penicillin is the antimicrobial agent of choice.[41] Oral fluids are not indicated in more severe cases, as their absorption is limited and they further contribute to rumen distention. Other supportive therapy may include subcutaneous injections of thiamin, B–vitamins, and calcium gluconate.[40] Even if one recovers an affected goat, secondary problems related to bacterial and fungal infections of the liver and rumen wall need to be addressed.

Prevention

The rumen system is best maintained on a consistent dietary regimen optimizing the feeding of forage. Feed changes all need to be made gradually over several days so the flora have time to adapt, generally 10 to 21 days. Grain feeding within a diet must be controlled and managed appropriately. Dramatic changes in dietary forage-to-concentrate ratio, total amount of concentrate fed, and increased concentrate fermentability will be conducive to lactic acidosis. Feeding sequence should always offer forages or high roughage supplements before feeding grain concentrates, as forage or fiber consumption will stimulate rumination and increased saliva and buffer production. Diets containing minimal fiber (<19% acid detergent fiber), fiber that is easily sorted out, or fiber sources chopped too finely are at greater risk for acidosis. In situations in which large quantities of grain concentrates are required (high production, poor quality forages), grain feedings should be distributed into two or preferably more feedings of no more than 300 g per meal.[40] Inadvertent access to grain storage must be prevented.

Addition of rumen buffers, Na bicarbonate (1% of concentrate, 25 g/doe/day), or Mg oxide (0.4% of concentrate, 10 g/doe/day) can be added to the concentrate meal. These rumen buffers can have an additive effect when combined (2 to 3 parts Na bicarbonate to 1 part Mg oxide).[53] Dietary buffers can mitigate risk of acidosis and increased milk yield and milk fat content. Availability of free choice Na bicarbonate has been advocated for early lactation does. Although observations suggest adequate consumption of free-choice bicarbonate, does are more likely consuming the bicarbonate for the Na and may reduce their intake of free-choice trace mineral salt if it is being offered. Ionophore agents such as sodium monensin have been shown to reduce rumen lactic acid production and risk of acidosis by altering rumen microflora populations.[54] Although inclusion of sodium monensin (Rumensin, Elanco) has been recently approved for lactating dairy cow diets, it has not been approved for use in lactating goats' diets.

LOW MILK FAT SYNDROME

Milk composition is an important aspect of dairy goat production, as it influences income and quality of product. Low milk fat syndrome is a commonly encountered problem in dairy cows and one frequently observed in dairy goat production. Low milk fat is defined as a milk fat content well below standards for a breed with possible inversions of milk protein and fat content. For most dairy goat breeds milk fat percentage is typically between 3.8% and 4.2%. In low milk fat syndrome, milk fat content may decline below 3%.

The phenomenon of low milk fat syndrome has been well studied and a number of hypotheses have been proposed as to the cause.[55] Recent research with dairy cattle has unified two observations as to dietary causes of low milk fat syndrome. Diets low in fiber and high in grain can produce milk with low fat content. Similarly, diets with higher polyunsaturated fats can cause the same problem. Currently research suggests an intermediate compound resultant from rumen biohydrogenation of dietary polyunsaturated fatty acids produces a family of compounds identified as conjugated linoleic acids (CLA).[55] Many isomers of CLA have been identified, but one, trans-10, cis-12 CLA, has been shown to suppress fat synthesis in the mammary gland. The suppression in milk fat production is dose-dependent to the amount of trans-10 CLA. Recently reported research has shown identical mechanisms of altered CLA production with milk fat suppression when feeding high grain and polyunsaturated fat sources to lactating goats.[56,57]

There is no treatment other than to prevent the formation of trans-10 CLA in the rumen. Low-fiber diets with high grain intake seem to initiate the right rumen conditions to generate more trans-10 CLA. Feeding diets higher in vegetable fats will also increase trans-10 CLA production. Preventive practices should focus on appropriate fiber to concentrate levels in the diet and minimizing additional vegetable fat supplementation (whole soybeans, sunflower seeds, linseed oil, whole cottonseed).

CHAPTER 76

Periparturient Infections and Structural Abnormalities

WILLIAM BRAUN, JR.

A variety of periparturient conditions may interfere with normal parturition or adversely affect the health or fertility of does after parturition. Fortunately, these conditions are not encountered frequently in goats but they are of grave concern to owners when they do occur.

HYDROPS

Excessive accumulation of fluid in the amniotic (hydramnios) or the allantoic (hydrallantois) sacs are infrequent complications of pregnancy. They are common in cattle but are rare in other species,[1] although there are two published reports of hydrops in goats.[2,3] The underlying cause of this condition is not known, but hydrops is encountered in the latter half of pregnancy and is characterized by rapid and progressive abdominal distention. The distention is a reflection of the accumulation of excess fluid within one or the other of the placental compartments. Normal fluid amounts in the pregnant goat uterus are 0.5 to 1.5 L, which may be increased greater than 10-fold in cases of hydrops. Other clinical signs are the result of compression of other organs by the expanding uterus and include a decrease in appetite, tachycardia, tachypnea, dyspnea, generalized weakness, and, finally, recumbency.

The excess fluid that accumulates in hydrops has an electrolyte composition more similar to extracellular fluid than to amniotic or allantoic fluids. In cows, an abnormal fetus (hydramnios) or placenta (hydrallantois) is associated with excessive accumulation of fluids. In goats, the fetus may have congenital abnormalities, be underdeveloped, or be apparently normal but not viable. The placenta has gross and microscopic pathologic changes, most commonly edema and necrosis. The placentomes are reduced in number and are structurally abnormal.

Diagnosis is based on presenting signs and the results of a physical examination. Differential diagnosis includes intestinal obstruction, ascites, ruminal tympany, hydrometra, and normal multiple fetuses.[2] Palpation and ballottement of the abdomen reveal the fluid accumulation, whereas ultrasonography shows that the accumulation of fluid is within a thin-walled uterus. Rectal palpation, as used for cattle, is impractical for diagnosis

CHAPTER 76

Periparturient Infections and Structural Abnormalities

WILLIAM BRAUN, JR.

A variety of periparturient conditions may interfere with normal parturition or adversely affect the health or fertility of does after parturition. Fortunately, these conditions are not encountered frequently in goats but they are of grave concern to owners when they do occur.

HYDROPS

Excessive accumulation of fluid in the amniotic (hydramnios) or the allantoic (hydrallantois) sacs are infrequent complications of pregnancy. They are common in cattle but are rare in other species,[1] although there are two published reports of hydrops in goats.[2,3] The underlying cause of this condition is not known, but hydrops is encountered in the latter half of pregnancy and is characterized by rapid and progressive abdominal distention. The distention is a reflection of the accumulation of excess fluid within one or the other of the placental compartments. Normal fluid amounts in the pregnant goat uterus are 0.5 to 1.5 L, which may be increased greater than 10-fold in cases of hydrops. Other clinical signs are the result of compression of other organs by the expanding uterus and include a decrease in appetite, tachycardia, tachypnea, dyspnea, generalized weakness, and, finally, recumbency.

The excess fluid that accumulates in hydrops has an electrolyte composition more similar to extracellular fluid than to amniotic or allantoic fluids. In cows, an abnormal fetus (hydramnios) or placenta (hydrallantois) is associated with excessive accumulation of fluids. In goats, the fetus may have congenital abnormalities, be underdeveloped, or be apparently normal but not viable. The placenta has gross and microscopic pathologic changes, most commonly edema and necrosis. The placentomes are reduced in number and are structurally abnormal.

Diagnosis is based on presenting signs and the results of a physical examination. Differential diagnosis includes intestinal obstruction, ascites, ruminal tympany, hydrometra, and normal multiple fetuses.[2] Palpation and ballottement of the abdomen reveal the fluid accumulation, whereas ultrasonography shows that the accumulation of fluid is within a thin-walled uterus. Rectal palpation, as used for cattle, is impractical for diagnosis

in goats. Ultrasonography can be used to demonstrate abnormal placentation in hydrallantois, abnormal placentomes, and a decrease in placentome numbers.

Treatment is directed at evacuation of the uterus by cesarean section or induced termination of pregnancy with prostaglandin. Uterine distention predisposes to uterine inertia, and assistance is necessary to remove the fetuses from the uterus. Cesarean section may be contraindicated in these cases as it risks uterine rupture, cardiovascular problems, and potentially fatal hypotension, all from the rapid loss of uterine fluids. Intravenous fluid therapy may be a useful adjunct therapy. Retained placenta and metritis are possible sequelae, requiring therapy after delivery.

VAGINAL PROLAPSE

Vaginal prolapse is fairly common, although not as common as in cattle or sheep. One author claims that it is seen most often in Saanens.[4] The predisposing causes are thought to be similar to those in cattle or sheep and include heredity, increased intra-abdominal pressure from advanced pregnancy, excess estrogen in the forage, previous dystocia, and relaxed perineal tissues due to confinement. If left uncorrected, vaginal prolapse will progress in severity and ultimately result in dystocia.

Early or mild cases are seen only when the doe is recumbent. A small, egg-sized portion of the vaginal floor protrudes through the vulvar lips and disappears into its normal position when the doe rises. Treatment often is not necessary in these cases, although the owner should watch these does to determine whether the condition progresses. Oily antibiotic preparations can be applied to keep the tissues moist and the doe can be confined at night with her hindquarters elevated. Adequate exercise can also be beneficial.

Complete vaginal prolapse does not correct itself spontaneously. The floor and walls of the vagina protrude from the vulvar lips and often result in tenesmus, which further aggravates the condition. The exposed tissue is prone to trauma and may become lacerated and infected. Enlargement due to edema occurs because of disruption of the vasculature of the vagina when prolapsed. In some cases, the urinary bladder is trapped within the prolapse and cannot be emptied, and thereby causes further enlargement of the prolapse. A vaginal-cervical prolapse occurs when the cervix becomes exteriorized along with the vagina. The cervical seal may be dislodged with vaginal-cervical prolapse, exposing the uterus to possible infection.

Treatment of vaginal prolapse entails cleaning the exposed tissue, decreasing its size, and replacing it into normal position. Epidural anesthesia assists replacement of the prolapse and helps to relieve tenesmus after replacement. The vagina is cleaned with mild soap and lubricated with an emollient. Elevation of the exposed tissue assists in evacuation of the bladder. Application of diffuse pressure to the organ, such as with a towel, and elevation of the hindquarters can reduce some of the edema. The vagina is replaced, making sure that fingertip pressure, a potential cause of lacerations, is not used.

After replacement, the vagina is retained in some manner. A paddle-shaped ewe prolapse retainer can be inserted to hold the vagina in place. This instrument does not interfere with parturition but may be difficult to hold in place in goats. Various suture patterns have been used to restrict the vulvar opening, thus preventing a subsequent prolapse. These need to be monitored carefully and opened prior to kidding, or dystocia will result. A shoelace pattern has been advocated because it has the advantage of being easily opened by the owner during parturition but can be left in place to secure the vagina after delivery. A modified Buhner suture secured by a bow knot accomplishes the same goal. Nonsteroidal analgesics, such as flunixin meglumine (1.1 mg/kg IM, daily), may suppress straining after replacement of the prolapse.

Prevention of vaginal prolapse is based on culling previously affected individuals. Once a doe suffers a vaginal prolapse, the prolapse will be repeated during each subsequent pregnancy. Some owners may not want to cull these goats, so they should be advised to watch affected does carefully during late pregnancy. Sexual rest for several years may allow the vaginal tissues to heal. Adequate exercise and prevention of obesity are also important to reduce recurrence.

UTERINE PROLAPSE

Uterine prolapse occurs infrequently after parturition in goats. The entire uterus is everted, often with the placenta still attached. Underlying causes include dystocia, uterine inertia, hypocalcemia, and a lack of exercise. Prepartum vaginal prolapse does not predispose to postpartum uterine prolapse. If the exposed tissue is not badly traumatized, the prognosis is usually good, even in cases of 24 hours' duration.[5]

The exposed tissue should be washed and as much of the placenta removed as possible, providing that trauma to the caruncles is avoided. Straining may inhibit replacement, so epidural anesthesia should be employed. To assist replacement, the exposed uterus and the hindquarters of the goat should be elevated. The uterus is then replaced using the same principles as replacement of a vaginal prolapse. The tips of the uterine horns should be completely returned to their normal position. This may be facilitated by uterine lavage, which allows fluid and gravity to assist in replacement of the tips of the uterine horns if they are not accessible to the operator's hand. Closure of the vulvar opening for several days may be warranted, as with vaginal prolapse.

Subsequent therapy includes oxytocin, systemic antibiotics for 3 to 5 days and tetanus prophylaxis. Lacerated and severely soiled prolapses may be complicated by metritis or peritonitis, so these cases should be closely monitored. Severe cases may require amputation of the uterus. Rupture of uterine blood vessels and hemorrhage are not common in goats. In uncomplicated cases, fertility is usually not reduced.

UTERINE RUPTURE

Spontaneous and induced rupture or tears in the uterine wall occur in goats. Most ruptures are associated with dys-

tocia and are cranial and ventral to the cervix. They occur as a result of manual traction placed on the fetus to effect delivery when fetal parts such as the head or shoulder exert pressure on the uterine wall and trap it against the maternal pelvis. Ruptures also occur in the dorsal wall of the body of the uterus from exuberant efforts to repel a fetus back into the uterus. On rare occasions the uterus may spontaneously rupture during late gestation and partially empty its contents into the abdomen, with subsequent peritonitis in some cases.

Tears or ruptures related to dystocia may be diagnosed when the uterus is explored for more fetuses. Little hemorrhage is evident in these cases. Minor tears can be treated by administration of oxytocin to hasten involution of the uterus. This is especially true for tears that occur in the dorsal wall of the uterus. More extensive ruptures may require manual eversion of the uterus and closure of the laceration with an appropriate suture. Systemic antibiotics and tetanus prophylaxis should be provided.

RETAINED PLACENTA

Fetal membranes are considered retained if they are not passed within 12 hours after the birth of the last kid. Diagnosis may be difficult in goats, as does often eat part or all of the placenta. Postpartum straining may indicate retained membranes or an undelivered fetus. Retained placenta is often associated with abortion or dystocia. Selenium deficiency has been incriminated in herd outbreaks of retained placenta.[6]

Diagnosis can be by the observation of the obvious tissue hanging from the vulva, or a vaginal speculum examination may be necessary. Retained placenta is treated by gentle attempts at manual removal or by hormone therapy. Vigorous attempts to manually extract the placenta should be avoided, as the caruncles may be damaged, causing excessive hemorrhage. Treatment with oxytocin (10–20 IU) at 2-hour intervals may be beneficial. Prostaglandin (5 mg $PGF_{2\alpha}$ IM or SC) may also assist in expulsion of the placenta and involution of the uterus. Metritis often accompanies retained placenta, and a regimen of systemic antibiotics for 3 to 5 days, or until the placenta is passed, is warranted. If the cervix is still open, intrauterine infusion of tetracycline (0.5–1.0 g IU) may be administered. Some clinicians advocate tetanus prophylaxis in cases of retained placenta.

METRITIS

Metritis is often a sequela to retained placenta or trauma to the uterus during dystocia. It may be an important cause of infertility in some goats. Acute, postpartum metritis is characterized by a malodorous, dark red uterine discharge. Does are febrile (40–41.5° C) and anorectic. Severe metritis may be complicated by peritonitis. Therapy includes systemic antibiotics and fluid therapy, if necessary. Repeated oxytocin or prostaglandin injections may facilitate uterine evacuation. Clostridial organisms, frequently *Clostridium tetani* and *Clostridium perfringens,* may colonize the uterus and cause fatal toxemia in affected goats. Tetanus and enterotoxemia prophylaxis, as adjunct therapy, may be prudent.

Chronic metritis or endometritis may occur after parturition or during the breeding season. Affected goats eat normally and are afebrile but have a whitish vaginal discharge. Chronic infections may be the result of postpartum metritis or the result of bacterial contamination during breeding. Systemic antibiotics and prostaglandin are the treatments of choice in these cases.

PYOMETRA

Pyometra is infrequent in goats. Anestrus, persistence of the corpus luteum, and an enlarged, exudate-filled uterus are the hallmarks of classic pyometra. Does give birth during the anovulatory season and do not resume estrous cycles again until many months later. Some Nubian and dwarf goats resume estrous cycles shortly after parturition and may develop pyometra. During the breeding season, cervical damage or bacterial infections introduced at breeding may progress to pyometra. Hydrometra or mucometra are far more common than pyometra in goats, and ultrasonography can be used to differentiate between these conditions. Pyometra is characterized by an echogenic, fluid-filled uterus as opposed to the echolucent intrauterine fluid characteristic of hydrometra. A purulent vaginal discharge may be present in some cases of pyometra. Treatment is the same as for chronic metritis.

CHAPTER 77

Infectious Causes of Abortion

SEYEDMEHDI MOBINI

The female goat is normally a very fertile animal[1,2]; however, goats have a high incidence of abortion when compared with other farm animals. Infectious causes of abortion play an important role and could be a major source of economic loss in a goat herd. In an abortion outbreak, the safest approach is to assume that all causes of abortion are infectious in nature and to proceed from there.[3,4] Several microbial agents have been incriminated as causes of abortion in the goat, but the most common ones are *Chlamydia psittaci, Toxoplasma gondii, Campylobacter* spp., *Mycoplasma* spp., *Coxiella burnetii,* and *Brucella melitensis*. In the United States, chlamydiosis and toxoplasmosis are the most frequently identified infectious causes of caprine abortion.[5,6] In a study of 1784 abortion and stillbirth specimens submitted during a 10-year period, *T. gondii, Campylobacter* spp., and *C. psittaci* caused about 25% of all abortions in sheep.[7] Many of the organisms that cause abortion in sheep also cause abortions in goats, with the exception of campylobacteriosis, which is rare in goats in North America.[6]

The lesion common in all cases of infectious abortion is placentitis. Because of placentitis, the fetus either dies due to inability to exchange nutrients through the placenta, or becomes infected and dies.[4] Economically and emotionally, midterm or late abortions are of great concern to the owner, whether the animal is on a commercial or hobby farm, because the fetuses are lost and the unproductive female must be maintained until next breeding season or sold at a loss. A prolonged period of uterine disease and infertility may follow and in cases of infectious abortion, the disease threatens the rest of the herd.[8]

This section reviews the most common infectious causes of fetal loss in the goat.

CHLAMYDIOSIS

Chlamydiosis is the most common cause of infectious abortion in goats in the United States.[4,9] The disease is also one of the major causes of reproductive wastage in sheep breeding.[10] The disease has been described in Scotland, England, and in the western United States.[11] Chlamydia also causes pneumonia, keratoconjunctivitis, epididymitis, and polyarthritis in sheep and goats.[8,10,12,13]

Etiology

C. psittaci, a gram-negative, intracellular organism that contains both RNA and DNA, is the agent responsible for chlamydiosis.[5] This organism was established as the causative agent of enzootic abortion of ewes in the late 1950s.[14]

The antigenic strains found in goats appear to be closely related to those in sheep. Antigenic type 1 is implicated in abortions, birth of stillborn or weak kids, and in neonatal chlamydial pneumonia, whereas type 2 isolates cause polyarthritis and conjunctivitis in adult goats.[15–17] Serotype 2 has been recently reported as an abortion-inducing strain in ruminants as well.[10] There is no cross protection between these two antigenic types.[15]

Epidemiology and Pathogenesis

Pigeons and sparrows can serve as reservoirs for the organism, and it has been suggested that ticks or insects may play a role in transmission of the disease.[16,17] *C. psittaci* can persist in the feces of infected animals, which may explain why the infection carries over from one kidding season to the next.[10,14] Aborting does shed large numbers of organisms from the uterine discharge, fetus, and placenta, particularly during the first 3 weeks after abortion. Elimination of chlamydiae from the uterus is complete within 3 months.[18,19] Inflammation and necrosis caused by multiplication of the chlamydiae prevent normal transfer of nutrients across the placenta, and the fetus dies and is aborted.[5] Does exposed to *C. psittaci* for the first time in the first half of gestation abort that pregnancy, whereas susceptible does exposed for the first time during the last half of pregnancy usually abort during the subsequent pregnancy.[20] Regardless of the time of infection in the female, the organism does not begin to proliferate and attack the placenta until about day 90 of gestation.[21] Even though chlamydiae have been isolated from the semen of experimentally infected rams for up to 29 days after inoculation, venereal transmission during breeding has not been investigated.[16,17]

There is no evidence of infertility during the subsequent breeding season in aborting does, and immunity after an abortion lasts about 3 years. Older does may abort because of chlamydiae repeatedly.[4,9] Outbreaks of abortion among goats by co-infection with *Coxiella burnetii* have also been reported.[22]

Clinical Signs

In the United States, 25% to 60% of does in endemically infected herds that are kidding for the first time abort.[9] Abortions usually occur during the last month of gestation but can occur as early as day 100 of gestation.[4,8,18,19] Does are not normally ill but may show a bloody vaginal discharge 2 to 3 days prior to abortion. The fetus may be

autolyzed or fresh. Some weak newborns are seen, and a few does may retain the placenta.[4,9] Pathologic changes in the fetus are nonspecific. The fetus may be delivered in a fresh state but may be autolyzed if retained in the uterus for a day or two. The placenta shows regional to generalized placentitis (white to yellow necrotic areas) involving the cotyledons and intercotyledonary space.[4,9]

Diagnosis

Diagnosis is based on a history of abortion along with clinical signs and demonstration of characteristic inclusion bodies in impression smears of placenta, fetal tissue, or uterine discharge. A definitive diagnosis is made by culturing the organism from the placenta or fetal tissue.[4,9,12,13] Serologic testing is also a valuable aid in diagnosis. Ewes, does, and cows have significant rises in antibodies against chlamydial antigen after abortion.[23] Paired blood samples from the doe, 2 to 3 weeks apart, are necessary for serologic tests.[4,13,14] Antibodies may be detected in fetal serum as well. The tests of choice are the enzyme-linked immunosorbent assay and the indirect inclusion fluorescent antibody test.[23] Titers in the range of 1:32 to 1:256 suggest chlamydial infection. A fourfold increase in antibody titer between paired serum samples is significant.[14]

When chlamydiosis is suspected, the following samples should be submitted for diagnostic evaluation[14]:

1. Fresh placenta and fetus packed in ice.
2. Vaginal swab taken within 3 days of parturition, if the placenta is not available.
3. Paired serum samples from the aborting dam and a normal doe.

Treatment and Control

Limited success has been achieved in controlling an outbreak by treatment of all females with tetracycline in the last 4 to 6 weeks of gestation.[4,9,13] Suppression of the organism may prevent additional placental damage and also reduce shedding of chlamydiae by treated does. Large herds are commonly treated with oral tetracycline (400 to 500 mg per head per day) for 2 weeks.[5,24] This would be a reasonable approach for fiber-producing does. In dairy herds, it is more customary to treat individual nonlactating does by injection of long-acting oxytetracycline at a dose of 20 mg/kg IM every 10 to 14 days.[5] Other authors have given the drug twice a week in the last 4 to 6 weeks of gestation.[4,9,13] Considering the management difficulties and cost associated with prevention, the most effective protocol appears to be one injection of long-acting oxytetracycline at 6 to 8 weeks prior to parturition, followed by a second injection 3 weeks after parturition.[17]

Enzootic abortion is of such serious economic consequence in some countries that compulsory government vaccination programs have been implemented.[11] A killed vaccine for sheep is available in the United States and can be used in goats (extra-label use) but may cause a local as well as a systemic reaction for several days (marked soreness and stiffness).[6,25] The vaccine is usually available only in combination with *Campylobacter* bacterin or *Campylobacter* and *Escherichia coli* bacterin (*Campylobacter fetus–Chlamydia psittaci–Escherichia coli* bacterin*).[6,25] The vaccine should be given IM or SC 8 weeks prior to breeding and followed in 4 weeks with a second vaccination.[25] Even though trials in sheep have shown that protection from abortion lasts for about 3 years, annual revaccination is recommended.[25,26] Vaccination helps to prevent abortion, but it does not eliminate infection.[5] Aborting does should be removed from the herd for at least 3 weeks, and the fetus and placenta should be burned or buried. Care must be taken to prevent contamination of feed and water. No feed should be given on the ground, and feeders should be designed to prevent goats from getting into them.[11]

Zoonotic Potential

Chlamydia psittaci is contagious to humans. During kidding season, pregnant women assisting with parturition may become infected and abort. An influenza-like syndrome has also occurred in men assisting with lambing in infected flocks.[5] Veterinarians and farmers attending normal parturition, dystocias, or abortions should wear plastic gloves to limit exposure to uterine fluids. The same precautions apply when collecting fetuses or placentas for disposal or diagnostic evaluation. Pregnant women should avoid contact with the herd during the kidding season.[5]

TOXOPLASMOSIS

Toxoplasmosis is one of the most common parasitic infections in goats, other livestock, and humans worldwide.[27,28] Toxoplasmosis is a major cause of abortion in sheep in New Zealand and England and is known to cause reproductive losses in goats and other animals.[29]

Etiology

The protozoan *Toxoplasma gondii* is the agent that causes abortion, mummification, stillbirth, and birth of weak kids in goats as well as in sheep.[5,27]

Epidemiology and Pathogenesis

Cats are pivotal in the transmission of *T. gondii*.[30] They become infected by ingestion of infected rodents and birds, which can lead to excretion of large numbers of environmentally resistant oocytes. Transplacental infection can develop in cats, and kittens infected in utero can shed *T. gondii* oocytes after birth.[30] Cats often defecate and bury their feces in the hay and food bins of barns. Does become infected by ingestion of food or water contaminated with oocytes from feces of infected cats. The organism enters the blood and spreads to other tissues within 2 weeks of ingestion of oocytes. In pregnant does, toxoplasmas can invade and multiply in the placenta and then spread to the fetus, causing abortion, fetal death,

*Pfizer, Animal Health, Exton, PA.

resorption of the fetus, stillbirth, birth of a live but weak kid, or birth of a normal kid, depending on the stage of pregnancy.[27] Nothing is known about the breed susceptibility to toxoplasmosis in goats. Although *T. gondii* can be found in goat semen, it is doubtful that venereal transmission is important in causing abortion.[28]

Clinical Signs

Goats appear to be more susceptible to toxoplasma infection than sheep.[31] Abortion can occur in does of all ages but primarily in does that acquire infection during pregnancy. Abortion may be repeated in the next gestation.[28] The incidence of abortion in a flock may vary from 3% to 30%. Ewes and does infected prior to breeding do not abort. Those infected 30 to 90 days after breeding usually have fetal resorption or mummification. Most observed abortions occur in the last trimester of gestation, 2 to 3 weeks before term, after infection during the latter half of gestation.[8] The does themselves are generally clinically normal at the time of abortion.[28]

Abortion occurs because of necrosis of the placenta, particularly the cotyledons, or fever in the doe. The intercotyledonary areas of the placenta are usually normal, with the cotyledons having white to yellow focal areas of necrosis and calcification up to 1 cm in diameter (Fig. 77-1). These lesions are clearly visible when the cotyledons are washed in saline. The lesion is characteristic of only toxoplasmosis and can be used in the field as a diagnostic tool.[4,8,13,28,29] On the other hand, *C. burnetii, Brucella* spp., and *Chlamydia* spp. usually cause placentitis that includes the intercotyledonary region.[29]

Diagnosis

Rapid diagnosis of infectious abortion in goats is important. Several tests are available for diagnosis. A presumptive diagnosis can be made from placental lesions alone; however, placenta often is not available for examination because it may be decomposed.[31]

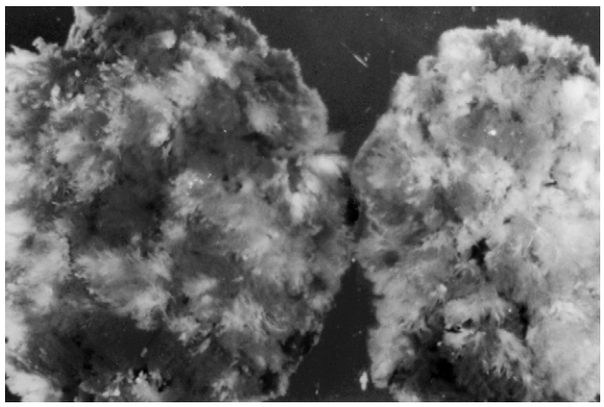

Fig. 77-1 White to yellow focal areas of necrosis in fetal cotyledons of does naturally infected with *Toxoplasma gondii.* (From Dubey JP: Toxoplasmosis: zoonosis update. *J Am Vet Med Assoc* 1990;196:123.)

The preferred diagnostic procedure is determination of *T. gondii* antibody in fetal fluids or presuckling serum. Their presence indicates transplacental toxoplasma infection.[32] The absence of *T. gondii* antibody does not preclude the possibility of infection, however. It is important to ensure that serologic examination of kids is done before colostrum is given because the amount of antibody in colostrum is several times greater than that in serum and may cause high neonatal antibody titers.[28] The presence of high antibody titers in doe serum is not necessarily diagnostic of recent infection because titers may remain high into the next breeding season. However, absence of antibodies is considered to be conclusive evidence that toxoplasmosis was not the cause of abortion.[5,28] The modified agglutination test can be used to detect antibody in fetal and maternal serum. The modified agglutination test is easy to perform and more sensitive than other tests.[32] The enzyme-linked immunosorbent assay and the indirect fluorescent antibody tests have also been used.[28]

Positive diagnosis of toxoplasmosis requires isolation of the organism from the placenta or fetal brain, lung, and muscles.[32] The samples for isolation studies should be shipped on ice but not frozen.[28]

Treatment and Control

Control of toxoplasmosis is based on preventing exposure of goats to cat feces. Cats should be prevented from defecating in feeders or in hay. Fetal membranes and dead fetuses should be buried or incinerated to prevent infection of cats and other animals.[30] Cats should not be allowed near pregnant sheep and goats, but in practice this is difficult.[28,30] A vaccine that contains a strain of tachyzoites (S48) that do not persist in tissues of sheep is available in Europe and New Zealand, but it is not available in the United States. Ewes vaccinated with the S48-strain vaccine remain immune for at least 18 months.[30] Breeding goats that have been exposed to *T. gondii* infection are likely to be relatively resistant to the effects of reexposure during subsequent pregnancies and are less likely to abort again from this cause and therefore should not be culled.[33]

Zoonotic Potential

Fetal membranes and dead fetuses from sheep or goats that abort should be handled with caution by persons wearing gloves to prevent infection in humans.[30] Toxoplasmosis has been reported in human beings after drinking raw goat milk. Therefore, goat milk should be pasteurized or boiled before human consumption. This is particularly true for its use in infants, who are more susceptible to toxoplasmosis than adults.[34]

Q FEVER

Query or Queensland fever is a zoonotic infection affecting a variety of animal species and human beings. It can be the cause of abortion in sheep and goats[5,35] and has been reported in Canada, the United States, and many other countries.[4,5,8,35,36]

Etiology

Q fever is caused by *C. burnetii,* an obligate intracellular rickettsial organism.

Epidemiology and Pathogenesis

Cattle, sheep, goats, and wildlife can carry the organism, which is shed in large numbers in placentas, uterine fluids, colostrum, and milk.[5,36] Therefore, cows and sheep may be a source of infection for goats when they share a pasture. Animals and humans can be infected by inhaling contaminated dust. Contaminated grazing pastures and tick bites are other modes of transmission.[5]

Clinical Signs

The primary significance of this disease is its zoonotic potential. In livestock, the disease is usually unapparent; however, occasional abortion outbreaks due to *C. burnetii* have been reported in sheep and goats.[6,37] Clinical signs are infrequent, but abortion or stillbirth usually occurs late in gestation owing to severe damage to the placenta and necrosis of the cotyledons and thickening of the intercotyledonary areas.[4,36,37] Some does abort without apparent clinical signs, while others show anorexia and depression 1 to 2 days before abortion.

Diagnosis

Diagnosis is based on placental findings, serology, and isolation of the organism.[4,36] Isolation of *C. burnetii* is the ideal means for diagnosis of the disease, but it is usually not feasible because of the contagious and zoonotic potential of the organism. Very few diagnostic laboratories are willing to handle this organism because of strict biosafety procedures.[37] The fluorescent antibody test can be used to identify the organism in frozen sections of placenta. Even though a variety of serologic tests have been described, asymptomatic infections without abortion are possible and a diagnosis of abortion cannot be given solely on the basis of positive serologic test results.[38] Antibody titers of 1:20 or higher indicate exposure to *C. burnetii*. A fourfold increase in antibody titer between acute and convalescent samples indicates recent infection.[37] A rapid presumptive diagnosis of *C. burnetii* is possible by identification of large number of characteristic organisms in the placental tissue together with elimination of other causes of placentitis such as *Brucella, Campylobacter,* and *Chlamydia* spp.[6,37]

Treatment and Control

Once an infection is established, the organism is carried by the doe indefinitely and is shed in the milk and at parturition. Placenta and aborted fetuses should be burned or buried.[36] There is no vaccine for goats. In cattle, treatment with tetracycline for a period of 2 weeks has been shown to prevent excretion of the organism at parturition. In an outbreak of Q fever abortion in goats, abortions stopped following feeding of 200 mg per animal per day of chlortetracycline in the feed for 19 days.[36] Some authors recommend injection of 20 mg/kg of long-acting oxytetracycline every 3 days or every 10 to 14 days.[6]

Zoonotic Potential

Q fever is a zoonotic disease transmitted to humans by milk, placenta, and feces. The disease is characterized in humans by influenza-like symptoms.[12,36] In the majority of human cases, there is a history of contact with infected sheep, goats, or cattle.[37] The organism is killed by pasteurization but is readily transmitted by nonpasteurized milk. A mask should be worn when manure is removed from barns and gloves should be worn at time of kidding or when handling an aborted fetus.[5]

LISTERIOSIS

Listeriosis most commonly causes meningoencephalitis but can also cause abortion and septicemia in goats.

Etiology

Listeria monocytogenes, a gram-positive, non–acid-fast organism, is the agent responsible for listeriosis. Abortion-causing strains are often serotype 1.[5]

Epidemiology and Pathogenesis

Listeria monocytogenes may be found in soil, water, plant litter, silage, and the digestive tract of ruminants and humans.[5] The organism can survive in soil and feces for a very long time and grows in poorly fermented silage (pH > 5.5).[2,4,5,8] On some farms abortion is attributed to silage feeding, but abortions have been reported on farms on which the goats were fed hay with the addition of concentrate.[5,39]

Clinical Signs

Abortion results from infection early in gestation, but later infection results in stillbirth or weak kids. The abortion form and the encephalitic form of listeriosis do not usually occur simultaneously in a herd.[5] Abortion occurs during the last 2 months of pregnancy, preceded by septicemia.[4,5] Signs of septicemia may include fever, decreased appetite, and reduced milk production. Kids grafted to aborting does may die of listerial septicemia contracted through the milk.[5]

Diagnosis

Diagnosis is based on culture of the organism from the placenta, aborted fetal tissue, and vaginal discharge. High serum antibody titer to *L. monocytogenes* in goats that have aborted is indicative of listeriosis as a probable causative agent of abortion.[39]

Treatment and Control

Feeding of poor-quality or spoiled silage should be discontinued. Vaccination with the aim of producing cellular immunity has been investigated. Theoretically, a live vaccine should be more effective than killed preparation.

Two doses of reduced-virulence live vaccine before breeding is reported to have provided significant protection against experimental challenge in pregnant does.[5]

LEPTOSPIROSIS

Sheep and goats are among the domestic species that are less susceptible to leptospirosis. There are very few investigations of the incidence of leptospirosis in these species.

Etiology and Epidemiology

Several serotypes of *Leptospira interrogans* have been shown to cause abortion in goats, but the prevalence of losses is not known.[5] Other *Leptospira* serotypes such as *L. icterohaemorrhagiae, L. grippotyphosa,* and *L. pomona* have been reported to be the main causes of leptospirosis in goats.[40] Goats appear to be more susceptible to leptospirosis than sheep.[40] Goats probably do not serve as primary reservoirs for leptospirosis, and infection probably occurs from exposure to an environment contaminated by the urine of other species.[5] In a study of 262 herds of goats with abortion in Spain, 2.6% revealed leptospires as the causative agent, with serotype *L. pomona* being the most prevalent (75%), followed by *L. sejroe* (12.5%), and *L. icterohaemorrhagiae* (12.5%).[40]

Clinical Signs

Clinical signs include anorexia, fever, marked jaundice, hemoglobinuria, anemia, nervous signs, and abortion.[5,40] Abortions have been reported during the last trimester of gestation.[40]

Diagnosis and Control

Dark-field microscopy, immunofluorescence testing, and silver stains of placenta and fetal tissue and fluids are used to confirm the diagnosis.[5,40] The organism is difficult to isolate from contaminated specimens. Paired sera from does that have aborted showing an increase in titer would be suggestive of abortion associated with leptospirosis.[5]

Vaccination twice a year is indicated in regions where leptospirosis is prevalent in goats. Other measures recommended include separation of animal species, controlling rodents, and maintaining a clean water supply.[5]

OTHER INFECTIOUS CAUSES OF ABORTION

Any systemic illness that induces a febrile response or generalized illness such as septicemia and toxemia may cause abortion in does. Some of the disease conditions that lead to occasional abortions are briefly described in the following sections.

Mycoplasmosis

Mycoplasma spp. are important pathogens of goats and cause mastitis, arthritis, keratoconjunctivitis, and occasionally vulvovaginitis and abortion.[8,41] Abortion is not the dominant clinical finding in an outbreak. *Mycoplasma mycoides* and *M. agalactia* have been reported to cause abortion in goats in the United States.

Abortion occurs in does during the last trimester of gestation. Does that abort will probably have the organism present in their milk, liver, kidney, spleen, amniotic fluids, and placenta. The organism may also be found in cotyledons, liver, and spleen of the fetus. Diagnosis of abortion due to *Mycoplasma* spp. is by culture and serotyping of the isolate.[41]

In other countries, treatment with tetracycline or tylosin may be preferred for economic reasons, but in the United States slaughter is recommended.[41]

Campylobacteriosis

Campylobacter (formerly *Vibrio*) is the most significant cause of abortion in sheep in the United States.[8,13] However, *Campylobacter* abortion has been rarely documented as the cause of abortion in goats in North America.[5,8,42]

Etiology

Of the cases reported in the United States, *Campylobacter jejuni* and *C. fetus* (formerly *Vibrio fetus intestinalis*) have been identified as the causative organisms.[5,42]

Clinical Signs

Clinical signs include late-gestation abortions in does and weak or stillborn kids. Aborting does may or may not show signs of systemic illness. A mucopurulent or sanguinopurulent vaginal discharge is reported in all aborting does.[42] In South Africa, where *Campylobacter* abortion appears to be common, as many as 30% of aborted kids have grossly visible liver necrosis. The placenta is often edematous, with necrosis of cotyledons.[5]

Diagnosis

Definitive diagnosis of *Campylobacter* abortion is by isolation of the organism. Direct microscopic examination and isolation of *Campylobacter* spp. from placenta, fetal abomasal contents, and maternal vaginal discharge is the preferred diagnostic procedure.[43] Serologic tests can be done at a few specialized laboratories.

Treatment and Control

Treatment is similar to that used in sheep. The antibiotic regimen is penicillin/streptomycin preparation or tetracycline in feed.[13,42] In a confirmed outbreak, vaccination of all pregnant does with an ovine *Campylobacter* bacterin is advisable.[5]

A combined killed bacterin of *C. fetus* and *C. jejuni* is available for use in sheep but not routinely used in goats. The vaccine is administered prior to breeding with a booster in 2 to 3 months. Revaccination annually shortly before or just after breeding is recommended.[25]

Because of the probable oral route of infection, sanitary conditions, avoiding fecal contamination of feed, and isolation of aborting does are recommended.[42] As with other abortions, placentas and aborted fetuses should be burned or buried deeply.

Zoonotic Potential

Campylobacter jejuni has been recognized as a cause of mild gastroenteritis in humans and is of public health importance. Domestic animals and unpasteurized milk are thought to be the source of *C. jejuni* infection in humans. Aborted fetuses infected with *C. jejuni* should be handled carefully. In Scotland, shepherds giving artificial resuscitation to infected lambs have acquired the disease.[42]

Brucellosis

Brucellosis is an infectious disease of goats characterized by abortion, the birth of weak kids, mastitis, and formation of localized lesions in various tissue.[44] The incidence of brucellosis in goats is extremely low to nonexistent in the United States, but the disease is widespread in the Middle East, India, Pakistan, Africa, Mexico, and parts of South America.[2,4,12] Sporadic outbreaks have been reported from Texas and Colorado.[2]

Etiology

Brucella melitensis, a small gram-negative coccobacillus specific for goats, is the cause of brucellosis in goats as well as cause of Malta fever in humans.[2,4,12] Occasionally, *Brucella abortus* infection occurs in goats running with infected cattle or after vaccination with strain 19 by ill-informed veterinarians, but it does not spread within the herd and is not readily transmitted between herds.[44]

Epidemiology and Pathogenesis

The most common route of transmission in goats is by ingestion of contaminated feed and water. The organism enters through mucous membranes and becomes localized in the lymph nodes, udder, uterus, testes, and spleen.[2,44] In pregnant animals, localization in the placenta leads to the development of placentitis with subsequent abortion. The organism is excreted in milk, urine, feces, and placenta and for 2 to 3 months in vaginal discharge. Kids born alive to infected does often are infected and capable of shedding the organism.[2,5,44]

Clinical Signs

Infection occurs in both sheep and goats, producing abortion during late pregnancy.[44,45] As in other species, there may be an "abortion storm" when the disease is introduced followed by a period of resistance during which abortions do not occur. A systemic reaction characterized by fever, depression, loss of weight, and sometimes diarrhea occurs and may be accompanied by mastitis, lameness, hygroma, and orchitis in males.[2,44] On gross examination, the placenta is normal.[2,3]

Diagnosis

A diagnosis of brucellosis as the cause of abortion is usually made by isolation of the organism from an aborted fetus, placenta, or vaginal discharge. Various agglutination, precipitation, and complement fixation tests are used to detect carrier goats.[5]

Treatment and Control

There is no treatment for brucellosis in goats. In countries where the prevalence of infection is very low, slaughter of the entire herd (both sheep and goats) would probably be the control measure of choice. This was the method successfully used to eradicate the outbreak reported in Texas.[2,5,45] In other situations, a test and slaughter program may be more appropriate. All new animals imported to a farm should be blood-tested, and bucks should be tested before they are used for breeding.[2] Placentas and aborted fetuses should be burned or buried deeply.

Vaccination of goats is not permitted in the United States. In most countries where caprine brucellosis is prevalent, the disease is controlled by an intensive vaccination program that is very effective. A live attenuated strain of *B. melitensis* Rev 1 is usually given subcutaneously to kids and lambs 3 to 8 months of age.[5,45] The vaccine will cause abortion, and thus is to be avoided in pregnant animals or those within 1 month of mating. Immunity from a single dose is considered to be lifelong.[5]

Zoonotic Potential

Goats were the first species associated with brucellosis in humans on the island of Malta.[44] Often, the first indication of brucellosis in goats is undulant fever in humans who consume unpasteurized milk or cheese.[2,5] Therefore, a large percentage of the infections occurring in humans can be prevented by pasteurization of goat dairy products.

Salmonellosis

Salmonella infection causes abortion, metritis, and systemic illness in does.[24] *S. abortus-ovis* was first implicated as a cause of abortion in 3- to 4-month pregnant goats in Cyprus. The organism also has been isolated from goat fetuses and placentas in France.[5] Only sheep and goats are affected by *S. abortus-ovis; S. typhimurium* and *S. dublin* both have been associated with abortion.[5]

Specific agglutinins can be demonstrated in the sera of adults in the herd and in aborted fetuses. Control measures include injecting pregnant does with tetracycline and administering two doses of vaccine, followed by an annual booster.[5]

Akabane Virus Disease

Akabane virus causes arthrogryposis and hydrencephaly in cattle. It has also been reported in goats.[2,8,12] The disease may cause abortion, stillbirth, and mummified fetuses in goats. It has been reported from Australia, Japan, South Africa, the Middle East, and Argentina.[2,8,12] The disease is exotic to the United States.[5]

Akabane virus is an arbovirus, transmitted by gnats and mosquitos.[5] Clinical disease has been observed in sheep, goats, and cattle. Infection of nonpregnant goats is subclinical. Pregnant goats may remain healthy, but abort or deliver stillborn kids. Veterinarians may first encounter Akabane disease when assisting a goat in labor, because dystocias are common when arthrogryposis is present (Fig. 77-2).[5]

Akabane virus disease is diagnosed on the basis of arthrogryposis and/or hydrencephaly in newborn kids and the identification of a positive antibody titer in those

Fig. 77-2 A fetus showing arthrogryposis and hydrencephaly delivered by cesarean section.

kids or aborted fetuses. There is no treatment for Akabane virus infection; however, effective vaccines have been developed and are used in advance of the breeding season in epizootic areas.[5]

Yersiniosis

Yersinia pseudotuberculosis is a zoonotic bacterium commonly carried by wild birds or rodents. Fecal-oral infection of goats can result in an enteric infection with subsequent bacteremia. Abortion and early neonatal death of kids have been reported in the United States. *Yersinia* has been recovered from placenta and fetal abomasal contents.[5,24,46]

Tick-borne Fever

Ehrlichia (Rickettsia) phagocytophilia, a tick-borne disease of sheep, goats, and cattle in the United Kingdom, Europe, Africa, and India causes fever, listlessness, decreased milk production, lameness, and abortion. Diagnosis is by demonstration of cytoplasmic inclusions in granulocytes and monocytes in the blood of does and by complement fixation tests. The organism does not invade the fetus, so smears of fetal tissues are not helpful.[5]

Sarcocystosis

Sarcocystis is a cyst-forming protozoan, frequently noted as an incidental finding on histologic examination of cardiac and skeletal muscle of many species. Experimental inoculation of goats, 75 to 105 days pregnant, with *Sarcocystis capracanis* resulted in illness and abortions.[5] Naturally occurring abortion and birth of stillborn kids by sarcocystosis has been reported in a herd of milking Saanen does in Australia.[47] Some of the does exhibited a vulvar discharge but no other clinical signs. The mechanism of *Sarcocystis*-induced abortion is unknown but may relate to maternal fever.

Anaplasmosis

Anaplasma ovis, a tick-borne disease of goats, usually causes a subclinical, mild, febrile disease. However, abortion has been reported in *Anaplasma*-infected Boer goats in a semiarid region of South Africa that had to walk long distance for food.[5]

SPORADIC CAUSES OF ABORTION

Other sporadic causes of abortion are reported in the literature and include a *Neospora*-like protozoal infection associated with abortion in two pygmy goats,[48] *Enterobacter cloacae* abortion in a flock of 35 goats,[49] *Actinomyces pyogenes,*[50] enterotoxemia caused by *Clostridium perfringens* type D,[24] foot and mouth disease, Nairobi sheep disease, Rift Valley fever, and Wesselsbron disease.[5]

DIAGNOSTIC INVESTIGATION OF CAPRINE ABORTIONS

A systematic approach is essential for the diagnosis of abortions in goats. Whenever losses continue or abortion storms occur, there is a need for a thorough investigation of the problem. Many different causes need to be considered and each requires special tests. The laboratory needs to be aware of the infectious agent most likely to be present in the area. The practitioner must obtain a good nutritional and clinical history, including possible exposure to carrier animals. Although history seldom provides information pointing directly to the cause of abortion, clues may be found that will indicate what needs to be done to determine the diagnosis. It is up to the clinician and the owner to provide a complete and accurate history. The owner should keep detailed records and accurately identify each aborting animal and the stage of gestation at which the animal aborted.

The first abortion in a herd may be the most important one, but many owners do not become seriously concerned until an abortion storm is evident. The owner should be instructed to freeze any fetus and placenta, no matter how certain he or she might be that the abortion was caused by fighting or a fall. When abortion occurs, the does should be isolated and any aborted fetus kept for further laboratory examination. Each diagnostic laboratory has slightly different preferences for specimens to be submitted. Therefore, the diagnostic laboratory should be consulted prior to sample submission.[51] In sheep and goats, the entire fetus, placenta, and paired serum samples from aborting does should be submitted to the diagnostic laboratory.[51] Without the placenta, identification of chlamydiosis and toxoplasmosis is unlikely. If the placenta and fetus cannot be quickly and suitably transported in their entirely, samples may be removed and one portion placed in a fixative and another in plastic containers packed on ice for culture. Tissues may be frozen for future viral culture or tested for agents using the fluorescent antibody technique. Samples from the fetus for culture should include caruncle, placenta, abomasal content, lung, liver, spleen, and kidney. Whenever possible, a fetus and placenta from several aborting does should be submitted. Mummified fetuses (a brownish,

Table **77-1**

Diagnostic Summary of Infectious Abortion in Goats

	EPIDEMIOLOGY			LABORATORY FINDINGS		
Disease	***Transmission***	***Time of Abortion***	***Clinical Data***	***Fetus***	***Serology***	***Vaccination***
Chlamydiosis *(C. psittaci)* type1	Ingestion	Last 2–3 weeks	Vaginal discharge before; retained placenta and metritis after; thickening and necrosis of cotyledonary and intercotyledonary tissue	Autolyzed or fresh	ELISA or IIFA	Killed vaccine 8 weeks prior to breeding followed by second dose 4 weeks later
Toxoplasmosis *(T. gondii)*	Ingestion	Last 2–3 weeks	Abortion, fetal death, stillbirth, neonatal death; multiple white to yellow focal areas of necrosis and calcification in fetal cotyledons; intercotyledonary area normal	Fresh or mummified	MAT	Strain S48 available in Europe or New Zealand
Q fever *(Coxiella burnetii)*	Ingestion, inhalation	Late in gestation	Abortion or stillbirth, cotyledonary and intercotyledonary necrosis and mineralization	—	FA of frozen placenta	None
Campylobacteriosis (*C. jejuni* and *C. fetus*)	Ingestion	Late in gestation	Metritis after abortion; placental edema, necrosis of cotyledons	Organism in fetal stomach content	In few specialized laboratories.	Combined killed bacterin prior to breeding
Brucellosis *(B. melitensis)*	Ingestion	Late in gestation	Fever, depression mastitis, orchitis, lameness, or abortion; placenta normal; not in US	Organism in placenta or fetal stomach	Complement fixation, agglutination	Live attenuated *B. melitensis* Rev 1 vaccine in prevalent areas; none in US
Listeriosis *(L. monocytogenes)* serotype 1	Ingestion, poor silage	Last 2 months	Septicemia, metritis, no placental lesion	Stillborn or weak	Agglutination	Live vaccine before breeding, if needed
Leptospirosis *(L. interrogans, L. pomona)*	Ingestion	Last trimester	Anorexia, fever, jaundice, anemia, abortion	Organism in fetal tissue	Immunofluorescence test	Vaccination in prevalent area
Mycoplasma (M. mycoides, M. agalactia)	Ingestion	Last trimester	Vulvovaginitis and abortion, mastitis, arthritis, keratoconjunctivitis	Organism in fetal cotyledons, liver, spleen	—	None
Salmonellosis *(S. abortus-ovis)*	Probably ingestion	Last 6 weeks	Abortion, metritis, systemic illness	Organism in fetus and placenta	Agglutination test	None
Akabane disease (virus)	Gnats and mosquitoes	Late abortion	Abortion, arthrogryposis and hydrencephaly in newborn kids; exotic to US	Stillborn or mummified	Antibody titer	Vaccine in epizootic area before breeding season

ELISA, enzyme-linked immunosorbent assay; FA, fluorescent antibody; IIFA, indirect inclusion fluorescence antibody; MAT, modified agglutination test.

Box **77-1**

Materials to Be Submitted to Diagnostic Laboratory for Abortion Investigation

Frozen or Refrigerated Tissues
- Whole fetus and entire placenta preferred
- Fetal lung, liver, kidney, spleen
- Fetal stomach content
- Dam's serum

Formalin-Fixed Tissues
- Fetal lung, liver, kidney, spleen
- Fetal brain
- Fetal heart and skeletal muscle
- Placenta

Other Data
- History
- Feed if indicated
- Water if indicated

hairless fetus with an elongated muzzle and sunken eyes) are unsuitable for either culture or histologic examination. Autolysis commonly obscures diagnostic changes. A summary of diagnostic materials that may be needed for an abortion investigation is presented in Box 77-1.

Paired serum samples may be required to confirm or deny suspicion of toxoplasmosis or chlamydiosis. Results of examination of a single serum sample from an animal that has aborted must be interpreted with great care, or confusion may result. Although certain titers are set as significant for disease regulation purposes, there is no specific titer for any infection that absolutely will differentiate infected from uninfected animals. Serologic results should always be correlated with herd history, clinical findings, and necropsy and laboratory findings.[52] Table 77-1 presents a diagnostic summary of infectious abortions in goats.

The diagnosis in the event of an abortion storm often is not available for several days. It is reasonable to begin treatment of remaining pregnant does with tetracycline in the event that a susceptible infectious agent is involved. One possible protocol is three injections of long-acting tetracycline (LA-200*) at 20 mg/kg at 3-day intervals.[5] Withdrawal time in lactating does should be observed.

Most of the diseases that cause abortion in goats are zoonotic, including chlamydiosis, Q fever, toxoplasmosis, campylobacteriosis, listeriosis, and brucellosis. Owners should be instructed to wear gloves when handling aborted fetuses and to burn or bury any placentas and fetuses not needed for diagnostic efforts. In addition, pasteurization of goat milk for human consumption should be stressed.

CHAPTER 78

Noninfectious Prenatal Pregnancy Loss in the Doe

WILLIAM BRAUN, JR.

Many noninfectious agents have been named by producers as responsible for pregnancy loss in the goat. Unfortunately, most of this information is anecdotal and not well documented, although it is passed on to other producers as fact. Often an agent or event is implicated because abortion or pregnancy loss follows closely after its application or occurrence. Stress is a good example of this, whether in the form of changing weather patterns or harassment of the does by dogs. Various pharmaceutical and biologic agents have been implicated as causes of abortion when in reality rough handling during administration actually caused the loss.

EARLY EMBRYONIC DEATH

In many cases, it is difficult to differentiate between early embryonic death and conception failure. Fertilization failure and embryonic loss prior to day 15 of gestation both result in return to service at the normal time of the next expected estrus. Most embryonic loss takes place before day 30 of gestation.[1,2] Although fertilization rates may approach 95%, embryonic mortality rate ranges up to 85% with a mean of 20% to 30%.[2] A great amount is known about embryonic death in sheep, but there is a paucity of data for goats. Embryonic losses of 6% to 42% suggest that survival of goat and sheep embryos is similar.[1]

The reason for loss of morphologically normal embryos remains obscure but is probably attributable to physiologic or environmental factors. The selective loss of genetically abnormal embryos is unavoidable. Genetically abnormal embryos contribute a relatively constant, and significant, proportion of observed losses.[2] This loss takes place early in gestation and offers a chance for rebreeding in a relatively short time. In humans, pregnancy occurs in only 18% to 28% of the menstrual cycles.[3] The majority of losses are from embryos with gross chromosomal abnormalities, with trisomy in almost half of these cases.[4] Chromosomal abnormalities, such as centric fusions and translocations, cause an unstable karyotype. Animals are inconsistent with humans, having a lower incidence of chromosomal abnormalities. One study showed that animals had an incidence of chromosomal abnormalities of 8.7%, with mosaicism predominating.[5] The incidence of abnormalities, especially polypoids, increases with aging of the female gametes.

The maternal environment may be unable to support normal development of the embryo or an inappropriate relationship may exist between the embryo and its dam.[4] The maternal environment may be inadequate to support normal gestation either because of an inherent abnormality of the reproductive tract or as a result of an inappropriate hormonal pattern or other outside factors. Progesterone and estrogen determine the proper function of the uterus in preparation for embryonic development. A steroid imbalance may induce asynchrony between the embryo and uterus[2] as shown when embryos are transferred to recipients that are not synchronous with the donor. In these cases, pregnancy is not established and the embryos are lost. The variability of progesterone concentration around estrus and the timing and extent of the luteal rise in progesterone concentration account for a proportion of embryonic deaths.[2]

Ovulation rate seems to play a role in embryo survival in goats. The chance of an embryo surviving in any doe decreases as the ovulation rate rises above two.[2,6] Embryo transfer in the goat has shown that transferring two embryos results in better pregnancy rates and embryo survival than transferring one or three embryos.[7] Prolificacy may be lowered if there is a significant partial loss of multiple embryos with the female remaining pregnant.

Nutrition and stress are two environmental factors that may adversely affect embryo survival. Heat-induced embryonic death is at times an important factor in goat productivity.[2] Does exposed to high ambient temperatures around breeding and during the early cleavage stages experience some embryo loss. Poor nutrition is often implicated when there appears to be no other reason for embryo loss. In sheep, overfeeding or underfeeding may reduce embryo survival.

GENETIC DISORDERS

Habitual abortion is an inherited disorder of some older Angora does. Affected does typically have fine hair coats of high yield, the result of adrenal malfunction. These does conceive normally in their first years, but from the fourth or fifth year begin the habit of aborting. Abortion occurs around day 100 of gestation from continued fetal growth but retardation of placental growth.[8] Prevention is directed at culling aborting does and their earlier offspring.

Does running with rams during the breeding season may breed with the rams without the manager's knowledge. Ram sperm will frequently fertilize goat ova, but the resultant embryo typically dies by 40 to 60 days of gestation. Owners then witness the expulsion of this goat-

sheep hybrid as an abortion. This hybrid has a chromosomal number (57) intermediate to the goat (60) and the sheep (54). Mummification is an occasional sequela.

NUTRITIONAL FACTORS

Nutritional deficiencies, especially energy and protein deficiencies, are suspected of causing some cases of abortion, although their exact mechanism is unknown. Undernourished Angora does may abort after experiencing stress, especially young does that have not been grown out well. During late gestation, inadequate protein and energy levels have been thought to result in abortions, stillbirths, or the birth of weak kids. However, some does near starvation have carried pregnancy to term. Nutritional stress, the withdrawal of concentrates from a basal diet of poor-quality forage, was the reported cause of an abortion storm.[9] Some 62.5% of pregnant does aborted in this report. Abortion from nutritional stress usually occurs between 90 and 120 days of gestation.[9,10] This is the period of accelerating fetal growth, a time when nutrition is crucial to the developing fetus.

Deficiency of energy during late gestation may lead to pregnancy toxemia.[11] The exact etiology of pregnancy toxemia is somewhat vague, but predisposing factors are multiple fetuses that cause the expanding uterus to compress and displace the rumen, and lack of exercise of the pregnant doe resulting in an overconditioned, fat doe prone to fatty liver, stress, and suboptimal feed intake. Undernutrition may be gradual or sudden but leads to hypoglycemia that triggers the onset of pregnancy toxemia.

The disease usually manifests itself during the last 4 weeks of gestation. The initial sign is partial anorexia, with the subsequent loss of energy consumption, causing hypoglycemia. Signs then become progressively more severe. Eventually the doe quits eating and cannot stand unless assisted. The doe then exhibits weight loss, dehydration, forced breathing, and grinding of the teeth. In the final stage, the doe becomes nonresponsive to external stimuli, becomes comatose, and dies. During this later stage she may also abort multiple fetuses.

Diagnosis is based on clinical signs, ketonuria, and hypoglycemia. Common necropsy findings include a yellow-orange fatty liver, enlarged adrenal glands, and multiple fetuses in the uterus. Treatment is based on early recognition of the disease, carbohydrate supplementation, stimulation of gluconeogenesis, and removal of the fetuses. Fluid therapy may be warranted, using dextrose to raise blood glucose levels, bicarbonate or lactate, and balanced electrolytes. Oral supplementation with 4 to 8 oz (120–240 ml) of propylene glycol twice a day may be all that is needed until appetite is restored, if the condition is recognized early. Glucocorticoids have been used to stimulate gluconeogenesis, and they may also cause the premature expulsion of the fetuses. Removal of the fetuses hastens recovery of the dam. This is achieved either by induced abortion or parturition or by cesarean section.

Several mineral deficiencies have been associated with lowered conception rate, embryonic death, and abortion. Deficiencies of iodine, copper, magnesium, and manganese have all been shown to cause abortion or birth of weak kids.[12] Selenium deficiency may cause abortion, and prolonged selenium toxicity is reported to cause abortion.[13] Iodine deficiency may cause stillbirths and delivery of kids with goiter. Copper-deficient does may abort mummified fetuses.

Severe vitamin deficiencies have been blamed for some pregnancy losses. A severe vitamin A deficiency, over a 6-month span, was reported to have caused multiple abortions in a goat herd.[12] This case was associated with a diet limited to dry feed for about 6 months and severe parasitism.

TOXIC PLANTS AND PHARMACEUTICALS

Teratogenic changes or abortion have been associated with several plant species, including *Gutierrezia, Lupinus formosus, Conium maculatum, Nicotiana tabacum,* and *Veratrum californicum.*[12,14] Other plants have been incriminated as possible causes of abortion in goats but data are scarce. Nitrate poisoning may cause plant-induced abortion in pregnant animals. Consumption of stressed nitrate accumulators, such as oat or wheat hay, sorghums, Sudan, rape, pigweed, and others, will change hemoglobin into methemoglobin, causing tissue anoxia that is the probable cause of abortion. Phytoestrogens found in many plants may reduce ovulation rates, reduce fertility, and increase embryonic mortality rate.

Various pharmaceuticals have proved to be abortifacients, or at least their use has been reported to be followed by abortion. A number of anthelmintics are used during late gestation in goats at the time when infectious causes of abortion are most pronounced in their action. The subsequent abortions may be related to the compounds administered, to the handling of the pregnant animals, or to infectious causes. Phenothiazine, given in the last month of gestation, may cause abortions, as might the use of levamisole. Cambendazole and elevated doses of albendazole may be embryotoxic in early pregnancy, but their use later in pregnancy seems to be safe. The use of xylazine or high doses of acetylpromazine in the first half of pregnancy may cause abortion because of their adverse effect on placental perfusion.[15]

The indiscriminate application of hormones in pregnant goats will induce abortion; these have been used purposely for the termination of some pregnancies. The goat is totally dependent on progesterone production by the corpus luteum throughout pregnancy. Little or no progesterone is produced by the caprine placenta. Corticosteroids, estrogens, and prostaglandins given to pregnant goats will induce abortion. Exogenous corticosteroids are not effective in terminating pregnancy until late gestation when the placental pathways have matured. Corticosteroids function by increasing estrogen production by the placenta. Whether from placental production or exogenous administration, estrogens stimulate prostaglandin synthesis and sensitize the myometrium to the effects of oxytocin.[16] Prostaglandin F_2 alpha and its analogues are luteolytic from day 5 of gestation until term. Estrogens and prostaglandins are abortifacient throughout most of gestation.

CHAPTER 79

Noninfectious Infertility in the Doe

WILLIAM BRAUN, JR.

Infections of the genital tract are seldom causes of infertility in goats,[1] although infectious causes of abortion are important. Postpartum genital tract infection seldom has a residual effect during the following breeding season because of the long period between parturition and breeding, which allows time for recovery. Noninfectious causes of infertility are relatively more common in the goat, and to some extent are a result of their seasonal breeding pattern.

CYCLE LENGTH ABERRATIONS

Aberrations of estrous cycle length adversely affect fertility through early involution of corpus luteum (CL) in cases of short cycles. Such events as puberty, time within the breeding season, introduction of the male, and hormone therapy may result in short estrous cycles that are infertile. Extended cycle length may likewise cause infertility or be a result of infertility, as in cases of early embryonic death.

Puberty

Young does should have reached about 65% of their mature body weight by the time of first breeding. This may not occur during the calendar year of their birth, if they were born late in the kidding season, late spring or early summer. The next year these does are of sufficient

CHAPTER 79

Noninfectious Infertility in the Doe

WILLIAM BRAUN, JR.

Infections of the genital tract are seldom causes of infertility in goats,[1] although infectious causes of abortion are important. Postpartum genital tract infection seldom has a residual effect during the following breeding season because of the long period between parturition and breeding, which allows time for recovery. Noninfectious causes of infertility are relatively more common in the goat, and to some extent are a result of their seasonal breeding pattern.

CYCLE LENGTH ABERRATIONS

Aberrations of estrous cycle length adversely affect fertility through early involution of corpus luteum (CL) in cases of short cycles. Such events as puberty, time within the breeding season, introduction of the male, and hormone therapy may result in short estrous cycles that are infertile. Extended cycle length may likewise cause infertility or be a result of infertility, as in cases of early embryonic death.

Puberty

Young does should have reached about 65% of their mature body weight by the time of first breeding. This may not occur during the calendar year of their birth, if they were born late in the kidding season, late spring or early summer. The next year these does are of sufficient

size to successfully breed. Does born early in the kidding season, late winter or early spring, should have reached adequate size to start breeding during the fall that same year. Restricted feed intake around the time of puberty may slow development or result in anestrus. Young, lightweight does have an increased frequency of abnormal first cycles, either short or long.[2] Although mating may occur during these first cycles, pregnancy would not be expected to be established. It is prudent to allow young does to cycle two or three times prior to breeding for the first time.

Season

Short estrous cycles are a natural part of the onset of the breeding season.[3,4] These short cycles may be associated with ovulation but followed by a CL that is short-lived. These short cycles have a luteinizing hormone peak of low amplitude, which may be responsible for defective CL formation. Camp and associates,[5] in a study of short estrous cycles, found that 86% of these cycles occurred early in the breeding season and that 55% appeared to be anovulatory. They found that there was no difference in the duration of estrus for short (2.9 ± 0.3 days) versus normal (2.8 ± 0.8 days) cycle groups.

Aberrant cycle length also occurs at the end of the breeding season when does are in transition to the anestrous season. These cycles typically have an extended length. At the end of the breeding season, nonreturn to estrus is not trustworthy to detect pregnancy because long estrous cycles are likely to occur.[2] Some does enter an anestrous period after late breeding and may be mistakenly assumed to be pregnant by their owners.

Male Effect

During the late transition season, novel introduction of a male to a group of females will initiate estrus and cyclicity within the group. Some 97% of females ovulate about 3 days after introduction of the male, but 75% experience short luteal phases of 5 days, followed by a second ovulation with estrus in 89%.[6] Only 68% of the initial ovulations are accompanied by estrus. Fertility at first estrus following exposure to the male is quite variable, but it seems that the shorter the time elapsed from male introduction to first estrus, the lower the fertility.[2] Fertility returns to normal at the second estrus.

Hormone Therapy

The use of hormone therapy during the breeding season has resulted in alteration of the normal cyclic pattern in some goats. Pregnant does given 5 mg prostaglandin F_2 alpha to induce abortion often experience a short cycle following the postabortion estrus.[4] These short estrous cycles are associated with delay and decreased magnitude of the preovulatory luteinizing hormone. Armstrong and colleagues[7] reported that goats experience a high incidence of premature luteal regression following superovulation with pregnant mares' serum gonadotropin. This is usually associated with low embryo recovery. Dexamethasone given in repeated 10 mg daily doses, starting during diestrus, has been shown to extend the estrous cycle by a mean 8.75 ± 0.96 days.[8] Corticosteroid therapy causes a progressive decline in luteinizing hormone response to gonadotropin-releasing hormone and may result in the development of cystic follicles.

Early Embryonic Death

Any condition that results in early embryonic death may result in extended cycle length. The caprine embryo signals its presence between day 16 and 17 of gestation with caprine type I trophoblast interferon.[9] This substance prevents luteolysis and expulsion of the embryo. Removal or death of the embryo after day 15 extends the interestrous interval by about 10 days.

PSEUDOPREGNANCY

Pseudopregnancy, hydrometra, and mucometra are all terms used interchangeably to describe a common occurrence in goats characterized by persistent CL, anestrus, and a variable accumulation of fluid within the uterus. In two large French studies of more than 5000 ultrasonographic scans, the incidence of pseudopregnancy was less than 3%, but some farms experienced more than 5%.[10] This condition may follow a normal breeding or occur without breeding. The accumulation of fluid is often sufficient to result in abdominal enlargement, and the persistent CL causes elevated progesterone concentrations that may remain high for up to 5 months, mimicking normal pregnancy. The spontaneous evacuation of the accumulated fluid is called "cloud burst" by owners. These does may search for a nonexistent kid and some will start lactation.

Some does show no external signs of hydrometra other than a period of anestrus. At the end of this period, a bloody vaginal discharge may be seen. In mated does, this is taken as evidence of abortion. Affected does may show a repetitive pattern of hydrometra or may experience it only once. There is no evidence of an association between hydrometra and cystic ovaries or an obstructed cervix.[1]

The etiology of this condition is unknown. Early embryonic death with persistence of the CL is thought to play a role in the establishment of hydrometra in some recently mated does. The condition also follows estrus during which does are not mated, so early embryonic death would explain only some of the cases. Diagnosis is based on anestrus and ultrasonographic demonstration of an enlarged, thin-walled, fluid-filled uterus without evidence of a fetus, placenta, or placentomes. Progesterone assays would show progesterone concentrations similar to those associated with normal pregnancies. Treatment is with a single dose of prostaglandin F_2 alpha or oxytocin (50 IU IM, twice a day for 4 days).[11] Hydrometra may reoccur after treatment.

CYSTIC OVARIAN DISEASE

Cystic ovarian disease is a clinical diagnosis frequently made in goats. However, little is understood about this condition. A slaughterhouse survey showed that of 1020

tracts examined, 24 (2.4%) had ovarian cysts.[12] In goats, mature graafian follicles measure an average of 10 mm. Follicular structures larger than 12 mm were considered cystic. This same study found 11 cases (1.1%) of parovarian cysts. Unfortunately, no histories were available on any of these goats, so the effect of cysts on cyclicity and fertility is unknown.

The owner's diagnosis of cystic ovaries is based on nymphomaniac behavior of the cycling doe. Abbreviated cycles are typically 5 to 7 days in length, with several in succession. Diagnosis is speculative, based on the history of repeated short cycles. An attempt can be made to examine the ovaries with ultrasonography, but to date no scientific work has been published on this form of diagnosis. Treatment has been extrapolated from that used in cattle, and either human chorionic gonadotropin (250–1000 IU) or gonadotropin-releasing hormone (50–100 μg) is used in an attempt to establish regular cycles. The doe should be bred on the induced estrus.

MISCELLANEOUS CAUSES OF INFERTILITY

Other potential causes of noninfectious infertility in goats include such things as unobserved estrus, anatomic defects, nutrition, and neoplasia. Except for unobserved estrus, these other causes are rare or of minor concern. The doe shows very few outward signs of estrus unless a male is present. In some situations, does will show mounting behavior, but this may be inconsistent. If a teaser animal is not present, many females in estrus will be missed and breeding opportunities lost. Aids to estrus detection include teaser or breeder males, an intersex goat with male behavior, and a buck jar. A buck jar consists of a rag that has been rubbed on the scent glands on the poll of an intact male and kept in a tightly closed jar until needed. The jar is warmed and opened, and the does are allowed to sniff its contents. Estrous does will react to the buck jar as they would to a male.

Anatomic defects may result in infertility or anestrus. The most common of these is the intersex condition. A phenotypic female may behave as a male. Although intersexes are infertile, some breeders use them as teaser animals.

Poor nutrition may result in anestrus or infertility. Starvation or a lack of energy and protein in the diet adversely affects reproduction. Deficiencies of some minerals, including phosphorus, iodine, copper, and manganese, alter cyclicity. Heavy intestinal parasite loads may act synergistically with poor nutrition to cause reproductive failure.

Neoplasia of the reproductive tract is rare in goats, but tumors can result in infertility. Granulosa cell tumors and dysgerminomas of the ovaries have been reported.[1,10] Uterine tumors reported include leiomyosarcoma, adenocarcinoma, and leiomyofibroma.[1,10]

CHAPTER 80

Inherited Sex Abnormalities in Goats

PARVATHI K. BASRUR and HARPREET S. KOCHHAR

The process of sex differentiation is vulnerable to disruptive events emanating from unfavorable maternal environment and abnormal developmental forces created by mutant genes or aberrant chromosomes of the conceptus. These disruptive events may affect the differentiation of the gonads, gonaducts, or the external genitalia, and may lead to the birth of an animal that is difficult to identify as a male or as a female. Such animals with ambiguous sex phenotype are referred to as *intersexes* or *hermaphrodites,* and are further classified as *true* or *pseudohermaphrodites* based on their gonadal morphology. Intersexes whose gonads represent testis and ovary or a combination of testicular and ovarian structures in one or both gonads are referred to as *true hermaphrodites,* whereas those which carry exclusively testes or exclusively ovaries are referred to as male pseudohermaphrodites or female pseudohermaphrodites, respectively. Examples of these types of malformations occur in all domestic animals, tend to recur in families and pedigrees, and represent the most common type of developmental defects detected at birth.[1]

PREVALENCE

Intersexes are relatively common in domestic goats. Even though they occur in all goat breeds, their prevalence varies, depending upon the breed, prolificacy of the line, and the selection practice adopted by breeders.[2] Among the domesticated goats, male pseudohermaphrodites are more frequently seen in dairy breeds than in wool breeds. Their prevalence is extremely low among horned feral goats, whereas they occur at a high rates in lines selected for twinning and/or lack of horns.[2] In the Saanen and Toggenburg breeds raised in the United States, the prevalence of intersexes during the early part of this century was as high as 11% and 6%, respectively, whereas more recent surveys on European dairy goats cross bred to native breeds from different parts of India indicate the prevalence to be under 2%. Among the Shami breed of goats raised in Jordan, 6% of the newborn kids surveyed over a period of 8 years were intersexes.[3] In this breed, selected for the hornless (polled) trait, the most prevalent type (33.6%) of malformation seen was that involving the reproductive system.[3] A majority of goats displaying malformation of the reproductive system are male pseudohermaphrodites, which are sex-reversed genetic females, whereas true hermaphrodites constitute a much smaller percentage of caprine intersexes.

MALE PSEUDOHERMAPHRODITES

The appearance of caprine male pseudohermaphrodites varies from nearly normal females to nearly normal males in their external genitalia, although a majority of these are female-like at birth. As the age of sexual maturity approaches, these animals become larger than their normal female counterparts and acquire a more masculine head with more erect hair on their neck. Their teats are generally small, and the external genitalia are often represented by a short penis or a bulbous clitoris, which becomes enlarged and externally visible at the age of puberty. Hypospadias, represented by narrow slits of varying lengths on the ventral midline due to incomplete fusion of urethral folds, may be present. In some cases the slit may lead into a pouch that, when filled with urine, may overtly resemble a scrotal sac in the normal location, or anywhere between the anal and the urethral openings. The anogenital distance may vary from 3 to 33 cm in length among caprine intersexes depending upon the type of gonads and gonaducts they carry.[4] As a rule, intersexes showing short anogenital distances (3 to 6 cm) have intra-abdominal gonads; poorly developed epididymis, vas deferens, and seminal vesicles; and moderately well developed müllerian duct derivatives, including oviducts, uterine horns, and body of the uterus. Intersexes with greater anogenital distance show exaggerated masculinization of the external and internal genitalia, including scrotal or inguinal gonads, enlarged clitoris or a penis with sheath, and poorly developed body and horns of the uterus.[4] At the age of sexual maturity, intersex goats may start to butt like bucks and act aggressively toward other goats and people and may begin to dribble their urine or stretch out with a concave back and urinate forward between the legs. They also develop the odor characteristic of bucks, and show pronounced male libido in the presence of a normal doe in estrus. The testes are generally intra-abdominal in the normal location of the ovaries, or they may be partially or totally descended. The partially descended testes located in the inguinal region sometimes can be mistaken for udders, especially when the animal reaches the age of puberty and the fat pads become prominent. The testes are generally intra-abdominal, in the normal location of the ovaries, or they may be partially or totally descended. Occasionally, the uterine horn, wrapped around or attached to the ipsilateral testis, herniates through the corresponding inguinal ring into the scrotum. In some cases, the posterior parts of the horns are either connected to a short body of the

uterus that opens into a cervix, or in close association with the vas deferens. The uterine horns are generally filled with mucus and distended in adult life. In some cases the bilateral hysteroceles, resulting from the herniation of the uterine horns into the scrotum, may be mistaken for highly enlarged scrotal testes at the age of puberty.[5]

Intra-abdominal testes of the intersex are invariably smaller than those of normal bucks of corresponding age. The seminiferous tubules of younger intersexes resemble those of immature males but, as they reach the age of sexual maturity, the tubules appear more narrow or irregular in outline and internally lined exclusively by Sertoli cells. In older intersexes the tubular basement membrane is thick and hyalinized, and the seminiferous tubules generally appear atrophic with abundant interstitium consisting of mature and immature Leydig cells and cells resembling fibroblasts. The principal steroid produced by the gonads of caprine intersexes is generally testosterone, although the plasma concentrations of testosterone tend to be lower than those of normal bucks of corresponding age. Because germ cells are always absent in the testes of adult intersexes, these male pseudohermaphrodites are always sterile.[2,4]

TRUE HERMAPHRODITES

True hermaphrodites among caprine intersexes carry bilateral ovotestes or an ovotestis on one side and a testis or an ovary on the other side. Follicles at various stages of development and hormonal activity are seen in the ovaries or on the ovarian structures located on the periphery of the ovotestes. Seminiferous tubules, generally located toward the middle of an ovotestis, are devoid of male germ cells and generally inactive. Adult intersexes of this category with abdominal ovotestes and ovaries often show gonadal hyperplasia or gonadal tumors, or both. These animals generally resemble females more closely in their external and internal genitalia.[2,4]

True hermaphrodites are generally whole-body chimeras. This type of chimerism results from the admixture of cells from male and female embryos at an early stage in embryogenesis or through the fertilization of the second polar body and the ootid by different spermatozoa, one of which carries an X and the other a Y chromosome. This type of intersex may occur in all breeds of goats because accidents of this nature during fertilization or during early embryonic development can take place in any breed. However, the prevalence of this category of intersexes is relatively low in goats, but male pseudohermaphrodites are encountered more frequently in lines of dairy goats selected for twinning and multiple births.[2]

INTERSEXES IN TWINS

Twinning occurs in goats as often as single births, and in selected lines of domestic goats, twins and triplets occur more frequently than singles. Although the birth weight of the kids in twin births is similar to that of single-born normal kids and the incidence of perinatal death is lower in twins compared to that in single births and triplets, the prevalence of intersexes is higher among twins and triplets than in singles.[6] Caprine intersexes among twins and multiple births generally represent the counterparts of freemartins in cattle. As in cattle, caprine freemartinism is caused by the fusion of fetal membranes in twin gestation and the subsequent vascular anastomosis that allows the passage of cells and hormones from a male fetus to the female fetus. Freemartins can be differentiated from the other types of caprine intersexes from their birth history and chromosome makeup. Sometimes the birth status as a twin may not be recognized if one of the twins died in utero. In these cases, confirmation of freemartinism can be obtained by chromosome analysis of peripheral blood cultures. Caprine freemartins would reveal exclusively female cells in solid tissues and the coexistence of male and female cells in blood, even though the proportion of male cells in hematopoietic tissues may often be very low. The external and internal genitalia of caprine freemartins, as in other male pseudohermaphrodites, vary greatly. However, the masculine features are generally more exaggerated and the gonads are partially descended testes devoid of germ cells.[6] Unlike the situation with twinning in cattle, vascular anastomosis does not occur in a majority of caprine twin pregnancies, or it occurs later in gestation after the critical period in ovarian differentiation in the female fetus. As a result, freemartinism is encountered at a much lower rate than that of gestation involving heterosexual twins or triplets in goats. Twinning and multiple births occur in horned and polled goats. Because of this, freemartin-type intersexes can be seen in both types of goats, although polled does, which are more prone to produce twins and triplets, are also more likely to produce freemartins. It would appear that the freemartin-type of male pseudohermaphroditism accounts for approximately 6% of all caprine intersexuality whereas the remaining (over 90%) belong to the category of intersexuality associated with the polled trait.[6]

POLLED INTERSEXES

Intersexes are more abundant among polled (hornless) dairy goats than among their horned counterparts. Polled intersexes are genetic females (XX) and thought to be homozygotes for the polled gene based on their occurrence in proportions matching the genetic expectation among the progeny of polled-to-polled matings. The prevalence of intersexuality in homozygous polled female goats was thought to be due to the closely linked nature of the dominant gene (P) for polled, which is fully penetrant in males and females, with a recessive gene that leads to intersexuality in genetic females (XXPP).[7] According to this hypothesis, the polled does that are fertile are all heterozygotes for the polled locus (XXPp) and all horned does are homozygotes for its recessive allele (XXpp). The mechanism that leads to sex reversal of polled females is not totally understood as yet, although it is clear that the caprine P gene itself, or a segment close to it, in homozygous state has the capacity to initiate testicular induction in XX fetuses, even though they lack the Y chromosome. Furthermore, tests for the male-specific gene sequence referred to as the sex-determining region of the Y chromosome *(SRY),* which is one of the

major genes responsible for testicular induction in mammals, have shown that the polled intersexes are *SRY*-negative.[8] This caprine paradox is explained to some extent by the more recent findings on the polled mutation.

