CURRENT THERAPY IN LARGE ANIMAL THERIOGENOLOGY, SECOND EDITION
ISBN 13: 978-0-7216-9323-1
ISBN 10: 0-7216-9323-7

Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Editors assumes any liability for any injury and/or damage to persons or property arising out or related to any use of the material contained in this book.

ISBN 13: 978-0-7216-9323-1
ISBN 10: 0-7216-9323-7

Publishing Director: Linda Duncan
Senior Editor: Penny Rudolph
Managing Editor: Teri Merchant
Publishing Services Manager: Patricia Tannian
Project Manager: John Casey
Senior Book Designer: Teresa McBryan

Contributors

Gregg P. Adams, DVM, MS, PhD, Diplomate ACT
Professor, Veterinary Biomedical Sciences
Western College of Veterinary Medicine
University of Saskatchewan, Saskatoon, Saskatchewan, Canada
Reproductive Anatomy and Life Cycle of the Male and Female Llama and Alpaca
Semen Collection and Artificial Insemination in Llamas
Ovarian Function in Llamas and Alpacas
Pregnancy Diagnosis in Llamas and Alpacas
Embryo Technologies in South American Camelids

Bruce Abbitt, DVM, MS, Diplomate ACT
Pathologist
Texas Veterinary Medical Diagnostic Laboratory
College Station, Texas
Protozoal Abortion in Cattle

Glen W. Almond, DVM, MSc, PhD
Professor, Pig Health and Production
Population Health and Pathobiology
College of Veterinary Medicine
North Carolina State University, Raleigh, North Carolina
Clinical Examination of Female Reproductive Organs
Diagnosis of Pregnancy
Infertility Associated with Abnormalities of the Estrous Cycle and the Ovaries

Gary C. Althouse, DVM, MS, PhD, Diplomate ACT
Professor and Chief
Section of Reproductive Department of Clinical Studies
School of Veterinary Medicine, New Bolton Center,
University of Pennsylvania, Kennett Square, Pennsylvania
Reproductive Physiology and Endocrinology of Boars
Infectious and Noninfectious Causes of Infertility in Boars
Reproductive Surgery in the Boar
Artificial Insemination in Swine: Boar Stud Management

Sandra F. Amass, DVM, PhD, Diplomate ABVP
Assistant Professor of Swine Production Medicine
Department of Veterinary Clinical Sciences
School of Veterinary Medicine
Purdue University, West Lafayette, Indiana
Postpartum Care of the Sow and Neonates

Mark L. Anderson, DVM, PhD
Professor of Clinical Diagnostic Pathology
California Animal Health and Food Safety Laboratory
School of Veterinary Medicine
University of California, Davis, California
Epizootic Bovine Abortion (Foothill Abortion)

Geoffrey William Asher, BSc, MSc, PhD
Senior Scientist, AgResearch Limited
Invermay Agricultural Centre, Mosgiel, New Zealand
Reproductive Cycles in Female Cervids
Reproductive Behavior of Red Deer and Wapiti

Sandra L. Ayres, DVM, MA, Diplomate ACT
Assistant Professor
Department of Biomedical Sciences
School of Veterinary Medicine
Tufts University, North Grafton, Massachusetts
Reproductive Health Program

Peter B. Bahnson, DVM, PhD
Faculty, College of Veterinary Medicine
University of Wisconsin, Madison, Wisconsin
Using Statistical Process Control to Investigate Reproductive Failure

Pawel M. Bartlewski, DVM, MSc, PhD
Assistant Professor, Biomedical Sciences
Ontario Veterinary College
University of Guelph, Guelph, Ontario, Canada
Clinical Reproductive Physiology of Ewes

Albert D. Barth, DVM, MVSc, Diplomate ACT
Professor, Theriogenology
Large Animal Clinical Sciences
Western College of Veterinary Medicine
University of Saskatchewan, Saskatoon, Saskatchewan, Canada
Evaluation of Potential Breeding Soundness of the Bull

Parvathi K. Basrur, CM, PhD
Professor Emeritus
Department of Biomedical Sciences
Ontario Veterinary College
University of Guelph, Guelph, Ontario, Canada
Inherited Sex Abnormalities in Goats

Fuller Bazer, PhD
Regents Fellow
Distinguished Professor and O.D. Butler Chair in Animal Science
Texas A&M University, College Station, Texas
Pregnancy Diagnosis

Nora M. Bello, VMD
Reproductive Physiology
Department of Animal Science
Michigan State University, East Lansing, Michigan
Synchronization of Ovulation Strategies in Dairy Cattle Using $PGF_{2\alpha}$ and GnRH

Jim Blackford, DVM, MS, Diplomate ACVS
Professor and Section Head
Department of Large Animal Clinical Sciences
College of Veterinary Medicine
The University of Tennessee, Knoxville, Tennessee
Surgical Correction of Abnormalities of the Female Reproductive Organs

John E. Blake, DVM, MVetSc
Veterinary Services
University of Alaska, Fairbanks, Alaska
Reindeer Reproductive Management

Robert H. BonDurant, DVM, Diplomate ACT
Professor and Chair
Department of Population Health and Reproduction
School of Veterinary Medicine
University of California at Davis, Davis, California
Epizootic Bovine Abortion (Foothill Abortion)

William Braun, Jr., DVM, Diplomate ACT
Veterinarian, Watertown, Wisconsin
Parturition and Dystocia in the Goat
Preparturient Infections and Structural Abnormalities
Noninfectious Prenatal Pregnancy Loss in the Doe
Noninfectious Infertility in the Doe
Induced Abortion and Parturition in the Goat

P. Walter Bravo, DVM, MS, PhD
Alpacas of America, Tenino, Washington
Breeding Soundness Examination of the Male Llama and Alpaca

Mike J. Bringans, BVSc, MRCVS
Arundel, Quebec, Canada
Cervid Semen Collection and Freezing
Estrous Synchronization and Artificial Insemination in Domesticated Cervids
Application of Embryo Biotechnologies in Farmed Cervids

Brian C. Buckrell, DVM, MSc, Diplomate ACT
Retired, Department of Population Medicine
Ontario Veterinary College
University of Guelph, Guelph, Ontario, Canada
Artificial Insemination and Embryo Transfer in Sheep

Marie Bulgin, DVM, MBA, Diplomate ACVM
Coordinator
Caine Veterinary Teaching Center and Idaho WOI Program
University of Idaho, Caldwell, Idaho
Diseases of the Periparturient Ewe

Claire Card, DVM, PhD, Diplomate ACT
Professor, Department of Large Animal Clinical Sciences
Western College of Veterinary Medicine
University of Saskatchewan, Saskatoon, Saskatchewan, Canada
Infectious Diseases of the Puerperal Period

Carla L. Carleton, DVM, MS, Diplomate ACT
Associate Professor of Theriogenology
College of Veterinary Medicine
Michigan State University, East Lansing, Michigan
Clinical Examination of the Nonpregnant Equine Female Reproductive Tract

Stan W. Casteel, DVM, PhD
Professor, Research Toxicology
Department of Veterinary Pathobiology
College of Veterinary Medicine and Director
Veterinary Medical Diagnostic Laboratory
University of Missouri-Columbia, Columbia, Missouri
Reproductive Toxicants

A.B. Caudle, DVM, Diplomate ACT
Caudle Veterinary Practice, Watkinsville, Georgia
Inflammation of the Tubular Reproductive Tract of the Mare
Bacterial Causes of Infertility and Abortion in the Mare

Peter J. Chenoweth, BVSc, PhD, Diplomate ACT
Professor of Veterinary Reproduction
School of Agricultural and Veterinary Sciences
Charles Sturt University, Wagga Wagga, New South Wales, Australia
Clinical Reproductive Physiology and Endocrinology of Bulls

Tracey Chenier, DVM, DVSc, Diplomate ACT
Assistant Professor, Large Animal Theriogenology
Department of Population Medicine
Ontario Veterinary College
University of Guelph, Guelph, Ontario, Canada
Physiology and Endocrinology of Stallions

Rodney A. Christmas, DVM, MS, Diplomate ACT
Technical Consultant, Elanco Animal Health
Eli Lilly and Company, Greenfield, Indiana
Ultrasound Determination of Fetal Gender

Brian D. Cleaver, PhD
Associate Director of Operations
Human Applications Laboratory
Molecular Genetics and Microbiology
University of Florida, Gainesville, Florida
Clinical Aspects of Seasonality in Mares

James E. Collins, DVM, MS, PhD, Diplomate ACVP
Professor, Veterinary Population Medicine
Director, Veterinary Diagnostic Laboratory
College of Veterinary Medicine
University of Minnesota, St. Paul, Minnesota
Using Statistical Process Control to Investigate Reproductive Failure

Jill Colloton, DVM
Owner, Bovine Services, LLC, Edgar, Wisconsin
Ultrasound Determination of Fetal Gender

Ross P. Cowart, DVM, MS
Associate Professor
Food Animal Medicine and Surgery
College of Veterinary Medicine
University of Missouri-Columbia, Columbia, Missouri
Parturition and Dystocia in Swine

Gheorghe M. Constantinescu, DVM, PhD, Drhc
Professor and Medical Illustrator
Department of Veterinary Biomedical Sciences
College of Veterinary Medicine
University of Missouri-Columbia, Columbia, Missouri
Clinical Reproductive Anatomy and Physiology of the Mare

Nancy M. Cox, MS, PhD
Associate Dean for Research
Associate Director Agriculture Experiment Station
Professor Animal Sciences, College of Agriculture
University of Kentucky, Lexington, Kentucky
Clinical Reproductive Physiology and Endocrinology of Sows: Mating Management

Wayne Cunningham, DVM, MS
Retired Colorado State Veterinarian, Gill, Colorado
Pregnancy Diagnosis

Maisie Ernestine Dawes, BSc, DVM, Diplomate ACVIM
Clinical Instructor
Veterinary Pathology and Veterinary Medicine and Surgery
College of Veterinary Medicine
University of Missouri-Columbia, Columbia, Missouri
Principles of Colostrum Feeding

Lionel J. Dawson, BVSc, MS, Diplomate ACT
Associate Professor, Veterinary Clinical Sciences
College of Veterinary Medicine
Oklahoma State University, Stillwater, Oklahoma
Clinical Examination of the Female Reproductive Tract
Manipulating the Estrous Cycle in a Doe

Stanley M. Dennis, BVSc, PhD, FRCVS, FRC Pathology, Diplomate ACT
Retired, Clinical and Population Sciences
Ross University of Veterinary Medicine
St. Kitts, West Indies
Equine Herpesvirus Infections
Equine Viral Arteritis
Fungal Abortion

Gary D. Dial, DVM, PhD, MBA
Swine Veterinarian, Williams, Iowa

Preface

This edition of *Current Therapy in Large Animal Theriogenology* is a continuation of the long-standing tradition of providing a theriogenology text that summarizes the reproductive information available for the large animal species. Included in this text are the equine, bovine, caprine, ovine, swine, camelid, and deer. The veterinary practitioner as well as students and academic clinicians will find this an excellent reference for their quest for knowledge.

Until recently, the importance of theriogenology to the veterinary practitioner was often overlooked, because their situation was usually not life threatening except perhaps for obstetrics or severe uterine infections. However, today its relevance to the livestock producer and large animal companion owner has become more significant. Owners demand more from their veterinarians with respect to technology and procedures such as embryo transfer, oocyte fertilization, semen freezing, shipped semen, timed inseminations, maintained reproductive performance, and so forth. These topics and more are addressed with the latest in pertinent information.

Veterinary students and academic clinicians will likewise find this textbook very informative and an invaluable aid in both their classroom and clinical work. The information presented for each species includes reproductive anatomy, physiology, methods of pregnancy diagnosis, breeding soundness examinations, surgical procedures, obstetrical procedures, and other theriogenology techniques that would be appropriate for various conditions.

Chapters are specifically devoted to each of the numerous species addressed herein. The material for this textbook was drawn from the expertise of many professionals for the benefit of its readers. We wish you only EXCELLENCE!

Walter R. Threlfall, DVM, MS, PhD
Theriogenologist

CHAPTER 1

Physiology and Endocrinology of Stallions

TRACEY CHENIER

ANATOMY AND PHYSIOLOGY

Normal spermatogenesis in stallions is a complex event, requiring a functional hypothalamic-pituitary-testicular (HPT) axis and a normal testicular environment capable of producing and supporting specific regulators of spermatogenesis (Fig. 1-1). Briefly, the anatomic features involved in the reproductive physiology of stallions include the pineal gland, hypothalamus, pituitary gland, and testis. For a detailed review of reproductive anatomy and spermatogenesis, the reader is referred elsewhere.[1,2]

The **pineal gland** is located between the cerebral hemispheres and lies dorsal to the pituitary gland. This gland produces the hormone melatonin in response to visual light signals it receives from the retina. In long-day breeders such as horses, an increase in duration of light exposure results in a decrease in melatonin production by the pineal gland. Melatonin is released in the greatest quantities during the hours of darkness. High levels of melatonin have the effect of lowering levels of gonadotropin-releasing hormone (GnRH), possibly through an influence of the feedback mechanisms exerted by androgens on GnRH release.[3] Located at the base of the brain, the **hypothalamus** produces GnRH in a pulsatile manner in response to a variety of stimuli. Olfactory, tactile, auditory, and visual signals alter the production of GnRH by the hypothalamus, which is transported via portal vessels to the anterior **pituitary gland.** Pulsatile secretion of GnRH stimulates the production and pulsatile release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) by the pituitary.

Within the testis, the **seminiferous tubules** of the adult stallion make up about 70% of the testicular parenchyma. The tubules consist of **Sertoli cells** and germ cells in various stages of development. The Sertoli cell is both a structurally and physiologically supportive cell to the process of spermatogenesis. As shown in Figure 1-2, developing sperm cells are embedded into, or in intimate contact with, the Sertoli cells throughout maturation. Most of the remainder of the testis consists of **Leydig cells,** myoid cells, and blood vessels of the interstitial compartment.

In adult stallions, pituitary LH binds to Leydig cell receptors, stimulating the production and release of estrogens and testosterone by the cells. Pituitary FSH stimulates the production and release of multiple factors from the Sertoli cells of the testis, including inhibin, activin, androgen-binding protein (ABP) and insulin-like growth factor (IGF). These testicular hormones and proteins feed back to the hypothalamus to regulate the pulsatile release of GnRH and therefore the continued production of LH and FSH. Estrogens, not testosterone, produced by the Leydig cells appear to regulate LH release from the pituitary gland of the stallion, either at the level of the hypothalamus by altering GnRH pulse amplitude and frequency, or directly at the level of the pituitary.[4] Treatment of long-term geldings with estradiol resulted in increased LH levels and decreased FSH levels, suggesting that estrogens may also play a role in modulating FSH secretion.[5] Because testosterone, inhibin, and FSH levels follow similar season patterns, with levels of all three hormones highest during the breeding season and lowest in the nonbreeding season, it has been suggested that inhibin may act together with testosterone to regulate FSH secretion by the pituitary.[6] Testosterone also exerts a negative feedback mechanism on hypothalamic production of GnRH. Normal function of these many complex feedback mechanisms is critical if spermatogenesis is to proceed normally.

Androgens synthesized by the Leydig cells under the influence of LH diffuse into the blood and lymph surrounding the seminiferous tubules, becoming bound by ABP. In order for normal spermatogenesis to occur, high local concentrations of androgens, especially dihydrotestosterone (DHT), must bathe the tubules. Junctional complexes between adjacent Sertoli cells form the functional blood-testis barrier, ensuring a specific physiologic environment for the developing germinal cells on either side. The blood-testis barrier also serves to isolate diploid spermatogonia and spermatocytes from the haploid postmeiotic spermatocytes, spermatids, and spermatozoa. Myoid cells lie within the lamina propria of the tubule, just beneath the basal compartment. Containing actin filaments within their cytoplasm, these cells play a role in transport of spermatozoa toward the lumen of the tubule. The paracrine factors transforming growth factor (TGF-β) and PmodS, produced by the myoid cells under testosterone influence, may regulate Leydig cells through ABP actions and modulate Sertoli cell functions.[6,7] Myoid cells may also contribute to the stability of the blood-testis barrier.[8] Recently, the degeneration and transformation of myoid cells into fibroblasts was demonstrated in the testes of a group of aged (23–24 years) stallions.[9] These findings suggest that myoid cells may play a significant role in the progression of testicular fibrosis in aged stallions and perhaps also in stallions with testicular degeneration.