Polled Mutation

Recent studies by scientists in France have shown that the gene for polled is located on the long arm of chromosome 1 of the goat karyotype, at the band designated as 1q43.[9] By haplotype analysis, the segment that carries the polled mutation in goats was localized within a 100-kb segment of DNA homologous to a region on human chromosome 3 (band 3q23).[9] This region of human chromosome 3 harbors the gene for the forkhead transcription factor *(FOXL2),* which, when mutated, causes the disruption of development and maintenance of ovary, eventuating in premature ovarian degeneration and a malformation characterized by drooping eyelids with excessively thick epidermis, referred to as blepharophimosis ptosis epicanthus-inversus syndrome (BPES).[10] A more exhaustive study using positional cloning approach narrowed the location of the caprine mutation to a 25-kb area within this 100-kb segment, and further showed that the mutation responsible for the polled trait-related intersex syndrome (PIS) in goats represents an 11.7-kb deletion.[11] The segment deleted (through PIS mutation) consists of a repetitive sequence-enriched segment of DNA, with long-range regulatory effect on two important genes involved in horn bud development and gonadogenesis. One of these is a noncoding gene located 20 kb away from the deletion and referred to as PIS-regulated transcript 1 *(PISRT1)* because the transcription of this gene is regulated by the PIS locus involved in the deletion. The other gene, located 200 kb away from the PIS locus, is the caprine homologue of the forkhead transcription factor *(FOX L2)* involved in human BPES.[11] Transcription of both these genes is involved in the development of fetal ovaries and horn bud potential, with the levels of transcription in the skin surrounding the future horn bud region depending upon the genotype of the fetus.[11]

PISRT1 *and* FOXL2 *in Gonadogenesis*

In normal goat fetuses free of the polled mutation, *PISRT1* gene transcribes an RNA required for the initial stages of ovarian morphogenesis, but *FOXL2* transcription is also elevated in the mesonephros and in fetal gonads. However, gonadal expression of both these transcripts displays a sex-dependent dimorphism with much higher levels in normal female (XXpp) fetal gonads at 30 and 36 days post coitum (dpc) when the bifunctional gonad is still attached to the mesonephros, compared to that in normal XY male gonads at corresponding stages of growth. Between 40 and 56 dpc, *PISRT1* expression reaches a 5 to 200 fold higher level in normal fetal ovaries relative to that in fetal testes whereas in the latter *PISRT1* expression begins to increase only at 70 dpc and the level increases during gestation, reaches a plateau at birth, and continues to be maintained at high levels throughout sexual maturation and adult life. Transcription of *FOXL2*, which also is elevated in normal fetal ovaries at the early stages of gonadogenesis (30, 36, and 40 dpc), reaches a 30- to 300-fold increase relative to that in fetal testes at these stages. Transcription of *FOXL2* is also slightly increased in fetal testes after 70 dpc, but remains low throughout gestation and postnatal growth period and is absent in adult testes.[11]

PIS Deletion and Sex Reversal

In XXPP goat fetuses (which carry the PIS deletion in both chromosomes of the pair at 1q43), no impact of this deletion is evident during the early stage of gonadogenesis characterized by the formation and growth of the genital ridge.[12] At these stages (up to 36 dpc), the gonads of XXPP fetuses histologically resemble those of normal female fetuses, which are either free of the polled gene (XXpp) or carry the polled gene in heterozygous state (XXPp). However, by 40 dpc, XXPP fetuses begin to display evidence of disrupted ovarian differentiation including elongation of the sex chords and replacement of the coelomic epithelium with the presumptive tunica albuginea, and by 70 dpc the gonads of a majority of XXPP goat fetuses resemble fetal testes while others retain a few oocytes and developing follicles in the cortical region of the ovary.[12]

The gonadal expression of *PISRT1* in XXPP fetuses closely follows the pattern of normal female fetuses at the initial stage of gonadogenesis (before 36 dpc); however, *PISRT1* and *FOXL2* transcription in follicular cell precursors is drastically reduced at 36 dpc.[12] Other evidence of ovarian disruption detectable at this stage is the striking reduction in the transcription of cytochrome P-450 aromatase *(CYP19)* gene, which is responsible for catalyzing the conversion of androgen to estrogen in normal fetal ovaries, even though no departure in ovarian morphology is detected at 36 dpc compared to that of normal XXpp fetuses of corresponding age. By 40 dpc, however, the ovarian cortex is drastically reduced, and the formation of seminiferous tubules and the tunica albuginea is initiated, and the fetal Sertoli cells begin to produce the anti-müllerian hormone (AMH). Unlike normal female fetuses of this age, 40 dpc XXPP goat fetuses generate elevated levels of mRNA for the *SRY*-related high mobility box (SOX9) protein belonging to a family of conserved DNA-binding proteins expressed exclusively in the Sertoli cells. The SOX9-aided secretion of AMH is thought to be the first sign of fetal gonadal function as the testis which, in XXPP fetuses, is already evident by 40 dpc. By 56 dpc, the gonads of XXPP fetuses begin to resemble that of normal male fetuses in morphology as well as in *AMH* and *SOX9* expression pattern, and in their impact on müllerian duct regression. Ovarian germ cells, which in normal (Xxpp) caprine fetuses enter meiosis around 55 dpc, become extremely reduced in XXPP fetuses after 56 dpc, and continue to degenerate throughout gestation. By 70 dpc, signs of masculinization of the gonaduct as epididymis and the initiation of the prostatic buds become evident. Thereafter, the pattern of differentiation of the external genitalia and the expression pattern of other genes follow in the male direction, while the genes expressed in normal fetal ovaries, including *CYP19* and one of the signal protein genes, *WNT4,* required for preventing Leydig cell differentiation in fetal ovaries, remain suppressed.[12]

These events indicate that the functional aspect of the sex reversal process in PPXX fetuses is initiated as early as 36 dpc when the *CYP19* gene is down-regulated, probably by the reduced transcription of *PISRT1* or *FOXL2*. The impact of this reduction is manifested by 40 dpc in the histologic changes taking place in the ovarian cortex, coinciding with the up-regulation of *SOX9* gene expression in the Sertoli cells, suggesting that the follicular cell precursors are the first cell types to be affected by the PIS deletion eventuating in sex reversal.[12]

According to the current concept of mammalian sex determination, the process involves multiple steps, each of which is susceptible to the expression of negative and positive regulator genes located on the autosomes and sex chromosomes, with overt or subtle dosage effects on the expression of other genes.[9] Although all the genes involved in the sex determination cascade have not been identified as yet, some of these active in the genital ridges of both sexes up to the formation of the bipotential gonads, and those specific to, or overexpressed in, the testicular morphogenesis pathway have already been identified.[9] In contrast, only a few genes involved in the morphogenesis of fetal ovary have been identified to date. However, the autosomal genes involved in the male pathway also exist in females and are required for ovarian differentiation. These genes remain suppressed in females by other genes located either on the sex chromosomes or autosomes, such as the autosomal Z locus proposed for human sex differentiation.[13] In normal males, *SRY* codes for the DNA-binding (and bending) protein that functions as a repressor of the autosomal *Z* gene. Because the *Z* locus remains repressed by *SRY* in normal XY males, the expression of male-specific autosomal genes goes uninterrupted, whereas in normal XX females, which lack *SRY,* the *Z* gene is allowed to be expressed and to produce the proteins that would inhibit the genes promoting testis induction.[13] The caprine *PSRT1* is thought to serve as an "anti-testis" gene that inhibits *SOX9* gene expression in fetal ovaries while *FOXL2* ensures the maintenance of fetal ovaries.[12] It has been suggested that a mutation that renders the autosomal *Z* gene inactive *(Z^-)* could allow the male-specific genes of XX individuals to express and, as a result, lead to testis development even in the absence of *SRY.* The PIS deletion, therefore, would appear to be the caprine counterpart of the Z^- mutation implicated in human XX sex reversal because this deletion, through its abrogatory impact on *PISRT1* and *FOXL2* genes, allows testis differentiation-promoting genes to be active in fetal ovaries to cause sex reversal in female goats.

STERILE BUCKS

Testicular Hypoplasia

Prevalence and the leading cause of sterility in bucks vary in goat populations. In general, approximately 33% of sterile bucks also display varying degrees of testicular hypoplasia.[14] Although some of these may be sex-reversed genetic females (freemartins or polled intersexes) erroneously identified as males, other causes of testicular hypoplasia and infertility have also been detected. Testicular hypoplasia is seen in caprine sex chromosome mosaics with XXY/XY cells similar to the partial Klinefelter syndrome in humans.[14] The XXY/XY sex chromosome composition could result from the failure of the sex complements to separate during gametogenesis in either of the parents, followed by the loss of an X chromosome during early cell division in the conceptus. Alternatively, failure of separation of the X chromosome during cell division (nondisjunction) could occur in one of the blastomeres of a male (XY) conceptus. In such situations, the blastomere receiving no X chromosome (due to nondisjunction) is often eliminated early in embryogenesis, and the resulting conceptus displays only the coexistence of XY and XXY cells. Regardless of the mechanism that leads to the mosaic status of the bucks, they may be totally or partially sterile, depending upon the proportion of normal XY cells that happen to populate their seminiferous epithelium.

Sterility in Polled Bucks

Familial type of sterility is more common in polled bucks than in horned bucks.[2] Although the proportions exhibiting sterility vary from 20% to 30%, even among polled bucks, their pedigree indicates that the type of sterility detected is associated with the polled mutation.[4] Unlike the polled female goats that become intersexes, polled bucks show no malformation of the external genitalia at birth and no overt phenotypic abnormality later, other than the lack of horn. These polled bucks undergo normal growth and maturation at puberty, their testes achieve the normal size, and the seminiferous tubules display active and often precocious spermatogenesis. However, they tend to be sterile because of a defect in their gonaduct system resulting in a blockage (stenosis) in the epididymis.[4] The blockage, interrupting the passage of spermatozoa through the duct system, causes retention of spermatozoa in large masses in the lumen of the duct. Occasionally, in older bucks, the seminiferous tubules close to the rete testes degenerate or rupture, causing the release of spermatozoa in the interstitium (extravasation), which often leads to sperm granuloma formation. This type of epididymal stenosis leading to sterility is detected in less than 30% of polled bucks resulting from polled-to-polled matings, but it is believed that the afflicted bucks are homozygotes for the polled gene.[6] Thus, homozygosity for the polled mutation (PIS deletion) appears to be disadvantageous to both sexes: it causes poor differentiation of the androgen-dependent duct system and leads to sterility in the male, and allows the expression of genes in the testicular differentiation pathway leading to the masculinization of the gonad, gonaduct, and external genitalia in the female. The mechanism leading to the interruption of wolffian duct differentiation in XYPP males is not as yet known.

Persistent Müllerian Duct Syndrome

Another malformation of the duct system leading to sterility in the bucks is that referred to as persistent müllerian duct syndrome (PMDS).[15] This defect is considered distinct from caprine intersexuality because affected indi-

viduals are karyotypically males (60XY) with a well-developed penis and bilateral cryptorchidism. Failure of müllerian duct to regress in PMDS males is attributed either to arrested or delayed function of the fetal Sertoli cells, which normally produce the high-molecular-weight glycoprotein dimer, anti-müllerian hormone (AMH) during the differentiation of the embryonic ducts. Müllerian duct regression could also be impeded by the absence of receptors for binding this hormone on the embryonic paramesonephric derivatives. In either case the retention of these embryonic duct systems could lead to cryptorchidism in males because the abdominal müllerian duct derivatives could interfere with the transabdominal testicular descent. This anomaly in goats probably is inherited as an autosomal recessive trait, as in humans and dogs.[15] However, the true identity and frequency of this syndrome in goats may not be resolved, because cases exhibiting male and female internal genitalia with and without bilateral cryptorchidism generally will be included as caprine intersexes. It is also possible that some cases diagnosed as bilateral cryptorchidism in goat breeds may represent PMDS because not all cases are subjected to routine postmortem examination or karyotype analysis. Regardless of the true identity of their affliction, goats with PMDS could develop testicular tumors as they age, as their counterparts in other domestic animal species do.

ELIMINATION OF SEX ANOMALIES

Identification of the cause of an undesirable trait is often the first step leading to its elimination from domestic animals. The discovery of the PIS deletion as the molecular basis of the most common type of sex anomaly in different breeds of dairy goats is an important breakthrough for its relevance to solving the hitherto paradoxical association of two seemingly unrelated attributes in goats and for the light it sheds on the regulation of ovarian differentiation and sex reversal, in general. In the caprine context, polled trait–related intersexuality and epididymal stenosis can be eradicated by avoiding polled-to-polled matings. In contrast, the freemartin type of sex reversal occurs as a result of the destruction of female meiotic germ cells by the cells and hormones communicated by the male co-twin through the shared placenta. The occurrence of this category of sex reversal, associated with twinning and multiple births in goats, is less easy to predict and more difficult to eliminate except by selecting against prolificacy. On the other hand, true hermaphroditism, albeit rare, is likely to remain at the same rate in goat populations because accidents in fertilization or embryogenesis leading to whole-body chimerism and development of bisexual gonads can occur in any breed or type of goats, and the causes of these accidents remain unknown.

CHAPTER 81

Induced Abortion and Parturition in the Goat

WILLIAM BRAUN, JR.

Elective induction of abortion or parturition is easily accomplished in goats. A functional corpus luteum (CL), the sole source of progesterone, is essential for maintenance of pregnancy throughout gestation in does. The caprine placenta produces little or no progesterone. Anything that interferes with proper function of the CL during gestation will result in termination of pregnancy. By far the most commonly used agent to achieve termination of pregnancy in goats is prostaglandin F_2 alpha ($PGF_{2\alpha}$) or its analogues, but corticosteroids and estrogens have also been employed.

INDICATIONS FOR TERMINATION OF PREGNANCY

The typical reason for a client's request for early termination of pregnancy is mismating. Bucks are clever individuals that are at times almost impossible to keep in their pens. If does are in estrus, bucks will attempt to reach them if at all possible. Mismated does may be too young or small for breeding, held in reserve for breeding at some future date, or scheduled to be bred by artificial insemination or to a different buck. Some older does may have been retired from breeding. Injury or disease that may compromise the life of the doe or the completion of pregnancy may also result in a request for termination of pregnancy.

Induction of parturition has the benefit of allowing prediction of the time of kidding. Many owners prefer this arrangement, as they are able to know in advance when a doe, or group of does, will kid and thus can be prepared for the event. Kiddings can take place when the owners have the time or personnel to attend or assist kiddings. Attended kiddings allow owners to remove the kids from their dams prior to suckling and ingestion of colostrum. This is important in some disease-control programs, especially caprine arthritis-encephalitis and mycoplasma infection, for which the prime mode of transmission to the new generation is through colostrum or milk. Other indications for induced parturition include injuries to the doe during late gestation and impending or early cases of pregnancy toxemia.

INDUCTION PHARMACEUTICALS

Events that lead to normal parturition in goats require functional maturation of the fetal adrenal cortex. Parturition is triggered by activation of the fetal pituitary-adrenal axis.[1,2] Adrenocorticotropic hormone (ACTH) is released by the fetal pituitary, which stimulates release of corticosteroids by the fetal adrenal glands. An increase in fetal corticosteroids stimulates placental estrogen biosynthesis, which in turn stimulates the synthesis and release of $PGF_{2\alpha}$ from the placenta and endometrium. The cascade continues and $PGF_{2\alpha}$ causes luteolysis, which results in a decrease in progesterone. An increase in estrogen and decrease in progesterone stimulate myometrial activity, which is further enhanced by the effects of $PGF_{2\alpha}$, causing a direct effect on the myometrium and stimulating oxytocin release. By mimicking some of these events, abortion or parturition can be artificially induced.

Both ACTH[1,2] and corticosteroids[3,4] have been used for early termination of pregnancy in goats. Infusion of 10 µg ACTH per hour into the fetus on day 126 of gestation resulted in live births on day 131, with placentas expelled within 18 hours after delivery. Daily doses of cortisol acetate (100 mg IM) to does before day 112 and after day 136 resulted in delivery at normal term, but cortisol acetate given on days 113 to 120 resulted in abortion by day 125.[3] Administration of methylprednisolone acetate to does prior to day 84 caused no early termination of pregnancy, but doses of 240 to 270 mg IM given on day 111 or day 125 resulted in abortion in 6 days.[3] In another experiment,[4] nine does were given 16 mg dexamethasone IM on day 144 and all delivered live kids in a mean of 119 ± 29.8 hours, and only one experienced retained fetal membranes 24 hours after delivery.

Exogenous estradiol-17β causes the release of $PGF_{2\alpha}$ and thus induces luteolysis.[5] When infused intravenously into goats pregnant 124 to 142 days, it causes the delivery of fetuses within 54 to 81 hours. All the fetuses died of respiratory failure within 1 hour of delivery. The administration of estradiol benzoate (12 mg IM) to goats at 126 to 138 days of gestation resulted in delivery of live, nonviable fetuses in 58 to 87 hours.[5] In another study, goats given estradiol benzoate (15–25 mg IM) on days 147 and 148 of gestation delivered kids on day 149.[6]

During the breeding season, $PGF_{2\alpha}$ is effective in inducing luteolysis in goats. Luteolysis will occur if the doe is on day 4 to 17 of the estrous cycle when $PGF_{2\alpha}$ is administered. Because the doe is CL-dependent throughout gestation, $PGF_{2\alpha}$ is effective in terminating pregnancy from day 4 until term. Doses as low as 1.25 mg $PGF_{2\alpha}$ have been shown to be effective[7] for luteolysis, as has 0.0385 mg/kg (1.75 mg $PGF_{2\alpha}$/100 lb).[8] One study reported that 15 mg $PGF_{2\alpha}$ given on day 30 or 65 of gestation resulted in abortion at 34 to 54 hours and at 54.5 to 75.5 hours, respectively, after injection.[9] Many does induced to abort with

5 mg or 15 mg $PGF_{2\alpha}$ during the breeding season experienced one or more consecutive interestrous intervals of 2 to 15 days.[10,11] Progesterone concentrations associated with these short cycles suggest failure to form a functional CL or the formation of an atypical CL, either of which was accompanied by a luteinizing hormone surge of decreased magnitude.[10]

The drug of choice for induction of parturition in goats is $PGF_{2\alpha}$ or one of its analogues. When administered IM at doses of 2.5 mg,[12] 5 mg,[12] 15 mg,[9] or 20 mg[4] on days 140 to 144 of gestation, $PGF_{2\alpha}$ will induce parturition and delivery of live kids 29 to 57 hours (average, 43 ± 11.8 hours), 28 to 48 hours (average, 35 ± 8.6 hours), 36 to 56 hours, and 31.5 ± 1.1 hours, respectively, after injection. The higher doses of $PGF_{2\alpha}$ result in a more predictable time of parturition. Treatments are followed by a dramatic decrease in plasma progesterone concentration 24 hours after injection.[4,12] Few cases of retained fetal membranes have been reported with $PGF_{2\alpha}$-induced parturition. Induction of parturition on day 144 did not result in the birth of kids that were smaller than the species average.[12] Owners have reported that some does produce less colostrum when parturition is induced.

MANAGEMENT OF PREGNANCY TERMINATION

The drug of choice for induction of abortion is also $PGF_{2\alpha}$ or one of its analogues. In cases of mismating, the doe should not be treated until 5 to 7 days after breeding, at the earliest, to allow the CL to mature and become receptive to the effects of $PGF_{2\alpha}$. A luteolytic dose of $PGF_{2\alpha}$ is administered IM and the doe is expected to show estrus in 3 to 5 days. If gestational age is 30 days or greater, $PGF_{2\alpha}$ will terminate pregnancy, but the subsequent estrus may be anovulatory, followed by a shortened interestrous interval. Does in which abortion is induced late in the breeding season may not show estrus or cycle again until the next breeding season.

For induction of parturition, gestational age should be at least 144 days. Care must be exercised to ascertain that no unrecorded breedings or errant bucks have caused a miscalculation in gestation length. If the doe is only 123 days instead of 144 days pregnant, induction may produce poorly viable kids. A doe at the correct stage of gestation given 10 to 20 mg $PGF_{2\alpha}$ early one morning can be expected to kid normally the next afternoon, some 30 to 35 hours later. This allows owners to plan the time and day of kidding so that assistance is available or the kids can be removed from their dams prior to suckling.

CHAPTER 82

Reproductive Health Program

SANDRA L. AYRES

Goats are important livestock animals throughout the world. This is in part related to their ability to survive on suboptimal forage in more arid environments, combined with their smaller size, shorter gestation period, and increased litter size, particularly when compared to bovids. The Food and Agriculture Organization (FAO) figures for 2004 estimate the total goat population in the world at approximately 780 million animals.[1] Even in the United States, where goat production is lower than in other parts of the world, the 2004 kid crop was estimated to be 1.67 million animals.[2] Goats in the United States were used primarily to produce meat (1.97 million animals), goat's milk (283,500 animals), and fiber (274,000 animals).[2]

The success of any goat production operation depends upon optimizing reproductive health. Although the basic requirements for good reproductive health are similar in all types of goat operations, there are some differences in the reproductive demands and husbandry practices, particularly for dairy animals as compared to goats raised for meat and fiber. Areas of importance for reproduction in goats include how the herd is housed and pastured, the nutritional requirements of the herd relative to type of production and breed, disease and parasite control, reproduction program, and special requirements for dairy operations.

HOUSING AND PASTURE

Most goats reared for meat and fiber are housed on pasture or range. Some access to protective shelter or housing is preferable, particularly during the kidding season. Goats are unlike sheep; whereas newborn lambs immediately follow the dam, does naturally hide their kids for the first few days after birth, thus making newborn kids vulnerable to predation.[3] This also means that pastures should be carefully checked for young kids if moving the herd during the kidding season.

Unless breeding is being timed or synchronized, it is common to run the bucks with the does, allowing breeding to occur throughout the breeding season.[4] A stocking rate of 1 buck to 50 does is usually suggested, although stocking rates as high as 1 buck to 250 does have been reported.[5]

Dairy operations usually keep goats housed indoors, sometimes with access to pasture. If bucks are kept on the premise, they are separated from the does so that estrous synchronization and breeding can be controlled. Bucks that are kept isolated from females can be used to synchronize the does via a pheromonal phenomenon known as the "male effect" or "buck effect."[6–8] Some goat dairies do not keep bucks on the premises, but rely upon artificial insemination (AI) for breeding and to increase genetic variability within the herd.[9]

Bucks that live together establish a dominance hierarchy. Fighting among bucks to establish this hierarchy can be severe, particularly during the breeding season. In addition to acquiring physical injuries, bucks housed with females or near females during the breeding season can lose significant amounts of weight by fighting among themselves rather than eating. Dominance behavior in group-housed bucks usually takes the form of rearing and fighting, but can also include homosexual behavior during the breeding season.[10] Although this behavior has the potential to spread disease, venereal disease among bucks is not as great a concern as it is in rams where *Brucella ovis* is spread by this behavior.[5] Subordinate bucks can have their breeding potential reduced by dominant bucks. If more than one buck is housed with does during the breeding season, the dominant buck can physically interfere with other bucks attempting to breed, a phenomenon sometimes called the "dominance effect." Even when separated from dominant bucks, subordinate bucks can be psychologically intimidated from breeding does if the dominant male is close by ("audience effect"). Subordinate bucks can be induced to breed by putting them in a pen with females situated at a distance away from the dominant buck, or by housing the male with a group of smaller or younger bucks (personal communication, Dr. William Gavin, Stephen Blash, GTC Biotherapeutics).

Does will also form dominance hierarchies. If a group contains both horned and de-horned or polled does, the does with horns will most often become the alpha goats. Dominant does will sometimes physically attempt to keep the most subordinate does from feeding. This is particularly true in situations in which hay and grain is delivered in stationary feeders that can be "patrolled" or defended by the alpha doe. In some situations it may be necessary to separate the alpha does from the subordinate does during feeding to ensure that subordinate does get their fair share of the feed, and that the alpha does eat rather than "patrol" the feeder.[11]

Because of the young age at which goats can attain puberty, it is important to separate young bucks from does at an early age.[12] Bucks as young as $3^1/_2$ months of age have been known to impregnate does, including their siblings or dam.

NUTRITION

Good nutrition is necessary for goats to successfully reproduce. It is suggested that goats attain two thirds of

their adult weight before being used for breeding.[5] Breeding young does that are very small in stature can result in dystocias, particularly in small does carrying large singletons. It is also possible to stunt the growth of the doe by breeding at too young an age.

It is important to understand the nutritional requirements of the breeds being kept to prevent overconditioning as well as underconditioning of animals. Meat breeds such as Boers or Spanish goats can convert feed to muscle mass at a far greater efficiency than most dairy breeds (e.g., Saanens, Alpines) and therefore require less feed for maintenance. This can be problematic when different breeds are housed together, or when dairy maintenance regimens that include grain are used for meat breeds.

Meat and fiber goats can obtain adequate nutrition when reared on good quality pasture. Goats are selective browsers and usually avoid eating toxic plants, but problems can arise if the pasture is marginal, or if vegetation is sparse during dry periods. Goats will then consume forage that can result in reproductive problems. A study in Texas showed that bucks grazing pastures containing plants with high levels of dietary phenolic amines such as those found in shrubs of the genus *Acacia* had a significant reductions in serum testosterone, scrotal circumference, and semen volume.[13] Other toxic plants that can lead to reproductive problems include *Lupinus formosus, Conium macilatum, Nicotiana tabacum,* and V*eratrum californicum*.[3]

Breeding bucks need to be in good body condition. A body score of 3.0 to 3.5 has been suggested.[12] It is important that good body condition be attained prior to the breeding season, as bucks tend to lose weight during this time, particularly when group-housed. Feeding regimens should be changed with care, as there can be problems associated with increasing nutritional planes in bucks. Such increases in feeds are most commonly seen in bucks or wethers being raised for the meat market when additional feeds are used to increase muscle mass or decrease the time needed to attain market weight. A variety of substances have been added to a basic grass diet to increase weight gains including grains, and by-products such as soy hulls, corn gluten, wheat middlings, etc.[14] Diets that result in high protein can lead to ulcerative posthitis, a condition related to production of high levels of ammonia in the urine that, if severe, can reduce a buck's willingness to breed.[3,5] Diets that are high in phosphorus can change the calcium-to-phosphorus ratio to less than 1.5:1 to 2.0:1 and result in the formation of struvite uroliths within the urethra and bladder. Feeds that are high in calcium, such as alfalfa or subterranean clover, can also contribute to the formation of uroliths. Access to clean water, and addition of salt and ammonium chloride to the diet can help prevent the production of uroliths in males.[12]

Feed regimens are important reproductively for females as well as for males. Does should be in good condition prior to breeding. Body scores of 2.5 to 3.5 (out of 5) have been suggested as optimal.[12] Like ewes, does can respond to increased nutrition just prior to the breeding season (flushing) with an increase in the average number of ovulations. But overfeeding of does, particularly dry does, is to be avoided. Overfeeding of grain can result in obese females that exhibit high body condition scores and are more prone to dystocias, in part related to fat deposits in the area of the birth canal. Overconditioned females are also predisposed to develop pregnancy toxemia.[15,16] Inadequate nutrition can also interfere with reproduction. Low nutrition can result in poor ovulation rates or cessation of cycling. When cycling does were fed a restricted diet (30% of requirement) they did not ovulate in response to an estrous synchronization regimen, exhibiting a reduced frequency of luteinizing hormone (LH) pulses.[17]

DISEASES AND PARASITE CONTROL

Diseases can affect reproductive health in a number of ways. Most diseases of goats, such as pneumonia, have at least an indirect effect on reproductive health through reduction of appetite, production of fever, loss of weight, or reduction of ambulation. A sick animal is less likely to breed and to carry pregnancy to term. Chronic illnesses such as Johne's disease, caseous lymphadenitis, and caprine arthritis-encephalitis (CAE) can sometimes have insidious effects on reproductive health. Caprine arthritis-encephalitis is a slow lentivirus of particular concern to the dairy goat industry. Early CAE can negatively impact milk production while producing few clinical signs.[18] The prion diseases, including scrapie and the transmissible spongiform encephalopathies, not only cause a wasting disease but are also of concern for public health.[19]

The set of diseases that most directly impacts goat reproductive health consists of those that cause abortion. Abortion occurs sporadically in goats, but endemic infectious abortion has the greatest economic impact. Many infectious agents have been incriminated in goat abortions, but *Chlamydia psittaci, Toxoplasma gondii, Coxiella burnetii,* and *Mycoplasma mycoides* are the most commonly diagnosed.[16] Ovine chlamydial vaccines provide moderate protection against abortion. Toxoplasmosis is best prevented by controlling cat populations, especially by preventing reproduction, and also by control of rodents. Ionophores fed to dry does may decrease abortion in exposed individuals. The control of *Mycoplasma* infection requires a multifactorial approach with detection of carriers, control of milk transmission, and culling of identified carriers.

Chlamydia is the most common cause of infectious abortion in high-density confinement goat dairies. Does exposed any time (including neonates) prior to day 90 of gestation are susceptible to abortion of that pregnancy, while does exposed from day 100 of gestation onward are at risk of aborting during the next pregnancy due to the long incubation period required to develop necrotic plancentitis that leads to abortion. Although *Chlamydia* infection is traditionally associated with last semester abortion, experimental infection around day 60 of gestation, when the organism first crosses the placenta, may result in fetal death with resorption or abortion.[16]

Disease can be controlled by good husbandry practices and vaccination programs. If animals are housed indoors, particular attention should be paid to keeping animal

densities from becoming too high, having a good waste removal program, and having adequate ventilation. Vaccination programs vary depending upon region and country, but usually include vaccines for *Clostridium perfringens* types C and D, and *Clostridium tetani*.[3,12] If rabies, chlamydiosis, or leptospirosis is endemic, appropriate vaccines are also included. In areas deficient in soil selenium, vitamin E and selenium are administered to prevent white muscle disease.[20] It is important to schedule vaccinations to pregnant does 3 to 4 weeks prior to delivery to ensure adequate antibody production in colostrum.[3,12]

Large parasite loads can induce chronic weight loss, diarrhea, and anemia in animals and thereby reduce reproductive potential.[21] This is of increased concern with the development of strains of parasites such as *Haemonchus contortus* that have become resistant to anthelmintic treatments.[22] Understanding the ways in which choice of anthelmintic drugs and timing of treatments for parasite control contribute to selection for resistance (e.g., frequent use of the same class of anthelmintic) are important to prevent the development of resistant parasites.[23] For animals on pasture, knowledge of parasite cycles combined with schedules of pasture rotation may be effective in helping reduce parasite loads.[23] Investigations are ongoing to find genetic markers for goats that are more resistant to parasite infection, as well as ways to increase natural resistance. For example, it has been suggested that high-producing dairy goats may benefit from supplemental protein in the diet as a way to increase resistance to nematode infection.[24]

REPRODUCTIVE PROGRAM

It is important to maximize fertility in both does and bucks. In females, constraints to maximizing reproductive potential include failure to conceive, early embryonic death, endometritis, pregnancy toxemia, short estrous cycles, ovarian disorders, hydrometra, and abortion. Mucometra, pyometra, and mummified or macerated fetuses are conditions that may result in failure of the dam to show heat or conceive. Real-time ultrasonographic examination and vaginal speculum examination are essential to scrutinize does with apparent reproductive failure.[5] Blood concentrations of hormones (progesterone, estrogen, testosterone), laparoscopy, or laparotomy can also be used.[5] Does with a history of reproductive failure have a poor prognosis for recovery, and a high cost is associated with diagnosis and treatment.

In males, the overall breeding soundness of the buck is often not considered because in many operations there is a high buck-to-doe ratio. The breeding potential of the male is of concern in synchronized breeding schemes that require maximum breeding soundness, or when a valuable buck is providing stud services, or having semen frozen. In any case, breeding soundness examinations (BSEs) should be performed on bucks that are used in breeding programs. Such examinations are important not only to confirm the potential fertility of a buck (scrotal examination, sperm morphology and motility) but also to identify conformational and physical problems that could affect fertility.[5] In addition, buck fertility may be affected by testicular atrophy associated with increased age, poor libido, sperm granulomas in the epididymis, systemic disease, high environmental temperatures, and genetic factors.

In both sexes, the intersex condition related to the polled gene can lead to reduced fertility or infertility.[25] This should be a consideration in young animals in herds containing polled animals, and can be managed by using horned bucks for breeding. Does 6 to 10 months of age that fail to breed with their cohort should be culled unless there are compelling reasons to maintain an individual animal.

In many operations it is important to synchronize the breeding of animals or to breed animals outside the breeding season. This is of particular importance for timed artificial insemination, for dairy operations that want to maintain a year-round supply of milk, as well as for meat operations that want to take advantage of holiday demands for meat. The most common methods of synchronization involve the "buck or male effect," hormones, or manipulation of light. The "buck effect" is most commonly used to synchronize does at the beginning of the breeding season.[26] The scent of the male induces ovulations within 5 days of introduction. The first heat is often not fertile, as it is accompanied by premature luteal regression and a short cycle, but the heat following the short cycle is fertile. If males are housed at a distance from the females, the "buck effect" can also be used to synchronize does during the breeding season. There has also been success in synchronizing does by replacing the original male in the herd with a novel male.

Hormones are commonly used by the dairy industry and in research to precisely control the estrous cycle and to induce cycling outside the breeding season. Hormones used include prostaglandin F2 alpha ($PGF_{2\alpha}$) during the breeding season, and combinations of progesterone (sponges, controlled internal drug releasing devices [CIDRs], subcutaneous implants, injections, and oral supplements [melengesterol acetate]) with follicle-stimulating hormone (FSH) or equine chorionic gonadotropin (eCG) and pregnant mare serum gonadotropin PMSG) during both the breeding and nonbreeding seasons.[27,28] Regulations vary by country as to the use of these hormones in animals used for milk and meat. For example, the current sponges, CIDRs, and subcutaneous implants on the market have not been approved for commercial use in the United States, leading producers to seek alternative methods to cycle animals.[29]

Manipulation of light cycles is also used to synchronize does and induce cycling out of season.[28] Many programs incorporate 6 weeks of long light (>12 hours per day) followed by a period of shorter light. These programs work best with goats that can be housed indoors. An example of this type of light management cycle is shown in Figure 82-1.

Another important reproduction management technique is to determine those animals that have been bred so that open does can be separated or culled, and the pregnant animals can potentially be segregated according

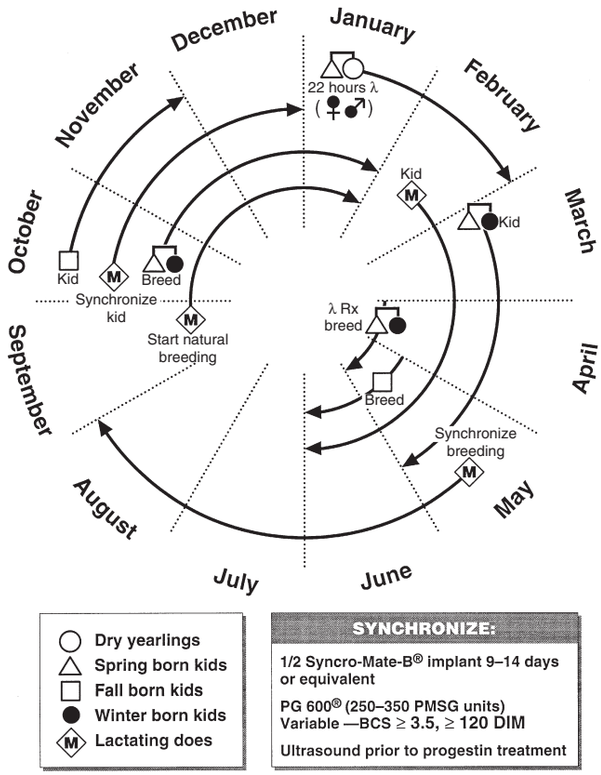

Fig. 82-1 A model to minimize seasonality of milk production in a commercial goat dairy. λ = exposure to lights.

to the number of kids the does are carrying. One method of pregnancy detection involves looking for a return to estrus 18 to 21 days after breeding. In this case it is important that the dates of breeding are known. Another method is to ultrasound the herd approximately 40 to 60 days after breeding. B-mode live ultrasound can detect pregnancy at 45 days with approximately 98% accuracy.[5] Using ultrasound, it is possible to distinguish does carrying singletons from does carrying multiple kids. In addition, ultrasound can be used to determine viability of kids during pregnancy and to distinguish pregnancy from hydrometras.

Advanced or assisted reproductive techniques are now being used in some goat operations.[28] AI has been used, particularly in the goat dairy industry, to produce pregnancies without keeping a male on the premise.[9] With the ability to synchronize the estrous cycle and induce superovulation, it is possible to perform embryo transfer (ET).[27] The difference between performing ET in horses and cattle and goats is the necessity to use a laparoscope or surgical approach for collection and transfer of embryos. Trans-surgical collection has been attempted but appears to be operator-dependent in regard to success.

For all aspects of reproductive management, it is imperative to keep good records. Individual health records assure that data is kept on vaccination and herd health programs as well as affording a way to track infectious disease trends, especially those related to abortion. Records should be kept for all matings so that success rates can be calculated for both males and females. Animals with poor breeding records should be removed from the breeding herd. In addition, animals born with congenital anomalies should be culled and if the anomaly is genetic, the dam and sire should be removed from the breeding herd as well as other related animals.

SPECIAL CONCERNS FOR DAIRY OPERATIONS

In goat dairies, the necessity to produce an even milk supply throughout the year combined with intense housing requirements means that these operations need different husbandry and reproductive programs when compared to meat and fiber operations.

Out-of-season breeding of does is required to maintain a viable commercial goat dairy. Attention to detail, records, and planning are essential for success. About one third of the does should kid from October through December to maintain adequate milk production. Dry stock can be induced to breed out-of-season using exposure of bucks and does to increased light for 60 days in January and February. Estrous cycles should begin 4 to 6 weeks later. Does are loosely synchronized and often have more than one estrous cycle. Although lactating does can be exposed to light treatment, the response is more predictable if synthetic progestins and pregnant mares' serum gonadotropin (PMSG) are utilized. The dosage of PMSG is adjusted based on month of breeding, geographic factors, and reproductive history of the dairy. A single synchronized estrus results, with expected conception rates of 65% to 85% (breeding May 1 to August 31). Doe kids born from these breedings will have one or two heat cycles in the spring, which results in kidding at 10 to 15 months of age. In selection of mature milking does for estrus synchronization, one should choose does with body condition scores of 3 or higher (on a scale of 1 to 5) and at least 120 days in milk. Does with a history of reproductive problems or concurrent disease are best not used in estrus synchronization programs. When planning for does to freshen, it is safest to estimate that only 65% of synchronized does will kid to that mating. If more than 20 to 30 does are synchronized, extra help is needed, because hand-mating is required to maximize success. Artificial insemination can be used in estrus synchronization programs if high-quality frozen semen (determined by post-thaw microscopic examination) is available; however, artificial insemination is an additional variable affecting conception rate.[9] All does exposed to bucks should be examined by ultrasonography 35 to 45 days after breeding and again at 60 to 70 days to confirm pregnancy (in order not to miss the chance of breeding an open doe) and then again when they are dried off. Does that develop hydrometra should be treated with prostaglandin as soon as the condition is detected, rechecked in 10 to 14 days, and re-treated if fluid is still present in the uterus. Does that kid in the fall to early winter may have estrous cycles after kidding and develop hydrometra. Ultrasonographic examination of these does in January to March allows treatment prior to breeding. It is important for pregnant does to have a 60-day dry period if they are expected to reach maximum milk pro-

duction. A truncated dry period may result in production losses of at least 20% to 30%. Open does detected at the "due to dry date" can continue to be milked if production is adequate. Generally, these does increase their milk production for a period, or yield a fairly constant amount during their extended lactation.

Of special concern to dairy operations is the disease caprine arthritis-encephalitis (CAE). The three forms of this disease are a fatal encephalitis affecting young kids, a condition known as "hard udder" affecting milking does, and an arthritic form that affects joints, particularly the carpal joints. CAE is a slow lentivirus that is usually transmitted vertically from mother to young, but can also be transmitted horizontally. Detection can be difficult, as the disease often does not manifest until the animal is 18 months of age or older.[30] The disease is most commonly transmitted via untreated colostrum and unpasteurized milk fed to kids, and can possibly be transmitted in utero.[31,32] Steps can be taken in a dairy operation to eliminate CAE in the herd. The herd should be tested for CAE, and those animals that test positive should be separated from the rest of the herd or culled. Births should be attended, particularly of CAE positive does, and the kids removed from the dam immediately at birth so the kids do not suckle. There has been some recent success using a "goat-side" progesterone assays (enzyme immunoassay) to predict the 24-hour window in which the doe will give birth.[33] Kids should be fed colostrum heat-treated at 56°C for 1 hour, and fed pasteurized milk. Kids from positive mothers should not be mixed with kids from negative mothers. After 6 months of age, kids should be tested for CAE, and only negative animals used for breeding. Positive kids should be culled. Because there is evidence that CAE can be found in oviductal cells,[34,35] granulosa cells,[36] and in embryo flush medium,[31,35] care must be taken when performing embryo transfers that embryos are produced from animals testing negative for CAE. Although animals have been known to seroconvert,[37] particularly when mixed with animals that are seropositive for CAE, regular testing schedules and careful rearing of young combined with culling of positive animals or closing the herd has resulted in eradication of the disease from some facilities.[18,32,38]

Dairy operations differ from other goat operations in the increase in labor needed to milk animals and rear young, as well as dealing with milking-related diseases such as milk fever and mastitis. Many large dairy facilities milk their animals two to three times per day, although recent work indicates that once-a-day milking can be used without impacting udder health, and may be effective for small operations by offsetting the reduction in milk volume with a reduction in labor needed.[39] Most dairies remove the kids from the dam at birth or soon after as part of disease control programs and to prevent bonding between the doe and kid, although programs have been designed that allow kids to suckle the dam while still being milked once a day.[40] Kids need to be fed heat-treated colostrum within the first 24 hours after birth and can then be fed pasteurized goat milk, goat milk replacer, or even cow milk twice a day for 7 to 9 weeks. In milking does mastitis is a concern.[41] A number of agents can produce mastitis, with *Staphylococcus aureus* frequently reported for clinical mastitis, and coagulase-negative staphylococci are often reported in subclinical mastitis.[42] Unlike cattle, in which somatic cell count (SCC) can be used to monitor mastitis in a herd, SCC in goats is a less reliable indicator of mastitis because the cell level is influenced by many factors including age of the animal, stage of lactation and level of milk production, breed, infection with CAE, and estrus.[43] Mastitis in the herd can be reduced by careful attention to sanitation and proper functioning of milking equipment, proper cleaning of the udder, good diagnosis, and treatment of mastitis with culling where appropriate, and awareness of the possibility of genetic components for susceptibility and resistance to mastitis.[42,43]

CHAPTER 83

Reproductive Biotechnologies in the Goat

GABRIELA FLORES-FOXWORTH

In recent decades, scientists have contributed to develop powerful biotechnologies such as estrus synchronization, superovulation, artificial insemination, embryo collection and transfer, in vitro embryo production, cryopreservation, a variety of embryo micromanipulation procedures, and nuclear transfer. The development of these technologies enables the manipulation of animal reproduction to rapidly propagate superior or desired animals and genes, the genetic modification of animals to improve their production quality, and the production of medically significant products. The goat's diversified commercial value, size, relatively short gestation period (when compared to the cow), and popular demand make it a convenient species for new technologic research and application.

EMBRYO COLLECTION AND TRANSFER

Embryo collection and transfer are very valuable techniques for the rapid dissemination of desirable genetics. Commercial application of this technology in goats was somewhat limited in the United States until the importation of the South African Boer goat. Embryo transfer programs in goats yield highly variable results. The major contribution to this variability is the unpredictable response to superovulation. Incorporation of recent protocols to control follicular wave dynamics in the bovine permits the initiation of superovulatory treatments at a self-appointed time, reducing the variability of the response, and this is applicable in goats. Goats are also extremely sensitive to both nutritional and physical stress; this must be taken into account when handling goats in any embryo transfer program. Recipients should be healthy, well-grown animals that have been on location for preferably at least 4 months. Otherwise, relatively high percentages (up to 25–30%) of treated animals will not be usable on the intended day of transfer for reasons such as failure of ovulation or early luteal regression.

Synchronization and Superovulation

Many combinations of treatments for the purposes of embryo collection and transfer are available. Estrus can be synchronized by the administration of progestogens such as progesterone implants or synthetic progestins (flurogestone acetate, FGA; medroxyprogesterone acetate, MAP) given either orally or by the insertion of a vaginal sponge. The most widely used synchronization device for goats is the control internal drug release progesterone implant (CIDR-G, 0.3 g progesterone, Eazi Breed, InterAg, New Zealand) which is inserted in the goat's vagina using a special applicator. Most traditional schemes consist of a long progestagen (12–18 days) treatment; recent protocols use a shorter progestagen treatment (5–9 days) accompanied by a prostaglandin F2 alpha ($PGF_{2\alpha}$) analogue injection.[1] During the breeding season an analogue of $PGF_{2\alpha}$ is commonly given at the time of device insertion to destroy the corpus luteum and obtain a greater percentage of estrus synchronization. The method for synchronization of estrus is the same for both the donor and the recipients. Owing to the hormonal treatment administered to donors, estrus occurs sooner than in the recipients; therefore implants should be removed from recipients 12 hours prior to removal of the progesterone or progestin source from donors. Some synchronization programs recommend the replacement of the progesterone or progestin source midway through a long synchronization regimen to maintain high levels of progesterone during gonadotropin therapy.

For the induction of superovulation of donor goats, pituitary extracts of follicle-stimulating hormone (FSH) and pregnant mares' serum gonadotropin (PMSG; also called equine chorionic gonadotropin, eCG) are the gonadotropins most used. Commercially available FSH products are: Folltropin V (Vetrepharm, Ontario, Canada), Ovagen (ICP, Auckland, NZ) and Super-Ov, (Ausa International, Tyler, TX). Several protocols can be used for superovulating goats, most commonly the injection of multiple doses of FSH on the last 3 to 4 days of the progestagen treatment. Due to the short half-life of the FSH molecule, it is traditionally administered every 12 hours. One example is the twice-a-day injection of a series of decreasing doses of FSH (5, 5; 3, 3; and 2, 2 mg per injection), with a total dose of 20 mg, with the next to last injection accompanied by progesterone removal and an injection of 150 μg of a $PGF_{2\alpha}$ analogue. Goats display behavioral estrus at approximately 24 hours after implant removal. Folltropin V can also be administered in decreasing doses (3.6, 3.6; 3.2, 3.2; 2.4, 2.4; and 1.6 mg) with a 17-day progestagen treatment; a simpler protocol consists of six injections at a level dose given every 12 hours (total dose equivalent to 20 mg NIH-FSH-P1).[2] An average of 17 ovulations have been obtained per doe using this protocol.[3] Super-Ov is a highly purified preparation of FSH that is marketed in units of FSH activity per milliliter rather than in milligrams per milliliter. Doses are calculated as milliliters of the reconstituted product; a 10-ml vial contains 75 units of activity. One

commercially used regimen of Super-Ov in goats is a 4-day declining dose (1.0, 1.0; 0.8, 0.8; 0.6, 0.6; and 0.4, 0.4 ml) that is reduced by 0.2 ml per injection for young does. Another example is a level dose of 0.7 ml bid for 4 days. Superovulatory treatments using Ovagen (which has a consistent level of LH activity) consist of eight IM injections of 1.25 ml given twice daily starting 60 hours before progestagen removal. The response to this protocol has been reported to be of 14.3 ± 0.5 corpora lutea, 11.3 ± 0.5 recovered embryos, and 6.8 ± 0.4 viable embryos per goat.[4]

Recently the use of estrogens at the time of progesterone implant insertion and removal have improved superovulation responses. The ovarian response in terms of number of corpora lutea has been shown to be correlated to the number of dominant follicles at the onset of gonadotropin treatment. A higher number of 2- to 6-mm follicles tended to be associated with a lower embryo recovery rate. Estrogens (such as estradiol benzoate, EB) have been shown in the bovine to induce regression of those dominant follicles, which are likely to be immature or in the process of atresia, followed by a synchronous follicular wave emergence (4–5 days after EB injection). This wave generally coincides with the time of the administration of the FSH treatment. Therefore, at the time of FSH injections a uniform cohort of follicles is recruited and no dominant follicles are present.[2,4,5]

When PMSG is used, a single injection 24 to 48 hours prior to implant removal is administered to the donor doe. Doses of PMSG range from 500 IU to 1500 IU, depending on breed, age, and size of doe and previous responses to treatment. One of the disadvantages of using PMSG is the tendency to produce persistent follicles that interfere with fertilization and overall embryo collection rates.[6]

It is important to note that there is a high variability in response rate to superovulatory treatments between animals, and factors such as follicular status, nutrition, lactation, seasonality, and management, among others, have an influence on the superovulatory response.

Estrus Detection and Breeding

Estrus is detected in donor does by observation of mating; in recipients estrus should be detected using vasectomized bucks or androgenized females. The time from beginning of estrus to ovulation in goats is approximately 32 to 36 hours. If laparoscopic artificial insemination is to be performed, does should be inseminated 12 and 24 hours after the animals were first seen in estrus or 45 to 50 hours after implant withdrawal.[7]

LAPAROSCOPIC INSEMINATION

Laparoscopic artificial insemination allows semen to be placed directly into the lumen of the uterine horns considerably closer to the site of ovum fertilization. High fertilization rates (80%)[8] can be achieved with this technique, compared with transcervical insemination (50%) using fresh diluted semen.[7]

The goat is secured in a laparoscopic cradle and is tilted head down at an angle of 40 degrees or more. Pneumoperitoneum is produced by introducing CO_2 through a Verres needle inserted transabdominally. This separates the abdominal wall from the viscera, clearing the field for manipulation of the reproductive tract. The trocar and cannula for the laparoscope (5–7 mm diameter) are inserted into the peritoneal cavity approximately 10 cm cranial to the udder and to the left of the midline. The secondary trocar and cannula (5 mm diameter) are inserted to the right of the midline. The laparoscope is inserted through the cannula and the uterus is located just cranial to the bladder. An assistant prepares the inseminating gun (IMV International Corp-USA, Minneapolis, MN) or pipette (glass) and hands it to the operator. The operator guides the tip of the inseminating gun toward one uterine horn. Care should be taken not to perforate any viscera with the sharp needle or tip of the inseminating device. While visualizing through the laparoscope, the site of insemination is selected along the major curvature of the uterine horn and the needle is stabbed through the myometrium and into the lumen in a perpendicular position (Fig. 83-1). Semen should be deposited with no resistance and no swelling of the uterine wall should be seen, indicating that the needle is correctly positioned in the lumen of the uterine horn. The inseminating gun is removed, and the operation is repeated on the other uterine horn. The instruments are removed and the abdominal wounds are sutured. In most cases the dose of semen contained in one straw (40–100 million motile sperm cells) is divided in both uterine horns. If fresh semen is being used, reports indicate that the effective dose is about 20×10^6 for laparoscopic AI, and 100×10^6 for cervical AI.[8]

Anesthesia: Animal and Equipment Preparation

Animals are taken off feed 18 to 24 hours prior to any surgical procedure. The animals are anesthetized with an anesthetic of choice. A review of commonly used anesthetic regimens is available.[9] In this author's laboratory, a combination of xylazine and ketamine (0.15 mg/kg xylazine and 3.6 mg/kg ketamine) is used intravenously to perform laparoscopic embryo transfer into recipients or for induction when gas anesthesia is used for embryo collection. When gas anesthesia is not available, a combination of xylazine and ketamine can be used alone (0.22 mg/kg xylazine and 5.5 mg/kg ketamine), with half the dose administered IV and half IM to maintain anesthesia during embryo collection. If necessary, animals can be re-dosed with 1.9 mg/kg ketamine IV. Because of profound effects of higher doses of xylazine (>0.15 mg/kg) on cardiovascular and respiratory parameters in sheep, it has been recommended that dosing in goats also be as conservative as possible.[9] The effects of xylazine can be reduced postoperatively by administration of an antagonist such as yohimbine (0.11 mg/kg IV). However, if ketamine levels are still elevated at this time, reversal of xylazine will result in tremors. A combination of tiletamine and zolazepam (Telazol, Fort Dodge Laboratories, Fort Dodge, IA) at a dosage of 5.5 mg/kg IV has been reported to provide at least 1 hour of anesthesia.[9] In our experience, when goats are elevated in a laparoscopic

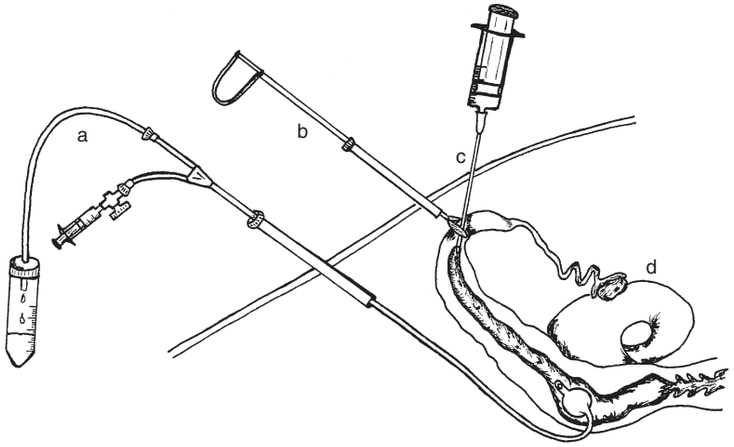

Fig. 83-1 Laparoscopic embryo collection in the goat. a, Ballooned Foley catheter and collection tube; b, laparoscopic atraumatic grasping forceps; c, intravenous catheter (18 gauge, $15^1/_2$ inches long); d, uterine horns.

cradle, a second dose of anesthetic is frequently needed within 30 minutes. In these cases, doses of 0.5 to 1 mg/kg are administered IV as needed.

The abdominal area cranial to the udder is shaved and aseptically prepared for laparotomy or laparoscopy. For the nonsurgical procedures, the perineal area is also aseptically prepared.

Laparoscopic and nonsurgical equipment can be soaked in disinfectant solutions. These solutions are spermicidal and embryotoxic, so instruments should be rinsed thoroughly with sterile water and shaken or otherwise dried prior to their use.

Embryo Collection

The first successful embryo collection and transfer in goats was reported by Warwick and associates.[10] Although their interest was in creating hybrids between goats and sheep, they reported the birth of a kid to a doe following surgical collection of a four-cell goat embryo and replacement of the embryo in the donor's reproductive tract. It was not until 30 years later that further reports on embryo transfer in goats appeared.[11]

In most instances, surgical procedures have been used for the recovery of embryos from goats. However, alternative techniques for collecting embryos from goats, such as laparoscopic and nonsurgical or transcervical embryo collection techniques, have been developed. The embryo collection technique to be used depends on the day that the embryos are to be collected. Embryos can be collected as early as day 1 after breeding, or as late as day 7 or 8 after breeding.[6,12–15]

Early luteal regression (ELR) has been reported in synchronized and superovulated goats.[16,17] Early luteal regression is characterized by small, white-pink corpora lutea and may occur in 10 to 32% of treated animals by the time of embryo collection (days 5–7 after breeding) or transfer. Embryo recovery rates from donor does with ELR are poor; there are observations that ELR can be reduced by administering a luteolysin inhibitor during the period between breeding and embryo collection. Also, progestins or progesterone administered during this period may help reduce the effect of ELR by keeping progesterone levels high during the early stages of embryo development (days 0–7). Another way to avoid embryo loss associated with ELR is to collect embryos on day 3 after breeding, before luteal regression occurs and embryos are expelled from the reproductive tract. Embryos are located in the oviducts at this stage; therefore, an oviductal flush is required.

Surgical Embryo Collection

Although there has been some progress in developing alternative methods for collecting embryos from small ruminants, goat embryos are most commonly harvested by surgical means.[14] This ensures high recovery rates, which can reach 100%. Animals are positioned in dorsal recumbency position with an inclination of 20 to 30 degrees with the head down. Three procedures involving laparotomy have been described for the collection of embryos, all of which involve exteriorization of the uterus through a midventral incision with or without examination of the ovaries to determine the response to superovulation treatment. This procedure should be carried out by skilled surgeons with attention to the principles of surgery; otherwise adhesions of the reproductive tract will develop.

In the first procedure, embryo flushing medium is injected into the uterine horn and expressed out through a fluted plastic catheter inserted into the oviduct through the fimbriated end. This technique can be used for collecting oviductal-stage embryos.[14] In the second procedure, the oviductal contents are flushed from the fimbria into the uterus and out of the uterus through a Foley catheter (size 8 Fr) inserted in the uterine horn near the bifurcation.[18] This technique can be used for collecting embryos at any stage. In the third procedure, the uterine horn is flushed from the tip near the uterotubal junction toward a Foley catheter (8 Fr) inserted in the uterine horn near the bifurcation.[12,19,20] This technique results in fewer adhesions because it eliminates the need to manipulate the oviduct, fimbria, and ovaries. However, the technique is limited to use 4 or more days after estrus, at which time the embryos will have reached the uterus.[21] Embryo collection rates using the surgical approach in goats average 85%.[12,20]

Although anecdotal reports of numerous repeated surgical collections from individual goats exist, several other reports have shown detrimental effects of repeated surgical embryo collections. These effects may be noticed as soon as the second embryo collection is performed in the form of adhesions to the reproductive tract if inadequate surgical procedures are followed during embryo collection.[22] This is a potential limiting factor for the use of embryo transfer for genetic improvement. Therefore, it is important that the surgeon minimize handling the reproductive tract, and once the uterus or part of the uterus is exteriorized, it should be continuously moistened using a soft mist of saline solution and antibiotics.

Laparoscopic Embryo Collection

Laparoscopy has been a useful tool in reproduction for small ruminants. Several researchers have applied this technique to investigate the role of ovarian function in the control of the reproductive cycle,[23,24] to determine the time of ovulation,[25,26] to perform artificial insemination,[27] and to collect and transfer embryos.[12,28,29] It has been reported that in goats the number of ova and embryos collected by laparoscopy compared with the number of corpora lutea (CL) (recovery rate) is approximately 15% lower than through surgery.[12] On the other hand, laparoscopic embryo collection can be repeated successfully on the same goat with few complications. It eliminates the need for exteriorization and manipulation of the reproductive tract and for suturing of the body wall. This prevents formation of postoperative adhesions. However, as mentioned earlier, the same surgical care should be emphasized during these procedures.

As an early alternative to laparotomy for the collection of uterine-stage embryos from sheep, a laparoscope was used to visualize the ovarian response and to exteriorize the tip of one uterine horn at a time through a small incision.[30] Flushing medium was introduced into the tips of the horns through an intravenous catheter and was collected through a glass vaginal speculum placed against the external os of the cervix into a glass recovery dish. This procedure yielded a 46% embryo recovery rate.

Very little research has been reported on the use of laparoscopic embryo collection and transfer in goats.[12,28,29] However, a great deal of laparoscopic embryo transfer research has been conducted in sheep[31] and these techniques are applicable in goats.[32] The donor animal is positioned in the laparoscopic cradle, and pneumoperitoneum is created. The primary trocar and cannula are inserted into the peritoneal cavity approximately 10 cm cranial to the udder and 2 to 3 cm to the left of the midline. Care should be taken to avoid major vessels under the skin and internal organs. The secondary trocar and cannula (5 mm diameter) are inserted to the right of the midline. The laparoscope (5–7 mm diameter) is inserted through the primary cannula and the uterus is located just cranial to the bladder. In some cases, the omentum or visceral fat may obscure the uterus. These can be pushed cranially with a manipulating rod placed through the secondary cannula. Once the uterus is located and the ovulation points counted and evaluated, a third cannula (5 mm in diameter) is inserted on the midline 2 cm cranial to the others. Through this third cannula, a long blunted paravertebral needle (12 gauge, 25 cm long) is used to make a puncture wound in the uterine wall cranial to the bifurcation of the uterus, which is secured through the second cannula with atraumatic laparoscopic forceps. This allows the insertion of a balloon Foley catheter with stylet through the small puncture into the uterine lumen. The balloon on the catheter is inflated and the stylet removed. The uterus is secured by the inflated balloon.

If a three-way catheter is used, atraumatic grasping forceps must be used to block the uterotubal junction to prevent flow of the medium and embryos toward the oviduct. The flushing medium is introduced through the catheter and into the uterine horn by means of an inner extendable tube that reaches the uterotubal junction. Return of the flushing medium is initiated by pressure and gravity. Each horn is flushed with 30 ml of medium, and 79% embryo recovery rates have been achieved.[12]

If a two-way catheter is used (Fig. 83-2), the tip of the uterine horn is secured with atraumatic forceps and cannulated using an intravenous catheter (18 gauge, $5^1/_2$ inches long). After the stylet is removed, a collection medium (60 ml) is introduced through the intravenous catheter and collected through the Foley catheter. The procedure is repeated for the other horn, the instruments

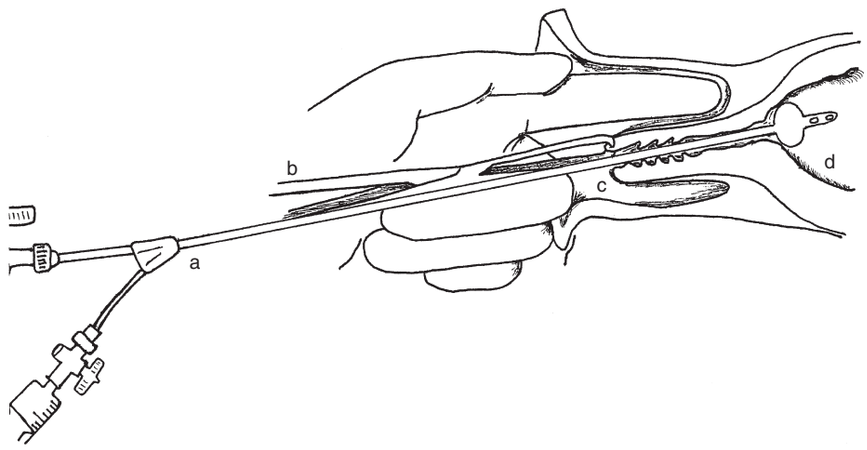

Fig. 83-2 Nonsurgical embryo collection in the goat. a, Flushing catheter; b, Allis tissue forceps; c, vagina; d, uterine body. (From Kraemer DC: *Theriogenology* 1989;31:141.)

are removed, and the abdominal incisions are closed. With this technique collection rates range from 50% to 80%.[29,31]

A postoperative problem could be encountered when a large Foley catheter (>12 Fr) is used. The wound in the uterine wall is usually not sutured; consequently, the endometrium occasionally grows out through the puncture wound to the serosal surface (personal observations). This could interfere with the female's reproductive health. In general, this technique requires considerable practice and skill and has not become the method favored by most practitioners.

Nonsurgical (Transcervical) Embryo Collection

Nonsurgical (transcervical) embryo collection techniques avoid the formation of postsurgical adhesions and maintain the value of genetically superior donors following multiple embryo collections. Moore stated that nonsurgical embryo collection procedures, as used in the cow, would appear difficult owing to the narrow and tortuous nature of the cervical canal of ewes and does.[33]

Nevertheless, reports of successful nonsurgical embryo collection in goats have been published.[34–37] These groups obtained embryos at the blastocyst stage by priming the cervix with a combination of prostaglandins E_2 and estradiol,[38] dilating the cervix prior to flushing with a *Laminaria japonica* tent or mechanically using an oral probe designed for use in rats. The tents were inserted into the cervical canal for 6 to 12 hours and held in place by packing of the cranial vagina with gauze. The flushing procedures were performed in standing animals with a variety of catheters such as a modified two-way 24-gauge Foley catheter through which a stainless steel tube (50 cm long, 1.5 mm inner diameter) was inserted. A Sovereign catheter (5 Fr) was inserted through the stainless steel tube to introduce the medium. Other flushing cannulas were based on the model of the two-way catheter that was developed for use in cattle.[35] The cannula was a concentric double tube with a metallic inner tube (Cathelin needle) for inflow of flushing medium and a polyethylene outer tube for outflow. Using this catheter, the practitioner flushed each uterine horn individually by pulling the catheter back into the uterine body prior to reinsertion into the other horn. Some of the problems encountered during these procedures were the incomplete passage of the cannula through the cervical lumen and the puncture of the uterine wall with the flushing device. Embryo recovery rates were 89.5% for 15 females (34/38 CL), but the collection rate among all the subject animals was not very high.

A method for catheterizing the sheep cervix and collecting embryos nonsurgically without the aid of a cervical dilator was developed by Coonrod and associates.[39] This procedure has been adapted for use in goats.[29,40,41] Animals are tranquilized or anesthetized and positioned in dorsal recumbency. The cervix is visualized using a vaginal speculum and a strong light. A section of the external cervical os is grasped with long Allis tissue forceps. The forceps and the cervix are retracted into the vagina. A catheter (e.g., Verres needle, section of urinary catheter size 8 or 10 Fr with stylet, Ott catheter size 8 Fr) is placed into the external os of the cervix as far in as possible. The vaginal speculum is removed and the index finger of a gloved hand is inserted into the vagina alongside the retracted cervix. The finger is used to guide the catheter through the cervix. Once the catheter is in the body of the uterus or in one of the horns, the stylet is removed and the balloon filled (when catheters with balloon are used) (Fig. 83-3). The tubing for inflow and outflow is connected to the catheter by means of a three-way stopcock, and small amounts of medium (5–10 ml) are introduced at each flush to keep the pressure low and minimize fluid leakage. The catheters without balloons are moved slightly in and out to induce return of fluid. Massaging the abdominal area toward the pelvic cavity helps to recover the flushing medium. The return medium is collected in an embryo filter via the outflow tubing. A novel approach for improving the practicability of the nonsurgical method for embryo collection in goats is the administration of a luteolytic dose of $PGF_{2\alpha}$ 8, 16, or 24 hours before flushing. This procedure will decrease the plasma progesterone concentration and luteolysis and will promote uterine contractility in response to infusion of the flushing medium, increasing from 43% to 80% embryo recovery rates.[36,37]

A combination of a laparoscopic/cervical technique can be carried out. The cervix of a multiparous goat is catheterized with a Foley catheter and the balloon is inflated to secure the catheter and prevent flushing medium from leaking between the cervix and the catheter. Medium is injected under laparoscopic visualization into the tip of each uterine horn collecting the medium via the Foley catheter.[32]

Embryo Handling

Flushing medium consists of a solution of phosphate buffered saline to which 10% newborn calf serum (NBCS) and penicillin-streptomycin are added. Embryos are flushed and maintained in this medium throughout the procedure. Following embryo collection, the embryo filter is taken to the laboratory and the contents are poured into a square grid dish while being rinsed thoroughly using a 30-ml all plastic syringe (AIR-TITE, Virginia Beach, VA) containing flushing medium. The embryos are retrieved from the searching dish with an embryo pipette, washed in clean medium, and placed in a sterile two- or four-well covered dish that contains holding medium (phosphate buffered saline + 30% newborn calf serum + antibiotics).

Embryos are carefully examined under a dissecting microscope and an assessment of stage of development and quality is performed. The quality grade is an indication of predicted survivability of the embryo. One of the most common grading systems consists of four categories (grades 1, 2, 3, and degenerate). Grade 1 indicates that the embryo is nearly perfect with more than 98% of the cell mass active and healthy; grade 2 indicates that 70% to 98% of the cell mass is active and healthy and some extruded blastomeres are found; grade 3 indicates a poor quality embryo with less than 70% of the cell mass active and healthy, and several extruded blastomeres are present; degenerate indicates that none of the cell mass appears active and most of the membranes are broken down. Figure 83-4 depicts the different developmental stages of goat embryos.

Embryo Freezing

Embryo freezing or cryopreservation permits the long-term storage of valuable genetics. Embryos can be cryopreserved using conventional freezing[42] or vitrification techniques.[43] Conventional freezing techniques involve the exposure of goat embryos to concentrations of approximately 10% glycerol or ethylene glycol for equilibration. Subsequent exposure to controlled cooling with a computerized embryo freezing unit containing an alcohol bath, and then immersion in liquid nitrogen for storage. Puls-Kleingeld and associates cryopreserved goat embryos by using phosphate buffered saline + 20% heat-inactivated goat serum + 1.4 M glycerol as the freezing medium, and compared the one-step (1.4 M glycerol) and the three-step (0.47, 0.94, and 1.40 M glycerol) equilibration methods.[44] Reports indicated that blastocysts cryopreserved better than morulae, and the one-step technique yielded better results than the three-step procedure (45% versus 19% embryo survival rates, respectively). Vitrification involves (a) exposure of embryos to high concentration of cryoprotectants (20–25% ethylene glycol or glycerol and 20–25% dimethyl sulfoxide or propanediol), (b) loading the embryo in a thinned (pulled to approximately half the original diameter) 0.25-ml straw by capillary action, (c) followed by direct immersion in liquid nitrogen in a vertical position with the thinnest end of the straw first.[42] Vitrification avoids ice crystal formation during the cryopreservation process. The faster cooling rates reduce toxicity of the cryoprotectant and circumvent the chilling sensitivity of embryos. As a result of these advantages, goat embryos have been successfully vitrified[45] with an overall embryo survival rate of 64% (18/28) compared to 42% (10/24) for conventional frozen embryos.[36] Vitrification does not require special equipment; therefore, it may be very well adapted to routine field use with goats.

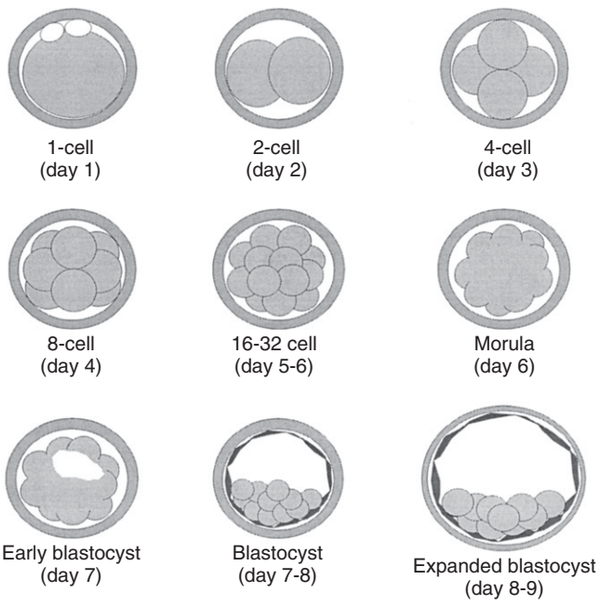

Fig. 83-4 Developmental stages of goat embryos.

Transfer of Embryos

Transfer of embryos can be achieved surgically, laparoscopically, or nonsurgically to recipients that are detected in estrus at the same time as the donor doe, plus or minus 24 hours.[12] Synchrony of donors and recipients is one of the most important factors in the success of an embryo transfer program.

The number of embryos transferred per recipient is correlated with the survival of embryos. Studies indicate that there is a significant improvement when two embryos rather than one or three are transferred. Survival of embryos was also higher when unilateral transfer of both embryos was performed. The possible explanation is that there may be synergy between embryos in influencing each other's survival.[46]

Surgical Embryo Transfer

In most embryo transfer work with goats, surgical procedures similar to those described for sheep have been used. The reproductive tract is approached through midventral laparotomy and exteriorized to allow visual confirmation of a CL prior to transfer of the embryos. Embryos are transferred to the oviducts via the fimbria using a tomcat catheter, Drummond pipette, or Pasteur pipette, if embryos are in the early stages of development (<day 4). Older embryos (>day 4) are transferred to the uterine horns using a Pasteur pipette or tomcat catheter through

a small stab wound made with a rounded needle or with the eye of a suture needle.[12,21]

Laparoscopic Embryo Transfer

Laparoscopic techniques for transferring embryos to a predesignated site within the uterine horn of recipients were developed in sheep.[47,48] The feasibility and efficiency of this technique have been demonstrated in goats.[28,29,49]

Recipient animals are placed in a cradle angled to 40 degrees with the head down. Pneumoperitoneum is produced by introducing CO_2 through a Verres needle inserted transabdominally. Two stab wounds are made in the abdominal wall, each 2 to 3 cm from the midline and approximately 10 cm cranial to the udder. One is for insertion of the laparoscope and the other for insertion of the laparoscopic grasping forceps. Using the grasping forceps, the terminal one half of the uterine horn ipsilateral to the CL is secured. Embryos designated for transfer are drawn into a 3.5-cm Fr tomcat catheter attached to a 1-ml syringe. For cannulation of the uterine horn, a 16-gauge 5.5-cm long Teflon catheter is inserted through the abdominal wall at the site directly ventral to the secured horn. The catheter is gently inserted into the uterine horn and upon penetrating the lumen, the stylet is withdrawn. The catheter is considered intraluminal when it is passed 2 cm and can be manipulated back and forth freely. The Teflon catheter is removed and the tomcat catheter containing the embryos is guided through the cannula and into the lumen of the uterus (Fig. 83-5). After the catheter can be freely maneuvered, the embryos are slowly expelled. The instruments are withdrawn and the incision sites on the abdominal wall sutured.

An alternative technique uses the laparoscope for visualization of the ovulation site on the ovaries, and with the aid of Babcock forceps, a loop of the terminal half of the uterine horn ipsilateral to the CL is grasped and exteriorized through a 2-cm abdominal incision approximately 2 cm from the linea alba (in place of the secondary trocar cannula). Once the section of uterine horn is outside the abdominal wall, a puncture wound is made through the uterine wall with a rounded needle (16 gauge). Through the same perforation, a tomcat catheter containing the embryos is introduced into the uterine lumen approximately 2.5 cm toward the uterine body, and the embryos are deposited.

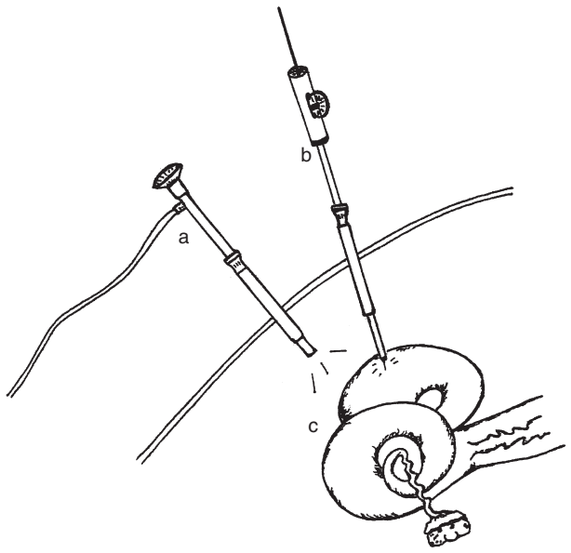

Fig. 83-5 Laparoscopic artificial insemination in the goat. a, Laparoscope; b, laparoscopic inseminating gun; c, uterine horns.

Nonsurgical Embryo Transfer

In small ruminants, manipulation of the genital tract per rectum is not possible. Nevertheless, nonsurgical embryo transfer has been successfully performed in goats by catheterizing the cervix and manipulating the genital tract in a different way.[29,50] The earliest study in goats of a nonsurgical technique to transfer embryos was performed by Otsuki and Soma.[11] With the hypothesis that stimulation of the cervix and consequent release of oxytocin was one of the reasons for failure to obtain pregnancies from nonsurgical embryo transfer, they administered hyoscine-*n*-butylbromide or cocaine hydrochloride prior to transfer in an effort to block parasympathetic nerve transmission from cervical stimulation. The instrument used to transfer the embryos consisted of metal tubes, a polyethylene tube, a 1-ml syringe, cervical forceps, and a vaginal speculum. In the control group (no treatment, $n = 11$), zero pregnancies were obtained; in the group treated with 1% to 2% cocaine hydrochloride as a local anesthetic ($n = 5$), zero pregnancies were obtained; and in the group treated with a subcutaneous injection of 0.02 to 0.03 mg of hyoscine-*n*-butylbromide ($n = 7$), ova implantation succeeded in one case and a female kid was born. In five cases, prolongation of the estrous cycle to 29 to 39 days suggested temporary implantation of the transferred ova.