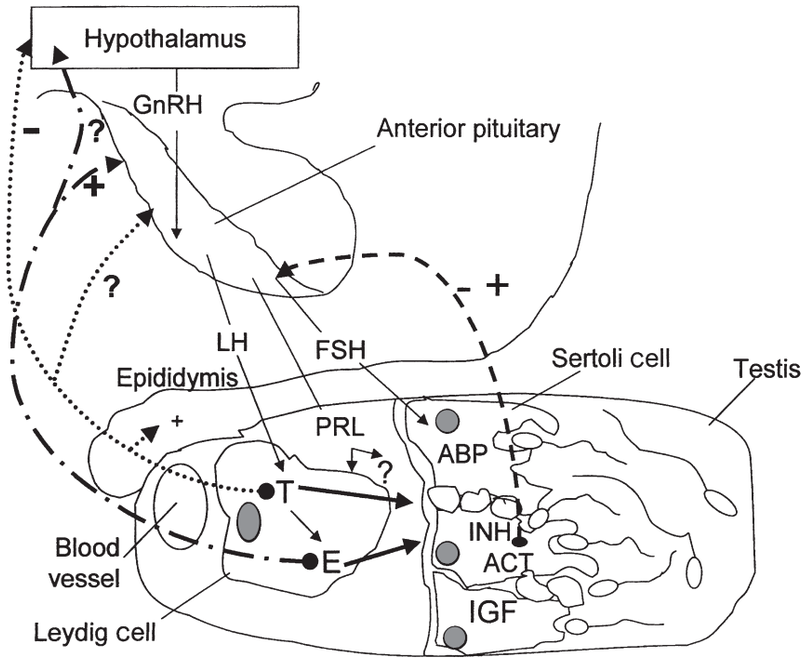

Fig. 1-1 Equine hypothalamic-pituitary-testicular axis. Hypothalamic gonadotropin-releasing hormone (GnRH) regulates the release of luteinizing hormone (LH) and follicle stimulating hormone (FSH) from the anterior pituitary. The major regulator of Leydig cells is LH. The major products of Leydig cells are testosterone (T) and estrogens (E) in adult stallions. The major regulator of the Sertoli cells is FSH. Androgen-binding protein (ABP), inhibin (INH), activin (ACT), and insulin-like growth factor (IGF) are products of the Sertoli cells. The role of the pituitary hormone prolactin (PRL) on testicular function is unknown. Testosterone produced by the Leydig cells feeds back on the hypothalamus to inhibit GnRH production. Estrogen modulates GnRH-induced LH release. The roles of T and E in modulation of FSH release from the pituitary are unknown. Inhibin inhibits FSH release from the pituitary. Activin has been shown to positively modulate the release of FSH at the level of the pituitary in other species, but its action in the horse is unknown. (From Roser JF: Reproductive endocrinology of the stallion. In Samper J (ed): *Equine breeding management and artificial insemination.* Philadelphia: WB Saunders, 2000.)

PARACRINE AND AUTOCRINE FACTORS

A paracrine factor is a product of a cell that acts locally on another nearby cell to modulate functions. An autocrine factor is a cell product that acts directly back on the cell that produced it. Testosterone, TGF-β, IGF, inhibin, and activin are some of the paracrine factors produced by the Sertoli cell that are known to regulate spermatogenesis in other species (Fig. 1-3).[10] A growing body of evidence suggests a strong role for paracrine-autocrine factors in the initiation and maintenance of spermatogenesis in stallions as well. In a recent study of stallions aged 6 months to 23 years, plasma and testicular levels of IGF-I were significantly higher in colts younger than 2 years of age than in older stallions.[11] These results suggest an involvement of IGF-I in testicular development and the onset of spermatogenesis. No significant differences in IGF-I levels were found among stallions over 2 years of age. No association of IGF-I levels with declining fertility was found. IGF-I levels were found to be higher in the breeding season than the nonbreeding season, but the authors cautioned that the separation of age and seasonal effects in the young stallions in the study made interpretation of this finding difficult. Inhibin, a glycoprotein hormone, has been shown recently to be produced by both Sertoli and Leydig cells in stallions.[12,13] Although inhibin appears to act together with testosterone to regulate FSH secretion at the level of the pituitary gland, research in subfertile and infertile stallions suggests an important local autocrine role as well. Testicular inhibin concentrations decline in stallions with poor fertility before levels of other testicular hormones are altered,[14] suggesting that a local defect in Sertoli cell function occurs first in stallions with declining fertility.

EFFECTS OF SEASON ON REPRODUCTIVE PARAMETERS IN STALLIONS

The effects of season and day length are not as dramatic in stallions as in mares. However, stallions do experience a circannual rhythm, with testicular size, semen production, libido, and hormone concentrations varying by season. An increase in the duration of light exposure results in decreased melatonin production by the pineal gland, leading to increased GnRH production by the hypothalamus. Increasing GnRH levels stimulate

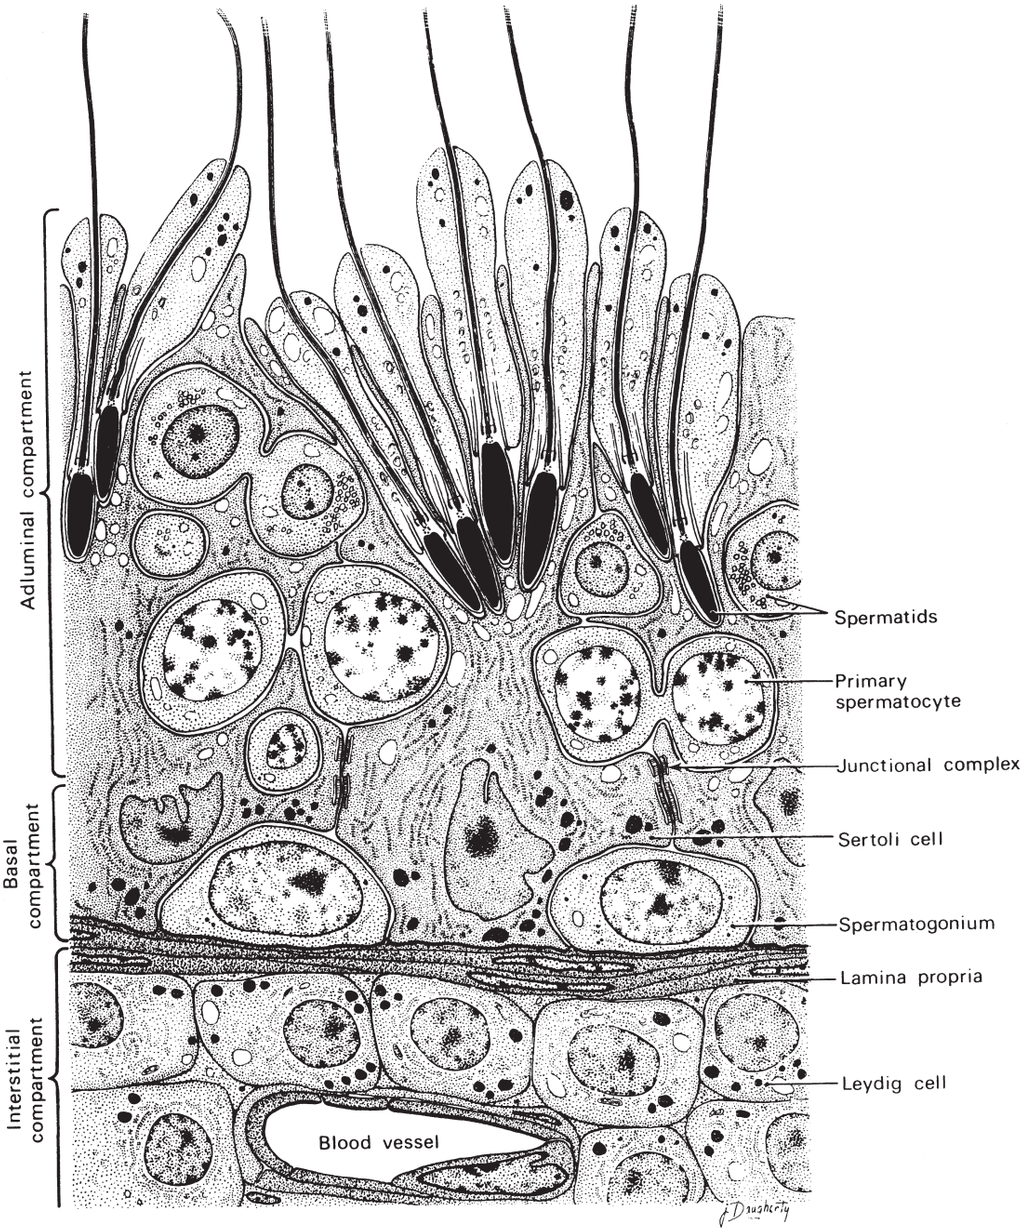

Fig. 1-2 Drawing of a section of a stallion seminiferous tubule showing the relationship of germinal cells and adjacent Sertoli cells in seminiferous epithelium. Spermatogonia, primary spermatocytes, secondary spermatocytes, and spherical spermatids all develop in the space between two or more Sertoli cells and are in contact with them. Primary spermatocytes are moved, by the Sertoli cells, from the basal compartment through the junctional complexes and into the adluminal compartment. During elongation of spermatids, they are repositioned by the Sertoli cells to become embedded within long pockets of cytoplasm of individual Sertoli cells. Note the intercellular bridges between adjacent germinal cells in the same cohort or generation. (From Pickett BW: *Management of the stallion for maximum reproductive efficiency II.* Animal Reproduction Laboratory Bulletin No. 05. Fort Colins, CO, 1989.)

increased LH and FSH production by the pituitary and corresponding increases in testosterone, estradiol, and inhibin levels. The result is an increase in testicular size and weight, sperm production, and libido during the breeding season. The release of another pituitary hormone, prolactin, is suppressed by melatonin, resulting in high plasma levels of prolactin during the long days of the breeding season in stallions. Although the role of prolactin has not been elucidated in the stallion, work in other species has shown that together with LH,

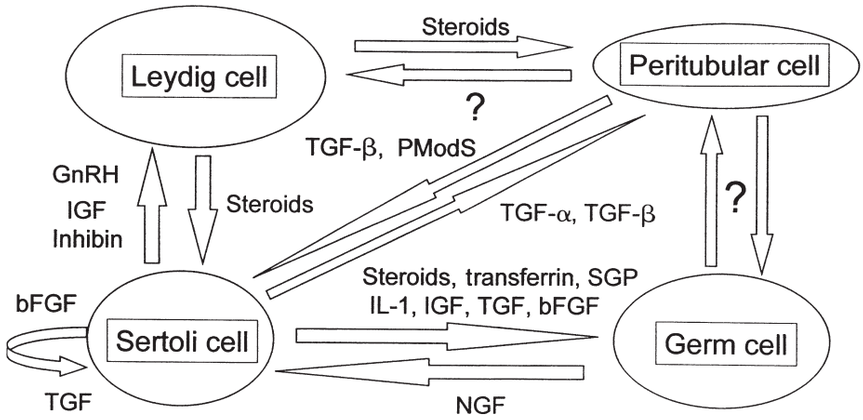

Fig. 1-3 Paracrine-autocrine regulation of testicular function. Many of the local interactions in the equine testis are unknown. The figure presents a hypothetical paracrine-autocrine system based on what has been observed in other species. GnRH, gonadotropin-releasing hormone; IGF, insulin-like growth factor; bFGF, basic fibroblast growth factor; TGF, transforming growth factor; TGF-β, transforming growth factor beta; TGF-α, transforming growth factor alpha; IL-1, interleukin 1; SGP, sulfated glycoprotein; NGF, nerve growth factor; PmodS, a nonmitogenic paracrine factor produced by peritubular cells that modulates Sertoli cell function. (From Roser JF: Reproductive endocrinology of the stallion. In Samper J (ed): *Equine breeding management and artificial insemination.* Philadelphia: WB Saunders, 2000.)

prolactin controls testicular LH receptor expression and activates androgen synthesis within the testis.[15] Hypothalamic inhibition of prolactin release by the pituitary gland appears to be determined by dopaminergic systems; dopamine inhibits prolactin release in all species studied to date. An opioidergic inhibition of GnRH/LH release may be partially responsible for seasonal effects in stallions. In contrast to rams and hamsters,[16] administration of the opioid antagonist naloxone induced LH release, followed by an increase in testosterone, in stallions during the nonbreeding season, but not during the breeding season.[17,18] Geldings treated with naloxone during or outside the breeding season did not demonstrate any differences in LH production. Treatment of long-term geldings with testosterone demonstrated that the hypothalamic and pituitary feedback mechanisms sensitive to testosterone switch from a negative to positive effect between the nonbreeding and breeding seasons.[19] It appears that the effects of photoperiod are dependent upon gonadal steroid feedback mechanisms, and the presence of gonads is required for seasonal effects on hypothalamic and pituitary hormones to be seen.

The endogenous reproductive rhythm of stallions can be only partially controlled by lighting conditions. Stallions maintained on continuous short days (8 hours of light: 16 hours of darkness) for 20 months continued a normal pattern of changes in reproductive parameters during the breeding season.[20] Exposure of stallions to continuous long days (16:8), beginning in December (Northern Hemisphere) following a period of short days, results in an earlier attainment of peak reproductive characteristics than stallions exposed to normal environmental conditions, clearly demonstrating that seasonal reproductive recrudescence is photoinducible in stallions. However, stallions exposed to extended periods of long days appear to become refractory to light. Peak reproductive characteristics are not maintained indefinitely, with testicular regression occurring despite continued exposure to long days. This photorefractory state is an important consideration in the management of stallions servicing mares in both Northern and Southern Hemispheres. Such stallions should be exposed to several weeks of short days at the end of one breeding season before being exposed to the long days of the breeding season in the other hemisphere, to ensure a "resetting" of the circannual rhythm.

HORMONAL IMBALANCES IN THE STALLION WITH IDIOPATHIC SUBFERTILITY AND INFERTILITY

The nature of reproductive dysfunction in stallions leading to idiopathic subfertility and infertility is poorly understood. There are many known causes of poor fertility in stallions, including tumors, history of steroid treatment, trauma, illness, and poor management. However, many times an examination of a stallion with poor fertility results in no evidence of the causal factor(s). Many of these stallions demonstrate hormonal imbalances, usually beginning with increasing levels of FSH, followed later by decreasing estradiol, inhibin, and LH levels, and finally, decreasing levels of testosterone and significant reductions in spermatozoal production. These stallions typically show a decrease in testicular volume, with small, firm testes found on palpation. Semen evaluation may demonstrate low total sperm numbers, increased numbers of morphologically abnormal sperm, and low motility. Findings vary depending on the stage and degree of progression of the disease process. Attempts have been made to identify these stallions early on in the disease process using hormonal testing; however, clinical experience with hormonal therapies aimed at reestablishing a normal hormonal environment for spermatogenesis have been disappointing. The observa-

tions of hormonal aberrations in subfertile and infertile stallions suggest that both a pituitary and testicular disorder may be present in affected stallions. Recent evidence suggests that the primary site of the disorder in affected stallions is the testis itself, and not the HPT axis. As mentioned earlier, intratesticular inhibin concentrations decrease before testicular and circulating levels of the pituitary hormones FSH and LH are altered, suggesting that Sertoli cell dysfunction occurs first.[14] Declining inhibin levels lead to the observed increases in FSH through reduced negative feedback influences at the pituitary gland. The presence of a circulating biologically inactive LH isoform in affected stallions has been described.[21] Blanchard and associates (1995)[22] also found differing levels of LH isoforms in fertile versus subfertile stallions. A biologically inactive form of LH may occupy Leydig cell receptors competitively and not permit adequate testosterone production within the testis to support normal spermatogenesis. Receptor-binding kinetic studies demonstrated similar receptor affinity constants and no differences in LH receptor numbers per mole of testis weight among fertile, subfertile, and infertile stallions.[23] These results suggest that defects in local postreceptor mechanisms within the testis may be involved in subfertility.

Fertile and infertile stallions appear to differ in the response of the HPT axis to hormonal challenge. Treatment of normal stallions with human chorionic gonadotropin (hCG) resulted in an increase in testosterone and estrogen levels as expected, and a decrease in inhibin.[24] Infertile stallions treated with hCG in the study demonstrated significantly lowered testicular responsiveness, with minimal changes in testosterone and estrogen levels after treatment, and no changes in inhibin levels. The results of subsequent studies show that the lowered responsiveness likely originates at the level of the testis. No significant differences were found in pituitary gland function among fertile, subfertile, and infertile stallions 1 year following castration.[25] In a second study conducted 1 year following castration of a group of fertile, subfertile, and infertile stallions, no differences among stallions were observed in pituitary response to steroid replacement therapy.[26] Steroid replacement therapy increased plasma testosterone and estradiol concentrations in all three groups, and no significant differences in LH or FSH levels among the groups of stallions were found before or after treatment. In all three groups of stallions, estradiol treatment significantly increased plasma LH levels and decreased FSH levels, but testosterone treatment decreased LH levels and increased FSH. In addition, fertile, subfertile, and infertile stallions responded similarly to GnRH challenge, with no differences in LH or FSH levels after GnRH stimulation among the groups 1 year after castration. Taken together, these recent studies indicate that removal of the testes removes the problem, allowing the hypothalamic-pituitary axis to return to normal. This suggests that the testis likely represents the primary site of disorder in stallions with idiopathic infertility. However, the exact nature of the disorder remains unknown. Additional work in these areas is needed to further characterize the nature of endocrine-paracrine dysfunction in affected stallions and to permit the development of effective therapies.