Another study in which no nerve block was attempted resulted in successful nonsurgical embryo transfer in Taiwan goats using a 16-gauge, 7.5-cm catheter and cervical manipulation.[50] The cervix was catheterized by introduction of the left index finger of a gloved hand into the vagina to manipulate the ventral surface of the cervix and guide the catheter into the uterus. This technique resulted in five of eight females pregnant, and produced a total of six fetuses. The authors believed that the short length and rigidity of the catheter plus manipulation of the cervix made the procedure very easy and contributed to its usefulness. Pregnancy rates of approximately 40% after nonsurgical embryo transfer have been reported in which the cervix of recipient goats was catheterized with an intravenous catheter (14 gauge, 14 cm long; Abbott Hospitals, Inc., North Chicago, IL), which has a modified rounded smooth stylet to stiffen the catheter.[29,51] During cervical catheterization, embryos are loaded in an intramedic tubing (17 cm long, 0.76 mm inner diameter; 1.22 mm outer diameter) connected to an 18-gauge needle attached to a 1-ml syringe. Once the cervix is catheterized, the intramedic tube containing the embryos is passed through the catheter and into the uterus. The practitioner expresses the embryos into the uterus by gently pushing the plunger of the syringe.[29]

FOLLICLE ASPIRATION

In vitro produced embryos can originate from oocytes collected from postmortem ovaries or from live donors by follicle aspiration. Compared with oocytes from postmortem ovaries, oocytes aspirated from live animals are of known health status, which could be of vital importance for the production of transgenic animals.[52] Bovine oocytes are commonly collected by ultrasound-guided transvaginal "ovum pick up" (OPU). In small ruminants, oocytes from live animals are obtained by laparotomy[53] or by laparoscopy,[54] but there are reports in goats in which ultrasound-guided transvaginal oocyte aspiration were performed. In this experiment, goats were subjected to either a laparoscopic aspiration or a transvaginal ultrasound-guided aspiration, and results demonstrate a similar percentage of oocyte recoveries (71 versus 68%, respectively).[55,56] Follicle aspiration by laparoscopy is simple and allows the repeated production of IVF (in vitro fertilization) or NT (nuclear transfer) embryos from live donors of particular value with or without the need of superovulation. However, repeated laparoscopic aspirations may lead to adhesions in the oocyte donor does and the techniques demand great skill.[55] Oocyte retrieval after laparoscopic aspiration from unstimulated goats provides 4 to 6 good oocytes per female.[57] Gonadotropin treatments of a multi-injection (133 mg NIH-FSH of Folltropin-V) or a single injection regimen (80 NIH-FSH of Folltropin-V and 300 IU eCG) for stimulation of oocyte donors have also been used and similar numbers of oocytes have been obtained (12.7 ± 5.6 versus 10.0 ± 5.7 oocytes, respectively).[52]

For laparoscopic follicle aspirations, animals are placed in a standard laparoscopic position and under general anesthesia. Pneumoperitoneum is produced by introducing CO_2 through a Verres needle inserted transabdominally. Two stab wounds are made in the abdominal wall, each 2 to 3 cm from the midline and approximately 10 cm cranial to the udder, one for the insertion of the laparoscope and the other for the atraumatic forceps. Under laparoscopic observation, a short beveled 20-gauge 2-inch long paravertebral needle is passed through the abdominal wall to aspirate the follicles on the surface of the ovaries while the ovary is secured at the mesovarium by the atraumatic forceps. The needle is connected to a collection tube containing Tyrodes lactate HEPES medium, 100 µg penicillin, 100 mg streptomycin, and 2500 units of heparin for every 100 ml of medium, and via Teflon tubing, to a vacuum pump (25 to 50 mm Hg).

The growing interest in the production of embryos from prepubertal animals (3 to 5 months of age) has encouraged numerous researchers to investigate the developmental competence of oocytes from prepubertal females.[58–60] Results have shown that oocytes from prepubertal goats are capable of undergoing IVM, IVF, and developing to the blastocyst stage in culture at rates similar to those of oocytes from adult goat ovaries.[59,61] Baldessarre and associates reported acceptable pregnancy rates from oocytes aspirated from prepubertal goats following IVM-IVF.[52] This offers a useful tool for fundamental research and a way to shorten the generation interval.[62]

IN VITRO MATURATION AND FERTILIZATION

The first goat kid produced by in vitro fertilization of ovulated matured oocytes was produced by Hanada.[63] In vitro maturation (IVM) and fertilization (IVF) in goats have resulted in several kids. In vitro embryo production requires precise methodologies to successfully produce transferable embryos and subsequent pregnancies. The process includes oocyte maturation, sperm preparation, fertilization, and culture. Each of these must be developed individually and then combined into an integrated program. IVF offers the advantage of producing embryos from animals when production of embryos in vivo is difficult or impossible. In addition, efficient IVM and IVF procedures are important for the development of other biotechnologies such as embryo splitting, sexing, nuclear transfer, and gene transfer. Oocytes for IVM and IVF may be of postmortem origin or from follicle aspiration from the ovaries of live animals. Ovaries collected post mortem (untreated females) provide an abundant source of oocytes at low cost. Ovaries can be minced or follicles can be aspirated in the laboratory to obtain the oocytes. Cumulus-surrounded oocytes and homogeneous ooplasm recovered from 2- to 5-mm follicles are washed in TALP-HEPES (Sigma) twice and then incubated in M199 (Earle's salts) supplemented with 20% goat serum plus 4 µg/ml FSH and 4 µg/ml LH for 24 hours in a 5% CO_2 atmosphere at 39° C. Maturation rates of approximately 90% have been obtained in goats.[66]

In vitro fertilization is commonly performed with frozen-thawed spermatozoa. The frozen-thawed sample is subjected to one of two methods for separating live-dead cells: (a) Percoll density-gradient centrifugation and (b) swim-up in sperm-Tyrode's lactate at 37° C. The Percoll method yields a greater number of motile sperm after a 25-minute process when compared to the swim-up method, which is a 2-hour process. As the motile sperm cells swim up in the medium, the supernatants are collected and motile spermatozoa are recovered.

Regardless of the sperm separation method, the concentration is measured with a hemocytometer and, if needed, sperm are diluted to the final concentration of 1×10^6 cells/ml.[66] One of the most important components of the procedure is thought to be capacitation of the spermatozoa.[67] Heparin is commonly added to the fertilization medium to capacitate the sperm cells, which leads to acrosome reaction and will enhance fertilization rates. However, the quality of the embryos produced when heparin is added to the IVF medium is questionable. Embryo survival rates demonstrate higher percentage of viable kids when capacitation is induced with heat-inactivated estrous serum than with heparin (61% versus 25%).[66,68] An average of 70% normally fertilized goat oocytes can be routinely obtained in vitro, indicated by the presence of both the male and female pronuclei or by cleaved ova within 48 hours of culture.[69] The incidence of polyspermy in goat oocytes has been reported to be relatively high following IVM-IVF, affecting nearly 20% of the fertilized oocytes.[66]

Progress in the culture of IVF goat embryos has been made: domestic chicken eggs have been used to culture

in vivo collected goat embryos to the blastocyst stage,[70] and more recently, coculture systems with oviduct epithelial cells have been used successfully to produce blastocysts and live offspring following embryo transfer.[59,71,72] Several researchers have successfully used synthetic oviductal fluid to culture goat IVM-IVF embryos and obtained live offspring (61% resulted in live kids) after transfer of blastocysts.[73,74]

MICROMANIPULATION OF OVA AND EMBRYOS

Intracytoplasmic Sperm Injection

The process of assisted fertilization by intracytoplasmic sperm injection (ICSI) has been used in human fertilization clinics for treatment of male infertility. In farm animals, ICSI has been used to study methods to overcome problems encountered during IVF, such as sperm capacitation and poor or nonmotile sperm. Studies indicate that fertilization by sperm injection varies between species; therefore, further studies are required to establish protocols for sperm treatment and oocyte activation in the goat. Following ICSI in goats using IVM oocytes, embryos have been produced that successfully developed to the blastocyst stage.[75]

Embryo Splitting

Early attempts to produce identical animals were based on embryo splitting. Embryo splitting produces monozygotic twin individuals, which offer various possibilities for experimentation and production traits studies. A few reports on the splitting and transfer of goat embryos demonstrate the feasibility of this technology.[76,77] Briefly, while viewing under a microscope (75×), a glass suction micropipette is used to hold the embryo, and the zona pellucida (ZP) is opened with a finely drawn glass needle. The embryo is surgically dissected with a glass knife into halves or embryo parts. One of the halves is left in the original ZP and the other half is placed into an empty ZP. "Half" embryos, or demi-embryos, can be cultured, transferred immediately to synchronized recipients, or frozen.[78,79] Pregnancy rates of 36% have been obtained after transferring two goat fresh demi-embryos each to 11 recipients.[76] Goat embryos seem to be very sensitive to micromanipulation compared to other livestock embryos, and to increase demi-embryo survival rates, micromanipulation techniques need to be improved. Cells in the morula stage are loosely associated; thus, manipulations cause the disintegration of most embryos. Tsonuda and associates demonstrated that hatched blastocysts were most suitable for goat embryo bisection.[77] Demi-embryos have been frozen inside a zona pellucida or without a zona pellucida and results following embryo transfer demonstrate a lower kidding rate from demi-embryos frozen without a zona pellucida.[79]

Nuclear Transfer (Cloning)

This technique is applied for the production of genetically identical animals. Early work in nuclear transfer involved the use of totipotent blastomeres and inner cell mass cells from early embryos to create identical animals.[80,81] In the goat, normal identical kids have been produced by transferring blastomeres from a 4- to 32-cell embryo into an enucleated mature oocyte.[82] It was not until Dolly's birth[83] that adult somatic cells were successfully used by different laboratories to produce cloned offspring.[84–87] The first cloned goats by somatic cell nuclear transfer were produced by Baguishi in 1999.[85] Nuclear transfer involves the production of enucleated oocytes, called a cytoplast, that serves as sufficient medium to reprogram and express the genetic heritage of the donor nucleus. Oocytes in metaphase II from in vivo or in vitro sources are used for this purpose. Enucleation involves the removal of the metaphase spindle with its associated maternal chromosomes from the mature unfertilized oocyte. This procedure is usually performed with the aid of a DNA-specific fluorochrome, which allows visualization of the chromatin and confirmation of successful removal under ultraviolet light.[88] Commonly an intact donor cell is injected into the perivitelline space of the enucleated oocyte and their membranes electrofused. An alternate technique involves the direct injection of the isolated nucleus into the enucleated cytoplasm.[89,90] In goats, both skin fibroblasts and cumulus-granulosa cells have been used successfully as donor cells.[91,92] The transferred nucleus goes through various changes characterized by remodeling of the nucleus, which presumably results in reprogramming of the transferred nucleus so that it behaves developmentally as if it were a one-cell zygote.[93] Although embryonic development can be activated by the electrofusion step in some species, it is common to chemically activate the oocytes with a combination of an ionophore and a protein kinase inhibitor. The successfully fused and activated cells are placed in culture or are transferred into a synchronized recipient immediately.

In the context of animal husbandry, reproductive cloning can be applied to rapidly upgrade the quality of a flock by cloning an animal noted for its exceptional production traits; it can also be applied to reproduce an animal that cannot reproduce naturally nor by assisted reproduction (i.e., castrated, ovariohysterectomized) or deceased animals. To apply this technology, a skin biopsy is taken from the animal to be cloned, the cells are grown in tissue culture flasks in an incubator and when the cells reproduce in vitro and form a monolayer, they are usually trypsinized and passaged several times to produce around 10 million cells, which are then cryobanked using cryoprotectants such as dimethyl sulfoxide. It is of great importance that tissue banking is performed from exceptional animals when they are alive. In case of an unexpected death, the carcass should be cooled to 4°C as soon as possible and tissue samples collected and cultured as discussed previously.

Embryo Sexing

Methods to determine the sex of embryos before transfer have traditionally focused on cytologic techniques[94] or the use of antibodies to male-specific antigens such as the H-Y antigen.[95] Now molecular procedures such as poly-

merase chain reaction (PCR) also offer opportunities for embryo sexing.[96] Removal of a few cells from preimplantation embryo is necessary. Amplification of single copy genes (sex-specific sequences) in small samples such as embryonic cells is performed by PCR, with subsequent visualization of these sequences on agarose or polyacrylamide gels. This technique has been applied in goats to amplify these sequences from male and female genomic DNA to identify the sex.[97]

Gene Transfer

The dramatic advances in molecular biology and the development of new technologies like gene transfer have provided a potential tool for genetic improvement of domestic animals. The process of gene transfer adds specific genes to existing animal breeds to enhance production characteristics or to produce pharmaceutical products from milk of goats expressing the transgene in their mammary gland. One of the methods successfully applied in goat studies for incorporation of specific genes into embryos is accomplished by microinjection of the recombinant DNA into the pronuclei of recently fertilized eggs, followed by embryo transfer into synchronized recipients.[98] Between 500 and 1000 copies of the genes are injected into the male pronucleus. After the injection, embryos are either cultured or transferred directly to the recipient goat. The rates of incorporation of the foreign DNA and the survivability of injected goat embryos is low, with only 1% of injected embryos resulting in transgenic goats.[98,99] A more predictable method is by transfection of a cell line followed by nuclear transfer. The donor cells that produced the first cloned goats by somatic cell NT were derived from a transgenic fetus.[85,87]

Dairy goats have been used to produce a commercial prototype for large-scale manufacture of high market-volume proteins in their transgenic mammary gland. To achieve protein expression, a human gene controlled by milk protein promoter sequences is inserted into the surrogate embryos (goat) and when the resultant transgenic animals begin to lactate, they secrete the human protein in their milk. The protein is then purified from milk. Several specific reasons were considered in choosing goats: (1) They produce large volumes of milk; (2) they have short gestation and developmental periods; and (3) the biochemical features of goat milk have been extensively characterized. One of the therapeutic proteins expressed by transgenic goats in their milk has been a longer-acting tissue plasminogen activator protein, which has a tremendous pharmaceutical value to cardiac patients.[99] Incorporation, expression, and transmission of the foreign gene in domestic animals occurs at low frequencies; therefore, extensive research continues.

Marker-Assisted Selection

Increasingly today DNA technology has been advancing to identify genetically important traits. Utilizing genetic markers, some traits like disease resistance or growth and carcass performance, can be screened in individual animals and flocks to identify and perpetuate those animals with economically beneficial characteristics. Also animals carrying an undesirable trait can be screened and eliminated for a more profitable goat industry.[100] Marker-assisted selection incorporated with AI, ET, and cloning technologies are expected to accelerate the production of animals that exhibit desirable traits.

The techniques for isolating DNA can be used for screening embryos, semen, blood, and tissue banked cell lines. Therefore, tissue banking from individual animals will allow for the possibility to screen for genetic markers and evaluate past, present, and future production performances.

CHAPTER 84

Reproductive Physiology of the Ram

JIM FITZGERALD and GREGOR MORGAN

An understanding of basic ram reproductive physiology forms the foundation to the designing of practical approaches to management of a breeding program and improved reproductive efficiency. In addition, this knowledge has the potential to improve our ability to advance flock genetics through indirect selection for reproductive merit.

ORGANIZATION OF THE REPRODUCTIVE SYSTEM

The cryptorchid condition can be used to illustrate some important concepts about the developmental organization of primary and secondary sex organs and reproductive development in the ram. Histologically, seminiferous tubules of cryptorchid testes are juvenile in appearance and devoid of germ cells[1]; however, despite the fact that these rams are sterile, few differences in other male traits occur. Growth rate, male-type body and carcass characteristics, and the accessory sex glands are little affected. A similar situation is seen in rams with short scrotums who, although usually sterile, nonetheless reach normal physical maturity.

The cryptorchid and short scrotum conditions can be used to gain information about male reproductive development. First, reproductive competence and fertility in rams depend on migration of the testes to the scrotum at birth. The scrotum is where the testes reach full maturation and where spermatozoa acquire fertilizing potential. In hot humid areas such as the southwestern desert in the United States, the scrotum affords some protection against the deleterious effects of heat, although even with this efficient cooling mechanism, temperature-induced sterility is often a problem. Although scrotal descent is essential for fertile sperm production, it is not needed for all endocrine functions of the testes. Testes formed during in utero development are fully capable of secreting androgens.[2] It is this organizational effect of androgen, occurring 30 to 40 days after conception,[3] that directs differentiation of the reproductive tract toward the male system.

The hormone inhibin, which is produced by Sertoli cells within the seminiferous tubules, is lost together with the germinal epithelium in the cryptorchid state. However, the androgen-producing cells (Leydig cells) continue to have the capacity to secrete. Androgen secretion throughout the juvenile period of the ram lamb stimulates growth and maturation in cryptorchid or normal rams.

During gestation, sexual organization of neural tissue occurs under the direction of the testes. Among the many neural systems undergoing profound changes, two are critical. The first involves development of the hypothalamus, which produces and secretes gonadotropin-releasing hormone (GnRH). The second is the development of brain regions involved with sexual behavior.

Gonadotropin-releasing hormone plays a pivotal role in male reproduction, directing the secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the anterior pituitary gland, and ultimately affecting testicular function. Although marked gender differences are observed in the secretion of LH, and presumably of GnRH,[4] no differences in neuroanatomy (number or appearance of GnRH neurons) have been found between male and female sheep.[5] This suggests that androgens in utero alter the secretory capacity of the GnRH neuronal network and thereby establish distinct male and female patterns of release.

Fetal testicular androgen secreted during early development organizes hypothalamic and extrahypothalamic neurons involved with the expression of sexual behavior in the adult ram. Masculinization, or the ability to express male sexual behavior, is established in utero between days 20 to 80 of gestation.[3] Androgens given to pregnant ewes by mid-gestation masculinize female offspring. As adults, such ewes not only fail to show typical estrous behavior and ovulate, but display courtship and mounting behavior typical of rams.

ACTIVATION OF THE REPRODUCTIVE SYSTEM

The appearance of spermatozoa and the onset of mating behavior that herald the initiation of puberty in rams usually occur at 5 to 6 months of age, depending somewhat on breed and season of birth.[6] Spring-born rams from temperate climates show a gradual increase in testicular size that parallels changes in growth rate with a more rapid phase of testicular growth occurring in the fall. Changes in GnRH-induced LH secretion drive the final maturation of the testes, including stimulation of testosterone secretion. Onset of mating activity is synchronized by changes in steroids. The rise in LH secretion that occurs during the peripubertal period is likely caused by (1) a steroid-independent drive of hypothalamic GnRH secretion and (2) a change in feedback inhibition of testosterone on the GnRH/LH axis.[7]

The importance of GnRH and LH to drive events that lead to puberty is further shown by differences in age at which inadequately nourished rams reach sexual maturity,[8] because low planes of nutrition are associated with inadequate increments in LH release.

Seasonality

Testicular size, semen quality, mating behavior, and wool growth change during the year in rams in temperate climates. Photoperiod is the primary cue that regulates this annual rhythm. Two mechanisms have been identified that explain these cycles. The first involves an inherent, steroid-independent mechanism of GnRH secretion. During transitions from long to short days, the hypothalamus becomes more active in the secretion of GnRH, stimulating secretion of LH and FSH from the pituitary. Under the influence of increasing gonadotropin levels, a cascade of events occurs, including growth of the testes, stimulation of sperm production, and increased mating behavior. The regulation of GnRH and subsequent gonadotropin secretion depends on the negative feedback effects of androgen (testosterone) from the testes. During transition periods into and out of breeding seasons, testosterone varies in its effectiveness as an inhibitory hormone to GnRH and gonadotropin secretion. Melatonin is responsible for the seasonal change in testosterone feedback sensitivity and, ultimately, gonadotropin stimulation of the testes. It is secreted from the pineal gland during the dark portion of the photoperiodic cycle. During the shorter days of the fall season, blood melatonin concentration is elevated for a longer portion of the day. The melatonin and GnRH axis has evolved as an effective system to translate the environmental effect of season. This has ensured that under natural conditions mating occurs in the fall, and lambs are born at a favorable time of year.

Sexual Behavior

The activation of mating behavior in rams occurs at puberty, thereafter occurring seasonally in the mature adult. Ram lambs castrated at birth rarely show onset of courtship behaviors because of the absence of testosterone. Replacement of testosterone in a castrated male will elicit onset of sexual behavior and, at the appropriate threshold dose, copulation. Proficiency in courtship and mating has learned components that can be observed when lambs are weaned. Ram lambs frequently mount other males when they are put in all-male groups (an important consideration for disease transmission). Rams that are reared with females can achieve an earlier onset of mating activity. The frequency of various courtship behaviors varies by season of the year, occurring less frequently and less intensely in periods that are typical of anestrus in ewes. The seasonal changes that occur in mating behavior should not be confused with situations in which rams fail to perform sexually. Sexual performance is highly variable among rams, irrespective of season. Both sexual inactivity and homosexual behavior have been described, and approach an incidence of 10% to 20% in populations of rams.[9] In a series of studies designed to elucidate physiologic correlates to these abnormal behaviors, differences in gonadotropin secretion and receptors in the brain for estradiol were found.[10–12]

BEHAVIOR

Rams have characteristic courtship patterns that precede mating. Typically a ram approaches a ewe in a low stretch position with the head angled to the side. Often the ram contacts the flank of the female, kicks out a foreleg, and sniffs the vulva. After contact by the ram, the ewe often urinates. The ram sniffs both the vulva and urine, and the flehmen response usually occurs in which the ram arches the head upwards and with an open jaw draws odors rapidly over the nasal passage and turbinates. The flehmen response is believed to facilitate the detection of estrus. Some rams will mount several times before ejaculating, and others may service a ewe during the first mount. Furthermore, sexually inexperienced rams or ram lambs often have orientation problems with respect to mounting behavior. Young rams are typically subordinate to more experienced rams and the dominance order can affect the efficiency of multiple-sire mating. At least three rams per multi-sire pen are recommended to lessen dominance effects. Within a group of ewes, rams also show some preference for certain females while ignoring others in estrus and this accounts for some differences in the distribution of lambing.

SPERMATOGENESIS

The spermatogenic cycle takes approximately 6 weeks in mature rams. Stem cells are the precursor stage, and not all stem cells start the cycle at the same time; rather, cell division of groups of cohort cells occurs every few days, thus ensuring a continuous flow in sperm production. Although sperm appear normal when they arrive within the seminiferous tubules after commencing their journey 6 weeks earlier, they are not fully mature. During their passage from the seminiferous tubule to the epididymis, which takes about 2 weeks, changes occur that render the sperm fully fertile. Heat stress or other environmental effects that interrupt the flow of cells can cause a ram to be temporarily sterile. It can take up to 6 weeks, or one full cycle, for a ram to recover. Sperm production is related to testis weight and size with rams producing large numbers of sperm per gram of testicular tissue.

APPLICATION OF PHYSIOLOGIC PRINCIPLES

The previous sections have outlined some physiologic principles involved with reproduction in rams. The following sections raise some questions about past application of this knowledge but also present some potential new applications in the future.

Testes Size

The testes are readily palpable endocrine organs that reflect changes in season and reproductive physiology.

Land[13] first proposed using testes size as a selection criteria. However, there are many conflicting studies, which make any recommendations about indirect selection for testis size and flock reproductive potential questionable.[14] Some studies show that determining ram-to-ewe ratios by volume of testes can extend "ram power" for the short term.[15] Yet under most conditions, testes size is not a limiting factor,[16,17] nor is a difference in semen quality correlated with size of the testes.[18] Perhaps rather than a general recommendation of "bigger is always better," testes size of fertile rams should be taken only as a primary factor for specialized breeding conditions, such as low ram-to-ewe ratios, large numbers of synchronized ewes, transitional period to anestrus when semen quality is limiting, and use of ram lambs for breeding. Excellent semen quality, no palpable lesions of the testes or epididymides, a negative test for brucellosis, and outstanding sexual performance are more appropriate criteria to be considered in ram selection.

Gonadotropin-Releasing Hormone for Selection

The response of rams to an injection of GnRH has been evaluated as a potential means of assessing degrees of reproductive competence. Because LH secretion in rams is episodic and random, the use of GnRH decreases variability when LH is measured. Furthermore, both ewes and rams share this system, making the measurements in rams a potentially valuable indirect selection criterion that can be correlated with ewe reproductive efficiency. In an experiment using data from eight generations of selection for GnRH response, significant divergence in LH secretion was observed.[19,20] Interestingly, a correlated response in ewes showed a tendency for earlier onset of sexual maturity and a higher ovulation rate at the beginning of the breeding season. Replication of these data in other breeds and environments is needed, but application of this technique may some day lead to more rapid ways of selecting flock replacements.

Serving Capacity

Serving capacity is a measure of mating ability. Serving capacity tests measure the number of ejaculations or services during a period of time. This test can be predictive of success in pen-mating.[21] The relationship between ram contacts in field mating conditions with overall lamb production[22] suggests that serving capacity should be given credence as part of a breeding soundness examination. Improvements in flock reproductive performance using serving capacity tests to screen rams occur through more lambs per ewe joined, a decrease in the length of the lambing season, and a more uniform lamb crop. Serving capacity as a measure of ram performance goes beyond these short-term gains in flock breeding. Measures of sexual performance suggest a relationship to long-term genetic gain. Libido and other aspects of male mating performance have been shown to be heritable in both beef and poultry. Although selection studies with rams have not yet been accomplished, there is indirect evidence of a genetic relationship. Ewes selected for improved performance in pounds of lamb weaned produce rams with higher serving capacity scores.[23] Interestingly, rams born co-twin to a male sibling also tend to have higher serving capacity scores.[24] The application of serving capacity tests for long-term genetic progress depends on development of paradigms for identifying superior rams. Physiologic indicators of ram performance may prove valuable for screening rams, making this aspect of evaluation more practical in the future.[25]

Seasonality

Technology to change the breeding performance of both rams and ewes and reduce seasonal constraints is available. Two principal approaches have been used to manage rams for optimal breeding performance at any time of the year. One is to house rams in barns to control the length of the photoperiod. This technique has been used to elucidate endocrine patterns and improve fertility of rams for out-of-season breeding. Novel light schedules suggest that indoor housing facilities can be made to serve more practical functions.[26] In one such scheme devised in France, rams kept in barns under light control have less dramatic changes in testes size. The light control schedule consists of changing the daily light pattern from 8 hours of light to 16 hours of light per day every 60 days. This more frequent light and dark contrast shows promise for reducing seasonal breeding limitations. An option for extensive operations where lighted barns are not practical is to use an implant of melatonin. These implants alter seasonality in rams and improve lamb production out of season.[27] Availability of implants to producers remains a problem, however.

CHAPTER 85

Breeding Soundness Evaluation and Surgical Sterilization of the Ram

CLEON V. KIMBERLING and GERILYN A. PARSONS

Breeding soundness evaluation (BSE) is an overall assessment of the ram's capacity for serving and impregnating a number of ewes during a breeding season. An overall physical examination is performed with special emphasis on the reproductive system. The BSE includes anatomic and structural correctness, freedom of disease, body condition, scrotal circumference, and semen quality. The ram accounts for the major genetic changes in a flock. An economic soundness evaluation (ESE) is an assessment of the ram's potential contribution to the profitability of a sheep enterprise. An ESE includes an evaluation of ram management and an assessment of the potential genetic contribution of the ram.

ECONOMIC SOUNDNESS EVALUATION

The ram genotype influences not only the quality but also the quantity of production per ewe exposed. A highly fertile ram can increase lamb crops by impregnating more ewes and by producing more multiple births per ewe.[1] Research has shown that over three generations the ram is responsible for approximately 87.5% of the genetic influence on a flock.[2] Therefore, specific criteria

CHAPTER 85

Breeding Soundness Evaluation and Surgical Sterilization of the Ram

CLEON V. KIMBERLING and GERILYN A. PARSONS

Breeding soundness evaluation (BSE) is an overall assessment of the ram's capacity for serving and impregnating a number of ewes during a breeding season. An overall physical examination is performed with special emphasis on the reproductive system. The BSE includes anatomic and structural correctness, freedom of disease, body condition, scrotal circumference, and semen quality. The ram accounts for the major genetic changes in a flock. An economic soundness evaluation (ESE) is an assessment of the ram's potential contribution to the profitability of a sheep enterprise. An ESE includes an evaluation of ram management and an assessment of the potential genetic contribution of the ram.

ECONOMIC SOUNDNESS EVALUATION

The ram genotype influences not only the quality but also the quantity of production per ewe exposed. A highly fertile ram can increase lamb crops by impregnating more ewes and by producing more multiple births per ewe.[1] Research has shown that over three generations the ram is responsible for approximately 87.5% of the genetic influence on a flock.[2] Therefore, specific criteria

Table **85-1**

Heritability Estimates

Trait	Heritability (%)
Reproductive	
Ewe fertility	5
Prolificacy	10
Scrotal circumference	35
Age at puberty	25
Carcass	
Carcass weight	35
Weight of trimmed retail cuts	45
Percent trimmed retail cuts	40
Loin eye area	50
Fleece	
Grease fleece weight	35
Clean fleece weight	25
Percent yield	40
Staple length	55
Fiber diameter	40

should be established for both production and reproductive traits.

Heritability

The estimated heritability of different traits varies greatly. Although many production traits, such as carcass, dairy, and wool characteristics, are highly heritable, most reproductive traits are not (Table 85-1).[3] Selection pressure for traits with low heritabilities must be intense over several generations for progress to be noted. Genetic progress is generally slower when selecting for multiple traits. It is also important to be aware that selection for some traits may have a negative impact on others. For example, many carcass characteristics and wool characteristics are negatively heritable.

Scrotal circumference (SC) is probably the most important genetic trait associated with reproduction efficiency. The heritability of SC is estimated at 35%. SC is correlated with sperm output, age at puberty of the female offspring, ovulation rate, and the number of multiple births produced. In addition, some British researchers have reported a positive correlation between SC and the ratio of muscle to fat in the offspring. Failure to properly select for SC has the potential to reduce reproductive performance and production, thereby reducing the potential profitability of subsequent generations.

Cost of Ram Power

The cost of ram power per lamb produced is an important component of the ESE. The cost of ram power is determined by purchase price and by the number of lambs sired by an individual ram. Table 85-2 gives an example of annual costs per ram, exclusive of purchase price. Based on this example, Table 85-3 shows how the ram-to-ewe ratio and lambing percentage affect the annual cost of a ram per lamb produced.

Table **85-2**

Annual Ram Costs*

Example Purchase Price $350.00	
Fixed Costs	
Depreciation/3y	117.00
Interest on investment at 12%	42.00
Total Fixed Cost	$159.00
Variable Costs	
Feed and maintenance	60.00
Overhead	5.00
BSE	15.00
Death loss/15%	52.50
Total Variable Costs	132.50
Total Costs	291.50
Income from Wool	20.00
Annual Cost per Ram (exclusive of purchase price)	271.50

*These figures are representative of Colorado producers as reported by CSU farm management specialists Rod Sharp and Paul Gutierrez.

Table **85-3**

Estimated Cost of Ram Power per Ewe Exposed and per Lamb Produced

		COST PER LAMB PRODUCED, $	
RAM:EWE Ratio	Cost per EWE Exposed, $	125% Lamb Crop	175% Lamb Crop
1:1	271.50	—	—
1:25	10.87	8.70	6.20
1:50	5.43	4.74	3.10
1:100	2.71	2.17	1.55

Breeding Capacity

The breeding capacity of a ram is determined by sperm production, semen quality, and libido. The breeding capacity of a highly fertile ram is one of the most difficult concepts for many sheep producers to accept. Under most range and semiconfinement conditions, a ram in good physical condition, with high libido, can successfully serve 100 or more ewes during a 17-day breeding cycle. For example, one 5200-ewe western range operation using 1.5 rams per 100 ewes consistently lambs over 90% of the bred ewes during the first 17 days of the lambing period and averages a 140% lamb crop.[4] In this type of an operation, a higher ram-to-ewe ratio cannot be economically justified.

BREEDING SOUNDNESS EXAMINATION

The BSE is one of the most essential components of the overall economic soundness of a sheep operation.

Reproductive efficiency is a key element of economic efficiency.

Brucella ovis

Brucella ovis is the primary cause of lowered fertility in multi-sire breeding systems in the western United States. *B. ovis* is also a major concern in Australia and New Zealand. *B. ovis* infection in a flock can have a devastating effect on the level of production by decreasing the number of ewes bred, decreasing the number of multiple births, and increasing the lambing interval. *B. ovis* ram epididymitis is a contagious venereal disease generally affecting mature rams in multi-sire breeding systems. The disease is transmitted via homosexual activities or via the ewe during the breeding season. The ewe does not become permanently infected, but serves as a mechanical vector for the spread of the disease.

The *B. ovis* organism enters the blood through the mucous membranes and infects the reproductive tract. Clinical signs include enlargement and fibrosis of the epididymis with wasting of testicular tissue. In some cases, infection of the secondary sex organs occurs without involvement of the epididymis. In these instances, no palpable lesions are evident, and diagnosis must be made by microscopic examination of the semen, semen culture, or serology. Table 85-4 shows a comparison between the semen qualities of a *B. ovis*–free and a *B. ovis*–infected ram population.

Antibiotic treatment of *B. ovis* is disappointing, as about half of the cases do not respond. Vaccination interferes with the enzyme-linked immunosorbent assay (ELISA) serologic test, and is strongly discouraged. It is recommended that all rams in a multi-sire flock have an annual ELISA test, preferably during the period of lowest sexual activity. In single-sire flocks, the ram should be tested at purchase and retested 30 days later. All rams that test positive should be immediately culled. With the potential of *B. ovis* being in a latent stage and not showing a positive test in a multi-sire flock, the entire group of rams should also be retested at the end of the breeding season/shearing, once again culling all positive rams.

Table **85-4**

Semen Quality of a *Brucella Ovis*-Free and a *Brucella Ovis*-Infected Ram Flock

	B. Ovis-Free	*B. Ovis*-Infected

*In an infected population, *B. ovis* infection is correlated with seminal leukocytes and detached spermatozoal heads.
†Removed without semen evaluation.
Data from *Ram Breeding Soundness Evaluation Records*, Fort Collins, CO: Department of Clinical Sciences, Colorado State University, 1990.

Libido

Libido refers to the willingness of a ram to breed ewes. A serving capacity test or direct observation of a ram with ewes is an important component of the BSE, but is frequently neglected. It has been estimated that approximately 10% of all rams have no interest in breeding ewes. In addition to not siring lambs, these rams can interfere with other working rams and should be removed from the breeding population. The behavioral evaluation of a ram should be conducted before the evaluation of the reproductive tract and the semen evaluation. Rams with inadequate libido should be culled without incurring further expense.

Physical Examination

Restraint can vary, depending on the number of animals being tested and the number of people available to assist. The most important factor in restraint is that it should allow for a complete examination of both structural and physical characteristics. An adequate examination can be conducted on a standing ram restrained by a halter and pushed against a wall or fence. However, a calf table or sheep cradle makes restraining a ram for proper examination much easier.

Structural soundness refers to the capacity of a ram to remain sound during the breeding season under normal environmental stresses. The feet, legs, and teeth should be examined for structural soundness. *Physical* soundness refers to the health of the ram. The ram should be examined for conditions that may prevent optimal performance, or that can be transmitted to the ewes, such as foot rot, lip and leg ulcerations (ulcerative dermatitis), and pizzle rot. Body condition should also be noted during the physical examination. A body condition score of 2.5 to 3.5 is recommended for rams entering the breeding season. Structural and physical conditions should be noted at the time blood is collected for the *B. ovis* ELISA test, in conjunction with libido testing, and before examination of the reproductive tract and semen evaluation. If there are structural or physical conditions that cannot be corrected, the ram should be culled before incurring further expense.

Examination of the Reproductive Organs

Testes and Epididymides

The testes and epididymides should be examined for palpable gross abnormalities. Testicular tone and symmetry should be assessed. Swellings, atrophy, and lack of tone or symmetry often indicate pathologic problems and decreased fertility. The caput (head), corpus (body), and cauda (tail) of the epididymis are readily palpable in the

normal ram. The most commonly encountered epididymal lesions usually involve enlargement of the epididymis due to inflammation and fibrosis. The major infectious agents resulting in epididymitis are *B. ovis* in mature, sexually exposed rams, and *Histophilus* spp. or *Actinobacillus* spp. in young, virgin rams. Other organisms, such as *Corynebacterium pseudotuberculosis*, can also produce epididymitis.

The circumference of the two testes and scrotum should be measured using a scrotal tape. This measurement is an estimate of potential sperm production. The Western Regional Coordination Committee on Ram Epididymitis and Fertility recommends that ram lambs over 150 lb have a scrotal circumference (SC) of greater that 30 cm. And yearling rams (12–18 months) should measure greater than 33 cm. Producers of seed or breeding stock should set higher standards. Rams weighing 250 lb or more should have a SC greater than 36 cm.

Scrotal circumference varies with season.[5] The SCs recommended here are those expected during the breeding season but before the ram has been used for breeding. At this time, the testicles are their largest and should feel turgid. Soft, flaccid testes on a ram that has not been used for breeding are highly correlated with poor semen quality.

The production of spermatozoa takes place in the seminiferous tubules of the testes. The functions of the testes are regulated by gonadotropins, which are released into the bloodstream by the pituitary gland the primary external stimulus that affects the release of gonadotropins is the amount of daylight. In most breeds, a decrease in the amount of daylight is followed by an increase in the secretion of gonadotropins and an increase in sexual activity. Scrotal circumference can be 2 to 3 cm smaller and semen quality poorer as daylight hours increase and hormone levels decline. The testes can also show a decrease in size and tone following an active breeding program, as spermatozoa stores are repeatedly depleted. Depending on breed, duration of breeding exposure, environment, and season, testicular size and tone are generally regained following 30 to 45 days of sexual rest.

Prepuce

The prepuce should be free of any raw or ulcerative lesions at the orifice. Lesions can indicate conditions such as pizzle rot (sheath rot, ulcerative posthitis), lip and leg ulceration, or phimosis.

Penis

The penis should be extended and examined. If the penis cannot be extended, a previous injury or disease may have produced adhesions. The glans and urethral process should also be examined. Ulcerative dermatosis and urethral calculi can destroy the glans.

Semen Evaluation

A semen evaluation should be conducted only after the ram has been determined to be free of *B. ovis,* has passed a serving capacity test, and has passed a structural and physical examination. A listing of recommended equipment and supplies, including manufacturers, for the collection and evaluation of ram semen is provided in Table 85-5.

Semen Quality

Ram fertility can be compromised by a wide variety of infectious and noninfectious conditions. Some of the primary infectious agents that affect semen quality, including *B. ovis, Histophilus* spp., *Actinobacillus* spp., and *C. pseudotuberculosis,* have already been mentioned. Others include the blue tongue virus and any agent causing an elevation in body temperature. The noninfectious conditions affecting semen quality are generally stress related. These stressors tend to be environmental (e.g., extreme temperatures, high humidity, transportation, and nutritional compromise). Increased morphologic abnormalities of sperm cells are evidence of an insult on the reproductive tract. In many instances, it is difficult to determine whether such abnormalities are transient or permanent in nature.

Spermatogenesis in the ram requires approximately 49 days. An additional 10 to 14 days are required for the spermatozoa to travel through the epididymis. During passage through the epididymis, maturation of the spermatozoa continues and several functional changes occur. These changes include the potential for sustained motility, the progressive loss of water, the distal margination and eventual loss of the cytoplasmic droplet, and development of the potential capacity to fertilize ova.[6] Thus, semen collected on any given day was produced 59 to 63 days earlier. Therefore, the semen evaluation portion of the BSE should be conducted as near to the start of the breeding season as possible.

Collection Technique

1. Insert the lubricated probe into the rectum and put pressure on the accessory reproductive glands by pulling up slightly on the handle of the probe. Massage the seminal vesicles firmly with four to six strokes using the probe. This provides slight stimulation to the ram. Leave the probe in place.
2. Extend the penis by grasping the penis in front of the scrotum. Push the penis forward while bringing the prepuce back. Grasp the glans with a clean gauze sponge. Extend the penis and secure it by grasping the shaft of the penis immediately behind the glans using the other end of the clean gauze sponge.
3. Place the tip of the penis and the urethral process into a warm 17 × 100 mm plastic tube. It is essential that the semen sample be collected in as clean a manner as possible to prevent contamination from the glands or prepuce. Cells and cellular debris from contamination may interfere with proper evaluation.
4. With the rectal probe already in place, apply pressure on the accessory reproductive glands by pulling up slightly on the handle of the probe. Massage the seminal vesicles firmly with six to eight strokes using the probe. This massage is critical to obtaining a good collection. With steady pressure applied to the seminal vesicles

Table **85-5**

Equipment and Supplies for Collection and Evaluation of Ram Semen

Instrument or Material	Comments
Microscope	A phase contrast microscope is recommended. A light microscope with good optics can be adequate, although defects of the aerosomal cap are more clearly delineated under phase contrast. The optics for either type of microscope should include 10× eyepieces with a 10× or 20× objective for observing motility and white blood cells, plus a 100× oil immersion lens for evaluating morphology.
Electroejaculator[a,b]	A hand-held ram ejaculator is ideal. However, if only a few rams are to be examined each year, ram probes that attach to the larger bull ejaculator are satisfactory.
Slide warmer	Any good slide warmer with temperature regulation is adequate. Temperature should be from 37–38°C for the slide and tube warmer.
Tube warmer	A number of inexpensive tube warmers are available or some type of block holder can be devised in conjunction with the slide warmer.
Lubricant[c]	Carboxymethylcellulose is an excellent, reasonably priced rectal probe lubricant. Any lubricant, e.g., obstetrical lubricant, is satisfactory. When doing multiple examinations, it is advisable to mix the lubricant with a disinfectant.
Scrotal tape[a,d]	
4 × 4 Gauze sponges	Used to secure the extended penis for examination and semen collection.
Test tubes	Plastic 17 mm × 100 mm nonsterile disposable test tubes without caps work well for collecting the sample. Whirl Pak or 3 × 5 Col-Palmer Minigrip Reclosable Bags are also satisfactory and can be placed directly on the slide warmer.
Stain[a,d]	Eosin-nigrosin stains are generally used for evaluating morphology. The most common are Blom's and Hancock's.
Cell counter	An eight-place cell counter used in hematology is ideal for doing morphology counts.
Diluent	Lactated Ringer's solution, 2.9% buffered sodium citrate or 0.9% saline can be used.
Transfer pipettes	5½" Pasteur pipettes or plastic bulb pipettes work well for transferring diluent, stain, and semen.
Microscope slides	25 × 75 mm microscope slides (frosted ends are helpful).
Cover slips	18 × 18 mm or 22 × 22 mm are recommended.
Oil	Non-drying type A or B immersion oil.
Miscellaneous	For example, lens cleaner and lens paper, marking pens for labeling samples, pens/pencils, evaluation forms, paint sticks, spare microscope bulbs, extra batteries for ejaculator.

[a]Lane Manufacturing Co, 2075 S. Valencia, Denver, CO 80231.
[b]Western Instrument Co, PO Box 16428, Denver, CO 80216.

using the probe, apply electrical stimulation to the ram for 8 to 10 seconds. Release the stimulus and wait until the ram completely relaxes (this may be 10–12 seconds), then apply six to eight massage strokes, again with pressure on the seminal vesicles. A second electrical stimulation for 8 to 10 seconds may be necessary and usually produces a good ejaculate. Observe whether the semen comes from the tip of the penis, the urethral process, or an opening in the urethra along the shaft of the penis. An old urolithiasis lesion on the urethra, midway up the penis, may allow the semen to be misdirected during breeding.

Poor technique often results in poor collection that contains mostly seminal fluid and very few spermatozoa. Inadequate stimulation resulting from weak batteries in a handheld ejaculator will also produce a poor, thin ejaculate. Applying too much voltage is the most common mistake when a large bull electroejaculator with a ram probe is used for collection. If stimulation is too severe, rams tend to urinate or lose their erection.

Microscope Evaluation

The semen sample *must* be maintained at 37°C!

Motility. With a Pasteur pipette, transfer a tiny drop of semen onto one end of a warm microscope slide. On the other end, place a drop of warm (37°C) diluent (e.g., saline, lactated Ringer's solution, or 2.9% buffered sodium citrate). With the corner of a coverslip, transfer a small amount of semen to the diluent, mix, and place the cover slip over the diluted semen. Inadequate dilution is a common error. Using a 10× or 20× objective, observe a number of fields and evaluate *progressive* motility of individual spermatozoa. If a field is too crowded, individual spermatozoa cannot be evaluated and an accurate estimate of progressive motility *cannot* be made. A good sample should have greater than 40% progressively motile sperm. Motility can be affected by a number of extraneous factors, such as urine contamination, cold shock, and the number of stimulations required to obtain a collection. Therefore, motility alone is not always a good indicator of potential fertility.

White blood cells. When observing motility, the presence of white blood cells (WBCs) should also be noted. WBCs appear as round, shiny, or refractory objects. Under

increased magnification, the nucleus can also be observed. Although WBCs can be observed using a standard microscope, they are seen more clearly with a phase contrast microscope. The presence of WBCs indicates inflammation or infection of the reproductive tract. It is not uncommon, however, to observe an occasional WBC in a sample contaminated by preputial fluids. In older rams, WBCs can signal *B. ovis* infection. In young virgin rams, WBCs often indicate *Actinobacillus* spp. or *Histophilus* spp. infection.* A ram with greater than 10 WBCs per 20× field and no palpable lesions should be considered for treatment and re-evaluated. If *B. ovis* is indicated in a mature ram, the animal should be culled.

Morphology. With a Pasteur pipette, transfer a small drop of semen onto the end of a microscope slide. Adjacent to the drop of semen, a ribbon of eosin-nigrosin stain is placed across the slide. With the center of a second slide, pick up a small sample of semen and mix it with the stain (similar to a blood smear for staining). The slide is allowed to dry, and observed under oil immersion. Count 100 spermatozoa and record the number of normal sperm, as well as the number and type of abnormal sperm. The percentage of normal spermatozoa is of foremost importance; however, noting the types of abnormalities observed in a poor-quality sample may provide information as to the cause and recovery potential. Figure 85-1 is an example of normal sperm morphology.

Common morphologic defects

DETACHED HEADS. Detached or separated heads (Fig. 85-3*A*) are frequently observed in conjunction with testicular degeneration. This may be a transient condition, as in the case of heat stress or a mild frostbite, or a permanent condition, as in the case of *B. ovis* infection. Figure 85-2 is typical of an ejaculate obtained from a *B. ovis* infected ram.

HEAD DEFECTS. Misshapen heads (Fig. 85-3), pyriform heads (Fig. 85-4*B*), macrocephalic heads, and microcephalic heads (Fig. 85-4), are all associated with testicular hypoplasia or mild degeneration.

ACROSOMAL DEFECTS. Acrosomal defects (Fig. 85-5) can have a major impact on fertility. Knobbed, flattened, dented, ruffled, and missing acrosomes are not uncommon and are generally associated with testicular degeneration. There is also some evidence that the knobbed defect may have a hereditary basis.[7]

CYTOPLASMIC DEFECTS. Cytoplasmic droplets generally migrate down the midpiece and are shed as the sperm cells mature in the epididymis. Unshed droplets are generally in a proximal (Fig. 85-6) or distal (Fig. 85-7) position on the midpiece. Proximal droplets are associated with immaturity, periods of low hormonal activity, overuse, and testicular degeneration. Cytoplasmic droplets are frequently associated with bent and coiled tails.

TAIL DEFECTS. The distal midpiece reflex (Fig. 85-4*C*) is the most common tail abnormality. A cytoplasmic

*Unlike *B. ovis* infection in mature rams, *Actinobacillus/Histophilus* infection can generally be cleared up with tetracycline therapy. For treatment to be effective, it must be initiated before permanent damage has occurred. A therapeutic level of tetracycline must be maintained for approximately 6 days.

Fig. 85-5 Acrosomal defects in ram sperm.

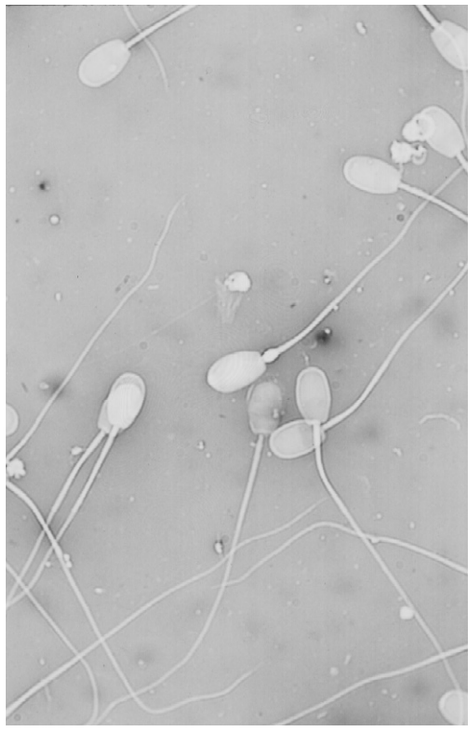

Fig. 85-6 Proximal cytoplasmic droplets from ram sperm.

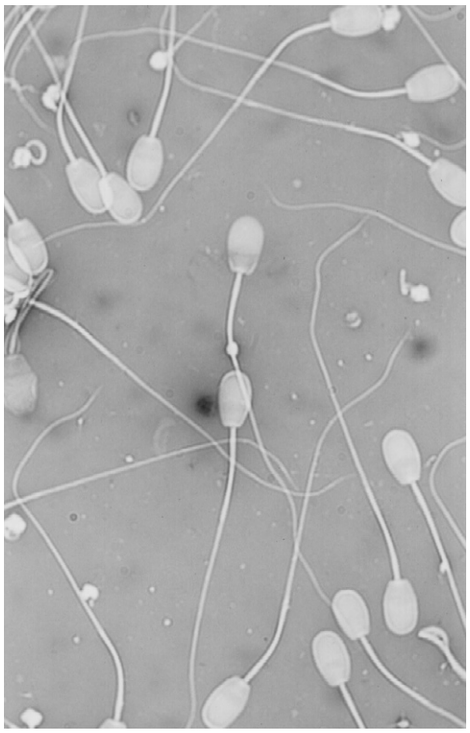

Fig. 85-7 Distal cytoplasmic droplets from ram sperm.

Fig. 85-8 Tail defect in ram sperm: distal midpiece reflex.

droplet is frequently trapped inside the bend. Sperm with a distal midpiece reflex appear to be swimming backward. Trace minerals have been found to play an important regulatory role in development and maturation of certain sperm tail components.[8] Tightly coiled tails (Fig. 85-8) are frequently associated with testicular degeneration.

ARTIFACTS. Improper staining technique can produce artifacts of sperm abnormalities. For example, incorrect stain osmolality can result in numerous reflex midpieces.

Classification

Table 85-6 presents recommendations for classifying the potential breeding capacity of a ram. These recommendations assume that the ram is *B. ovis* free, has passed a structural and physical examination, and displays good libido.

SURGICAL STERILIZATION

Vasectomy

Vasectomy can be performed using an epidural block of lidocaine for regional anesthesia. The skin area on the posterior portion of the scrotum, as it joins the body, is aseptically prepared. Assuming the surgeon is right-handed, he or she grasps the cord (which includes the cremaster muscles, pampiniform plexus, vas deferens, veins, artery, and nerves) (Fig. 85-9) with the left hand. By grasping the cord tightly between the fingers and thumb, one

Fig. 85-9 Spermatic cord of the ram, grasped in preparation for vasectomy.

Table **85-6**

Recommendations for Classifying the Potential Breeding Capacity of Rams

	Excellent	Satisfactory	Questionable	Unsatisfactory
Ram Lambs, 6–12 mos	SC > 33 cm Mot > 50% >90% Normal sperm	SC > 30 cm Mot > 30% >70% Normal sperm	SC < 30 cm Mot < 30% <70% Normal sperm	SC < 30 cm Mot < 30% <50% Normal sperm
Yearlings, 12–18 mos	SC > 35 cm Mot > 50% >90% Normal sperm	SC > 33 cm Mot > 30% >70% Normal sperm	SC < 33 cm Mot < 30% <70% Normal sperm	SC < 33 cm Mot < 30% <50% Normal sperm

Mot, motility; SC, scrotal circumference.

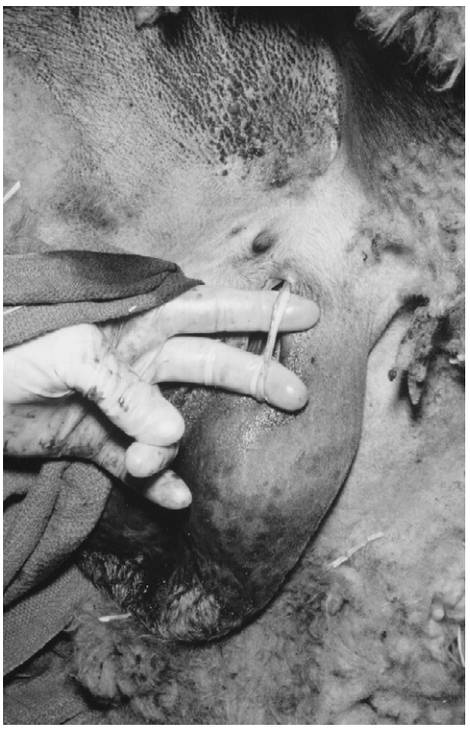

Fig. 85-10 Isolation of the spermatic cord in the ram, for vasectomy.

can roll the cord and identify the vas deferens. Using a scalpel, the surgeon cuts down onto the vas deferens, identifies the structure, and isolates it by blunt dissection. A nonabsorbable ligature is placed at the proximal and distal portions of the exposed vas deferens, and a 1- to 2-cm section is removed (Fig. 85-10). The wound is closed with an appropriate skin closure technique.

Epididymectomy

An epididymectomy is the removal of the tail portion of the epididymis. This operation is performed under regional anesthesia as described for vasectomy. The skin of the scrotum is again aseptically prepared. The surgeon grasps both testes and forces them firmly into the ventral portion of the scrotum incising the skin that overlies the tail of the epididymides to expose the epididymis. Using surgical scissors, the surgeon separates the tail of the epididymis from the body of each testis. This separation should extend to the body of the epididymis on the medial aspect of each testis. A nonabsorbable ligature can then be placed around the body, and the tail of each epididymis can be removed. Again, an appropriate skin closure is used.

Caution! Complete reproductive sterility of the ram is not immediate following surgery. Success should be verified by microscopic examination of an ejaculate collected 60 days after surgery.

CHAPTER 86

Artificial Insemination and Embryo Transfer in Sheep

C. F. B. SHIPLEY, BRIAN C. BUCKRELL, M. J. A. MYLNE, JOHN POLLARD, and J. R. HUNTON

Artificial insemination and embryo transfer in sheep offer many advantages for genetic improvement. They are not new techniques, but several advances in technology have made them somewhat easier for cost-effective implementation. At this time, many of the drugs that are routinely used for synchronization and superovulation are not available to U.S. veterinarians, yet they are commonly used in most foreign countries.

ARTIFICIAL INSEMINATION

Benefits

Artificial insemination (AI) provides many benefits to the producer. They include, but are not limited to, the following:

- Increased genetic gain by allowing increased selection pressure on the ram population to hasten genetic improvement
- Increased offspring from a superior sire
- Availability of a superior sire to small flocks
- Frozen and fresh semen that can be shipped and stored and moved nationally or internationally with fewer health risks and welfare implications than live animals
- Disease control through testing of rams before use and treatment of the semen with antibiotics to lessen the threat of disease
- Semen that can be frozen as insurance against injury or death of a superior sire
- Sire evaluations that can be carried out in many environments to assess the superiority of that sire over many different production types

Selection and Management of the Ram

The ram should have a complete physical examination and be superior in genotype and phenotype. He should be in good body condition (body condition score [BCS] 3–3.5) and be evaluated for locomotion. The reproductive tract should receive special attention and the prepuce examined for lesions and discharge. Testing for any diseases should be done at this time.

The penis should be manually examined for defects or injuries. This can accomplished by setting the ram up on its dock and pushing on the sigmoid flexure while pushing back on the prepuce. There should be no scars, adhesions, or abrasions and the urethral process should be intact.

The scrotal circumference should be measured and compared to normal values for age, breed, and season. Minimum circumferences should be per age and size and carefully adhered to. Sperm production is linked closely to testicle size, as is pubertal age of the offspring.

The testicles should be palpated in a routine fashion so that no abnormalities or defects are missed. The testicles themselves should be firm with no palpable hard or fluctuating lesions that might suggest neoplasm, trauma, abscess, or venous damage. The head, body, and tail of the epididymis should be palpated as well for any lesions with particular attention to the tail of the epididymis and the spermatic cord where varicoceles and sperm granulomas may be found.

The scrotum should be symmetrical and not have any scars, adhesions, or evidence of parasites and it should hang low to help maintain a scrotal temperature 4° to 7°C below body temperature. There should be no signs of scrotal hernia, cryptorchidism, testicular hypoplasia, or other defects. Any such abnormality should exclude the ram from use as an AI sire.

Libido testing should be done if possible. Rams should mount and breed freely and have no feet abnormalities.

All stressful management procedures such as shearing, deworming, vaccinations, vitamin and mineral injections, and hoof trimming should be done 6 to 8 weeks before collection to avoid causing damage to sperm during the spermatogenic cycle.

The rams should be on a rising plane of nutrition and be fed ad lib good quality hay or forage as well as protein and concentrate that is low in Mg^{2+} and Ca^{2+} and may contain 1% ammonium chloride to help prevent urolithiasis. Depending on the area of the country and the quality of forage and concentrate available, supplementation of vitamin E and selenium may be advisable. Low blood copper and zinc have been implicated in reduced libido and fertility, and assessment of these in the diet or blood may be advisable.

Exposure of rams to cycling ewes at this time may also help semen production, especially in rams from more seasonally dependent breeds.

Two weeks before semen collection, rams should be individually housed to help prevent injury, avoid homosexual behavior (especially in ram lambs), and help control any special dietary needs of individual rams. This may also help more submissive rams increase their libido. All contact with ewes should stop at this time, but it is

important to maintain ewes within sight, smell, and sound of the rams.

Although semen may be collected at any time of year, it is important to note that many of the breeds are seasonal and their semen quality and quantity are affected when collected out of the normal breeding season. To this end, it is important to collect those rams during the natural breeding season even if the semen is to be used out of season.

RAM TRAINING FOR SEMEN COLLECTION WITH THE ARTIFICIAL VAGINA

Rams can be trained to mount a teaser ewe and ejaculate into an artificial vagina with a collector kneeling beside him. Many factors affect how long this training will take, but age of ram, breed, season, libido, mating experience and temperament all affect training time. Most mature rams will mate an ewe restrained in a standing position. Ejaculates may be collected daily from healthy mature rams, but sperm concentration and quality should be evaluated on a daily basis and collections adjusted accordingly to achieve optimal use of the ram.

Rams with low libido or inexperience may be taught to mount and collect by following these guidelines:

- Move the rams to the collection area or similar surroundings 2 to 4 weeks before collection and accustom them to hand feeding, gentle handling, and the presence of humans.
- Introduce one or two estrus ewes into the pen and allow the rams to mount normally. Teaser ewes may be made for such use by ovariectomizing them and giving 1 mg of estradiol benzoate once weekly. If two ewes are kept and injected on a Monday/Thursday morning schedule, at least one of them is available throughout the week.
- Let the ram mount a ewe that has been restrained in a head catch with a handler in close proximity.
- After the ram is comfortable with mounting, the handler then starts to gently touch the sheath upon mounting to condition him to handling. Techniques such as changing the ewe, allowing the ram to watch another ram mount, or allowing a ram to choose a ewe may help the slower, more timid ram to mount. Short periods of training are preferable to longer periods and direct contact between rams should be avoided.
- Once regular mounting is achieved, the handler diverts the penis into the artificial vagina (AV) for collection by moving the sheath. Patience and gentle handling go a long way to improving collection and performance of the ram.

The Artificial Vagina

The AV is made up of a liner inside a hard casing that is firmly held in place with rubber bands. These can be purchased commercially or homemade but must be watertight because sperm is killed by any direct contact with water. A stopcock or other device is drilled through the casing to add water and air to control the temperature and the pressure. A glass or plastic collection vessel is attached to one end and a cover or sleeve is applied over it to prevent cold shock to the semen. The open end is lubricated with a nonspermicidal sterile obstetric gel.

Each ram should have his own AV and liner, which should be cleaned with purified water and then rinsed with alcohol and let air-dry between uses. Collectors should wear clean vinyl examination gloves for handling and collecting semen.

Just before use, the AV should be filled half full with water that is 50° to 55°C and the collection container inserted into one end. Correct pressure is attained by blowing air into the AV through the control valve and is easily evaluated by inserting a clean gloved finger into the AV through the open, lubricated end. Exact pressure and temperature will vary between rams, but a final collection temperature (internal) of 40° to 45°C and a pressure that allows easy entry of the penis but still allows for moderate pressure will usually work best.

Semen Collection

The ram will approach the restrained ewe and the collector should be positioned near the ewe, ready to collect with a properly prepared AV. The ram will normally smell, lick, and paw at the ewe, who will respond by urination, vocalization, and tail deviation. Time to mount will vary, but well-teased males tend to produce more semen per collection. When the ram mounts, the collector should deflect the prepuce of the ram to the side, allowing the penis to deviate into the AV. The AV should be applied in such a way that the ram's ejaculatory thrust is not impeded in an upward manner. The penis itself should not be handled.

Problems that may occur with collection with the AV include failure to ejaculate due to improper AV temperature or pressure or improper collector technique; delayed ejaculation after the AV is removed, usually due to poor technique or to over- or understimulation; and lastly, premature ejaculation due to poor technique, high libido, or overteasing.

Once trained, most rams are easy to handle for collection of semen and the ejaculate is superior to that obtained from electroejaculation because it usually does not contain excessive accessory gland secretions.

Electroejaculation for Semen Collection

Electroejaculation of the ram is a relatively simple and easy procedure with the correct equipment. In rams that are going to be used extensively in an AI program, it cannot be recommended because of the repeated stresses on the animal, but for minimal collections or animals that are too debilitated to mount a teaser, it is a viable alternative for the practitioner. It is also useful when examining a large number of rams in a day, for collection of vasectomized rams before use or for rams that refuse to serve an AV. It has also been observed to increase libido in some low-libido rams.

Most common equipment includes either a Bailey or a Ruakura ram probe, although other probes by other manufacturers will also work. These types of probes have a

simple on/off switch that delivers stimulation of 10 to 15 volts of 30 to 50 sine or square waves. Operators should thoroughly familiarize themselves with whatever equipment they are using and use it appropriately for the situation.

Rams may be collected with or without sedation depending on their disposition, skill of the operator and assistants, as well as the frequency and objectives of the collection. Xylazine (15–20 mg IM) or acepromazine (10 mg IM) have been very effective in the authors' experience. The ram should be restrained in lateral recumbency and the penis exteriorized (may be easiest to accomplish while the ram is set up on its dock and then lowered to lateral recumbency). The penis is grasped just below the glans with a sterile gauze sponge and the glans and urethral process directed into the collection container. Care must be taken not to cold shock the semen, so either a cover or water bath around the collection vessel is appropriate. The penis and prepuce may be cleaned and clipped at this time to decrease chances of contamination of the semen. Phosphate buffered saline (PBS) or saline may be used so if contamination with them occurs, it will not affect semen. The rectum is then cleared of any feces by a gloved hand and lubrication applied liberally to the probe and anus. Gentle massage of the accessory glands with either the fingers or probe will help to stimulate the ram and may ease collection. Generally this is done for 10 to 15 seconds and then stimulation applied with the probe in a rhythmic on/off sequence of 3 to 5 seconds on and 5 to 15 seconds off with gentle downward pressure toward the pelvic floor. Gentle movement of the probe during the on/off sequence may help the collection and help to find the proper depth of the probe for maximum stimulation. Individual rams vary in their response, but generally, ejaculation occurs after 3 to 5 stimulations and if collecting for freezing and maximum sperm numbers are desired, stimulation may continue for several more stimulation sequences until ejaculation is not apparent or sufficient semen is obtained. If no ejaculation occurs after several stimulations, the probe should be removed and cleaned of feces and the battery checked on the electroejaculator. Having several collection containers available may help to fractionate the sample so only the sperm-rich semen is collected with minimal accessory gland contamination or, in some cases, urine. Encouraging the ram to urinate before collection is also helpful to eliminate or reduce the chance of contamination with urine. Any accessory fluid that is collected should be discarded, or in some cases, the semen may be centrifuged so that the accessory fluid can be discarded. Once collected, the semen is handled and examined as in AV collection.

HANDLING, EXAMINATION, ASSESSMENT, AND EVALUATION OF SEMEN

Semen must be handled carefully to avoid heat shock; cold shock; contamination with water, disinfectants, sunlight, and air; and any other process or product that may decrease viability. Sperm will die if temperatures exceed 45°C and any increase above 37°C will increase metabolic rate and thus decrease sperm life. Cold shock may be avoided if all equipment that semen comes into contact with is kept at 30° to 37°C. All containers that come into contact with the semen should be either plastic or glass and cleaned with laboratory type cleaners, or in the authors' opinion, single-use containers are preferred, if practical.

Semen should be examined as soon as possible after collection and transferred to a sterile collection tube held in a 30°C water bath. The criteria used for a breeding soundness examination of rams should be followed in the examination and evaluation of the semen. Color should be milky off-white. Pink usually indicates contamination with blood, and a gray or brown color may be indicative of a reproductive tract infection. Urine contamination is usually yellow with a characteristic odor and the semen will appear dilute. Any off-quality semen should be discarded and not used for AI.

Volume will range from 0.5 to 1.5 ml and may vary based on frequency and type of collection. Repeated collections over several days will decrease volume. Motility will normally be wave-like on gross examination under low power (10–50×) on a prewarmed slide without a coverslip. The motion is scored as in Table 86-1 and any sample scoring 2 or below is discarded.

Concentration should be calculated accurately because a reliable number of sperm per insemination is critical to pregnancy rates. An average ejaculate will contain 3.5 to 6.0 billion sperm per milliliter. A hemocytometer, spectrophotometer, computer-assisted analysis, or other accurate method of counting sperm is best, but under some field conditions, concentration of the sperm may be estimated by consistency of the sample using Table 86-2. Thick, creamy samples contain more sperm than those of a more dilute, watery consistency.

Other tests that may be useful include a morphologic and acrosome integrity test using eosin-nigrosin stain or

Table **86-1**

Scoring System for Wave Motion Under Low-Power Microscopy, 10× to 50×

Score	Class	Description
5	Very good	Dense, very rapidly moving waves; individual sperm cannot be observed; >90% of the sperm are active
4	Good	Vigorous movement, however waves and eddies are not as rapid as those in score 5; 70 to 90% of the sperm are active
3	Fair	Only small, slowly moving waves; individual sperm may be observed; 40 to 65% of sperm are active
2	Poor	No wave motion forming, but some movement of sperm visible; 20 to 40% of sperm are active
1	Very poor	Less than 10% of sperm active; possible to observe slight "flickering" of sperm with poor motility
0	Dead	No movement apparent

hypo-osmotic swelling tests. Individual sperm motility and progressive forward movement by dilution of the sample with extender, sodium citrate, or phosphate buffered saline. Longevity of sperm using various extenders and examination at set intervals (usually 1–2 hours) over time may be used to evaluate both the sperm and which extender gives greatest sperm life. Temperature and holding conditions must be carefully monitored to be sure that the sperm is not affected by outside factors and the evaluation is valid.

DILUTION AND INSEMINATION DOSE USING FRESH SEMEN

During natural mating, a mature fertile ram normally deposits approximately 3 billion sperm. Of these, only 100 million to 150 million penetrate the cervix and get into the uterus. Doses of semen containing 100 million sperm have achieved acceptable conception rates when deposited into the cervix. If undiluted, this small volume is very hard to handle and measure accurately. Dilution not only solves this problem, it provides the sperm with a suitable environment for preservation during the insemination and handling process.

Various extenders are available for fresh dilution, but the two most commonly used are heat-treated cow milk or Dulbecco's phosphate buffered saline (with or without 2% equine serum albumin or 10% fetal calf serum). Ultra-high temperature milk may be purchased or made by heating whole milk to 92° to 95°C for 8 to 10 minutes. Water must not splash into the milk, which must not be allowed to boil. The extender must be either cooled or warmed to 30°C and then added slowly to the extender as soon as possible after collection and used as soon as practical (within 1 hour).

Table **86-2**

Concentration of Ram Semen Assessed for Consistency

		Number of Sperm ($\times 10^9$)	
Score	**Consistency**	***Mean***	***Range***
5	Double creamy	5.0	4.5–6.0
4	Creamy	4.0	3.5–4.5
3	Milky	3.0	2.5–3.5
2	Thin milky	2.0	1.0–2.5
1	Cloudy watery	>1.0	0.3–1.0
0	Clear (watery)	Insignificant	0.3–1.0

Note: Score 0 to 2 semen should not be normally used for insemination.

Freezing Semen

There are many protocols for freezing ram semen. One-step and two-step methods have been described, but because of its ease, the one-step method is the most commonly used. Semen is diluted to the final prefreezing dilution rate at 30°C with the cryoprotectant. Straws are then loaded and cooled slowly (using a water bath) by placing them in a refrigerator and cooling to 5°C over 1.5 to 2 hours. One formula that can be used is tris(hydroxymethyl) aminomethane (24.2 g) plus citric acid (13.6 g) plus fructose (10.0 g) plus glycerol (64 ml) plus egg yolk (200 ml) in sufficient quantity to produce 1 L at a pH of 6.8. Commercial extenders have been used with success by the authors and for small numbers and ease of use are very satisfactory.

Freezing semen in straws is similar to freezing bull semen, but the extender, dilution rates, cooling rates, and other factors will vary from laboratory to laboratory. Ram semen is more difficult to freeze than bull semen and some rams (5–10%) will not freeze successfully with current techniques and extenders that are available. Normally ram semen is diluted to at least 1:8 with the chosen extender with final dilution depending on the type of insemination (laparoscopic AI versus cervical AI versus transcervical AI). Doses of semen for the various techniques can be found in Table 86-3.

Semen can be loaded into straws or cooled before loading into straws, then cooled slowly to 4° to 5°C over a period of 1.5 to 2 hours. Depending on the laboratory or extender, semen is then either frozen over nitrogen vapor (4 cm for 0.25-ml straws or 6 cm for 0.5-ml straws) on a chilled (5°C) rack or held for several more hours to allow equilibration and then frozen as described previously. After 8 to 10 minutes in the vapor, the semen is then plunged into the liquid nitrogen and from there loaded into canes and transferred to a tank for storage using standard techniques. When using a programmable

Table **86-3**

Typical Dose Rates and Inseminate Volumes Required for Different AI Techniques

Technique	Type of Semen	Volume, ml	Required Dose of Progressively Motile Sperm	Concentration of Inseminate/ml
Cervical	Fresh only	0.2	Min 200×10^6	1000×10^6
Vaginal insemination	Fresh only	0.2	Min 400×10^6	2000×10^6
Transcervical intrauterine	Fresh or frozen	0.5	$50–100 \times 10^6$	$200–400 \times 10^6$
Laparoscopic intrauterine	Fresh or frozen	0.05	$20–40 \times 10^6$	$400–800 \times 10^6$

Min, minimum.

freezer, chilled filled straws are loaded into the freezer and cooled at the following rate: 4°C per minute until semen reaches –12°C, then 40°C per minute from –12° to –40°C, then finally 50°C per minute from –40° to –140°C. After this point is reached, straws are loaded into canes and stored as described previously.

Semen can also be frozen in pellets by using a block of dry ice into which small depressions have been punched using a metal rod or die for multiple depressions. Semen frozen in pellets is usually diluted to only 1:3 to 1:4, depending on sperm evaluation. Then 0.1 to 0.15 ml of semen is pipetted into each depression and after 2 to 3 minutes the pellets are transferred to plastic goblets, labeled, and put in liquid nitrogen. For thawing, pellets are put into an extender prewarmed to 40°C, or two to three pellets are placed in a sterile dry test tube or Whirl Pak bag and put in a water bath at 40°C and shaken or stirred vigorously till the pellets melt. The semen is then transferred to a 30°C water bath, where it may be held for up to 18 hours, till insemination. This technique does not require expensive or sophisticated equipment, but labeling and identity of the semen are harder to maintain.

Frozen ram semen can be expected to achieve conception rates of 65% when using laparoscopic intrauterine AI.

EWE SELECTION AND MANAGEMENT

The success of the AI program depends as much on the successful management of the ewes as it does on the other techniques mentioned previously. Ewes must be in good health and condition and be free of any diseases. They should be neither fat nor thin; have sound feet, legs, udder, and teeth; and be free of heritable faults. Lambs should be weaned at least 6 to 8 weeks before insemination, and stressful procedures such as shearing, vaccination, and deworming should also be avoided during this time as well as for 4 weeks after insemination. Best conception rates and lambing percentage will be obtained when ewes are flushed (increasing calories and protein) 2 to 3 weeks before breeding. Identification of the ewes and accurate records are very important, especially when multiple sires are being used. Best conception rates are obtained when breeding during the natural breeding season.

SYNCHRONIZATION AND DETECTION OF ESTRUS

To achieve optimal pregnancy rates, it is imperative to time insemination to estrus and ovulation. Accurate detection of estrus in the ewe for insemination using a marking harness on a teaser ram can be used to detect heat with the expectation of 6% of ewes to be in heat each day over a 17-day estrous cycle.

Synchronization programs for AI, especially for out-of-season breeding, may make utilization of time, personnel, and equipment more efficient. This will reduce the time spent in a program and allow for selection of the optimal number of ewes to be inseminated each day. The following is a typical program:

Day 0: progesterone started (CIDR [controlled intravaginal drug release] or sponge or Synchromate implant)
Days 12 to 14: progesterone withdrawn and pregnant mare serum gonadotropin (PMSG) (300–600 IU depending on breed and season)
+ 24 hours: teasing by vasectomized ram
+30 to 36 hours: gonadotropin-releasing hormone (GnRH), 50 to 100 µg
+48 hours: inseminate with fresh semen
+53 to 58 hours: inseminate with frozen semen

The recent addition of GnRH to the synchronization program may help pregnancy rates and give a tighter synchrony of ovulation. Using fixed-time AI, fertility may be decreased and it may be helpful, if not imperative, to present only ewes that have been marked by the teaser or seen in estrus.

METHODS OF INSEMINATION

Using frozen semen, intrauterine insemination is currently the only way to achieve acceptable pregnancy rates. Sheep have a complex cervical canal that is approximately 7 cm long with a series of 6 to 8 rear-ward facing, offset rings that make transcervical insemination difficult, if not impossible, because the cervix cannot be digitally manipulated per rectum as in the cow. Using fresh semen, vaginal and cervical deposition may result in acceptable pregnancy rates if using the appropriate dose of semen (see Table 86-3). Attempts to standardize transcervical AI using the Guelph system and an adapted rigid endoscope for AI using frozen semen have yielded less than stellar results and have fallen into disfavor.

Vaginal Insemination

Vaginal insemination using fresh or chilled semen is done after cleaning the vulva (do not use disinfectants or other spermicidal agents) and inserting the insemination pipette along the dorsal wall of the vagina to the anterior vagina and depositing the semen there. This is also referred to as the "shot in the dark," or SID, method. Pregnancy rates with frozen semen are not acceptable, but the technique is very fast; and fresh or chilled semen may yield acceptable rates, but it is a very inefficient use of semen.

Cervical Insemination

Cervical insemination is performed with the ewe restrained "over the rail" by an assistant and the use of a speculum, head light, and angled tip insemination gun. The speculum is inserted to approximately 12 cm with the jaws parallel to the lips of the vulva, then rotated 90 degrees and its jaws opened (Fig. 86-1). The cervical os is located and the tip of the insemination pipette inserted as far into the cervix as possible without using excessive force. The speculum is then withdrawn or closed, semen is deposited, and the insemination pipette is withdrawn so as to exclude any air and help keep semen backflow to a minimum. The cervical os may be hard to locate or may

Fig. 86-1 Ewe positioned over a bale. Vaginal speculum is in place and insemination pipette is inserted into cervical os.

be covered with mucus, and the ewe may have to be repositioned or mucus drained by raising the front end of the ewe to make the os visible. A human sigmoidoscope may also be used. Any urine should be drained and the vagina flushed with saline or milk before insemination if the ewe has urinated when presented for insemination.

Laparoscopic Intrauterine Insemination

Laparoscopic intrauterine insemination is performed using specialized equipment and small amounts of semen. It has a success rate of approximately 65%, but this rate will vary depending on the quality of semen, time of year, condition of the ewes, and skill of the inseminator. The main disadvantages are the need for expensive laparoscopic equipment, invasive surgery, and the technical expertise needed to perform the procedure. Cost usually limits the procedure to expensive semen, valuable animals, or breeding companies.

Ewes should be held off feed for 24 to 36 hours and off water for 12 to 18 hours to decrease rumen fill, decrease chances of regurgitation, and reduce rumen size to allow easier visualization of the uterus. Equipment, personnel, pens, and handling devices should be arranged so that the procedures are done as quickly and efficiently as possible. Ewes are typically sedated 30 to 45 minutes before insemination with 5 to 10 mg of acepromazine IM and stressed as little as possible. Ewes are restrained in a laparoscopic cradle in dorsal recumbency and securely restrained. Wool 10 to 20 cm cranial to the mammary glands is surgically clipped and the skin is prepared for surgery using standard surgical technique. A local anesthetic is injected at the two penetration sites approximately 5 to 7 cm cranial to the udder and 3 to 4 cm on each side of the midline. Care should be taken to avoid major blood vessels.

At this point, the cradle is tipped up so that the ewe is on a plane at approximately 45 degrees with the head down. The abdominal organs are displaced cranially to allow better visualization of the bladder, rectum, and uterus. The gas trocar is introduced into the abdomen through one of the anesthetized areas, and CO_2 is used to insufflate the abdomen to the satisfaction of the operator, and then the other trocar is introduced through the other anesthetized area. Both trocars are removed and the laparoscope is inserted into one of the ports and the internal organs are identified. The uterus is usually located just under the bladder or under the caudal omental fat. After the uterus is identified and moved into position if necessary, the loaded insemination pipette is introduced and directed toward the uterus midway between the bifurcation and the uterotubal junction. A quick stab is made into the lumen and one half the dose is deposited in one horn and then the procedure repeated in the other horn.

After insemination, the insemination pipette is removed, then the laparoscope. The abdomen is deflated and the cannulae removed. Bleeding can be stopped from the puncture sites with either pressure, suture, or staples. Some operators close all punctures with suture, and others only close those that need it. Prophylactic antibiotics may be given as well as protection for tetanus. Instruments should be sanitized between animals by bathing in a suitable antiseptic such as 0.5% benzalkonium chloride. An experienced team in a well-equipped and organized operation may be able to do 300 or more ewes in a day using this technique.

Transcervical Intrauterine Insemination

The Guelph system for transcervical AI (GST-AI) requires special positioning of the animal, cervical retraction and stabilization, and the use of specially designed instruments for the stabilization and passage of the insemination pipette through the cervix. These instruments are no longer commercially available to the authors' knowledge. Ewes are restrained in dorsal recumbency in a fetal-like position to ease stabilization and retraction of the cervix. A foot trimming table may work well for this as well as a specially designed crate. A Plexiglas vaginal speculum (30 mm outside diameter) with light source is lubricated and introduced into the vagina. The speculum should have a 1-cm opening along one side for instruments to pass. The cervix is identified and a pair of Bozeman forceps is introduced to grasp the tissue near the cervical os. This part of the procedure is critical and requires much expertise and training for consistent success. Correct attachment of the forceps facilitates entry and passage of the insemination equipment through the cervix. The cervix is then retracted and the handle of the forceps is passed through the side opening in the speculum so that the cervix can be better visualized. The bent-tipped preloaded insemination gun (modified Cassou) is then introduced into the cervical canal and rotated continually while attempting to negotiate through the cervical rings. Manipulation of the cervix at the same time with the forceps may improve or help passage through the rings. Once the cervical rings are penetrated, semen is deposited in the uterus, the pipette withdrawn, cervix released, and the speculum removed. Trained, experienced inseminators may penetrate the cervix in as much as 75% to 85% of ewes, more in accelerated lambing programs.