HORMONAL TESTING OF SUBFERTILE AND INFERTILE STALLIONS

The clinician's approach to diagnosis in cases of subfertility and infertility should include a thorough history and evaluation of breeding records over the last few years if possible, a detailed general physical examination, a complete breeding soundness evaluation, and possibly testicular biopsy. An evaluation of the hormonal status of stallions experiencing fertility problems can give insight into the origin and seriousness of the disorder. Serial evaluations over the course of several months and subsequent breeding seasons can assist the clinician in monitoring the stallion for progression of fertility problems. Considerable variation across laboratories and studies exist in the reported normal values of reproductive hormones. For this reason the clinician is directed to interpret results of hormonal testing with their specific laboratory's normal expected values in mind. Readers are reminded that season affects hormone levels in stallions; levels of LH, FSH, and testosterone are lowest in the winter months and highest during the spring and summer. Time of the day also influences results. Hormone levels are lowest early in the day and peak about midday. It has been suggested that the optimal time for hormonal testing in stallions is before 9:00 AM in order to avoid confusion between challenge test responsiveness and normal midday peaks. Recommended hormone tests in stallions include those discussed in the following paragraphs.

Baseline Plasma or Serum FSH, LH, Estradiol, Testosterone, and Inhibin

Single blood samples are taken each morning for 3 consecutive days, or serial samples are taken at 30-minute intervals one morning for a total of six to eight samples. Owing to the pulsatile nature of hormonal secretion, frequent sampling gives a more accurate picture of true baseline levels. Because single samples can vary as much as threefold or fourfold from one another, the mean value of several samples results in a more accurate baseline value. The typical pattern of hormonal aberration observed in stallions with poor fertility includes high FSH levels, low estradiol and inhibin levels, normal to low LH, and normal to low testosterone levels. Hormonal aberrations generally tend to appear in the preceding order as fertility declines over time. Monitoring baseline hormone concentrations on a yearly basis is a recommended routine procedure for stallion management.

Single-Pulse GnRH Challenge (Sample for LH and Testosterone)

This test assesses both testicular and pituitary response to GnRH. Blood is collected 1 hour and again 30 minutes prior to an intravenous injection of 25μg GnRH, and at 30-minute intervals post injection for 2 hours (four additional samples). All blood samples are analyzed for testosterone and LH levels. Subfertile and infertile stallions have lower than expected LH and testosterone stimulation in response to the GnRH injection than normal stallions do, indicating either a primary pituitary problem or

a primary testicular problem; this test is not able to differentiate between the two.

Low-Dose Three-Pulse GnRH Challenge (Sample for LH and Testosterone)

This test may be more useful in assessing pituitary responsiveness to GnRH, particularly in stallions with a primary testicular disorder.[6] Blood is collected 1 hour and again 30 minutes prior to the beginning of the test. Three intravenous injections of 5μg GnRH are given at 1-hour intervals. Blood sampling continues every 10 minutes, starting immediately following the first injection, and continuing for 60 minutes following the final injection. A total of two prestimulation samples and 18 poststimulation samples should be collected. Samples are analyzed for LH and testosterone levels. Similar to the single-pulse challenge, subfertile and infertile stallions show lowered hormone response to the GnRH injections.

hCG Stimulation Test (Sample for Testosterone Levels)

Human chorionic gonadotropin (hCG) has distinct LH-like activity in the horse. This test provides information about the ability of the testis to respond to LH stimulation. Blood is taken 1 hour and again 30 minutes prior to an intravenous injection of 10,000 IU of hCG. Sampling is repeated immediately following injection and at 30-minute intervals for 3 hours following the injection. Samples are analyzed for testosterone. Some workers also suggest evaluating these samples for estrogen levels. Similar to the other challenge tests, subfertile and infertile stallions demonstrate lowered testicular responsiveness to the hCG injection, resulting in lower testosterone and estrogen levels post injection compared to normal stallions.

By compiling the information gathered during thorough physical, reproductive, and hormonal evaluation of breeding stallions, the clinician is better able to inform the owner about a stallion's fertility status and recommend management changes that may improve results. It currently appears that the best treatment for subfertility is good stallion management. Optimum timing of insemination or natural cover, limiting a stallion's book of mares, proper semen handling, and good nutrition and exercise are the best options a clinician can give the owner. Many hormonal therapies have been tried, including GnRH, hCG, and FSH, but all have met with limited and controversial success. In stallions exhibiting severe hormonal changes, the prognosis is guarded to poor. It has been suggested that low estrogen levels (below 124 pg/ml) likely reflect irreversible damage to the seminiferous epithelium, and hormonal therapy in these stallions is likely to be unrewarding.[27]

PROGESTAGEN TREATMENT OF BREEDING STALLIONS

A demand exists for a temporary, reliable, and reversible method of removing undesirable sexual and aggressive behavior common to breeding stallions. Show, competition, and racing stallions may improve their performance if less distracted from their work. Several studies have evaluated the use of progestagens to alter stallion behavior, and their effects appear to be dose-dependent. Miller and associates[28] treated stallions once daily for 30 days with a dose of 0.044 mg/kg altrenogest (Regumate. Intervet Ltd.). These workers demonstrated minimal effects on stallion behavior and no effect of treatment on spermatozoal characteristics. Although plasma FSH concentrations were not affected by treatment with altrenogest, plasma LH, testosterone, estrogens, and inhibin concentrations were all significantly lowered during treatment. Plasma LH, estrogen, and inhibin values returned to pretreatment levels by 30 days after cessation of therapy, but plasma testosterone levels continued to be suppressed even 60 days after cessation of therapy. Johnson and associates (1997)[29] evaluated a higher dose of altrenogest in stallions (0.088 mg/kg) given a 57-day course of therapy. These workers found a significant decrease in scrotal circumference, daily sperm output, plasma testosterone concentrations, libido, and sexual aggressiveness in treated stallions throughout the study, and also demonstrated differences in the testicular morphology of biopsy specimens from treated stallions compared to control stallions. Some of the changes induced by treatment persisted into the 8 week after cessation of therapy observation period in this study as well. Although the higher dose of altrenogest appears to significantly affect sexually aggressive behaviors and sperm output in stallions, the long-term effects and reversibility of this therapy remain unknown and further study is warranted.

PROSPECTS FOR IMMUNOCASTRATION OF STALLIONS

Recently, studies have been aimed at producing a temporarily castrated effect in stallions by immunization against GnRH. Inhibition of reproductive activity by active immunization against GnRH has been shown in several species including the dog, ram, bull, and boar. Initial studies in horses used an oil-based GnRH vaccine that, although effective in producing GnRH antibodies capable of suppressing testicular function, caused significant injection-site reactions in many of the test animals.[30] Use of a water-soluble GnRH vaccine in young colts younger than 2 years of age reduced tissue reactions, and produced reduced sexual aggression and loss of libido in the colts. However, considerable variation between individual animals in immunologic response to the vaccine existed, and multiple injections were required to produce an antibody response.[31] Malmgren and associates (2001)[32] recently evaluated the effect of a five-injection course of a water-soluble GnRH vaccine in three mature stallions. Even though all the stallions responded to the vaccine by production of anti-GnRH antibodies, there were significant variations in response among the individual stallions. Two of the stallions demonstrated a significant reduction in testosterone and estrone sulfate levels following immunization, and the third stallion showed a slight reduction in testosterone and no change in estrone sulfate concentrations. Sexual activity and aggressiveness were markedly decreased in all stallions. Semen quality

deteriorated significantly in two of the stallions by 8 weeks following the initial injection, with significant reductions in total sperm number, sperm motility, and number of morphologically normal sperm being observed. In the third stallion minimal changes in semen quality were seen. The GnRH vaccine appears to significantly reduce sperm production and sexually aggressive behavior in mature stallions, but it does not eliminate stallion-like behavior entirely, and does not produce a sterile effect, which would guarantee contraception. The reversibility of the effect remains unknown. In the early studies, examination of the testes at 9 and 18 months following immunization demonstrated that antibody and testosterone levels had returned to normal; however testicular function had not recovered to preimmunization levels.[30,31] The concept of GnRH immunization to produce a castration effect shows promise, but the reasons for considerable individual variation in response to the vaccine and assurances about its complete reversibility need further study.

CHAPTER 2

Reproductive Examination of the Stallion: Evaluation of Potential Breeding Soundness

CHARLES C. LOVE

The stallion breeding soundness evaluation (BSE) is intended to *estimate* a stallion's reproductive potential, which is the current ability of a stallion to impregnate mares, resulting in the birth of a normal foal. This *estimation* is based on criteria provided by the Society for Theriogenology that list reproductive characteristics, including breeding history, physical examination of the whole stallion, physical examination of the reproductive tract, breeding behavior, determination of bacterial growth in association with the reproductive organs, and semen quality measurements. It is recommended that the manual published by the Society for Theriogenology be used as a reference for performing this evaluation.

Following the description and listing of the foregoing characteristics, the clinician categorizes the stallion into one of three classifications: Satisfactory, Questionable, and Unsatisfactory. If a stallion is considered deficient in two or more of these categories (total scrotal width, progressively motility, percent morphologically normal sperm), he is considered either a Questionable or Unsatisfactory prospective breeder. The difference between these two categories is a matter of degree. A stallion considered Questionable would fall *slightly below* the cutoffs for Satisfactory, and an Unsatisfactory stallion would be *very low* in two or more categories. Although this may seem like a subjective judgment, in practice the distinction is usually quite clear.

Historically, a Satisfactory classification is intended to recognize a stallion's ability to impregnate a full book of mares (45 by natural cover or 125 mares by artificial breeding) in an efficient manner (75% of the book in two or fewer normal estrous cycles) using fresh semen deposited in the uterus by natural cover or artificial insemination. These numbers were not based on biologic or intrinsic stallion fertility, but rather on a legal standard (i.e., the number of shareholders) set by the syndicate members. Since the publication of the Society manual, conditions under which stallions are bred have changed, including an increase in the mare book as well as how mares are bred (cooled-stored and frozen semen). The Thoroughbred industry, which uses natural (live) cover exclusively, has increased the maximum number of mares that stallions will breed to over 100, with some stallions approaching 200 mares. The major change in the Standardbred and Quarterhorse industries has been the widespread application of cooled-shipped semen to the point that some stallions breed almost their entire book using this technology, with some stallions breeding 150 to 200 mares.

Since the increase in the number of mares in some stallion books it has become clear that stallions have the biologic potential to breed larger mare books at a level of fertility that is similar to the smaller books described in the Manual. The Thoroughbreds have been using these larger mare books for approximately 10 years. It is the author's opinion that these larger books have not altered the overall fertility and that stallions that would have been Satisfactory prospective breeders for 45 mares are just as capable of handling larger mare books with similar pregnancy rates.

The intent of the classification system is to provide a *framework* around which the clinician can describe, evaluate, and interpret the breeding potential of a stallion. This approach is distinct from the bull BSE, in which a classification less than Satisfactory in many cases results in the elimination of the bull from the breeding population. The primary criteria used are based on sperm quality (motility and morphology), total sperm numbers, and testicular health (testes' size and efficiency of sperm production). Any attempt to define in absolute terms (i.e., using cutoff values), based solely on sperm values and testicular size, a process as complex as fertility will be subject to criticism. However, without guidelines and a framework there is essentially no process by which the results can be interpreted. The guidelines set by the Society for Theriogenology provide a reliable, conservative (i.e., some "fertile" horses may be Questionable, but it is less likely that a Satisfactory stallion will be "subfertile") estimate of a stallion's fertility. For instance, criticism may arise when a young stallion, recently retired from training, is classified as Questionable or Unsatisfactory, but subsequently "does fine in the breeding shed." Once the stresses of racing are removed and the stallion is allowed to "let down," they can show dramatic improvement in their reproductive parameters. In this case, although the BSE may be criticized for "not getting it right," the criteria applied to the day of the evaluation determined that at that point in time the stallion may be limited in his reproductive ability. While the chances of improvement should be discussed with the owner, the final classification must be made based on the findings the day of the evaluation. In addition, the classification allows the

clinician an opportunity to describe management options to the breeder that will maximize the stallion's reproductive potential. As the number of mares bred to stallions increases, the role of management and the input that the clinician can provide will play a greater role.

It is important that the clinician performing the BSE provide more than a simple classification of a stallion, especially in cases when a stallion does not fit into the Satisfactory category. In this case, the stallion owner may become particularly concerned about the reduced classification status of the stallion and assume that the stallion is infertile, subfertile, or that the "condition" is irreversible. It is therefore critical that the clinician be able to communicate, in written form, the significance and interpretation of the findings recorded on the BSE form. It should be recognized that the results of the BSE and subsequent classification of a stallion can have important economic implications for a stallion's breeding future; therefore, the routine evaluation should be performed as completely as possible and thoroughly interpreted to the stallion owner. If a complete evaluation cannot be accomplished, as occurs in many cases, the limitations of the clinician's evaluation should be stated clearly to the owner.

HISTORY

A general as well as reproductive history of the stallion should be recorded as part of the BSE. The general history should include any illnesses and medications administered as well as recent use of the stallion such as in racing or performance. The reproductive history should include a thorough review of the breeding records if the stallion has a breeding history. These records provide an objective record of a stallion's reproductive past, and values such as seasonal pregnancy rate, cycles per pregnancy, and the type of mares in the book (maiden, foaling, barren) can be determined. In general, a stallion's reproductive history falls in one of three categories:

1. *Novice or sexually inexperienced* tend to be young (<3–6 years old) and have recently been in training. It is important to recognize these stallions may not be sexually mature at the time of the evaluation, may have recently been exposed to the stresses of training (exercise and medication), and have not been previously bred to mares. Combined, these factors make these individuals a challenging group to evaluate. Stallions that are not sexually mature or have been under prolonged stress may not produce either the quality of normal sperm or the number of sperm they will produce when sexually mature and removed from the stresses of training. In addition, stallions with no prior breeding experience have no fertility track record to which the results of the BSE can be compared, and therefore, all conclusions about the stallion's future breeding potential must be based on the results of the evaluation alone.
2. *Breeding stallions of any age that are presented with no history of subfertility* may be presented for prepurchase or routine evaluation prior to the breeding season. They are different from novice stallions because they have a previous breeding history and their fertility, in most cases, has been acceptable to the owner. Nevertheless, the clinician should confirm that the fertility reported by the owner is consistent with the recorded history. These stallions have previously sired foals and have an established record of impregnating mares; therefore, the challenge to the clinician is to determine not whether a stallion can get *a mare* pregnant but how many mares he can impregnate in a given time period if the owner wants to increase the number of mares to which he is bred. In addition, the clinician will need to determine, for either the owner or potential buyer, whether the results of the BSE are consistent with the historical fertility of that particular stallion.
3. *Breeding stallions of any age, with a history of subfertility* are presented because their fertility is reduced below a level that is acceptable to the stallion's owner. In some cases, it is incorrectly assumed, by the owner and in many cases the clinician, that the stallion is the sole and primary cause of the reduced fertility. Often the mares to which the stallion is bred and how these mares are bred may be the primary reasons for reduced fertility; therefore, a thorough evaluation of the mare book and management procedures should be performed. Often, as a stallion's fertility decreases, management and mare factors are involved in the decline as well. The clinician should be particularly aware of management and mare factors being major contributors to a reduction in fertility when semen quality is good to excellent.

Group 3 stallions, along with group 1, are perhaps the most challenging, because the veterinarian must make recommendations with respect to the future management of the stallion. Few stallions are intrinsically sterile, but many experience some form of reduced fertility. Therefore, the evaluation should focus on identifying the specific causes of the reduced fertility such that subsequent recommendations can be based on managing those causes. It is also important to identify the source(s) of reduced fertility so that inappropriate therapies are not instituted that may have no effect or worsen the subfertile condition.

Although stallions are classified following completion of the evaluation as a means of simplifying the process for the client, the veterinarian should be prepared to thoroughly explain why that stallion may fall in a particular category and the significance of that particular category. To the layperson, a categorization less than Satisfactory may be interpreted to mean that the stallion is subfertile or sterile or that the "condition" is permanent. In the case of the young stallion described earlier, the lower classification may be temporary and after a period of time the stallion may show improvement. Therefore, reexamination of a stallion may be recommended.

SEMEN EVALUATION

Historically, the hallmark of the BSE is the evaluation of the semen; however, it is only a part of the examination and should not receive more weight than other parts. The routine evaluation of the semen involves the evaluation of sperm motility, sperm morphology, longevity of sperm motility, and the determination of total sperm numbers. The clinician should make an attempt to collect the semen using an artificial vagina, since this provides the most physiologic, representative sample.