Cervical injury, abscesses, infections, and poor pregnancy rates are all associated with this technique, but vary by operator, semen dose, ewe condition, and experience. Pregnancy rates are generally lower than with laparoscopic AI, but this procedure may be a viable alternative when reduced pregnancy rates are acceptable.

FACTORS AFFECTING THE SUCCESS OF AN AI PROGRAM

Close attention to all details is critical in the success of an AI program. Any problems with any of the steps may be magnified many times over when the final results are tallied.

Conception rates will vary depending on the type of semen, storage method, and AI technique used (Table 86-4).

In the event of program failure, the steps taken during the program should be carefully evaluated to find the cause of failure. The semen source and all steps in the collection, processing, freezing or shipping/storage of fresh as well as the thawing, handling, and actual insemination technique should be investigated. Insemination dose should be carefully calculated and semen evaluated at every step in the process that is practical.

Correct timing of insemination is critical. Every care should be taken to be as close as possible to the recommended time of insemination with the technique chosen. Ovulation time has been reported to vary between groups of ewes; hence the addition of GnRH may decrease variation in ovulation time and increase conception rates. Frozen semen is not viable for long in the reproductive tract, and it is important to time insemination carefully to approach 50 to 55 hours after progesterone removal.

The use of vasectomized rams or testosterone-treated wethers is recommended, as this will also help with ovulation synchrony. Some reports of vasectomized rams serving cervical or vaginally inseminated ewes have improved pregnancy rates (A.R. Cobb, personal communication). This also ensures that only those ewes in estrus are presented for insemination. Supplies and equipment available from several sources are listed in Box 86-1.

Table **86-4**

Conception Rates Achieved in Well-Managed Programs Using Different Artificial Insemination (AI) Methods With Freshly Diluted or Frozen-Thawed Semen

Type of Semen	Dose of Progressively Motile Semen	Location of AI	Expected Lambing Rates (%)
Fresh	400×10^6	Vaginal	20–60
	200×10^6	Cervical	40–80
	20×10^6	Laparoscopic	70–100
	100×10^6	Transcervical	40–80
Frozen-thawed	400×10^6	Vaginal	5–20
	200×10^6	Cervical	
		Synchronized estrus	25–40
		Natural estrus	30–60
	20×10^6	Laparoscopic	40–80
	100×10^6	Transcervical	30–70

EMBRYO TRANSFER

Embryo transfer (ET) has had limited use in sheep because of its expense and invasive technique. Lack of access to the rectum and cervical anatomy contribute to the surgical, rather than nonsurgical, techniques being used for cattle and being developed in goats. The subsequent cost-benefit ratio has thus limited its use. In spite of this, ET has grown recently in popularity and is a useful technique in a variety of situations.

Benefits

ET enables increased genetic improvement through reduced generational interval, as ewe lambs may be used as soon as they reach puberty. These animals may have reduced birthing rates compared to more sexually mature donors, but if they have had several estrous cycles, the problem is not severe. Breeding strategies, such as multiple ovulation and ET schemes described by Smith (1988) is based on selection programs to create nucleus flocks of elite genetics and the use of multiple ETs to distribute these superior genetics at an accelerated rate.

Diseases are not readily spread by embryos and thus genetics can be successfully transferred nationally and internationally with regulatory restrictions the only limiting factor. Embryos can be processed to greatly reduce or eliminate the risk of disease transmission. ET can be used to repopulate flocks of known disease status, to move genes from country to country where certain diseases are endemic, and in disease research. Embryos can be collected while health data testing is being done.

Lastly, embryos may be frozen and stored indefinitely and shipped anywhere with reasonable expectation of pregnancy. New techniques such as one-step freezing and thawing reduce the time and equipment necessary to freeze embryos as well as reduce the difficulty in implantation. Genetic and disease evaluation programs can be instituted while the embryos are preserved.

Expected Success Rates

Success rates for sheep ET using fresh or frozen embryos are comparable with cattle and goat programs. Success of the program can be measured by the following:

1. Number of corpora lutea from superovulation (measures response)
2. Number of embryos obtained per corpora lutea (measures flushing success)
3. Number of fertilized embryos (measures breeding success)
4. Proportion of fertilized embryos suitable for fresh versus freezing techniques
5. Number of recipients that become pregnant (measure of embryo quality, recipient selection, management, and transfer technique)
6. Number of embryos transferred that produce lambs (measure of embryo quality, recipient management, selection, and technique)

Most authors average 8 to 12 embryos recovered per flush with 6 to 8 fertilized and 5 to 6 of these of transferable quality. In a well-managed program, two to four lambs should be obtained from each superovulation and transfer attempt. The range, however, is very wide, from 0 to 30 embryos and offspring per flush. Freezing of the embryos decreases the lambing rates by 10% to 20%. Embryo splitting raises the lambing rate to approximately 1:1 of the original transferable embryo number.

Factors Affecting Success

Recipient and donor selection will influence success rates. The more prolific breeds will usually respond better to superovulation and have higher transferable embryo rates than the less prolific breeds. Seasonal influences also play a role as late winter programs tend to have poorer flush results and maintenance of pregnancy becomes a problem. Ewe lambs also produce fewer embryos than more mature donors, but may make acceptable recipients, especially if they have gone through two or more estrous cycles. Recipients and donors must be in good body condition (BCS 3–3.5) and on a rising plane of nutrition. Fat ewes and those on an excessively high protein diet may have decreased embryonic survival rates.

Response to superovulation is the greatest single variable affecting success. Breed, season, BCS, drug used for superovulation, and dose and route of administration all affect the outcome. Timing of the program during the estrous cycle may also affect response. Programs using PMSG may have a prolonged period of estrogen production and delayed or incomplete ovulation. This estrogen production may also affect sperm transport through the reproductive tract and lead to decreased fertilization rates.

Better results are almost always obtained during the natural breeding season. It is also best to keep stress to a minimum to decrease premature luteal failure, which leads to decreased pregnancy rates.

Donors and recipients must be synchronized so that ovulation is no more than 24 hours apart. It is generally best for the recipient ewes to be behind rather than ahead of the donors if they cannot be same day.

Regulation of Embryo Export and Import

The potential for disease transmission by embryos is classified by the Office International des Ipizooties (OEI) and observed by the International Embryo Transfer Society (IETS). There are very few, if any, diseases that can be spread by properly processed and handled embryos. More research to further clarify disease spread is necessary. Most regulatory agencies have specific handling practices that must be followed and are detailed in the *Manual of the International Embryo Transfer Society* (Table 86-5).

Embryo Transfer Protocol

Almost all ET programs rely heavily on hormonal manipulation of the estrous cycle. Most, if not all, of the commonly used hormones are not commercially available in the United States. Most foreign countries have these hormones readily available for use, which puts the U. S. practitioner at a distinct disadvantage. Legislation is pending for use in “minor species” that may help with the supply of the drugs needed for such programs.

Table **86-5**

Disease Risk from Embryo Transfer

Category	Potential	Small Ruminant Disease
I	Sufficient evidence accrued to show risk is negligible provided that embryos are handled according to guidelines between collection and transfer	None
II	Substantial evidence accrued to show risk is negligible provided that embryos are handled correctly, and for which additional transfers are required to verify	None
III	Risk is negligible provided that embryos are properly handled, but for which additional in vitro and in vivo experimental data are required to verify existing data	Bluetongue Campylobacteriosis Foot and mouth Scrapie (sheep)
IV	Diseases for which preliminary research has begun	Ureaplasmosis Maedi-visna Pulmonary adenomatosis Scrapie (goats) Bluetongue (goats) *Brucella ovis* Border disease BSE agent

Superovulation of the Ewe

Follicle-stimulating hormone (FSH) products are usually derived from the ovine or porcine pituitary. The half-life of FSH is generally shorter than 6 hours and it may have varying levels of luteinizing hormone (LH). LH is associated with increased variability of response and reduced numbers of quality embryos. It is usually administered in a decreasing dosage regimen over a 3-day period starting 2 days before progestin withdrawal. It is generally administered twice a day with the final dose given 12 hours following progesterone withdrawal. The total dose of porcine FSH given is usually between 18 and 22 mg, depending on breed and weight. A sample program is outlined in Table 86-6. Other products are given in a similar manner, but whenever using an FSH product, careful attention to the product description and source must be given. There may be variation in product and LH level that may affect success of the program.

Equine chorionic gonadotropin (eCG), also referred to as pregnant mare serum gonadotropin (PMSG), has a longer half-life of approximately 72 hours. It also has more LH-like activity than FSH-like activity, and there is considerable variation between batches of the product. It is associated with overstimulation of the ovaries, hence produces large numbers of follicles and ovulations; but with residual, nonovulating follicles producing estrogen, a larger number of unfertilized ova (UFO) and poor-quality embryos may be produced. eCG, if used, is usually given 72 to 48 hours before progestin withdrawal at a dose of 1000 to 1500 IU, depending on breed and body size. The one advantage of eCG is that only a single injection is required.

A combination of FSH and eCG has been used in superovulation programs. A single, low dose of eCG (150–250 IU) given simultaneously with the first or second injection of FSH is reported to improve consistency of the program without the associated overstimulation associated with the larger dose of eCG by itself.

Table **86-6**

Example Superovulation and Synchronization Program

Day	Donor Procedure	Recipient Procedure
1	Begin progestin	Begin progestin
12	First FSH AM, second FSH PM	
13	Third FSH AM, fourth FSH PM	
14	Fifth FSH AM and progestin removed; sixth FSH PM	Remove progestin 500 IU PMSG
15	Ram introduced, GnRH 50 μg	Use teaser ram/50 μg GnRH
16	Ram remains or laparoscopic AI	
21	Remove food and water	Remove food and water
22	Embryo recovery (day 6–7 stage)	Transfer embryos

AI, artificial insemination; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone.

Breeding Management of Superovulated Ewes

Superovulation affects the dynamics of estrus, including time of onset and duration as well as sperm transport. All these factors affect fertilization rates and subsequent recovery of quality embryos. The optimal ram-to-ewe ratio for breeding superovulated ewes is 1:3 during the normal breeding season and 1:2 for out of season. The ram should not be allowed with the ewes until 36 hours

after progestin removal even though some will show estrus as soon as 18 to 24 hours after withdrawal.

As an alternative to natural mating, laparoscopic AI has been shown to increase fertilization rates. Recent work suggests that embryo recovery rates may be decreased in a laparoscopic AI program, but breeding 60 hours after progestin removal has been shown to maximize embryo fertilization and recovery rates. Administration of GnRH 30 or 36 hours after eCG or FSH respectively has been reported to improve the yield of fertilized ova from both naturally and laparoscopically bred ewes.

Anesthesia for Embryo Recovery and Transfer

Ewes may be induced with any of the common inhalant gas anesthetics or a combination of xylazine (0.2 mg/kg IM) followed in 5 to 10 minutes with ketamine (5 mg/kg IV or 5–11 mg/kg IM) with local anesthesia infiltrated at the surgical site. A lighter dose of either xylazine and a local or xylazine plus ketamine plus a local may be adequate for transfer of embryos by laparoscopic technique by a skilled operator. Xylazine may be reversed in 30 to 40 minutes with tolazoline (2–4 mg/kg slowly IV or IM) or yohimbine (0.125 mg/kg slowly IV or IM) after the procedure if desired by the operator. Both of these reversal drugs should be titrated to effect. The authors prefer the IM route because of the ease of administration and a decrease in cardiac effects.

Embryo Collection

Surgical collection of the embryos is a common procedure, and many highly skilled and trained operators do laparoscopic assisted recoveries. No technique yet exists for nonsurgical collection of embryos, as in other species, and because of the anatomy of the sheep cervix, a nonsurgical procedure may never be developed without special instrumentation. An experienced team may be able to flush as many as four ewes per hour. Supplies and equipment are readily available and the surgery is not technically difficult. Careful manipulation of the uterus is essential to minimize adhesions, and the tissues must be kept moist constantly with heparinized saline or lactated Ringer's solution. Multiple collections per season can be done, but it is recommended that after one to three recoveries the ewe be allowed to carry a pregnancy to term, as the enlarging uterus may help to break down any adhesions that may have formed. Most embryos are recovered 6 to 7 days after ovulation when the embryos are in the late morula or early blastocyst stage of development. At this time, the embryos are in the distal portion of the uterine horn. If the embryos are to be recovered earlier (usually day 3), they are recovered from the fallopian tubes by flushing through the fimbria into the uterus, where a catheter has been inserted near the uterotubal junction. This technique causes more adhesions of these delicate tissues and offers no advantages to the later flushing time.

The actual technique for surgical recovery consists of a ventral midline incision approximately 10 cm cranial to the mammary gland and just large enough for the surgeon to examine the ovaries and the uterus. The ovaries are first examined to determine response to the superovulation and an attempt to count number of corpora lutea made. The uterus is then exteriorized and carefully packed off using moist toweling and kept constantly moist. A stab incision is made at the base of the uterine horn with a mosquito forceps and a 10-gauge Foley catheter is inserted and the cuff inflated with 3 to 5 ml of air (Fig. 86-2). Another puncture is made near the uterotubal junction using a blunt 20-gauge needle and an open-ended tom-cat catheter is introduced and 25 to 40 ml of flushing medium are injected. The flushing medium is collected out of the Foley into a sterile container and any remaining medium is flushed from the uterus with air. The procedure is then repeated for the opposite horn.

Transfer of Embryos

Several different techniques are used to transfer embryos. The operator should be familiar with the equipment and skilled if using the laparoscopic method. Nonsurgical transfer has had some success using the Guelph system of transcervical insemination, but owing to the difficulties of consistently placing the embryos in the uterus, it cannot be recommended for routine use at this time.

Surgical transfer is performed through a midline laparotomy and the tip of the uterine horn exposed. A puncture is made into the lumen of the uterine horn with a blunt 20-gauge needle and a tom-cat catheter loaded with the embryos and a very small amount of medium injected into the uterus in the direction away from the oviduct. Most operators place two embryos at the one site and pregnancy rates are reported to be better than using either one or three embryos.

Laparoscopic transfer is widely used. It is faster and less invasive, but requires more skill. With this technique, the

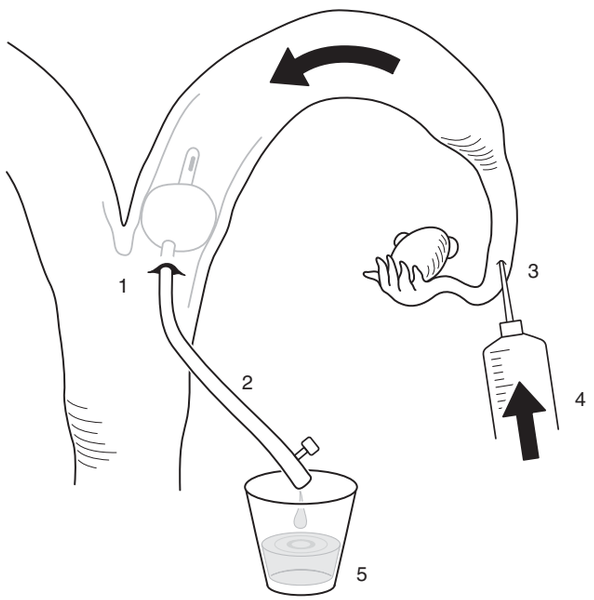

Fig. 86-2 Surgical recovery of embryos.

uterine horn ipsilateral to the corpus luteum (CL) is grasped and a blunt stab is made into the horn through the abdominal wall and a tomcat or similar catheter inserted into the uterus approximately 2 cm; the embryos in a small amount of medium are expelled into the uterus. A variation of this technique includes using the laparoscope to identify the CLs and using a grasping tool to then exteriorize the tip of the ipsilateral horn through the stab incision that is now lengthened just enough to allow catheterization and deposition of the embryos as described previously.

Embryo Bisection

Bisection of the embryo usually results in an increase in the number of offspring born to approximately 100% of the embryos transferred. An experienced technician can easily become skilled at bisecting embryos. Fresh bisected embryos can be frozen; however, frozen-thawed embryos are rarely bisected with high success rates. Use of bisection may be beneficial in some programs or in the production of identical twins for research purposes.

Assessing Embryo Quality

Accurate embryo grading is important to the success of an ET program. Poorer quality embryos should not be frozen and in some cases should not be transferred. They are graded and classified according to the guidelines of the IETS. Fertilization status, stage of development in relation to the day of recovery (normal rate of development versus retarded), and evidence of morphologic damage to the embryo and zona are all taken into account.

REPRODUCTIVE TECHNOLOGY IN THE FUTURE

The last 20 to 30 years have led to exciting discoveries in the knowledge of the reproductive cycle, ways to manipulate it, and the technology to use this knowledge to make advances in AI, ET, real-time ultrasound (RTU), in vitro fertilization (IVF), cloning, and so on. Future technologic advances will continue to be made and may bring many changes to sheep reproduction and the advancement of science and genetic progress. Some of these advancements, if proved successful in obtaining pregnancies, will be adopted in the sheep industry.

RTU has provided us with keys in the understanding of the estrous cycle of the ewe. It has allowed us to observe follicular dynamics, and hopefully, this knowledge will help to improve the efficacy of superovulation programs. A greater understanding of corpus luteum function and maintenance may help maintain pregnancies from transferred embryos. Supplementation of the CL with progestin or stimulating accessory CL formation may help maintain these embryos to establish into a viable pregnancy. Interferon-τ is the pregnancy recognition signal in the ewe, secreted by the developing embryo between 14 and 16 days of gestation. It stops prostaglandin F_2 alpha secretion, thus stopping CL regression. A recombinant interferon-τ now available theoretically may be given to relieve the compromised embryo from the burden of producing this signal and allow it time to recover.

Cryopreservation of embryos has progressed from the traditional three- or four-step procedures to the one-step procedure using ethylene glycol as the cryopreservative of choice. This has allowed direct thaw and transfer, which simplifies the use and handling of these embryos. Vitrification of the embryos also offers hope for higher pregnancy rates after thaw but at this time needs further development to bring it from the laboratory to the "field."

In Vitro Embryo Production

Of all the developments in reproductive technology over the past decade, the establishment of methods for in vitro embryo production (IVEP) may be the most significant in terms of its practical implications. The collection of immature oocytes from either living donors or ovaries collected at slaughter would eliminate the need for surgical collection of embryos from superovulated donors. The collection of mature oocytes from superovulated donors would eliminate the need for in vitro maturation of oocytes. Both adult ewes and juvenile lambs (8–12 weeks of age) have been successfully used to produce viable oocytes. In sheep IVEP, relatively high levels of maturation and fertilization (>60%) can be obtained in conjunction with good development rates to the blastocyst stage (>30%). Upon transfer, in vitro–derived sheep embryos give acceptable initial pregnancy rates (~50%); however, the majority of these fetuses are aborted during gestation, leaving only approximately 20% of transferred embryos to result in live lambs. A significant impediment to the widespread use of IVEP in sheep is the ram-to-ram variation in response of sperm to in vitro capacitation and culture. This is particularly pronounced with frozen-thawed semen. Despite setbacks, the IVEP procedure constitutes an enormous advancement in our ability to acquire large numbers of embryos by means other than from superovulated donors. The future should see the development of effective in vitro maturation, fertilization, and culture systems for all of the small ruminant species, resulting in embryos of high quality and viability.

Gamete Transfer

For all of the small ruminant species for which ET requires surgical procedures, the transfer of gametes (sperm and oocytes) may offer certain advantages over both traditional ET and IVEP techniques. Gamete transfer has been used extensively in the treatment of human infertility, where it has generally implied the transfer of a mixture of mature oocytes and processed sperm into the lumen of the donor's own uterine tube. Oocytes collected from a donor at slaughter or by laparoscopic aspiration would be matured and then transferred into the uterine tubes of a number of synchronized preovulatory recipients. At the time of donor oocyte transfer, all of the recipients' preovulatory follicles would be aspirated to remove the "native" oocytes, and sperm (fresh or frozen) would be

placed within the recipients' uterine lumen. Removal of native oocytes from the recipients' preovulatory follicles should lead to luteinization and the development of functional corpora lutea. The ability to acquire large numbers of oocytes from a single donor is considerably greater than the ability to recover an equivalent number of embryos over a restricted period of time. The principal advantage of gamete transfer over currently available IVEP procedures is that sperm capacitation, fertilization, and embryo development all occur in vivo, eliminating concerns regarding ram-to-ram variation and reduction in viability of cultured embryos. Developments in this area should include the evolution of oocyte transportation systems in which immature oocytes mature during transport, as well as the establishment of methods for the successful cryopreservation of oocytes. As more experience is gained in acquiring and maturing small ruminant oocytes, gamete transfer may become a routine procedure for transfer specialists of the future.

Embryo Multiplication

Techniques have been developed to multiply mammalian embryos and produce multiple live offspring from a single original embryo. Blastomeres from early cleavage-stage sheep embryos (two- and four-cell) can also be isolated and subsequently cultured to produce genetically identical embryos and offspring. Each of the individual blastomeres from a single four-cell sheep embryo maintains totipotency following isolation; thus, four identical offspring can be produced by the procedure. The combination of blastomere isolation and effective in vitro embryo production systems may lead to increased utilization of this technique in the future.

Further expansion of embryo multiplication has come with the development of cloning procedures, wherein blastomeres are fused with enucleated oocytes, which in turn reprogram the blastomere nucleus to develop as if it were a zygote. Cloning methods expand upon simple blastomere isolation procedures by permitting cells from later-stage embryos (eight- to 16-cell embryos, compact morulae, and inner cell mass cells from blastocysts) to be used as donor nuclei. Cloned embryos suffer the same insufficiencies that have plagued the use of in vitro derived and cultured sheep embryos in terms of fetal loss, increased size at birth, and postnatal mortality.

Beyond cloning with blastomeres, it has been proposed that permanent totipotent embryonic stem cell lines could be produced in sheep from which donor nuclei could be derived for cloning. Embryonic stem cell lines have been established from individual mouse embryos, which have been used to produce germ-line chimeras of altered genetic makeup. Embryonic stem lines have the potential to produce millions of identical totipotent cells, which may be studied or altered genetically before use in the production of embryos. The potential use of embryonic stem cell lines cannot currently be predicted in sheep, as they have not yet been produced in any small ruminant species, and it is not known whether their production will be biologically possible. Embryo multiplication methods may find a home in certain production situations wherein supply cannot meet demand and the value of offspring warrants the use of such techniques.

Marker-Assisted Selection

The use of genetic markers for the identification of animals carrying a specific gene is known as marker-assisted selection. Economically important major qualitative genes such as those for fecundity (Booroola-FecB; Thoka), health (scrapie resistance), growth and carcass characteristics (Callipyge), and sex have all been recently identified in sheep. The Booroola, Callipyge and male-specific genes have additionally been isolated after identification by molecular techniques. Genetic markers allow individuals to be screened for specific genes that may not be expressed (fecundity genes in males) or before phenotypic expression is normally observed in expressing animals. This advantage is most pronounced if marker-assisted selection is combined with ET and manipulation, and embryos can be screened for the presence of specific genes before they are transferred. Future developments should include the evolution of screening methods by which an embryo's genetic makeup could be determined through noninvasive methods. Marker-assisted selection will play an increasingly important role in livestock selection as more genes and gene markers are identified.

CONCLUSION

Practical programs for embryo production and transfer must be developed if veterinarians and producers are to take advantage of the promised gains in genetics and molecular biology. Efficient oocyte collection, consistently successful in vitro fertilization, rapid cryopreservation methods, and nonsurgical ET techniques are needed. Without an efficient method of animal propagation like ET, the expected advances in research will never be applied beyond the laboratory. Although the level of invasiveness has been greatly reduced by the introduction of laparoscopic methods, future development and increased application of embryo-based technologies will be closely tied to the development of nonsurgical procedures. Prospects for the development of widespread transcervical ET methods in sheep now appear promising, following the use of the transcervical insemination techniques to transfer embryos.

CHAPTER 87

Clinical Reproductive Physiology of Ewes

NORMAN C. RAWLINGS and PAWEL M. BARTLEWSKI

REPRODUCTIVE PATTERNS

The ewe is seasonally polyestrous, with breeds derived from northern latitudes having a defined breeding season spanning the fall and winter months. Breeds developed closer to the Equator show less seasonality. The estrous cycle of the ewe is usually 16 to 17 days long, with estrus lasting approximately 30 to 36 hours. Spontaneous ovulation occurs late in estrus. Gestation length is approximately 147 days, with minor variations between breeds.[1]

REPRODUCTIVE CYCLE

Folliculogenesis

A resting pool of primordial follicles (containing primary oocytes) is established in the ewe prenatally, and in the adult ewe 3 to 4 follicles move from this pool and are committed to a growing pool (primary follicles) every day.[2] Although luteinizing hormone (LH) receptors are present in the theca and follicle-stimulating hormone (FSH) receptors are in granulosa cells quite early in follicular development (tertiary or preantral follicles of about 0.1 mm in diameter), folliculogenesis appears to be gonadotropin independent in sheep up to the 1- to 2-mm stage (early antral follicles). Most follicles are lost to atresia in a process of programmed cell death (apoptosis), particularly at the preantral and antral stages of development. Recent use of transrectal ultrasonography has allowed description of antral follicle dynamics (follicles with diameter > 2 mm) in the ewe (Fig. 87-1).[3] During the estrous cycle, antral follicles emerge or grow from the pool of follicles of 1 to 2 mm in diameter, approximately every 4 days (3–4 follicle waves per estrous cycle). The ovulatory follicle emerges around day 12 of the cycle. Unlike in cattle, the wave-like production of larger antral follicles in the ewe is not reflected in any change in the total numbers of small antral follicles (1–3 mm) in the ovary, apart from a small increase around ovulation.[3–5] In each wave, follicles reach a maximum diameter of 4 to 7 mm; maximum diameter is lower in prolific compared to nonprolific ewes. The largest, nonovulatory follicles of waves have a life-span of 5 to 12 days (emergence to regression or atresia), and life-span is longer for follicles emerging early in the cycle, before luteal progesterone secretion is fully established. Large antral follicle life-span in the ewe consists of a 2- to 4-day growing phase, a static phase (no apparent change in size, 1–4 days), and regressing phase (1–5 days). Each follicular wave emerges after the antral follicles of the previous wave have ceased active growth or are regressing in the ewe. However, in the ewe, there is little evidence for follicular dominance as seen in cattle, except perhaps in the ovulatory wave, where growth of the ovulatory follicle in the ewe exceeds that of other follicles in the wave.[4,6] Based on earlier, non-ultrasonographic studies, it was suggested that prolific ewes ovulated more follicles by reducing follicle atresia, recruiting more antral follicles into final growth and development, or by having a wider window of time over which ovulatory follicles were allowed to emerge.[2] In comparing nonprolific ewes to the prolific Finn, using ultrasonography, it was clear that the increased ovulation rate was due to the ovulation of more follicles from follicle waves emerging before the final wave of the cycle (extended period of recruitment).[3] Ovulation rate also increases from early to midbreeding season.[1]

In the cyclic ewe, the day of emergence of each follicle wave is synchronized to a small peak in serum concentrations of FSH (see Fig. 87-1).[3] Serum concentrations of estradiol increase from follicle wave emergence and peak when the largest follicle of a wave reaches its maximum size. Antral follicles of prolific breeds of sheep have fewer granulosa cells than those of nonprolific breeds, but steroidogenic potential is greater as serum concentrations of estradiol can be greater in prolific compared to nonprolific ewes throughout the cycle.[2] Termination of follicle growth and decreased secretion of estradiol could provide a signal for the subsequent peak in serum FSH concentrations that precedes and may induce the next wave of follicle emergence.[3,7] Although inhibin specifically regulates FSH secretion, it is probably less involved in regulating peaks in FSH secretion as inhibin is secreted from a wide size range of follicles. The duration and amplitude of peaks of FSH and estradiol do not vary across the estrous cycle.[3] LH pulse frequency is higher early in the cycle, before serum concentrations of progesterone have reached a maximum,[8] and this could explain the longer life-span of the first follicle wave of the cycle.[3] Interestingly, although mean serum FSH is greatest at wave emergence, FSH pulse frequency increases during the follicle growth phase of follicle waves.[7] In the ewe, growth of follicles beyond 2 mm in diameter is FSH dependent, but the larger follicles of waves can transfer their dependence from FSH to LH (LH receptors develop in granulosa cells).[2] This probably explains the ability of the preovulatory follicle to grow when serum FSH concentrations are at their lowest point in the cycle. The

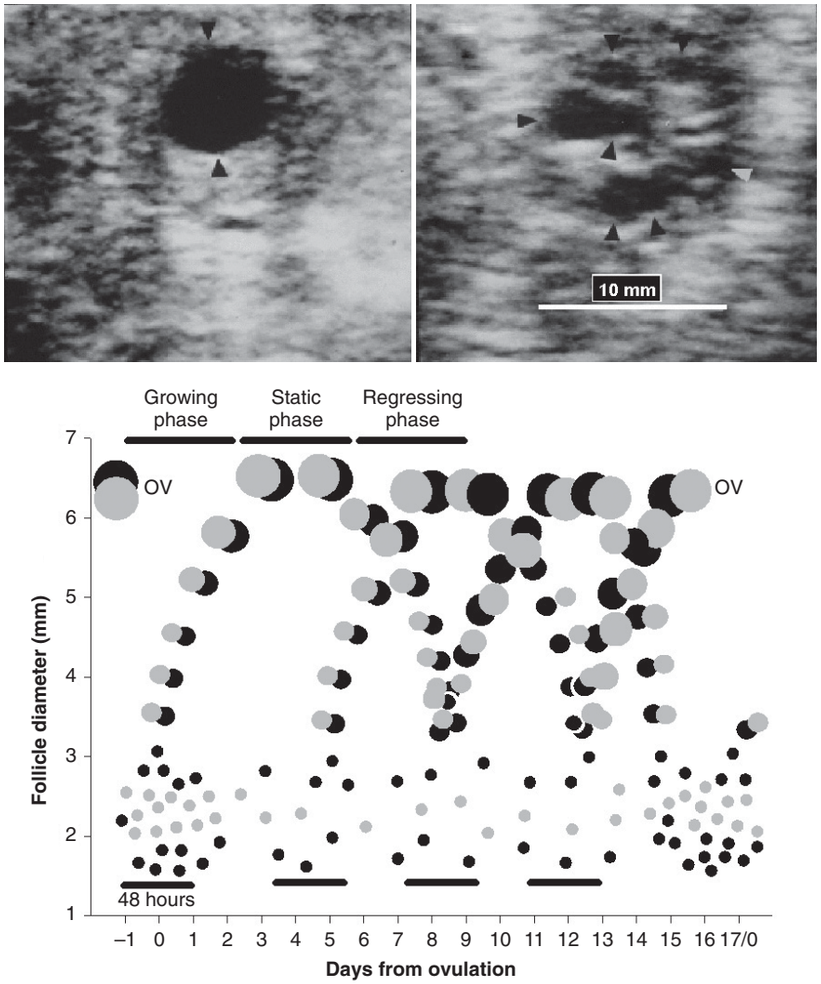

Fig. 87-1 The growth of ovarian antral follicles greater than 1 mm in diameter during the ewe's estrous cycle. The largest follicles (reaching ovulatory diameters of ≥5 mm) emerge in an orderly succession throughout the interovulatory period giving 3 to 4 follicular waves. Follicular emergence, or beginning of the growth of follicles to ovulatory sizes, occurs within a 48-hour period, approximately every 4 days during the luteal phase of the cycle. OV, ovulation. Photographic reproductions of ultrasonograms depict: *a*, a large antral follicle on the day before ovulation, and *b*, a cohort of small ovarian follicles (1–3 mm in diameter), obtained using transrectal ultrasonography of ovaries in Western white-faced ewes (nonprolific breed). Ultrasonography utilized a 7.5-MHz rectal probe connected to Aloka 500-SSD echo camera.

recent application of transrectal ovarian ultrasonography to the study of antral follicle dynamics in the ewe, described previously, promises to produce simple methods to increase ovulation rate and to synchronize follicle waves and ovulation to facilitate high fertility fixed-time insemination.[3]

In addition to endocrine regulation, follicular growth is subject to intraovarian control mechanisms. Insulin-like growth factors (IGFs) stimulate follicle growth and enhance gonadotropin responsiveness. The mRNA encoding IGF-II has been found in the theca of ovine follicles, but it is unclear if IGF-I is actually produced in the follicle or is supplied by production from the liver. Interestingly, a family of IGF binding proteins (IGFBPs) regulates the biologic activity of the IGFs, and a decrease in concentration of binding protein in antral follicles, as they grow, may enhance the biologic activity IGFs and gonadotropins. Inhibins and activins, members of the TGFβ superfamily, are produced by the growing follicle.[9] Inhibin has an α subunit coupled to either a βA or βB subunit; activins are dimers of βB, βA, or βB/βA. Activins promote granulosa cell proliferation and differentiation and estrogen production and are anti-atretogenic. Follistatin, an activin binding protein, can oppose the effects of activin. Inhibin α and inhibin/activin βA subunits are expressed in increasing amounts as antral follicles mature in the ewe; however, the local roles of inhibin are not as clear. Other potential regulators of follicle development are transforming growth factors α and β, epidermal growth factor (EGF) and fibroblast growth factor (FGF).

The antral follicle(s) emerging near the end of the ovine estrous cycle and destined to ovulate does not necessarily grow any larger than nonovulatory follicles of earlier waves, nor does it produce more estrogen.[3] The ovulatory follicle undergoes final development largely dependent on LH, and the preovulatory LH surge causes ovulation, luteinization, and maturation of the primary oocyte to a secondary oocyte.[2] Recent work in the ewe has shown that the preovulatory LH signal causes secretion of plasminogen activator from the ovarian and ovulatory follicle wall.[10] Plasmin activates collegenases, which disrupt the ovarian and follicle wall; plasmin also causes release of tumor necrosis factor alpha (TNF_α), an apoptotic agent.

Luteal Function

The collapsed, ovulated follicle contains a blood clot and little luteal tissue. This structure grows rapidly and organizes; it is called a corpus hemorrhagicum until day 4 or 5 of the cycle, when it starts to produce significant amounts of progesterone, and thereafter it is called a corpus luteum. In Western white-faced ewes, serum progesterone concentrations increase to around day 12 of the cycle and then decline to day 16; however, from days 8 to 13 serum progesterone concentrations do not differ significantly (see Fig. 87-1). Based on recent ultrasonographic data from Western white-faced ewes,[11] luteal volume increased to day 10 after estrus and then declined to day 17 of the cycle; however, luteal volumes did not differ significantly between days 8 and 13. Therefore, in Western white-faced ewes, a rapid increase in serum concentrations of progesterone preceded a marked increase in luteal volume. At luteolysis, functional and structural luteal regression seemed to commence coincidentally but the decline in serum concentrations of progesterone was somewhat sharper than for luteal volume. Prolific Finn ewes produced more but smaller corpora lutea and had lower serum concentrations of progesterone compared to Western white-faced ewes.[11] Interestingly, ultrasonographic studies in the ewe have revealed luteinized follicles and short-lived corpora lutea developing in parallel with normal corpora lutea.[3,7,11] In two ewes with the estrus cycle of 23 days each, normal life-span corpora lutea appeared to almost completely regress and then redevelop for a further luteal phase. In addition, serum progesterone concentrations vary with season; concentrations are greater in midbreeding season compared to the early or late season.[11]

The corpus luteum consists of small luteal cells derived from the theca cells of the follicle, large luteal cells derived from granulosa cells, fibroblasts, and endothelial cells. Only small luteal cells are LH responsive but the large cells probably produce most of the progesterone; prostaglandin receptors are restricted to large luteal cells. During luteogenesis small luteal cells divide but large luteal cells increase in size. Pulsed LH secretion does not appear to be necessary to maintain luteal progesterone secretion in the ewe but maintenance of progesterone secretion and luteal weights requires basal LH secretion.

Luteolysis is caused by pulses of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) from the endometrium of the uterine horn ipsilateral to the corpus luteum, between days 14 and 17 of the estrous cycle.[12] The $PGF_{2\alpha}$ is transported by a countercurrent exchange between the uterine vein and ovarian artery and the lymphatics are also involved. The pulsed release of $PGF_{2\alpha}$ is driven by pulsed secretion of oxytocin from the corpus luteum and perhaps the posterior pituitary. What actually initiates the pulsed secretion of oxytocin and $PGF_{2\alpha}$ is unclear. For oxytocin to stimulate $PGF_{2\alpha}$ secretion, the development of endometrial oxytocin receptors is pivotal. Development of oxytocin receptors is blocked until days 10 to 12 of the cycle by progesterone. However, progesterone eventually downregulates its own receptors, allowing an increase in estradiol receptors; estradiol is then able to stimulate production of oxytocin receptors.[12] Prostaglandin $F_{2\alpha}$ can cause functional luteolysis (loss of progesterone secretory ability) through receptors on large luteal cells and by disrupting cholesterol transport across mitochondrial membranes.[12] $PGF_{2\alpha}$ can also cause the release of endothelin 1 from endothelial cells in the corpus luteum. Endothelin 1 reduces progesterone secretion from luteal cells as well as causing vasoconstriction. Endothelin 1 may also attract monocytes to the corpus luteum and the release of transforming growth factor α from macrophages could be an early signal for apoptosis and structural regression of the corpus luteum. Prostaglandins (10–15 mg $PGF_{2\alpha}$ IM) have been used to cause luteolysis and synchronize estrus in ewes; the corpus luteum is only responsive from day 4 of the cycle.[1] Estrus occurs about 40 hours after $PGF_{2\alpha}$ but the estrous response and fertility to breeding with $PGF_{2\alpha}$ treatment are more variable than with other methods of estrous synchronization.

Endocrine Regulation

Gonadotropin-releasing hormone (GnRH), and hence LH and FSH, are released in a pulsatile manner in the ewe.[8] In blood sampling sites distant from the pituitary effluent, the pulsatile pattern of serum concentrations of FSH is unclear, possibly due to its long half-life. During the luteal phase of the ovine estrous cycle, LH and FSH secretion is suppressed and LH pulse frequency is low (1 to 2 pulses per 6 hours; see Fig. 87-1). LH pulse frequency is decreased by the negative feedback effects of progesterone and estradiol, operating in concert.[8,13] At luteolysis as progesterone concentrations decrease, LH pulse frequency increases (1 to 2 pulses per hour). Increased LH pulse frequency increases estradiol production from the follicles destined to ovulate, and rising titers of estradiol in the absence of progesterone elicit a surge of LH/FSH secretion lasting 12 to 14 hours.[8,14] Although LH/GnRH pulsatility persists throughout the preovulatory surge, a surge of GnRH is also released. Ovulation occurs about 24 hours after the onset of the preovulatory LH surge and the surge occurs early in estrus. Following the preovulatory LH surge, elevated LH pulse frequency is initially maintained, suppressed eventually by the increasing progesterone secretion from the corpus hemorrhagicum/luteum.[14] Following ovulation, a second peak in serum FSH concentration is seen, heralding the first wave of antral follicle growth of the subsequent estrous cycle.[3] Treatment with exogenous progesterone suppresses LH pulse frequency, and progesterone or synthetic progestogens in Silastic rubber intravaginal devices or sponges, respectively, will suppress cyclicity and give good estrous synchrony when withdrawn.[1,13] Intravaginal devices or sponges are left in place for 12 to 14 days, and ewes come into estrus about 48 hours after sponge removal.

Estrous Behavior

The ewe in estrus will seek out the ram and stand as he conducts his investigative courtship. The estrous ewe will often shake her tail and turn her head to look back at the ram. Ewes out of estrus will squat and urinate at the ram's approach and move away if he approaches her

aggressively. Vulval swelling is often seen in the estrous ewe with a copious thin vaginal mucous secretion. Estral vaginal mucus dries into a typical fern crystal pattern on a glass slide.[15] Estrus is clearly timed by a period of progesterone priming (luteal phase), following by progesterone withdrawal and exposure to estradiol. Timing of estrus and the preovulatory LH surge are influenced by the peak concentrations of progesterone during the luteal phase and the slope of the progesterone decline at luteolysis;[16] higher luteal progesterone concentrations and a slower decline delay estrus and the LH surge.

MATERNAL RECOGNITION OF PREGNANCY

Progesterone is essential for the maintenance of pregnancy and following conception the corpus luteum of the cycle has to be maintained. The conceptus must be present by day 12 to 13 of the cycle in the ewe to rescue the corpus luteum from luteolysis. The ovine trophectoderm produces interferon tau (IFN-τ) between days 10 and 21 of pregnancy, with a marked increase in production between days 13 and 15.[12] Interferon tau blocks the pulsatile secretion of $PGF_{2\alpha}$, but not basal secretion, probably by suppressing production of the endometrial estrogen receptor and hence the increase in oxytocin receptor numbers required to trigger the luteolytic release of $PGF_{2\alpha}$. Embryo elongation is important to provide an antiluteolytic signal to the uterine horn ipsilateral to the corpus luteum, and ewes with higher serum concentrations of progesterone very early in the cycle (days 2–4) develop faster and produce more IFN-τ.[17] Therefore, there may be a role for progesterone supplementation in early pregnancy to reduce the chance of early embryonic death.

PREGNANCY AND PARTURITION

The corpus luteum is essential to pregnancy until day 50 or 60 of gestation; thereafter, the placenta assumes the role of progesterone production.[18] Serum concentrations of progesterone increase markedly after day 80 of gestation.

Pregnancy Diagnosis

Real-time ultrasonography can be used to detect pregnancy and assess fetal numbers as early as day 25 of gestation. Pregnancy-specific protein B (PSPB) can be detected as early as day 20 of gestation. Progesterone concentrations in serum in late gestation differ between ewes carrying singletons, twins, and triplets as the placental mass varies with fetal numbers. However, there is too much overlap between ewes with different fetal numbers for this to be useful in predicting fetal numbers.

Parturition

Apart from isolated, uncoordinated contractions, the uterus of the ewe remains quiescent until the forceful and coordinated parturient uterine activity that lasts just 9 to 12 hours (Fig. 87-2).[19] Once initiated, uterine contractions increase in amplitude and frequency, in coordinated waves, from ovarian to cervical ends. During this period, the cervix dilates under the mechanical influence of uterine contraction and fetal pressure. Fetal expulsion occupies no more than the final 25% of the period of parturient uterine activity, and this is usually followed by placental expulsion within several hours. Over the last days to weeks before parturition, connective tissue in the cervix and pelvic ligaments relaxes, and in preparation for delivery, the fetus is orientated into the birth position.

Parturition in the ewe is initiated by the fetus.[18] During the last 2 to 3 weeks of gestation secretion of corticotropic releasing hormone (CRH), adrenocorticotropic hormone (ACTH), and adrenal cortisol and androstenedione increase in the fetus; serum concentrations of cortisol increase rapidly in the fetus over the last 2 to 3 days before delivery (see Fig. 87-2). It is not clear whether this increase in activity in the fetal hypothalamic-pituitary-

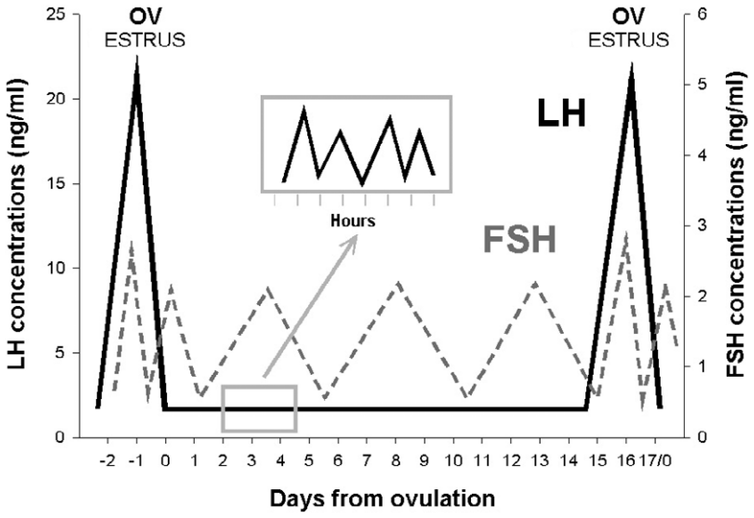

Fig. 87-2 Diagram illustrating changes in circulating concentrations of gonadotropic hormones, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), at different stages of the ovine estrous cycle.

adrenal axis is purely a developmental progression or an increased sensitivity to stressors such as hypoxia.[21] In addition, increased estrogen concentrations in the fetus (placental origin) increase ACTH secretion and androstenedione and prostaglandin E_2 (placental origin) can reduce the negative feedback regulation of ACTH secretion by cortisol (Figs. 87-3 and 87-4). During the last 2 to 3 weeks of gestation, the fetal adrenal gland grows rapidly and increases in sensitivity to ACTH.[18,22] Increased fetal cortisol concentrations primarily enhance placental 17α-hydroxylase activity to force a change from placental progesterone production to estrogen production.[20,22] In the ewe, serum concentrations of progesterone decline over the last 5 to 15 days of gestation while serum estradiol concentrations gradually increase; however, the major and most dramatic increase in estradiol is restricted to the last 1 to 2 days before fetal delivery.[18,19] The shift in the estrogen-to-progesterone ratio is critical for initiating parturition. The decline in progesterone secretion and increase in estrogen production promote the production of myometrial contractile proteins, enzymes needed for energy production, and gives a marked increase in sensitivity to oxytocin (increased receptor numbers). Progesterone tends to have a hyperpolarizing effect on the myometrium while estrogens tend to render the myometrium more hypopolarized or more unstable and responsive to stimulation. These effects involve influences on production of ion channels and calcium handling in the myometrium. The shift in the estrogen-to-progesterone ratio increases gap junction production in the uterus, enhancing electrophysiologic coupling. The initiation of parturition and development of contractibility involves stimulation by $PGF_{2\alpha}$, whose production by the placenta is enhanced by the shift from progesterone to estrogen production. This same steroidogenic shift enhances posterior pituitary production of pulsed secretion of oxytocin, which stimulates uterine contraction both directly and by release of prostaglandins

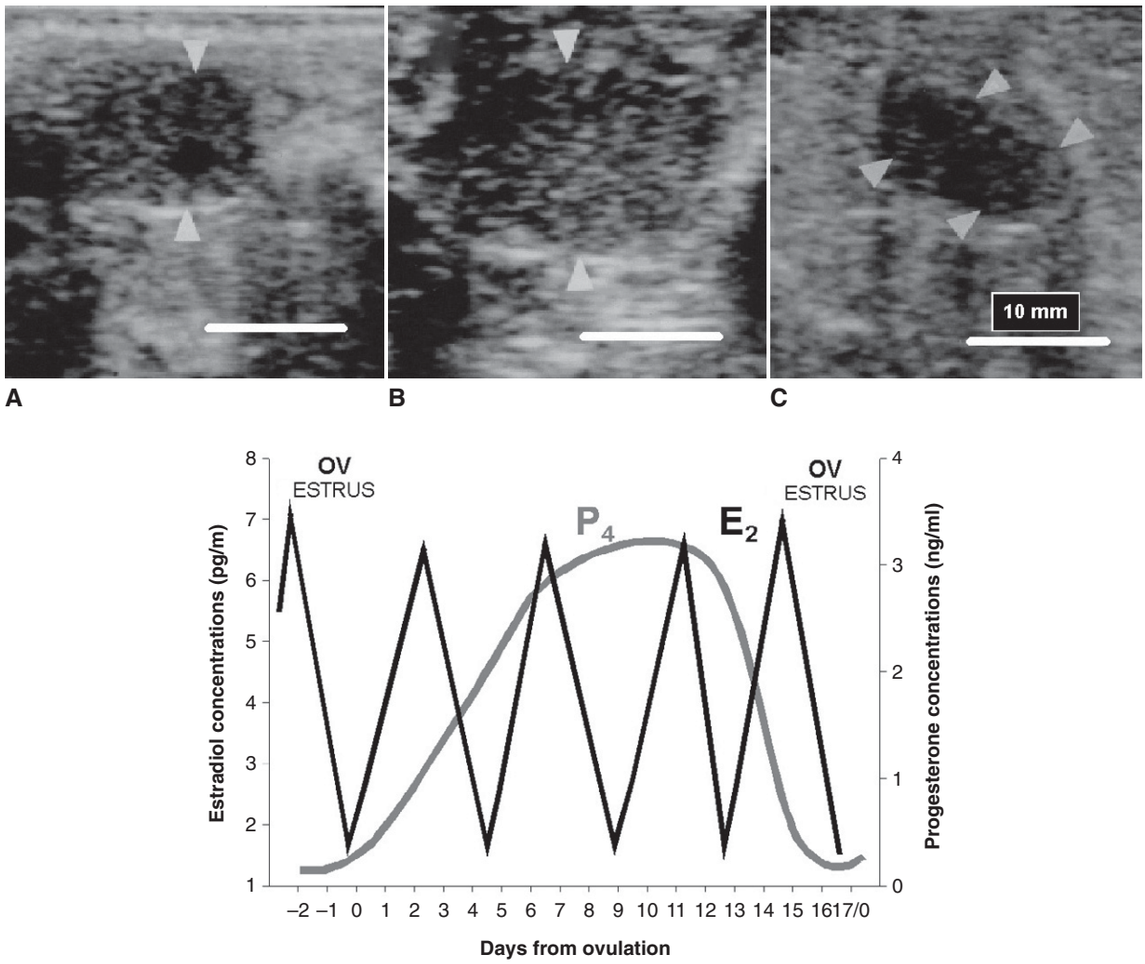

Fig. 87-3 Changes in mean serum concentrations of progesterone (P_4) and estradiol 17-β (E_2) throughout the sheep estrous cycle. Secretion of luteal P_4 closely reflects physical changes in corpora lutea (CL). Peaks of transient increases in serum E_2 concentrations coincide with the end of the growth phase of the largest follicles of waves, and follicular wave emergence is associated with the onset of successive E_2 fluctuations. Photographic reproductions of ultrasonograms depict: *A*, corpus luteum (CL) containing a small central cavity in the ovary of a ewe on day 5 of the estrous cycle; *B*, ovine CL detected at midcycle (day 11); and *C*, two regressing CL detected on day 15 after ovulation.

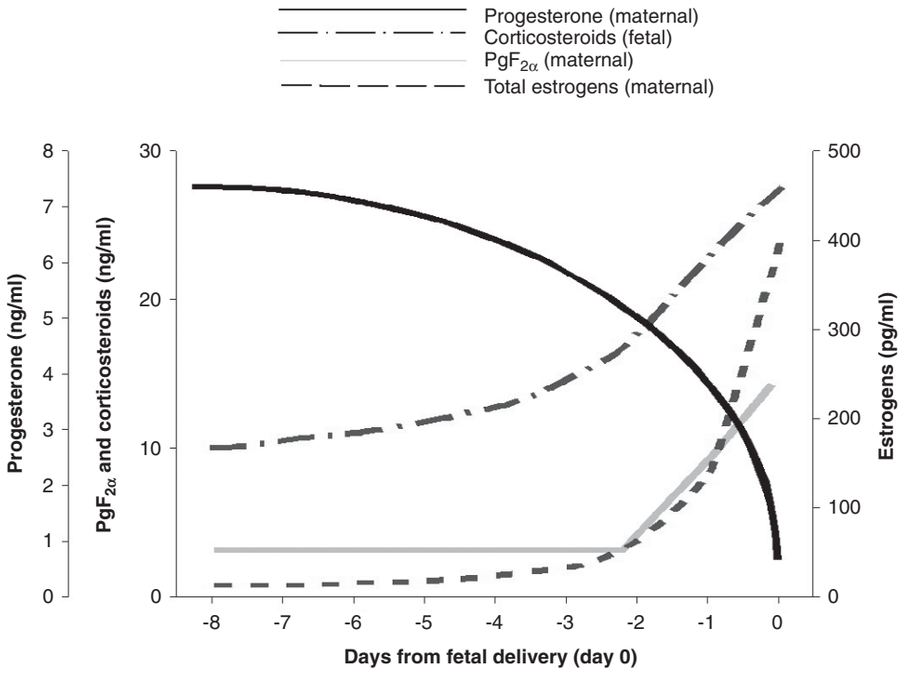

Fig. 87-4 Endocrine changes occurring before and during parturition in the ovine fetus and pregnant ewe.

from the endometrium. As the fetal head enters the cervix and contacts the vaginal wall, there is a neuroendocrine release of oxytocin, and spinal reflexes bring abdominal contractions to bear to reinforce each uterine contraction. The relaxation of pelvic ligaments and cervical softening (ripening) are due to release of collagenase under the influence of estrogens and PGE_2; PGE_2 is produced in increasing amounts by the placenta and cervical mucosa over the last 2 to 3 weeks of gestation. The hormone relaxin is probably also involved in the process of parturition in the ewe, inhibiting myometrial contractility until near term and causing cervical ripening.

Induction of Parturition

Parturition can be induced with synthetic glucocorticoids (15–20 mg dexamethasone IM) given within 4 to 5 days of expected term.[1] Induction is successful earlier in gestation (20–30 days before term), but fetal dysmaturity is a problem. The interval from induction to lambing averages about 48 hours. Estrogens can also be used (estradiol benzoate 2–20 mg IM), with an interval from induction to lambing of around 40 to 45 hours.[23] It is obviously necessary to have accurate breeding dates to avoid premature induction of lambing; however, if a low dose of estradiol benzoate is used (2 mg IM), ewes 17 days preterm are not induced to lamb. Prostaglandins will terminate pregnancy up to about day 30 of gestation but are not useful thereafter, probably because they induce luteolysis and later in gestation the ewe produces progesterone from the placenta.[1]

POSTPARTUM PERIOD

Ovarian follicular development is suppressed during pregnancy and until days 20 to 30 post partum, particularly in the ovaries containing or previously containing corpora lutea.[24] This suppression appears to be due to, or a residual effect of, the fetus. In general, postpartum recovery of ovarian function is not a practical problem as ewes generally lamb into their seasonal anestrus.

SEASONALITY

Ewes derived from northern latitudes and managed in temperate climates are regarded as short-day breeders. The ewe appears to have an endogenous rhythm to its seasonality, with a periodicity of 1 year. This endogenous rhythm is cued to season by photoperiodic signals. This endogenous annual cycle is maintained when ewes are exposed to constant day lengths but becomes disassociated from season.[8] Photoperiod influences reproduction through the pattern of pineal melatonin secretion. Melatonin is secreted during the hours of darkness and hence the period of melatonin secretion during each 24-hour period varies with day (night) length. Information from the eye is transmitted to the suprachiasmatic nucleus of the hypothalamus, and from there it is routed to thoracic spinal nerves and by way of the superior cervical ganglion to the pineal gland. Not all the annual melatonin secretory profile is used by the ewe to cue its annual reproductive rhythm to season. Spring and fall components may have an influence but the summer pattern of melatonin secretion (summer solstice to autumn equinox) is most critical. The sites where melatonin interfaces to regulate reproductive seasonality is unclear, but it is probably in the medial basal hypothalamus in sheep.

The onset of seasonal anestrus is abrupt in sheep, with the failure to ovulate at the end of a luteal phase. The growth of waves of antral follicles continues during anestrus.[25–27] Some irregularity in waves is noted transiently at the end of the breeding season but not at the onset of the next season. Waves are initiated by peaks in

FSH secretion and follicles grow to ovulatory sizes; however, estrogen production is limited in anestrus. Wave periodicity is around 5 days. The number of small follicles (<3 mm) is greater in anestrus than the breeding season. At the onset of the breeding season there is a variable length period of progesterone secretion (normal luteal phase length and shorter) that is produced by a preovulatory-like LH surge, but is not preceded by ovulation or estrus. The source of this progesterone is unclear; in some ewes it emanates from luteinized follicles. The second LH surge of the season is accompanied by ovulation and estrus. At the onset of anestrus, specific dopaminergic neurons are activated that inhibit GnRH pulse frequency. These neurons are sensitive to estradiol, such that estradiol has a powerful inhibition of LH pulse frequency during anestrus.[8] These inhibitory influences are reversed at the onset of the following breeding season and melatonin secretory patterns are able to cue these shifts in inhibitory influences. Interestingly, an intact thyroid is required for the onset of anestrus.[8]

Estrus can be induced in anestrus ewes by a 12-day treatment with a progestagen-impregnated intravaginal sponge; 500 IU of equine chorionic gonadotropin (eCG) is given at sponge removal. Without eCG, few ewes show estrus and ovulate. The success of synchronization in anestrus depends on the breed used and stage of anestrus. Fertility is better close to the breeding season compared to deep anestrus and ewes with a shorter anestrus respond more consistently. Introduction of a novel ram to anestrus ewes, after a period of isolation from the male, will induce increased pulsed secretion of LH within minutes, an LH surge within 48 hours, followed by a silent ovulation. The following luteal phase can be normal length or short (6–7 days) but is followed by estrus and ovulation. The short luteal phase can be prevented by exposure to progesterone before ram introduction. Again, the response to the ram varies and works best in ewes late in anestrus. Artificial day-length manipulation can be used to advance the breeding season. A typical treatment would be a month of exposure to long days in late winter, spring, or early summer, followed by an abrupt or gradual reduction to short days. Response time varies depending on the season in which the treatment is started, being shorter the closer treatment is applied to the onset of the breeding season. Ewes have also been treated with melatonin orally or by implant to advance the breeding season; treatment will not prolong the season. Treatments given in May or June, for 60 to 70 days, have been effective in advancing the breeding season and improving fertility early in the season but results have not been positive in all cases.

SEXUAL MATURATION IN THE EWE LAMB

Suffolk and Western white-faced ewe lambs show first pubertal estrus at around 30 weeks of age.[28,29] The onset of cyclicity at sexual maturity is similar to the adult ewe in transition from anestrus to the breeding season, in that silent ovulation or a short luteal phase may be seen. In the ewe lamb, LH pulse frequency increases markedly several weeks before puberty. Using ultrasonography, numbers of large antral follicles and maximum follicle size were shown to increase from 8 to 24 weeks of age, with a peak at 16 weeks of age.[28,29] Timing of sexual maturation in ewes is dependent on nutrition and an adequate rate of growth as well as photoperiodic influences. The well-grown ewe lamb must experience long days and then decreasing day length to show first estrus and the breeding season. Lambs need to be born early enough in the year to be able to grow adequately to show estrus in the fall. Again, as in the adult transitioning out of anestrus, LH pulse frequency increases owing to a decrease in responsiveness to estradiol negative feedback. This decrease in negative feedback is influenced and cued by adequate growth and photoperiod.

CHAPTER 88

Sheep Breeding Strategies

DUANE H. KEISLER

Sheep are among the most versatile of the livestock species managed today in adaptability to diverse production environments and purveyors of various products throughout the world. Certainly the origin of this diversity evolves from the 400 to 800 different breeds of sheep that exist worldwide. As an example, although most sheep breeds birth 1 to 3 lambs per lambing, unique breeds such as the Booroola Merino exists functionally as litter-bearing ruminants, giving birth to 6 or more offspring per lambing. Compounding this diversity among breeds is the fact that sheep are seasonal short-day breeders, and adherence to or deviation from the short-day breeding activity will vary with the geographic latitude of their origin and subsequent management. Therefore, as advantageous as this diversity may be, it also imposes the liability that one set of recommendations cannot fit all paradigms. The objective with this chapter therefore is to describe the major variables that influence breeding activity and subsequent lambing performance in a manner that allows the informed individual to plan or diagnose schemes for managing breeding strategies that optimize ewe production performance.

CONSIDERATIONS IN SELECTING A BREEDING STRATEGY

Breeding Ewe Lambs

From a producer's perspective, a major dilemma exists in the decision of which ewe lambs should be kept as replacement females to enter the flock and which ewe lambs should be sold to capture market lamb prices while that "window of opportunity" still exists. Certainly the animal's genetic merit, production potential, and structural integrity are important variables to consider, but perhaps not as critical, but still significant, are the answers to the following two questions: (1) Will the selected ewe lambs ever achieve reproductive competence—(given that 10% to 20% of ewe lambs may possess some anomaly that prohibits the ability to ever reproduce)? (2) If the ewe lambs are capable of reproducing, when will they exhibit that capability (research has noted that ewe lambs that reach puberty at an early age are more reproductively efficient throughout their lifetime than are ewe lambs that reach puberty at an older

CHAPTER 88

Sheep Breeding Strategies

DUANE H. KEISLER

Sheep are among the most versatile of the livestock species managed today in adaptability to diverse production environments and purveyors of various products throughout the world. Certainly the origin of this diversity evolves from the 400 to 800 different breeds of sheep that exist worldwide. As an example, although most sheep breeds birth 1 to 3 lambs per lambing, unique breeds such as the Booroola Merino exists functionally as litter-bearing ruminants, giving birth to 6 or more offspring per lambing. Compounding this diversity among breeds is the fact that sheep are seasonal short-day breeders, and adherence to or deviation from the short-day breeding activity will vary with the geographic latitude of their origin and subsequent management. Therefore, as advantageous as this diversity may be, it also imposes the liability that one set of recommendations cannot fit all paradigms. The objective with this chapter therefore is to describe the major variables that influence breeding activity and subsequent lambing performance in a manner that allows the informed individual to plan or diagnose schemes for managing breeding strategies that optimize ewe production performance.

CONSIDERATIONS IN SELECTING A BREEDING STRATEGY

Breeding Ewe Lambs

From a producer's perspective, a major dilemma exists in the decision of which ewe lambs should be kept as replacement females to enter the flock and which ewe lambs should be sold to capture market lamb prices while that "window of opportunity" still exists. Certainly the animal's genetic merit, production potential, and structural integrity are important variables to consider, but perhaps not as critical, but still significant, are the answers to the following two questions: (1) Will the selected ewe lambs ever achieve reproductive competence—(given that 10% to 20% of ewe lambs may possess some anomaly that prohibits the ability to ever reproduce)? (2) If the ewe lambs are capable of reproducing, when will they exhibit that capability (research has noted that ewe lambs that reach puberty at an early age are more reproductively efficient throughout their lifetime than are ewe lambs that reach puberty at an older

age)? The factors that regulate the age at which lambs reach puberty can be categorized as genetic, environmental, and the interactive effects of genetics and environment.

Lambs of the British breeds, such as Southdown, Shropshire, Oxford, Hampshire, Suffolk, and Dorset, generally reach puberty at an earlier age than do lambs of the Spanish breeds, such as Merino, Rambouillet, Columbia, and Corriedale. In general, most lambs reach puberty within 6 to 10 months of birth, providing that environmental determinants such as nutrient availability, health status, and photoperiodic environment are favorable. Prolific breeds, such as Romanov and Finnish Landrace, may reach puberty at earlier ages. Therefore, among the first considerations to be made in assessing a realistic breeding scheme is whether the ewe lambs in question are of *sufficient age to reproduce*. Once some reasonable determination has been made that the lambs meet or exceed the breed-defined age parameters to reproduce, focus can then be placed on environmental conditions that permit the lamb to express its minimum age at puberty.

There are many environmental determinants of a lamb's age at puberty; however, the most frequently overlooked factor is the nutritional status of the developing lamb. The relationship between age and weight (or "condition") of lambs at puberty is critical. Figure 88-1 illustrates this relationship for lambs growing at three different rates. The long-dash line illustrates the growth rate of lambs belonging to a producer who overfeeds his lambs in an effort to minimize their age at puberty. What this producer will find is that the "long-dash line" lambs do not reach puberty until they also satisfy the minimum age requirements. The cost of this mismanagement or unnecessary investment in excess feed is evident in the excess weight or condition carried by the "long-dash line" lambs as they start to cycle. Furthermore, evidence now exists that animals carrying excess fat have reduced fertility.

In stark contrast to the overconditioned lambs represented by the long-dash line are the lambs managed by a producer who inadequately feeds his lambs (represented by the short-dash line), maintaining the presumption that the "short-dash line" lambs will begin to reproduce when they are of sufficient age. Clearly, in this situation the "short-dash line" lambs will surpass their genetically defined minimum age at puberty owing to insufficient metabolic reserves to initiate the reproductive process. In the ideal situation (represented by the solid line), a producer should feed lambs to a target weight and age to conserve feed without sacrificing reproductive performance. The minimum age requirement is dictated by the breed and the minimum weight requirement is generally 68% of their projected adult body weight. Producers who choose to breed ewe lambs at the minimum limits of their age and weight should manage the lambs so that they satisfy both minimum requirements at least 2 to 3 weeks prior to the time it is desired to have them cycling.

When ewe lambs start to cycle, the next logical question is when should they *first be bred*. Much research has provided evidence to support the argument that with few exceptions ewes should be selected, managed, and bred to produce offspring by 1 year of age. The benefits are reduced preproduction costs, shortened generation intervals (thus permitting more rapid genetic progress), and finally, increased lifetime productivity. The risks are slowed growth rates of the dam, low initial conception rates, and potential birthing or mothering problems as the result of the young dams giving birth to multiple or oversized offspring. The key to making the correct decision lies in the ability to plan and manage this process. For example, the earlier lambs are bred in the breeding season, the greater the probability those young dams will conceive single offspring, thus reducing the incidence of birthing difficulties associated with multiple births and reducing the risk of insufficient milk for multiple offspring. Furthermore, lambs could be bred to breeds of rams noted for their lambing ease to minimize potential lambing difficulty. Perhaps most the valuable information gained in efforts to breed ewe lambs at a young age is the identification and thus ability to select ewe lambs with the ability to reproduce.

Nonetheless, once the young dams lamb, it is critically important to feed them adequately to ensure their con-

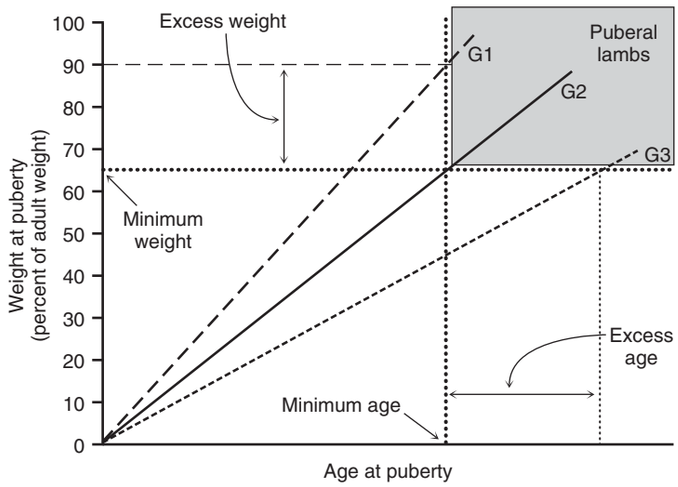

Fig. 88-1 Relationship between age and weight of lambs at puberty that are growing at three different rates.

tinued growth and development while lactating and beyond. Failure to adequately feed dams that lamb at a young age is one of the most common mistakes made by producers.

Also important in selecting replacement ewe lambs is their date of birth (Fig. 88-2). The reason for this selection variable is because in order for ewe lambs to reach puberty, they must first be exposed at an early age to increasing day lengths (summer solstice = June 21) and later to decreasing day lengths (winter solstice = Dec. 21), the latter of which provides the stimulus for them to begin to cycle. Offspring born prior to June have the greatest likelihood of reaching puberty and starting to cycle during the subsequent fall or winter if conditions are favorable, whereas offspring born after June are less likely to reach puberty during the first fall or winter but will wait until the following fall or winter to reach puberty at over 1 year of age.

Finally, it should be noted (as illustrated in Fig. 88-3) that for ewe lambs, the breeding season will typically begin 3 weeks after the adult ewes and cease 3 weeks prior to the adult ewes. The consequence of these restrictions is reduced opportunity to conceive at a time in the ewe's life when conception rates are typically low to begin with—thus the concern over delayed age at puberty.

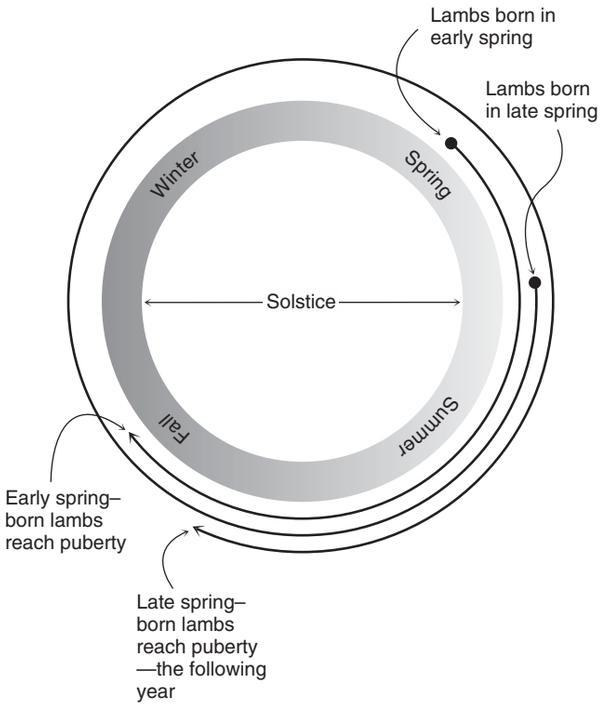

Fig. 88-2 Relationship between date of lamb's birth, length of daylight, and age at puberty.

Breeding Adult Ewes

A proportion of all ewes will cycle year round (also represented in Fig. 88-3 and Table 88-1) and typically for ewes living closer to the Equator (e.g., Idaho versus Texas), the proportion of ewes cycling year round increases. In contrast, it should be noted that relocation of breeds of sheep that are adapted to the equatorial latitude to locales more distant from the equator will result in a lower proportion of ewes cycling year round. As an example, efforts to establish a flock of ewes that breed year round in New York simply by importing ewes from the tropics will not be effective.

As an added note of caution, behavioral estrus and the occurrence of ovulation are not necessarily co-dependent. With this in mind, it is important to note that the proportion of ewes ovulating in Table 88-1 is often greater than the proportion of ewes that display estrus. This phenomenon is especially true during the times of the year when ewes make the transition into or out of the breeding season. The reason for this disconnect between estrus and ovulation may be due to either a failure in the ability to detect estrus or failure by the ewe to show estrus at the time of ovulation (silent estrus).

Finally, among ewes that cycle throughout the year, ovulation rate will vary with season of the year (see Table

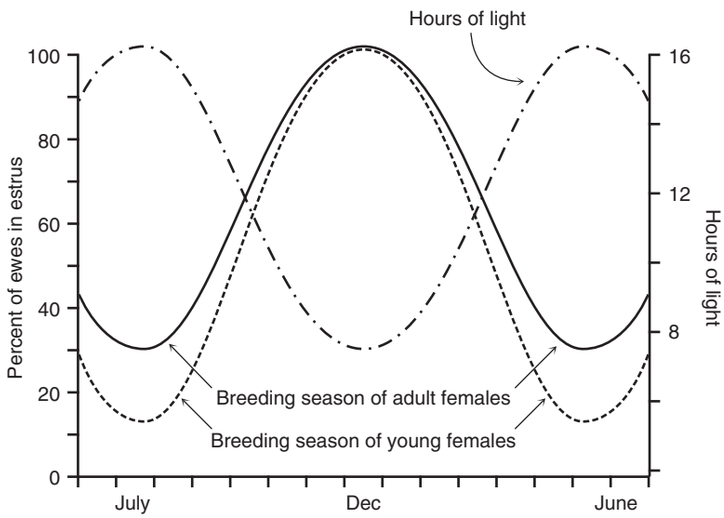

Fig. 88-3 Breeding activity in sheep in the Northern Hemisphere relative to length of day and month of the year. The solid line symbolizes ewes with longer breeding seasons than those represented by the short dashed line.

88-1). More specifically, ewes that are bred during the summer months (e.g., June) produce fewer lambs (ovulation rate = 1) than the same ewes bred during the fall or winter months (ovulation rate = 1.7–1.8). This latter point is especially important to consider for producers who manage a program to breed ewes "out of season" (during the summer months) in an effort to produce more lambs per year.

EFFECT OF LIGHT CONTROL PROGRAMS

Reducing the exposure of ewes to long day lengths can be used to induce cyclic activity. Implementing this approach is usually achieved by blocking the exposure of ewes to the light of morning or evening through the use of "light-tight" barns. This morning/evening type of restriction attempts to minimize the exposure of ewes to the adverse effects of the high ambient temperatures associated with long days. In reality, implementing "blackout" conditions to initiate cyclic activity is seldom used due to facility requirements or limitations.

In contrast to reducing ewes' exposure to light, a radical experimental approach with considerable merit may be achieved through supplemental (artificial) lighting. This approach involves exposing ewes to artificial lights beginning on the shortest day of the year, so as to expose ewes to a total of 20 hours of light (8 hours natural plus 12 hours artificial). Subsequently, the amount of artificial light the ewes are exposed to on a daily basis is eventually reduced to 0 hours on June 21 when the natural length of day is approximately 14 hours. This paradigm effectively inverts the seasonal fluctuation in length of daylight, dictating that ewes see "long days" (i.e., more light) during the winter and "short days" (i.e., less light) during the summer, potentially resulting in the induction of cyclic activity during the summer, which is traditionally the "nonbreeding" season. The advantage that this approach offers over the light deprivation approach is the ease with which artificial light can be added relative to the investment necessary to establish "light-tight" facilities. Unfortunately, this approach is purely experimental and has received little attention; thus, its efficacy is not well established.

Certainly the advantages of a breeding scheme that relies on phototherapy (or melatonin treatments to mimic phototherapy as discussed subsequently) appear obvious and the "natural" approach, yet two inherent disadvantages exist: (1) the need to treat ewes on a daily basis and (2) the long lag time (4 to 6 weeks) from initiating treatments to initiation of cyclic activity by the ewes.

Table **88-2**

Effect of Temperature on Variables of Reproductive Importance

	HOUSING FOR RAMS AND EWES (AUGUST)	
Variable	**Outside**	**Air-Conditioned Room**
% eggs fertilized	26%	64%
% embryonic death	49%	22%
% ewes lambing	13%	50%

Dutt and Simpson, 1957.

EFFECT OF ENVIRONMENTAL TEMPERATURE

When seasons change, so does temperature. Temperature does not appear to play a major role in dictating the cyclic activity of ewes, but it does have a major detrimental effect on embryo survival, especially when temperatures are high during the week following breeding (Table 88-2). When ewes and rams were housed in a hot climate versus a cool climate, the hot weather resulted in a lower percentage of fertilized eggs, greater embryonic death, and consequently fewer ewes lambing. Any condition that limits an animal's ability to cool itself (e.g., high humidity) adversely affects reproductive performance.

EFFECT OF EWE AGE AND BREED

Breed and age also affect the breeding activity of ewes (Table 88-3). Some breeds of sheep, such as Rambouillet, Merino, and Dorset, have longer breeding seasons than others, such as Southdown and Cheviot. Fortunately, long breeding seasons are genetically dominant; therefore, it is possible to increase the length of the breeding season through selective breeding. Within a breed, as an animal's age increases, the length of the breeding season and fertility also increases (see Table 88-3). Ewe lambs that are starting to cycle for the first time generally tend to start cycling about 3 weeks after the adults and stop cycling about 3 weeks before the adults (see Fig. 88-3). As age increases, reproductive efficiency also increases when measured by number of surviving offspring (due, in part,

Table **88-3**

Effect of Age of Dam on Three Lamb Production Traits Independent of Breed, Year, Type of Birth, and Type of Mating

9+	54	82	153	99

From Sidwell et al., 1962.

to learned mothering ability) and number of offspring produced (due, in part, to an increase in ovulation rate as ewe age increases).

EFFECT OF NUTRITION

For animals to produce, they must be adequately nourished and be maintained in good body condition. Poorly nourished animals cannot meet their needs for maintenance and be expected to produce a product. Clearly, ewes with the greatest nutrient intake respond most rapidly to the onset of the breeding season and continue to respond with an increase in ovulation rate until the termination of the breeding season. In contrast, ewes receiving less than National Research Council recommendations exhibit only a modest increase in ovulation rate at the initiation of the breeding season, and fail to maintain that slight increase; most likely owing to other energetic demands.

The rapid response of ewes receiving greater than National Research Council nutritional recommendations with an increase in ovulation rate has long been known and referred to as *flushing*. In order for the technique of flushing to be effective, it is usually initiated 2 to 3 weeks prior to the beginning of the breeding season and is accomplished by supplementing ewes with a high-energy feed such as 0.5 to 1.5 lb of corn per head per day. The most effective time of the year to use the technique of flushing to increase ovulation rates of ewes is when ovulation rates are marginal and especially when ewes are transitioning into or out of the breeding season. Flushing is also most effective in ewes with greater energetic demands. As can be seen in Table 88-4, regardless of the fact that both fat and thin ewes are gaining weight at an equivalent rate in response to the flushing stimulus, only the thin ewes respond with an increase in ovulation rate. It should also be noted that the increase in ovulation rate in response to the flushing stimulus does not exceed that capability exhibited by the fat ewes regardless of energy intake. Consequently, flushing is a short-term technique that merely permits the animal to express its genetic potential to ovulate. Neither flushing nor feeding the animal in excess of its needs permits the animal to supersede its genetically defined limitations. In contrast, limiting nutrient availability not only reduces ovulation rates but also shortens the length of the breeding season, limits the animals' milking ability, and compromises other systems related to production. Simply put, when animals are not fed, they fail to produce.

Table **88-4**

Effect of Ewe Condition on Ovulation Response to Flushing

Ewe Condition	Treatment	Rate of Gain	NUMBER OF EWES OVULATING	
			Singles	*Twins*
Thin	Flushed	.23	12	8
	Unflushed	.02	20	0
Fat	Flushed	.21	10	10
	Unflushed	.04	8	12

From Clark: *Anat Rec* 1935;60:125.

EFFECT OF STRESS

The stress imposed on animals can come from disease, parasites, confinement, lactation, suckling stimulus (an effect independent of lactation), and other factors both known and unknown. Stressful situations typically reduce production performance.

When considering the stress of suckling, ewes that suckle lambs take longer to return to estrus than ewes from which lambs have been weaned at an early age (Fig. 88-4). The recipe for predicting the outcome of stress management approaches may not always be as anticipated, depending on the source of the stress. Consequently, selective removal of specific stressful stimuli can produce responses that are either ineffective, permissive, or facilitating (e.g., ram introduction, discussed subsequently) to reproductive performance. The ability to

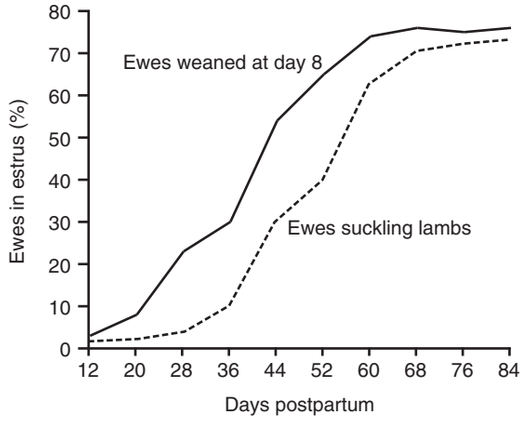

Fig. 88-4 Effect of early weaning versus suckling on ewes returning to estrus.

predict the outcome of selective stressful stimulus requires the ability to collectively assess the total impact of that stress on the balance that exists between the animal's inherent drive to reproduce and the demands that keep her from reproducing. For example, although early weaning of lambs may appear to provide a simple solution to accelerate the rebreeding of ewes, the technique is ineffective when used as the only stimulus to induce cyclic activity in ewes lambing during the spring or summer months. The differential response between groups of ewes lambing in the fall versus the summer can be attributed to the powerful inhibitory effects of long day lengths. In contrast, by creating an environment in which several inhibitory stressors are negated, using combined approaches, such as lamb removal and flushing, may be sufficient to initiate cyclic activity in ewes even in the presence of other inhibitory influences such as long day lengths.

EFFECT OF SEASON

It is likely that a far greater proportion of ewes initiate cyclic activity during the nonbreeding season in response to combined management approaches than is realized. Ewes initiating cyclic activity following a period of anestrus typically exhibit a silent first ovulation. Consequently, producers fail to realize the impact of their actions and relax their efforts to rebreed ewes, thus permitting the inhibitory influences to again suppress the ewe's drive to reproduce. Should these efforts occur during the influence of positive environmental conditions, behavioral estrus will follow silent ovulations within 3 weeks. During transitional phases (e.g., from anestrus to estrus or from prepuberty to puberty), a hastening of the onset of breeding activity can be achieved in a greater proportion of ewes with techniques such as short-term lamb removal and flushing. Some reports also cite the positive effects of ram introduction and transportation stress on inducing ewes to ovulate. Management of transportation stress to evoke a positive response is likely among the most difficult to assess because of the delicate perception of transportation as a stimulatory as opposed to an inhibitory stimulus.

EFFECT OF RAM INTRODUCTION

The most powerful stimulus that is widely known and used is the introduction of a novel ram. In general, to evoke a ram-introduction response, ewes need to be isolated from the sight, sound, and smell of rams for approximately 30 days prior to introduction, although reports in the literature vary greatly with regard to the completeness and duration of isolation. Typically, the ram-introduction technique involves the use of teaser rams to hasten the onset of the breeding season. Once ewes are cycling, fertile rams are introduced. When attempting to induce estrous cycles in anestrous or prepubertal ewes using the ram introduction effect, it is recommended that the planned herd sires and not teaser rams be used because the response of ewes may be short-lived. Fertile mating should be encouraged at every opportunity because the likelihood of nonpregnant ewes recycling following a ram-induced ovulation during anestrus is low.

HORMONE THERAPIES USED IN BREEDING SCHEMES

Hormonal manipulations of the reproductive processes offer many advantages that are difficult to attain without their use. These advantages include concentration of the breeding and lambing seasons, permitting (1) more efficient use of labor and facilities and (2) greater supervision of ewes and lambs at lambing, thus providing (a) greater opportunity for less death loss and (b) greater success in cross-fostering lambs. Concentrated breeding and lambing also permits ewes and lambs to be managed more uniformly in flock health, nutrition, management, marketing, and processing activities. The use of hormones to induce estrus and ovulation can facilitate early breeding of ewe lambs, out-of-season breeding, potential to yield a greater litter size, and the use of artificial insemination and embryo transfer.

The advantages of exercising hormonal control over the reproductive processes may be appealing but the liabilities often include additional inputs and in some cases pose potential risks. Aside from the added costs of hormonal treatments, considerable thought and planning must be given to ensure that sufficient ram power is available for synchronized breeding. Furthermore, a synchronized estrus certainly does not imply greater fertility, and at times, therapies can and do impair fertility. It should also be noted that synchronous breeding of ewes results in a relatively synchronous parturition; consequently, sufficient facilities and equipment must exist and be prepared ahead of time for this outcome. Producers should be cautioned that concentrating the lambing of ewes in a common environment will yield greater opportunity for newborn lambs to be orphaned or mismatched with their dam.

Unquestionably, effective hormonal therapies have been established to control the reproductive processes of ewes. Most therapies are available for commercial use in

the major sheep-producing countries, only a few are available in Canada, and none have been approved for commercial use in the United States. The inability to take advantage of pre-existing hormonal therapies may be frustrating to U. S. producers, but it necessitates that greater emphasis be placed on culling animals for poor reproductive performance in order to remain competitive. Hormonal control of the reproductive processes should never be used as a substitute for good management practices. In fact, in species in which hormonal therapies are available for reproductive management, one may question whether producers are actually making reproductive progress or are inadvertently propagating the evolution of animals that ultimately will require hormonal intervention to reproduce!

HORMONE PROGRAMS

The challenges of most programs for hormonal control of breeding are (1) to synchronize the estrous cycles of ewes during the fall and winter breeding seasons; (2) to induce a fertile estrus during the late winter and early spring anestrous period; and (3) to advance the breeding season into the summer transitional period.

Thus, the goals of the producer will require a management decision to be made based on the season of the year. In other words, the producer must determine *what proportion of ewes are cycling versus noncycling*. One approach to determine this is to check all ewes for estrus with teaser rams at least one cycle length (average 16.5 days) prior to administering treatments. If the entire flock is cycling, greater than 95% of the ewes will be in estrus within a 16.5-day period. This means that approximately 6% of the ewes in the flock should be in estrus each day (100% ÷ 16.5 days = 6%/day). Alternatively, rather than determining the proportion of ewes that are cycling throughout one cycle, another approach, albeit potentially less accurate, would be to determine the proportion of ewes in estrus each *day* as a guide to estimate the proportion of ewes in the flock that are cycling. Note, however, that failure to detect estrus does not imply that ewes are not cycling. Conversely, not all ewes that are marked or stand to be mounted by a ram are cycling (e.g., up to 28% of ewes that conceive at a previous estrus will subsequently show estrus). Another option, albeit less producer "friendly," is to measure plasma or serum progesterone. Elevated progesterone concentrations in a single sample will identify 70% to 80% of ewes with corpora lutea (CL). Two samples, taken 8 to 10 days apart, enable identification of virtually 100% of ewes with CL, which is indicative of the fact that the ewes are either cycling or pregnant.

SYNCHRONIZATION OF ESTRUS IN CYCLING EWES

Inducing Luteolysis

Prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) is the preferred means for synchronizing estrus and ovulation in cycling ewes (Table 88-5). Fertility of ewes following a $PGF_{2\alpha}$-synchronized estrus does not differ from that observed in ewes bred at a spontaneous estrus. The mechanism of action of $PGF_{2\alpha}$ is to induce regression of CL found in cycling and pregnant ewes; therefore, it is completely ineffective in ewes without CL, such as anestrous and prepubertal ewes. When a single $PGF_{2\alpha}$ injection is given to a flock of cycling ewes, 60% to 70% of the ewes in the flock exhibit synchronized estrus 30 to 48 hours after treatment. The actual interval from treatment to estrus depends on the day of the estrous cycle when ewes are treated. The proportion of ewes that fail to respond to $PGF_{2\alpha}$ do so because (1) ewes are not cycling, (2) ewes are in the process of forming new CL—when they are known to be unresponsive to $PGF_{2\alpha}$, (3) ewes are in the process of regressing the current CL, or (4) ewes are in the late stages of pregnancy, when they are also known to be unresponsive to $PGF_{2\alpha}$. Ewes in the third category exhibit estrus during the interval between $PGF_{2\alpha}$ treatment and the synchronized estrus. If complete synchronization of the flock is desired, such as for timed artificial insemination, this can be achieved by giving two $PGF_{2\alpha}$ treatments 9 to 11 days apart. The greatest proportion of ewes (virtually 100%) will be synchronized following the second injection.

A conservative approach to concentrate the breeding season of a flock of cycling ewes (using less $PGF_{2\alpha}$ and yielding less synchronization) requires that a $PGF_{2\alpha}$ treatment be given on the fourth day of a 7-day breeding period. This approach is as follows: during the first 4 days of this approach, ewes that exhibit estrus are bred. On the fourth day, ewes that were not bred should be treated with $PGF_{2\alpha}$. During the 3 days following $PGF_{2\alpha}$ treatment, the remainder of the ewes should exhibit estrus and be bred. Using this approach, all ewes should be bred within 7 days.

Delaying Estrus and Ovulation

Progestins are commonly used in synchronized breeding programs as an effective means of controlling estrus and

Table **88-5**

Prostaglandin Analogs Used to Synchronize Estrus During the Ovulatory Season in Sheep*

Product	Drug	Dosage	Source
Lutalyse	Dinoprost	15 mg at 9- to 11-day interval	Upjohn Co, Kalamazoo, MI
Estrumate	Cloprostenol	125–150 μg at 9- to 11-day interval	Bayer, Animal Health, Shawnee Mission, KS

*Note: Prostaglandins are not approved for use in sheep in the United States.

ovulation. Progestins are effective in cycling ewes but are less effective in noncycling ewes without additional treatment. Progestins can be used in situations in which ewes are potentially pregnant without yielding any detrimental effects on the fetus. The effectiveness of a progestin to serve as a synchronization agent can be judged by (1) its ability to delay estrus and ovulation, (2) the means by which it must be administered, (3) the length of time it must be administered, (4) how rapidly it can be removed from the ewe's system, and (5) its effect on subsequent fertility. The ability of a progestin to delay estrus and ovulation is a function of the potency of the progestin and the dose administered. Progesterone, a natural progestin, is effective in delaying estrus and ovulation, but large doses are required. As a result, synthetic progestins have been developed that are more potent than progesterone. The various properties of the progestins have permitted the use of several approaches to deliver progestins to ewes: (1) daily or twice-daily injections, (2) intravaginal sponges or pessaries, (3) implants of various sizes placed subcutaneously, and (4) feed additives. Although each delivery system has its advantages and disadvantages, the approach used must be capable of continuously maintaining the minimal effective concentration necessary to delay estrus and ovulation for the duration of treatment.

Progestin-Impregnated Vaginal Pessary

Pessaries are inserted with a clean, lubricated speculum. Cleanliness is essential to avoid vaginitis. Rough handling or lack of lubrication causes vaginal irritation and adhesion of the sponge to the mucosa. Many specula have pointed ends that can irritate or injure. Proper restraint is important to further ensure that no injury occurs. Improperly placed pessaries are often introduced into the urethra or through the vaginal wall. Producers report a fall-out rate of pessaries to be between 2% and 25%. On occasion, the string attached to the sponge becomes entrapped in the vagina and the producer may mistakenly believe that the pessary has fallen out. A ewe without the string exposed should be checked for the presence of a retained pessary. Maiden ewes often have vaginal strictures or hymenal remnants that can be damaged, resulting in mucosal injury and adhesions and often allowing the pessaries to adhere to the vaginal wall. The presence of a pessary results in accumulation of vaginal fluids in the vagina that drain upon removal. Rams will be attracted to these ewes and attempt to breed, thus potentially reducing sperm available for breeding at the ovulatory estrus.

Controlled Intravaginal Drug-Releasing Devices

Controlled intravaginal drug-releasing devices (CIDRs) are an alternative to the vaginal pessary. CIDRs contain natural progesterone impregnated into the silicone. The device is easier to insert than a pessary and fewer losses are reported. Reports on fertility comparing pessaries with CIDRs show no difference. Less vaginal irritation (with less accumulation of vaginal fluid) occurs with CIDR use.

Norgestomet Implants

Norgestomet (Syncro-Mate-B) implants are inserted subcutaneously in the back of the ear. Some will dislodge if not inserted to sufficient depth. Implants are removed by making a small incision at the base of the implant and expressing the implant. A single implant contains 6 mg norgestomet. Normally, only one half of an implant (3 mg) is used in sheep. Implants normally are left in place for 10 to 14 days.

Oral Progestagens

The only orally active progestin available for livestock is melengestrol acetate (MGA). Feeding of MGA daily (0.125 mg fed twice daily for 8 to 14 days) produces a somewhat less synchronous occurrence than that achieved by norgestomet implants, pessaries, or CIDRs.

Injectable Progesterone

Progesterone in oil has been given as an IM injection of 5 to 25 mg daily.

INDUCTION OF FERTILE ESTRUS IN ANESTROUS OR TRANSITIONAL EWES

During late winter and early spring, an interval of progestin administration followed by treatment of ewes with gonadotropins induces fertile estrus in most ewes. Any of the progestin products can be used (Table 88-6). Most

Table **88-6**

Progesterone or Progestagen Products Used to Synchronize Estrus*

Product	Drug	Location	Days	Source	Country
Veramix pessaries	60 mg medroxyprogesterone acetate	Vagina	14–16	Upjohn	Canada
Cronolone pessaries	30 and 40 mg flurogestone acetate	Vagina	14–16	Intervet, London, Ontario	Canada
CIDR-G	330 mg progesterone	Vagina	14–16	AHI Plastics	Australia, New Zealand
MGA	Melengestrol acetate	Feed: 0.125 mg bid	8–14	Upjohn	United States
Syncro-Mate-B	3 mg norgestomet (one half implant)	Ear implant	10–14	Sanofi, Inc, Overland Park, KS	United States

***Note:** Most of these products are not approved for use in sheep in the United States.

Table **88-7**

Gonadotropin Products Used in Sheep

Product	Drug	Dosage	Source
Equinex	PMSG	400–500 IU in anestrus/0 to 200 IU in breeding season	Ayerst Laboratories, Montreal, Quebec, Canada
Stimukron	PMSG	Same	PVU-Sanofi Saute Animale, Montreal, Quebec, Canada
Folligon	PMSG	Same	Intervet, London, Ontario, Canada
PG-600	PMSG + hCG	200 IU + 400 IU	Intervet, Millsboro, Delaware, USA

hCG, human chorionic gonadotropin; PMSG, pregnant mare serum gonadotropin.

common choices are the progestin pessary, norgestomet implant, or the MGA feed additive. Most programs use the progestin for 8 to 14 days. The gonadotropin most widely used is pregnant mares' serum gonadotropin (PMSG, or equine chorionic gonadotropin [eCG]) (Table 88-7). PMSG induces a prolonged period of gonadotropin stimulation, primarily as a result of its follicle-stimulating hormone (FSH)–like activity with lesser and varying amounts of luteinizing hormone (LH)–like activity. It is normally administered at the time of progestin removal or within 48 hours prior to removal. An alternative, and often more readily available product in the United States, is PG600, which consists of a combination of PMSG and human chorionic gonadotropin. FSH products, traditionally used for superovulation, which have also been used when the other gonadotropins are not commercially available.

BREEDING EWES DURING THE SUMMER TRANSITIONAL PERIOD

Early in the spring transitional period, the most successful method to induce fertile estrus is treatment with a combination of progestin and gonadotropins. As ewes approach the first ovulation of the season, the ram effect can also be used successfully, both to induce ovulation and to synchronize estrous cycles. Ram exposure results in increased LH production in receptive ewes, followed by ovulation without estrus (silent ovulation) within a few days. The silent ovulation is followed by development of a CL, which either fails prematurely (about 4- to 6-day lifespan) or persists for the normal 14 days and is followed by a normal ovulatory estrus. Those ewes with premature luteal failure may experience a second silent ovulation, followed by development of a CL that persists for a normal lifespan and a normal estrus 17 days later. This results in two peaks of estrous activity at about 18 and 24 days after introduction of the teaser animal. The success of inducing estrous cycles and the proportion of ewes that follow either path depend on the breed and the time interval to or from the natural breeding season. The shorter that interval, the better the probability of a positive response.

Administration of progesterone prior to introduction of teaser rams may improve the synchrony of estrus. Vaginal pessaries, melengestrol acetate fed for 8 to 14 days, or an injection of 20 mg of progesterone in oil given the day of ram introduction has been shown to work well in conjunction with teaser rams during the transitional season. Sixteen days following ram introduction, $PGF_{2\alpha}$ can be given to yield an effective means of inducing a synchronizing estrus and ovulation in anestrous, transitional ewes.

It is generally recommended that the females be abruptly introduced to the male following isolation from the sight, sound, and odor of rams for the 30 to 60 days prior to introduction. Recently, however, it has been shown that introduction of a novel male (new to the females) works as well and may be easier than housing all males at a distance. The novel ram need only be introduced for 48 hours to have full effect. For optimum response, ewes must be weaned prior to ram introduction and be in good breeding condition.

Males can be rendered sterile by vasectomy or epididymectomy. Castrated males or cull females can be androgenized by administering 100 mg testosterone in oil weekly for 3 weeks.

MANAGEMENT OF OVULATION AND LAMBING RATES

Although some improvement in the number of lambs born can be realized by increasing ovulation rates, the relationship between ovulation rate and pounds of lamb marketed is constrained by a multitude of other factors. Although ewes have the capacity to ovulate a large number of eggs in response to hormonal stimulation, limitations exist that do not permit the survival of superfluous embryos or neonates. It should also be noted that as ovulation rates increase, the number of live offspring begins to decline (Fig. 88-5).

Management Considerations That Influence Ovulation Rates

Breed

A number of breeds, such as Booroola Merinos, Finnsheep, and Romanov, can be used in crossbreeding programs to increase ewe productivity. This approach is very powerful, is repeatable, and is the easiest to implement, yet is often the most difficult to encourage producers to adopt.

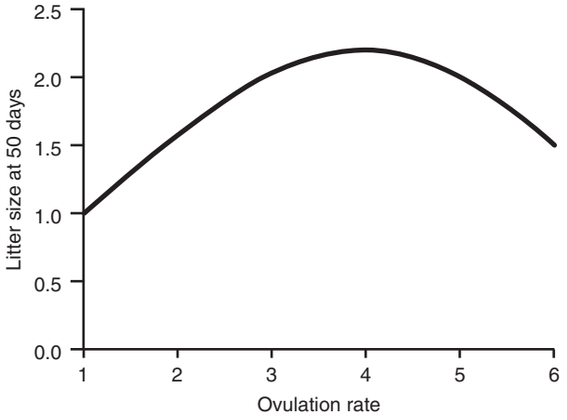

Fig. 88-5 Relationship between ovulation rate and litter size at 50 days after lambing.

Age
Ovulation rates are lower in ewe lambs than in mature ewes.

Season
Ewes bred out of season typically have lower ovulation rates than ewes bred in season.

Nutritional Status
The nutritional status of the animal directly dictates the ability or inability to express genetic potential. Flushing can be used as a short-term means of relieving a nutritional deficit and to permit ewes to express their genetically predetermined capacity to ovulate.

Active Immunization of Ewes to Increase Ovulation Rates
Immunization of ewes against reproductive hormones has been used as an approach to increase ovulation rates. Two avenues of investigation have been pursued.

Antiandrostenedione. Products for immunizing ewes against the gonadal steroid androstenedione became commercially available in some countries in 1983. These products are prepared by linking the hormone androstenedione to human serum albumin. When this complex is injected into ewes, the ewes produce antibodies against the complex, which inactivates endogenous androstenedione. Although the precise mechanism by which this approach functions to increase ovulation rate is incompletely understood, it is likely that a greater secretion of gonadotropins from the pituitary is permitted or follicular receptivity to the gonadotropins is enhanced. Following initial immunization, only a single annual booster immunization is required 3 to 4 weeks before rams are introduced. An increase in lambing rate of 0% to 47% has been observed. The response of the ewe does not appear to be dependent on the age of the ewe, but may be influenced by breed and body condition of ewes. Ewes in poor body condition show little or no improvement in lambing rates. There have been no detrimental effects of the vaccine in terms of congenital abnormalities, lamb survival, lamb growth, wool growth, or wool characteristics.

Anti-inhibin. Secretion of FSH is regulated in part by follicular secretion of inhibin, which suppresses pituitary secretion of FSH. Ewes actively immunized against inhibin exhibit increased peripheral concentrations of FSH and consequently increased ovulation rates. Although active immunization of ewes against inhibin has yet to reach commercial application, the efficacy of this approach has been well documented.

Gonadotropin Therapy
Hormones with gonadotropic properties such as LH, FSH, PMSG, and human or equine chorionic gonadotropin (eCG or hCG) function to stimulate follicular development or induce follicles to ovulate, or both. Traditionally, FSH and PMSG have been used to recruit follicular development in animals in which a superovulatory response is desired. Dosages of PMSG in excess of 600 IU have been reported to increase ovulation and lambing rates in well-managed ewes. Dosages of 750 to 1500 IU are used to cause superovulation in ewes for embryo transfer and are not recommended for ewes expected to carry pregnancies to term.

Melatonin Therapy
Melatonin has been used to alter the traditional breeding season and has been reported to be associated with increased ovulation and lambing rates.

Factors Affecting Ovulation and Lambing Rates

Many factors affect the success of a breeding program. This following list is intended as a guide for consideration in the success or failure in a breeding program.

Ewe Factors

Breed
Age
Parity
Fertility
Lactational status
Time from previous lambing
Body condition

Ram Factors

Breed
Age
Libido
Body condition
Fertility

Breeding Management

Season of year
Ram : ewe ratio
Progestin treatment: duration, handling, product
Gonadotropin treatment: product, dose, handling
Time of ram introduction
Use of teaser males
Stress at breeding
Environmental temperature before and after breeding

Diet

Ration
Flushing
Phytoestrogens in pasture, hay, and moldy feeds

OTHER HORMONAL THERAPIES USED FOR MANAGED BREEDING

Melatonin

Sheep are short-day breeders; therefore, as day length increases, breeding activity decreases. In response to darkness, the pineal gland secretes the hormone melatonin. When melatonin is administered to ewes for several weeks, it simulates the endocrine events characteristic of short days and induces ewes to initiate cyclic activity. Ewes may be given melatonin as an oral drench, as a feed additive, as an injection, or as an implant placed in the rumen, vagina, or subcutaneously. When fed, injected, or drenched, doses of 2 to 3 mg melatonin per head per day have been used and are administered approximately 6 to 8 hours before darkness. It should be realized, however, that following the initiation of melatonin treatments, the onset of cyclic activity is not immediate and may require 4 to 6 weeks before an effect is realized. Once ewes have begun cyclic activity in response to melatonin, the treatment must be continued to maintain breeding activity. Treatment of ewes with implants containing melatonin may be a more practical means of controlling breeding activity. Implants of melatonin are available in some countries. An added advantage of melatonin implants is purported to be a slight increase in ovulation rate, resulting in an increase in lamb production.

ACCELERATED BREEDING PROGRAMS

The single most important factor contributing to pounds of lamb marketed per ewe per year is the number of lambs born. With a gestation length of approximately 146 days, it is possible for ewes to produce more than one lamb crop per year. However, when considering implementation of an accelerated lambing system, it is critical to remember that if one cannot or does not do a good job of managing ewes to lamb once a year, one will not do a good job of managing ewes to lamb more than once a year. In North America, the two accelerated systems of production that are most common regiment ewes to a schedule permitting them to produce three lamb crops in 2 years (three-in-two) or five lamb crops in 3 years (the Star system; Fig. 88-6). Lambing-to-breeding intervals in these two systems are 8 months and 7.3 months, respectively. Other systems also exist, such as the CAMAL (*C*ornell *a*lternate *m*onth *a*ccelerated *l*ambing) system, which permits a lambing-to-breeding interval of 6, 8, 10, or 12 months and is accomplished by exposing ewes to rams every other month. By far, the most popular and well-studied system is the Star system.

With the Star system, the calendar year is depicted in a circular fashion and segmented into 5 intervals of 73 days each, which is also one half the gestation length of most ewes (146 ÷ 2 = 73 days). Each of the points of the star coincides with the start of that time period when a given group of ewes is exposed to rams. Each of the limbs emanating from the point coincide with when that group of ewes is scheduled to lamb (first limb) and is subsequently re-exposed to rams (the second limb). For example, if a ewe is bred on the first day of a 30-day breeding period, she should lamb on the first day of the lambing season two periods later. Concomitantly, while one group of ewes is being bred, another group of ewes is lambing. Contingent upon when they lamb, ewes lactate for 36 to 63 days before being weaned (over a 7-day interval) and subsequently are re-exposed to rams for 30 days. Ewes that fail to conceive during the 30-day breeding period are re-exposed at a subsequent breeding period, which occurs every 73 days until ewes conceive or are culled. In an ideal scenario, ewes will conceive or lamb at every third point of the star.

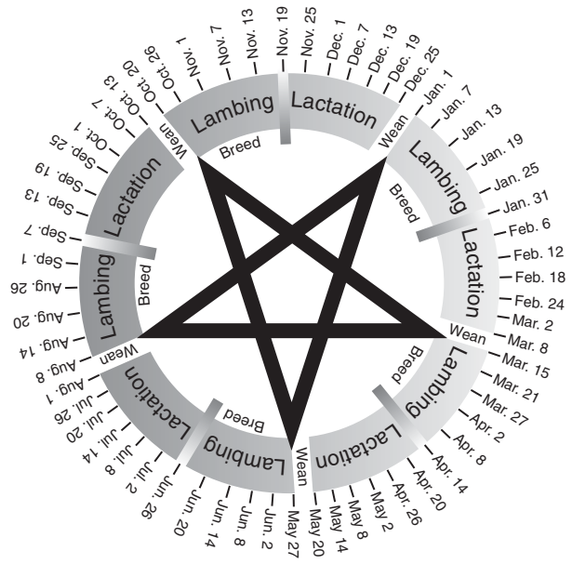

Fig. 88-6 The Star accelerated lambing system, with five annual, concurrent breeding and lambing intervals.

The advantages cited for the Star system, as with any accelerated system of production, include the following:

1. Greater reproductive performance by the ewes, permitting ewes to lamb up to five times in 3 years. In addition, this system also facilitates the identification of those ewes that will breed out of season, as well as those with a short postpartum anestrous interval.
2. Fewer rams are needed because only one fifth to one third of all ewes will be bred at any time.
3. More effective or less seasonal use of labor and facilities. Although the lambing barn need not be as large as that required to accommodate the entire flock, it must permit *efficient* feeding and waste removal. Good management skills are of the utmost importance.
4. Improved cash flow as the result of a more steady supply of marketable lambs.

Factors to consider and possibly concessions to make before implementing the accelerated system are noted in the following sections.

Genetics of the Ewe

The most important consideration or possible concession to make is in choosing the breed of sheep. The genetics of the animal has the greatest impact on the success of an accelerated system of production. Highly seasonal breeds cannot be used to constitute the genetics of the ewe flock. Maternal breeds with the least seasonal breeding influences, shortest gestation lengths, and highest ovulation rates afford the greatest opportunity for a successful accelerated system of production.

Genetics of the Ram

Considerable attention must be given to the ram or system of breeding to ensure year round performance. Typically, ram breeds are used as terminal sires in the accelerated system. Although semen production is a continuous process throughout the year, the capacity or interest of rams to mate during the nontraditional breeding season could influence the success of an accelerated program. Artificial insemination of ewes is a tempting solution but presents significant challenges.

Management of the Ewes

Early weaning of lambs (36 to 63 days post partum) may predispose ewes to mastitis, which contributes to a greater turnover rate of ewes in an accelerated system of production.

Performance of the Offspring

The offspring generated from an accelerated system of production are offered solid feed at an early age and may lack the genetic constitution to compete at the marketplace with lambs selected for carcass traits.

Pregnancy Status of Ewes

It is essential to know the pregnancy status of ewes in accelerated systems. An accurate system for early pregnancy diagnosis is essential to identify open ewes for the next breeding group.

Feed Requirements

Feed usage is typically greater in an accelerated system because more demands are placed on the ewes, and because of the added requirements generated by early weaning of lambs.

Seasonal Influences

An issue that must be reconciled is the seasonal influence on ovulation rate and neonatal or embryonic mortality rate. Typically, ewes bred out of season produce fewer lambs than those bred in season. This is of significant concern, because two of the three breedings in the 2-year system and three of the five breedings in the 3-year system occur out of season. Consequently, the issue to be addressed is whether the opportunity to produce more lambs justifies the more intense management inputs. The answer is unique to each operation. Marketing incentives must exist to foster the adoption of accelerated systems of production.

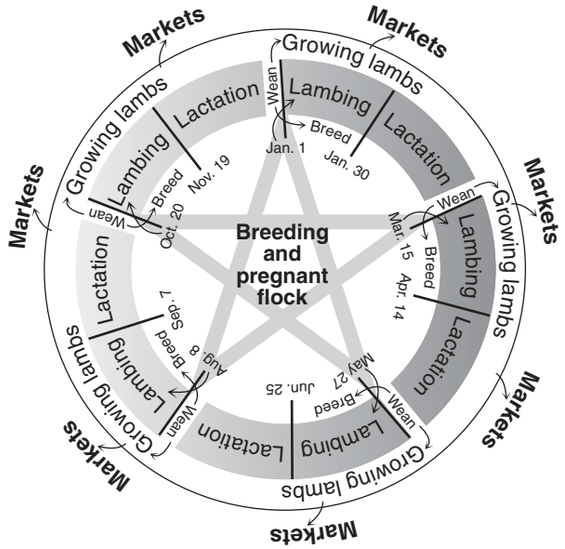

Fig. 88-7 An example of the time management decisions that must be made in an accelerated system of production.

Time Management

Developing a schedule and adhering to it is critical to the success of an accelerated system of production. At any point in time, the manager will have to simultaneously manage feeding and care of replacement ewes and rams, the ram battery, lambs in various stages of growth and development, and ewes that are being bred, lambing, lactating, or in various stages of gestation (Fig. 88-7).

CHAPTER 89

Pregnancy Diagnosis

FULLER BAZER, WAYNE CUNNINGHAM, and DEBORAH MARSH

Pregnancy diagnosis in sheep is an important management practice because of the impact of reproductive performance on economic return from the flock. Early pregnancy diagnosis, determination of fetal numbers and estimation of day of gestation, and recognition of abnormalities of pregnancy can provide producers with significant management opportunities to enhance reproductive efficiency. Historically, producers of small ruminants have had few options with regard to pregnancy diagnosis. They have been forced to wait a sufficient period of time to visibly detect return to estrus or to detect pregnancy based on mammary development and abdominal enlargement. The latter method, although relatively accurate in multiparous females, can give false negative results in primiparous females and can only be performed with a high degree of accuracy during the latter stages of gestation. Earlier diagnosis based on return to estrus following mating has commonly relied on use of a vasectomized ram with brisket paint or fitted with a crayon marking harness. The nonpregnant ewes that continue to cycle during the breeding season are marked by the teaser ram. However, some pregnant ewes will continue to exhibit estrus and be marked by the teaser ram. High-libido teaser rams may mark pregnant ewes that are not exhibiting estrus, as well as nonpregnant ewes not exhibiting estrus.

CHAPTER 89

Pregnancy Diagnosis

FULLER BAZER, WAYNE CUNNINGHAM, and DEBORAH MARSH

Pregnancy diagnosis in sheep is an important management practice because of the impact of reproductive performance on economic return from the flock. Early pregnancy diagnosis, determination of fetal numbers and estimation of day of gestation, and recognition of abnormalities of pregnancy can provide producers with significant management opportunities to enhance reproductive efficiency. Historically, producers of small ruminants have had few options with regard to pregnancy diagnosis. They have been forced to wait a sufficient period of time to visibly detect return to estrus or to detect pregnancy based on mammary development and abdominal enlargement. The latter method, although relatively accurate in multiparous females, can give false negative results in primiparous females and can only be performed with a high degree of accuracy during the latter stages of gestation. Earlier diagnosis based on return to estrus following mating has commonly relied on use of a vasectomized ram with brisket paint or fitted with a crayon marking harness. The nonpregnant ewes that continue to cycle during the breeding season are marked by the teaser ram. However, some pregnant ewes will continue to exhibit estrus and be marked by the teaser ram. High-libido teaser rams may mark pregnant ewes that are not exhibiting estrus, as well as nonpregnant ewes not exhibiting estrus.

TRADITIONAL OR HISTORICAL METHODS OF PREGNANCY DIAGNOSIS IN EWES

Radiography

This technique has been used effectively for rapid testing of up to 400 to 600 ewes per day for pregnancy diagno-

sis and determination of number of fetuses; however, the cost of the equipment and risk to operator and animal health makes radiography impractical.

Rectal Abdominal Palpation

This technique requires a lubricated glass rod (1.5 by 50 cm) to be inserted into the rectum of ewes lying on their back. With the operator's hand on the abdomen and movement of the rod with the other hand, the attempt to diagnose pregnancy was done without a high level of accuracy until late in gestation. Although cheap, simple, and quick, this technique has too low a rate of accuracy to be useful.

Concentration of Progesterone in Blood

Determination of the concentration of progesterone in blood using an enzyme immunoassay provides a reliable method for detecting pregnancy as concentrations are expected to be high for pregnant ewes that maintain functional corpora lutea. However, this method is not reliable for diagnosing the absence of pregnancy due to embryonic death, uterine pathology, or failure of the corpus luteum to regress at the expected time. This method can allow one to estimate the presence of multiple fetuses as the increase in number of corpora lutea is associated with higher concentrations of progesterone in blood, but one cannot accurately estimate day of gestation or the exact number of fetuses.

Concentrations of Estrone Sulfate in Blood

This method has not proved to be useful because it is most accurate from after day 70 of gestation and does not provide useful information with respect to number of fetuses or estimates of day of gestation.

Pregnancy-Specific Protein B in Blood

Pregnancy-specific protein B (PSPB) from binucleate trophectoderm cells of conceptuses of ruminants is detectable in blood by about days 18 to 19 after onset of estrus. PSPB assays have been reported to provide 100% accuracy in detecting pregnancy, but only 83% accuracy in detecting nonpregnancy between days 26 and 106 of gestation.

Interferon Tau

Interferon tau is the pregnancy recognition signal in ruminants that acts to inhibit expression of estrogen and oxytocin receptors by uterine epithelia to prevent their release of luteolytic pulses of prostaglandin F_2 alpha ($PGF_{2\alpha}$). Many unsuccessful attempts have been made to detect interferon tau in circulating blood and lymphatic vessels. However, there are reports of increases in expression of some interferon-stimulated genes in immune cells in blood of sheep (Mx protein) and cattle (2′,5′-oligoadenylate synthase). The use of these interferon-stimulated gene products has not been proved reliable as an indication of pregnancy because any type I interferon, for example, as a result of infection or other pathology, may cause increases in expression of these interferon-stimulated genes. With respect to pregnancy diagnosis, the risk for false positives is expected to be high.

ULTRASONOGRAPHY

The inability of traditional and historical diagnostic methods to provide early, accurate pregnancy information has led to the development of alternate techniques. During the past 20 years, various types of ultrasonographic systems have been developed to diagnose pregnancy in small ruminants. Ultrasound can be defined as high-frequency sound waves above the audible range. The frequency of these sound waves is described in cycles per second, or hertz (Hz). Frequencies in the range of 20 to 20,000 Hz can be detected by the human ear; however, frequencies used for diagnostic ultrasonography are typically in the range of 2 to 10 million cycles per second, or megahertz (MHz). Two basic types of ultrasonography have been used for pregnancy diagnosis, amplitude depth (A-mode) and brightness (B-mode).

A-Mode Ultrasonography

A-mode systems are based on two different principles: sonar and Doppler shift. A-mode systems that utilize the sonar principle rely on echoes to detect differences in impedance between tissue interfaces that are separated by fluid. Accuracy is in the 80% to 85% range from day 60 of gestation to term. A-mode systems that utilize the Doppler shift principle produce a signal (either light or audible sound) when sound waves rebound from a vibrating surface, such as the maternal middle uterine artery or the fetal heart. The frequency of the waves reflected from the vibrating surface is different from that transmitted. Although Doppler systems should identify multiple fetuses by detecting two or more fetal heartbeats, actual results in practice have been poor. Depending on operator experience, stage of gestation, and animal preparation, the accuracy of the Doppler systems ranges from 70% to 90%.

B-Mode (Real-Time) Ultrasonography

In recent years, B-mode or real-time ultrasonography has become the preferred means of pregnancy diagnosis for small ruminants. Real-time ultrasonography gets its name from the appearance of image movement. The impression of movement is given by the rapid change of the image as it is displayed and is analogous to an animated cartoon. In addition to determining pregnancy status, the image of the gravid uterus produced by real-time ultrasonography allows the operator to count fetuses, determine stage of gestation, and evaluate the health status of the pregnancy. Competent operators can provide this information rapidly (250 to 300 ewes per hour) with 95% to 98% accuracy.

Real-time ultrasonographic systems include a handheld transducer and an electronic control unit with a cathode ray tube (CRT) monitor. An electrical current passes through one or more piezoelectric crystals con-

tained in the transducer and is converted into short (1 μsec) bursts of sound. Between bursts, the transducer acts as a receiver and converts the returning ultrasound waves into electrical impulses that produce a two-dimensional image on the CRT monitor. The brightness of the image depends on strength of the returning signal, which is determined by both the position and the density of the reflecting tissues.

Intrarectal and transabdominal placements of the probe for ultrasonographic scanning are used for pregnancy diagnosis in small ruminants. For transabdominal scans, the transducer is placed in contact with the area of the abdomen in the inguinal region next to the udder that lacks wool. Ultrasound waves will not pass through air; therefore, a coupling agent (such as carboxymethylcellulose) is necessary to ensure proper contact between the transducer and tissue. Wool, dirt, grease, and feces disperse sound waves, resulting in an inferior or nonreadable image.

Pregnancy diagnosis in small ruminants typically utilizes ultrasound frequencies from 3.5 to 7.5 MHz. The lower frequencies provide deeper penetration into underlying tissues but poorer resolution, and higher frequencies do not penetrate as deeply, but provide greater definition of superficial structures. A 5-MHz transducer is most versatile and provides a good diagnostic image for either transabdominal or intrarectal scanning. A 3.5-MHz transducer works well for transabdominal scans, but a 7.5-MHz transducer is preferred for transrectal diagnosis of early pregnancy and examination of ovarian structures.

There are two basic types of B-mode ultrasonographic transducers: linear array and sector.

Linear Array Ultrasonography

Linear array transducers tend to be more versatile for veterinary practitioners who use ultrasonography in a variety of species and for multiple applications. For pregnancy diagnosis, the physical size and shape of the linear transducer lends itself to both intrarectal scans of the abdomen and transabdominal scans. The linear array transducer contains a number of piezoelectric crystals arranged in a line to emit sound ("fire") sequentially and then receive the rebounded sound waves to produce a rectangular image.

Intrarectal scans provide excellent resolution and definition of fetal and placental structures and can be used to diagnose pregnancy from as early as day 18 to as late as day 120 of pregnancy. However, it should be cautioned that very early pregnancy diagnosis and fetal counts prior to day 45 of gestation may not correlate well with lambing rates, as ewes are at greater risk of fetal loss during the early stages of gestation.

The accuracy of counting fetuses using rectal scans is limited because the entire uterus cannot be examined and the operator may experience difficulty in maintaining orientation for accurate counting of fetuses. As pregnancy advances beyond day 60, accuracy in counting fetuses increases, but as the gravid uterus moves further ventral and cranial with advancing gestation, it becomes more difficult to advance the probe sufficiently to scan the entire uterus.

With the ewe restrained in dorsal recumbency, rectal scanning using a 7.5-MHz transducer is an excellent means for examining ovarian structures (corpora lutea and follicles), and for diagnosis of very early pregnancy. In this position, the reproductive tract lies against the transducer, allowing one to obtain a complete image of the uterus and ovaries.

Linear array transducers can also be used effectively transabdominally to diagnose pregnancy between days 35 and 100 or more of gestation. Operators can determine pregnancy status and fetal number, but accurate fetal counts require patience and experience. The entire uterus usually cannot be imaged with a single placement of the transducer, so the operator must remember fetal orientation to ensure that the same fetus is not counted twice.

Sector Ultrasonography

In general, sector transducers are less versatile than linear transducers, but are preferred for transabdominal pregnancy diagnosis. Small sector transducers can be used intrarectally in large species for reproductive diagnosis, but are unsuitable in small ruminants. Sector transducers are available with different scan angles and can facilitate greater scanning speed and greater fetal count accuracy. Ninety-degree angle transducers provide excellent quality images, similar to those produced by linear transducers, but require more effort and time for accuracy. Wide-angle transducers provide a complete image of the gravid uterus and permit rapid fetal counts and estimation of stage of gestation. Although resolution is reduced with the wide-angle transducer, the image is of sufficient quality to achieve accurate pregnancy diagnosis and determination of fetal numbers. Between 45 and 90 days after breeding, experienced operators can easily scan 250 to 300 ewes per hour with greater than 95% accuracy.

Pregnancy detection using a sector transducer is limited to days 30 to 120 of gestation. Early pregnancy diagnosis requires scanning high in the inguinal region, as the uterus has not changed from its nongravid position, particularly in primiparous ewes. As pregnancy progresses beyond 90 days, fetuses grow rapidly and it becomes more difficult to view the entire uterus clearly. In addition, fetal bone structures become very dense by days 110 to 120 of gestation and they scatter reflected ultrasound waves to prevent them from forming a readable image. Thus, after day 110 of gestation, fetal counting is difficult and less accurate than during earlier stages of gestation.

Sector-Linear Ultrasonography

Recent advances in ultrasonographic equipment have combined the features of linear and sector transducers. Some of the newer systems can also store images for later recall and comparison or for transfer to remote computers for analysis and image enhancement. Regardless of the type of equipment used for pregnancy diagnosis, it is important to identify the time during gestation when the examination will provide the greatest amount of useful and accurate information. That optimal period may vary according to the goals of the producer and intended application of the ultrasonographic information provided. As a general rule, the ideal time for ultrasono-

graphic pregnancy diagnosis is between days 45 and 90 of gestation. Therefore, it is important to know when the ram was with the ewe flock. Eighty days after introduction of the ram is optimal for accurate diagnosis and speed (a two estrous cycle breeding season plus 45 days).

Interpretation (Sector Scanner)

Ultrasonographic images are created by the echogenicity of the structures being scanned. Depending on tissue density, the image will include all shades of the gray scale and range from black (anechoic or nonechogenic) to white (highly echogenic). Fluid (urine, allantoic fluid, and amniotic fluid) is anechoic and appears black on the CRT. Developing bone is highly echogenic, reflecting most of the ultrasound waves, and thus appears white.

Pregnancy is diagnosed based on three primary images: fluid, placentomes, and fetal structures. Fluid in the trophoblastic vesicle is the earliest indication of pregnancy. This fluid can be visualized using a sector scanner on about day 30. The fluid-filled vesicle continues to be the most prominent sign of pregnancy until day 45. The fetus can be identified, and, with careful observation, the fetal heartbeat can be visualized at day 35. Cotyledons begin to develop around day 22 and by day 40 appear as small gray C- or O-shaped structures around the edges of the fluid-filled vesicle. By day 45, skeletal structures are sufficiently dense to reflect most of the sound waves, creating a very bright image. As gestation progresses, the fetus continues to develop and specific structures become more easily identifiable.

It is important to remember that the image produced is two-dimensional. The sound path is roughly analogous to a sheet of paper (a plane) passing through, or "slicing," a structure. Thus, the difference in the appearance of the structure examined is related to the angle at which the sound beam penetrates the structure. For example, rotating the transducer 90 degrees will alter a longitudinal view of a fetal trunk to a cross-sectional view.

Determination of crown-rump length or biparietal diameters with electronic calipers and charts gives an accurate (±1 to 2 days) indication of fetal age. Changes in fetal size and development tend to remain relatively consistent through day 80 of gestation, regardless of the number of fetuses. Therefore, if nutritional requirements of the pregnant ewe are being met, fetal structure measurements provide an accurate indication of day of gestation. This technique is, however, time-consuming and is best used to teach operators to accurately estimate day of gestation. A more rapid estimation of day of gestation compares the size of a cross section of the fetal trunk to the size of a series of circles predrawn or precut to correlate with specific days of gestation. This guide is placed next to the CRT for quick comparison with the ultrasonographic image.

Counting fetal numbers accurately depends on the stage of gestation, the transducer used, and the technician's expertise. Image interpretation for multiple fetuses depends on visualizing at least two fetuses with a septum separating them. The cotyledons (C-shaped) open into the uterine horn toward the fetus they supply. The septum between fetuses is often seen with cotyledons opening in opposite directions. Because the uterus of a ewe with multiple fetuses develops more placentomes than a ewe with single fetus, the operator can surmise that there is more than one fetus present by simply noting increased numbers and concentration of placentomes. After day 90 of gestation, the fetus and uterus enlarge to such an extent that it is difficult to scan the entire fetus or fetuses and make accurate counts. Counting triplets and quadruplets is generally less accurate and more time consuming.

Once an operator understands the images that allow accurate diagnosis of pregnancy, the images for accurate diagnosis of the nonpregnant state must be learned. A nonpregnant ewe tends to cause the operator to be apprehensive in the absence of classical signs of pregnancy. Transrectal linear array transducers provide an image of the nongravid uterus, but a sector transducer does not generally produce an interpretable image of the nongravid uterus. However, when an operator using a sector transducer completes a thorough, methodical scan that results in a bland gray image, the diagnosis of nonpregnant is justified. It is the wise operator who classifies a ewe as nonpregnant before day 30 of pregnancy. Establishment of a methodical scanning technique will assure that the operator considers all possibilities and conditions. When scanning uteri of ewe lambs and ewes in early pregnancy, the operator can achieve the best examination with the transducer high into the inguinal area. In contrast, during late pregnancy, the best results are obtained by placing the transducer as far cranial and toward the midline as possible while still maintaining adequate contact with skin that is free of wool. Regardless of stage of pregnancy, scanning the uterus both transversely and longitudinally improves accuracy, particularly when counting fetal numbers. With experience and scanning during optimal stages of gestation, diagnostic images can be obtained within a few seconds.

Errors and Artifacts

Operator error can easily occur at either end of gestation. Early pregnancies can be missed if the transducer is not placed high enough in the flank. Late stage pregnancies can be overlooked if the scan is confined to the inguinal area and does not extend cranially and ventrally on the abdomen. Artifacts may result from improper contact due to material interposed between the transducer and skin. Structures such as the bladder may also confuse the inexperienced operator as it is seen as a circumscribed fluid-filled structure just cranial to the pelvis. Rumen fill can displace the uterus from its anticipated location and result in the operator mistakenly identifying a pregnant ewe as nonpregnant. Rumen gases also tend to produce a distorted image.

There are several explanations for lambing results not correlating with the ultrasonographic diagnosis. Operator error is assumed to be the most frequent source of error. In some situations this is justified, but in other situations the operator may be unjustly accused. One situation mentioned previously is that of embryonic/fetal death before day 40 of gestation. Another situation is loss of a twin owing to nutritional deficiencies, disease, or some unidentified cause. Advising a client of these possibilities is an important part of establishing credibility as a com-

petent operator. Providing the producer with the opportunity to observe ultrasonographic images on the screen and offering an explanation of the images can be an invaluable client teaching tool.

Ultrasonographic Pregnancy Diagnosis Justification

Real-time ultrasonography provides four types of information: (1) early diagnosis of pregnancy, (2) number of fetuses, (3) estimated day of gestation, and (4) abnormalities associated with the pregnancy. However, it is important that both veterinarians and their clients remember that the real value of this technology is realized only when the information provided is used to increase the efficiency (reproductive and economic) of the sheep operation. Defining and understanding the producer's goals will indicate whether pregnancy diagnosis will be beneficial.

Early diagnosis of pregnancy. Early pregnancy determination provides producers with opportunities to make important economic decisions. Identification and early culling minimizes the investment in nonproductive ewes and provides the opportunity to replace them with productive ewes. Results from one study determined that the cost of maintaining one nonpregnant ewe through the entire production year is equivalent to the profits from six to seven productive ewes.

Ewes not mated to the desired ram or not intended to be bred can be identified early in the breeding season and corrective actions taken to either terminate pregnancy and rebreed to the desired ram or, in the case of ewe lambs, manage them to enhance lambing rates.

Ewe lamb breeding programs can be managed more effectively. Ewe lambs that exhibit early sexual maturity and become pregnant can be identified with ultrasonography. Increasing this characteristic in a flock increases lifetime profitability of ewes. Ewe lambs that do not become pregnant can be marketed before 1 year of age.

Pregnant ewe lambs entering feedlots can be identified early and separated from their contemporaries and either marketed prior to lambing or observed more closely.

Fetal numbers. The most important economic parameter for sheep operations is pounds of lamb sold per ewe in the breeding flock. Optimizing nutritional status of ewes with multiple fetuses will help ensure that more lambs are born and survive to weaning and market. Providing an increased quantity and quality of forage to multiparous ewes will enhance implantation rates for conceptuses, placental development, fetal growth and development, birth weights, and survival of neonates. Proper nutrition also helps prevent pregnancy toxemia, increase milk production, and enhance mothering ability of ewes.

Stage of gestation. Estimating the day of gestation helps producers plan their lambing season needs based on the entire flock and individual ewes. Grouping ewes at similar days of gestation stage reduces labor and facility requirements during lambing, as well as allowing for more efficient nutritional management.

Identification of abnormal pregnancy conditions. Ultrasonographic examination for pregnancy can be an important diagnostic tool. Impending abortions can be identified prior to expulsion of aborted fetuses. In the case of campylobacteriosis, intervention with antibiotics can potentially prevent extensive abortion losses. Border disease virus and bovine viral diarrhea infections cause characteristic changes that can be identified with ultrasonography, as do effects of some poisonous plants (e.g., astragalus and water hemlock). When ultrasonographic findings suggest greater numbers of lambs than are actually born, fetal losses resulting from nutritional deficiencies can be suspected.

SHEEP HANDLING AND PREPARATION

Once an operator becomes proficient in interpreting ultrasonographic images of pregnancy, the foremost constraint to the number of ewes that can be scanned per hour is the handling of sheep and the movement of sheep through an efficiently designed scanning chute.

Minimizing Stress

When sheep are excessively stressed, they do not tend to move quickly and easily through the scanning area and are less than cooperative during the scanning procedure. The key elements to minimizing stress are (1) properly designed facilities that facilitate each movement of ewes; (2) handlers that understand and use good basic sheep psychology; (3) the absence of dogs to avoid their tendency to bark and bite at the sheep, causing ewes to become anxious and attempt to escape when the transducer is applied to their inguinal area; and (4) withholding feed and water from ewes for 12 hours prior to scanning to enhance handling and make scanning much easier for the operator.

Restraint

A variety of devices can be used to provide adequate restraint for scanning. The choice of the most appropriate cradle or chute depends on the type of machine and transducer being used. Rectal transducers require that the caudal aspect of the ewe be readily available, while transabdominal scanning requires easy access to the inguinal region of the ewe. Designing light, portable handling equipment can significantly reduce stress on both human and animal. Occasionally, it is easier to have the client manually hold ewes when there are only a few sheep to be scanned, but caution should be taken to ensure that equipment is protected from possible damage when performing scans on handheld sheep.

Scanning ewes with a sector scanner can be accomplished in several ways, depending on the operator's preference and the movement of sheep. Using a ramp to elevate ewes several feet above ground level in a restraining device allows the seated operator easy access to the inguinal area of the ewe. Some operators prefer to sit facing backward on the right side of the ewe, and others prefer to face forward on the left side of the chute and reach between the rear legs of the ewe. When large numbers of ewes are to be scanned, operator comfort is paramount. Protection from inclement weather might include a tent with a heater. A small tent also has the advantage of obscuring bright sunlight, which interferes with the operator's ability to see the image on the CRT.

Proper design of the working facilities helps keep sheep flowing to the scanning cradle. Owen Wright of Burley, Idaho, designed a system that allows ewes to move as fast as the scanning operator is able to accurately read the images. His design consists of two solid panels 12 ft long leading to the scanning cradle. A small ramp located at the back of these two panels allows ewes to easily enter the space just behind the scanning cradle and then step up about 6 inches onto the cradle floor. The ewe is not restrained except for a closed head gate to prevent forward movement of the ewe, but the ewe is able to see through the head gate. In front of the scanning chute are two more solid panels, which accommodate two ewes. The lead ewe is marked according to her pregnancy status and the second ewe draws the attention of the ewe being examined. Identifying ewes and separating them into groups at the time of examination reduces handling and increases assurance that ewes are properly grouped according to the ultrasonographic findings. When the ewe being scanned is released, she naturally wants to follow the ewe immediately in front of her, and the ewe waiting to enter the scanning chute quickly follows the departing ewe. With this system, 300 to 400 ewes can be scanned per hour. Wool cards placed on the inside of the chute opposite the operator helps anchor ewes to the chute. Further, the use of a plywood spacer reduces available space for movement of ewe lambs and smaller ewes to keep the ewe close to the operator. A breastplate centered on the floor toward the front of the chute helps keep ewes from kneeling while the operator is performing the scan.

CHAPTER 90

Abortion in Sheep: Diagnosis and Control

PAULA I. MENZIES

CLINICAL PRESENTATION

Pregnancy loss in the ewe before day 12 of gestation results in an early return to estrus when it occurs during the breeding season. Later pregnancy loss will manifest variably as one or more of the following:

- Return to estrus
- Failure to lamb in the absence of clinical signs of abortion
- Presence of a blood-tinged vaginal discharge with no fetus or placenta found
- Occurrence of abortion with identification of a fetus and/or placenta
- Birth of a stillborn and/or weak lamb at term (>142 days of gestation)

INVESTIGATION OF ABORTION

In most flocks, the proportion of sheep visibly aborting generally is less than 2%. The accepted proportion of sheep visibly aborting in a flock should be less than 5%. The abortion rate can be calculated as follows:

Abortion rate
= (number of ewes aborting)
÷ (number of ewes pregnant or exposed to the ram)

Rates exceeding 5% or a clustering of abortions in time or location (e.g., pen or farm) suggests the need for a more thorough study. Chronic abortion rates between 2% and 5% suggest an endemic problem that may require investigation. Diagnostic accuracy rates of 0.30 to 0.40 are possible when a careful investigation is carried out.

History

The following factors may be important in determining the cause of abortion:

Number and percentage of animals aborting
Animal movements—new additions or sharing of rams with another flock
Previous abortions and diagnoses
Age of sheep aborting (i.e., ewe lambs versus older ewes versus whole flock)
Specific pen or group or breed aborting
Stage of gestation at abortion (e.g., early pregnancy loss versus only late-gestation abortions)
Vaccination and nutritional history (e.g., salt or mineral supplementation or toxic weed exposure)
Possible exposure to toxins including drugs (e.g., an anthelmintic with a known teratogenic effect)
Environmental factors (e.g., extreme heat during early pregnancy, stress, predation)
Clinical illness in the individual ewe either before, during, or after abortion

SPECIMENS TO SUBMIT TO DIAGNOSTIC LABORATORY

Fetus and Placenta

- Gloves and protective clothing should be worn for handling fetuses, placentas, or discharges.
- All fetuses and placentas that can be obtained should be submitted for analysis.
- Contaminants such as manure or dirt should be gently removed from the specimens.
- The specimens must be kept chilled (NEVER frozen!).
- Specimens are submitted in leakproof, clean containers (e.g., no feed bags) as quickly as possible and kept chilled.

Processed Samples

If swabs, fetuses, and placentas cannot be sent for evaluation immediately, then the farmer should contact the flock veterinarian to collect appropriate samples of the fetuses and placentas.

Serum from Ewes

- Specimens from all aborting ewes and from a minimum of 10% of pregnant ewes should be obtained.
- Paired sera—acute and convalescent (10 to 21 days after acute sample)—are submitted to demonstrate a rising titer.

MANAGEMENT OF THE ABORTING FLOCK

Management should begin with removal of pregnant ewes from the aborted ewe group to a clean area. Mixing of pregnant, at-risk ewes with other groups of livestock should be prevented. Aborted ewes should be left in the contaminated pen or pasture.

Specific control measures may be initiated on the basis of a likely diagnosis, before diagnosis is confirmed.

Some of the infectious agents responsible for abortion in sheep pose significant zoonotic risks. The farmer should be advised to wear gloves, boots, and protective clothing that are changed before managing the rest of the flock. The unaffected sheep should be examined first. Filter masks should be worn for cleaning the barn. Pregnant women should not assist at lambing and should, if possible, not have contact with the pregnant, aborting, or newly lambed sheep and lambs.

If the aborted ewes are to be culled, they should be sent directly to slaughter once the vaginal discharge has cleared. They should *not* be sold at an auction, where they might be taken into another flock as breeding animals.

INFECTIOUS CAUSES OF ABORTION

Viral Causes

Bluetongue

Agent. Bluetongue virus (BTV) is an arthropod-transmitted orbiviral disease of domestic and wild ruminants. In North America, it is found endemically in the southern and western United States, as well as in parts of the Caribbean, Mexico, and Central America.[1] Serotypes known to occur in these regions include 10, 11, 13, and 17. In Canada, occasionally serologic reactors (mostly bovine) to serotype 11 have been identified in the Okanagan Valley of British Columbia.[2] At least 24 serotypes have been recognized worldwide.

Transmission. The virus requires an arthropod midge vector, *Culicoides veriipennis,* for transmission. The subspecies *C. veriipennis sonorensis,* found mostly in the Southwest, is thought to be the most important vector. Clinical expression of the disease tends to be seasonal (fall) and linked to the midge's seasonal cycle. Preferred breeding conditions include predominantly wet conditions and a warm environment. Cattle—considered to be an important vertebrate reservoir—can remain viremic for up to 90 days and show no clinical signs. Infected sheep clear the virus within 21 days but may experience a case fatality rate of 10% to 50%. BTV also has been isolated from bovine semen. Although the vector is found across southern Canada, whether it can propagate infection is questionable.

Clinical picture. Sheep infected with BTV show signs of high fever; swollen ears, face, and tongue; oral and nasal ulcers; and lameness. Up to 20% of fetuses infected in early gestation are found to have various degrees of hydranencephaly and skeletal deformities and may be aborted or carried to term. Some experimental studies have failed to show disease in fetuses born to infected ewes.[3] Plant toxicity and Cache Valley virus (CVV) infection are important to rule out in the diagnosis.

Diagnosis and control. Some areas of the United States (e.g., California) may have serotype-specific attenuated virus vaccines available. Little to no cross-protection occurs between serotypes. Sheep need to be vaccinated once before the season of risk and again before breeding to avoid congenital central nervous system (CNS) lesions.[4,5] Control measures also can include housing sheep at night and/or pasturing away from wet areas during the season of peak vector activity. In Canada, suspected cases of bluetongue must be reported to the local office of the Canadian Food Inspection Agency. Virus isolation and serologic studies in the aborting dam are done to rule out infection with BTV.

Border Disease

Agent. Border disease virus (BDV) is a pestivirus closely related to bovine viral diarrhea virus (BVDV) and classical swine fever virus (CSFV). It has been reported sporadically across North America and in many parts of the world. Many different strains of BDV have been isolated from animals with clinical border disease.[6] Some outbreaks of border disease have been associated with persistent infection with BVDV.[7]

Transmission and pathogenesis. The virus invades the ewe and causes a transient viremia of 7 days' duration; it does not cause disease in the ewe but attacks the placenta. During the viremia, BDV is shed in the urine, feces, and saliva. Necrosis occurs at the junction of the villous trophoblast and maternal caruncle, with resultant perivascular necrosis. This necrosis leads to separation of the fetal-maternal-placental bond, with subsequent interference with fetal nutrition and blood gas exchange.[8] Most fetuses infected in utero before day 60 to 85 of gestation die because of this damage and are either reabsorbed, aborted, macerated, or mummified.[9] If they survive, various degrees of damage may be seen. Myelination of nerve cells is disturbed, particularly in the cerebellum. Hair follicles also can be affected and produce hair, rather than wool. These fetuses also are born persistently infected with BDV, shed virus continuously, and fail to clear the infection. Fetuses infected after day 85 may abort, or the lamb may be born weak or unaffected, or may be virus negative and with a precolostral titer to BDV. It is possible for several levels of signs to be present in the same litter of lambs.

Clinical picture. An increase in the number of open ewes, as well as abortion, is seen in the flock, followed by the birth of lambs with or without clinical signs, including weak lambs that are persistently infected.[6] These lambs are small, with shortened facial and long bones, and have a wool coat that frequently is hairy and darkly pigmented, particularly over the shoulders, neck, and head. They also may show mild to severe body tremors. Accordingly, affected lambs commonly are termed "hairy shakers." Nervous signs diminish in severity in those lambs that survive. Persistently infected lambs grow more slowly than do their healthy cohorts and appear to be more susceptible to disease.[10] Some evidence indicates that persistently infected lambs may succumb to a disease similar to mucosal disease of cattle.[11] At necropsy, findings include gross thickening of the distal ileum, cecum, and colon resulting from focal hyperplastic enteropathy, and cytopathic BDV can be recovered from the gut.[6] Usually a history of a recent introduction of animals either before, during, or shortly after breeding season can be elicited from the farmer, or the disease may follow contact with cattle, suggesting exposure to BVDV.

Diagnosis. BDV can be isolated from aborted fetuses and from the buffy coat in centrifuged blood specimens

from affected lambs. Antigen-capture enzyme-linked immunosorbent assay (ELISA) can be used on the sera of suspected persistently infected adults and lambs older than 2 months.[6,12] CNS changes, both gross (cerebellar hypoplasia, hydranencephaly) and microscopic (hypomyelination, microgliosis), help make the diagnosis. Immunohistochemical analysis is equally sensitive to virus isolation, except in autolytic fetuses.[13] In autolytic fetuses, use of formalin-fixed, paraffin-embedded fetal brain for immunohistochemical analysis is more sensitive than virus isolation. It also appears to be more sensitive than antigen-capture ELISA on fetal tissues.[13] Serum virus neutralization or ELISA titers of antibody from the aborted ewes tend to be high, although this finding in itself is not diagnostic. Demonstration of a rising titer in aborting ewes is difficult because infection generally is historical—preceding abortion by at least 2 months. If an aborting ewe is persistently infected, then antibody levels will be low or absent and virus can be isolated or detected from the serum or buffy coat.

Control and prevention. After an outbreak of border disease–related abortion, all lambs with congenital pathologic conditions and those demonstrating poor performance should be sent to slaughter when they are as young as possible and, before that, should be kept separate from the breeding flock. Replacement lambs older than 2 months should be screened for virus using virus isolation or antigen capture ELISA.[6] New additions to the flock should be isolated for at least 2 weeks before introduction to the breeding flock, and consideration should be given to screening them as well. Cattle and sheep should be kept well separated, with no shared feeders or water sources, and an effective vaccination program for BVDV should be maintained in the cattle herd. Available evidence suggests that cross-protection is poor between BVDV and BDV; therefore, vaccinating sheep with a killed or modified live BVDV vaccine confers no advantage.[6] At present, one border disease vaccine is commercially available.[14] It is a killed adjuvanted vaccine that contains strains of BDV as well as of BVD-1.

Cache Valley Disease

The agent. The Bunyaviridae family, of which CVV is one species, contains several species that are associated with ovine abortion. Organisms in this family of viruses are arthropod borne. Akabane virus is considered to be exotic to North America but is a very important cause of congenital ruminant deformities in Australia, Japan, Korea, and Israel and probably also is present in the Middle East and Asia. In North America, CVV has been implicated in outbreaks of congenital deformities in the U.S. Southwest, particularly Texas, and occasionally in the Northeast (Illinois, Michigan, New York, Maryland, and Pennsylvania) and southern Ontario.[15] Experimentally, Main Drain virus and, to a lesser extent, San Angelo and LaCrosse viruses also cause ovine fetal malformations.[16] LaCrosse virus is an important cause of viral encephalitis in children.[16]

Transmission and pathogenesis. CVV is transmitted mainly by mosquitoes that prefer to feed on large ruminants. Akabane virus mostly is transmitted by *Culicoides* midges. The vertebrate reservoir for CVV is not known but is speculated to be wild or domestic large ruminants (e.g., deer, cattle). Two days after infection of the sheep by the infected mosquitoes, a viremia of 2 to 5 days' duration develops. At this time the infected sheep may demonstrate fever, depression, and a reluctance to move. The virus invades the placenta and fetus if implantation has occurred. Little inflammatory response is observed in the placental tissues. The virus then invades the fetal brain, spinal cord, and skeletal muscles. The severity of the lesions is dependent on gestational age at the time of infection. Early infection from day 28 to 32 generally results in early embryonic death and mummification. Infection between days 32 and 37 manifests as CNS and musculoskeletal deformities characteristic of severe arthrogryposis. Infection from day 37 to 48 manifests as milder musculoskeletal lesions with nonsuppurative encephalitis and encephalomyelitis.

Clinical picture. The dominant clinical picture is one of stillbirth or live birth of congenitally deformed lambs. The predominant deformities are arthrogryposis, brachygnathia, hydranencephaly/porencephaly, microencephaly, agenesis or hypoplasia of the spinal cord, and possibly other CNS deformities. It is possible to see all syndromes in one flock outbreak and more than one syndrome in a litter. Morbidity rates are variable depending on viral load in the mosquito population. Fetuses from cattle and goats also may be affected.

Diagnosis. It is important to rule out ingestion of locoweed as a cause for arthrogryposis. Osteochondrodysplasia (spider lamb) is inherited in an autosomal recessive fashion and affects mainly Suffolks and Hampshire sheep; neurologic disease and arthrogryposis are not seen. By the time of parturition, CVV has been eliminated from the dam and fetuses, so that virus isolation is unrewarding. In endemic areas, ewes may have background titers to the virus. Diagnostic titers can be obtained only from fetal heart blood or precolostral serum from affected lambs. Absence of a diagnostic titer in the fetus or lamb will not rule out CVV infection but in the dam does rule out this disease.

Control and prevention. No vaccine is available to prevent CVV in sheep, although an inactivated vaccine for Akabane virus is available in Australia and parts of Asia. Immunity from natural infection is long term and may be for life. It is difficult to predict an epizootic of CVV infection. In geographic areas with a history of CVV infection, the farmer is advised to avoid breeding sheep in mosquito-infested pastures; in temperate parts of North America, the farmer should wait until after a killing frost before turning in the ram.

Bacterial/Chlamydial/Rickettsial Causes

Brucellosis

Agent. *Brucella ovis* is a common cause of epididymitis in rams and more rarely causes abortion in ewes. It is widely distributed in the United States and to a lesser extent in Canada, and more commonly in the western regions. *Brucella melitensis* also can cause ovine abortion and is found in Mexico but not in the United States or Canada.[17]

Transmission and pathogenesis. The organism is spread through contact between mucous membranes (vaginal, preputial, conjunctival), both ram to ewe and ram to ram, but not ewe to ewe. Rams infected with this organism are not always infertile and pass the organism in the ejaculate. Ewes clear the organism within a few weeks of aborting and usually are not sources of infection to the flock the following year. Sources of infection may be the carrier ram and infected material from abortions.

Clinical picture. Abortion levels of 25% to 35% have been reported. Stillbirths and lamb weakness also may be seen; affected animals may show lesions of suppurative pneumonia.[18] Placentitis is severe, with a thickened, necrotic placenta—a common finding. Examination of the breeding rams will reveal clinical or subclinical epididymitis.

Diagnosis. Titers in the sera of aborting ewes are variable, and such tests may be misleading because a negative titer does not rule out the disease. The sensitivity of the complement fixation test ranges from 96.3% to 100% and the specificity from 98.4% to 99.9%. The ELISA specificity is reported at 99.4% and the sensitivity at 100%.[19] Culture of or use of a polymerase chain reaction (PCR) assay on the stomach contents of the fetus, as well as culture of the cotyledons, generally is successful.[20] Serologic testing and examination of the rams also should be performed. *B. melitensis* infection should be a consideration in the differential diagnosis, particularly in states bordering Mexico.

Prevention and control. In endemic areas, such as the western part of North America, a control program using a combination of serologic testing (ELISA or complement fixation test or both), routine scrotal palpation of breeding rams, and vaccination of ram lambs with a killed bacterin will reduce the prevalence of disease.[21] The vaccine is regarded as having poor efficacy, and the serologic tests and scrotal palpation have only fair sensitivity. Rams should not be shared between flocks, nor should they be housed at any time with rams used in other flocks. In Canada, serologic testing is not readily available for screening of rams. Rams from affected flocks should be slaughtered and replaced with virgin rams from clean sources.

Vibriosis/Campylobacteriosis

The agent. Both *Campylobacter jejuni* and *Campylobacter fetus* subsp. *fetus* have been implicated in ovine abortion, and both are also pathogenic to humans. They can reside in the intestinal tract of sheep and many other species, including dogs and birds. *C. jejuni* is implicated more commonly when abortion is sporadic, although it can affect up to 20% of the pregnant flock. *C fetus* subsp. *fetus* is more frequently associated with large outbreaks of abortion that affect a significant percentage of the flock and may occur from year to year. Several serotypes of *C fetus* subsp. *fetus* have been recognized. In the United States, most of the isolates associated with abortion are A2 and C.[22] Occasionally other species and biovars of *Campylobacter* have been isolated from aborted ovine fetuses.

Transmission and pathogenesis. The organisms are harbored in carrier sheep in the intestine and gallbladder.[23] Sources of contamination are feces, aborted fetuses and placentas, and vaginal discharges from aborted ewes. Carrion-eating birds such as crows may transmit the organisms between flocks. Incubation ranges from 8 to 60 days.[24]

Clinical picture. Ewes generally start to abort in the second half of gestation. Most abortions occur during the third trimester about 3 days after fetal death.[25] Fetuses are expelled well preserved with the placenta. Ewes are not ill, although transient diarrhea has been reported. Ewes infected 2 weeks before lambing may give birth to stillborn lambs, or to weak lambs with a very poor chance of survival. The placenta of aborted fetuses tends to be edematous, with congested swollen cotyledons. The fetus may have subcutaneous edema and an enlarged abdomen with pleuritis, peritonitis, and hepatitis, with occasional target lesions of hepatic necrosis. Abortion levels of up to 70% have been reported, but levels of 10% to 20% are common in enzootically infected flocks. Immunity from one species of *Campylobacter* species is not cross-protective for another, but natural immunity to the infecting species can occur without abortion and lasts at least 3 years.[26]

Diagnosis. Stain impression smears of cotyledons or fetal stomach contents will demonstrate the organism. Darkfield or contrast microscopy will demonstrate the live organism from fetal stomach contents. It also can be cultured from the placenta or stomach contents. *Flexispira rappini* infection should be a consideration in the differential diagnosis.[27] Antibiotic sensitivity testing should be done on the isolate, because resistance to penicillins and tetracyclines can occur.[28]

Prevention and control. In the face of an outbreak, all pregnant ewes should receive treatment with an antibiotic that is likely to be efficacious. Long-acting oxytetracycline at the label dose (20 mg/kg) can be used successfully. For large flocks, for which individual injections may be more difficult, tetracyclines may be added to the feed at a level of 250 to 300 mg/head/day until lambing is finished.[29] Daily injections of penicillin (400,000 IU) and dihydrostreptomycin (0.25 g) at a dose rate of 6 to 10 ml per ewe also have been recommended.[30] Pregnant ewes should be removed from the aborted ewe flock and the contaminated area. Vaccination with a multivalent bacterin can be done in the face of an outbreak, but sufficient immunity to stop abortions takes 2 weeks to develop.[29] In flocks in which campylobacteriosis has been diagnosed, vaccination should be routinely done according to label directions. This protocol involves vaccinating all breeding ewes with a bivalent killed bacterin twice, the first before breeding and the second injection 60 to 90 days later. Annual revaccination before breeding should be maintained.

A lack of efficacy of the vaccine may be due to any of several factors. The vaccine may not contain the correct serotype of *C. fetus* subsp. *fetus,* or the responsible pathogen may be another species of *Campylobacter* or *F. rappini.*[22] Culture and typing should be done to rule out this possibility.

Enzootic Abortion of Ewes (Chlamydiosis)

Agent. The genus *Chlamydia* has recently undergone reclassification.[31] *Chlamydia psittaci* immunotype 1, the abortion strain for sheep and goats, is now classified as *Chlamydophila abortus* type strain ATCC VR 656. *Chlamydia pecorum,* a fecal chlamydial species that may be nonpathogenic or cause arthritis and conjunctivitis and often cross-reacts on tests with *Chlamydia abortus,* is now classified as *Chlamydophila pecorum* type strain ATCC VR 628, Bo/E58. Organisms belonging to this genus are obligate intracellular bacteria that replicate in the phagosome.[32]

Transmission and pathogenesis. Transmission may occur from exposure to aborted materials or vaginal discharge or from environmental contamination and ingestion.[32] Experimental oral inoculation of the tonsillar crypts, but not intraruminal inoculation, produces abortion.[32] Contact of the nasopharynx with infected placentas in recently lambed ewes can cause abortion in those ewes during the subsequent pregnancy.[33] *Chlamydia*-naive pregnant sheep infected vaginally will give birth to infected weak lambs, suggesting that the venereal route also may be important in the transmission of this agent.[34] When naive nonpregnant sheep were experimentally infected, the organism could be detected in a variety of organs, including the abomasum and jejunum, and lymph nodes, but shedding in the feces was not detected.[35] *C. pecorum* strains, frequently present in large numbers in the feces of healthy ewes, can cause abortion when injected into the muscle of healthy ewes, but not when ingested.[32] In nonpregnant ewes, at approximately 1 week after infection, *C. abortus* becomes undetectable by any means.[36] In infected rams, *C. abortus* may be isolated from the semen and seminal vesicles.[36] When the infected ewe becomes pregnant, the organism moves by a hematogenous route to the trophoblast cells of the chorionic epithelium.[36] By 95 days of gestation, the infection has spread from the cotyledons to the intercotyledonary areas.[39] The fetus also becomes infected, but histopathologic changes are minor. The primary target is the placenta.

Ewes rarely abort at less than 100 days' gestation, but fetal loss and resorption before 100 days can occur.[34] Latent infections occur when ewes are infected either while not pregnant or during late gestation. These ewes will abort during the subsequent pregnancy.[32] Ewes that abort once do not abort again for at least 3 years. Although maternal immunity prevents repeated abortion, ewes that have aborted from *C. abortus* infection subsequently shed the organism in vaginal secretions during estrus and have persistent low-level titers.[37] Contamination of mucous membranes or of feed by vaginal secretions, or of the ram's penis during breeding, may be a mechanism of continuing the infection in the flock.

Clinical picture. Abortion tends to occur in late term pregnancies, but early fetal death and resorption also occur.[37] The placenta is necrotic, with lesions affecting both cotyledons and intercotyledonary spaces. The placenta becomes thickened and necrotic, as well as hemorrhagic at the edges of the lesions.[39] Fetuses may be aborted necrotic, well preserved, or rarely mummified. Weak and stillborn lambs also are commonly seen. Abortion levels can be high (up to 30%) in the first year of the disease but decrease in subsequent years to 10% to 15%, with only ewe lambs and new introductions affected in subsequent years. Ewes infected in very late pregnancy or when open may not develop protective antibodies and may be susceptible to infection in the next pregnancy. Chronic infection of the uterus or uterine tubes occurs after abortion and may eventually impair fertility.[34]

Diagnosis. The severe placentitis of both the cotyledons and intercotyledonary zones is typical but not diagnostic. Smears made from the chorionic villi and stained with appropriate stains (e.g., Machiavello, Wright-Giemsa, xanthine dye–thiazine dye mixture, Giminez, modified Ziehl-Neelsen, or *Brucella* differential) will demonstrate clumps of small, red, coccoid intracellular elementary bodies.[40] The organisms can be confused with *C. burnetii*. Immunologic staining methods such as those using immunoperoxidase can be used on fixed tissues.[41] Various tissues (fetal lung, spleen, liver, placenta, and vaginal swabs) also can be submitted for culture using either a *Chlamydia* isolation procedure modified from Stortz or embryonated chick eggs.[40] Chlamydiae are difficult to isolate, however, because they lose infectivity during transport to the laboratory.[39] Fluorescent antibody can be used to detect the organisms in smears and culture, but this technique appears to be less sensitive but perhaps more specific than a chlamydial genus–specific ELISA that detects lipopolysaccharide.[42]

Infected ewes that have not yet aborted do not have significantly elevated antibody titers. Serologic testing of aborting ewes should always use paired acute and convalescent sera. Low-level titers detected in screening the breeding flock may be due to a lack of test specificity, or to chronic *C. abortus* infection.

The complement fixation test is not very specific because it detects genus-specific lipopolysaccharide, so that cross-reaction occurs with other species of *Chlamydophila,* notably *C. pecorum*.[34] This test should not be used for diagnosis in individual aborting sheep or in lambs or rams, or beyond 3 to 6 weeks after abortion.[32] Many ELISAs that detect lipopolysaccharide or outer membrane or unstated antigens failed to perform adequately with respect to either specificity (range of 51% to 96%, depending on the test), sensitivity (range of 51% to 81%, depending on the test), or both.[43] A new indirect ELISA based on detection of the outer membrane protein of *C. abortus* has improved sensitivity (84.2%) and specificity (98.5%) over the complement fixation test.[44] PCR assay is highly sensitive, but again specificity may be poor owing to the contaminating presence of *C. pecorum*.

Prevention and control. At present, only inactivated vaccines produced from cultures of *C. abortus* are available in North America. The vaccination procedure is to give an initial injection 60 days before breeding and administer a second dose 30 days later. Annual revaccination is required. Inactivated vaccines do not prevent shedding of chlamydiae at lambing.[32] Prolonged use of these vaccines may even select for more virulent field

strains of *C. abortus*.[32] Inactivated vaccines have been shown to provide reasonable protection,[45] but a potential problem is considerable batch-to-batch variability, with variable potency of the vaccine, which may account for failure of some vaccines to elicit an immune response or to provide protection.[32,46] For this reason, the use of a temperature-sensitive mutant of *C. abortus* (1B strain) as a vaccine was investigated. The result was the production of a commercial vaccine (Enzovax*), which is not available in North America. When injected in ewes or does before breeding, it did not interfere with the subsequent gestation, it protected against abortion, and it prevented chlamydial shedding at delivery.[32] Vaccination of an uninfected flock will offer good protection if the disease is acquired after vaccination. If vaccination is not done until the disease has been diagnosed in aborting ewes, the subsequent lambing will still see significant levels of abortion due to latent infections. After the second year of flock vaccination, however, the abortion level in infected flocks will decline, because fewer susceptible animals exist. To increase ease of use, research also has been looking at developing an effective vaccine using purified subcellular antigens such as the outer membrane protein (90 kDa), which produces a very strong protective immune response after abortion.[47]

In an outbreak or commencing after 80 days of gestation in flocks known to be infected, injections of long-acting oxytetracycline at label dose (20 mg/kg of body weight given once), and repeated every 2 to 3 weeks, may prevent some abortions, although probably less than 50%, and some authorities disagree whether use of multiple treatments is justified.[48–50] Often the placental damage in pregnant ewes is so severe that antimicrobial therapy is of limited efficacy, and shedding of organisms at lambing is not reduced.[48,49] Pregnant ewes should be separated from the aborted ewes, and ewe lambs should be managed as a separate flock until after lambing. In view of the persistence of the organism in vaginal secretions, culling of ewes that have aborted should be considered. In chronically infected flocks, feeding levels of 250 to 500 mg/animal/day of tetracycline, starting 60 days before the first expected lambing date, is thought to be helpful in reducing the incidence of abortion (M. Bulgin, personal communication, 1998). Higher levels generally are fed during an outbreak of abortion, and lower levels are fed prophylactically, although actual recommendations on dose and length of time vary, and little information on true efficacy has been published.