Initial sperm motility in the raw form is the first parameter that should be evaluated immediately following semen collection. This parameter is highly dependent on extrinsic factors such as semen handling technique, environmental temperature, semen extender, semen handling instruments, components of the artificial vagina, and expertise of the examiner. Therefore, although this is an important parameter regarding sperm quality, the clinician should recognize that there are many extrinsic factors that can artificially reduce sperm motility resulting in a reading not representative of the stallion being evaluated. All materials (slides, coverslips, microscope stage, pipettes, and semen containers) that will be involved with the evaluation should be maintained at 35 to 37°C, because the portion of the whole semen sample that is evaluated is very small (10–20 µL). Therefore, temperature extremes can quickly alter motility, resulting in an inaccurate estimation. A phase-contrast microscope with a warming stage, although more expensive, is preferred because of the enhanced resolution, especially when morphologic evaluation is performed. Therefore, it is critical that excellent technique be maintained when performing motility estimates, such that the results are meaningful and representative of the stallion being evaluated.

A total and progressive motility estimate is given to each ejaculate. This is accomplished by placing a drop (approximately 10–20 µl) of semen on a clean glass slide and placing a coverslip on top and scanning multiple areas of the slide before determining the estimate. It is recommended that both raw and extended semen be evaluated to establish consistency and to assure that the extender is good quality. Total motility is the total percentage of sperm that exhibit any type of movement, regardless of the movement quality. Progressive motility is intended to identify those sperm whose quality of motion is better (progressive) and theoretically consistent with sperm that have a better chance of "fertilizing." The definition of progressive is subjective and subject to considerable variation due to evaluation conditions, evaluator experience, and the inherent motion of the sperm themselves. A progressive motility score of 60% has been used as a minimum guideline value. It should be recognized that this minimum sets a high standard and many stallions that are "fertile" will fall below this level.

Longevity of Sperm Motility

This parameter has traditionally been evaluated using raw and extended semen at room temperature (~22°C) and is an approximation of the ability of the sperm to live in the mare's reproductive tract. Recently, with the advent of cooled semen it has become important to determine the ability of sperm to withstand the cooling process, which occurs primarily at 5 to 7°C. There are no strict cutoffs to separate good from bad sperm longevity, but stallions whose sperm *consistently* experience very short longevity at room temperature (i.e., 10% motility after 6 hours in the raw form or after 24 hours in the extended form) or after cooling should be further evaluated to determine whether the problem is characteristic for that stallion or whether conditions can be altered to improve longevity. The same extrinsic factors that affect initial motility will be magnified when longevity is evaluated; therefore, certain insults to the sperm are not detected if only initial motility is evaluated, but may be obvious when the semen is evaluated over time. One factor that plays a prominent role in reducing the longevity of motility is the level of seminal plasma in the extended sample. Seminal plasma provides nutrients and ingredients that activate sperm motility, but it does not have the ability to enhance longevity. If longevity is to be measured critically, seminal plasma level should be limited to 5 to 10% of the extended volume.

Morphologic Evaluation

Evaluation of sperm morphologic features can be accomplished by mixing raw semen (several drops if the ejaculate is concentrated or 1–2 ml if dilute) with a buffered-formol saline (BFS) solution. A phase-contrast microscope should be used for this evaluation if BFS is used as a fixative. An alternative is the use of a background stain such as eosin-nigrosin. The use of the BFS has the advantage of higher quality image without producing the artifactual changes that the eosin-nigrosin stain can if not maintained properly. In the stallion, there are specific abnormalities that, when they occur together in high levels, are associated with a reduction in fertility; therefore, individual abnormalities (abnormal heads, detached heads, abnormal midpieces, etc.) should be counted in addition to the number of normal sperm. If an individual sperm has more than one abnormality, both abnormalities should be recorded; however, only one sperm should be counted as part of the total number of sperm that are counted. Documentation of all abnormalities is important to aid the diagnosis and prognosis. Fertility-limiting abnormalities include abnormal heads, abnormal midpieces, detached heads, coiled midpieces, and premature germ cells. In contrast, high levels (40–60%) of individual abnormalities that result in a low percentage of normal sperm are less likely to have a dramatic effect on fertility as a combination of defects. Therefore, using other classification systems, such as identification of primary, secondary, and tertiary abnormalities or identifying only the most proximal abnormality on a sperm may limit the clinician's ability to interpret the results of the morphologic evaluation.

Total Sperm Numbers (Concentration × Volume)

The calculation of total sperm numbers is required to determine the following:

1. Number of mares that can be inseminated from a single ejaculate
2. Efficiency of sperm production based on the total testicular volume
3. Daily sperm output (DSO)

The first step in determining total sperm numbers is calculating the concentration of the sperm sample and requires taking a fixed volume of raw semen and mixing with a fixed volume of diluent. This can be performed using a hemacytometer, spectrophotometer, densitometer, or a computer-assisted motility analyzer. The hemacytometer has the advantage of being the cheapest and the only method that directly counts sperm, because the spectrophotometer and densitometer evaluate fluid opacity and have the potential to give false high readings due to the presence of debris or other nonsperm matter. This is important when some dilute ($<50 \times 106$ sperm/ml) semen samples are evaluated. In this case the contribution of nonsperm material can account for a large percentage of the spectrophotometer or densitometer reading and resulting perception of greater sperm numbers than are actually present, leading to the insemination of a below threshold number of sperm and potentially reduced fertility. These methods tend to work well with ejaculates of higher concentration, in which the debris contribution is less.

Daily Sperm Output

Daily sperm output (DSO) refers to the total number of sperm that a stallion can ejaculate on a daily basis following depletion of extragonadal sperm reserves. These reserves are primarily in the tail of the epididymis and can be three to four times the actual DSO value. Therefore, unless these sperm reserves are reduced prior to making an evaluation of a stallion's fertility potential, the number of sperm collected will not be representative of what will be produced during an active breeding schedule. DSO is a reference point to allow estimation of the number of mares a stallion can breed on a daily basis during the breeding season. Therefore, estimation of sperm numbers based on a single semen sample collected at sexual rest is of limited value.

DSO can be determined by ejaculating the stallion once or twice daily for 5 to 7 days. The first 1 to 5 days either the stallion can breed the mare, which may be more convenient and cost effective for the owner, or his semen can be collected in an artificial vagina and daily semen evaluations can be performed. At the very least, the semen should be collected by artificial vagina during the fifth through the seventh days so those ejaculates can be completely evaluated and the DSO estimated. In general, most stallions reach DSO around day 3 or 4, but this can only be determined retrospectively. It is desirable if the clinician can evaluate as many of the ejaculates as possible so that a more accurate overall impression of the stallion's semen quality can be determined.

The major limitation of DSO is the time and client expense involved in taking multiple ejaculates to establish a plateau of sperm output that is representative of DSO. It can require between three and seven daily semen collections to establish the level of DSO. In the event that the clinician is unable to establish DSO, the alternative is to collect two ejaculates an hour apart and use the sperm numbers in the second ejaculate as an estimate of DSO. Although this has the advantage of convenience and reduced cost, there may be more variation in this estimation than there might be when a DSO value is determined, requiring a broader clinical interpretation.

Once the stallion's total sperm numbers at DSO have been determined, the number of mares to which that stallion can be bred on a daily basis can be determined.

Spermatogenic Efficiency

Determining the total number of sperm as well as the quality of the sperm forms a critical aspect of the breeding soundness evaluation. An additional parameter that can be evaluated is the efficiency of sperm production by the testicles. The intent of this measure is to determine whether, on a per gram basis, a stallion's testes are producing a normal level of sperm. The average stallion should produce 15 million to 20 million sperm per gram of testicular parenchyma. This requires determining DSO, and then comparing those *actual* sperm numbers with the *expected* number of sperm that the testicles should produce based on their size (volume). In effect, this comparison determines whether the testes are producing, in terms of actual numbers of sperm, what they should be, based on the size. Because testicular size is positively correlated with sperm number, larger testes should produce more total sperm, but the efficiency in terms of sperm per gram of testis of a normal testis, of any size, should be similar.

Diagnostically, the actual DSO estimate can be compared to the expected DSO value extrapolated from the volume of the testes. This can be performed in the following sequence:

1. Measure the length, width, and height of each testicle
2. Determine the volume of each testicle using the formula: testicular volume (cm^3) = $0.523 \times$ length $\times$ width $\times$ height
3. Add the volumes of the left and right testes to calculate total testicular volume
4. Calculate expected DSO (billions of sperm) based on the following formula: expected DSO = $0.024 \times$ (total testicular volume in cm^3) $- 1.26$

If *actual* DSO value is less than the *expected* estimate, this indicates that the testes are maintaining their size but the efficiency of sperm production (sperm produced per gram testicular parenchyma) has decreased. This is an early sign of an insult or stresses to the testes that may or may not lead to gross end-stage testicular changes such as a reduction in testicular size or change in testicular texture and may be one of the earliest signs of testicular stress. Another application is when the "small" size of a stallion's testes are questioned. Often "smallness" is associated with "abnormal," but some testes are "small" but function efficiently and normally and therefore may be as efficient as a "larger" testis.

PHYSICAL EXAMINATION OF THE REPRODUCTIVE TRACT

Although the routine BSE focuses on evaluation of the reproductive tract, the clinician must also evaluate the overall physical condition of the stallion. Conditions not related to the reproductive organs can have direct manifestations on reproductive behavior, such as the effect of musculoskeletal pain on the ability of a stallion to comfortably mount and complete the breeding process.

The physical examination of the stallion reproductive tract includes evaluation of the penis and scrotal contents as well as per rectum examination of the accessory glands and ampullae, terminal aorta, bladder, and internal inguinal rings. Ultrasonographic and manual evaluation of these structures can be used to add completeness to the evaluation, especially if the cause of a stallion's problem could be related to these structures or the surrounding areas. The clinician should always be aware of the difficulties associated with per rectum evaluation of either the mare or stallion and only proceed if the evaluation can be performed safely.

The accessory glands of the stallion include the seminal vesicles, prostate, and bulbourethral glands. The ampullae are the terminal portion of the ductus deferens and have a prominent glandular component. Both the seminal vesicles and ampullae are the sites most commonly affected by pathologic changes.

Seminal vesiculitis, uncommon in overall frequency, is the most common condition affecting this gland. It may be uni- or bilateral and is manifest by the presence of polymorphonuclear cells and blood in the final portion of the ejaculate. The extent of blood and PMNs can vary considerably, ranging from only a trace to large amounts of both. Examination findings will vary depending on the severity of the condition and range from normal to palpable changes such as thickening of the vesicle wall and the presence of ultrasonographically detectable echogenic material in the lumen. This condition is commonly misdiagnosed if bacteria originating from the surface of the penis contaminate urethral or semen cultures and it is assumed the bacteria originate from the seminal vesicles. The colonization of bacterial pathogens, such as *Klebsiella pneumoniae* and *Pseudomonas aeruginosa,* on the external surface of the penis is more common than actual infection of the seminal vesicles.

Seminal vesiculitis can be difficult to treat using a systemic regimen of antibiotic therapy because of altered or reduced antibiotic efficacy in the vesicle lumen due to the alkaline environment or the inability of the antibiotic to penetrate into the vesicle wall due to the inflammation. If possible, the vesicle(s) should be treated locally. Local treatment can be performed by passing an endoscope guided catheter up the urethra, into the opening of the seminal vesicles, lavaging the vesicular lumen, then following that with an infusion of an appropriate antibiotic.

Perhaps the most common condition affecting the reproductive status of the stallion is accumulation of sperm in the ampullae, resulting in partial or complete blockage of one or both ampullae. This commonly occurs early in the breeding season because the stallion has been sexually abstinent since the previous breeding season and sperm have had the chance to accumulate in the ampullae. A common presentation is *incomplete* obstruction of the ampullae, resulting in the ejaculation of large numbers (20 billion to 70 billion sperm) of immotile sperm with or without a high percentage of detached heads. Both the immotile sperm and detached heads are a result of the sperm residing at body temperature (i.e., in the ampullae) for time. Treatment for this condition includes per rectum massage of the ampullae, oxytocin administration to contract the ampullar smooth muscle, followed by frequent ejaculation to remove the accumulated sperm and promote the flow of normal sperm from the tail of the epididymis.

This is an important condition and because of the severe presentation (azoospermia or poor sperm quality), it may be assumed that the stallion has an irreversible fertility-limiting condition. In most cases, however, this condition is completely reversible and if diagnosed correctly the affected stallions can be returned to a normal breeding schedule.

Evaluation of the scrotal contents includes manual and ultrasonographic evaluation of the scrotum and testes. Testicular evaluation also includes measurement of the length, width, and height of each testicle by either caliper or ultrasound. Ultrasonographic evaluation is preferred because the testicles can be directly visualized for measurement and qualitative evaluation can be performed on the testicular parenchyma, spermatic cord, and epididymis. The measures used to calculate the volume of each testis as described earlier are subsequently used to determine the efficiency of sperm production. Total scrotal width should also be determined because a value of at least 8.0 cm is one of the criteria considered when final classification is determined.

CHAPTER 3

Infertility and Diseases of the Reproductive Tract of Stallions

WILLIAM B. LEY and STEVEN H. SLUSHER

Although horse breeding has evolved considerably in the last 50 years, reproductive research has not approached the levels that already exist in other species. Much of the research effort in horses has been directed toward understanding stallion fertility. Many factors have been reported to affect a stallion's fertility, including a variety of diseases. Clinicians should have a working knowledge of reproductive physiology, ideal stallion characteristics, management expectations, extrinsic and intrinsic influences on fertility, and methods for semen evaluation before assessing stallion fertility. This chapter deals with some of the diseases and problems that affect stallion fertility.

An evaluation should estimate the stallion's fertility when compared with other stallions with known fertility. Stallions should be expected to achieve at least a 75% pregnancy rate when bred naturally to 40 mares or 90% pregnancy rate when bred artificially to 120 mares. These numbers coincide with a single breeding season, good management, and mares of good fertility.

Stallions can be used for performance or for breeding and are sometimes utilized for both during the breeding season. Commonly, young stallions are retired for breeding after a successful performance career. Stallions may be able to breed and perform during the same breeding season, but physically demanding athleticism adversely affects sperm production.

Stallions are usually evaluated for breeding soundness under specific circumstances: if semen is to be frozen for later use or cooled for immediate transport; if the breeding method should change; prior to purchase; due to an increase in the size of the mare book for the coming breeding season; following a significant injury or systemic disease episode; or when decreased fertility is suspected. Serial evaluations to determine daily sperm output are most helpful following disease or injury or with an increase in the mare book. Following an evaluation, the stallion should be classified as satisfactory, questionable, or unsatisfactory for the intended use.

The farm manager or owner is responsible for daily operation of the breeding farm. He or she determines the degree of veterinary involvement, the quality and quantity of mares in the stallion's book, the methods used to select mares for breeding each day, and the level of herd health practices used. Management decides when to begin and end the breeding season and the breeding method appropriate for the farm. Management skills ultimately determine the farm's success as measured by the number of the stallion's mares that foal the next year. Additionally, management should keep accurate records of the breeding season events. These records are necessary for periodic and end-of-season analysis of breeding efficiency and management expertise. Analysis of the records allows future changes in the breeding operation and identification of problems.

An increased number of barren or problem mares in a stallion's book can make the stallion appear subfertile as judged by conception rates per estrus or foaling rates. Overbooking a stallion, that is, breeding too many mares per unit of time (day, week, or month) could deplete his sperm supply. Overuse may also cause abnormal behavior, especially in immature stallions. Examples of undesirable behavior include reduced libido, aversion to serving an artificial vagina, savaging mares, and aggression.

Breeding farm managers should be knowledgeable about basic reproductive physiology. They should be aware that horses are seasonal breeders and are most fertile during the long days of summer. Practically, this knowledge could potentially reduce the number of breedings per estrus and per pregnancy. Management must utilize veterinary expertise to enhance breeding efficiency.

Inappropriate herd health measures or poor breeding hygiene may adversely affect a stallion's fertility. Spermicidal chemical residues on equipment that contact the stallion's ejaculate may cause failure to conceive. Veterinary clinicians asked to help find causes for infertility should carefully examine the management practices used on the breeding farm as a potential source of the stallion's perceived subfertility.

The age at which puberty occurs can vary among breeds of horses, but stallions generally begin producing significant spermatozoa for ejaculation at an average of 83 (±2.9) weeks of age. Sexual maturity may not occur for another 1 to 3 years, depending on breed.

Extremes of body condition can affect fertility. Stallions that are maintained either too fat or too thin may experience decreased sperm production when compared with stallions in optimal body condition. Adjustments in the plane of nutrition are necessary during certain times of the year to maintain optimal body condition; stallions not actively breeding mares require lower caloric intake, as opposed to during the breeding season when they need more calories. The greater the number of breedings per week and the more active a stallion is when not

breeding, the more calories he will need. Ideally, periodic nutritional adjustments should be made to maintain stallions in optimal body condition.

The greater the frequency of ejaculation, the more the stallion's sperm numbers may be depleted. Younger stallions with smaller testes produce fewer spermatozoa, which can be depleted more quickly, than do mature stallions with larger testes. The optimal number of ejaculates per unit of time depends on information found by serial semen collections, as well as on the stallion's age and testicular size, the season of the year, and appreciation of the stallion's inherent fertility gained by assessing his previous ability to impregnate mares.