Eradication of *C. abortus* from an infected flock is difficult. In the U.K., accreditation of *Chlamydia* status is based on serologic status of the breeding flock. Test sensitivity and specificity currently hamper success of these kinds of programs. Embryos obtained from infected ewes do not appear to harbor the organism, however, and can be used to transfer valuable genetics to a clean flock.[51]

Zoonotic risk. Occasionally *C. abortus* can cause significant human disease, particularly in pregnant women with significant contact with aborting or lambing ewes.[52] Infection may be more common than disease, but because of the risk of fetal or maternal death, it is important that producers and veterinarians handling infected animals take appropriate precautions.[53]

*Intervet, Milton Keynes, UK.

Coxiellosis (Q Fever)

Agent. *Coxiella burnetii* is a rickettsial organism (an obligate intracellular gram-negative bacterium) that can infect a wide range of hosts, including ruminants (cattle, sheep, and goats), swine, guinea pigs, cats, dogs, rabbits, rodents, and humans, as well as birds and ticks.[54–59] It can survive in a dried state for many years.

Transmission and pathogenesis. Inhalation of contaminated air or dust, or mucous membrane contact with aborted materials, vaginal secretions, or fluids and membranes from normal birthing of many species, as well as possibly semen from infected males, can serve as a means of acquiring infection.[60] Ticks also may shed the organism, thereby contaminating the wool. If the ewe is pregnant and immunologically naive, then placentitis may develop; if this infection is severe enough, abortion due to hypoxia and starvation of the fetus may result. Abortion is more common in goats than in sheep. Although the organism commonly is shed in the milk of cattle and goats, it does not appear to be shed in the milk of sheep.

Clinical picture. In sheep, infection at lambing is more commonly seen than abortion. Abortion rates within a flock can range from 5% to 35%. Fetuses may be aborted in late term, and in the same outbreak, lambs may be stillborn or born weak; however, severe suppurative placentitis is a common feature with all three presentations. Uterine inertia and uterine rupture at the time of abortion have been reported in goats.[61] Abortion in subsequent years is unusual because most of the flock is exposed and immune. The risk is that the fluids and the newborn lamb from a healthy lambing constitute a source of infection to humans. In a flock with little abortion, as many as 47% of the lambing ewes may be shedding *C. burnetii* in the vaginal secretions for up to 2 months after lambing, and significant proportions also shed the organism in the milk (18%) and feces (6%) during the first week after lambing.[62] It is common to have no reports of abortion despite endemic infection in the flock.[63]

Diagnosis. Either demonstration by staining with a modified Ziehl-Nielseen stain or culture of the organism from the cotyledons and fetal abomasal contents is a highly reliable method of diagnosis. Histologic examination of the placenta reveals a foamy vacuolation of the trophoblast cells of the chorion.[61] Analysis of paired sera using a complement fixation test or ELISA will demonstrate very high titers in some flocks; this finding, however, is not diagnostic for abortion but rather is indicative of active or recent infection only. During infection, two distinct antigenic phases are recognized. Phase 1 antibodies are produced during the acute infection stage. Phase II antibodies are produced later in the disease process or are produced more prominently by some strains of *C. burnetii*. Only moderate correlation has been found between ELISA titers and shedding.[62] Several PCR tests have been developed to detect shedding in the milk, feces, and vaginal secretions.[64,65]

Prevention and control. No commercial vaccines for livestock are available in North America, although killed vaccines are available in Europe. The best protection appears to be offered from chloroform-methanol residue vaccines made from phase 1 organisms, although they may not stop shedding.[59,66] In the face of an outbreak, long-acting oxytetracycline injections at 20 mg/kg have proved effective in stopping abortions but do not clear the carrier state.[62] Cats, cattle, goats, and rodents also may be a source for continuing re-infection. Moreover, the organism can remain viable in a dried state in the environment for years, which also can lead to re-infection. It is doubtful if eradication of the organism can be accomplished on a commercial farm but may be possible in a research institution when strict culling and disinfection are practiced.

Zoonotic disease. The disease in humans—Q fever—makes this organism very important.[67] Although most people who become infected do not become critically ill, the risk of severe and prolonged illness is significant. Disease in humans can manifest as acute atypical pneumonia, undulant fever, hepatitis, extreme myalgia, or endocarditis, which is the most common form of chronic Q fever.[59] Prompt diagnosis and treatment are necessary for full recovery. Physicians generally are unfamiliar with the disease, and the vagueness of the signs may delay appropriate therapy. Death is a risk, particularly for elderly and immunocompromised patients. People may become infected from handling infected placentas and lambs, from being present when sheep are lambing, and from inhaling windborne organisms from infected premises or dried organisms in the dust of barns.[68–70] In one outbreak associated with goats, the most important risk factors were contact with the placenta (odds ratio [OR] 12.32), being a smoker (probably increases the risk of oral contamination, OR 3.27), eating goat cheese (OR 5.27), and petting goats (OR 4.33).[71] Unsuspecting persons may become infected at shows or in sales barns where dust is evident. Barn clothing should never be worn in the house.

Disposable rectal sleeves should be worn by persons assisting with lambing or handling an abortus or the placenta. Masks should be worn for cleaning the barn. Vaccination of humans at risk for contracting Q fever should be practiced. Abattoir workers in Australia are routinely vaccinated.[59] In view of the difficulty of eradicating coxiellosis from domestic livestock and preventing shedding in infected animals, vaccination of farm workers and researchers offers a means to decrease human risk.

Parasitic Causes

Toxoplasma gondii *Infection*

Agent. *Toxoplasma gondii* is a protozoal parasite that has a worldwide distribution. In many countries, it is one of the most commonly diagnosed causes of ovine abortion. The sexual part of the organism's life cycle is completed only in domestic and wild cats. The oocysts shed in their feces are infective for up to 18 months when protected from desiccation and sunlight. The asexual component of the *Toxoplasma* life cycle may occur in any warm-blooded animal.[72]

Transmission and pathogenesis. Nonimmune cats, particularly kittens first learning to hunt, may become infected by ingesting food or animals containing cysts, including rodents, offal from slaughtered farm animals, birds, and aborted fetuses and placentas. Cats rarely show clinical illness and will shed millions of oocysts from 4 to 12 days after ingestion of contaminated material and then become immune, although they may again excrete oocysts in smaller numbers if stressed.[72] They also may be infected by ingesting sporulated oocysts shed by other cats, although this results in fewer numbers being shed and a longer incubation period.[72] Sporulation occurs within 4 days of excretion. Feces and thus oocysts are ingested by rodents or inadvertently by sheep through contamination of feed or pasture. The organisms invade by passing through the small intestine to the mesenteric lymph nodes, and a parasitemia develops, which generally lasts 5 to 12 days after infection.[72] As the animal develops immunity, the tachyzoites encyst in the muscle and brain as bradyzoites. They persist throughout the life of the animal and can be infective after death in chilled carcasses for up to 60 days. In a pregnant sheep, approximately 14 days after ingestion, the organism infects the fetus through the trophoblast cells of the fetal villi.[72]

Clinical picture. Fetuses at all stages of gestation are susceptible to infection, although the clinical picture varies. Infection before 40 days results in resorption; between 40 and 120 days, in maceration, mummification, or abortion; and after 120 days, in stillbirth or birth of weak or healthy immune lambs. Abortion levels within the flock may vary, ranging from 5% to 100%. Ewe immunity, timing of exposure, and dose of oocysts determine the abortion rate. The flock history usually includes contact with kittens, either directly or from fecally contaminated forages or grain. A few weeks to days before the expected onset of lambing, ewes may start to abort. Often all levels of infection can be observed within the same outbreak and sometimes within the same litter—for example, a weak lamb may be born along with a mummified fetus.[72] Liveborn weak lambs often do not survive beyond the first week. Ewes do not appear ill and recover from the abortion quickly. Immunity to further abortion from toxoplasmosis appears to be life-long, although this may not be true in goats. In a study done on Ontario farms that examined the proportion of ewes that were seropositive, spaying female cats and shearing the perineum of the ewe before lambing were protective, whereas sharing pasture with other livestock species, indoor summer housing of replacement ewes, purchasing sheep from other flocks, and raising pigs on the same farm all were found to increase the prevalence of *Toxoplasma*.[73]

Diagnosis. The fetuses may be mummified or aborted in a decomposed state. Subcutaneous edema and blood-tinged fluid with strands of fibrin in the body cavities may be seen. The placental cotyledons appear bright to dark red and speckled with white foci of necrosis 2 to 2 mm in size.[72] The intercotyledonary placenta appears normal. Histologic examination of these necrotic foci also may reveal calcification. The toxoplasmas are not numerous and often are seen only on the periphery of lesions.

Because of the marked decomposition usually present in the aborted fetus and placenta, however, the organism is not easy to discern on histopathologic examination. Immunohistochemical techniques (either an indirect immunoperoxidase or a peroxidase-antiperoxidase method) will help demonstrate organisms more clearly, even in decomposed tissues.[72,74] PCR assay also can be used successfully to detect the presence of organisms in decomposed placentas.[75–77]

Serologic studies may be done using either an immunofluorescence antibody test or an ELISA or latex agglutination test.[78,79] Approximately 2 weeks after infection, titers rise and remain high for several years.[80] A suggested interpretation of latex agglutination test titers is as follows: less than 32 indicates a negative result; 32 indicates a weak positive or nonspecific result; a titer of 64 to 256 indicates a positive result but possibly declining or long-term static; and a titer of 512 or greater indicates a positive result and possibly is indicative of a recent or active infection.[79] A seropositive flock is one with at least two ewes with titers of 128 or greater. A positive titer is not necessarily an indication of abortion, because titers as high as 2048 have persisted for up to 3 years in some ewes.[79] A positive titer from an aborted fetus is diagnostic. Fetuses infected between 45 and 90 days of gestation have been shown to seroconvert within 28 to 35 days after infection.[81] Negative titers in the ewe will aid in ruling out toxoplasmosis.

Control and prevention. In flocks in which toxoplasmosis has been diagnosed, little can be done during that lambing period. To prevent infection from being continued to the following year, contaminated bedding should not be spread onto pastures the following year.[82] Cats should be prevented from defecating in feed or bedding by either eliminating all farm cats, spaying all queens to reduce the population of kittens, or preventing access of cats to sheep feed. Contamination of stored feeds can be reduced by sealing grain in metal bins (with the added benefit that rodents cannot get access either), by providing a cat litter box in the barn to discourage defecating in feeders, and by not feeding square bales stored on top to pregnant ewes, because they may be contaminated by cat feces. These bales can be put aside and fed later to lactating ewes. Water sources should be raised so as to reduce the risk of contamination with feces. These control measures may still be inadequate, because a significant feral cat population usually exists in most rural areas and infection can occur on pasture where kittens are learning to hunt. Commercially prepared supplements may be contaminated without the producer's knowledge. In addition, mice can transmit the infection vertically to their fetuses, thereby perpetuating a reservoir of infection for new generations of kittens.[83]

Feeding monensin (Rumensin, Elanco) throughout gestation at a dose rate of 15 mg/head/day throughout pregnancy has been shown to be an effective prophylactic measure.[83] Decoquinate (Deccox*), if fed at a rate of 2 mg/kg of body weight daily throughout gestation, also protects against infection.[84] Prophylactic use of chemotherapeutics should be considered if toxoplasmosis persists in the flock despite use of the preceding control measures.

Using live tachyzoites of the S48 "incomplete" strain of *T. gondii*, a vaccine (Toxovax*) has been developed that confers excellent immunity for at least 18 months and probably for life but is not yet available in North America.[85] Inactivated tachyzoite vaccines have failed to provide protection against abortion, even if the vaccine elicited a good humoral response.[85] The S48 vaccine is given at least 3 weeks before mating to the entire female breeding flock and, in subsequent years, only to female flock additions. The drawback with this the vaccine is that it has a very short shelf life (7 to 10 days) and is capable of infecting humans.

Zoonotic disease. Approximately 30% of adults in the United States have antibody titers to *T. gondii*.[86] Pregnant nonimmune women are the most at risk of disease. *T. gondii* can cause congenital neurologic disease and blindness in human fetuses. It is an important cause of encephalitis in humans suffering from acquired immunodeficiency syndrome (AIDS). Most humans probably become infected from consuming undercooked meat, although handling of cat feces should be considered as a source. Freezing meat to –12° C for 1 day or cooking meat to 67° C will kill tissue cysts.[86] Microwave cooking is uneven and may leave some cysts viable.[86]

Miscellaneous Infectious Causes

Endotoxin Abortion

Available evidence indicates that in many species, endotoxins released from gram-negative bacteria (e.g., coliform mastitis, salmonellosis, contaminated drugs, sepsis) cause release of prostaglandins in very high levels, with subsequent abortion. The abortifacient effect during pregnancy in sheep has not been well studied, however.[87,88]

Flexispira rappini *Infection*

The clinical presentation of abortion following infection due to *F. rappini*, a flagellated, anaerobic agent, is very similar to that of abortion following infection due to *Campylobacter* spp.[27,89] Suppurative placentitis and fetal liver necrosis are features, as well as mummified fetuses, abortions, and stillbirths. Findings on darkfield microscopic examination of fetal stomach contents are negative, however, in cases due to *F. rappini*. Culture of liver, stomach contents, and placenta on blood agar, incubated in an atmosphere of 80% nitrogen, 10% hydrogen, and 10% carbon dioxide, will grow filamentous organisms that stain faintly gram negative.[89] The organism is sensitive to oxytetracycline.

Histophilus ovis *Infection*

Histophilus ovis has been implicated in ovine mastitis, polyarthritis in lambs, epididymitis of rams, and many other pathologic conditions. It also is occasionally a cause of ovine abortion.[90] The organism not unusually is found

*Alpharma, Fort Lee, NJ.

*Intervet, Milton Keynes, UK.

in vaginal cultures of young ewes. It is speculated that abortion is caused when the organism ascends in carrier ewes.[90,91] Abortion may be sporadic or occur in up to 50% of pregnant ewes. The placenta is hemorrhagic and swollen. The fetuses may be mummified or necrotic. Diagnosis is made by culture of the fetus or placenta. Control should focus on the entire flock, because the organism may be present in rams or carrier ewes.

Leptospirosis

The most common agent of leptospirosis in sheep is *Leptospira interrogans* serovar *hardjo,* although *Leptospira pomona* has been isolated in some cases.[92] It is an unusual cause of abortion in sheep but should be considered in areas in which leptospirosis is a problem in cattle, pigs, or wildlife. Ewes abort or have stillborn lambs and also may have high fevers, flaccid agalactia, hemoglobinuria, and jaundice. An important consideration in the differential diagnosis for *Leptospira*-related abortion is copper toxicosis.

Diagnosis is confirmed by a fourfold rise in titer in the aborting ewe or a positive immunofluorescence test or darkfield microscopic examination of internal organs of the fetus or the placenta. Dihydrostreptomycin (in a dose of 25 mg/kg of body weight) has been reported to stop abortions. Vaccination with a commercial multivalent vaccine may be effective in preventing further abortions. Leptospirosis is a zoonotic disease.

Listeriosis

Listeria monocytogenes causes abortion, encephalitis, and septicemia in sheep, goats, and cattle and in humans, as well as in many other mammals.[93] *Listeria ivanovii* has been implicated only in sheep abortions.[94] *Listeria* organisms grow well in poor-quality, alkaline silage (pH > 6.0).[95] Contamination of the silage occurs from mouse, bird, or other animal feces that are inadvertently ensiled. Outbreaks also have occurred on pasture, where it is likely that the environment was were contaminated with feces containing the organism. *Listeria* causing encephalitis probably enters through the oral cavity and, after an incubation period of 2 to 6 weeks (average 30 days), travels up the facial nerves to invade the brain. Abortion occurs 7 to 30 days after oral inoculation.

Silage feeding most frequently is part of the history. Shed feeding, particularly in wet conditions, also favors infection.[94] Sheep that abort may be very ill, and metritis may follow abortion. The fetuses often are found to be very autolyzed. The organism is a facultative microaerophilic organism and difficult to grow. Tissue examination of the liver and brains of aborted fetuses, which reveals microabscessation of those organs, will help to confirm the diagnosis.

Treatment of clinical cases often is unrewarding, particularly in sheep with the encephalitic form. In an outbreak, prophylactic treatment of susceptible sheep with long-acting oxytetracycline (20 mg/kg) may avoid further cases. A live attenuated vaccine has been used in Norway to control ovine listeriosis.[96] Prevention should focus on providing only good-quality silage or avoiding silage feeding altogether. Silage should be preserved anaerobically. If bags are used, they should be kept tightly sealed. Addition of acidifying agents at ensiling time may help reduce the pH sufficiently to inhibit growth of *Listeria.* Holes may be made in bagged silage by cats' claws or by core sampling for forage analysis. Silage that appears spoiled or moldy should not be fed to sheep or goats.

Listeriosis is an important zoonotic disease. Immunocompromised people seem to be the most susceptible to infection. Most human outbreaks have occurred as a result of consuming contaminated dairy products or contaminated vegetables that were stored under cold conditions for long periods before being consumed. Contamination of dairy products usually occurs during or after processing.

Neospora canis *Infection*

Neospora canis, a protozoal parasite of livestock and companion animals, is one of the most common causes of abortion diagnosed in dairy and beef cattle. Surveys for evidence of infection with *Neospora* in aborted ovine fetuses have not shown this infection to be common in sheep.[97] As well, there are few reports in the literature of naturally occurring *Neospora* infection in sheep and none linking infection specifically to abortion,[98,99] although infection may be more common in goats.[100] Experimental infection of pregnant ewes, however, shows that this species is very susceptible to the organism, because they readily abort or deliver weak lambs and may continue to abort or deliver weak, infected lambs in subsequent pregnancies.[101,102] Histopathologic lesions are very similar to those found with toxoplasmosis abortion. Protozoal cysts can be detected in the brain of aborted fetuses using immunohistochemical staining that detects the bradyzoites. Aborted fetuses also may have a nonsuppurative myositis. Weak, live lambs also can have evidence of cerebral necrosis and meningitis. Nonsuppurative, necrotizing placentitis commonly is seen. An ELISA to detect *Neospora*-specific antibodies in ovine serum has been developed for which cross-reactivity with other protozoal infections, including toxoplasmosis, has not been observed.[103] In view of the susceptibility of sheep to this organism, *N. canis* infection should be considered as a diagnosis if toxoplasmosis is ruled out in cases of protozoal abortion. Methods of diagnosis include immunofluorescence antibody testing or ELISA of blood and PCR assay of fetal tissues.[72] If diagnosed with neosporosis, the aborting ewe should be culled.

Salmonellosis

Many species of *Salmonella* have been implicated in ovine abortion. Three species—*S. abortusovis, S. montevideo,* and *S. arizonae*—have a predilection for the ovine and often cause abortion outbreaks without significant adult disease.[104,105] Abortion rates in these outbreaks can range from very low (<1%) to as high as one third of the pregnant flock. An efficacious live attenuated vaccine against *S. abortusovis* is available in Europe for use in high-risk flocks.[106] *S. abortusovis* and *S. montevideo* are more common in Europe, and *S. arizonae* is more common in North America.

Many other species of *Salmonella* have been implicated in ovine abortion with significant adult mortality. *S.*

dublin, S. typhimurium, S. schwarzengrund, and other species have been reported to be associated with abortion and ewe death due to metritis and septicemia. One outbreak was associated with feeding lincomycin to ewes to control campylobacteriosis.[29] These organisms may be introduced through contaminated feed or by carrion birds and carrier animals such as dogs, cats, rats, and livestock. Usually these sporadic, opportunistic outbreaks disappear from the flock and do not persist to the following season.

Sarcocystosis
Abortion due to *Sarcocystis* spp. is unusual, but definitive diagnosis may be difficult. Sheep may be infected by four species of *Sarcocystis*. Two species—*Sarcocystis tenella* and *Sarcocystis arieticanis*—are pathogenic and may cause abortion during the acute-phase infection.[107] *Sarcocystis gigantea* and *Sarcocystis medusiformis* are not considered to be pathogenic to sheep. Detection of infection with pathogenic species can be done using a species-specific PCR assay on blood samples of infected sheep[108]; such testing also will help differentiate this entity from infection with other protozoal parasites of sheep. Suggested control measures include prevention of contamination of feed and pastures by feces from dogs, foxes, or other canids or cats or by preventing access of young susceptible animals to places where contamination cannot be prevented.[72]

Yersinia enterocolitica
Occasionally *Yersinia enterocolitica* (O serotype) has been isolated from ovine abortion samples—both field cases as well as experimental infections.[109] Length of incubation is 50 days. Fetuses generally are aborted dead. The placentitis is suppurative and necrotic, with thickened cotyledons. The fetuses show no external gross changes. Internal changes are consistent with microbial invasion. Thoracic and peritoneal cavities are filled with turbid serosanguineous fluid, and internal organs are hemorrhagic. The organism can be recovered from vaginal discharges up to 2 weeks after abortion. Ewes aborting from this infection can subsequently conceive and carry full-term healthy pregnancies.

NONINFECTIOUS CAUSES OF ABORTION

Stress and Trauma
Abortion can be seen after an unusual stress, such as from predator attack, shearing, or inappropriate handling. Although it is possible to handle sheep before lambing, care should be taken. Associated with inappropriate handling is the risk of fetal trauma (ruptured liver or kidney). Traumatic injury may be incurred while the ewe is in a chute or being run through a gate, but fighting and shoving between ewes at a feeder also constitute a possible cause.

Hyperthermia
Sheep that do not thermoregulate well tend to have poorer placental growth than sheep that do, although whether hyperthermia is severely detrimental to lamb survival is not clear.[110]

Energy/Protein Deficiency
At the time of breeding, energy deficiency and, to some extent, protein deficiency are associated with embryo loss. If the ewe is not fed adequately for the first and second trimesters, placental growth and attachment to caruncles will be adversely affected. Birth of small weak lambs and mummification are potential outcomes. Some abortions also may be due to in utero starvation of the fetus. Inadequate energy in the third trimester will inhibit fetal growth. Lambs will be born small, with poor body fat reserves and increased risk of hypothermia.

Overnourishing of Adolescent Ewes
If peripubertal ewes lambs are fed a balanced ration intended to promote rapid growth, a marked detrimental effect is observed on placental mass, the number of cotyledons per placenta, and subsequent birth weight of the lambs.[111] These smaller lambs experience much higher mortality rates than those for normal lambs. Laboratory data on these lambs reveal elevated serum urea, and abnormalities of the kidneys and gut are seen at necropsy. These findings underlie the need not to overfeed pregnant ewe lambs.

Astragalus *spp. and* Oxytropis *spp.*
(Locoweed) Abortion
Ingestion of locoweed can cause abortion of dead fetuses, birth defects such as arthrogryposis, right heart hypertrophy resulting in hydrops amnios and hydrops allantois, reduced birth weight, and weakness of newborn lambs.[112] The severity of the effect is dose dependent on the amount of plant ingested and the time of gestation. The toxin is the indolizidine alkaloid swainsonine. The probable pathogenic mechanisms are delay of embryo implantation, interruption of vascular development, and induction of alterations in fetal fluid balance. The toxin appears to increase prostaglandin levels in the cotyledons ($PGF_{1\alpha}$ and $PGF_{2\alpha}$) and thus decreasing serum progesterone.[113] Ingestion of locoweed also causes reduced fertility in both rams and ewes and disruption of the maternal-offspring bond.[112] It has been suggested that in some geographic regions where these plants grow commonly, namely, the western United States, locoweed ingestion is a very important cause of abortion and reproductive failure.

Veratrum californicum *Abortion*
If *Veratrum californicum* (false hellebore, California corn lily) is ingested during the breeding season, such as on day 14 of gestation, the toxin causes cyclops and arthrogryposis in the lambs.

Iodine Deficiency
If noniodized salt is fed to ewes during gestation or if cobalt-iodized salt is not made available on a free-choice basis, abortion and stillbirth due to iodine deficiency goiter may occur. The fetuses exhibit swellings on either side of the neck region that are shown to be the greatly enlarged thyroid glands. Absence of wool also is commonly seen with late-term abortions. Lambs born alive are very weak and, unless supplemented with iodine, usually die. Once diagnosed, the rest of the flock should be supplemented with oral iodine. It has been suggested

that Lugol's iodine be added to the water or that 1 to 2 ml of tincture of iodine be painted on the woolless skin once per week. To prevent problems, iodine should be fed at a rate of 0.10 to 0.80 mg/kg of dry matter (DM) diet, with the higher end of the dose range recommended for pregnant ewes and growing lambs (1985 National Research Council [NRC] recommendations). Sheep grazing goitrogenic brassicas such as forage rape or turnip tops may require higher levels of supplementation, up to 2 mg/kg of DM.

Selenium Deficiency

Selenium deficiency has been associated with early embryonic death, abortion due to in utero white muscle disease, prolonged parturition (which increases the risk of stillbirths), and white muscle disease in lambs.[114] Selenium is the only mineral that is directly associated with embryo survival. Supplementation of other minerals and vitamins may be associated with increased conception levels, but this effect probably is due to increased ovulation rate. Selenium should be added to the ration at a rate of 0.1 to 0.3 mg/kg of DM diet, with 0.25 mg/kg the probable optimal level for supplementation of sheep fed deficient rations. A sustained-release bolus containing 50 mg of selenium was associated with improved reproductive performance through an increase in both the proportion of ewes lambing and the proportion giving birth to twins.[115] The selenium also may be fed as a supplement or salt-mineral mixture to be consumed at a rate of 0.23 to 0.46 mg/sheep/day. Higher levels have been associated with toxicity unless used in a very selenium-deficient region. With oral supplementation of selenium, it takes approximately 1 month for the blood selenium levels to increase to normal levels. Parenteral injection of the pregnant ewe with commercial selenium preparations at a rate of 0.056 mg/kg of body weight at 1 month before lambing has been shown to decrease the risk of congenital and newborn nutritional myopathy.

CHAPTER 91

Lambing Management and Neonatal Care

PAULA I. MENZIES

PRELAMBING MANAGEMENT OF PREGNANT EWES

Midgestation

Approximately 40 days after the ram is removed from the flock, scanning for pregnancy using real-time ultrasound examination is recommended to identify those animals that are not pregnant. To improve nutritional management of late-gestation ewes, fetal number also should be determined and ewes classified by body condition score.

Pregnant ewes can be grouped for feeding as follows:

- Ewes with singles in good condition
- Ewes with twins in good condition and ewes with singles in poor condition
- Ewes with triplets or more and ewes with twins in poor condition

One Month before First Expected Lambing Date

The following management procedures should be performed routinely approximately 1 month before lambing:

- Ewes should receive "booster" immunization with a multiway clostridial vaccine that includes antigens effective against tetanus, pulpy kidney (*Clostridium perfringens* type D), enterotoxemia (*C. perfringens* type C), malignant edema (*Clostridium chauvoei* and *Clostridium septicum*), and Black's disease *(Clostridium novyi)*. If the ewes have not

CHAPTER 91

Lambing Management and Neonatal Care

PAULA I. MENZIES

PRELAMBING MANAGEMENT OF PREGNANT EWES

Midgestation

Approximately 40 days after the ram is removed from the flock, scanning for pregnancy using real-time ultrasound examination is recommended to identify those animals that are not pregnant. To improve nutritional management of late-gestation ewes, fetal number also should be determined and ewes classified by body condition score.

Pregnant ewes can be grouped for feeding as follows:

- Ewes with singles in good condition
- Ewes with twins in good condition and ewes with singles in poor condition
- Ewes with triplets or more and ewes with twins in poor condition

One Month before First Expected Lambing Date

The following management procedures should be performed routinely approximately 1 month before lambing:

- Ewes should receive "booster" immunization with a multiway clostridial vaccine that includes antigens effective against tetanus, pulpy kidney (*Clostridium perfringens* type D), enterotoxemia (*C. perfringens* type C), malignant edema (*Clostridium chauvoei* and *Clostridium septicum*), and Black's disease *(Clostridium novyi)*. If the ewes have not

had a primary series as lambs, or if the previous vaccination was administered more than 12 months previously, then a primary series should be given starting at 2 months before the first expected lambing date. A vaccine that contains antigens to *Corynebacterium pseudotuberculosis* (the agent of caseous lymphadenitis) can be included if the disease is present in the flock.

- Shear or, in sheep maintained outdoors in inclement weather, crutch (remove wool from the perineal or escutcheon area) all pregnant ewes. Shearing increases dry matter intake, is associated with improved fetal lamb growth, and improves udder cleanliness for nursing lambs.
- Increase energy and energy density of ration.
- Increase energy to ewes in poor body condition.
- Loose, clean free-choice mineral formulated for sheep, with added salt to increase palatability, should be available at all times. Special attention should be paid to providing adequate calcium if cereal hays are fed; supplemental selenium, cobalt, copper, iodine, and molybdenum if regional soils and forages are known to be deficient; and vitamin E and vitamin A if stored feeds are fed.
- If sheep are bunk fed, feeder space should allow all ewes to eat at once (i.e., a minimum of 40 cm [16 inches] of feeder space per pregnant ewe) (Table 91-1).
- If sheep are housed in a barn or dry lot, additional space must be allowed for pregnancy (a minimum of 1.4 m^2 [16 square feet] per ewe) (see Table 91-1).
- Treatment with an anthelmintic is given to prevent preparturient rise in fecal egg count. This recommendation may be modified according to regional conditions.
- If sheep are shorn or if warranted, treatment for external parasites (lice, keds, and mange) is given.
- For ewes lambing at pasture, supplementation with a coccidiostat in the mineral premix may be helpful to reduce contamination of lambing grounds.

Two Weeks before First Expected Lambing Date

The lambing area is prepared as follows:

Lambing on pasture: Straw bales are positioned to create a windbreak and to bed lambing grounds. After lambing is finished, straw can be gathered in and burned or composted. Protection against predators (e.g., guard animals) should be ensured.

Lambing inside: Ventilation must be adequate for animal numbers. Temperature fluctuations where young lambs are to be housed should be avoided. Building or pens should be cleaned out and disinfected and fresh bedding applied to lambing area.

Lambing and lamb processing equipment and medications should be available (Box 91-1).

Table **91-1**

Housing Requirements for Ewes and Nursing Lambs

Production Period	Animal Class	Housing Type	Space	Numbers
Late gestation and lambing	Ewes	Pen feeder	16 ft^2/ewe 20 inches of feeder space/ewe for limit-fed animals, 6 inches for free-choice–fed animals	<40 ewes/pen
		Waterer	25–50 ewes/bowl, 15–25 ewes/foot of tank	
1–3 days of age	Ewes and lambs	Claiming pen	4–5 ft/ewe-lamb pair	12 pens/100 ewes: natural breeding 40 pens/100 ewes: synchronized breeding
Lactation	Ewes with lambs	Pen	20 ft^2 per ewe-lamb pair; extra 5 ft^2 for prolific breeds	*2–4 days old:* 5–10 ewes-lambs/pen *5–14 days old:* 20–40 ewes-lambs/pen *14 days to weaning:* 50–100 ewes-lambs/pen
		Feeder and waterer as for gestating ewes		
Nursing and early weaning (<28 days)	Lambs	Creep area	2 ft^2/lamb 2-inches of feeder space/lamb	As for nursing lambs; 25/pen for early weaned lambs

Data from Canadian Farm Buildings Handbook, Agriculture and Agrifood Canada.

Box 91-1

Lambing Equipment and Supplies Recommended for Sheep Producers

Lambing Equipment
Clippers or hand shears for crutching ewes
Prolapse retainers and soft rope
Chlorhexidine scrub for cleaning perineum
Clean terrycloth towels
Two clean buckets: one for warm water to wash, one for cold water to revive lambs
Sterile lubricant (e.g., K-Y jelly)
Plastic disposable rectal sleeves
Nylon lambing ropes and lamb snare

Identification Equipment
Paint for spraying/branding lambs
Ear tags and tagger
Tattoo and ink (optional)
Lambing diary

Lamb Feeding Equipment
Tube feeding kit with rubber tube and 60-ml syringe or 250-ml squeeze bottle
Source of frozen colostrum (bovine, caprine, or ovine)
Lamb milk replacer with nipples and bottles
Lamb bar (optional)
Equipment for fostering lambs (e.g., head gate)

Lamb Processing Equipment
2.5% iodine for painting umbilical cord stump
Sterile syringes: 1-ml, 3-ml, and 60-ml
Sterile needles: 22-gauge and 20-gauge, 1-inch
Empty Javex bottle with lid for sharps disposal
Warming box for chilled lambs
Digital thermometer with a readout to 36° C
Equipment for tail docking and castration (rings, hot-docker, Burdizzo emasculators)

Medications*
Propylene glycol and drench gun or drench bottle
Injectable vitamin E and selenium product labeled for newborn lambs
Multivalent clostridial vaccine
Tetanus antitoxin (optional)
Contagious ecthyma vaccine (optional)
Calcium borogluconate for subcutaneous administration
50% dextrose to be diluted for treatment of hypoglycemic lambs
Oral electrolyte (registered for calf use)
Antibiotics: penicillin and long-acting oxytetracycline
Larvicidal anthelmintic

*Provided for clients with an established relationship with the practitioner.

PARTURITION (LAMBING)

Gestation length varies considerably with breed of sheep. It also varies within breed with number of fetuses being carried. Triplet-bearing ewes usually lamb before single-bearing ewes bred on the same day. On average, sheep gestate for 145 days. Normal lambings have been reported as early as day 137, but generally sheep do not lamb earlier than day 142.

At 1 week before the first expected lambing date (day 138 after the ram is introduced to the breeding flock), ewes should be observed every 4 to 6 hours. Diseases to observe for include signs of pregnancy toxemia, which include refusal to eat grain, opisthotonos, teeth grinding, fine muscle tremors, and coma; signs of hypocalcemia, which include stilted gait, excessive salivation, and recumbency with hind legs extended behind; vaginal prolapse; abortion; mastitis; and rupture of the prepubic tendon. If any of these conditions occurs, prompt treatment should be instituted.

Signs of the **first stage of labor** include udder enlargement and engorgement with colostrum, relaxation of the pelvic ligaments, and vulvar swelling. The ewe will separate from the flock and begin nesting. If on pasture, she will seek an isolated spot with slight elevation or close to a fence line. Ewes may seek shelter, if it is provided, in order to protect their newborn lambs from inclement weather. Within a paddock, ewes may choose the same location in which to give birth, presumably attracted by the scent of birth fluids. In a pen, ewes may seek a corner or an open claiming pen. She will circle, paw at the straw, and bleat in a low voice. She will stop to smell any uterine or vaginal discharges. As the uterine contractions become stronger and the fetus moves up into the pelvis, she may lie down repeatedly and strain with the head raised.

The **second stage of labor** generally takes less than an hour from the start of intense straining to the delivery of the lamb. Time to delivery of lambs is approximately 30 minutes or less for a single lamb and up to 2 hours for triplets. Labor in primiparous ewes may take longer. No preference in time of day to deliver has been observed, but if disturbed, the ewe may stop labor for a few minutes until settled again. Normal presentation of the lamb is described as anterior dorsosacral with front limbs extended and preceding the nose by approximately 6 cm (2 to 4 inches). Also normal but associated with greater risk to the safe delivery of the lamb is posterior dorsosacral with hind limbs extended. If delivery is delayed and the umbilical cord is compressed between the lamb and the pelvis of the ewe, the lamb may suffocate before delivery is complete. After delivery of the lamb, the ewe stands, causing the umbilicus to rupture. The ewe turns and begins to nuzzle and lick the lamb to stimulate breathing and to clean it off.

INDUCTION OF PARTURITION

Induction of lambing can be done if the breeding date is known within an accuracy of 3 days—for example, if breeding was synchronized using hormones and only one breeding opportunity occurred. Ewes will respond to an injection of dexamethasone (16 mg given intramuscularly [IM]) or betamethasone (10 to 12 mg IM) after day 137, but it is preferred to wait until day 142 to ensure good fetal viability. Commonly, producers may wait for the first few lambs to be born and then induce the rest of the pregnant ewes. Lambing generally occurs between 36 and 60 hours after induction. Induction is not associated with an

increased risk of retained fetal membranes. In instances of vaginal prolapse or pregnancy toxemia, it may be advisable to induce as early as day 137, with the goal of saving the ewe.

MANAGEMENT OF DYSTOCIA

Common Causes of Dystocia

Causes of dystocia may include the following:

- Malpresentation of the lamb
- Maternofetal disproportion
- Poor cervical dilation
- Uterine torsion
- Uterine inertia

Malpresentation of the lamb (or lambs) may manifest in any of various ways: one or both front limbs retained; head retroflexed; true breech presentation, in which the lamb is in the posterior dorsosacral position but the hind legs are flexed forward; dorsopubic or dorsoiliac position; and in the case of multiple births, presence of multiple limbs or heads, or of more than one lamb, in the pelvis at the same time.

Maternofetal disproportion most commonly occurs when ewes that are carrying singles are fed too well in late gestation. Occasionally the ewe may simply have a congenitally small pelvis, or the disproportion may be the result of mating a small-breed ewe and a large-breed ram.

Poor cervical dilation may be due to vaginal prolapse; improper presentation, position, or posture of the lambs; fetal death before stage 1 labor (e.g., from abortion diseases); or possibly damage to the cervix from chronic exposure to phytoestrogens. **Ringwomb** is the term used to describe incomplete cervical dilation that is unresponsive to manual dilation. The cervix is hard, as it is before stage 1 labor. This condition occurs more frequently in primigravida lambs but may be seen in sheep of any age. Most flocks experience occasional cases of ringwomb, but outbreaks in which up to 15% of ewes are affected have been described.

Uterine torsion occurs occasionally and can be diagnosed on vaginal examination. It may be confused with poor cervical dilation.

Primary **uterine inertia** may occur if the ewe is ill (e.g., from hypocalcemia or pregnancy toxemia); secondary inertia occurs when the ewe is exhausted after a prolonged labor.

Correction of Dystocia

The practitioner should ensure that the proper tools and protection are available and that the gloves are well lubricated (see Box 91-1). The uterine wall is friable, so only gentle manipulation is advised. A tear in the uterus leads to peritonitis, which is not well tolerated in sheep.

If extensive manipulation is required, use of an epidural anesthetic procedure is advised. The epidural injection generally is performed at the sacrococcygeal space. After the area is clipped and disinfected, a 20-gauge needle is inserted at an angle of 20 degrees to the tail when held horizontally. Lidocaine hydrochloride is then injected at a dose rate of 0.5 mg/kg of body weight (1 ml of 2% lidocaine/40 kg). Additional analgesia may be obtained by combining xylazine with the lidocaine hydrochloride at a dose of 0.07 mg/kg of body weight (0.14 ml of 2% xylazine added to each milliliter of lidocaine hydrochloride). Adult ewes may range in mature body weight from 60 to 80 kg, depending on breed and maturity. This dosage may cause paresis and ataxia of the hindlimbs for up to 8 hours.

With a *retained front limb,* if the lamb is small, sometimes it may be extracted by gently pulling with the leg still back. With large lambs, however (or small ewes), it is necessary to correct the limb position before delivery is attempted. It generally is necessary to repulse the lamb gently back into the uterus if possible and then, after tracing the limb from the shoulder and elbow, hook the retained leg below the elbow with a finger, bending the carpus and then the fetlock in order to raise the foot over the brim of the pelvis. The practitioner must take care to protect the wall of the uterus from the foot by cupping the foot in the hand. If the fetus cannot be repulsed or if room in the pelvis is insufficient to allow correction of the position, a cesarean section is indicated if the lamb is still alive, or if the lamb is dead, a partial fetotomy is indicated. Viability is determined by checking for the following: suckle reflex, gag reflex, corneal reflex. If none are present, a partial fetotomy is performed by removing the head and neck to increase room to reposition the leg.

With *lateral retroflexion of the head,* again, an attempt is made to repulse the lamb in order to increase the available space for correction of the head position. A lamb snare around the head and front limbs can be used to help guide the head around. Traction on the lower jaw is avoided unless the lamb is dead, because this usually will result in a fracture to the mandible. If this maneuver is unsuccessful, cesarean section if the lamb is alive or partial fetotomy if the lamb is dead should be considered.

With *multiple fetuses,* care should be taken to trace limbs and head back to the body and identify which limbs belong to which lambs before repulsion or extraction is attempted.

Maternofetal disproportion may be present concurrently with malposture (e.g., head or limb retroflexion). Once the lamb is in the proper presentation, position, and posture, either soft ropes or the lamb puller can be used to apply gentle traction, ideally to both the front limbs and the head simultaneously. To determine if the lamb can be delivered vaginally, the examiner can assess whether both elbows and the head can be pulled into the pelvis at the same time. Inability to do so with relative ease indicates that vaginal delivery cannot be done safely for the ewe or the fetus. Plenty of lubrication is used to assist extraction. While the lamb is being pulled, after the thorax is clear of the vagina, the lamb is rotated approximately 30 degrees to prevent hip lock.

With *poor cervical dilation,* the practitioner attempts gentle manual dilation, keeping the hand and arm well lubricated. If after 10 minutes no progress is observed, the problem may be true ringwomb. In this condition, the cervix does not undergo the normal parturient softening.

The cervical softening process starts with the prepartal drop in progesterone. This triggers an infiltration of leukocytes, which causes collagen degradation and hence softening. The cause for failure of the cervical softening process is not known. Some success at treatment has been reported with application of an estrogen product or prostaglandin $E_{2\alpha}$ to the cervical area, or with injection of such agents, and followed in a few hours by oxytocin. The alternative is cesarean section.

With *uterine torsion,* the practitioner must determine the direction in which the torsion has occurred and then either gently flip the uterus around or hold the fetus and have assistants roll the ewe in the opposite direction of the torsion. In approximately 50% of the cases, poor cervical dilation is present even after detorsion has been accomplished. Cesarean section should be considered in those cases.

If *uterine inertia* is due to hypocalcemia, the ewe is given parenteral calcium before delivery. This is done by slow intravenous administration of 50 to 100 ml of a commercial calcium borogluconate solution, followed by an additional 50 to 100 ml injected subcutaneously.

After delivery of the lamb primarily responsible for the dystocia, oxytocin (30 to 50 IU) can be given (unless the dystocia is due to uterine inertia). After 10 minutes, the vagina is checked for the presence of additional lambs. If uterine inertia is present, both horns are carefully explored to their ends to locate more lambs.

Cesarean Section

Anesthesia for performing a cesarean section can be obtained using one of the following methods.

A line or inverted "L" block of 2% lidocaine (without epinephrine) can be given on the left flank if a flank laparotomy will be performed, or given ventral midline if that approach will be used.

For the left flank only, paravertebral anesthesia to block the T13, L1, and L2 paravertebral nerves is achieved using the following method: The midpoint of the first lumbar process is confirmed by palpation, and a 6-cm spinal needle is inserted 2.5 to 3.0 cm from the midline along a perpendicular line running from the midpoint of the first lumbar transverse process to the spine and at a depth of 4.0 to 5.0 cm. The needle may need to be directed forward to walk it off the front of the transverse process. After the needle is felt to penetrate the ligament between T13 and L1, 4 to 5 ml of 1% lidocaine hydrochloride is injected to block the 13th thoracic nerve. the needle is retracted and an additional 2 ml is injected to block the dorsal branch of the T13 nerve. The needle is then withdrawn and redirected caudally to block L1 and is walked off the back of the first transverse process. Another 4 to 5 mL is given; then the needle is withdrawn slightly and another 2 ml is injected. To block L2, this technique is repeated but just anterior to the second lumbar process.

An epidural using lidocaine, xylazine, or a combination of both (as described previously) may be used in conjunction with a line or inverted AL block.

Surgical technique is standard. If the fetuses are dead, the uterus should be packed off using sterile drapes before an incision is made. After the first lamb is extracted, both horns should be carefully explored to the tip to detect the presence of more lambs. The practitioner should avoid incising any caruncles because this may result in excessive bleeding. After suturing, oxytocin is administered once and parenteral antibiotics are given for 3 to 5 days.

Fetotomy

Not uncommonly, a dystocia may not be detected until the lambs have died, or in some instances, have become emphysematous. If the lambs cannot be pulled, a fetotomy is preferred to a cesarean section. If the fetus is emphysematous, the uterus also may be compromised and friable. A subcutaneous fetotomy can be performed using a finger knife to avoid vaginal or uterine damage. Again, oxytocin and antibiotics are given at the completion of the procedure.

CARE AND MANAGEMENT OF THE NEONATAL LAMB

Resuscitation of the Newborn Lamb

Lambs normally will begin to breathe within 30 seconds of delivery. Techniques to stimulate the lamb that is slow to breathe include rubbing the head and thorax vigorously with a dry towel, pouring cold water in the ear, and stimulating the sneeze reflex by tickling the nostrils. Swinging the lamb may help extract fluid from the nose but makes it difficult for the lamb to breathe because of centrifugal pressure on the diaphragm. Mouth-to-nose resuscitation should not be done because of the risk of contracting a zoonotic infection from the lamb, such as *Chlamydophila abortus* or *Coxiella burnetii* infection. A technique of inflating the lungs that has been used with some success is as follows: A lamb stomach tube is inserted into the esophagus of the lamb. By means of gentle pressure applied with a thumb and forefinger, the esophagus is closed off distal to the end of the tube. The other hand is used to close off the mouth and nostrils. The clinician softly blows once into the tube. With the esophagus closed off, the air will be forced down the trachea into the lungs. The tube is removed after delivery of one breath, and the lamb is reassessed.

Normal Behavior at Birth

Lambs should be standing within 10 to 20 minutes of birth. The normal cleaning behavior of the ewe stimulates them to stand. They are then attracted to the ventral line of the ewe's abdomen and will follow it down to where it meets the udder. The ewe's licking and nudging behavior encourages a suckle reflex. A low udder or an udder covered with wool, or pendulous, misshapen teats, will interfere with successful nursing. The licking also serves to provide olfactory stimulation to aid in maternal recognition of the lamb. This bonding generally occurs in the first hour after birth. It is critical that the ewe have an undisturbed opportunity to bond with her lambs, without the risk of attempts at stealing them by another

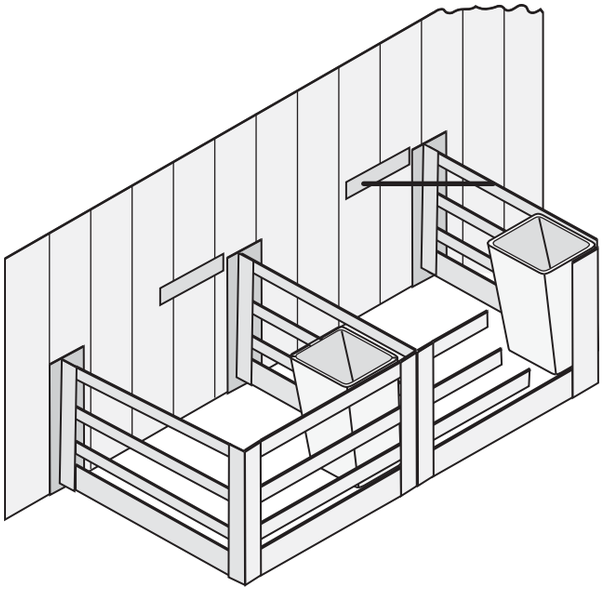

Fig. 91-1 Plan for a claiming pen. (Courtesy of Ontario Ministry of Agriculture and Food, Ontario, Canada.)

ewe. Circling behavior is abnormal and indicates that the bonding process is failing. Failure to bond and failure to successfully find the teat are major risk factors for hypothermia/hypoglycemia and septicemia.

The chance of successful bonding will improve if the ewe and lambs are provided with a quiet area, undisturbed by other sheep. Mothering is optimized by confining them in a claiming pen (jug) for 12 to 24 hours. The producer can more easily check the status of the lambs (stomach fill and attitude) and the behavior of the ewe (for signs of rejection) at the time when lambs are most at risk. Claiming pen size should be a minimum of 4 feet by 4 feet; for larger breeds or ewes with multiple lambs, 4 feet by 5 feet is preferred (Fig. 91-1). The bottom panels should be spaced close together to prevent the lamb from escaping. Ewes should be provided with fresh water and feed. Heat lamps are optional and should not be used once the lambs are dry.

Passive Immunity

If the ewe is fed correctly in late gestation, is properly vaccinated, and does not have mastitis, she should be able to provide the lamb with colostrum of adequate quantity and quality. Exceptions to this rule of thumb may be observed with maiden ewes and with ewes that have more than two lambs. If the ewe has inadequate colostrum or if the lamb is too weak to nurse properly, then the lamb should be fed colostrum at a rate of 50 ml/kg of body weight within 2 hours of birth and at rate of 200 to 250 ml/kg of body weight over the first 24 hours of life. If the lamb is weak, the colostrum should be administered by stomach tube.

Alternate-Source Colostrum

If the ewe has inadequate colostrum or is considered a risk to pass on specific diseases (e.g., ovine progressive pneumonia [maedi-visna], Johne's disease), colostrum obtained from other animals can be fed. Most ideal is sheep colostrum from a ewe of known health status. Colostrum may be frozen up to 6 months without loss of quality. It should be frozen in 50-ml (approximately 2-ounce) aliquots to facilitate thawing. Rapid thawing with heat (e.g., microwave on high) will denature the immunoglobulins. It is recommended initially to freeze the colostrum in an ice cube tray and then, once it is frozen, to transfer the cubes to a freezer bag labeled with the donor's identification data and the date of freezing. Only first-milk colostrum should be used.

Bovine and caprine colostrum also may be used, but associated risks have been recognized. Ideally, source animals should not be infected with infectious agents that may cause disease in sheep, such as bovine leukosis virus, *Mycobacterium avium* spp. *paratuberculosis,* bovine viral diarrhea virus, caprine arthritis encephalitis virus, and *Mycoplasma mycoides* spp. *mycoides*. The quality of the colostrum can be improved by vaccinating the donor animals against clostridial diseases.

Anemia due to an unknown factor in cow colostrum has been reported in lambs 1 to 3 weeks of age. This factor appears to increase the rate of red blood cell destruction both in circulation and in the bone marrow of affected lambs. They appear weak and pale. Although many recover without treatment, those severely affected, as indicated by a packed cell volume less than 10%, can be transfused by administering blood (10 ml of whole blood with anticoagulant per kg of body weight given intravenously or by intraperitoneal instillation).

Antibodies obtained from nonhost species may have a shorter half-life. A consequence of this limitation may be a higher risk of infectious diseases such as pneumonia. This also is true of commercial colostrum supplements, which are made from bovine sources. Whey-based products may not contain adequate levels of immunoglobulins. It is not known if serum-derived colostrum supplements provide sufficient protection to lambs.

Umbilical Care

Many opportunistic pathogens may gain entry through the stumps of the umbilical veins or arteries. A solution of 2.5% iodine in an alcohol base should be used to dip the entire navel soon after birth. Solutions containing a higher concentration of iodine may cause chemical burning and inflammation. Products containing glycerin (e.g., commercial teat dips) should not be used, because these prevent drying of the umbilical tissue. Paper disposable cups should be used, and excess dip and the cup discarded afterward.

Vitamin E and Selenium Supplementation

If the flock is located in a selenium-deficient area and the pregnant ewes have not been adequately supplemented, newborn lambs should be injected with a commercial vitamin E plus selenium preparation. The single dose of

0.75 mg of selenium, given by the intramuscular or subcutaneous route, should not be repeated. Toxicity and death have been associated with as little as 1.0 mg of selenium. It is safer and more effective to supplement pregnant ewes at a rate of 0.1 to 0.3 mg of selenium/kg of dry matter (DM) total ration, depending on the natural levels in the feed and governmental restrictions. If the ewe is to be injected with a commercial product rather than supplemented in the feed, 3 mg/45 kg of body weight is given up to every 2 weeks in the last trimester. Only products labeled for use in adult sheep should be used. Although vitamin E does not cross the placental barrier, it should be supplemented to the pregnant ewe at 15 IU/kg DM total ration (1.5 IU = 1.0 mg/dl of α-tocopherol). This will increase vitamin E levels in the colostrum. Lamb rations should contain 20 to 40 IU vitamin E/kg DM total ration. Vitamin A and D injections can be administered to gestating ewes if the ration is deficient.

Identification

Each lamb should be assigned a specific identifier at birth for two reasons: to identify lambs to retain as replacements at a future date and to identify ewe-lamb pairs. Methods include ear tagging, paint branding, and spraying on the back or side with the lamb's identification, the ewe's identification with or without the birth order number and litter size (e.g., 132P-13 would be the first-born lamb of ewe 132P out of a litter of triplets, and 132P-33 would be the third-born lamb of ewe 132P), or a unique design (e.g., a spiral). The ewe also should be paint-branded at the same time—for example, 132P-3 means that she has 3 lambs at foot. Permanent identification (tag or tattoo) can be given to lambs at birth or at weaning.

Contagious Ecthyma Vaccination

If the flock has significant problems caused by contagious ecthyma virus infection (mastitis, lamb losses, or diminished productivity), then it may be advisable to vaccinate the lambs at birth with a commercial vaccine (if available). The vaccine should not be used in unaffected flocks and need not be used if the disease is only mildly manifested in the flock.

Taildocking and Castration

Taildocking should be routinely performed in all long-tailed breeds within the first 7 days and preferably within the first 24 hours of life, but only after the lamb has received adequate colostrum. Use of either rubber bands or an electric docker is the preferred method. The tail should be docked distal to the end of the tailfold and should be long enough to cover at least the vulva in a ewe lamb. Short docking has been associated with increased risk of rectal prolapse and spinal abscesses.

Castration need not be performed in ram lambs to be marketed before puberty, to take advantage of the improved feed conversion rates of intact rams. If ram lambs are to be castrated, surgery should be performed before 7 days of age if the rubber rings or cut-and-pull technique will be used, and before 90 days of age if the spermatic cord will be crushed. Lambs castrated with rubber rings after 7 days of age should have the cord crushed first in order to destroy the nerves. This appears to reduce the pain associated with that procedure. Lambs born to inadequately vaccinated ewes should be given tetanus antitoxin (250–300 IU administered subcutaneously) at the time of docking or castration. Analgesia at the time of castration or taildocking has been used with variable success. Injection of long-acting local anesthetics proximal to the surgical site may offer temporary relief. Postoperative analgesia may be best provided by administering xylazine before surgery, but animals should be constantly observed until the sedative effects have worn off.

Nutrition of the Nursing Lamb

Peak milk production in ewes occurs approximately 30 days after lambing, and ewe nutrition in the early lactation period should be geared to maximize this production. Ewe's milk provides most of the nutrient requirements for lambs until they reach 30 to 45 days of age. At 10 days of age, lambs will start to consume small amounts of solid feed, but depending on the availability of ewe's milk, intakes of solid feed are low until weaning. To increase intake of solid feed, texturized 16% protein "creep feed" should be available, consisting of mixed grain, pellets containing minerals and medications, and a binding compound, commonly molasses. Feeders should be structured to prevent fecal contamination and wastage of feed. Restricted-access turkey or pig feeders work well for lambs.

Fostering or Artificial Rearing of Lambs

Indications

Indications for fostering or artificial rearing of lambs include the following:

Dam-related: Death or severe illness may require separation of the lamb from its dam, or the dam may reject the lamb. Other causes may include mastitis or other reason for insufficient milk production, poor udder conformation (too low or teats malformed), and birth of too many lambs to be reared by their dam; or another dam that has lost all her lambs is available as a foster mother.

Lamb-related: The lamb is unable to nurse its dam effectively because of weakness or congenital deformity.

Owner-specific: The producer prefers not to have dams rear more than 2 lambs, or not to have dams rear singles, to make nutritional management easier.

Artificial Rearing of the Nursing Lamb (First 4 Weeks)

Most orphan or rejected lambs can be raised on milk replacer until the age of 21 to 28 days, when they can be weaned onto a high-quality creep ration such as described earlier. Lamb milk replacer is higher in fat than calf or kid milk replacer, so the latter should not be used to rear

lambs. An example of a good milk replacer is one containing 22% protein from milk sources, 28% fat from animal sources, and 24% lactose. Milk replacer should be fed cold (4° C) and *ad libitum* from a lamb bar to prevent engorgement and abomasal bloat. In absence of a lamb bar, lambs can be bottle fed from a nipple bottle but should be fed frequently (e.g., 4 times per day). If abomasal bloat losses occur, formaldehyde added to the milk replacer (1 ml/L of milk) will decrease losses.

Foster Rearing

When cross-fostering is used, if at all possible the weakest lambs should be left with the dam, and all fostered lambs should have received adequate colostrum first. Successful fostering of lambs may be accomplished in any of several ways, but ultimately the attitude of the foster dam often determines the success. Attitude may be individual or may be breed determined.

Interventions used to promote successful fostering include the following:

- Manipulating the ewe's detection of scent by skinning the dead lamb and tying the hide to the foster lamb; washing the foster lamb in birth fluids or rubbing it with the fresh placenta; applying various scent blocks to the nares of the ewe.
- Manipulating the ewe's maternal instinct by cervical or vaginal stimulation; removing her own lamb and returning the foster lamb back with her at the same time; "hog-tying" the back leg of the foster lamb to mimic the behavior of a newborn lamb; bringing in a dog to "threaten" the ewe.
- Restraining the ewe so that the lamb can successfully suckle until the ewe accepts the lamb. A stanchion or head gate is the most commonly used device to prevent the ewe from circling. She can still kick, however, so the lamb should be watched to ensure it is able to nurse.

PREVENTION OF PERINATAL LAMB MORBIDITY AND MORTALITY

The perinatal period extends from the first stage of labor. The end of this period is less well defined but this phase can be divided into periods in which specific causes tend to exhibit themselves more commonly. For investigating lamb mortality, losses often are divided into those deaths that occur ante partum, during parturition, and at less than 5 to 24 hours (i.e., until the "mothering-up" process has finished, when bonding has occurred and lamb has ingested colostrum), 5 to 24 hours up to 48 hours (i.e., before acquired infections after birth have caused disease), and beyond 2 days. After 2 days of age, perinatal events can still influence mortality, but effects generally are not observed beyond 2 weeks of age.

Excessive lamb mortality and stillbirth are important limitations on productivity. Stillbirth losses (number of lambs born dead of all lambs born) should not exceed 5%. Lamb mortality levels of greater than 15% before weaning are not uncommon, although with good management, it is possible to keep losses below 5%. Box 91-2 lists possible causes of perinatal lamb mortality.

Box **91-2**

Common Causes of Perinatal Lamb Morbidity and Mortality

Prepartal abortion diseases responsible for weak or stillborn lambs: infections due to *Chlamydophila abortus, Campylobacter fetus* spp. fetus and *Campylobacter jejuni, Coxiella burnetii,* and *Toxoplasma gondii;* border disease; iodine deficiency
Dystocia responsible for birth trauma such as:
  Fractured ribs and long bones
  CNS lesions: subdural hematomas, particularly in the posterior brainstem; petechiation in brain associated with hypoxia and anoxia during the birth process; lesions may not manifest as neurologic disease but as depression and difficulty with thermoregulation
  Ruptured liver, spleen, kidney
  Edema of entrapped limb/head
Starvation, hypoglycemia
Chilling, hypothermia
Infectious diseases: abortion diseases as outlined above; septicemia due to failure of passive transfer; other septicemias (e.g., listeriosis); omphalophlebitis; pneumonia; diarrhea; joint ill (chlamydiosis, erysipelas)
Nutritional deficiencies: vitamin E, selenium, copper, iodine
Predation
Trauma from misadventure
Congenital malformations: atresia ani, contracted tendons, cleft palate
CNS, central nervous system.

Investigation of Perinatal Lamb Mortality

A flock health management program should include routine necropsy of all aborted fetuses and stillborn and dead lambs. A simple form can be used to assist in collecting all necessary history and data (Fig. 91-2). Findings on gross necropsy can easily be used to diagnose why the lamb died, and to define the management area that is responsible for the loss of the lamb.

History

The history should include details of the farm environment and management, as well as ewe and lamb factors. Wet and cold weather can play an important role in lamb losses. Older ewes or ewe lambs may be at greater risk for losing lambs. In excessively thin ewes, risks are greater for production of small lambs, prolongation of labor, and production of inadequate amounts of milk. Litter size, birth weight, and history of dystocia all are important risk factors in lamb mortality. Routine management procedures should be noted, as well as any treatment lambs have received. Notations of previous losses will help to identify problem areas.

Examination of the External Carcass

The examiner should make note of specific abnormalities:

- Atypical condition of coat: abnormal quality and amount of wool, indicating premature birth or congenital infection with border disease virus; meconium staining, indicating stressful birth;

Diagnosis:

Recommendations:

A

Fig. 91-2 **A** and **B,** Example of a necropsy form for investigating lamb perinatal mortality.

adherent placenta, indicating lack of cleaning by the ewe
- Saliva staining around the mouth, indicating endotoxemia (watery mouth)
- Congenital abnormalities (e.g., spider lamb, atresia ani, intersex, cleft palate, arthrogryposis)
- Perineal staining from diarrhea

The footpads are examined to determine whether walking occurred before death, as indicated by some "wear" of the pads; intact footpads signify that the lamb never walked.

Skinning back the carcass, the examiner should note the following:

- Degree of dehydration, keeping in mind that length of time since death and freezing may confound accurate observation
- Subcutaneous edema (regional or generalized); ascites, anasarca, or swollen head due to dystocia

NECROPSY FINDINGS

✓ relevant findings in appropriate box

EXTERNAL APPEARANCE:

☐ Meconium stained
☐ Wool coat not cleaned
☐ Foot pads worn (walked)
☐ Congenital abnormalities
☐ Perineal staining (diarrhea)
Other observations:

SUBCUTANEOUS APPEARANCE:

☐ Edema generalized
☐ Edema localized (e.g., head)
☐ Petechial hemorrhages of limbs
☐ Dehydration
☐ Enlarged thyroid glands (goiter)
Other observations:

UMBILICUS:

☐ Pointed with clot adhered
☐ Pointed with clot
☐ Blunt–no clot
☐ Omphalophlebitis
Other observations:

FAT: (EPICARDIAL/RENAL)

☐ Present
☐ Partially metabolized
☐ Fully metabloized (absent)
Other observations:

INTESTINES:

☐ Empty
☐ Normal
☐ Milk fat in mesenteric lymphatics
☐ Diarrhea
Other observations:

LUNGS:

☐ Inflated
☐ Partially inflated
☐ Atelectic
☐ Aspiration
☐ Pneumonia
Other observations:

ABOMASUM:

☐ Empty
☐ Milk/Colostrum
☐ Solid feed
☐ Foreign debris

SUMMARY OF RELEVANT FINDINGS:

B

Fig. 91-2, cont'd

- Bilateral swelling on the neck, which may be an enlarged thyroid, suggesting goiter due to iodine deficiency
- Umbilicus, to determine whether the umbilicus is blunt and arteries are empty, evidence that the lamb died before or during the birth process; is tapered and contains blood, evidence that the lamb survived the birth process; or is tapered and contains an organized adherent clot, evidence that the lamb survived the birth process by several hours. Hyperemia, fibrin, and purulent material in the umbilical region indicate omphalophlebitis.
- The skeletal muscles, which should be checked for evidence of white muscle disease

The skin should be removed from the limbs and the subcutaneous tissues examined for hemorrhages, which indicate that the lamb was hypothermic before death.

For internal examination, the lamb carcass should be opened with its right side down and the organs examined in situ. The following should be noted:

- Evidence of pleural or peritoneal fibrin, indicating a septic condition before death. Swabs of this fluid should be submitted for culture. If an agent associated with abortion is suspected, abomasal contents and thoracic fluid or heart blood should be collected using sterile needles and syringes (see Chapter 90).
- Blood in the peritoneal cavity, which may be from a ruptured liver, kidney, or mesenteric or umbilical vessel and suggests trauma occurring in utero, during parturition, or post partum, depending on other findings.
- Blood-tinged fluid in the peritoneal or pleural cavity, which may indicate that the lamb died in utero 1 or 2 days before delivery.
- The amount of brown fat around the kidney and heart, which should be evaluated. Serous atrophy suggests that the lamb was hypoglycemic before death. Heart fat is depleted first, then kidney fat.
- Aeration of the lungs, which can be assessed quickly by dropping a piece of lung tissue in a jar of water to assess buoyancy, and evidence of pneumonia. Total atelectasis of the lungs indicates that the lamb never breathed. The trachea and bronchi should be opened to examine for aspiration pneumonia (the owner may have incorrectly passed a stomach tube).
- The tongue, diaphragm, and heart should be sectioned and examined for evidence of white muscle disease. The heart should be checked for congenital defects.
- The abomasum should be examined for type and quantity of content. An empty abomasum or an abomasum that contains dirt or grass, along with the finding of serous atrophy of fat, suggests that the lamb survived at least 5 hours but never nursed. Detection of milkfat in the mesenteric lymphatics suggests that several hours have passed since feeding.
- The skull and the brain, particularly the atlanto-occipital region, should be examined for hemorrhages, both subdural and throughout the brain, indicating the possibility of birth trauma.
- The joints all should be opened to look for evidence of septic arthritis.

By using the information gathered on gross necropsy (Fig. 91-3), the death of the lamb can be classified as follows (Fig. 91-4):

Prepartum—early. The lamb appears obviously premature, with decreased or absent wool coat. This should

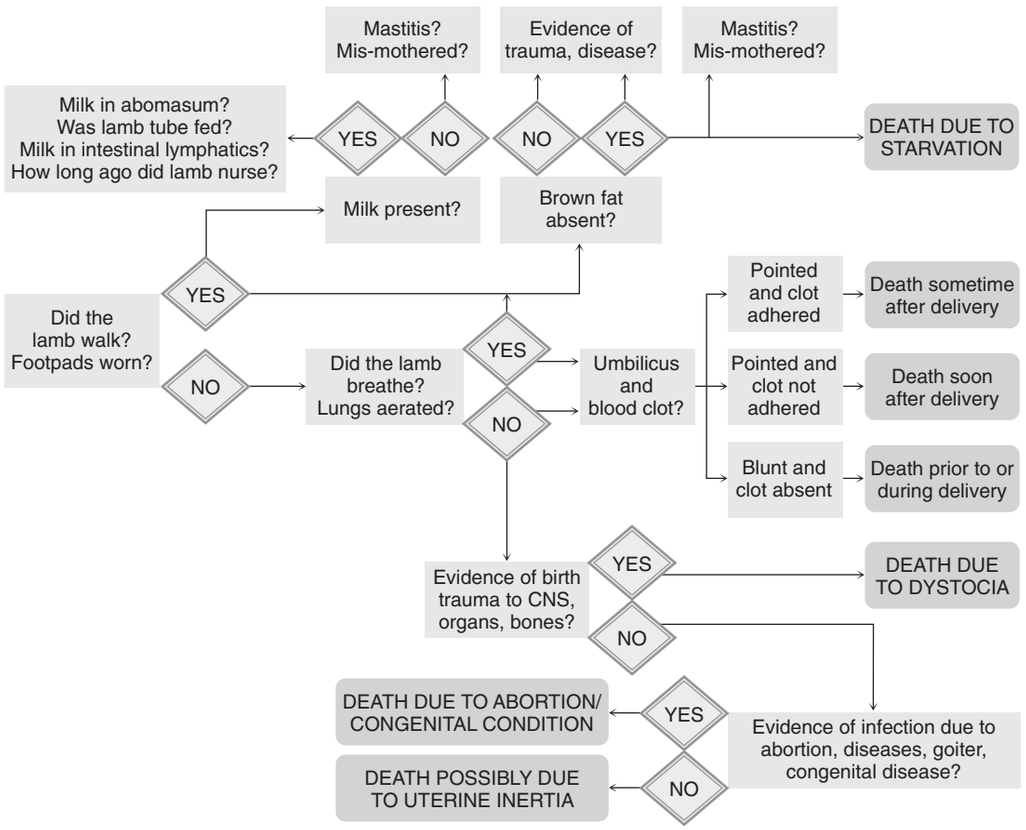

Fig. 91-3 Algorithm for classification of lamb perinatal mortality.

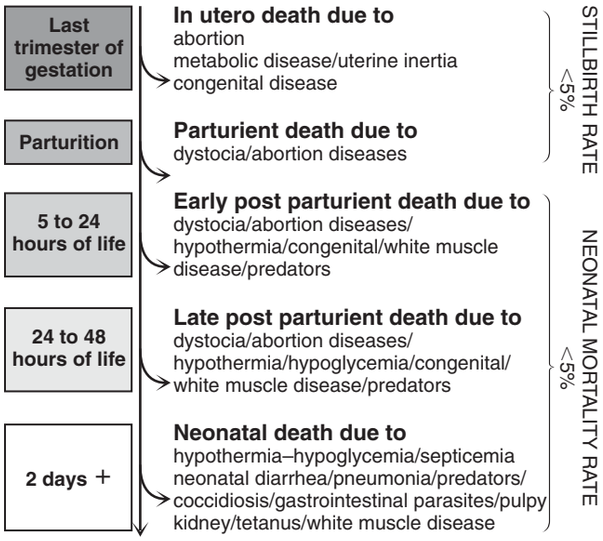

Fig. 91-4 Classification of timing of death in lambs and common causes of mortality.

be considered an abortion and investigated as such (see Chapter 90).

Prepartum—late. The lamb appears to be term but was delivered stillborn, with no evidence of birth trauma. Although the lamb's death may have been from delayed parturition due to uterine inertia , it is advisable to investigate the death as an abortion.

Parturient. Evidence of birth trauma is present, and the lungs are atelectatic.

Postparturient, early. Death occurred after birth but most often before 5 hours of age—up to 24 hours. Brown fat stores are evident, and the lungs are partially or fully inflated. The lamb may have been weak when born because of infection with abortion agents, may have succumbed to birth-related injuries, with or without evidence of hypothermia, or may have been primarily hypothermic.

Late postparturient, older than 5 to 24 hours. After 5 hours of age, lambs start to deplete their brown fat stores if they do not receive adequate nourishment (colostrum). Mismothering, inadequate colostrum supply, and weakness due to low birth weight or birth trauma will predispose the lamb to starvation (hypoglycemia). Up to 48 hours of age, death often is related to primary hypoglycemia with secondary hypothermia.

Neonatal, older than 48 hours. Although death after 48 hours may still be due to hypothermia or hypoglycemia secondary to birth trauma, mismothering, and other causes, after this time infectious diseases also can occur.

Recognition and Treatment of Weak Lambs

It is important to instruct the producer on how to recognize a sick lamb and how to apply appropriate nursing care. Hypothermia and hypoglycemia are the most common causes of lamb mortality; if recognized early, both are responsive to treatment. Affected lambs initially

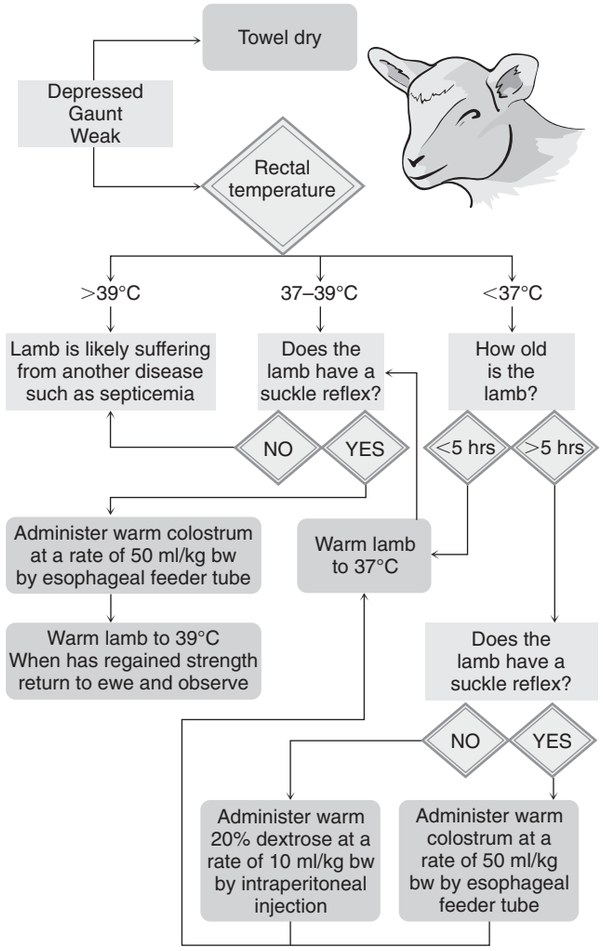

Fig. 91-5 Algorithm for treatment of hypothermia and hypoglycemia in neonatal lambs.

are hunched up and empty-appearing. If the problems are not detected early, these lambs will become recumbent. If in sternal position, the lamb may rise but appears depressed and slow to respond. Eventually, the lamb is laterally recumbent and comatose.

Figure 91-5 presents an algorithm for treatment for a lamb suspected of suffering from hypothermia or hypoglycemia. The client should be instructed in proper technique for tube feeding, with specific measures to avoid aspiration pneumonia: The client sits with the lamb on his or her lap, holding the lamb's head and neck gently in the nondominant arm. The tube is introduced slowly into the mouth and gently pushed toward the back of the throat. If the lamb sucks on the tube, a swallowing reflex is encouraged. Once the tube has been swallowed, the client can feel it pass down the lamb's neck in the esophagus. This maneuver should be practiced several times until the client can recognize the feel of the rubber end passing the fingers. If the tube enters the trachea, it cannot be felt externally. Premeasurement of the tube will help the client to determine if the tube has reached the abomasum. If the lamb coughs, the tube is withdrawn and another attempt is made. Colostrum can be fed by

syringe or squeeze bottle. The dose of 50 ml/kg of body weight should be fed slowly over 5 to 10 minutes, so that the abomasum does not overfill, leading to regurgitation. The client is instructed to kink the tube before withdrawal to prevent aspiration of milk.

Many ways to warm a lamb have been described. Immersion in warm water is the most rapid but requires that the client hold the lamb while in water and then dry it immediately, to avoid chilling from evaporation. Placement in a warming box in which the lamb lies on a grate that allows warm air to circulate around it generally works the best (Fig. 91-6). A household hair dryer works well for this purpose. Air temperature should not exceed 41° C. A warming pad will accomplish the same thing if the lamb also is covered with a blanket and turned frequently. Least efficient is use of a heat lamp, which offers only radiant heat to the exposed part of the lamb.

Lambs older than 5 hours of age require an energy source before warming. Failure to provide energy will result in central nervous system damage from hypoglycemia. If no suckle reflex is present, the lamb should have 20% dextrose administered into the intraperitoneal cavity. This procedure begins with drawing up 20 ml of 50% dextrose into a 60-ml syringe and adding to it 30 ml of hot, boiled, clean water. The resultant solution should be at body temperature. Instillation into the peritoneal cavity is accomplished by hanging the lamb vertically and injecting just off midline distal to the umbilicus, using a sterile 20-gauge needle and administering 10 ml/kg of body weight. After administration, the lamb can be warmed.

Once a lamb has received treatment for hypothermia/hypoglycemia, it and its dam should be identified for more intense observation. Factors that put lambs at risk for hypothermia and hypoglycemia include the following:

- Poor maternal nutrition during gestation (reduces the number of cotyledons and placental weight; brown fat stores [perirenal and pericardiac] in fetus; lamb birth weight; mammary development and subsequent milk production; colostrum quality and quantity)
- Low birth weight (<3 kg), which is highly correlated with poor brown fat stores
- High birth weight (>5 kg), which is highly correlated with dystocia
- Trauma or hypoxia due to dystocia or prolonged birth, which may be evidenced by meconium staining
- Premature birth (<142 days' gestation)
- Mismothering due to inexperience (e.g., ewe lamb), illness, stealing by another ewe, lack of availability of claiming area, claiming of only the firstborn lamb
- Insufficient milk available as a result of mastitis, poor late-gestation nutrition, maedi-visna (ovine progressive pneumonia) or other illness, low body condition score, poor udder or teat conformation, wool-covered udder
- Poor environmental conditions at birth of the lambs, such as a cold temperature (<13° C if fleece is wet), drafty conditions, and dirty or wet bedding or ground

Two exceptionally high-risk periods have been recognized:

Birth to 5 hours, when the lamb is wet. Losses at this time are due primarily to hypothermia or are secondary to birth trauma.

5 hours to 7 days, when hypothermia most often is secondary to hypoglycemia. Weakness after 48 hours of age also may be complicated by diseases stemming from inadequate colostrum intake.

CONTROL OF IMPORTANT DISEASES OF NEONATAL LAMBS

Entropion

Entropion usually is apparent within the first 2 weeks of age and manifests as ocular discharge, blepharospasm,

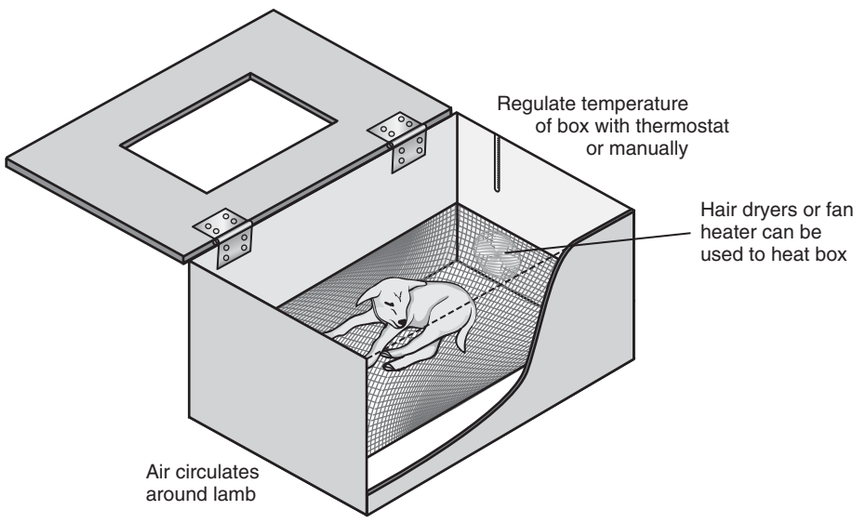

Fig. 91-6 Warming box for reviving hypothermic lambs.

corneal edema, and corneal ulceration due to irritation from inverted eyelids, usually the lower lid. Correction should be done immediately and may involve one of the following procedures: Mild cases may be resolved by manually everting the lid several times a day for a few days. Moderately severe cases may be resolved by an injection of penicillin into the palpebral conjunctiva. The resulting bleb should be sufficient to roll the eyelid out. Occasionally the procedure needs to be repeated in 5 to 7 days. Other, surgical-type methods include pinching a small amount of tissue into two wound clips placed parallel to the lower lid, crushing a fold of skin with hemostats parallel to the lower lid, and cutting a length of skin from below the lower lid and suturing it. With all of these latter methods, care must be taken to apprehend sufficient skin to allow proper eversion of the eyelid. Some evidence indicates that this is a heritable condition, so lambs with entropion should not be selected as replacements, particularly rams.

Diseases Due to *Clostridium* spp.

Tetanus, pulpy kidney, and enterotoxemia are diseases of neonatal lambs that can be easily prevented through a routine vaccination program with a multivalent vaccine. The vaccine should contain immunizing antigens to *Clostridium tetani, Clostridium perfringens* types C and D, *Clostridium septicum, Clostridium novyi* type B, and *Clostridium chauvoei*. Every replacement lamb should receive a primary series after 10 to 12 weeks of age and a booster at least every 12 months. To ensure optimal colostral protection to their lambs, the booster should be administered to pregnant ewes no later than 2 weeks before the first expected lambing date of their breeding group.

Coccidiosis

Clinical and subclinical coccidiosis is a major cause of poor growth in lambs. Management practices that will reduce environmental exposure to coccidial oocysts include use of properly designed feeders that do not allow for fecal contamination of the feed; provision of a clean bedding pack or slatted floors for nursing and growing lambs; and a raised water source. Thorough disinfection before lambing may reduce the level of coccidia in the environment, but adult ewes and then lambs quickly recontaminate the pens. It often is necessary to also use a drug that controls coccidia. Table 91-2 lists the commonly used preventive treatments for coccidiosis. Feed additives should be added to free-choice pelleted or texturized lamb rations to ensure adequate intakes. A prescription often is required for addition of these coccidiostats because of the variability among countries in licensing these drugs for use in sheep. Commercial cattle feeds or supplements with coccidiostats included should not be used because of the high risk of copper toxicity.

Table **91-2**

Drugs Commonly Used to Control Coccidiosis in Lambs

Commercial Name	Active Ingredient	Dose (BW/day)	Mode of Delivery	Comments
Various	Sulfadimidine-sulfamethazine	25–140 mg/kg	In water; 4 days on, 3 off, then repeat	Higher dose is used for treatment (4 days); toxic if treatment is prolonged; lower dose is used for prevention/control (long term)
	Sulfaquinoxaline	13 mg/kg	0.015% solution for 3–5 days	
Amprol*	Amprolium	20 mg/kg	5 days as a drench; 21 days in feed or water	Resistance reported; toxic at higher doses
Rumensin	Monensin	1 mg/kg	11 mg/kg in free-choice–fed or 22 mg/kg in limit-fed animals in complete feed for 6 to 8 weeks	Toxic if mixed incompletely or incorrectly
Bovatec	Lasalocid	1 mg/kg	36 mg/kg in free-choice–fed animals for 6 to 8 weeks	Moderate toxicity
Deccox 6% Premix	Decoquinate	0.5–1.0 mg/kg	1.5 kg of premix/ton of complete feed, or calculate according to known intakes for minimum of 75 days	Not toxic; can be added to mineral premix to prevent disease in pastured weaned lambs
Clinicox 0.5%	Diclazuril	1 mg/kg	Either 1 dose or 2 treatments 14 days apart at 3–4 weeks of age	Disease may occur despite treatment in highly challenging environmental conditions

*Merial, Duluth, GA.
BW, body weight.

Neonatal Diarrhea

Lambs are susceptible to the same infectious agents as those identified for calves. Generally, enteropathogenic *Escherichia coli* causes disease at 2 to 7 days of age. Rotavirus and coronavirus may cause diarrhea from 2 days to 3 weeks of age. Cryptosporidia most often affect lambs after 2 weeks of age. *Salmonella* spp. and *Giardia* are less common causes. If the flock is experiencing high morbidity from neonatal diarrhea during the lambing period, ewes that are still pregnant should be moved to a clean area for lambing. People managing the sick lambs should not handle newborn lambs without changing and washing their clothes in disinfectant soap. Vaccination of pregnant ewes with a bovine *E. coli* scour vaccine has been done, but a preferred approach is first to attempt to break the cycle by focusing on cleaning and disinfection of the lambing and lamb-rearing environments.

Pneumonia

The most common cause of pneumonia in neonatal lambs is *Mannheimia hemolytica*. Most often the strain involved is A2, with A1 being the most common strain in bovine pneumonia. Other agents that may be involved are *Mycoplasma ovipneumoniae* and *Pasteurella trehalosi*. Various viruses may play a role in increasing susceptibility of lambs to these disease agents. Environmental conditions, however, appear to be more important in determining the incidence of pneumonia in young lambs. Stocking density, humidity, diurnal or nocturnal temperature fluctuations, extreme heat and cold, frequency of air changes, ammonia levels, and dust all increase the stress on the respiratory system. In outbreaks of pneumonia, metaphylaxis has been used with success. Drugs that are licensed for use in sheep for pneumonia include short-acting oxytetracycline, tilmicosin (Micotil*), and ceftiofur (Excenel†). Other antimicrobials that may be effective but are not licensed for sheep include long-acting oxytetracycline and florfenicol (Nuflor‡).

Generally, antimicrobial resistance is not a reason for treatment failure. Most often the reason is failure to detect sick animals soon enough or not treating for long enough. It is important to train the client to observe nursing lambs carefully for depression. This should be done outside the pen so as to not arouse the lambs until identified for further clinical examination. Necropsy of dead lambs is a good way to determine the reason for treatment failure. A vaccine against *M. hemolytica* infection in sheep is not available in North America.

CHAPTER 92

Diseases of the Periparturient Ewe

MARIE BULGIN

Excluding the abortion diseases, the problems of the periparturient ewe often are metabolic and related to fetal number, nutrition, and management. With the advent of more prolific and productive sheep, the likelihood that the large animal practitioner will be called on to treat one of these various problems is high. As with many other diseases, the clinically ill animal may represent just the tip of the iceberg, and the challenge to the practitioner is determining whether the illness constitutes an isolated case or reflects a flockwide ailment.

THE "DOWNER" EWE

No doubt the most common problem seen by practitioners during the last trimester of pregnancy is the **"downer" ewe.** Although most owners and many practitioners associate this condition with pregnancy ketosis, a number of other conditions may manifest in the same way and should be ruled out before treatment for ketosis is initiated.

Outside of parturition itself, the last 3 to 4 weeks of the third trimester is the period of highest risk for the ewe as a number of changes occur. It is at this time that the fetus(es) has reached its period of maximal nutritional demand. The ewe's ruminal capacity is compromised as a result of abdominal space required for fetuses and the ewe herself becomes ponderous and unwieldy.

ACIDOSIS

To compensate for the reduced rumen volume, most owners begin the feeding of concentrates to the ewes during the last trimester, but because of disparity in gestation and fetal numbers, intake among the ewes may not be equal. Some owners inadvertently feed too much to begin with or increase the amount too rapidly. Occasionally, ewes escape and find their way to a concentrate source. Rarely, an alternative feed, high in fermentable carbohydrates, such as bread or tacos, may be offered in too great a quantity. The same amount of a cracked, rolled, or ground grain may be substituted for the whole grain, which ferments much more slowly.

Diagnosis

The ewe presents with signs similar to pregnancy ketosis. She will be anorexic, depressed, standing alone, and sometimes ataxic or down and reluctant to rise. Usually the history of being recently started on concentrates or of breaking into the granary will have to be extracted

CHAPTER 92

Diseases of the Periparturient Ewe

MARIE BULGIN

Excluding the abortion diseases, the problems of the periparturient ewe often are metabolic and related to fetal number, nutrition, and management. With the advent of more prolific and productive sheep, the likelihood that the large animal practitioner will be called on to treat one of these various problems is high. As with many other diseases, the clinically ill animal may represent just the tip of the iceberg, and the challenge to the practitioner is determining whether the illness constitutes an isolated case or reflects a flockwide ailment.

THE "DOWNER" EWE

No doubt the most common problem seen by practitioners during the last trimester of pregnancy is the **"downer" ewe.** Although most owners and many practitioners associate this condition with pregnancy ketosis, a number of other conditions may manifest in the same way and should be ruled out before treatment for ketosis is initiated.

Outside of parturition itself, the last 3 to 4 weeks of the third trimester is the period of highest risk for the ewe as a number of changes occur. It is at this time that the fetus(es) has reached its period of maximal nutritional demand. The ewe's ruminal capacity is compromised as a result of abdominal space required for fetuses and the ewe herself becomes ponderous and unwieldy.

ACIDOSIS

To compensate for the reduced rumen volume, most owners begin the feeding of concentrates to the ewes during the last trimester, but because of disparity in gestation and fetal numbers, intake among the ewes may not be equal. Some owners inadvertently feed too much to begin with or increase the amount too rapidly. Occasionally, ewes escape and find their way to a concentrate source. Rarely, an alternative feed, high in fermentable carbohydrates, such as bread or tacos, may be offered in too great a quantity. The same amount of a cracked, rolled, or ground grain may be substituted for the whole grain, which ferments much more slowly.

Diagnosis

The ewe presents with signs similar to pregnancy ketosis. She will be anorexic, depressed, standing alone, and sometimes ataxic or down and reluctant to rise. Usually the history of being recently started on concentrates or of breaking into the granary will have to be extracted

from the owner who generally is not aware of the significance of this information. The rectal temperature will be normal, diarrhea may or may not be present, ruminal sounds are absent and the ewe is depressed. Blood glucose and other blood chemistries will be in the normal range. Blood pH may be low normal to definitely acidotic coinciding with the intensity of the signs. A rumen pH below 5.5 is diagnostic. Rumen contents are usually easily extracted through the body wall of the left lower lumbar fossa, using a 35-cc syringe and 14G 1.5- to 2-inch needle. Rumen contents also can be extracted per os through a stomach tube. The pH is checked using a multicolor indicator pH paper.*

Treatment

Treatment is focused on returning blood and rumen pH to normal (7.4 and 6.5, respectively). Rumen pH varies according to the diet of the ewe. The rumen pH in ewes on forages ranges from 7.0 to 8, whereas that in ewes that have been on diets rich in carbohydrates for any length of time may be as low as 5.5. In a ewe on hay and a small amount of grain, rumen pH should be in the vicinity of 7.0. Intravenous administration of 2 to 4 L of bicarbonate (50 g/gal of water [313 mEq/L]) is in order if the blood pH is below 7.2; otherwise, oral medication usually is adequate. Calf electrolytes with bicarbonate such as Biolyte,† Calf Quencher,‡ Delyte H20K,§ Enterolyte,¶ Resorb,¶ or magnesium hydroxide** should be administered orally. Additional bicarbonate must not be added to electrolyte fluids, because sodium toxicity is likely to occur.

After administration of oral electrolytes, ruminal contents should again be tested for pH and further medication administered if necessary. Mineral oil can be given orally to promote rapid evacuation of the rumen, and an oral antibiotic such as neomycin or tetracycline given to reduce the activity of the fermenting bacteria. Flunixin meglumine†† injections (150–250 mg given intramuscularly) will make the animal more comfortable. Bicarbonate treatment usually has to be repeated in 2 to 4 hours, as determined by the amount of depression and results of another rumen tap.

A rumenotomy to remove the fermenting ruminal contents is the treatment of choice, particularly in severe cases; however, most owners balk at the cost of the surgery.

Prevention

Prevention is focused on starting supplemental concentrate feeding slowly (no more than 1/4 pound per feeding), increasing the amount fed no sooner than every 3 to 4 days and no more than 1/4 pound at a time. Ground, cracked, or rolled grains should not be substituted for whole grain unless the amount is cut by half. About 24 inches of feed bunk space per unshorn adult ewe should be allowed. Ewes close to lambing, which are large and awkward, should be separated from the more mobile and agile ewes so that competition for the concentrates is relatively even and none are able to overeat.

TRAUMA

In cold climates, frozen or muddy ground causes footing to be unstable. When scrambling to reach the feed bunk, aggressive agile ewes may cause other ewes late in pregnancy, heavy with multiple fetuses, to slip and fall. Ruptured round ligaments, fractured pelvises, torn stifle ligaments, and fractured femurs are not uncommon. Obviously, these ewes will be found "down."

In such instances the ewe is bright and alert and will readily eat and drink. Her rectal temperature will be in the normal range. The complete blood count and blood chemistries are normal. A thorough examination of the rear legs, however, often will reveal crepitation or muscle fasciculation in the pelvic or thigh region.

Treatment

Pelvic fractures often heal on their own; however, the healed bone may be somewhat malaligned, causing narrowing of the pelvic opening with the risk of future dystocia. Fractures of the long bones are more difficult to manage. Use of Thomas splints usually is not feasible; the ewe generally is too clumsy and heavy to get up and walk with the device while she is still pregnant. The ewe typically will remain down for the remainder of her pregnancy. After lambing, if the tendons of the front limbs have not become contracted, some ewes become mobile, depending on the location and severity of the trauma.

Most owners will not agree to the expense of x-ray films or surgery. Many, however, are very willing to devote time to nursing care. Providing a place for the ewe unmolested by the rest of the flock, stretching the front legs daily, keeping her well bedded, and turning her once a day to prevent decubitus ulcers are recommended measures.

Prevention is similar to that for acidosis. Enough bunk space and the separation of ewes heavy with multiple fetuses will keep injuries at a minimum.

HYDROPS

Hydrops allantois and hydrops amnion are not unknown in the sheep. Generally, by the time the veterinarian sees the ewe, her abdomen has become so enlarged that the animal can no longer support her weight and becomes a "downer." Hydrops allantois is characterized by more

rapid enlargement of the abdomen than with hydrops amnion and is more likely to cause rupture of the prepubic tendon. Determining which one of the two is the cause of the enlargement is difficult, however, and probably makes little difference in the outcome.

Diagnosis

The most diagnostic sign of hydrops is the huge size of the abdomen. Ballottement performed through the body wall or ultrasound imaging will suggest excessive fluid. Often the ewe is depressed and anorexic, although if the condition has been present for only a short time she may still be alert and eating. Rectal temperature and blood parameters generally are normal.

Treatment

This condition carries a grave prognosis because the increasing size of the abdomen puts pressure on both the rumen and the diaphragm, reducing their capacity. Induction of parturition is in order, although dystocia with ensuing shock, dehydration, and death is not an uncommon outcome. Several injections of dexamethasone (10 mg, 24 hours apart) may have to be administered.

Dystocia occurs because the enlarged uterus tends to be atonic and probably is unable to push the fetus into the birth canal. There may be failure of the cervix to dilate, and the fetus may be hard to reach during attempts to help. The fetus(es) usually is small in size and often premature and born dead. Fetal ascites, anasarca, or maceration also can be observed and, in the bovine, usually is associated with hydrops allantois. Hypovolemic shock is the usual cause of death in the ewe, which dies during or just after parturition. Surviving ewes probably should be culled.

CALCIUM DEFICIENCY

In the bovine, calcium deficiency or milk fever is one of the most common problems of the period just before and after parturition, and low blood calcium is associated with many bovine problems after parturition. The ewe differs in that clinical hypocalcemia is relatively uncommon under normal conditions. When it is seen, however, it usually will be in large outbreaks. Up to 30% of ewes exposed to long-distance transport, experiencing sudden deprivation of food or feed supplying calcium, or grazing on oxalate-containing plants in late pregnancy may experience clinical hypocalcemia.

Because the calcium concentration is low in both grasses and concentrates, subclinical hypocalcemia may be an unrecognized factor in other periparturient problems when grass hay is used as winter feed.

Diagnosis

The clinical signs appear suddenly. Initially the ewe appears agitated or anxious, and tremors may be evident. As the problem progresses, the ewe goes down and may be found with the hind legs extended behind. The head may be stretched out or folded back into the flank as seen in the cow. The animal may be unresponsive and appear comatose. Regurgitation through the nose is not uncommon, and bloat occasionally may be present.

Response to intravenous calcium solutions designed for bovine milk fever is diagnostic but is confirmed by serum calcium determination, which will be below 4.5 mg/dl.

Treatment

Calcium gluconate solutions can be given subcutaneously. Calcium chloride solution, however, may cause skin irritation and occasionally causes sloughs, so intravenous administration is preferable. Calcium paste or gel* (1/5 or less of a tube) can be administered orally to animals that are still ambulatory but is very unpalatable and causes a burning sensation of the mucous membranes. Also, the pastes may not be very effective in animals that are mostly comatose.

Providing alfalfa hay is perhaps the best way to prevent further problems in the remaining nonaffected animals in the flock. Trace mineral-salt mixes with added limestone also can be made available.

PREGNANCY KETOSIS

Also known as pregnancy disease, pregnancy toxemia, and twinning disease, pregnancy ketosis generally is brought on by the competition for glucose between the ewe and her fetuses. This disease is the result of the negative energy balance secondary to an energy intake that is not sufficient to compensate for the increased energy demands of the fetus(es) in the third trimester. Thus, it is seen in multiparous animals on limited-energy diets, late in gestation.

Pathogenesis

The maintenance of adequate concentrations of glucose in the blood is critical to fetal growth, brain function, and milk production. Very little dietary glucose, however, is absorbed in the ruminant, because glucose is efficiently fermented by the ruminal flora. The greater part of ruminant energy needs is met by the short-chain fatty acids, acetate, propionate, and butyrate, produced by the ruminal flora. Blood glucose levels are largely maintained by gluconeogenesis, 85% of which takes place in the liver. Excess glucose is stored in the liver as glycogen, stores of which are small and inadequate for the ruminant's needs in late gestation.

In ruminant gluconeogenesis, the most important glucose precursor is propionate, which is derived from ruminal fermentation of high-carbohydrate-content feeds. Other glucose precursors include endogenous and exogenous amino acids, and glycerol and lactate are utilized to a much lesser degree. Ruminal fermentation of

*CMPK Gel nutritional supplement for dairy cattle, AgriLabs, St. Joseph, MO.

forage produces acetate, which is the precursor of long-chain fatty acids for fat storage.

A negative energy balance, induced by feed deprivation or a sudden demand for energy, results in a decreased ratio of insulin to glucagon, which, together with other hormones, activates lipases that convert tissue fat to free fatty acids (FFAs) and glycerol. This glycerol may be converted to glucose in the liver. The FFAs can be utilized by most body tissues, although the liver removes a large proportion of them. In the liver, the FFAs are used to produce energy (by means of the Krebs cycle) or are converted into ketones (acetone, acetoacetate, and β-hydroxybutyrate). The direction of FFA metabolism is dependent on availability of oxaloacetate. If production of ketones predominates, and levels increase above normal, appetite will be depressed. Thus, a negative energy balance in ruminants with ketonemia and appetite depression will, unless immediately rectified, tend to further reduce feed intake. This complex series of reactions culminates in an irreversible downward cycle known as **ovine pregnancy disease** or **pregnancy toxemia.**

Experimental models of ketoacidemia have shown that systemic hypertension can occur in pregnant ewes after as little as 24 hours of food deprivation.[2,3] Renal dysfunction begins with the onset of hypertension and results in as much as a 51% decrease in glomerular filtration rate. A great deal of variation has been reported in the ease with which the disease can be produced experimentally in sheep, but no apparent breed disposition has been confirmed. The variation apparently is dependent on the metabolic efficiency of the liver.[2] An ineffective gluconeogenic response to the continued preferential demands for glucose predisposes ewes to this disease.

Risk Factors

Pregnancy toxemia can be a primary condition resulting from a combination of a fall in the plane of nutrition during the latter third of pregnancy and a sharp increase in energy needs. It can be precipitated by a short period of fasting associated with crutching, shearing, vaccinating, or transport. Stress of sudden winter storms, shearing during inclement weather, or absence of adequate shelter may be involved as well. Multiparous thin or aged ewes, very fat ewes, and confined ewes in their last trimester are those mostly at risk.

Secondary pregnancy toxemia may occur as a result of any other condition that restricts feed intake or increases energy needs, such as acidosis, water deprivation, hypocalcemia, footrot, pneumonia, heavy worm infestation, or the chronic wasting diseases.

Diagnosis

Early signs include anorexia, separation from the flock, depression, and sometimes blindness similar to that caused by thiamine deficiency. Tremors, chomping of the jaws, presence of foam at the mouth, a strong sweet smell of acetone on the breath, "star gazing," circling, ataxia, hind end weakness, head pressing, and muscle tremors tend to occur a day or two later. Recumbency and occasional convulsions occur within several days, and the ewe becomes profoundly depressed or comatose before dying several days later. Fetal death may occur and sometimes results in a transient recovery. Toxemia caused by the retention of the dead fetus, however, eventually will cause death of the ewe. The clinical course often is shorter in fat ewes. Affected ewes usually have difficulty in lambing, and the lambs may be dead.

Blood chemistry analysis usually, but not always, reveals hypoglycemia (<40 mg/dl), an elevated blood urea nitrogen (BUN) and serum aspartate transaminase (AST), and acidosis. Hypocalcemia also may be present. Results of assays for urinary and blood ketones will be positive, although any ewe with twins close to parturition will test positive for urinary ketones. As the disease progresses, blood glucose and cortisol levels may be elevated (to greater than 70 mg/dl and10 ng/ml, respectively) as a result of fetal death. Dehydration and renal failure may be apparent.

At necropsy, liver is pale, tan in color, and swollen and will float in water. Multiple late-term fetuses will be found.

Treatment

Early intervention may have a favorable result, but in general, response to treatment usually is poor, because the disease becomes irreversible in its later stages. For best results, blood chemistry and electrolyte analyses should be done and the animal treated accordingly.

Traditionally therapy has been targeted at providing an appropriate energy source and reducing the energy drain. Constant-drip 5% intravenous glucose is ideal but may not be practical. An intravenous catheter could be placed and the owner instructed on administration of 25 to 50 g of glucose (50–100 ml of 50% glucose) several times a day. In an attempt to provide oral glucose precursors, many small doses of propylene glycol (10 ml) given every 2 hours over the course of the day is preferable to one or two doses of no more than 30 ml per treatment two or three times a day. A 500-ml bottle of amino acid–vitamin–electrolyte solution* can be given in small doses over a 12-hour period as a drench or added to drinking water. Calf electrolytes for neonatal diarrhea made up according to directions and given orally twice daily for the first day will combat acidosis and dehydration. Some of the glucose in the preparations may even bypass the rumen. An oral calcium supplement or an oral gel may be helpful, because hypocalcemia can be present in some cases, particularly if grass hay has been the major source of feed. Calcium, too, probably will be more beneficial if given in small doses over the day, rather than as one or two larger doses. Sodium propionate can be given if a source can be found. The B vitamins, cyanocobalamin (vitamin B_{12}) and biotin, are particularly indicated as adjuncts to gluconeogenesis, and thiamine (vitamin B_1) may help preserve brain function. Insulin, 25 U of protamine zinc given once daily, may be helpful, as well as vitamin E and selenium (25 mg given intramuscularly).

*Double "A" Solution, Vetco, Inc, St. Joseph, MO.

Ewes suffering from pregnancy toxemia may benefit from dipyridamole,* a thromboxane A_2 inhibitor and vasodilator used in human medicine with aspirin to reduce platelet adhesion.[1] It also produces a dose-related decrease in systemic and coronary vascular resistance, leading to decrease in systemic blood pressure and increase in coronary blood flow in the dog. The onset of action takes about 24 minutes, and the effect persists for about 3 hours.[4]

Removal of the fetuses by means of cesarean section or induction of parturition with corticosteroids has met with some success if done in the early part of the disease. Intramuscular dexamethasone in a dose of 10 to 14 mg usually will initiate parturition within 24 hours. Occasionally, if the duration of the pregnancy is less than 140 days, a second dose will be required.

Prevention

Prevention centers on provision of adequate energy to late-term multiparous ewes. The practitioner should keep in mind that a ewe with a single fetus requires only 260 kcal/day at 140 days of gestation, whereas a ewe with triplets requires 570 kcal/day—a 220% increase.

Heavy, awkward, ponderous ewes should be separated from those due to lamb later and fed separately with plenty of feed bunk room. Generally, identifying these ewes can be done by eye during the last stages of gestation, but ultrasound scanning would allow them to be separated earlier, so that feed to single-parous ewes could be reduced, whereas that to multiparous ewes could be increased. A good-quality fine-stemmed hay should be saved for the latter group, and these ewes also should receive at least $^1/_4$ pound of concentrate per fetus. Forced exercise by enlarging the distance between feed and water could be instituted in some cases.

OTHER PROBLEMS SEEN BEFORE LAMBING

Ringwomb and Early Dilation Syndrome

Ringwomb is a condition of sheep in which the cervix does not dilate during parturition. The specific cause of ringwomb is not known, but a lack of release of hormones involved in softening the collagen of the cervix or a lack of response of the collagen in the cervix to hormonal stimulation may be involved.

Mineral deficiency, malpresentation, premature lambing, presence of dead lambs, and consumption of feedstuffs that contain estrogen have been eliminated as causes of ringwomb. The occurrence of ringwomb has not been correlated with breed of sheep, age, and body condition score; a genetic correlation, however, has been recognized.[5] The occurrence of ringwomb appears to run within bloodlines, and when these bloodlines are inbred, the frequency of ringwomb increases.

Ewes with ringwomb generally do not isolate themselves, have a decreased appetite, or show the other normal signs of first-stage labor. No swelling of the vulva, relaxation of the pelvic ligaments, swelling of the vulva, or dilatation of the cervix is observed. Usually the first indication that something is wrong is the protrusion of fetal membranes from the vagina. If the ewe is left unassisted, the lamb(s) will die from hypoxia, presumably as a result of separation of the placenta. Even after the fetus(es) has died, the ewe will require assistance for delivery of the dead lambs. If no help is forthcoming, autolysis of the fetus will occur, leading to toxemia, septicemia, and death of the ewe. Antibiotics should be administered immediately to ewes found after the fetus(es) has died, to prevent systemic infection.

Early dilation syndrome is similar to but considered to be separate from ringwomb. Assistance is required for lambing because of incomplete dilation of the cervix approximately 1 to 2 weeks before term. If the ewe is left unassisted during lambing, she may be found dead as a result of uterine prolapse or uterine tears with evisceration. These ewes typically present with placental membranes protruding from the vagina and little or no udder development. As with ringwomb, no correlation has been detected with breed, nutrition, or toxicology.

Treatment

Treatment for ewes that are suspected of having ringwomb and in which the lambs are still alive is a cesarean section. This usually will result in the delivery of healthy live lambs. Because the condition appears to be genetic, lambs should not be kept for breeding stock. The ewe probably should be culled, even though such ewes usually are not affected by ringwomb during consecutive seasons.

Manual dilatation of the cervix with removal of the lambs is another option and often the one resorted to by the producer. Calcium administration and oxytocin usually have not been helpful, although they can be tried. Working one and then two fingers, and so on, through the cervix will eventually allow the practitioner to get a hand though the cervix. This takes time and patience, because the cervix can tear and the practitioner may suddenly find the hand in the abdomen. Once the lamb is grasped and delivered to the now half-open cervix, the pressure on the inside seems to aid in its final opening, and the lamb can be removed. Common sequelae to these two conditions are retained membranes, uterine infection, and cervical scaring.

Prolapse of the Vagina

Risk factors for prolapse of the vagina include overweight, multiple fetuses, and high-fiber diets. In addition, coughing, straining and genetic predisposition all can contribute to vaginal prolapse in the pregnant ewe.

Diagnosis is confirmed by presence of the unmistakable red, round ball of variable size protruding from the vagina of the ewe.

Treatment ranges from suturing the vulva closed to using a "prolapse harness" or prolapse paddle to keep the

*Persantine, Boehringer Ingelheim Pharmaceuticals, Inc., Ridgefield, CT.

vagina inside the vulva. All of these various techniques are effective if straining or coughing is not involved in the problem.

If the problem is merely ruminal overfill, and the ewe is not straining, then reducing space-occupying fiber in the diet and replacing it with more energy-dense foodstuffs constitute appropriate management. High-carbohydrate feed must be increased slowly to prevent acidosis. Higher-quality hay can safely replace poorer-quality hay and may help the situation considerably. Removal of dusty feed and antibiotic treatment or treating for lungworms may help to reduce coughing.

A caudal epidural block using a 21- or 20-gauge $1^1/_2$-inch needle and 4 mg of Xylazine (0.2 ml of 20 mg/ml solution) plus 2 ml of 2% lidocaine works well for placing sutures in the vulva. After 10 minutes, a purse-string or several horizontal mattress sutures using umbilical tape can be placed to secure the prolapsed vagina inside the vulva. The sutures must be placed close to the wool, where the skin is strongest; alternatively, stents or buttons must be used to keep the suture from cutting through the tender skin around the vulva. The ewe must be monitored closely for labor, at which time the purse-string suture is cut to allow delivery of the lamb(s).

If straining is the main cause of the prolapse, its control is necessary for the successful management of the prolapse. Coccidia have been implicated in some cases of straining, in which instance treatment with sulfa drugs has been helpful. In most cases, however, the cause of the straining forever remains a mystery. If intramuscular flunixin meglumine injections (150–250 mg) and an initial lidocaine epidural block are not successful, alcohol epidural blocks using equal volumes of 2% lidocaine and 70% isopropyl or ethyl alcohol occasionally are performed as a last resort. The volume of lidocaine-alcohol to use is determined by the response to a previous injection of lidocaine only. The duration and degree of response to the alcohol epidural block are variable. The sequelae to an alcohol epidural may include permanent paralysis of the tail and incontinence. Overdosage can result in permanent paralysis.

When the control of straining is not very successful, another method that may help is the Minchev technique, whereby the dorsal vagina is sutured in place by passing a ligature through the dorsal vaginal wall to the outside of the gluteal area, lateral to the second or third sacral vertebra. Both sides of the anterior dorsal vagina are anchored using umbilical tape or other heavy suture material. Buttons are fastened to both the skin and the vaginal ends of the suture, to prevent the suture from cutting through. This method usually secures the vagina despite constant straining, and because the vaginal opening is not restricted, the ewe can lamb without constant observation. Usually enough adhesions are formed to keep the vagina in place even after the sutures are removed.

Because this condition usually recurs and probably has a strong genetic component, prevention requires that these animals and others of the same bloodline be culled. Close monitoring of the body condition score of the ewes in the flock and preventing them from becoming overweight also will help. This is particularly important for ewes that have not lambed previously.

CHAPTER 93

Reproductive Health Management Programs

PAULA I. MENZIES

Throughout North America, many systems are used for managing sheep, from the traditional annual spring lambing with fall marketing of lambs off pasture, to managing several lambing groups per year, to marketing lambs year round. The basic principles for a reproductive health management program remain the same but need to be fine-tuned with each producer's limitations and goals in mind.

FACTORS TO CONSIDER IN DESIGNING A PROGRAM

- Types of products to be marketed
  - Meat (light lamb, heavy lamb, mutton)
  - Wool (fine wool, specialty spinner's wool)
  - Milk (length of lactation, seasonal production versus year-round production of milk)
- Purebred breeding stock
- Type of markets
- Specific local market (e.g., Easter "new crop" lambs)
- Processing plant's time constraints on cheese production
- Cash flow requirement (may dictate year-round production)
- Forward contracting constraints from regional abattoirs
- Seasonality of markets
- Relationship between lambing and marketing—how old are lambs when they reach market weight?
- Frequency of lambing
- Nutritional/housing/pasture constraints on lambing
  - Producer motivation and skills
  - Capable of managing a complicated management scheme
  - "Weekend" farmer interested in lifestyle farming

TYPES OF REPRODUCTIVE MANAGEMENT SYSTEMS

- Annual lambing in season (Fig. 93-1)
- Spring grass
- Early spring or late winter confinement lambing
- Annual lambing out-of-season
- Fall lambing
- Frequent or accelerating lambing
- Three lambings in 2 years (Fig. 93-2)
- Cornell Star (five lambings in 3 years) (Fig. 93-3)

SETTING GOALS AND MONITORING PRODUCTIVITY

The flock health cycle is composed of the following components:

- Monitoring on-farm productivity
- Goal setting
- Implementing strategies to achieve those goals
- Monitoring the response to the strategies and the effect of outside factors on flock productivity
- Setting goals again

It is a continuous process for which the backbone is monitoring and goal setting.

Guides for Goal Setting

- Regional production averages
- Breed production averages
- Best expected productivity for specific management system and breed
- Producer's past performance and analysis of limitations on productivity

Record-Keeping Systems

Monitoring requires a functional record-keeping system and the ability to easily turn the data into information useful in the monitoring and management of productivity and health. Examples of common sheep record-keeping systems include head counts at specific intervals (e.g., number at breeding, number of ewes lambing, number of lambs weaned or marked), lambing diaries, individual animal paper records, and computerized on-farm sheep management systems.

An ideal sheep record-keeping system should have the following characteristics:

- Flexible and powerful enough to suit the multitude of diverse management systems
- Easy to use
- Efficient, requiring only a few minutes a day to update
- Streamlined, minimizing the number of places the data need to be recorded
- Designed to produce usable action lists (e.g., ewes ready to lamb, lambs to be weighed, culling lists,

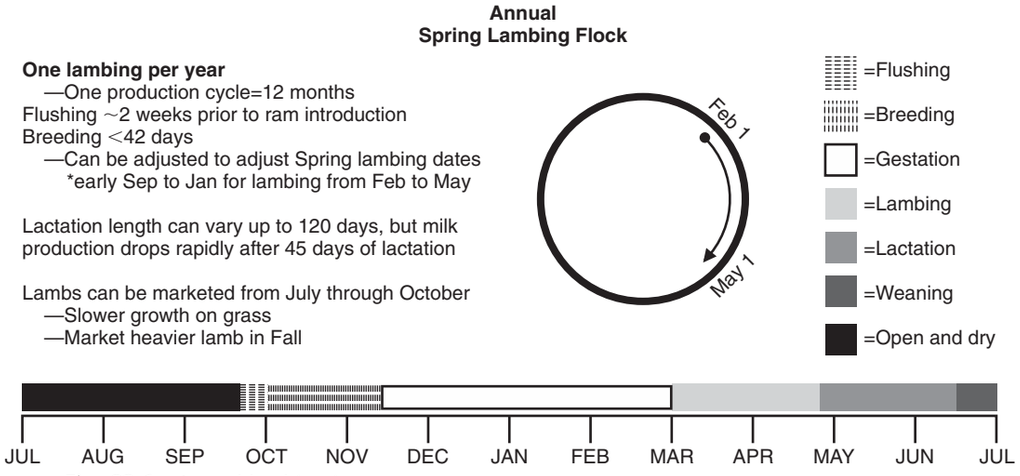

Fig. 93-1 Annual lambing in season.

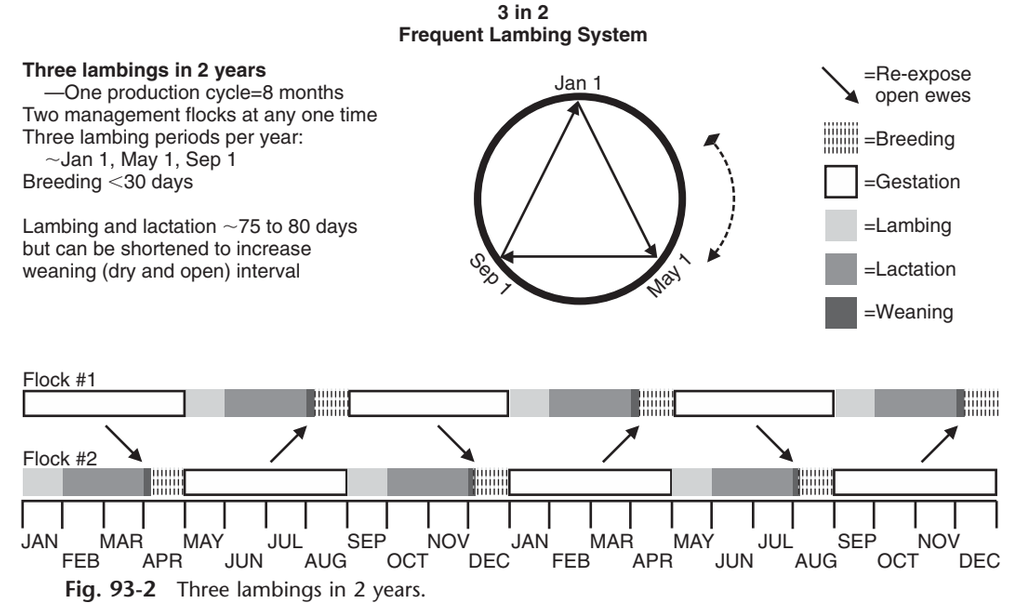

Fig. 93-2 Three lambings in 2 years.

animals to be vaccinated) that can be used in the barn, by the chute, or at the weigh scale
- Capable of monitoring reproduction, health and production performance and producing usable and meaningful analysis reports
- Compatible with regional, breed organization, or national production and health improvement schemes

It is unlikely with a flock size greater than 60 ewes that action lists and analysis reports can be produced easily and in a timely manner with any paper system. If individual animal records are to be kept, then it is necessary for the progressive producer to move to a computerized management system.

Information to Be Recorded

- Accurate numbers of animals at breeding, lambing, and weaning. Each ewe should be uniquely identified, and data pertaining to its performance are recorded at breeding, lambing, and weaning, as well as lamb or ewe morbidity, mortality, and culling
- Unique identification can be in the form of ear tags, tattoos, computer chips, or temporary paint branding
- Ram in and ram out dates, artificial insemination dates
- Ewes marked by ram marker harness during breeding. Color of marker can be changed every 14 days to record rebreedings

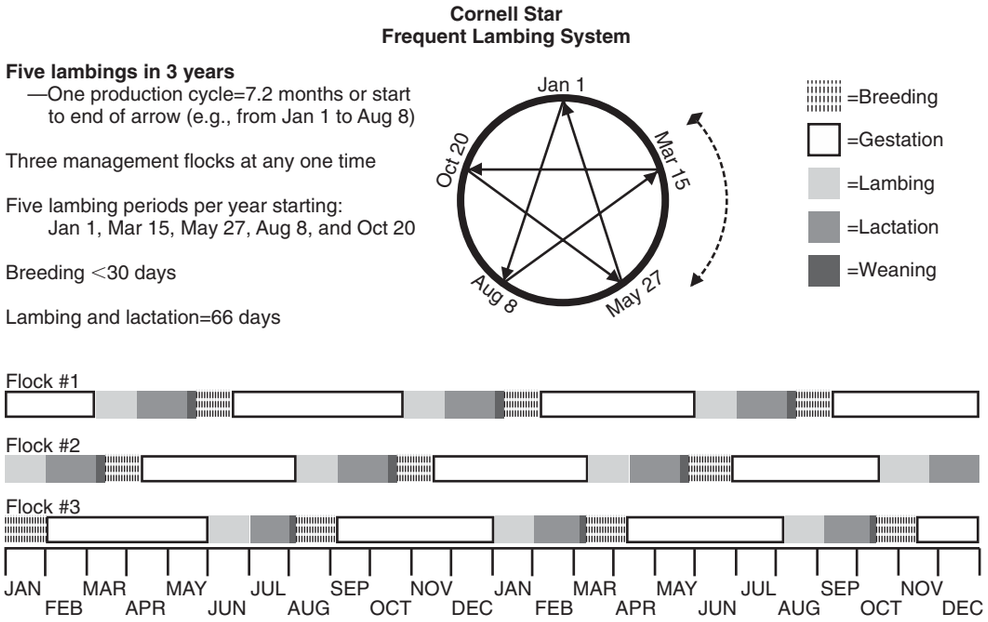

Fig. 93-3 The Cornell Star: Five lambings in 3 years.

- Observed abortions with diagnosis if available
- Lambing diary: ewe ID, lamb IDs, sex, status at birth (live/stillborn), assisted lambings, periparturient disease (e.g., pregnancy toxemia, vaginal prolapse, ring womb)
- Body condition score (BCS) at different stages of production
- Outcome of lamb rearing: died (age and diagnosis), marketed, or retained, or sold as breeding stock
- Fostered, artificial reared, supplemented on ewe
- Weaning weights (or weights recorded at other times if on national or regional record of performance [ROP] program)
- Prophylactic or preventive flock level treatments (e.g., anthelmintic dosing, vaccinations, hormones) and individual animal treatments
- Removals from the flock: involuntary culling including death, euthanasia, culling due to disease, and voluntary culling

MEASURES USED IN REPRODUCTIVE MANAGEMENT

Body Condition Score

BCS is a subjective evaluation of muscle development and fat cover and is a management tool rather than an outcome measure of productivity. Routine scoring of ewes and rams helps the producer make nutritional management decisions. If BCS is used correctly, many nutritional mistakes can be corrected before problems begin. See Figure 93-4 for an overview of a commonly used sheep scoring system. Sheep need to be handled in order to be accurately scored because of wool cover and because of breed differences in muscling and fat deposition. A maternal trait/dairy-type ewe (e.g., Finnish Landrace, Rideau, Romanov) will not carry the lumbar muscling of a meat trait breed (e.g., Suffolk, Texel) and may carry more internal fat. Practice and understanding of breed differences will allow a producer to accurately score both types. Ideally, one operator should perform all the scoring, because correlation between different scorers was poor, but with high intraobserver repeatability, in a 1998 study by Calavas and associates (see Bibliographic References at the end of the chapter). The sheep should be palpated over the spinous and transverse processes of the lumbar vertebrae, ribs, and shoulder and the muscles of the "twist" (hind legs and rump). This can be best done in a sheep race, with a drafting gate at the end to separate off the thin animals for special feeding. Goals for BCS and nutritional demands at the different stages of the production cycle are profiled in Figure 93-5.

Ram-to-Ewe Ratio

Factors used to determine the appropriate number of fertile breeding rams for the number of ewes include the age and experience of the ram (e.g., experienced versus maiden ram), ovulatory versus nonovulatory season, terrain (hill versus paddock), estrus synchronization in the ewe flock, length of ovulatory season of breeds being used, and fertility of those breeds during the nonovulatory season. Recommended ratios for common production situations are presented in Box 93-1.

Length of the Breeding and Lambing Period

The length of the breeding period—that is, period of exposure to the ram—will equal the length of the lambing season plus or minus approximately 3 days. Short, intense lambing seasons are useful for concentrating labor requirements, making more uniform feeding

SCORE 1
The sheep is thin and unthrifty with severe muscle wasting. The eye is sunken. The entire skeleton is easily palpated and sharp. The spinous processes of the lumbar vertebrae are prominent and when the sheep moves, the wool will part over the spine. All four fingers can easily press under the transverse processes and may lift the sheep from the ground in some cases. The sheep lacks energy and may lag behind the flock.

SCORE 2
The sheep appears thin yet strong. There is no muscle wasting but the entire skeleton is easily palpated. The transverse and spinous processes are slightly rounded but are still easy to discern. The eye is not sunken. Wool cover may mask the thin condition. The sheep will keep up with the flock but lacks sufficient reserves to withstand a prolonged period of underfeeding. Productive ewes may drop to this score after a heavy lactation.

SCORE 3
The sheep is thrifty with good muscle and some fat cover. The pelvis is still prominent but smooth. Boney prominences can be palpated with mild pressure but are smooth to the touch. A shorn sheep will have a smooth and healthy appearance. A productive ewe should be at this score before lambing and breeding.

SCORE 4
The shorn sheep appears bulky, particularly in the brisket area. The bony prominences cannot be felt easily except with pronounced pressure. The perineal and tail head area appear rounded. Breeding rams may reach this score before breeding. This is too heavy for a productive ewe.

SCORE 5
It is difficult for a productive sheep to achieve this score. Ewes that have been open for more than a year and have remained with productive ewes may get this fat. No skeletal features can be palpated on the body. The ridge along the spine actually dips in the center. The sheep has decreased exercise tolerance.

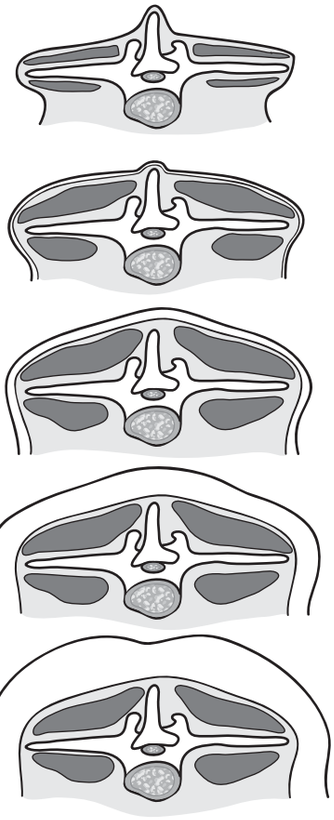

Fig. 93-4 Commonly used body condition scoring system for sheep.

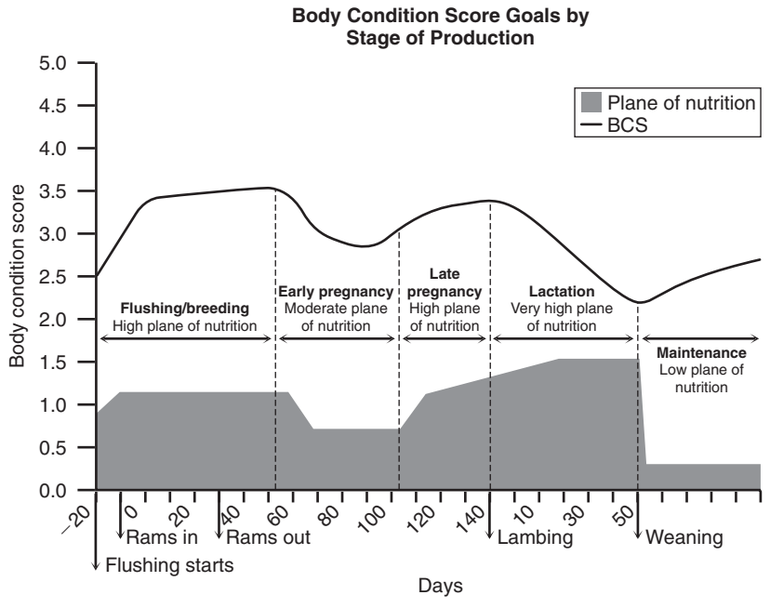

Fig. 93-5 Goals for body condition scores at different stages of production. (From *Body condition scoring of sheep.* Ontario Ministry of Agriculture and Food Factsheet, May 1985.)

practices, and improving lamb survival. In season, the normal duration of estrus in sheep is 17 days. So a 42-day breeding period is sufficient to achieve excellent conception rates in cycling ewes exposed to capable rams.

The practice of synchronization of estrus commonly is used to induce estrus during the transition period (3 to 6 weeks before the ovulatory breeding season), as well as out of season. Synchronization also can be used during the ovulatory season to shorten the breeding period even more. Figure 93-6 summarizes how the different methods of estrus synchronization can result in a tighter lambing period. If ewes are synchronized with sponges or prostaglandins in season, the breeding season will be 48 hours, optionally followed 10 to 12 days later with a clean-up ram for 6 days to catch repeating ewes. Out-of-season, synchronized ewes will have a breeding season of 48 hours.

Box **93-1**

Recommended Ram-to-Ewe Ratios

Mature ram in breeding paddock	1:40 ewes
Yearling ram in breeding paddock	1:25 ewes
Mature ram with maiden ewes	1:30 ewes
Mature ram on rough or barren terrain	1:30 ewes
Mature ram in flock synchronized with ram effect (transition)	1:20 to 1:25 ewes
Teaser ram used to synchronize flock (transition)	1:40 ewes
Mature ram in synchronized flock in season	1:15 to 1:20 ewes
Clean-up ram after synchronization (second cycle) in season	1:30 ewes
Mature ram in synchronized out-of-season flock	1:6 to 1:10 ewes

With some highly fertile rams on range conditions, ratios of up 1:80 to 1:100 have been used with success.

MEASURES OF PERFORMANCE: CALCULATION, INTERPRETATION, AND GOALS

Calculating Measures of Performance

Flock productivity is measured by calculating either ratios, proportions, or rates. A **ratio** compares measures that do not share any animals (e.g., ram-to-ewe ratio). For both **proportions** and **rates**, the **numerator** is the number of sheep that are affected (e.g., lambed, culled, died, treated) and the **denominator** is the number of sheep that are at risk of being affected (e.g., to lamb, the ewe must have been exposed to the ram). A rate also requires a specified time period (e.g., day, month, year, breeding season, birth to weaning) during which the animals were at risk. For example, *culling rate* is the proportion of sheep that were culled in 1 year (as defined in *Herd Health: Food Animal Production Medicine,* edited by O.M. Radostits, p. 53; see Bibliographic References).

Reproductive Measures of Performance

The following parameters measure different aspects of reproductive performance. Not all measures should be used in any one flock. A variety are presented here because it is important that parameters be clearly defined, as well as the method of calculation. The language of measuring reproductive performance in sheep is variable and not as well defined as with dairy, beef, and swine performance (as discussed in *Herd Health,* p 107).

The goals reported here will vary greatly depending on the management system and breeds used but are appropriate for most North American conditions. A schematic of these parameters is presented in Figure

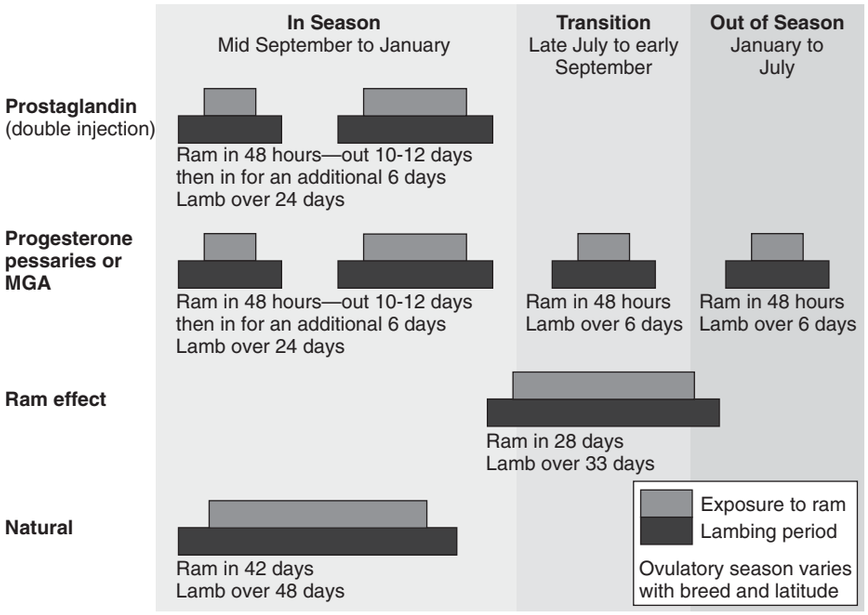

Fig. 93-6 Effect of estrus synchronization on length of lambing period. (Data from Henderson DC [ed]: *The veterinary book for sheep farmers.* Ipswich, UK: Farming Press Books, 1990, p 118.)

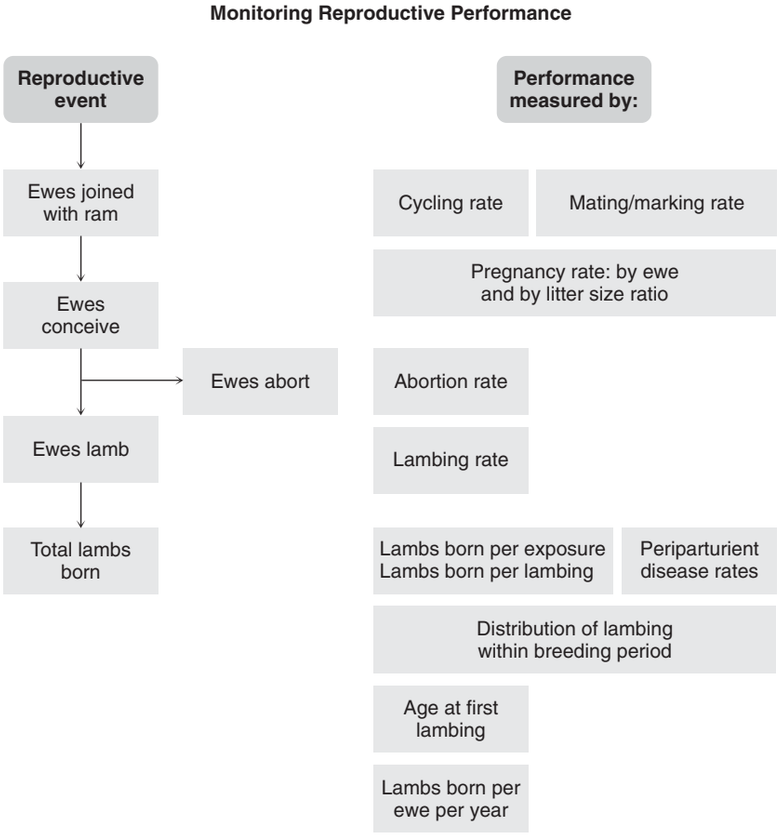

Fig. 93-7 Schematic of parameters used to measure reproductive performance.

93-7. Possible causes of reproductive failure are summarized in Box 93-2. Data from a 1996 survey conducted by the U.S. Department of Agriculture (USDA) (see Bibliographic References) are included where relevant. Table 93-1 summarizes data from Ontario flocks in the Sheep Flock Improvement Program and is useful for comparison with the USDA data.

1. **Distribution of lambing within the lambing period:** GOAL: For breeding during the ovulatory season, or if the ram effect is used during the transition period breeding, the ewe probably will have more than one opportunity to conceive. Approximately 75% of ewes should conceive to the first opportunity, 20% to the second opportunity, and less than 5% to the third. This is represented schematically in Figure 93-8.
2. **Cycling rate:** The percentage of ewes mated or marked by the ram during the first 14 days of the breeding period. GOAL: 70% of ewes in season. This is a measure of the serving capacity of the rams and how well the ewes are cycling. Failure of rams to mark the ewes with a marking harness may indicate problems with one or both groups.
3. **Mating rate:** The percentage of ewes mated or marked by the ram during the breeding period. GOAL: In season, a goal of 95% or greater is appropriate for mature ewes. Out of season, 70% is an achievable goal. The proportion for ewe lambs may be lower than this if they are 7 to 9 months of age and much lower if they are expected to breed at 7 months of age during the anovulatory season.
4. **Pregnancy rate:** The percentage of ewes exposed to the ram that are pregnant at pregnancy check per breeding period. GOALS: Mature ewes over two to three estrous cycles: greater than 95%; ewe lambs bred during the first year of life: greater than 75%; synchronized ewes in season, one breeding: greater than 70%; synchronized ewes out of season, one breeding: greater than 50%. Also termed **conception rate.**
5. **Abortion rate:** The percentage of ewes that have visible abortions before day 142 of gestation of ewes exposed to the ram, or pregnant at pregnancy check, per breeding period. GOAL: Visible abortion level should be less than 2%. Abortion rates of 5% to 7% may indicate enzootic disease. Some reabsorbed fetuses, early embryonic death, or missed abortions may be classified as conception failure in the ewe. The 1996 USDA survey indicates a mean abortion rate of 1.8% (±0.1).
6. **Lambing rate:** The percentage of ewes that lamb of those exposed to the ram per breeding period. GOAL:Mature ewes: greater than 90%; ewe lambs younger than 15 months of age at lambing: greater than 75%. This is a measure of fertility. Some producers and veterinarians use this term

Box **93-2**

Causes of Reproductive Failure in Sheep

Ram Failure

Failure to mate

Crayon failure
- Harness does not fit properly
- Wrong type of crayon

Lack of libido
- Disease
- Low BCS
- Photoperiodic effect

Reluctance to breed
- Infectious balanoposthitis ("pizzle rot")
- Contagious ecthyma of the penis or prepuce
- Lame (footrot, poor conformation)

Experience/age of male
- Too young or too old

Ram-to-ewe ratio
- Too few rams for season, terrain, breed, synchronization, age

Behavior
- Inter-ram aggression
- Ram bias against specific ewes
- Shy ram lamb

Failure to achieve pregnancy

May present as
- Returns to service
- Spread-out lambing period
- Late start to lambing
- Poor prolificacy in the ewes

Additional factors

Impaired fertility due to disease
- *Brucella ovis*
- *Histophilus ovis*
- *Actinobacillis seminis*
- Chorioptic mange of the scrotum
- Infertility after a fever

Impaired fertility due to injury
- Excessive heat
- Excessive cold
- Inguinal hernia
- Hematoma of scrotal sac

Impaired fertility due to environmental hormone disrupters (e.g., phytoestrogens or other toxins)

Testicular circumference too small because of age, season, genetics, disease

Abnormality of the penis due to congenital defect (anatomic) or trauma

Sperm abnormalities

Ewe Failure

Failure to be mated

Pregnancy

Anovulatory season
- May be more pronounced in ewe lambs

Prepubertal (age, breed, nutrition, time of year)

Failure of the synchronization program
- Improper feeding of MGA
- Pessary fallout
- Insufficient eCG dose or failure to give eCG
- Prostaglandins in anovulatory season

Environmental hormone disruptors
- Some clovers
- Toxins

Nutritional
- Thin or very fat

Lactation or recent weaning

Behavior
- Dominant ewe preoccupies ram
- Shy maiden ewes

Long tails physically impede breeding

Pseudohermaphrodite or intersex or freemartin

Failure to conceive or maintain pregnancy

May present as repeated marking if more than one opportunity to breed is provided

Problems with synchronization program
- Rams joined too early with ewes
- Too low a dose of eCG

Previous damage to reproductive tract

Early embryonic death from various causes
- Selenium deficiency
- Specific abortion diseases (border disease, chlamydiosis, toxoplasmosis)
- Vaginitis due to poor pessary hygiene
- Stress, e.g., run by predators, shipping
- Heat shock in early pregnancy
- High-level soluble protein in forage leading to high urea nitrogen levels in blood/tissues

Poor prolificacy

Insufficient energy at breeding (flushing, BCS)

Immaturity or old age

Seasonality

Insufficient dose of eCG

Genetics or breed of female

Any of above causes of early embryonic death

Severe nutritional deficiency after breeding

Also check for sufficiency of ram power

BCS, body condition score; eCG, equine chorionic gonadotropin; MGA, megestrol acetate.

incorrectly to state the number of lambs born to those ewes lambing. It is important that this term be clearly defined, similar to the cow-calf calving rate, to avoid misinterpretation.

7. **Lambs born per ewe:** This can be calculated in any of several different ways, each one giving a slightly different view of reproductive success. All lambs born at term should be included in the numerator, including stillbirths.

   Lambs born per ewe by breeding group: A *breeding group* is defined as a group of ewes managed similarly (e.g., same synchronization program, same breeding paddock) exposed (joined) to a ram(s) over a defined period—that

Table **93-1**

Summary of Annual Flock Productivity: Ontario, 1998–2000*

	YEAR		
Flock Characteristic	**1998**	**1999**	**2000**
Producers†	130	133	115
Breeding ewes	8,694	9,064	8,699
Lambings	9,717	10,296	9,730
Lambing interval (days)‡	354	333	330
Lambs born/lambing§	1.8	1.9	1.9
Ratio of singles-twins-triplets-quadruplets (%)	20.1:51.9:21.4:6.7	18.8:50.1:23.1:8.0	19.1:48.6:23.9:8.4

Average 50-day adjusted weight (kg)¶	23.7	24.0	23.7
Average adjusted daily gain to 100 days (kg)¶	0.32	0.32	0.32

*Flocks enrolled in the Ontario Sheep Flock Improvement Program, as reported by the Ontario Ministry of Agriculture and Food, Guelph, Ontario, Canada.
†Twenty-eight breeds of sheep are represented by these data. The most common breeds are Polled Dorset, Rideau, Suffolk, and cross-bred.
‡The lambing interval of less than 365 days reflects the presence of flocks on accelerated lambing systems.
§All statistics are calculated by lambing, not by exposure or by year.
¶Lamb mortality rate by age is reported only if lamb losses were coded by the producer. Calculated lamb mortality rate was derived using the formula [(lambs born per ewe – lambs weaned per ewe)/(lambs born per ewe)] ×100% and probably is a better reflection of true lamb mortality rates.
¶Weights are adjusted by parity of the ewe (5 years), sex of the lamb (ram lamb), litter size (single), and age of the lamb (to 50 or 100 days of age).

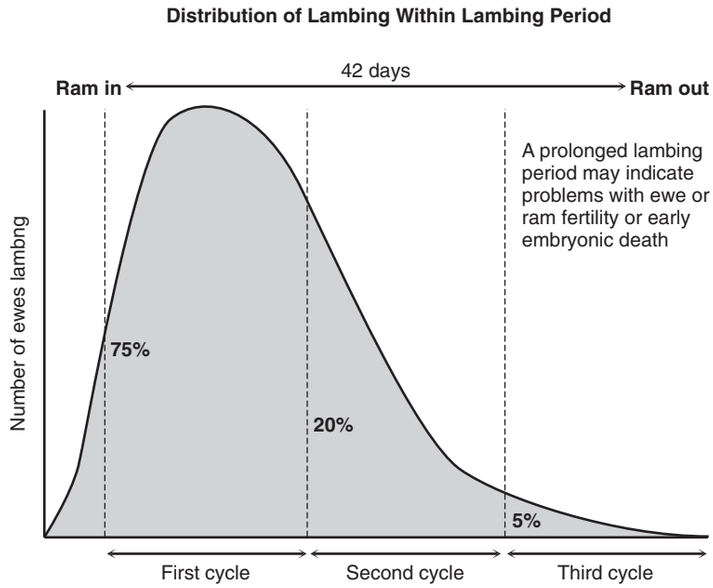

Fig. 93-8 Distribution of lambing within the lambing period.

is, with specific "ram in" and "ram out" dates. These can be expressed as a proportion (in decimal fraction form) or as a percentage (the proportion ×100%).

Number of lambs born per ewe lambing: This calculation is a measure not of fertility but of prolificacy. It often is termed **drop rate**, **litter size**, and (incorrectly) "lambing rate." It is one of the most often quoted measures of reproductive performance but can give a biased view of reproductive success because it ignores those ewes that did not conceive. GOALS: Range flocks: 1.3 to 1.6; prolific meat breeds under intensive management: 2.0 to 2.2.

Number of lambs born per ewe exposed to ram (reproductive rate): This calculation includes all ewes exposed to the ram in the denominator and therefore is a total measure of fertility, fecundity, and ability to maintain pregnancy in that breeding group. It sometimes is termed **reproductive**

rate because it reflects total reproductive performance for that breeding period. Producers should use this calculation as a critical assessment of the flock's or breeding group's reproductive performance. GOALS: Range flocks on rough terrain: 1.2 to 1.5; prolific meat breeds under intensive management: 1.8 to 2.2.

Number of lambs born alive per ewe exposed to the ram: This number subtracts stillborn lambs, which often are lost as a result of poor lambing management. GOALS: The 1996 USDA study indicates that of flocks surveyed, the mean number of lambs born alive was 1.213 (±0.012), with the highest numbers reported in flocks of less than 50 ewes (1.38 ± 0.014) and the lowest in flocks of more than 1000 ewes (1.08 ± 0.021). Producers may be tempted to count only those lambs born alive, but if stillborn lambs are ignored, this may give a biased view of reproductive success.

Distribution of litter size

Ratio of single births to twin births to triplet-plus births: Instead of calculating lambs born per ewe, some producers prefer to examine prolificacy by comparing the ratio of litter sizes. This measure of prolificacy can be calculated at lambing or, if available by real-time ultrasound using a sector scanner for fetal counting. GOAL: Optimizing the number of twins often is preferred, so that a reasonable goal for a moderately prolific flock might be 15%: 60%:15%, which would give a value of lambs born per ewe lambing of 1.8.

Lambs born per ewe by year: Although most flocks lamb only annually, many producers have switched to an accelerated (frequent) lambing system, with three lambings in 2 years being the most popular of these. It is important to analyze productivity by breeding group to ascertain problems with specific seasons, synchronization programs, or breeds, but producers also may opt to analyze the flock's reproductive performance by year in order to assess the overall performance of the accelerated lambing program. Total productivity by year should be significantly superior to annual lambing, although fertility may be somewhat sacrificed within breeding group, particularly outside of the ovulatory season.

Number of lambs born per ewe per year: Generally the denominator is all ewes that at any time during the year were part of the breeding flock (i.e., exposed to the ram), regardless of whether the exposure resulted in a pregnancy or whether the ewe was culled before the end of the year. Each ewe, however, is included only once in the denominator, even if she was exposed to the ram more than once. It is possible in some accelerated lambing systems for this statistic to be greater than 3 lambs born/ewe/year.

Number of lambs born per exposure per year: This is seldom calculated and is of use only in some accelerated lambing flocks. It would include all exposures and give limited additional information on the overall fertility and fecundity of the flock. Analysis by breeding group usually is of greater value.

Lifetime lamb production

Reproductive index: The total lifetime lamb production/(age of the ewe [years] – 1). This index includes all years in which a ewe was exposed to the ram for breeding, regardless of whether she lambed or not, and may be useful for indexing ewes within a flock, particularly with accelerated lambing systems (as reported by Burfening and colleagues in their 1993 article cited in the Bibliographic References).

8. **Periparturient disease measures:** Although not specifically related to reproduction, certain events, conditions, and diseases can cause greatly reduced productivity as a result of associated increases in ewe mortality rate and stillbirths.

Assisted lambings: The need for assistance in lambing will vary depending on the management conditions, but for an intensively managed prolific flock, less than 20% of lambings should be assisted, and for extensively managed, less prolific flocks, this level could be as low as 5%. Cesarean sections should be rare.

Vaginal prolapse: Preterm vaginal prolapse should be no more than 3% of the pregnant ewe flock. Higher levels should trigger an investigation of potential risk factors.

Pregnancy toxemia: Clinical pregnancy toxemia should occur in no more than 2% of pregnant ewes. Higher levels should trigger an investigation of β-hydroxybutyrate levels so that the nutritional status of the flock can be determined. In the 1996 USDA survey, 31.4% of producers surveyed felt moderate or high concern for this condition in their flock, and 19.2% reported that it was known to be present in their flocks within the previous 5 years. It was ranked 7th highest of 39 diseases listed.

Other diseases: The following diseases may occur sporadically or at significantly elevated levels:

- Ring womb, or failure of cervical dilation
- Premature cervical dilation, which may be associated with abortion diseases
- Hypocalcemia, which generally occurs 2 weeks ante partum
- Uterine inertia, which may be nutritional in origin

9. **Average age at first lambing:** The average age (in months) that ewe lamb's first lamb. GOALS: For meat breeds raised under intensive management, the goal

for breeding is 7 to 9 months of age so that ewe lambs first lamb at 12 to 15 months of age. Weight also is a consideration and varies with breed, but the ewe lamb should attain 70% of her mature weight at breeding, with a BCS of 3.0 to 3.5. Ewe lambs on extensive range conditions tend to be slower-maturing breeds (e.g., fine wool breed such as Merino or Rambouillet) and often are not exposed to the ram until the following year, to lamb at 2 years of age. This is not recommended for intensively reared ewe lambs for economic and ewe performance reasons. Age at first breeding will reflect voluntary management decisions to expose the ewe lambs to a ram. Age at first lambing also will reflect the breeding success of that exposure.

10. **Lambing interval:** The average days between lambings for the flock. GOAL: For once/year lambing flocks: 380 days; for flocks on accelerated lambing programs such as the "three in two," lambing interval should be closer to 260 to 280 days. This is a very historical measure of reproductive performance that is inherently biased because it includes only ewes with two lambings and does not include ewes that are culled as a result of poor reproductive performance or ewe lambs that fail to conceive.
11. **Lamb crops/ewe/year:** The number of lambings in a calendar year divided by the total number of ewes exposed to the ram during that year. GOALS: For once-a-year lambing flocks, 0.90 to 0.95; for accelerated lambing systems, 1.2 ("three in two") and 1.5 (the Cornell Star). This measure is useful only for sheep enterprises practicing accelerated lambing. All ewes that were exposed to the ram (i.e., at risk of lambing) should be included in the denominator, but only once.

Nonreproductive Measures of Performance

1. **Stillbirth rate:** The percentage of lambs found stillborn of the total number of lambs born per lambing period. GOALS: An appropriate goal would be less than 2% for less prolific flocks and less than 5% for highly prolific flocks. A stillborn lamb usually is one that is never identified as being alive at birth. In fact, the lamb may have lived for a short time, but death within 5 hours of birth is caused almost exclusively by parturient factors. Factors affecting stillbirth rate include dystocia (related to maternofetal disproportion, malpresentation, ringwomb, assistance), low lamb birth weight (less than 3 kg), intensity of observation of lambing, and exposure to abortion agents. Death after 5 hours may be related to environment or mismothering and therefore should not be counted as a stillbirth. The 1996 USDA survey reports stillbirth rate as a proportion of lambs born/ewe exposed to the ram. The value reported is 4% (±0.1%), for a ratio of 0.04 lamb born dead to 1.213 lambs born alive, or 3.3% of all lambs born.
2. **Preweaning mortality rate:** The percentage of lambs dying before weaning out of the total number of lambs born alive (or alive at 24 hours of age). GOAL: An appropriate goal for the total time period, as defined, would be less than 5%. Weaning occurs at various times depending on the management but usually occurs at 50 to 70 days of age. Many investigators studying perinatal lamb mortality (from birth to 7 days of age) prefer breaking the neonatal period into several time periods, such as less than 5 hours, 5 to 48 hours, 2 to 7 days, 7 to 30 days, and 30 days to weaning. Age at death is helpful in trying to determine the management factors involved in the increased mortality. The 1996 USDA study reports a preweaning lamb mortality rate of 9.4% (±0.3%).
3. **Lambs weaned per ewe:** As with lambs born per ewe, this parameter can be calculated by ewe exposed to the ram, by ewe lambing, and by year. This statistic is more valuable for economic calculations (i.e., the number of lambs available for sale or as replacements) than as an aid to the producer in identifying management problems. Poor reproductive and lamb survival performance is better investigated using the previous parameters.
   Number of lambs weaned/total ewes exposed to ram: GOAL: Slightly less than for lambs born per ewe exposed, as a result of lamb mortality.
   Number of lambs weaned per ewe lambing: Another measure used in extensively managed range and hill flocks is the **lamb survival** or **marking %** and is calculated as the ratio of number of lambs that come off pasture to be taildocked or castrated to total number of ewes exposed to the ram. It is a gross measure of reproductive performance and lamb survival and, as mentioned earlier, is more useful in economic calculations.
4. **Cull rate, mortality rate, turnover rate:** *Cull rate* is calculated as follows: (number of sheep culled)/(average number of sheep in the flock over a 12-month period). *Mortality rate* is calculated as (number of sheep dying of all causes)/(average number of sheep in the flock over a 12-month period). *Turnover rate* is calculated as [(number of sheep culled) + (number of sheep dying)]/(average number of sheep in the flock). Average flock number is calculated by averaging the number of ewes in the flock at the beginning of the year and the number at the end of the year. GOALS: Yearly ewe mortality rate should be less than 5%; yearly rate of involuntary culling should be less than 10%. Total culling rate (voluntary plus involuntary) should be approximately 20% of the adult flock. Cull rate can be further broken down into two broad categories: *voluntary* (as from breeding sales, low production, genetic turnover, and age) and *involuntary* (as from mastitis, mismothering, reproductive failure, and specific diseases that preclude successful production). Voluntary cull rates can be quite variable, depending on the goals of the producer. For health management programs, the rate of involuntary culling and mortality should be investigated. The 1996 USDA survey found that 16.1% (±2.0%) of adult sheep were culled annually and that another

5.1% (±0.1%) of adult sheep die, for an annual turnover rate of 21.2%. Of those sheep that left the flock, 6.0% left because of failure to lamb, 0.5% because of failure to meet ram breeding soundness evaluation parameters, and 1.9% from other reproductive problems.

5. **Average daily gain (ADG):** Weight of lamb at a specific age divided by the number of days of age. Timing of this measurement varies, but it usually is done at weaning (50 to 60 days) or at market age (100 to 180 days). GOALS: Goals are breed and management system dependent. For example, Suffolk lambs on full feed may gain 0.55 kg/day but less than 0.35 kg/day on pasture. Various ROP programs have adjustment factors for age of ewe, sex of lamb, and litter size in order to compare lambs and ewes within peer groups. Information on ADG can be used for ascertaining the growth performance of the group. Suboptimal performance should initiate investigations into nutrition and diseases that limit growth.
6. **Weight of lambs produced (kg)/ewe or hectare and weight of wool produced (kg)/ewe or hectare:** The total weight in kg of lambs weaned or marketed per ewe exposed to the ram, or per hectare of land used to support the sheep enterprise.

These are very broad measures and are designed to track economic progress. Although useful for the producer to determine efficiency of production, they are difficult to use for investigating poor performance.

FLOCK REPRODUCTIVE HEALTH PROGRAM

The common components of the reproductive health management program can be divided into those based on the ewe's reproductive cycle, presented in Table 93-2, and those components biologically based on season, presented in Box 93-3. To fit the many diverse sheep management systems, the veterinarian and the producer must consider both areas together. For example, parasite control should be based on season but may coincide with some reproductive procedures (e.g., pregnancy diagnosis).

CONSIDERATIONS FOR ACCELERATED LAMBING PROGRAMS

Programs become more complicated when accelerated (frequent) lambing programs are being used. Issues that need to be considered include the following:

- The producer must be able to cope with more than one production group at a time and to accurately time events such as breeding dates, ration changes, vaccinations, and other health management measures. This requires a more sophisticated record-keeping system and individual animal identification.
- Ewes are bred at traditionally infertile times of the year. The producer must have advanced knowledge on how to manage out-of-season breeding programs.

Box **93-3**

Sheep Health Management Program Based on Season

Winter—Temperate Climate

Advise producer:

- Drench all sheep for parasites with a larvicidal drug once sheep are housed or frost in ground.
- Ensure supplementation of selenium, iodine, and vitamin E to all sheep.
- Housing should be available to meet space recommendations for the different production groups.
- In cold climates, shear ewes if in closed "warm" barn.

Spring

Advise producer:

- Treat for parasites 3 weeks after turnout onto pasture; repeat in 3–4 weeks.
- *Warm climates:* Monitor parasite load using fecal egg counts or mucous membrane color (FAMACHA system).
- Shear if sheep are in long fleece.
- Treat for ectoparasites if these constitute a problem.
- Predator control measures should be in place.

Summer

Monitor for gastrointestinal parasites in ewes and lambs in mid-July using fecal egg counts or FAMACHA systems. Drench as necessary.

Instruct client on methods to prevent development of anthelmintic resistance

If footrot is diagnosed, institute control measures and follow-up eradication measures when spread time has passed.

Advise producer:

- Wean lambs onto clean pasture, stubble field, hay field, or dry lot.
- Predator control measures should still be in place.
- Monitor pasture productivity and, in combination with reproduction-related management procedures, monitor BCS.

Autumn

Nutrition Flock Health Visit

This visit may be in conjunction with veterinary-related tasks that occur at midgestation, such as pregnancy diagnosis.

Current year's forages should be analyzed and rations balanced for the following production groups:

Rams

- Breeding and maintenance

Ewes

- Maintenance and midgestation
- Flushing/early gestation
- Late gestation (based on expected prolificacy)
- Early lactation for singles and multiples

Lambs

- Creep
- Feedlot (market lambs)
- Replacement ewe and ram lambs

Drench for parasites if required (repeat monitoring for fecal egg count if was high in July).

Give iodine supplementation if sheep are on goitrogenic brassica pastures (forage rape/turnip tops).

Predator and footrot control measures should still be in place.

BCS, body condition score.

Table **93-2**

Sheep Health Management Program Based on Reproductive Cycle

Stage	Veterinary Tasks	Advise Producers to Perform Tasks	
Prebreeding 60 days before teasing required	Vasectomize rams for teasers	Reproduction	Vasectomized rams are not to be used for heat detection until 60 days after surgery
Prebreeding 7 weeks before breeding	Ram breeding soundness evaluation *B. ovis* serologic testing for high risk areas	Reproduction	Appropriate ram-to-ewe ratio Cull inferior rams
		Nutrition/housing	Nutritional flushing of rams to achieve appropriate BCS (3.5–4.0) Protect rams from adverse environmental conditions that might adversely affect spermiogenesis
		Disease control	Cull rams with epididymitis or orchitis
Prebreeding 4 to 3 weeks before breeding	Advise on abortion control (vaccination) Advise on parasite control	Nutrition	Sort and flush thin ewes <2.5 BCS Continue flushing until 3 weeks after removal of ram
		Disease control	Sort and cull unsuitable ewes (low BCS, bad teeth, mastitis, other disease such as footrot) Vaccination for abortion diseases if appropriate (veterinary advice) Optional anthelmintic treatment
Prebreeding 2 weeks before breeding	Advise on estrus synchronization program	Reproduction	*Transitional period*: introduce teaser rams at 40:1 for 14 days before fertile ram introduction *Estrus synchronization program*: vaginal pessaries in or start on MGA
Breeding 2 days to 42 days		Reproduction	*Anovulatory or transition season with P_4 synchronization program*: inject eCG Introduce rams ~24–36 hr after removal of synchronization agent Apply marking harness and change color every 14 days Record new marks every 2 to 14 days
Postbreeding		Reproduction	Remove rams and introduce teaser rams with marking harness to mark ewes still cycling (at risk of being open)—optional
Midgestation 7 to 12 weeks after ram removal	Pregnancy diagnosis with real-time ultrasound examination Check udders and BCS in ewes Discuss nutritional management of late-gestation ewes	Reproduction	Cull open ewes or slip to next breeding group if on accelerated lambing program
		Disease control	Institute prophylactic antibiotics when appropriate for control of infectious abortion
		Nutrition	Sort ewes by BCS and fetal numbers If no pregnancy diagnosis done, sort ewes by BCS so thin ewes can be supplemented
Late gestation 6 to 4 weeks before start of lambing	Prescription coccidiostat for lamb creep Discuss vaccination program for disease control in ewes Check lambing supplies/ medicines, including those for treatment of hypothermia/ hypoglycemia Discuss treatment algorithms for common diseases	Lamb care	Prepare lambing and lamb rearing facilities including milk replacer and equipment Order lamb creep with coccidiostat

Table **93-2**

Sheep Health Management Program Based on Reproductive Cycle—cont'd

Stage	Veterinary Tasks	Advise Producers to Perform Tasks	
	Discuss dystocia management, lambing, and neonatal care Investigate abortions		
		Disease control	Shear for indoor lambing Crutch for cold lambing and if wool is long Vaccinate ewes for clostridial diseases and CLA (optional) Ensure adequate vitamin E and selenium, either as injectable or delivered in feed Prelambing anthelmintic use if in program
		Nutrition	Increase energy and density of ration to all ewes, more to thin and prolific ewes Ensure adequate trace minerals and vitamins in ration
Lambing and lactation	*For high morbidity/mortality rates*: Perform necropsies of dead lambs Review treatment protocols for hypothermia/hypoglycemia	Lamb care	Work with veterinarian to determine reason for high morbidity/mortality rates Determine where breakdown occurs in lambing and lamb management protocols For infectious disease, institute corrective measures
Weaning	Calculate reproductive, health, and lamb performance statistics Make recommendations for change	Productivity	Cull ewes with udder disease, poor reproductive performance, history of prolapsed vagina, poor lamb performance, or other production-limiting disease Select superior replacements

BCS, body condition score; CLA, caseous lymphadenitis; eCG, equine chorionic gonadotropin; MGA, megestrol acetate.

- Although accelerated lambing systems make better use of facilities in that they are used year round, it is important that the facilities be large and elaborate enough that sheep can be separated by reproductive status and nutritional needs.
- Good handling facilities become essential so that sheep can be sorted accurately.
- The owner must be able to manage more finely tuned rations. Under traditional systems, ewes may have up to 5 months to recover weight after weaning before being bred again. In accelerated lambing systems, ewes may be expected to be ready for breeding almost immediately after weaning. BCSs should not be lower than 2.5 at weaning and should be 3.0 at breeding. This requires more accurate feeding of lactating ewes.
- Heavy feeding of lactating ewes may put them at increased risk of mastitis, particularly at weaning. This requires careful weaning management and monitoring of udder involution.
- Disease control becomes more difficult because of the mixture of age and production groups, and there is no "down" time in the flock. Accordingly, contagious diseases such as neonatal diarrhea become more difficult to control.