Testicular volume is a relatively accurate predictor of daily sperm output (DSO). Based on a formula for determining the volume of an ellipsoid, each testicle can be measured (mm) by ultrasonography[1] (see Chapter 2). This estimate may be used to compare with actual numbers produced by routine semen collection or with breeding suitability examination results. It may also serve as a basis from which a stallion's book may be predicted. A negative deviation from the expected DSO warrants further investigation for potential causes.

Several breeding methods or schemes are recognized for stallions: natural service either in a pasture setting or controlled by in-hand breeding; artificial insemination; cooled semen shipment to mares located at a farm other than where the stallion resides; and collection of a stallion's ejaculate for cryopreservation and storage for later insemination. The choice of breeding method may be dictated by the breed registry or association, governed by specific rules from such, or left entirely to the choice of the farm management. There are advantages and disadvantages to each of the breeding methods.

NONINFECTIOUS CAUSES OF SUBFERTILITY

Diseases that may cause infertility in a stallion can be arbitrarily divided into noninfectious and infectious sources. Either can affect the stallion's ability to produce or deliver sufficient normal spermatozoa to effectively produce pregnancy in mares. These disease problems may affect only the reproductive tract or may be systemic. Infectious problems may be caused by bacteria or viruses that can be transmitted venereally, by direct contact between horses, or by fomites. Noninfectious problems are not transmissible but can influence normal spermatozoa production and pregnancy rates of the afflicted stallion.

Physical Trauma

Stallions that must perform natural service will be at risk of trauma caused by the mare or from events associated with breeding. Poor footing in the breeding area may lead to musculoskeletal injuries that can limit the stallion's mounting ability or result in psychological trauma or both. When a mare kicks a stallion during breeding, there may be damage to his external genitalia, resulting in swelling, edema, abrasions, or lacerations. Blunt trauma to the penis and sheath may cause enough swelling to prevent retraction of the penis into the sheath (paraphimosis). With the penis swinging free outside the sheath, normal blood circulation to the glans is inhibited, leading to further swelling and edema. In addition, abrasion of the penis will occur as the stallion moves about. Abrasions can rapidly progress to ulceration, and without aggressive therapy the stallion's penis may require amputation because of irreversible damage.

The initial treatment consideration in the case of trauma should be stall confinement to prevent further damage. Second, the penis should be replaced into the stallion's sheath. With minimal swelling, the penis may be easy to replace. When edema is extensive, the swelling should be reduced before replacement within the sheath is attempted. Application of a compression bandage beginning at the glans penis may decrease swelling sufficiently for replacement. With the penis inside the sheath, nonabsorbable sutures should be placed across the sheath opening. Retaining the penis in the sheath will allow return of normal blood circulation, reduce edema, and prevent further damage. The stallion can urinate without extending the penis. Urine scalding of the internal sheath may result, but its effect may be lessened with daily application of emollients.

If penile swelling cannot be reduced or the penis prolapses after the sheath has been sutured, then a sling should be fashioned to support the penis.[2] A sling can be fashioned from a bag used for laundering delicate fabrics. These bags are made from soft cotton material and provide support without damage to the penile tissues. The bag should be cut into a rectangle of the proper length and width to accommodate the penis. The penis is suspended in the soft cloth bag close to the ventral abdomen. The bag is held in place with 3-inch gauze straps attached to the corners and tied over the stallion's croup. Several thicknesses of cotton beneath the gauze straps are necessary to prevent skin injury.

An alternative technique has been described using a plastic bottle that has been modified to be used as a preputial "splint." A 1-liter saline bottle has the bottom cut out and the sharp edges padded with tape to prevent abrasions. The bottle is lubricated with petrolatum jelly and the opened bottom is inserted over the end of the penis, once it is reduced to a size that will fit inside the bottle. The neck of the bottle is used to anchor stint supports of long 2- or 3-inch gauze. Four stints are made, two pair to go laterally over the flank to the croup, and two to go caudally on either side of the prepuce and testicles and up between the legs skirting the tail-head to meet the lateral stints over the back, and are tied. The bottle top is left open for urine to be passed through. The splint is reset daily following hydrotherapy as needed and the penis monitored closely for any sign of abrasion caused by the retention device.

With the penis either supported as described or placed within the sheath, cold hydrotherapy should be provided for 20- to 30-minute intervals, two to four times daily. Such therapy may enhance local blood circulation, which decreases swelling and edema. Hydrotherapy should be

continued as long as swelling and edema persist. Systemic administration of diuretics, glucocorticoids, and nonsteroidal anti-inflammatory drugs may be considered for reduction of edema but will not supplant the need for hydrotherapy and penile support. With full-thickness abrasion of the penile skin, systemic antibiotics are indicated to reduce bacterial contamination because secondary infections delay healing and promote swelling and edema.

Priapism is defined as penile erection in the absence of sexual stimulation that does not recede within a short period of time. The corpus cavernosum penis (CCP) is engorged with blood that soon develops fibrin and undergoes spontaneous clotting. The etiology is unclear but has been associated with the administration of phenothiazine tranquilizers, general anesthesia, neuromuscular dysfunction, equine herpesvirus infection, cachexia, dourine, and idiopathic. Early medical management consists of diuretics, nonsteroidal anti-inflammatory agents, manual massage, cold hydrotherapy, and suspension and support of the penis. General anesthesia and massage of the penis to decrease venous engorgement, application of a compressive elastic bandage, and lavage of the CCP using 10 to 12 gauge ingress and egress cannulas along with heparinized saline have all been described as useful when medical management is unrewarding or the value of the stallion warrants more aggressive therapy. When lavage is performed it is recommended to continue until arterial blood is flushed from the egress cannula. Several attempts to lavage or irrigate the CCP may be required for resolution. More aggressive surgical intervention may be considered by creation of a shunt between the CCP and the corpus spongiosum penis (CSP). Failure to aggressively manage and resolve this condition will lead to loss of the stallion as a breeding animal and may necessitate castration and phallopexy (Bolz technique).[3]

Trauma to the scrotum and testes may occur along with injuries of the penis and sheath. Scrotal and testicular injuries or edema require aggressive therapy to reduce the likelihood of permanent damage to the stallion's fertility due to compromise of the thermoregulatory mechanism. With swelling, edema, or inflammation of the testes and scrotum, abnormal spermatozoa will be produced until normal heat exchange can be restored.

When the scrotum or testes are injured, ultrasonographic examination of the involved organs is beneficial to help determine the extent of damage. Testicular injuries could permit exposure of spermatozoa to the systemic circulation and result in antisperm antibody production. Antisperm antibodies can cause subfertility or sterility.

Stallions that experience genital injuries may develop psychological or behavioral abnormalities, scarring within the reproductive system, and immunologic changes as described. Such residual damage may not become apparent until the stallion is reintroduced to the breeding shed routine. Management should be cautioned about the likelihood of psychological or behavioral problems, or both, that may occur in injured stallions and should be encouraged to slowly and gradually introduce the stallion back into his former routine.

Hemospermia

Hemospermia causes infertility that may vary with the quantity of red blood cells in the ejaculate. The mechanism by which blood causes infertility has not been determined. Hemospermia may result from either external or internal lesions in the stallion's reproductive organs. External lesions include those from traumatic injury such as lacerations, hematomas, abrasions, ulcerations, and dermatologic conditions. Lacerations and abrasions may occur during breeding, as when the mare's tail hairs cut the glans or urethral process during coitus. Hematomas may rupture externally or into the urethra causing spontaneous bleeding or hemorrhage during urination or ejaculation. Ulcerations may arise from infectious disease lesions either externally or internally.

Internal urethral ulcerations lead to contamination of the ejaculate with blood because of rapid expansion and contraction of the tissues during urethral pulsations. The ulcers may be located anywhere from the urethral process to the pelvic urethra near the ejaculatory ducts. Spontaneous hemospermia can occur in stallions that are bred heavily, as a sequela to bacterial urethritis, from scar tissue that results from a stallion ring, or from infection of the accessory sex glands.

Diagnosis of hemospermia may begin by observation of accumulated dried or fresh blood on the stallion's rear legs, sheath, or ventral abdomen. Fresh blood may be noted on the stallion's penis following coitus or may be visible grossly in the collection container after semen collection. If fresh blood appears on the stallion's penis following coitus, the source of hemorrhage could be from the mare's genitalia (vaginal or hymen rupture, or trauma of a varicocele within the vestibule) or from the stallion. To determine the origin of blood, the mare must first be ruled out as a source, then the stallion's penis and sheath should be examined with a small-diameter flexible endoscope, with care taken to prevent iatrogenic urethral trauma. The examiner should be cognizant that ulcers may occur anywhere along the urethra. The most frequent location for urethral ulcers may be in its pelvic portion as the urethra bends distally over the ischial arch, or near the ejaculatory ducts at the cranial termination of the urethra.

Treatment for hemospermia consists of sexual rest, local medications placed in the pelvic urethra via a perineal urethrostomy, systemic antimicrobial administration, acidification of the urine, or surgery (perineal urethrostomy). Laser surgery may be useful for cautery of the ulcer(s).

Dermatologic Conditions

Invasive dermatologic conditions, such as habronemiasis, lead to ulcers and can be found on the urethral process, glans, or prepuce. The ulcerated area can hemorrhage or cause pain during ejaculation. Recommended therapy usually consists of a combination of topical medications designed to kill the *Habronema* larvae and protect the mucosa, sexual rest to allow time for healing, systemic anthelmintics or glucocorticoids or both, or cautery of

the lesions. Surgical excision of the urethral process has been suggested but may result in stricture of the urethra or hemospermia. Complete healing may not occur until the offending stable flies disappear with onset of winter. Some horses seem prone to have chronic recurrence of this disease, regardless of therapy.

Tumors of the stallion's external genitalia cause subfertility by preventing erection, obstructing the urethra, causing hemorrhage into the ejaculate, or causing pain during ejaculation. Some tumors, owing to their size, may prevent copulation or normal retraction of the penis into the sheath.

Superficial neoplastic lesions must be differentiated from dermatologic conditions such as habronemiasis. Both may appear granulomatous and ulcerative and are associated with hemospermia or pain during breeding. A biopsy of the lesion should be obtained and analyzed prior to initiating therapy. Histopathology results can aid in proper therapy choices and accurate prognosis for return to breeding. Squamous cell carcinoma (SCC) and sarcoid are the most common external genital tumors and most frequently occur in stallions with some nonpigmented skin on the penis or prepuce. Successful treatment of tumors depends on early diagnosis and aggressive therapy. Neoplasms may be surgically reduced in size or completely excised. Initially, it may be appropriate to reduce the size of the tumor and then treat with cryosurgery, hyperthermia, or immune stimulation. Intralesional injection of cisplatin has been described for penile SCC, squamous papillomas, and sarcoids. Topical application of 5-fluorouracil in cases of SCC has been reported to be successful in causing tumor regression. It is necessary to provide sexual rest until the lesions have healed sufficiently to prevent hemospermia. During the breeding season, it may be necessary to assign the stallion's mare book to another stallion.

Tumors of the testes appear less frequently than skin tumors. Seminoma, the most common testicular tumor, may be either benign or malignant, and a successful outcome depends on early identification and treatment. Equine seminomas may develop from exposure of spermatozoa or seminal fluid to the surrounding tissues. A seminoma may begin as unilateral hardening and enlargement of a testis with subsequent invasion of the epididymis and tissues surrounding the spermatic cord and extension into the abdomen along the cord or lymphatics. The course of neoplastic invasion may be slowed or eliminated with hemicastration and removal of visibly diseased tissue. Once neoplastic invasion of the lymphatics has begun, the stallion may survive only a few months.

Urinary Tract Obstruction

Urinary tract obstruction may occur as a result of urinary calculi formation or scarring due to previous injury or surgical intervention. Urinary calculi may cause hematuria, cystitis, or obstructive disease. An accumulation of dried smegma in the urethral diverticulum of stallions may cause pain during urination. For a review of clinical signs, diagnosis, and treatment of urinary calculi, the reader is referred to other published sources. The treatment of smegma accumulation ("bean" formation) usually involves sedation of the stallion and removal of the "bean" by gentle flushing and washing with mild soap solutions.

Inability to Mount and Copulate

Lameness or injury may become related to fertility, especially when it involves rear limb problems, because it may delay or prevent proper mounting and copulation or lead to behavioral problems. Lameness problems are most critical when pasture breeding is used because the stallion must be able to follow his mares and copulate. Other breeding methods may allow more tolerance for lameness problems. Lame stallions required to cover tall mares can be helped if the mare's rear feet are placed in a pit during copulation. Also, stallions whose semen is collected while they mount on a phantom have the greatest flexibility because the phantom can be lowered to a more comfortable height. Careful observation of the stallion's movement and attention to subtle gait changes should allow early diagnosis of lameness and permit aggressive and successful therapy to keep the stallion from missed breedings. Necessary therapy may range from surgical intervention to administration of topical or systemic medications designed to alleviate pain associated with copulation. Stallions may also be trained to collect semen while standing on the ground, avoiding the jump mare or phantom altogether, using an artificial vagina.[4]

Ex copula ejaculation using prostaglandin F_2 alpha, detomidine, xylazine, or imipramine has been described.[5] Reports have included a variety of regimens, dosages, schedules, and combinations. Overall success rates have ranged from 30 to 75% for successful induction of ejaculation. One of the more tested and successful descriptions includes a treatment of 3 to 5 mg/kg imipramine orally, followed in 2 hours with xylazine at 0.66 mg/kg, intravenously. The stallion is in a stall without exposure to a tease mare. A collection device is made from a ring or hoop of wire or plastic large enough to insert snugly into the open arm of a sterile obstetrical sleeve. The hoop or ring is fashioned as a sling over the prepuce with gauze stints that extend laterally over the flanks to the croup and tied; additional stints may pass caudally between the rear legs and around the tail-head to the croup for better stability and anchoring. Tying off above the wrist area can shorten the sleeve and the excess material removed with scissors. The range of time to ejaculation in successful attempts was 1 to 14 minutes after the xylazine was administered. Occasionally, the stallion will ejaculate before the xylazine administration, and many will ejaculate in response to xylazine alone, without the imipramine before treatment.

Many neurologic diseases that affect stallions are discovered during a general physical examination. If such neurologic conditions are found to affect the stallion's ability to mount or copulate, then he should be rejected as a prospective breeder, or considered a candidate for ex copula ejaculation management.

Some diseases that affect a stallion's ability to mount and copulate include equine protozoal myeloencephali-

tis (EPM), cervical vertebral instability, equine herpesvirus myeloencephalopathy, and penile paralysis.

The parasitic disease EPM has been reported to cause cervical spinal cord and brain stem lesions. The *Sarcocystis neurona* organism can affect horses of nearly any age and causes microscopic damage to the ascending and descending spinal tracts, leading to rear limb instability.[6] An antemortem diagnosis of EPM is tentative and complicated by numerous false positive diagnostic test methodologies. A differential diagnosis should include cervical vertebral instability in horses younger than 3 years of age, neuritis of the cauda equina, and other neurologic disorders. Early diagnosis and treatment of EPM with a potentiated sulfonamide or with ponazuril may allow alleviation of clinical signs.

Cervical vertebral instability results from ventral spinal cord compression with proprioception deficit and ataxia of the rear limbs. Diagnosis of this condition depends on observation of clinical signs and on radiography. Generally, this condition is not treated, and, because it is likely to be heritable, afflicted males are not used for breeding.

Myeloencephalopathy induced by equine herpesvirus infection (EHV-1) occurs sporadically, and economic losses may vary.[7] The short-term mortality rate is low, but the long-term effects may be much more significant. Loss of rear limb proprioception, loss of urinary bladder control, inability to achieve erection, and rectal paralysis are potential complications that may prevent an affected stallion from performing his intended function as a breeding horse.

Spinal cord lesions in the ascending or descending spinal tracts, or both, cause variable loss of motor control to the rear legs. Motor control deficits limit ability to mount, thrust, and, perhaps, ejaculate. Affected stallions may learn to compensate for their deficits and with guidance and support from the handler may be capable of normal fertility. These considerations should be reserved for those stallions that develop nongenetic ataxic diseases.

Penile paralysis may result from administration of phenothiazine-derivative tranquilizers, spinal trauma, debilitating diseases, starvation, or direct trauma.[8] The etiologic pathogenesis of phenothiazine-caused penile paralysis remains obscure. It is recommended that administration of phenothiazine-derivative sedatives to breeding stallions be avoided. If sedation becomes necessary, other types of tranquilizers, such as xylazine or detomidine, may be used with less concern over penile paralysis. In the event that tranquilizer-induced paralysis occurs, it should be managed as described previously. Some penile paralysis cases can be resolved with proper care; however, many others will require surgical amputation of the penis (phallectomy).