CHAPTER 94

Reproductive Physiology and Endocrinology of Boars

CHRISTOPHER E. KUSTER and GARY C. ALTHOUSE

Modern swine operation viability depends on herd productivity and profitability. Herd productivity generally is assessed by reviewing herd reproductive performance and, in particular, performance of females in the breeding herd. Although gilts and sows constitute well over 95% of the breeding herd, the fact that overall reproductive performance is shared equally with the boars should not be overlooked. For this reason it is important to understand the underlying determinants of reproductive performance as they relate to boars used for natural service and those used for artificial insemination (AI).

PREPUBERTAL DEVELOPMENT

The prenatal testis develops in the fetal abdomen, near the embryonic kidney, and migrates caudally through the inguinal rings as it passes into the scrotum. In the pig, both testes should be fully descended at birth. Failure of one or both testicles to enter the scrotum results in cryptorchidism, a condition in which the retained gonad is capable of full endocrine function, although spermatogenesis is impaired owing to the thermal environment. Sperm production appears to be closely correlated with the number of Sertoli cells present in the testis, with a fixed ratio of spermatids to Sertoli cells being reported.[1] Sertoli cell proliferation in pigs is marked by two distinct phases, the first encompassing the period between birth and 1 month of age, and the second between 3 and 4 months of age.[2] Depending on the animal's genetics, steroid production from the Leydig cells of the testis and its subsequent effect on behavior (e.g., mounting pen mate, aggressiveness) can be apparent as early as 1 month of age onward.

PUBERTAL CHANGES

Puberty can be thought of a complex process leading up to full sexual maturity and is accompanied by distinct changes in the physiology and anatomy of the reproductive system.[3] The penis of the prepubertal boar lacks a sigmoid flexure and is attached to the lining of the prepuce by the penile frenulum. Under androgen influence, penis growth occurs and the boar's physical mounting activity increases; these events lead to the development of the sigmoid flexure and frenulum breakdown, respectively. Boars as young as 4.5 to 5 months of age can have spermatozoa present in the epididymis, but adequate libido for mating and ejaculation generally is not displayed until after 5 months of age.[4] Age at attainment of puberty can vary greatly between breeds and genetic lines.

MATURE BOAR

Reproductive Anatomy

The boar has a fibroelastic penis with a sigmoid flexure along its shaft and a characteristic corkscrew-shaped glans penis (Fig. 94-1). The boar's penis is retracted into the prepuce while at rest. The boar's prepuce runs medially along the distal third of the abdomen, with its wider cranial portion tightly attached to the ventral abdomen suspending the narrower caudal portion of the prepuce. It is normal for boars to maintain the penis in a retracted state and to display a jerking motion of the penis or prepuce during urination. In the dorsal aspect of the cranial portion of the preputial cavity, the boar has a unique structure known as the preputial diverticulum (see Fig. 94-1). This cavity collects urine, semen, and other fluids and harbors a large bacterial population. Contraction of the cranial preputial muscles in concert with mounting activity appears to empty the contents of the preputial diverticulum onto the shaft of the penis, providing lubrication for intromission. The glabrous, nonpendulous scrotum of the boar is located immediately ventral to the anus and contains a prominent medial raphe. Variation between boars in scrotal attachment may predispose some boars to be more susceptible than others to disruptions of spermatogenesis during the hot season of the year, especially those boars with testes held close to the body wall.

The testes are the site of spermatogenesis and hormone production. Boar testis weight has been shown to increase most dramatically between 4 and 6 months of age, reaching mature size by 8 months.[4] A recent study using B-mode ultrasound examination to measure testis diameter in vivo confirmed that in crossbred boars a plateau in testis growth is achieved by 8 months of age, with only a 2-cm difference in testicular diameter for boars 8 months to 2 years old.[5] The testes should by symmetrical and relatively uniform in size and have a distinct firmness to digital palpation. The epididymis functions as a site of sperm transport, maturation, and storage. The caudae epididymidis are palpable as distinct nodules located on the dorsal aspect of the testis within the

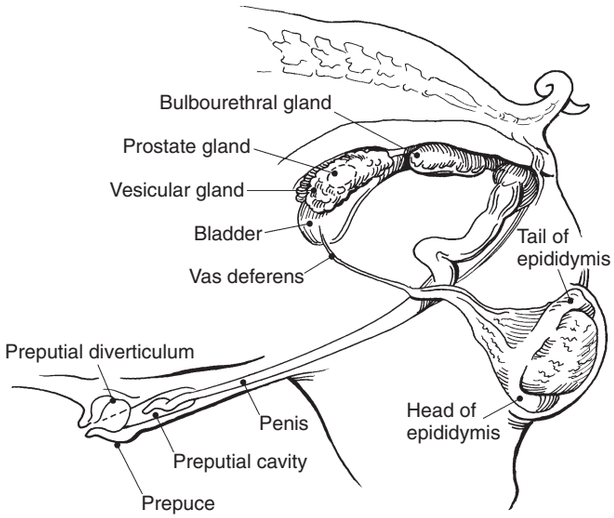

Fig. 94-1 Boar reproductive tract in situ.

scrotum. Proper location and identification of the caudae epididymidis are necessary in order to successfully perform epididectomy surgery in young pigs, a technique commonly used to create sterile teaser boars for estrus detection programs. The ductus deferens is the conduit used for passage of sperm from the cauda epididymidis to the pelvic urethra at the time of ejaculation. During vasectomy, sterility can be induced via ligation and segmental excision of a portion of the ductus deferens. The spermatic cord contains the ductus deferens and also serves as a vascular, lymphatic, and neural connection from the testis to the rest of the body. The scrotum, pampiniform plexus, and the cremaster muscle all aid in autonomic control of core testis temperature.

The boar reproductive tract contains accessory sex glands that contribute the seminal plasma portion of the semen (see Fig. 94-1). The vesicular glands are large, diffuse, lobulated structures, which contribute the bulk of the boar's ejaculate fluid volume. The prostate gland is much smaller relative to the other accessory glands and is located between the pelvic urethra and the ventrocaudal portion of the vesicular glands. The bulbourethral glands are large paired structures in the boar that straddle the internal pelvic inlet and produce the large gel fraction characteristic of boar semen.

Endocrinology

The reproductive endocrinology of the boar is discussed fully elsewhere[6]; a brief review is presented here. The pattern of gonadotropin-releasing hormone (GnRH) release from the hypothalamus stimulates the release of follicle-stimulating hormone (FSH) or luteinizing hormone (LH), or both, from the anterior pituitary gland. Sertoli cell function is regulated primarily by FSH. Sertoli cells are the only somatic cells found in the seminiferous epithelium and form the specialized blood-testis barrier. Sertoli cells are intimately involved in spermatogenesis, in addition to producing the hormones inhibin and estrogen. Inhibin provides the necessary feedback to the anterior pituitary to regulate FSH secretion. Estrogens influence sexual behavior and appear to control critical events during sperm maturation in the epididymis.[7] Leydig cells are the primary interstitial cells of the testis, and produce androgens under the influence of LH. Testosterone, the primary androgen produced, is necessary for normal sperm production and maintenance of the accessory sex glands and is involved with libido. Sexually excited boars chomp their jaws, eliciting the production of copious quantities of foamy saliva containing pheromones that stimulate sexual receptivity in estral gilts and sows. Active components in the saliva include the androgen metabolites 3α-androstenol and 5α-androstenone.

Spermatogenesis

Spermatogenesis is the process by which highly specialized spermatozoa are formed from primitive male germ cells. Spermatocytogenesis is the initial phase of spermatogenesis and consists of a series of mitotic divisions of the spermatogonia, ending in the production of primary spermatocytes. Primary spermatocytes undergo meiosis to produce haploid spermatids known as secondary spermatocytes. During spermiogenesis, haploid spermatids undergo dramatic morphologic transformations to become fully differentiated spermatozoa. After completion of spermatogenesis, spermiation ensues, which is the release of spermatozoa into the lumen of the seminiferous tubule. Sperm cells then undergo a final process of maturation in the epididymis in order to acquire motility and potential fertility. The cauda epididymidis also functions as the sperm storage reservoir until the time of ejaculation. Spermatogenesis takes approximately 35 days in the boar, with an additional 9 to 12 days needed for epididymal passage and maturation before becoming the fertile gametes emitted during ejaculation.[8–10] Therefore, it is not unrealistic to observe a 6- to 7-week lag time before a normal spermiogram can again be expected following a disruption in spermatogenesis.

Structure and Function of Spermatozoa

The sperm cell consists of the head and tail (consisting of a midpiece, the principal piece, and an endpiece). The head is 8 to 10 μm long by 4 to 4.5 μm in width and contains the haploid component of DNA in a highly condensed nucleus. Starting at the apex and encompassing roughly two thirds the length of the sperm head is a prominent acrosome containing the enzymes that aid the sperm cell in penetrating the surrounding mucoproteinaceous investments and intimate components of the oocyte. The midpiece is attached to the base of the head and makes up approximately 25% of the length of the tail. On light microscopy, the midpiece looks like a thickened portion of the tail. The midpiece contains a helical arrangement of mitochondria, which generate the energy required for the cell's motility. The midpiece ends bluntly, at which point the remainder of the tail continues on as the principal piece. The tail is very flexible and consists of nine outer dense fibrils (midpiece and principal piece),

an axoneme, and a fibrous sheath. The axoneme has nine pairs of microtubule doublets forming a ring around two central microtubules. Structural proteins link the outer microtubule doublets to the central pair of singlets, much like the spokes of a wheel; motor proteins attached to the outer ring of microtubules provide the force necessary to bend the tail to achieve motility. The axoneme continues through into the endpiece, the terminal 3 to 4 μm of the tail, which lacks the nine outer fibrils and the fibrous sheath.

Ejaculation

The boar is a pressure ejaculator, responding to the circumferential tightening of the sow's cervix around the glans penis. The gloved hand technique for semen collection takes advantage of this physiologic phenomenon by basically forming a fist around the glans penis, effectively "locking" the glans within a tightly gripped hand. The gloved hand technique is simple and quite effective, making the use of an artificial vagina outmoded and antiquated for porcine semen collection. Erection and ejaculation are primarily under the control of the autonomic nervous system, with ejaculation initiated by rhythmic contractions of smooth muscles lining the cauda epididymidis and ductus deferens. After initial thrusting motions, the boar will settle on a sow or collection dummy and proceed to ejaculate in phases for up to 5 minutes or more.

APPLIED REPRODUCTION IN THE BOAR

Prepubertal Boars

In general, crossbred boars reach sexual maturity at an earlier age than do purebred boars. Young boars that are reared in individual pens can experience a delay in puberty, poor sexual motivation, a decrease in mating performance, and increased locomotion difficulties compared with group-housed boars.[11] Interactions between pigs and their human caretakers are important in conditioning either approach or avoidance responses as the animal matures, which is an important point to remember in dealing with AI boars, which may fully mature at 225 kg or greater and will be handled in close quarters on a regular basis.[12,13] Developing boars may benefit from supplementary lighting that extends natural daylight to 15 hours per day by accelerating the onset of mating behavior[14]; however, sperm production, semen quality, and endogenous hormone profiles remain unaffected.[15–17] Although the detrimental effects of heat stress on mature boars are well documented,[18–20] it is not yet clear if high ambient temperatures during prepubertal development have long-lasting or permanent effects on sperm production or semen quality. Young boars have somewhat higher nutrient requirements than replacement gilts, but because growing boars are almost always reared under some method of performance testing for growth rate and feed efficiency, it is unlikely that their nutritional needs for sexual development or future reproductive capacity will go unmet. Exposure of prepubertal boars to commonly encountered levels of Zearalenone does not appear to have significant detrimental effects on future sperm production or semen quality.[21]

Postpubertal Boars

In general, crossbred boars tend to have heavier testes, increased sperm concentration, greater ejaculate volume, and improved semen quality in comparison with purebreds, although these differences may not be as dramatic as boars become older and full maturity is attained.[22] Significant differences in semen and reproductive characteristics (e.g., semen volume, sperm concentration, percentage of live spermatozoa, sperm motility, number of potential doses of semen) have been reported among breeds, although no single breed seems to stand out as excelling all categories.[23] Daily sperm output increases until purebred boars are about 18 months old, whereas crossbreds tend to peak earlier, at around 10 to 12 months of age.[4,5] Thereafter, sperm output remains fairly constant until it begins to decline at around 4 years of age, although a variety of factors may be involved in determining when senility sets in and sperm production drops off. Some studies have concluded that reproductive function in boars is stimulated by decreasing day length and inhibited by increasing day length, whereas others indicate that optimal sperm production is achieved when boars are exposed to a constant photoperiod of 10 hours per day versus 16 hours.[24,25]

Heat stress–induced reductions in semen quality are a major concern for boar study throughout many parts of the world. Considerable variation exists between boars in their individual susceptibility and response to heat stress, with genetically lean boars and those with testes held tight to the body wall at an increased risk. Variables such as the duration and intensity of the temperature elevation, relative humidity (RH), and ventilation in the housing area further complicate the issue. In general, exposure of boars to average daily ambient temperatures above 27°C and 60% RH poses a risk to semen quality. Much cooler temperatures, 15° to 20°C, appear optimal for boar comfort and semen quality. The detrimental effects of heat stress on the spermiogram begin to appear 7 to 14 days after insult. The observed increases in sperm abnormalities (e.g., head and tail abnormalities, cytoplasmic droplets), decreased motility, and decreased sperm output may be expected to continue for 5 to 8 weeks after the heat stress has been resolved. A similar pattern of events can be anticipated in boars that become systemically ill with concurrent pyrexia.

The ratio of boars to females in a natural service breeding program should be between 1:15 and 1:25. If the breeding program is 100% AI, then a ratio of 1:150 to 1:250 (average, 1:200) appears to be adequate. For efficient boar utilization, factors such as age, genetics, libido, season, and health should be considered in determining optimal collection and mating frequency. Suggested guidelines for boar usage are presented in Table 94-1. Increased collection frequency leads to lower sperm concentration and fewer sperm cells per ejaculate. Up to 60% of the sperm reserves stored in the cauda epididymidis are emptied in a single ejaculation, and it may take up to 8 days to completely replenish epididymal reserves once

Table **94-1**

Guidelines for Boar Usage Based on Type of Breeding Program

		NATURAL MATING PROGRAM		
Boar Age (mo)	AI Program Semen Collection Frequency*	Matings/Day	Total Matings/wk	Pen Breeding (No. of Females/mo)
6–8	1 time/week	1	4	<8
8–12	1–2 times/week	1	5–7	8–10
>13	More than 4 times/2 weeks	2 (spaced)	8–10	10–12

exhausted.[9] Decreases in semen quality with negative impact on fertility are a concern if boars are overused,[4] and long-term high-ejaculation frequencies (e.g., 1 a day for 10 days) have been determined to induce potentially damaging biochemical changes in seminal plasma and sperm cells.[26] Overuse of boars younger than 8 months of age may result in unsatisfactory fertility as these boars mature, leading to premature culling. For AI boars, collection frequency is largely a matter of economic concern, with the cost of labor to collect the boar weighed against the expected sperm numbers to be obtained. Most commercial stud operations have found that intervals from three collections every 2 weeks up to two collections per week are optimal for their conditions (average: 1.35 times/week), with consideration given to genetic line and boar age.[27]

Hormone Therapy

In the United States, clinical use of reproductive hormones in boars is governed by the Extra-Label Drug Use provision of the Animal Medicinal Drug Use Clarification Act. The clinician is ultimately responsible for determining the legality of applying the therapeutics described here.

Although normal endocrine functioning is required for spermatogenesis, attempts to increase daily sperm production in mature boars through the use of exogenous gonadotropins have proved ineffective. Administration of GnRH, adrenocorticotropic hormone (ACTH), or human chorionic gonadotropin (hCG) can increase testosterone production in mature boars; however, whether a direct relationship exists between testosterone level and expression of sexual behavior remains a subject of controversy.

F-series prostaglandins have been promoted as useful in stimulating boar libido. Some boars appear to exhibit increased aggression toward the semen collection dummy after being given F-series prostaglandins. In boars, spontaneous erection and ejaculation have been reported within 10 minutes of intramuscular administration of 20 mg of F-series prostaglandin.[29] By contrast, other studies have failed to show a significant decrease in reaction time to mounting of an estrous sow or collection dummy after administration of 7.5 to 20 mg of dinoprost tromethamine (Lutalyse*) to boars.[30,31] No detrimental effects on semen quality or viability have been described in boars treated with $PGF_{2\alpha}$.

Pheromones are airborne chemical messengers that send signals between individual animals to elicit a response in other members of the species. The naturally occurring volatile pheromone androstenone, 5-androst-16-en-3-one, is bound by the protein pheromaxein found in boar saliva.[32] Aerosol cans of synthetic boar pheromones are marketed for use in AI programs and sometimes are used as an aid in training young boars to mount a collection dummy. Experienced AI boars generally will attempt to mount any stationary object roughly the size and shape of a sow. Young boars, however, often benefit from additional stimuli during the training process. A collection area that has fresh secretions from an older boar (i.e., saliva, urine, semen) can help stimulate mounting behavior in a new boar. Pheromone sprays probably function in a similar manner by mimicking the effects of saliva from a mature boar.

CHAPTER 95

Infectious and Noninfectious Causes of Infertility in Boars

GARY C. ALTHOUSE

As in other livestock species, breeding soundness evaluations (BSEs) have value in identifying potentially subfertile or infertile boars. Unfortunately, BSEs have been and still are rarely performed on boars used in natural mating programs. With the recent exponential growth in the use of artificial insemination (AI) in the global swine industry, a more developed approach has evolved in evaluating the reproductive potential of an AI stud boar. Boars standing at an AI stud operation are routinely screened for selected pathogens that can reduce reproductive performance. Additionally, a large percentage of stud operations that collect and process semen from boars for AI routinely evaluate the motility, morphology, concentration, and volume of each ejaculate. The more recent incorporation of such screening protocols into swine breeding programs has greatly aided the industry in reducing the untoward effects of boar infertility or subfertility on herd reproductive performance.

Boar infertility is manifested in a herd as an elevated rate of normal returns to estrus, decreased litter size, increased litter scatter, or insufficient number of mated females per unit time. In retrospect, diagnosis of individual boar infertility is difficult to obtain because of the many confounding variables and management practices that can also influence herd reproduction. Accordingly, it is important that veterinarians and their producer clients take a proactive role in boar and ejaculate selection. One of the strengths of an AI program is the opportunity it provides to continuously monitor the boar's contribution to herd reproductive performance.

INFECTIOUS CAUSES OF BOAR INFERTILITY

Many of the pathogens that can cause boar infertility also have been found to use semen as a vector in their transmission. Infectious pathogens induce boar infertility through several general pathways. Certain infectious pathogens (e.g., *Brucella, Chlamydia,* Japanese B encephalitis virus [JEV], rubulavirus) can localize within the testicular parenchyma, with the ensuing inflammatory response disrupting spermatogenesis. Other infectious pathogens (e.g., swine influenza virus [SIV], *Mycoplasma,* the agent of erysipelas) indirectly disrupt spermatogenesis through the febrile response (with temperatures of greater than 40°F) associated with systemic illness. Finally, select infectious pathogens (e.g., the agent of classical swine fever, *Leptospira,* pseudorabies virus, parvovirus, porcine reproductive and respiratory syndrome [PRRS] virus) are shed in the semen of infected boars, causing disease in the female bred with the infected semen.

Owing to the devastating nature of infectious pathogens on herd reproductive performance, boar stud operations are constructed as independent facilities that preferably are sited away from any other livestock facility. Stringent biosecurity programs are followed to curtail the potential introduction of pathogens into the enclosed facility. Replacement boars, originating from selected pathogen-free herds, frequently undergo a 45-day (or longer) quarantine period. During quarantine, periodic serologic testing along with daily observation for clinical signs of disease is performed to minimize the introduction of disease to the resident stud group. If an animal exhibits clinical signs or has a positive test result for an unwanted disease, it is not uncommon for the farm to reject the entire group of replacement animals. Boar stud operations shoulder a great responsibility to maintain a disease-free herd so that economically devastating pathogens do not originate from them.

To elucidate the impact of infectious disease on boar stud productivity, a survey was conducted by Althouse in 2000 that encompassed 35 U.S. stud operations that stood 11,927 boars. A total of 25.7% (9 out of 35) of studs surveyed experienced a disease outbreak in the resident stud during 1999. Diagnosed causes included swine influenza [h1n1 or h3n2, or both—in most cases the specific type was not reported] (n = 6), PRRS (n = 2), mycoplasmosis (n = 1), salmonellosis (n = 1), and erysipelas (n = 1). In a typical disease outbreak, clinical signs were first observed approximately 4.6 days after the introduction of replacement boars into the resident stud group (n = 6 studs). Clinical signs usually were expressed by 26.7% of the boars standing at stud, with 89.2% fully recovering from any one incident. A negative effect on stud productivity (e.g., decreased semen quality) was observed an average of 32.4 days after onset of clinical signs.

SPECIFIC DISEASES

Porcine brucellosis is an infectious disease that can lead to swine infertility. Regulatory programs have been in place for several decades, effectively eliminating this disease from U.S. commercial herds. Feral hogs are considered a reservoir for this disease. Porcine brucellosis is

still prevalent and is considered a major cause of reproductive failure in swine of other countries (e.g., Africa, Asia, South America). In boars, *Brucella suis* (biovars 1, 2, and 3) initially invades regional lymph nodes, with ensuing bacteremia. This bacteremia leads to localization of *B. suis* in the genital organs, particularly those containing high levels of erythritol (e.g., the testis). A persistent orchitis or accessory sex gland infection ensues. *B. suis* is shed in the semen of infected boars, resulting in abortion and infertility storms. Diagnosis is by serologic testing. Depopulation of infected swine herds is recommended.

Leptospirosis is a common bacterial disease of swine that can cause reproductive loss. Multiple serovars of *Leptospira interrogans* (pomona, canicola, icterohemorrhagiae, grippotyphosa, muenchen, hardjo [sejroe], bratislava, tarassovi, australis) have been found to be involved in causing swine leptospirosis, with each serovar having a potentially different epidemiology. In boars, oftentimes leptospirosis infection is inapparent. Carrier animals or bulls with infected semen are responsible for disease spread. Screening or diagnosis of the disease in boars is by serologic testing. Effective commercial bacterins are available to prevent infection with this disease. These bacterins commonly are administered to all breeding stock according to label instructions. Antibiotics (e.g., tetracyclines, dihydrostreptomycin) can be administered to boars to reduce shedding of leptospires but may not eliminate the carrier state of the disease.

Chlamydial infections in boars have been associated with orchitis, epididymitis, urethritis, and reproductive disturbances. Weakness in newborn piglets and stillbirth can result from venereal transmission of *Chlamydia* organisms. The prevalence of chlamydial infections in swine herds is unknown, but serologic studies suggest that most herd infections are clinically inapparent. Diagnosis of chlamydial infections in swine herds as a cause of reproductive loss is uncommon.

Numerous viruses can affect boar fertility and may use semen as a transmission vector. Important pathogenic organisms in the global swine industry include pseudorabies virus (PRV), porcine parvovirus (PPV), and porcine reproductive and respiratory virus (PRRSV). Other viral pathogens of regional concern are hog cholera/classical swine fever virus, porcine rubulavirus, and JEV.

Pseudorabies, also known as Aujeszky's disease, is an important disease of swine worldwide. The disease, caused by a herpesvirus, is spread by contact, by aerosol transmission, transplacentally, or through excretion in the semen. Viral replication occurs in the genital tract. Semen quality in recently infected boars may be reduced indirectly because of fever. As with disease due to other herpesviruses, PRV infection can become latent, with recrudescence of the virus when the animal is under stress. Affected herds may be asymptomatic but often suffer reproductive failure, high neonatal mortality rates, and suboptimal growth performance. Commercially available vaccines control losses due to the clinical disease but do not prevent spread of the virus. Serologic screening of boar and biosecurity are essential to prevent PRV entrance into a swine herd. Economic losses were so great in the US that a national eradication program was justified. This current program involves test and removal, herd depopulation, or offspring segregation within infected herds.

PPV is a highly stable virus that is ubiquitous among swine throughout the world. Before preventive medicine programs, PPV was one of the most common causes of infectious abortion in swine. The most common routes of infection are oronasal and venereal. Naturally infected boars generally fail to show any clinical signs associated with infection but nevertheless can shed the PPV in semen. Embryonic and fetal death (including mummies and stillbirths) are common clinical signs observed in naive animals infected with PPV. Other clinical signs may include elevated rates of normal and delayed returns to service and abortion. Proper acclimatization of replacement animals, through vaccination and cull animal exposure, before introduction to the resident herd, has been quite successful in controlling this disease.

PRRSV, an arterivirus, has come to the forefront as one of the top etiologic agents of reproductive failure in swine today. Direct pig-to-pig contact seems to be a major route of PRRSV disease transmission, with infection also being able to occur by aerosol and through semen. Clinically infected herds experience reduced conception and farrowing rates, elevated neonatal mortality rates, and chronic respiratory disease with poor performance in growing swine. Symptomatic therapy appears to be only palliative. Vaccination appears to offer some control over the disease. In the absence of other significant endemic diseases, boars recently infected with PRRSV exhibit few clinical signs beyond those associated with a mild pyrexia. In the presence of endemic disease, PRRSV-infected boars generally exhibit pronounced clinical signs associated with the endemic disease, with disturbances in semen quality associated with the pyrexia. Excretion of PRRSV through semen appears to occur most frequently during the acute phases of the disease. Duration of excretion in semen appears to vary, with reported cases of prolonged or intermittent excretion well beyond 1 month after infection. Carrier states are believed to occur in some animals. Diagnosis of PRRSV disease in boars is based on serologic testing and screening of semen by polymerase chain reaction (PCR) assay.

The industry still struggles to define a program that provides effective control of PRRSV disease. Because of the inherent difficulties associated with endemic PRRSV infection, most boar stud operations typically strive to achieve a PRRSV-negative or -naive status. Many such operations apply a rigorous serologic and semen testing program during quarantine to minimize the chances of introducing PRRSV into the resident boar group. Accidental introduction of PRRSV into a boar stud group generally leads to its complete depopulation, followed by repopulation with naive animals. Boar vaccination with modified live virus attenuates may lead to shedding of the modified live virus in the semen; use of this semen may lead to seroconversion in the recipient animals, confounding future disease control strategies for the herd.

Hog cholera—classical swine fever—is a highly contagious, reportable disease of swine. Significant economic losses to the swine industry led to institution of a national program that resulted in its eradication in the

United States in 1976. Pigs appear to be the only natural host for the virus. Hog cholera virus, a pestivirus, is excreted with oronasal and lacrimal secretions and in urine, semen, and feces. Owing to the hardiness of the virus, mechanical vectors and garbage that contains pork products also appear to contribute to the spread of the disease. Acute infection induces a variety of clinical signs, usually leading to the death of the animal 10 to 20 days later. A 2000 report from Bouma and associates has demonstrated the regional spread of hog cholera through extended semen processed from recently infected hog cholera virus–infected boars. This possibility demonstrates the necessity for prudent quarantine and diagnosis for studs exhibiting clinical signs associated with infectious disease.

Porcine rubulavirus, a paramyxovirus, is the agent of blue eye disease, found in Central America, which can cause infertility in boars and sows. Central nervous system signs, corneal opacity, and high piglet mortality rates also can be observed in infected herds. Infected boars may show severe epididymo-orchitis and reduced semen quality, leading to temporary or permanent infertility. Diagnosis is based on clinical signs or with serologic testing, or both. Seropositive breeding stock should be culled.

Japanese B encephalitis is a mosquito-borne viral disease of swine that causes reproductive failure in several Asian countries. Summer infertility in boars appears to be associated with JEV, a togavirus. Experimental infections resulted in edematous and congested testes, epididymitis, reduced libido, and reduced semen quality. Infection can lead to temporary or permanent infertility. The virus can be shed in semen of infected boars, suggesting that semen can be a vector of disease transmission. Diagnosis of JEV disease in boars is through clinical signs or serologic testing, or both. Seropositive boars should be culled. Live attenuated vaccines have been used successfully to prevent infection in endemic areas.

NONINFECTIOUS CAUSES OF BOAR INFERTILITY

The most commonly observed cause of boar reproductive failure, infectious and noninfectious, appears to be heat stress–induced subfertility or infertility. Boars exposed to increased ambient temperatures (higher than 27°C and 50% relative humidity), or heat stress, exhibit a decrease in reproductive efficiency. More specifically, alterations in semen quality and libido are associated with heat stress in boars. Effects of heat stress on the spermiogram include decreased sperm motility, increased numbers of morphologically abnormal sperm, and a decrease in total sperm numbers. The negative effects of heat stress on the boar spermiogram are first evident starting approximately 2 weeks after initial heat stress exposure and can last for up to 5 to 8 weeks or longer, depending on the duration of the thermal insult. In some boars the changes remain unresolved; use of their semen in breeding programs will lead to decreased herd reproductive performance. Susceptibility to heat stress appears to be boar specific, with an as-yet undetermined genetic predilection. For optimal fertility, boars should be housed in a facility with a controlled environment. Environmental cooling (fans, water sprinklers, evaporative systems, geothermal cooling) is essential during hot weather to prevent heat stress in boars.

Cold stress–induced subfertility and infertility have been described in boars housed outside during winter conditions. Under severe circumstances, frostbite of the scrotum can result but does not appear to be necessary for the negative effects of cold stress to occur. Changes in the spermiogram include decreased sperm motility, increased numbers of morphologically abnormal sperm, and a decrease in total sperm numbers. In some situations, azoospermia may develop. Resolution of a short-term cold stress–induced infertility can take up to 2 months or longer. In some boars the changes go unresolved. Boars should be protected from extreme weather by use of insulated housing, adequate bedding, and proper nutrition.

Vaccine-induced subfertility and infertility also have been observed in boars. In the aforementioned 2000 survey, 45.7% (16 of 35) of the stud operations reported negative effects of preventive vaccination on overall stud productivity. Vaccine types reported to have a negative effect on sperm quality included PRRS ($n = 7$), SIV [h1n1 or h3n2, or both—in most cases a specific type was not reported] ($n = 8$), PRV ($n = 2$), or a combination of the aforementioned ($n = 2$). A reported 32.7% ± 25.0% of vaccinated boars were affected by vaccination during an event, with a time lapse of 20.3 ± 13.4 days before the negative effects on semen quality were observed. Total recovery of the spermiogram from an event was 5.5 ± 2.7 weeks after vaccination.

Nutritional imbalances can lead to disturbances in boar reproductive function. Excess feed creates overweight boars, which manifest signs of reduced libido. Additionally, overweight boars tend to exhibit an increased incidence of foot and leg problems, leading to their culling. Severely restricted energy and protein in the diet can impair boar reproductive performance. Studies addressing select deficiencies and excesses of vitamins or minerals on boar reproduction are sparse. Selenium deficiency is believed to cause a decrease in sperm production and motility. Zinc deficiency is thought to retard testicular development. Conflicting reports exist on the boar's tolerance to certain mycotoxins (e.g., aflatoxin B_1, vomitoxin, zearalenone) in the diet. As a precaution, routine use of mold inhibitors and binding agents, along with appropriate testing and blending of suspicious grains, can help to minimize their potential effects. Above all, an appropriate and balanced diet is paramount to good boar reproductive performance. Supplementation to a balanced diet should be approached with caution. A typical boar diet can be found in Chapter 98.

Inappropriate management of the boar can lead to subfertility or infertility. It is important that postpubertal immature boars be gradually introduced into service. Maturity of a boar is highly dependent on genotype, and age at maturity can range from 8 to 10 months to well over 1 year of age. Understanding onset of puberty and progression to maturity within genotype is essential to good boar management. Overuse of boars at any age can

result in reduced fertility. General guidelines for boar use can be found in Table 94-1.

CHAPTER 96

Reproductive Surgery in the Boar

GARY C. ALTHOUSE

Current swine breeding management strategies have placed an increased emphasis on the clinician's technical proficiency in performing boar reproductive surgery. Use of surgically sterilized boars in gilt development and institution of estrus detection programs have become commonplace in many of today's production systems. Critical, scrutinized genetic selection and the preferred distribution of these desired genetic traits through artificial insemination also have placed increased value on the boars that are standing at stud. It is not uncommon for boars selected for artificial insemination programs to have values 25 to 50 or more times greater than their market hog counterparts. These many varied factors contribute to the necessity for a clinician to be able to provide attention to the individual boar's health and reproductive viability and function.

GENERAL ANESTHESIA

Most surgical procedures performed in adult boars require the use of general anesthesia.[1–3] Drug combinations that have been used successfully to provide 30 to 60 minutes of general anesthesia include the following: (1) xylazine hydrochloride (2 mg/kg of body weight) plus tiletamine hydrochloride–zolazepam hydrochloride (Telazol*) (6 mg/kg), administered intramuscularly [IM]; (2) xylazine (1 mg/kg) plus butorphanol tartrate (0.1 mg/kg) plus Telazol (3 mg/kg), administered IM; (3) Telazol (5-ml vial) reconstituted with 2.5 ml of xylazine (100 mg/ml) and 2.5 ml of ketamine (100 mg/ml), with the resulting mixture given IM at a rate of 0.02 to 0.04 ml/kg; or (4)

*Fort Dodge Labs., Fort Dodge, IA.

result in reduced fertility. General guidelines for boar use can be found in Table 94-1.

CHAPTER 96

Reproductive Surgery in the Boar

GARY C. ALTHOUSE

Current swine breeding management strategies have placed an increased emphasis on the clinician's technical proficiency in performing boar reproductive surgery. Use of surgically sterilized boars in gilt development and institution of estrus detection programs have become commonplace in many of today's production systems. Critical, scrutinized genetic selection and the preferred distribution of these desired genetic traits through artificial insemination also have placed increased value on the boars that are standing at stud. It is not uncommon for boars selected for artificial insemination programs to have values 25 to 50 or more times greater than their market hog counterparts. These many varied factors contribute to the necessity for a clinician to be able to provide attention to the individual boar's health and reproductive viability and function.

GENERAL ANESTHESIA

Most surgical procedures performed in adult boars require the use of general anesthesia.[1–3] Drug combinations that have been used successfully to provide 30 to 60 minutes of general anesthesia include the following: (1) xylazine hydrochloride (2 mg/kg of body weight) plus tiletamine hydrochloride–zolazepam hydrochloride (Telazol*) (6 mg/kg), administered intramuscularly [IM]; (2) xylazine (1 mg/kg) plus butorphanol tartrate (0.1 mg/kg) plus Telazol (3 mg/kg), administered IM; (3) Telazol (5-ml vial) reconstituted with 2.5 ml of xylazine (100 mg/ml) and 2.5 ml of ketamine (100 mg/ml), with the resulting mixture given IM at a rate of 0.02 to 0.04 ml/kg; or (4)

*Fort Dodge Labs., Fort Dodge, IA.

premedication with xylazine (2 mg/kg given IM), followed in 10 minutes with intravenous administration of a 5% solution of thiopental sodium, given to effect. Animals should be isolated from herdmates during the recovery period. With any of the surgical techniques outlined, it is preferable to keep recovered boars isolated from other swine for at least 10 to 14 days after surgery to allow healing. Exposed skin sutures should be removed before reintroduction to herdmates, because pigs are curious animals and frequently will pull or bite on the sutures.

REPAIR OF PENILE INJURIES

Penile injuries are not that uncommon in the boar and often are related to facilities and management (e.g., bite wounds in boars kept in group housing or those used in pen and natural mating situations). Primary complaints that could signify a penile injury include the observation of blood in the urine or semen and hemorrhage from the preputial orifice. The challenge to the clinician in addressing penile injuries is the preoperative assessment of the condition to determine if sufficient damage has occurred to warrant medical or surgical intervention. Although penile injuries are not directly life-threatening, if they are not resolved quickly, the boar may become nonfunctional, leading to its early culling.

The penis is best examined while the boar is under general anesthesia. If the penis cannot be easily grasped and exteriorized using gauze pads, use of Bozeman's atraumatic uterine dressing forceps (10.5-inch size) has been found to be helpful for this purpose. If damage to the penis is limited to abrasions or superficial lacerations, adequate sexual rest (for 3 to 4 weeks) is all that usually is required for healing. If, however, urethral patency has been compromised (i.e., fistula formation), especially if located in the body of the penis, surgical correction may be necessary. Trauma to the urethra requiring surgery should be dealt with quickly to avoid the need for excessive débridement. With the animal under general anesthesia, an 18 to 20 Fr Foley catheter is passed into the urethra to act as a stent. After cleansing and débridement, the urethra is closed with a 4-0 absorbable suture, swaged to an atraumatic needle, with a simple interrupted pattern that incorporates the mucosa. Fascia and skin are then closed using 4-0 nylon suture in a simple interrupted pattern. A Malecot drain inserted through a prepubic cystostomy may be used to divert urine from the reconstructed urethral site and thus promote healing; the drain is removed once healing is sufficient for normal micturition. A total of 4 to 5 weeks of sexual rest is recommended before the boar's return to service.

CORRECTION OF PENILE PROLAPSE

Prolapse of the penis and preputial cavity mucosa have been reported after use of neuroleptics (i.e., acetylpromazine) or as a result of trauma to the penis during mounting activity. Penile prolapse should be considered an emergency situation, as additional injury to the penis is likely to occur the longer it remains prolapsed. The length of time elapsed since occurrence of the prolapse and the degree of insult to the prolapsed structures will determine the prognosis after correction.

With the animal under general anesthesia, the prolapsed tissues should be cleansed and examined for extent of injury. To reduce edema, the prolapsed tissues can be massaged during application of a topical antibiotic ointment. If the prolapsed tissues are too edematous to replace, compresses are applied for a short period of time before replacement is attempted. The prolapsed preputial mucosa and penis are then replaced into the sheath by gentle manipulation using the fingers rather than a surgical instrument. Correct repositioning has been accomplished when both the preputial mucosa and the penis are in place behind the ringlike division between the cranial and the caudal preputial cavities. To reduce the chance of postoperative recurrence, a temporary purse-string suture is placed around the preputial orifice. The suture is tightened sufficiently to retain prolapsed tissue but left loose enough to maintain patency for urination. If wounds or abrasions are present, the preputial cavity is flushed with a warm antiseptic solution; systemic administration of antibiotics and anti-inflammatory drugs over a 3- to 5-day period after replacement also is recommended. The purse-string suture is removed after a minimum of 14 days of sexual rest. Sexual rest may need to be extended an additional 15 to 45 days, depending on the severity of the wounds.

CORRECTION OF PERSISTENT PENILE FRENULUM

The frenulum is an epithelial attachment that runs from the mucosal covering of the penis to the base of the corkscrew behind the tip of the penis. This tissue normally is present in prepubertal and peripubertal boars, with breakdown and detachment occurring as a normal event in boars at or just before puberty. With failure of this breakdown process, the penis will "fishhook," or turn backward, when penile extension occurs (Fig. 96-1). Boars with persistent penile frenulum cannot successfully initiate coitus but sometimes can have their semen collected using the gloved hand technique. Depending on severity, surgical correction of this condition can be performed either during semen collection or with the animal under general anesthesia. Resection or, better yet, removal of this tissue is most easily accomplished using scissors. Hemorrhage is minimal, negating the need for ligation before or after excision. The animal can be used for breeding 10 to 14 days after surgery. Because persistent penile frenulum is thought to be heritable, breeding stock should not be selected from the offspring sired by affected boars.

REPAIR OF PREPUTIAL PROLAPSE

Prolapse of the prepuce in the boar is uncommon. In such an occurrence, however, quick action is paramount to successful replacement of viable tissue and minimization of edema. With the animal under general anesthesia, prolapsed tissue should be manually replaced. After replacement, a purse-string suture, using a 1 nonabsorbable monofilament suture, is placed around the preputial

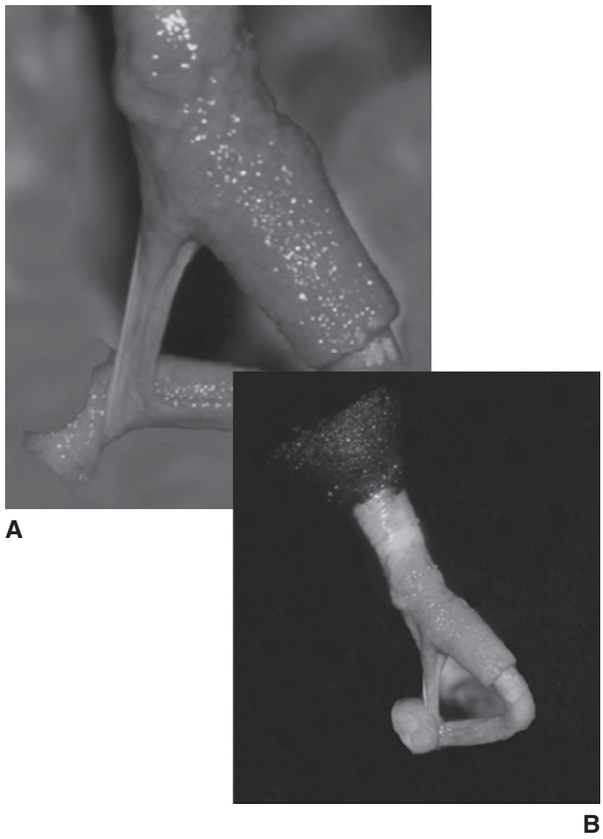

Fig. 96-1 **A,** Persistent penile frenulum in a 10-month-old Hampshire boar. **B,** Magnified view of the frenulum attachment between the internal lamina of the prepuce and the glans penis.

orifice. The purse-string suture should be tightened sufficiently to retain prolapsed tissue yet be loose enough to maintain patency for urination. Flushing of the preputial cavity with a warm, antiseptic solution is often performed daily over a 3- to 5-day period after replacement. At the end of treatment, the purse-string suture is removed, and the boar returned to service after an additional 14 days of sexual rest.

If the boar is presented with a prolapsed prepuce that is edematous and necrotic, surgical correction is warranted. With the animal under general anesthesia, the prolapsed tissue, prepuce, and preputial cavity are surgically prepared. A 1- to 2-cm-diameter tube is then introduced into the preputial cavity to act as a stent. Nonviable tissue is resected, with anastomosis of the two layers of the prepuce using a 1-0 absorbable, monofilament suture in an interrupted pattern. After anastomosis, antibiotic ointment is applied to the area, followed by replacement of the viable tissue back into the sheath. As a precaution, a purse-string suture is placed around the preputial orifice as described earlier. Concurrent removal of the preputial diverticulum should be considered to avoid potential complications associated with prepuce resection or amputation. Postoperatively, 4 to 6 weeks of sexual rest is recommended.

PREPUTIAL DIVERTICULECTOMY

The preputial diverticulum is a bilobed sac located on the dorsal wall of the preputial cavity (see Fig. 94-1). Removal of the preputial diverticulum is warranted to alleviate ulceration and bleeding of the diverticulum; to prevent diverticulitis and abscessation in boars with an enlarged prepuce (i.e., "urine pocket"); to remedy reduced breeding performance due to entrapment of the penis in the diverticulum during attempts at copulation (i.e., "balling up"); and to minimize urine dribbling and odor from the sheath of pot-bellied pigs kept as pets (so-called removal of the scent gland). Preputial diverticulectomy also can be used, albeit uncommonly, to aid in reducing bacterial contamination of semen in boars for use in artificial insemination programs.

Two surgical approaches have been described to excise the preputial diverticulum in swine.[4,5] Both require general anesthesia. In the first approach, the anesthetized animal is placed in either left or right lateral recumbency. The prepuce, including the diverticulum, is flushed with a 2% povidone-iodine solution. While flushing the prepuce and diverticulum, the surgeon can easily visualize the area of the prepuce to prepare for surgery. After surgical preparation of the area, the prepuce and diverticulum are filled and left distended with the disinfectant solution. A skin incision is made on the lateral surface of the prepuce approximately 5 cm caudodorsal to the preputial orifice and is extended caudally along the length and greater curvature of the distended diverticulum (usually 5 to 8 cm). The incision is continued through the subcutaneous tissue and the cranial preputial muscles, with particular caution observed in cutting through the muscles tightly affixed to the diverticulum wall. The thin muscle layer is bluntly dissected away from the fluid-filled diverticulum wall; gauze sponges may be helpful to provide a firm grasp of the thin tissues during dissection. After the most immediate sac has been dissected free, blunt dissection is continued across the top of the diverticulum, directed toward the remaining lateral sac. At the median septum between lobes, the superficial caudal epigastric vessels and supportive connective tissue are encountered. Blunt dissection is performed under these structures and around the remaining sac. Once dissection is complete, the distended diverticulum should be freely movable, with its point of attachment (i.e., neck) to the preputial vestibule. Using a 1 absorbable suture, a purse-string suture is placed around the neck opening but not tightened. The fluid-filled diverticulum is expressed; then, using the fingers, each sac is inverted through the neck of the diverticulum and out the preputial orifice. After sac inversion, the purse-string suture is tightened to reduce the remaining neck opening, and the inverted diverticulum is transected free at the neck. A continuous suture pattern is employed using an absorbable 1-0 or 0-0 suture to eliminate the cavity created by the removal of the diverticulum and to stabilize the cranial prepuce. The skin incision is then closed using a 1 nonabsorbable suture in a Ford interlocking or other supportive pattern. Alternatively, a subcuticular or subcutaneous pattern using an absorbable suture can be used.

A second approach involves using a curved forceps inserted through the preputial orifice to radically dissect the diverticulum and associated tissues, followed by exteriorization of the dissected tissues through the preputial orifice. After complete eversion, an absorbable mattress suture is placed around the diverticulum neck, and the diverticulum is excised. The remaining stump is allowed to retract back through the sheath orifice.

VASECTOMIZATION

Bilateral vasectomy[1,6] commonly is used to sterilize boars. Boars chosen to undergo vasectomy usually are postpubertal, with evidence of good libido. General anesthesia is required. A common surgical approach involves placing the anesthetized boar in dorsal recumbency and securing the legs to allow for easy access to the inguinal area. An area of skin on each side of the sheath extending back toward the scrotum is clipped and prepared for aseptic surgery. A 4- to 6-cm paramedian incision (2 to 4 cm lateral to the penis and 5 to 10 cm cranial to the scrotum) is made caudal to each superficial inguinal ring. Using blunt dissection, the spermatic cord is isolated within the common vaginal tunic and exteriorized (Fig. 96-2). The tunic is incised to expose the closely associated ductus deferens, nerves, vessels, and lymphatics. A 3- to 4-cm segment of the ductus deferens is then ligated using an absorbable suture, and a portion is resected between the ligatures. The common vaginal tunic is then closed using 2-0 absorbable suture, followed by closure of the subcutaneous tissue. The skin is then closed using an absorbable (0) suture in a subcuticular pattern. The same procedure is repeated on the other side.

An alternative approach for vasectomizing boars has been recently developed. The benefit of this approach is that the ductus deferens is easily isolated before incorporation into the spermatic cord, thereby eliminating the chance for damage to associated neurovascular structures that are essential to testicular viability. Additionally, this approach is performed with the boar positioned in lateral recumbency, reducing the anesthetic risk in pigs associated with use of dorsal recumbency. Under general anesthesia, the boar is positioned in either left or right lateral recumbency. The perineal and scrotal regions are surgically prepared. With the testes and scrotum left in their natural position, a longitudinal 2- to 3-cm skin incision is made parallel to the long axis of each testis, starting 1 to 2 cm off the medial septum and 3 to 4 cm medial to the abutment of the cauda epididymidis and capital extremity of the testis and extending caudally (Fig. 96-3). The incision is deepened through the tunica dartos muscle and parietal vaginal tunic, allowing entrance into the vaginal cavity. Entrance into the vaginal cavity is identified by examining the outer surface of the testis, which will have a glistening appearance and prominent vasculature. The ductus deferens, incorporated in the loosely attached mesoductus deferens, is located on the craniomedial surface of the testis. To exteriorize the ductus deferens, a closed Allis forceps is inserted into the

Fig. 96-2 Exteriorized spermatic cord in a dorsally recumbent boar.

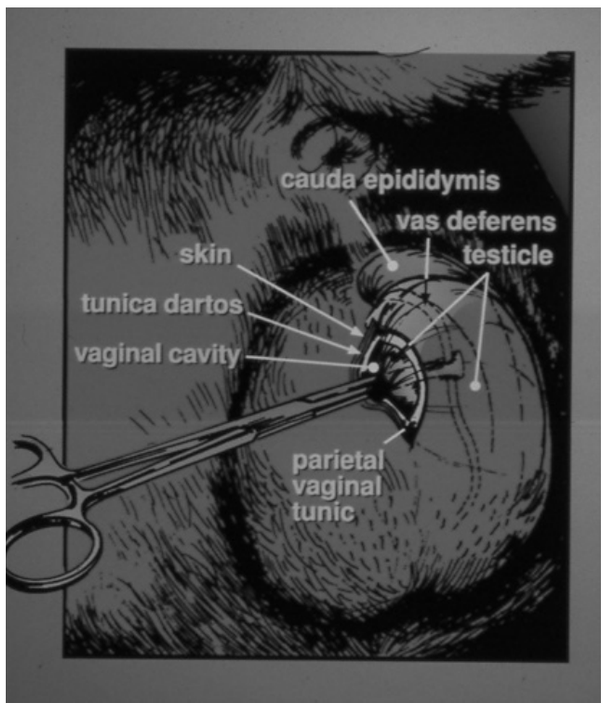

Fig. 96-3 Incision site and position of the ductus deferens in situ for scrotal approach vasectomy. Note the proper placement of the Allis forceps for use in exteriorizing the ductus deferens. (From Althouse GC, Evans LE: Removal of the caudae epididymidis to create infertile boars for use in estrus detection programs. *J Am Vet Med Assoc* 1997;201:676.)

vaginal cavity and directed toward the craniomedial surface of the testis in a slightly open position (Fig. 96-3); then the forceps is closed and the incorporated tissue is exteriorized through the incision site. The ductus deferens is bluntly dissected from the mesoductus deferens. A section of the ductus deferens is then resected between ligatures that have been placed approximately 2 to 3 cm apart. Deeper tissues need not be sutured. The skin incision is closed with 2-0 absorbable suture in a subcuticular or subcutaneous pattern. Alternatively, if the boar will be housed alone, skin closure can be performed using an exposed suture pattern with 0 monofilament, nonabsorbable suture material. The procedure is then repeated on the opposite testis. Antibiotic or antiseptic products, or both, can be applied to the area but are usually not necessary if a clean surgical technique was utilized.

EPIDIDYMECTOMY

Epididymectomy,[7] or surgical removal of the caudae epididymidis, is a simple procedure for creating sterile boars for use in estrus detection programs. This procedure usually is performed on the nonanesthetized neonate pig (1 to 2 weeks of age) in lieu of surgical castration. Chemical restraint may be necessary depending on the boar's size. The neonate pig can be restrained by grasping the hindlimbs, to allow easy access to the scrotum. Owing to the delicacy of the operation, a separate handler often is helpful for physically restraining the boar, allowing the surgeon to have both hands free to perform the operation. The nonpendulous scrotum and perineal area are prepared for surgery using standard techniques. Next, a free finger is used to push on the base of the scrotum, forcing the testes toward the dorsal portion of the scrotum. The cauda epididymidis is located on the dorsal pole (capital extremity) of each testis (Fig. 96-4). A 1- to 2-cm incision is made with a rounded (e.g., No. 20) scalpel blade through the skin directly over the greater curvature of the cauda epididymidis. With constant pressure applied at the base of the scrotum to stabilize the testis and cauda epididymidis, the incision is deepened further, through the tunica dartos muscle and parietal vaginal tunic. The incision through the parietal vaginal tunic should be long enough to allow the cauda epididymidis to be exteriorized but not too wide to allow exteriorization of the testis (Fig. 96-5). Complete exteriorization of the cauda epididymidis is done through the application of pressure at the base of the scrotum or with the use of thumb or Allis tissue forceps. The entire cauda epididymidis is transected free from its ligamentous attachment to the testis and corpus epididymidis using either scissors or a scalpel blade. Care should be taken to ensure that testicular parenchyma is not transected. After the cauda epididymidis is excised, pressure is released from the base of the scrotum, allowing the testicle to return to its normal position in the vaginal cavity. The procedure is repeated on the other testis.

Suturing of the small incisions made through the skin and deeper tissues generally is not required, because the weight of the testes in the scrotum provides for appropriate apposition and subsequent healing of the incision sites. Antibiotics or antiseptic products can be applied to incision sites but usually are not necessary if a clean surgical technique was utilized.

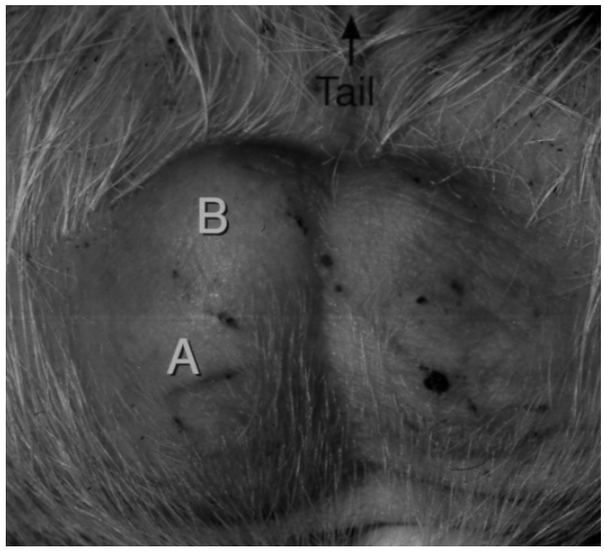

Fig. 96-4 Scrotum of a neonatal boar showing orientation of the left testis **(A)** and the cauda epididymidis **(B).** Notice that pressure applied to the base of the scrotum enhanced the outline of the cauda epididymidis in the dorsal aspect of the scrotum. (From Althouse GC, Evans LE: Removal of the caudae epididymidis to create infertile boars for use in estrus detection programs. *J Am Vet Med Assoc* 1997;210:678.)

Fig. 96-5 A correctly exteriorized cauda epididymidis ready for transection. The testis is allowed to remain in situ.

CASTRATION

In many parts of the world, bilateral castration is routinely practiced on young pigs destined for market, to curtail "boar taint" of the meat. In commercial production, castration is normally performed by the producer on pigs younger than 2 weeks of age. Using physical

restraint, a longitudinal incision approximately 1 cm long is made through the skin and into the testis using a No. 12 scalpel blade; this incisional depth allows for the testis to "pop out" through the incision. Once exteriorized, the testis is grasped and pulled in such a manner as to separate the cord while minimizing placement of lateral pressure on the inguinal rings.

In certain circumstances, clinicians may be required to perform unilateral or bilateral castration. For larger boars, some form of anesthesia is required. Along with the anesthetic protocols outlined earlier in the chapter, other acceptable anesthetic protocols that have been used in performing castration include lumbosacral epidural block with 2% lidocaine (1 ml/9 kg of body weight) and intratesticular injection of a 30% solution of pentobarbital (1 ml/7 kg of body weight).

The anesthetized boar is placed in lateral recumbency, and the scrotum and perineum are aseptically prepared. An incision (large enough to exteriorize the testis) is made through the scrotum starting at its most ventral aspect, its depth dictated by whether an open or a closed castration technique is performed. For boars with very thick scrotal skin, it may be advantageous to make a stab incision through the scrotum and then lengthen the incision from the inside out. In the preferred closed technique, the testis and vaginal tunic are dissected free and exteriorized. The testis and tunic are then twisted to occlude the spermatic cord up to the level of the external inguinal ring. At this point, either two transfixation ligatures (no. 1 absorbable) are applied to the cord, followed by transection distal to the last ligature, or an emasculator is used to crush and sever the cord at the level of the external inguinal ring.

The open castration technique consists of carrying the incision all the way through and into the testis. The testis and its vascular structures are exteriorized, followed by occlusion of the vascular supply by twisting the cord up to the inguinal ring; either transfixation ligatures and/or an emasculator is used as described earlier with the closed technique. With the open technique, everted tissues (e.g., tunic) must be ablated. For bilateral castration, the medial septum often is excised as well. If asepsis is maintained, the incision site can be closed using an absorbable suture in a subcuticular or subcutaneous continuous pattern. If the boar is housed alone, skin closure can be performed using a monofilament, nonabsorbable suture material in an exposed suture pattern. Suture placement should allow for adequate drainage at the ventral commissure of the incision. In cases in which sepsis is a possibility, the surgical wound can be left open to allow for drainage and left for healing by second intention. Systemic antibiotics should be administered for 3 to 5 days after surgery.

From an economic standpoint, surgical correction of cryptorchidism in the boar is rarely performed. Generally, cryptorchid boars are left completely intact so that they may be later identified at market weight and segregated from penmates at slaughter. Producers are offered less money for intact boars at slaughter, encouraging prudent identification and elimination of breeding stock that carry this undesirable genetic trait.

REPAIR OF TESTICULAR/ SCROTAL INJURIES

Testicular injuries tend to be of traumatic origin and generally are unilateral. Systemically spread infectious agents (e.g., *Brucella suis* or opportunistic pathogens) can elicit an orchitis and/or epididymidis. Testicular and peritesticular injuries constitute an emergency and should be promptly recognized, diagnosed, and treated. Proper diagnosis of the enlargement (e.g., orchitis, periorchitis, hydrocele, hematocele, seroma, hematoma) will aid in determining whether medical or surgical therapy is necessary. Digital palpation along with B-mode ultrasonography has been very helpful for obtaining the information necessary to arrive at a tentative diagnosis. Medical treatment usually consists of aggressive hydrotherapy, anti-inflammatory drugs, diuretics, and, if indicated, antibiotic therapy. If no improvement in the condition is observed over a 5-day course of treatment, surgical drainage or unilateral castration (see earlier) is recommended.

The scrotum has excellent regenerative capabilities. Because of this ability, cleansing the involved area with an antiseptic solution and wet-to-dry dressings usually constitute the only treatment that is necessary. Deep lacerations may benefit from débridement and placement of subcuticular sutures of an absorbable monofilament. If wound sepsis is suspected, open drainage along with systemic or local antibiotics, or both, is indicated.

CHAPTER 97

Artificial Insemination in Swine: Boar Stud Management

GARY C. ALTHOUSE

DISEASE CONTROL

Control of the introduction of pathogenic organisms into a boar stud operation cannot be overemphasized. Disease control not only is important for overall boar stud health and viability, but also is critical to minimizing the chance of disease transmission to other herds through the extended semen. Disease control consists of the following components: biosecurity, isolation, acclimatization, recovery, and monitoring.

Biosecurity should start with appropriate selection of stud and isolation site locations in order to physically assist in minimizing disease transmission between livestock facilities. Facility environment should be controlled to protect boars from the outside environment. Mandatory restrictions in the movement of animals, personnel, equipment, supplies, and sanitation protocols also are key components in a biosecurity program.

Selection of incoming boar source(s) should be dependent on health status equal to or better than that of the recipient boar stud group. **Isolation** procedures should be utilized on all boars before their introduction to the stud group to protect the recipient stud from the potential introduction of infectious agents that could cause economic distress. Isolation should be off site and away from any other pigs. Animal movement into and out of isolation should be handled in an all in–all out fashion. During isolation, boars should be monitored for signs of, or exposure to, disease through the strategic use of paired serologic tests and daily observation for coughing, sneezing, changes in consistency or amount of feces, decreased appetite or water consumption, skin lesions, lameness, or lethargy.

Acclimatization is used to prepare the replacement boars for the impending challenge of pathogens endemic to the recipient herd and to pathogens being controlled by the stud. Acclimatization starts immediately after isolation and consists of a controlled challenge to these select pathogens to stimulate but not overwhelm the immune system of the isolated boars. Exposure usually is provided through vaccination and direct exposure to young cull boars and their products. Clinical observation and serologic testing should be performed to confirm success of exposure.

The **recovery** phase is provided after acclimatization to allow the isolated boars time to build protective immunity to the controlled, exposed pathogens away from the resident herd. The recovery period also serves to reduce the risk of disease spread to the main stud from new boars still shedding pathogens. The length of time accorded to isolation, acclimatization, and recovery should be dictated by the pathogens that the boar stud operator is trying to control; in general, time periods range from 30 to 90 days.

Once the boar has been moved to the resident stud group, regular **monitoring** of the group should be performed. Monitoring is done through the use of serologic profiling (monthly or quarterly), daily observations of the resident boars, and temporal analysis of semen findings and stud production records.

BOAR HOUSING

Today's boar stud facilities are designed to ensure animal well-being, personnel safety, and ease of movement and handling of boars. Alley width is limited, to allow a boar to freely move in the forward direction but not turn on the handler. To aid in moving the boar into and out of his stall, stalls usually incorporate both vertical entrance and exit gates. Pen partitions are of either solid or open panel design, with vertical bars on open panels to aid in deterring animals from climbing up the panel. For boar movement and cleaning ease, gates, partitions, and panels should be around 1.2 m in height, with a floor clearance of approximately 10 cm. To accommodate variation in boar size (due to their different ages and genetics), stalls of differing sizes usually are included within the same facility.

Nonslip flooring is used in the housing area. Both solid and slotted flooring, either alone or in combination, have been used in boar stud facilities. Solid flooring in the boar housing area requires the use of bedding (e.g., straw, wood shavings) to keep the area and animal dry. Slotted flooring, the most common type of flooring in modern swine facilities, incorporates space between cement slats that allows for the free passage of waste into a pit. Passage of urine and feces into a pit minimizes soiling of the animal and eliminates the need for bedding. From a hygienic standpoint, total slotted floors are preferable to either solid or a combined slotted/solid floor for housing boars.

Semen collection should be performed in a pen specifically designed for this task. Because personnel are operating close to the boar, the pen should be designed to allow multiple escape sites out of the pen if the boar becomes aggressive. Two or three of the perimeter walls should be constructed using a 5-cm-outer-diameter (OD)

Fig. 97-1 Porcine semen collection area and dummy.

galvanized pipe. This pipe should be approximately 1 m in height and placed at 0.3-m intervals on center. The height and the space (approximately 0.25 m) between pipes should allow personnel to easily enter and exit the collection area without having to open or close gates but restrict the boar to the pen area. Collection pens should be 1.8 to 2.4 m in width and 2.4 to 2.75 m in length. A stable collection dummy (Fig. 97-1) should be placed in the collection pen. Added features of collection dummies may include capability for height adjustment and some type of support on the sides of the dummy that allow the boar to stabilize his front legs during mounting and thrusting. It is paramount that a nonslip surface be provided around the dummy so that the boar has secure footing during mounting and thrusting. It may be helpful to position the collection dummy in a corner of the pen or with one end against the wall so that the boar can easily be directed and maintained around the dummy. The pen and the collection dummy should be situated away from boars and other distractions that would divert the boar's attention away from the collection dummy. Some stud operators design their facilities to include a pen—commonly called a "warm-up" pen—that is in close proximity to the semen collection pen. This pen is used to queue a boar so that he observes and hears the actions of another boar in the collection pen; these stimuli frequently help to excite the boar, so that when he is moved into the semen collection pen, reaction time to mount of the dummy sow is minimal, and semen collection can be accomplished more efficiently.

BOAR NUTRITION

Traditionally, nutritional needs for boars were thought to be similar to those for gestating sows. The goal of these traditional programs was to provide boars with adequate caloric intake to meet their maintenance requirements, while minimizing weight gain. Under natural mating conditions, minimizing the weight gain of boars was critical to their length of usefulness in the herd, because gilts and sows have finite physical limitations on the amount of weight they can bear by the boar during the mating process. Once boars became too heavy, they were culled. This simple approach to defining boar feeding programs is still applicable for boars used under natural mating conditions. In today's global swine industry, however, artificial insemination (AI) has taken over in many breeding programs. With this change, the traditional feeding strategy does not appear to meet the nutritional needs of an AI boar, for which productivity is measured through sperm production (i.e., number of extended semen doses/ejaculate) rather than servicing capabilities.

Much early work addressed the effects of restricted nutrient intake on boar reproductive performance. Restrictions or deficiencies in protein,[1,2] energy,[2] and certain vitamins and minerals[3,4] have been shown to negatively affect boar reproductive performance. Conversely, overfeeding and excess body conditioning also can have a negative impact on boar reproduction. Ideally, adequate nutrition should be provided to active boars to meet their requirements for maintenance, growth, breeding activity, and sperm production. In general, feed intake is adequate in young (<16 months) boars if they show moderate (400 g/day) weight gains, and in mature boars if they show slight (200 g/day) weight gains. In practice, body condition scoring most often is used as an indicator of health and adequate feed intake. Depending on genetics and structural conformation, a body condition score of 3 to 3.5 (on a scale of 1 to 5) is a desirable target. To obtain a more objective assessment, backfat monitoring by means of B-mode ultrasonography also is being used to monitor boar body condition.

Feed constituents for boar diets vary widely and usually are dictated by local availability. Cost has become less important than with other swine diets because the boar ration is fed to only a small but valuable number of animals in a herd. A typical ration used in an AI boar stud operation contains approximately 3000 metabolizable energy (ME) kcal/kg, 16% to 18% crude protein (0.85% lysine), 4% fat, and 5% fiber.[5] Generally, a boar will consume 1.5 to 3.0 kg of this ration on a daily basis. Daily allowances may be modified according to season and environmental conditions. Thermoneutrality for the boar is approximately 20° C.[6] If temperatures fall below 20° C, the amount of feed provided to boars should be increased by 0.08 kg/day for every 1° C decrease. During periods of warmer ambient temperatures, it is not advisable to decrease feed amount, because this may lead to an unbalanced diet. Instead, energy density of the diet may be reduced to decrease body heat production but still maintain the ration's balance. Nutritional supplements such as certain vitamins, minerals, and fatty acids have been advocated as aids for improving or maintaining boar semen quality and quantity under stressful environmental or nutritional conditions; further research is warranted.

On some farms it is not feasible to have a separate diet and storage area for the small number of AI boars housed on the property. To address this problem, supplements that contain high levels of certain nutrients are available that can be top-dressed onto feed used in gestation or lactation diets.

BOAR TRAINING

When the boar is introduced to the semen collection area, sufficient time should be allowed for the animal to investigate and become comfortable with the surroundings. Patience is required in training boars for semen collection using a mounting dummy. Prior exposure of naive boars to the semen collection process by allowing them to observe, in an adjacent pen, a boar having semen collected often can be helpful. After the boar identifies the stationary dummy, some animals will readily mount it and begin to thrust, whereas others may need to be gently directed toward the dummy. Once the boar shows interest in the dummy, he is quietly approached from the rear or side (behind the shoulder). During this time, sudden movements, loud noises, and moving into and out of the boar's visual field should be avoided, to minimize the chance of startling the boar. To stimulate thrusting and exteriorization of the penis, the assistant gently reaches around and massages the boar's prepuce. Once the penis is exteriorized, digital pressure is applied to the spiral-shaped glans penis. If properly stimulated, the boar will fully extend his penis. Once it is extended, thrusting will cease and ejaculation will commence.

Training periods should be limited to no more than a single 15-minute interval once daily. Daily training periods should be provided until semen collection is successful. After a successful event, reinforcement training of the semen collection process should be provided on at least 2 consecutive days before resting the boar or placement into a regular collection schedule.

SEMEN COLLECTION

Contamination should be minimized when semen is being collected for use in an AI breeding program[7] (Box 97-1). Application of digital pressure to the penis using the gloved hand technique is the most popular method for collecting boar semen. Nonspermicidal gloves (e.g., vinyl, nitrile) should be used by the semen collector; some glove materials (e.g., latex) have been found to be spermicidal in this species.[8] The semen collector should place two gloves on the collecting hand. After the boar has mounted the collection dummy and has commenced thrusting, the collector reaches underneath the boar and massages the sheath. Sheath massage will allow for evacuation of contaminant preputial fluids and aid in exteriorizing the penis. After the penis is exteriorized, the top glove is discarded. Holding the semen collection container (e.g., a prewarmed, insulated thermos or Styrofoam cup with a filter over the opening) in the free, ungloved hand, the collector then kneels down and grasps the boar's corkscrew-shaped glans penis with the gloved hand. Constant pressure is applied to the glans penis with the fingers, so that the glans penis is "locked" in the hand; this grasp mimics the cervical lock that occurs during natural mating. Pressure applied elsewhere on the penis may elicit a negative response. If adequate pressure is applied, the boar will respond positively by fully extending his penis.

Ejaculation begins with emission of the presperm fraction (i.e., the first few jets of an ejaculate); this fraction is not collected. Sperm-rich and sperm-poor fractions are next emitted and the fraction(s) collected. Gel components, originating from the bulbourethral gland, normally are emitted in conjunction with the sperm-poor fraction. The gel fraction is of little value when semen is to be used in an AI program and is therefore separated from the fluid portion of the ejaculate by filter or gauze over the opening of the semen collection vessel. Once the boar has completed ejaculation, the raw ejaculate is protected from chemical (e.g., water, soap residues, alcohol), thermal (hot or cold), and light (i.e., ultraviolet) insults.

Box **97-1**

Techniques for Minimizing Contamination in Swine Semen Collection/Processing for Artificial Insemination

Boar Preparation/Semen Collection

1. Trimming of hair around the preputial opening
2. Use of double gloves, with the outer glove discarded after preparation of the boar, allowing for a clean gloved hand for grasping the penis
3. Using disposable vinyl gloves or hand disinfectant to reduce risk of cross-contamination between boars
4. Cleansing preputial opening and surrounding area (if needed) with a single-use disposable wipe
5. Manually evacuating preputial fluids before penis is grasped for semen collection
6. Holding penis perpendicular to the boar to minimize contamination of semen collection vessel with preputial fluid
7. Diverting initial jets of ejaculate (i.e., presperm fraction) and final gel fraction from the semen collection vessel
8. Disposing of rubber band and filter/gauze before the collected semen is sent to the laboratory for further processing

Semen Processing/Laboratory Sanitation

1. Using disposable products when economically feasible
2. Cleaning reusable laboratory materials (i.e., glassware, plasticware, plastic tubing, containers, and so on) that cannot be heat/gas sterilized or boiled, with a laboratory-grade detergent (residue-free), followed by multiple rinsings in distilled water and then in 70% alcohol (nondenatured), with sufficient ventilation for complete evaporation of residual alcohol
3. Rinsing reusables with semen extender before their first use of the day
4. Disinfecting countertops and equipment at the end of each processing day with a residue-free detergent
5. Mopping the floor at the end of the day with a disinfectant (e.g., phenolic, formalin product)
6. Breaking down bulk products into smaller, daily-use quantities
7. Installing ultraviolet lighting to aid in sanitizing reusables and laboratory surfaces
8. Using proper safety precautions to protect personnel from exposure

It is important to maintain the boar on a routine semen collection schedule. Both overusage and underusage of an AI boar may have a negative impact on herd fertility. Suggested guidelines for boar usage are presented in Table 94-1.

SEMEN EVALUATION

From a physiologic standpoint, several attributes appear to be necessary for a spermatozoon to fertilize an oocyte (Box 97-2). Because these necessary attributes are multiple and complex, it is easy to understand that a test of any single one of these attributes would, and does, correlate poorly with overall fertility. Ideally, determination of semen quality would consist of a test that examines all of these attributes. Unfortunately, a practical and simple in vitro test that can be routinely performed before ejaculate processing to determine the quality (e.g., fertility potential) of an ejaculate has yet to be developed. Several in vitro tests are available, however, that can examine selected attributes of sperm necessary for natural fertilization. Although individually these tests have limited usefulness in determining fertility potential, collectively they do have the ability of screening out overtly poor-quality semen.

Good-quality boar semen is essential to satisfactory herd fecundity rates. Accordingly, most progressive boar stud operations routinely assess every ejaculate collected at their facilities. Standard tests in evaluating boar semen include the cursory examination of color and odor, with more detailed analysis of sperm motility, sperm morphology, sperm concentration, volume, and total sperm numbers. Suggested indicators of quality for freshly collected boar semen to be processed and used for AI are indicated in Table 97-1.

After collection, the ejaculate should be visually assessed for color. A normal ejaculate will be gray-white to white in color and have a milky opacity. If the ejaculate exhibits abnormal color (e.g., brown, yellow, red) or a strong urine odor, contamination should be suspected. Since many of these contaminants exhibit spermicidal activity, these ejaculates should be discarded.

Sperm motility should be evaluated. The percentage of motile spermatozoa usually is determined using microscopic analysis. Accuracy of this subjective assessment is highly dependent on sample preparation, microscope quality, technician experience, and natural ability. To minimize the effects of human error, sample preparation and microscopic assessment should be standardized. The most common technique is to place a 7- to 10-µl sample of semen on a warmed (37° C) microscope slide, overlaid with a coverslip. When viewed under a microscope, the sample should appear as a monolayer of cells within which individual sperm motility is easily visualized. In some instances, neat semen may be too highly concentrated to be assessed without first diluting the sample with an equal-sized drop of a isothermal diluent before overlaying with a coverslip. Sperm motility is estimated to the nearest 5% by viewing sperm activity in at least four different fields on the slide at 200× or 400× magnification and then taking the average of these readings to obtain the final motility estimate. Sperm motility and viability normally decrease during storage; therefore, ejaculates should exhibit at least 70% to 80% gross motility to be considered for further processing.

Once sperm motility is determined, morphology should be evaluated. In the swine industry, both wet-mount and dry-mount preparations are used for objective quantitation of sperm morphologic abnormalities. With wet-mount preparations, sperm should be immobilized using a buffered formalin or glutaraldehyde solution. Wet-mount slides are then examined with microscopes that provide their own internal contrast (e.g., phase or differential interference contrast). A variety of contrast stains are used for morphologic study of boar sperm using dry-mounted slides. Proper contrast stains accentuate the outline of the sperm, allowing for easier visualization and identification of normal and abnormal sperm under the light microscope. To make a stained slide, equal volumes (e.g., 7–10 µl) of stain and sample are applied adjacently to a microscope slide. The drops are gently mixed together using the edge of a second slide. The edge of the second slide is then used to draw the mixture across the slide to produce a thin layer, which is allow to air dry. Under oil immersion, sperm morphology is assessed. For both wet- and dry-mount techniques, a minimum of 100 sperm should be morphologically assessed and categorized. Normal boar ejaculates generally exhibit less than 15% to 20% abnormal sperm.[9,10]

Box **97-2**

Sperm Attributes Necessary for Oocyte Fertilization

- Progressive motility
- Acceptable morphology
- Ability to undergo capacitation (i.e., plasma membrane modifications)
- Ability to undergo acrosome reaction (i.e., vesiculation/exocytosis)
- Ability to penetrate cumulus investments
- Ability to bind and penetrate the zona pellucida
- Sperm-oocyte plasma membrane fusion

Table **97-1**

Minimum Requirements for Use of Fresh Boar Semen for Artificial Insemination

Semen Variable	Descriptor/Value
Appearance	Milky to creamy consistency
Color	Gray-white to white
Gross motility (unextended)	≥70 % (if used ≤ 48 hr) ≥80% (if used ≥72 hr)
Abnormal morphology	≤25%*
Cytoplasmic droplets†	≤15%

*The 25% maximum includes cytoplasmic droplets.
†Includes proximal and distal cytoplasmic droplets.

The next step in ejaculate evaluation is determination of sperm concentration. The most common method of determining sperm concentration in gel-free boar semen is by measuring the degree of sample opacity using a photometer. In boar semen, opacity is dependent on the number of sperm cells and other seminal plasma components that interfere with the transmission of light through the sample. Boar semen normally is too opaque for light to pass readily through it; therefore, a small sample of boar semen is diluted into an isotonic solution before obtaining a measurement. For photometric measurement to be relatively accurate, it is essential that the instrument calibration be species specific. Additionally, owing to inherent differences between photometers, conversion charts should not be interchanged between instruments. Inaccuracies in photometric measurements can occur if readings fall outside the optimal operating range of the equipment or may be due to human error (e.g., incorrect dilutions, improper warm-up time, solution mishandling, delayed reading); moreover, innate differences commonly are found between boar ejaculates. Manufacturer recommendations should be followed.

Sperm concentration in boar semen also can be determined using a dilution apparatus and a counting chamber, although this is uncommon. A portion of the neat semen is first diluted 1:200 using a sperm-immobilizing, isotonic solution. This mixture is then charged onto each chamber of the hemacytometer. After 5 minutes, to allow sperm to settle onto the grid surface, the hemacytometer is placed under a microscope at 200× to 400× magnification for sperm counting. A minimum of 5 large (80 small) squares are counted in the center (RBC) grid on each side of the hemacytometer. Only sperm heads (i.e., not tails) touching the top and left lines of the large square are included in the count; those touching the bottom or right lines are not counted. The two counts are then averaged if they are within 10% of each other. If the two counts vary by more than 10%, the counts are thrown out, and the hemacytometer is again prepared and the two side counts repeated until the counts are within 10% of each other. This number *(N)* is then inserted into the formula supplied by the distributor of the hemacytometer at a 1:200 dilution to determine the number of sperm cells per milliliter of semen. The time required for hemacytometric counts, combined with their tediousness, makes them impractical for most AI laboratories. Photometric analysis remains the most commonly used technique for determining sperm concentration per milliliter of gel-free ejaculate.

Sperm concentration is next used to determine total sperm numbers in the ejaculate. Total sperm numbers are calculated by multiplying the total gel-free ejaculate volume with the sperm concentration. Ejaculate volume usually is determined by weighing the ejaculate, with the assumption that 1 g is equal to 1 ml.

Computer-automated semen analysis systems specific for the swine industry have been recently introduced. In addition to performing sperm motility and concentration assessment, these systems also come with software to assess sperm morphology. With technician input, these computerized systems have the ability to grade an ejaculate, calculate total sperm numbers, and determine the amount of diluent to add to the ejaculate to achieve the desired sperm per dose. Because of their speed of semen assessment and increased accuracy over existing methods, several large, high-volume stud operations have implemented use of this equipment.

Several other tests have been promoted for assessing boar semen quality and include various sperm-binding assays, hypo-osmotic swelling test, osmotic resistance test, selected biochemical assays of sperm and seminal plasma, and fluorophore assays. These tests can assess factors associated with sperm or the ejaculate other than those gained through routine assessment of sperm motility, morphology, and concentration. Because of the time, tedium, or expense involved in performing these tests, their routine use in boar stud operations has been limited to date.

SEMEN PROCESSING

Porcine semen extenders are readily available from many commercial vendors. Depending on the extender chosen, extended boar semen can be stored for up to 6 days with no appreciable loss in fertility potential.[11] Most recently, semen extenders purported to maintain sperm viability for up to 10 days are being marketed; field fertility trials, however, are equivocal at this time. In general, most commercial farms use extended boar semen within 3 to 4 days of processing. A majority of semen extenders come in powdered form and are reconstituted using purified (NCCLS/CAP Reagent Grade Type I or II) water. Reconstituted semen extender should be incubated at 37°C for 45 to 60 minutes to allow pH equilibration before use with semen.