Psychological Trauma

Stallions that suffer injuries associated with copulation may suffer psychological as well as physical trauma. After recovery from the physical trauma, the stallion may exhibit abnormal breeding behavior such as refusal to mount mares, mounting without intromission, and ejaculation failure. The more serious the physical trauma, the greater the likelihood of psychological damage. However, young timid stallions may exhibit psychological abnormalities from relatively minor injuries. Treatment of stallions exhibiting psychological or behavioral abnormalities requires sufficient time for recovery, as well as extreme patience by management. Psychologically affected stallions should be exposed only to mares at the peak of estrus; these mares must be as receptive and gentle as possible. When a session results in ejaculation and preinjury behavior, the stallion should be properly rewarded and praised and then removed from sexual contact until the next day. The handler should use all types of reward stimuli when the stallion shows the desired behavior. Positive reinforcement will ultimately restore normal sexual behavior. Care should be taken to prevent any subsequent copulation-associated injury; such reinjury would be a negative reinforcement with serious consequences.

Excessive disciplinary measures applied to breeding stallions can cause psychological problems and abnormal behavior. These behavior abnormalities may be manifested as failure to complete copulation or disinterest in mares. Treatment of such cases should proceed as described earlier. Excessive discipline cases often present a difficult diagnostic challenge for the clinician. A tougher challenge is to convince the stallion handler that he or she may be having an adverse effect on the stallion's behavior and thus his resultant fertility.

Urospermia

Urination during ejaculation will likely cause subfertility and may be caused by psychological abnormality or organic disease.[9] If the condition is behavioral, it may be amenable to treatment as outlined for other behavioral conditions. Management may include breeding or collecting semen only after observed urination. Administration of a diuretic followed by placing the stallion in a freshly bedded stall may assist this process. Those cases resulting from loss of bladder sphincter control may be treatable with the administration of flavoxate hydrochloride. Semen can be collected from the afflicted stallion with an open-ended artificial vagina to allow separation of the ejaculate fractions because many affected stallions urinate with the final ejaculatory pulsations.

Endocrine Abnormalities

Control of reproduction involves the gonadal steroids, gonadotropins, and other influential substances (e.g., autocrine and paracrine hormones and factors). These hormones influence the development of sexual organs, display of sexual behavior, production and maturation of spermatozoa, and production of seminal fluids. Endocrine abnormalities or imbalances can dramatically affect fertility.

Currently, measurement of follicle-stimulating hormone (FSH), luteinizing hormone (LH), total estrogens (TE), testosterone, thyroxine (T_4), tri-iodothyronine (T_3), cortisol, inhibin, and insulin in stallions is available.

Imbalances of TE and FSH in stallions can be associated with subfertility.[10] It has been shown that elevated concentrations of FSH and decreased concentrations of inhibin and TE are almost always associated with subfertility and onset of testicular degeneration, as evidenced by an increased number of breedings per pregnancy. Conversely, there have been cases of subfertility without demonstrable endocrine imbalance. One reason postulated for this paradox is the lack of evidence to demonstrate whether an endocrine imbalance precedes or follows seminiferous tubular degeneration. However, other reports indicate that declining inhibin and TE concentrations precede testicular degeneration. Periodic endocrine screening of breeding stallions to aid in predicting the onset of testicular degeneration is recommended.

Circulating concentrations of LH and testosterone should be measured before and after challenge with exogenous gonadotropin-releasing hormone (GnRH). Because circulating endocrine concentrations are affected by the season of the year and normal diurnal changes occur, these variations must be considered in the evaluation. The results of a GnRH challenge test may indicate a relationship between low total estrogens, low inhibin, high FSH concentrations, and subfertility. Stallions with idiopathic testicular dysfunction will display low motility (20–30% progressive motility), and marginal morphology (±40% normal sperm) along with some slight change in testicular consistency. In time, these stallions show decreasing inhibin, increasing FSH, and decreasing estrogen. Peripheral concentrations of testosterone and LH remain normal until such time as the sperm output significantly declines. Recent evidence in the stallion points toward initial pathologic dysfunction at the level of the Sertoli cells, spreading to the germ cells and then the Leydig cells, eventually moving to the hypothalamus and then the pituitary. Testicular inhibin (Sertoli cell) declined prior to changes in testicular steroid hormones in stallions studied progressively from normal fertility to subfertility.

Subfertile stallions may have low testicular response with respect to GnRH challenge tests because of a dysfunctional hypothalamic-pituitary axis producing bio-inactive LH, or a primary testicular dysfunction. Testicular biopsy may serve as an early indicator of endocrine/paracrine/autocrine dysfunction when used diagnostically in stallions being assessed for breeding soundness. The testicular tissues are submitted for direct endocrine analysis.

The efficacy of exogenous gonadotropin for treatment of stallion infertility has been seriously questioned. This lack of efficacy has been blamed on the paucity of knowledge regarding the interplay of hormone concentrations and season in normal and infertile stallions; lack of diagnostic criteria to indicate when treatment becomes necessary; and the lack of efficacious endocrine preparations to be used in stallions.

Other endocrine-related problems may be encountered in stallions. Cortisol, insulin, and glucose play a role in the diagnosis of pituitary tumors. Clinical signs of pituitary adenoma include chronic weight loss, shaggy hair coat with abnormal shedding patterns, polyuria and polydipsia, and hyperglycemia. These signs will likely appear well after age-related onset of testicular degeneration has contributed to fertility problems. Horses presented with evidence of testicular degeneration and one or more of these clinical signs should be tested for depression of endogenous cortisol in response to glucocorticoid administration. Thyroid dysfunction may be suspected in stallions with depressed libido and excessive body weight. Affected animals classically maintain their body condition with minimal caloric intake. Diagnosis of hypothyroidism should be based on T_3 and T_4 assays, thyrotropin-releasing hormone (TRH) challenge, and clinical signs. Therapy for hypothyroidism consists of daily supplementation with sodium levothyroxine (10 mg) or iodinated casein (5 mg). These measures should be combined with dietary restriction and exercise.

INFECTIOUS DISEASES

Systemic Infections

Systemic infectious diseases may decrease fertility by causing reproductive tract inflammation or through their effects on other systems. Such conditions may be readily transmissible through a variety of means, including venereal.

Systemic illness or any condition that causes pyrexia may decrease fertility. Prolonged pyrexia, inflammation of the scrotum, testes, or epididymides, may interfere with the thermoregulatory mechanism of the testes. Compromise of the thermoregulatory mechanism results in a significant reduction of progressively motile spermatozoa, increased morphologic defects, and significant reduction of total sperm. These effects last 60 to 70 days after resolution of the problem. Toxins, chemicals, or other substances may affect fertility by causing systemic illness or by direct effect on the testes. Systemic illnesses that produce lethargy or inappetence may decrease or eliminate libido. Such systemic conditions may not decrease numbers of spermatozoa or render them incapable of fertilization, but when a stallion is unwilling to copulate, his fertility is reduced. Treatment should be aimed at rapid elimination of the primary cause of the illness and should allow resumption of normal sperm production.

The clinician should recommend complete semen evaluation as soon as possible following abatement of the condition and reexamination 60 days later. During the 60-day recovery period, management should alter the stallion's mare book to compensate for his subfertility. After a 60-day rest, an estimate of fertility based on evaluation of semen quality will help determine when the stallion may be able to return to the previous breeding level. If poor semen quality persists, a reduced breeding load must be continued and further evaluations planned at approximately 15-day intervals until semen quality returns to preinjury status. This same protocol can be used for any condition found to temporarily decrease fertility.

Bacteria and Viruses

Subfertility caused by bacteria or viruses may affect the internal or external reproductive organs. These microorganisms may or may not be transmitted venereally. The stallion's external genitalia are not sterile, and most cultures or samples from these sites yield bacteria that may or may not not be related to infertility. Many bacteria have been considered part of the normal flora. Pathogenic bacteria that should be of concern are *Pseudomonas aeruginosa, Klebsiella pneumoniae, Streptococcus zooepidemicus, Taylorella equigenitalis,* and, rarely, others. These bacteria may be transmitted venereally to susceptible mares or exist in the stallion without being transmitted to mares.

Overt clinical signs of bacterial infection of the internal or external genitalia may not be apparent. Rather, infection is suspected based on assessment of breeding results and culture of the reproductive organs. Confirmation of suspected subfertility should begin with an indication that mares have been bred during several cycles without conception; reduced pregnancy rate; an increased incidence of early embryonic deaths; or a combination of these findings.

Once suspicions of subfertility are confirmed, evaluation of the stallion should be performed. In addition to semen collection and evaluation, the genitalia should be cultured. Prior to collecting culture swabs, the genitalia should be rinsed with clear warm water to remove debris and smegma and then dried with a clean cloth or paper towel. Scrubbing with soap, detergent, or disinfectant should be avoided.[11] Cultures should be obtained from the fossa glandis, the shaft of the penis, the urethra following sufficient teasing to cause discharge of preejaculatory fluids, the urethra following ejaculation, and optionally from the raw ejaculate. The recess of the fossa glandis has been shown to be a reservoir for potential pathogens. All swabs should be protected to prevent drying and rapidly transported to a microbiology laboratory using an appropriate transport nutrient medium. Aerobic and microaerophilic culture conditions need to be considered especially when screening for *Taylorella equigenitalis*.

Evaluation of the culture results should include consideration of the anatomic location where bacteria were found, whether they appeared on the growth medium in significant numbers within the first 24 hours of incubation, the species of organisms isolated, and whether the results correlate with subfertility. To be considered pathogens, bacterial colonies should grow in significant numbers within the first 24 hours of incubation, the organism should be uniformly distributed in all parts of the reproductive tract, and management records must indicate abnormal breeding efficiency. There may be an increased number of inflammatory cells in the ejaculate when the internal reproductive organs have been invaded by pathogens. Stained smears of the ejaculate should be examined for inflammatory cells. Isolation of pathogenic organisms from maiden stallions should be considered suspicious and the procedure repeated.

Pathogenic bacteria may be found throughout the stallion's reproductive tract, but the external genitalia and accessory sex glands harbor the organisms most frequently implicated as causes of subfertility. Pathogens residing on the epithelial surfaces of the penis and sheath or in the accessory glands may be transmitted to mares.[12] However, venereal transmission of pathogenic bacteria is difficult to substantiate by uterine cultures obtained immediately after breeding. Increased breeding of contaminated mares by natural service, or iatrogenic alteration of the normal bacterial flora of the penis and prepuce, or both, may be involved in increased bacterial contamination as the breeding season progresses. The first sign of increased bacterial contamination might be evidence of subfertility within a stallion's mare book as the season progresses.

The accessory sex glands contain pathogenic bacteria less frequently than the external genitalia. However, when present, infected accessory glands may exhibit localized swelling with discharge of purulent exudates into the ejaculate. Diagnosis of accessory gland infection can be confirmed by selective cultures, palpation, transrectal ultrasonography, urethroscopy, splitting the ejaculate during semen collection, and examination of stained preparations of the ejaculate for inflammatory cells. Documented accessory gland infections are difficult to ameliorate with systemic antibiotic therapy. Breeding management programs might include breeding with the minimal contamination technique or artificial insemination with extenders containing antibiotics. An ejaculate should be collected and mixed with semen extender containing antibiotics, and sufficient time (30 minutes) should be allowed before insemination. If artificial insemination cannot be used, antibiotic-containing semen extender should be infused into the uterus prior to the mare's copulation with the infected stallion. This method does not entirely prevent bacterial transmission but may allow successful breeding when other options do not exist. Another method for preventing bacterial transmission may be lavage of the mare's uterus 4 to 8 hours after copulation.

Bacterial contamination of stallions may arise from their covering infected mares or from overzealous scrubbing of the external genitals with soaps or detergents or may be transmitted by improperly cleaned equipment (e.g., artificial vagina). The external genitalia of breeding stallions should be cleansed with warm clear water only, and the use of soaps, detergents, and disinfectants should be avoided. Separate semen collection and handling equipment should be designed for each stallion on the farm and maintained in a clean and sterile manner to limit the probability of disease spread.

Taylorella equigenitalis, a bacterium transmitted venereally among horses, has been reported in Europe and has caused several outbreaks in the United States. The organism has been found to persist in the clitoral fossa and clitoral sinuses of carrier mares. Transmission to susceptible stallions during coitus has been reported; contaminated stallions in turn transmit the bacterium to susceptible mares. The organism may also be transmitted by fomites used in handling and treating mares or stallions. Mares infected for the first time usually exhibit a mucopurulent vaginal discharge for about 2 weeks. After 2 weeks, the

discharge disappears without treatment and the mare becomes a chronic carrier. Stallions are asymptomatic carriers and exhibit no apparent reduction in fertility, except when bred to susceptible mares. Stallions continue to transmit bacteria for an unknown time period.

Diagnosis of *T. equigenitalis* in stallions should include cultures of the urethral fossa, urethra, prepuce, the preejaculatory fluid, and semen.[12] Mares exhibiting vulval discharge should have cultures taken from the clitoral fossa and sinuses and the uterus. This organism requires special handling and transport on Amies charcoal medium to ensure proper growth and identification. To assist positive identification of the organism a polymerase chain reaction (PCR) assay has been developed for use in some laboratories. About 2 to 3 weeks following initial exposure, the mare will develop antibodies and be seropositive on a complement fixation test for *T. equigenitalis*. However, such tests are of no benefit for diagnosis of the disease in stallions. The International Organization of Epizootics (Organization International de Epizooties, OIE) recommends treatment to include daily washing of the infected stallion's penis with 2% chlorhexidine scrub, followed by 0.2% nitrofurazone cream over the entire penis and packing the urethral fossa.[13] The treatment is applied once daily for a minimum of 5 successive days.

Two important viral diseases of breeding horses in the United States are equine arteritis virus (EAV) and equine herpesvirus III (EHV-3; coital exanthema). There have been numerous outbreaks of viral arteritis at racetracks and on breeding farms in recent years. Acute EVA infection may cause systemic illness with clinical signs such as fever, stiffened gait, lacrimation and conjunctivitis, nasal discharge, skin rash, and edema of the lower limbs, scrotum, sheath, and head. Abortion has been known to occur in acutely ill or convalescent mares. Acutely infected horses transmit the disease primarily via the respiratory tract.

Stallions may become infected with EAV via aerosol transmission (nasopharyngeal and genitourinary secretions) from acutely ill horses or by venereal transmission from breeding an acutely infected mare. The acutely infected stallion may initially develop scrotal edema, resulting in temporary infertility from disruption of the testicular thermoregulatory mechanism. Compromise of the testes is primarily indicated by decreased progressive motility of sperm while other seminal parameters remain essentially normal. Infected stallions become asymptomatic carriers and shed the virus in the ejaculate. Virus shedding in the ejaculate may last from a few weeks to more than 3 years. Mares bred by chronic carrier stallions usually do not develop acute illness or reduced fertility, but they may transmit the virus venereally to another stallion.

Infection with EAV may be demonstrated in stallions by seroconversion using serum neutralization or complement fixation tests on serum samples collected at 3- to 40-week intervals. Attempts should be made to isolate the virus from the ejaculate of seropositive stallions, or they should be test-mated to seronegative mares. Test-mated mares are then monitored for seroconversion. After infected stallions have been identified, control measures should be instituted to prevent spread of the disease.

Measures for control and prevention of EAV include administration of a modified live vaccine approved for use in nonpregnant mares and in stallions in the United States or a formalin-inactivated vaccine available in Europe. Control programs should include stallions found to be chronic shedders of EAV in the ejaculate, first-season stallions that may be exposed to EAV, and seronegative broodmares. Vaccinated horses or any other horses with titers to EAV may not be eligible for export to certain countries.

Coital exanthema, caused by EHV-3, may occur as an external genital infection in mares and stallions. At times, the virus can cause systemic signs of infection, including dullness, anorexia, and fever. However, the most common evidence of this disease is vesicles on the penis and prepuce of stallions and on the vulva of mares. Stallions can become infected by coitus with infected mares and subsequently transmit the disease venereally to other mares. A few days after exposure, vesicles form on the penis and prepuce, rupture, then become pustules with ulcers beneath crusts. These ulcers may cause pain during coitus or hemorrhage into the ejaculate, or both. The disease is self-limiting and noninfectious once the ulcerative lesions have healed. Depigmented skin areas on the penis, prepuce, and the mare's vulva may follow once the ulcers have healed. Immunity to this virus is relatively short, and previously afflicted horses are subject to reinfection later during the same breeding season or during subsequent seasons. The disease may be transmitted on farms utilizing artificial insemination by contaminated instruments and equipment. A stallion used for natural service must be sexually rested until the lesions have healed. Stallions with active disease used for artificial insemination may continue to breed if they do not hemorrhage during semen collection. An open-end artificial vagina can be used to collect the semen to prevent contact between the ejaculate and contaminated surfaces, thus reducing the risk of virus transmission to the mares being inseminated. Stallions can be asymptomatic carriers for a long period of time, and occasionally the virus can be isolated from external genital culture sites.

Trypanosoma equiperdum is the etiologic agent for dourine. Although not a problem in the U.S. breeding population, it should always be considered with the risks associated with shipping horses and semen across international borders. Clinical signs include fever, purulent exudate from the urethra of affected stallions, and chronic weight loss. Definitive diagnosis is based upon serologic testing and culture of the organism. Infected stallions do not respond to treatment and are often euthanized.

CHAPTER 4

Surgical Correction of Abnormalities Affecting the Reproductive Organs of Stallions

JIM SCHUMACHER and DICKSON D. VARNER

INGUINAL HERNIATION AND RUPTURE

Inguinal herniation in the stallion occurs when intestine, usually the ileum or distal portion of the jejunum, enters the vaginal sac or cavity (i.e., the inguinal canal) through the vaginal ring. If intestine extends into the scrotum, this herniation is sometimes referred to as scrotal rather than inguinal,[1] but the terms are used interchangeably. Inguinal hernias of stallions are sometimes improperly referred to as "indirect hernias," a term used to describe a similar condition in human beings.

Ruptured inguinal (scrotal) herniation occurs when herniated intestine protrudes through a rent in the vaginal sac into the subcutaneous tissue of the scrotum.[2] Inguinal rupture is protrusion of viscera into the subcutaneous tissue of the inguinal canal or scrotum through a rent in the peritoneum and musculature adjacent to the vaginal ring.[1] Inguinal ruptures in horses are sometimes inappropriately termed "direct hernias," which is terminology borrowed from a somewhat similar condition in human beings. Direct hernias in human beings are caused by weakening of the inguinal musculature and are lined by peritoneum, whereas inguinal ruptures of horses are not lined by peritoneum. Direct herniation predominates in human beings, whereas inguinal herniation (i.e., indirect herniation) predominates in stallions.

Most inguinal hernias of foals are congenital and hereditary.[3] They occur when a vaginal ring is so large that it permits viscera to enter the vaginal sac. Congenital inguinal hernias in foals may occur unilaterally (usually on the left side) or bilaterally and may occur more frequently in Standardbreds, Tennessee Walking horses, and American saddlebred horses.[4,5]

Ruptured inguinal hernias occur most commonly in foals and may be caused by high abdominal pressure generated during parturition.[2,6] Inguinal hernias in adult stallions are generally acquired, but the underlying cause is usually a congenitally enlarged vaginal ring. The left vaginal ring is the ring most commonly involved.[5] Herniation has been reported to occur during breeding or

CHAPTER 4

Surgical Correction of Abnormalities Affecting the Reproductive Organs of Stallions

JIM SCHUMACHER and DICKSON D. VARNER

INGUINAL HERNIATION AND RUPTURE

Inguinal herniation in the stallion occurs when intestine, usually the ileum or distal portion of the jejunum, enters the vaginal sac or cavity (i.e., the inguinal canal) through the vaginal ring. If intestine extends into the scrotum, this herniation is sometimes referred to as scrotal rather than inguinal,[1] but the terms are used interchangeably. Inguinal hernias of stallions are sometimes improperly referred to as "indirect hernias," a term used to describe a similar condition in human beings.

Ruptured inguinal (scrotal) herniation occurs when herniated intestine protrudes through a rent in the vaginal sac into the subcutaneous tissue of the scrotum.[2] Inguinal rupture is protrusion of viscera into the subcutaneous tissue of the inguinal canal or scrotum through a rent in the peritoneum and musculature adjacent to the vaginal ring.[1] Inguinal ruptures in horses are sometimes inappropriately termed "direct hernias," which is terminology borrowed from a somewhat similar condition in human beings. Direct hernias in human beings are caused by weakening of the inguinal musculature and are lined by peritoneum, whereas inguinal ruptures of horses are not lined by peritoneum. Direct herniation predominates in human beings, whereas inguinal herniation (i.e., indirect herniation) predominates in stallions.

Most inguinal hernias of foals are congenital and hereditary.[3] They occur when a vaginal ring is so large that it permits viscera to enter the vaginal sac. Congenital inguinal hernias in foals may occur unilaterally (usually on the left side) or bilaterally and may occur more frequently in Standardbreds, Tennessee Walking horses, and American saddlebred horses.[4,5]

Ruptured inguinal hernias occur most commonly in foals and may be caused by high abdominal pressure generated during parturition.[2,6] Inguinal hernias in adult stallions are generally acquired, but the underlying cause is usually a congenitally enlarged vaginal ring. The left vaginal ring is the ring most commonly involved.[5] Herniation has been reported to occur during breeding or

exercise,[7] but it has also been identified in stallions being transported and in stallions confined to a stall. The incidence of acquired inguinal herniation is higher in Standardbreds, American saddlebreds, and Tennessee Walking horses than in the general equine population,[4,7] and the higher incidence in these breeds may be attributable to herniation of viscera through a congenitally enlarged vaginal ring. Inguinal ruptures in horses are rare and usually occur after a traumatic event.[1]

Inguinal hernias, ruptured inguinal hernias, and inguinal ruptures usually cause a noticeable increase in the size of the scrotum. Palpation of the scrotum of an affected horse may elicit a sensation of crepitus, and peristalsis of entrapped intestine may cause movement of scrotal skin. The contents of congenital inguinal hernias in foals, because of the relatively large size of the vaginal ring, are rarely strangulated and reduce easily. Rupture of a congenital inguinal hernia should be suspected if the viscera cannot be reduced, if the scrotum is cold and edematous, or if the hernia is accompanied by signs of colic.[2,6]

Acquired inguinal herniation is usually first recognized when the affected stallion begins to show signs of severe colic caused by strangulation of incarcerated intestine by the vaginal ring. Acquired inguinal hernias are usually accompanied by scrotal and testicular edema, because the vasculature of the spermatic cord becomes obstructed. Examination of the stallion's vaginal rings by palpation per rectum reveals that intestine has entered a vaginal cavity. Omentum may also enter the vaginal cavity independently or with intestine, but incarceration of omentum alone is unlikely to be accompanied by signs of colic.

Foals with a congenital inguinal hernia should be monitored regularly by palpation for signs of strangulation. The hernia often resolves spontaneously by the time the foal is 3 to 6 months old, but the mechanism by which this occurs is not well understood.[1,8,9] Application of a truss may hasten resolution (Fig. 4-1). The truss is applied with the foal in dorsal recumbency after the hernia has been reduced manually. Care should be taken to avoid interfering with urination by compressing the penis with the truss. The truss is usually changed at 3- to 5-day intervals. The hernia is often corrected within 1 to 2 weeks following application of the truss.

Congenital inguinal hernias of foals usually resolve spontaneously, but surgical correction becomes necessary if the hernia is so large that it is unlikely to resolve spontaneously or if the contents of the hernia become strangulated. To surgically correct an inguinal hernia, the foal is anesthetized and positioned in dorsal recumbency, and the inguinal region is prepared for surgery. An incision is created over the superficial inguinal ring of the affected side, the vaginal sac and its contents are exposed by blunt dissection, and the scrotal ligament, which attaches the vaginal sac to the scrotum, is severed. The contents of the hernia are replaced through the vaginal ring into the abdomen, and the spermatic cord is ligated close to the superficial inguinal ring and severed distal to the ligature. The superficial inguinal ring can be sutured for added security, and the incised subcutaneous tissue and skin are sutured or left open to heal by second intention.

Congenital inguinal hernias of foals can also be corrected laparoscopically with the foal anesthetized and positioned in dorsal recumbency.[10,11] After the contents of the hernia are reduced, the testis of the affected side is either removed laparoscopically or left in situ, and the vaginal ring is closed with a laparoscopic stapling device. Laparoscopic correction of congenital inguinal herniation is relatively quick and allows the foal to return quickly to normal activity.

Stallions with an acquired inguinal hernia, a ruptured inguinal hernia, or an inguinal rupture demand immediate attention, because the intestinal contents of the hernia nearly always rapidly strangulate. Reduction by external manual manipulation or rectal traction on inguinally incarcerated intestine is described,[12] but is difficult and rarely successful. Surgical reduction of an acquired inguinal hernia is necessary if the viability of the affected testis or incarcerated intestine is uncertain.

To surgically reduce inguinally incarcerated intestine, the stallion should be anesthetized, positioned in dorsal recumbency, and prepared for inguinal exploration and celiotomy at the ventral midline. A cutaneous incision is

created over the superficial inguinal ring or scrotum, the vaginal sac and its contents are isolated using blunt dissection, and the vaginal sac is incised to expose the testis, its spermatic cord, and the incarcerated intestine. Incarcerated intestine is most easily reduced by placing traction on it through a small ventral midline celiotomy. Often, the vaginal ring is so constricting that the intestine cannot be returned to the abdominal cavity without first enlarging the ring. The ring can be enlarged by cutting it with a curved bistoury or scissors.

Devitalized intestine (Fig. 4-2) can be resected and anastomosed at the inguinal incision, but resection and anastomosis are usually more easily accomplished after the intestine is returned to the abdominal cavity and exteriorized through a celiotomy at the ventral midline. Attempting to save the testis is impractical unless it and its vasculature appear to be undamaged. To remove the testis, the scrotal ligament is severed. The spermatic cord, including the parietal tunic, is ligated with heavy absorbable suture and severed distal to the ligature. The superficial inguinal ring is closed with a continuous or interrupted pattern using heavy absorbable suture. Inguinal fascia and skin can be sutured or left unsutured to heal by second intention. After removal of the affected testis, compensatory hypertrophy of the remaining testis may occur.[13]

TORSION OF THE SPERMATIC CORD

Torsion of the spermatic cord occurs when a portion of the spermatic cord rotates around its vertical axis.[14] Torsion of the spermatic cord is sometimes incorrectly referred to as testicular torsion. Torsions of 180 degrees or less seem to cause no discomfort to stallions and are often considered to be an incidental finding,[15] but torsion of a spermatic cord of 180 degrees may cause retrograde blood flow, indicating that torsion of this degree may have an injurious effect on testicular function.[16] Torsions of 360 degrees or more cause acute venous and arterial occlusion of testicular blood supply, and if the rotation is not reduced quickly, the testis and spermatic cord distal to the torsion become gangrenous.[14,15,17,18]

In human beings, torsion of the spermatic cord nearly always occurs intravaginally (within the vaginal tunic) rather than extravaginally (outside the vaginal tunic),[14] and likewise, torsion of the spermatic cord of the stallion apparently occurs primarily intravaginally.[15,17,18] Torsion may be caused by an abnormally long caudal ligament of the epididymis (ligament of the tail of the epididymis)[15] or by an abnormally long proper ligament of the testis (Fig. 4-3).[18] The gubernacular attachments of the contralateral testis may also be abnormally long, making that testis prone to torsion.[18] Torsion of the spermatic cord of horses is infrequently reported,[18,19] but torsion of 180 degrees is detected occasionally during examination of the external genitalia of the stallion. The spermatic cord of abdominally located testes may be more prone to torsion and may lead to gangrenous changes in the affected testis.[19]

Signs of torsion of the spermatic cord of stallions include scrotal swelling and signs of colic.[15,17,18] Other diseases, such as inguinal herniation, orchitis, and epididymitis, produce similar signs, but these diseases can usually be excluded by palpation of the scrotal contents, examination of the vaginal rings by palpation per rectum, and ultrasonography. Normally, the head of the epididymis lies on the cranial pole of the testis, the tail lies at the caudal pole, and the body attaches to the dorsolateral border of the testis. With torsion of 180 degrees, the tail of the epididymis lies cranial, but with torsion of 360 degrees, the testis and epididymis may appear to be correctly aligned. The affected testis and cord are enlarged and firm, and the testis may appear to be surrounded by fluid.[17,18] With torsion of 360 degrees or more, the scrotum and its contents may be so swollen that palpation of the epididymis is not possible. Ultrasonographic examination of the affected testis and cord may reveal increased fluid density throughout the affected side of the scrotum.[18] Torsion of the spermatic cord of an abdominal cryptorchid testis may cause the affected horse to show

mild signs of colic,[20] but affected horses may display no signs of colic.[21]

A 360-degree torsion of the spermatic cord typically necessitates removal of the affected testis. If the testis is salvageable, orchiopexy using nonabsorbable suture can be performed to permanently fix the testis in its proper position.[18] One suture is placed at the cranial aspect of testis and one at its caudal aspect. The suture is passed through the adjacent dartos tissue, vaginal tunic, and tunica albuginea. The surgeon should consider performing orchiopexy on the contralateral testis, because it may also be prone to torsion. Transient torsion of the spermatic cord of human beings may result in formation of antisperm antibodies or release of other factors that may affect fertility,[22] but the effect of transient torsion of the spermatic cord of stallions is not known.

HYDROCELE

A hydrocele is a pathologic accumulation of serous fluid between the visceral and parietal layers of the vaginal tunic.[23–26] Because of the insulating effects of the fluid, temperature-induced dysfunction of spermatogenesis is generally thought to occur, although one study did not reveal a substantial effect of hydrocele on semen quality. The vaginal tunic is secretory, and fluid produced by the vaginal tunic is resorbed through the veins and lymphatic vessels of the spermatic cord.[27] Hydrocele results when production of fluid by the vaginal tunic is increased or resorption is decreased. Hydroceles may accompany testicular neoplasia or scrotal trauma or they may be idiopathic. Some forms of idiopathic hydroceles may occur during hot weather, sometime in association with restricted exercise.[26] Because the vaginal cavity communicates with the peritoneal cavity, a hydrocele may form as an extension of ascites.[24] Migration of parasites into the vaginal cavity and associated structures has been implicated as a cause of hydrocele.[23]

A hydrocele appears as a painless, fluid-filled scrotal enlargement.[23–25,27] It may occur bilaterally or unilaterally and may develop acutely or insidiously. If the hydrocele is chronic, the testis within the affected tunic may become smaller than normal due to atrophy. A hydrocele can usually be differentiated from other diseases that cause scrotal enlargement by palpating the scrotal contents, by examining the vaginal rings per rectum, and by using ultrasonography. Ultrasonographic examination of a hydrocele reveals anechoic or hypoechoic fluid surrounding the testis (Fig. 4-4). Diagnosis is verified by aseptic aspiration of a serous, amber fluid from the vaginal cavity.

Exercise may cause a temporary decrease in the size of a hydrocele, and occasionally, a hydrocele may resolve spontaneously. Aspiration of fluid from a hydrocele usually gives only transient relief because the fluid soon re-forms. Treatment of a stallion with a hydrocele should be aimed at removing the inciting cause, but because the cause can rarely be identified, the usual treatment of a stallion with persistent, unilateral hydrocele is removal of the affected testis and vaginal tunic to avoid disruption of spermatogenesis of the contralateral testis that may be induced by increased scrotal temperature. Prognosis for fertility can be guarded if bilateral hydroceles persist, although the condition has been reported to have no ill effect on fertility in some cases.[26]

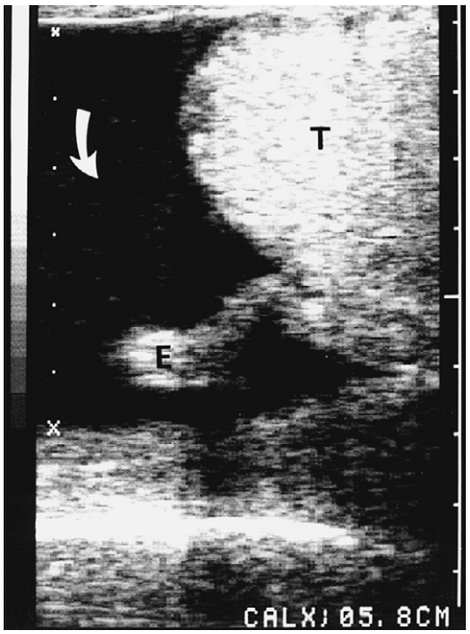

Fig. 4-4 Ultrasonographic image of the testis *(T),* cauda epididymis *(E),* and vaginal space *(arrow)* in a stallion with a pronounced hydrocele. (From Varner DD, Schumacher J, Blanchard TL, Johnson L: *Diseases and Management of Breeding Stallions.* St. Louis, 1991, Mosby.)

Hydroceles of men were successfully treated by sclerotherapy using either 2.5, 5, or 10% solutions of tetracycline injected into the vaginal cavity.[28] Injection of the sclerosant often caused severe pain, even if local anesthetic solution was injected into the vaginal cavity prior to treatment. Sclerotherapy, as a treatment for stallions with hydrocele, has not been reported.

HEMATOCELE

A hematocele resembles a hydrocele but is a collection of hemorrhagic, rather than serous, fluid within the vaginal cavity (Fig. 4-5).[25,29] Hematoceles are usually caused by trauma to the scrotum and its contents, but because the peritoneal and vaginal cavities of the horse communicate, they can occur as an extension of hemoperitoneum.[30]

A hematocele caused by acute trauma to the scrotal contents is usually accompanied by pain. Ultrasonographic examination of the contents of the scrotum may help differentiate hematocele from hydrocele and other causes of scrotal enlargement. Some causes of hematocele, such as rupture of the tunica albuginea of the testis, may be detected by ultrasonographic examination. Diagnosis is confirmed by aseptic aspiration of sanguineous fluid from the vaginal cavity. Scrotal swelling associated with hematocele can be quite pronounced.

A small hematocele may cause no problem with fertility and may dissipate without treatment, but a large hematocele may insulate the testes, causing interference

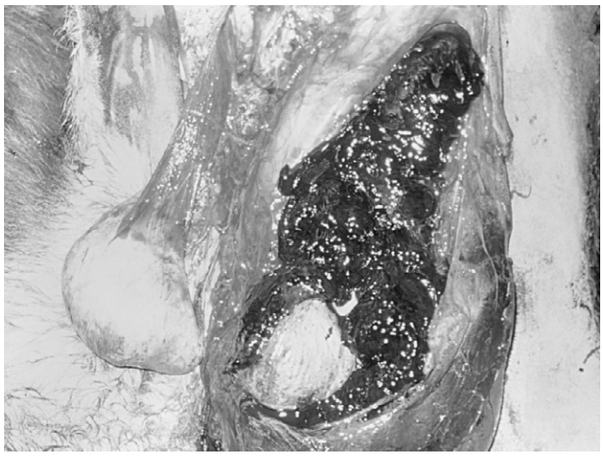

Fig. 4-5 Massive bleeding into the vaginal space of a jack emanating from a ruptured tunica albuginea and testicular hemorrhage. (From Varner DD, Schumacher J, Blanchard TL, Johnson L: *Diseases and Management of Breeding Stallions.* St. Louis, 1991, Mosby.)

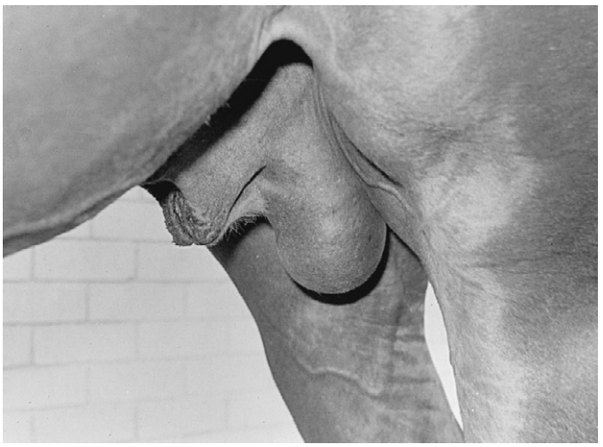

Fig. 4-6 Varicocele of the left pampiniform plexus in a stallion, resulting in abnormal thickening of the scrotal neck on the affected side. (From Varner DD, Schumacher J, Blanchard TL, Johnson L: *Diseases and Management of Breeding Stallions.* St. Louis, 1991, Mosby.)

with spermatogenesis. A large hematocele should be evacuated from the vaginal cavity, and the testis and epididymis should be carefully inspected to identify the source of hemorrhage. The tunica albuginea, if torn, should be sutured. Orchidectomy is indicated if the testis or epididymis is badly damaged. The effect of testicular trauma on formation of antisperm antibodies and secondary subfertility in stallions is not known. Removal of the affected testis may be indicated to minimize the likelihood of such a complication and to prevent depression of spermatogenesis of the contralateral testis from increased temperature caused by inflammation of the scrotal contents.

VARICOCELE

A varicocele is a dilatation and tortuosity of the veins of the pampiniform plexus and the cremasteric veins (Fig. 4-6).[24,25] Varicoceles of human beings and rams have been associated with testicular atrophy and decreased seminal quality, possibly caused by interference with normal exchange of heat from the testicular artery to the pampiniform plexus.[24] Varicoceles of stallions are uncommon, and their effect on fertility is not documented. More than 50% of men with varicoceles have normal seminal quality.[31] One of the authors (DV) has observed a varicocele in some stallions with normal seminal quality.

Most varicoceles are idiopathic, but a defect in the valves of the spermatic vein where it empties into the vena cava or renal vein, or a deficiency of elastic and fibrous tissue in the fascia that surrounds the spermatic vein has been postulated to cause varicoele.[24] Varicoceles of stallions are usually unilateral and, when palpated, produce no signs of pain. The affected spermatic cord appears enlarged and may have the texture of "a bag of worms."

Definitive treatment of stallions affected with varicocele is removal of the affected cord and testis, but therapy is unnecessary if seminal quality is unaffected. The venous loops of the pampiniform plexus have been ligated as treatment of human beings with varicocele.[32] A hydrocele has formed in a small percentage of human beings following ligation of the spermatic vein.

TESTICULAR NEOPLASIA

Testicular neoplasms of the horse are encountered infrequently, probably because most horses are castrated at an early age. Only primary testicular neoplasms (i.e., those that originate within the testis) have been reported, and these can be divided into germinal and nongerminal types.[33] Germinal neoplasms arise from the germ cells of the seminiferous epithelium and are the most common type of germinal neoplasm.[24]

Germinal testicular neoplasms reported to occur in the horse include the seminoma, teratoma, teratocarcinoma, and embryonal carcinoma. The seminoma is probably the most commonly reported testicular neoplasm of the horse. Nongerminal testicular neoplasms arise from testicular stromal cells and include the Leydig cell tumor and Sertoli cell tumor.[33] Nongerminal testicular neoplasms of the horse are uncommonly reported. Cryptorchid testes of human beings and dogs appear to be predisposed to neoplasia,[33,34] but for horses, a relationship between cryptorchidism and formation of testicular neoplasia has not been definitively established.

When examining a horse with a suspected testicular neoplasm, the clinician should use the contralateral testis for comparison, remembering, however, that bilateral testicular neoplasia can occur. The normal testis is smooth and compliant, and a neoplastic testis is often enlarged, with either a soft or hardened texture of the tumorous tissue. The neoplastic testis is often heavier than its normal counterpart. Small, neoplastic lesions located

deep within the parenchyma may not be palpable. A neoplastic testis is usually painless when compressed and usually remains freely movable within the scrotum. Scrotal enlargement caused by neoplasia must be differentiated from other causes of scrotal enlargement, such as torsion of the spermatic cord, orchitis, hydrocele, hematocele, and inguinal herniation or rupture. Careful external palpation of the scrotal contents and palpation of the vaginal rings and viscera per rectum can be used to differentiate these conditions. Painless, scrotal enlargement that develops insidiously is more likely to be caused by testicular neoplasia than by inflammation or ischemia.

Ultrasonographic examination of the contents of the scrotum may be helpful in determining if a testis is neoplastic. Normal testicular parenchyma is homogeneously echogenic, but a neoplastic testis usually contains areas of decreased echogenicity. Affected testes may contain single or multiple tumors. Testicular neoplasia can be confirmed by cytologic examination of a needle aspirate or by histologic examination of a needle or incisional biopsy of the testis. Incisional biopsy has been associated with complications, but needle biopsy is unlikely to have injurious effects on the testis.[35–38] Creation of antisperm antibodies and reduction in quality of semen reported to occur in other species after needle biopsy have not been found to occur in horses. Biopsy of neoplastic testes of human beings has been associated with a high incidence of neoplastic invasion of extratesticular tissue,[39] and so, if testicular neoplasia is strongly suspected, the affected testis should be excised.

Before a neoplastic testis is removed, the iliac lymph nodes should be palpated per rectum to aid determination of whether the neoplasm has metastasized (Fig. 4-7). The neoplastic testis should be removed using the closed technique, and the spermatic cord should be ligated and severed as far proximally as possible. The spermatic cord should be examined grossly and histologically for evidence of metastasis. The scrotal incision should be sutured to reduce postoperative inflammation, which may interfere with thermal regulation of the remaining testis, but good hemostasis is required before the scrotal incision is sutured.

PENILE AND PREPUTIAL INJURIES

Penile and preputial injuries include lacerations and hematomas and are usually caused by kicks, especially to the erect penis; mounting of stationary objects; attempting to breed a mare across a barrier; severe bending of the penile shaft during coitus or semen collection; and improperly fitted or maintained stallion rings.[40] Deep lacerations that extend into a corporeal body may result in hemospermia or impotence,[41] and those that extend into the urethra may result in severe necrosis of tissue from escape of urine.

Even superficial lacerations can result in severe penile damage if the horse is left untreated. An unattended laceration to the penile epithelium can result in cellulitis and preputial edema, which in turn, can lead to protrusion of the penis and internal preputial lamina from the preputial cavity. Protrusion of the penis and prepuce may lead to penile paralysis from damage to the pudendal nerves and to further damage to the exposed penile and preputial epithelium.

Fresh lacerations to penile and preputial epithelium should be sutured with soft, absorbable or nonabsorbable suture. An infected or heavily contaminated laceration should be left open to heal by second intention or closed at a later date when it shows no signs of inflammation. If the wound is left open, it should be dressed frequently with a nonirritating antimicrobial ointment. If the laceration is accompanied by severe preputial edema, the penis and prepuce should be retained within the preputial cavity with a retainer bottle, nylon netting, or hosiery suspended at the preputial orifice with a crupper and surcingle made of rubber tubing (Figs. 4-8 and 4-9).

Fig. 4-9 Nylon mesh, with attached tubing, fitted over the preputial orifice of a stallion to aid retention of the device shown in Figure 4-8 within the preputial cavity. (From Varner DD, Schumacher J, Blanchard TL, Johnson L: *Diseases and Management of Breeding Stallions.* St. Louis, 1991, Mosby.)

Fig. 4-10 A bandage is used to compress the penis against the ventral body wall.

The penis can be retained within the preputial cavity for several days with towel clamps or sutures placed across the preputial orifice or preputial ring, but sutures and towel clamps may exacerbate the preputial trauma. If the penis cannot be retained in the preputial cavity, it can be compressed against the ventral aspect of the belly wall with a bandage (Fig. 4-10).

Penile hematomas that continue to expand should be explored to identify a rent in the tunica albuginea. A laceration to the tunica albuginea should be identified and sutured. A laceration to the urethra should be sutured, and if the laceration is transverse, a large-bore catheter should be maintained in the lumen of the urethra to prevent formation of a stenosing cicatrix. A stallion affected with preputial and penile trauma should be isolated from mares until the wound has healed.

PARAPHIMOSIS OR PENILE PROTRUSION

Paraphimosis, or the inability of the horse to retract its penis into the preputial cavity, is usually caused by preputial edema that occurs secondary to trauma, such as preputial laceration or preputial hematoma, or from preputial edema that accompanies systemic disease such as dourine or purpura hemorrhagica.[40,42] Penile protrusion can be caused by damage to innervation of the penis, which may accompany some neurologic diseases, such as equine herpesvirus 1.[40,43] Penile protrusion has been associated with severe debilitation[44] and with administration of phenothiazine-derivative tranquilizers.[45,46] A phenothiazine-derivative tranquilizer can, though rarely, cause penile paralysis or priapism, especially in stallions, and for this reason, phenothiazine-derivative tranquilizers probably should not be administered to stallions.

Inability of a stallion to maintain its penis and prepuce with the preputial cavity, regardless of the cause, impairs venous and lymphatic drainage of the penis and prepuce, which leads to edema of the internal preputial lamina. As the internal preputial lamina swells, the preputial ring may become constricting, causing the penis distal to the ring to swell further. The exposed penile and preputial epithelium, if not protected, becomes excoriated and infected. Eventually, the internal preputial lamina becomes fibrotic, and the prepuce loses its normal telescoping action. In addition, the pendulous weight of the protruded penis and prepuce may damage the internal pudendal nerves, causing penile paralysis.[45]

The protruded penis should be replaced into the preputial cavity as soon as possible to protect it and the internal preputial lamina from further injury, but if the penis and prepuce are so edematous that they cannot be replaced into the preputial cavity, they should be compressed against the ventral aspect of the body wall with a bandage. The penis and prepuce should be kept lubricated with an emollient, antimicrobial dressing. The horse should receive a nonsteroidal, anti-inflammatory drug and should be exercised daily. If the preputial ring restricts penile retraction or impairs venous and lymphatic flow, it should be incised longitudinally.[43] This incision is allowed to heal by second intention.

If paraphimosis has caused permanent penile paralysis, the stallion is unlikely to be able to achieve erection. If a stallion with penile paralysis can ejaculate into an artificial vagina, and if the stallion's breed registry permits artificial insemination, the stallion's breeding life can be extended through artificial insemination of mares.[40,47] The stallion can be salvaged for uses other than breeding through amputation of the penis or permanent retraction of the paralyzed penis into the prepuce.

PHIMOSIS

Phimosis, or the inability of the horse to completely protrude its penis from the prepuce, occurs naturally in foals, because the internal preputial lamina is fused to the free part of the penis for about the first month after birth.[48] Excluding this normal physiologic condition, phimosis is usually the result of constriction of the external preputial orifice or the preputial ring caused by trauma or

neoplasia. When the horse is unable to protrude its penis, it urinates within the preputial cavity, causing excoriation of the preputial epithelium, which leads to further inflammation and scar formation, thereby compounding the problem.

A constricting external preputial orifice can be enlarged by removing a triangular segment of external lamina, whose base is the preputial orifice.[49] The cut edge of the external lamina is sutured to the cut edge of the internal preputial lamina. A constricting preputial ring can be opened by incising the internal preputial fold. After the penis is protruded, the constricting cicatrix can be removed by segmental posthectomy (i.e., reefing). See the next section for a description of the reefing operation.

NEOPLASIA OF THE PENIS AND PREPUCE

Any cutaneous neoplasm can affect the integument of the external genitalia, but the most common neoplasm of the penis and prepuce is the squamous cell carcinoma.[30,43,50] Lesions of squamous cell carcinoma are usually multiple and often involve the glans penis and the internal lamina of the prepuce.[24,51] Geldings develop squamous cell carcinoma of the genitalia more frequently than do stallions, and horses with nonpigmented genitalia, such as Appaloosas and American Paint horses, are most frequently affected.[43,51,52] Malignancy of squamous cell carcinomas of the penis and prepuce of the horse is usually low grade, and lesions tend to remain localized, but lymphatic spread may occur, first to the inguinal lymph nodes, if treatment of lesions is neglected.[24,51] Penile or preputial squamous cell carcinoma can metastasize to internal organs without causing detectable enlargement of the inguinal lymph nodes,[53] and slight metastatic enlargement of the inguinal lymph nodes may be difficult to distinguish from lymphadenopathy secondary to balanoposthitis.[54] Prognosis for survival is poor if squamous cell carcinoma has metastasized to the inguinal lymph nodes, and invasion of squamous cell carcinoma into a corporeal body is likely to result in hematogenous spread of the neoplasm to internal organs.[55] Before treatment of the horse for penile or preputial neoplasia is undertaken, the superficial inguinal lymph nodes should be examined to detect enlargement; the penile shaft should be palpated for evidence of invasion of a corporeal body; and the stallion's body condition should be observed for evidence of metastases.

Small preputial and penile neoplasms of stallions can be excised or destroyed using cryotherapy. Cryotherapy can be performed using liquid nitrogen administered as a spray or through a cryoprobe or with carbon dioxide administered through a cryoprobe (Fig. 4-11).[56,57] Lesions should be frozen to –20° C using two or three freeze-thaw cycles. A rapid freeze and slow thaw produce the most cellular damage. A thermocouple can be used to monitor the size and depth of the area affected by the cryogen.

Radiofrequency-induced hyperthermia has been used to treat horses affected with sarcoids and cattle and horses affected with ocular squamous cell carcinoma,[58,59] but its use for treatment of genital squamous cell carcinoma of horses has not been evaluated. Application of hyperthermia to a penile or preputial neoplasm may enhance the effect of chemotherapeutic agents.[59]

Fig. 4-11 Cryotherapy using a probe to treat a lesion of squamous cell carcinoma of the internal lamina of the prepuce.

Horses with precancerous and small lesions (<2–3 mm) of squamous cell carcinoma can be treated by application of 5% 5-fluorouracil at 14-day intervals.[60] Up to seven treatments may be necessary to bring about resolution of lesions. Horses with squamous carcinoma of the penis and prepuce have been treated successfully by intratumoral injection of cisplatin in sesame oil.[61,62] Affected horses are usually treated four times at 2-week intervals. Horses affected by metastasis of squamous cell carcinoma to internal organs can be treated by systemic administration of a chemotherapeutic agent, such as doxorubicin or piroxicam,[63] but little information is available about the efficacy of this treatment.

Stallions with extensive lesions of the internal lamina of the prepuce may require segmental posthectomy (i.e., reefing). To reef the internal lamina of the prepuce, the horse is anesthetized, positioned in dorsal or lateral recumbency, and prepared for surgery. The penis is extended by traction, and the urethra is catheterized. If desired, a tourniquet can be placed proximal to the surgical site. Parallel, circumferential, cutaneous incisions are made proximal and distal to the preputial lesion, and these incisions are connected by a longitudinal incision (Fig. 4-12). The diseased segment of prepuce between the circumferential incisions is removed from the penis using scissor dissection. All bleeding vessels are ligated with absorbable suture, and loose fascia is apposed with interrupted 0 or 2-0 absorbable sutures. Care must be taken to maintain the prepuce in proper alignment, and placing a suture in the fascia at four equidistant points around the circumference of the penis may aid in orientation. The integument is apposed with interrupted 0 or 2-0 absorbable or nonabsorbable sutures. The amount of internal lamina that can be surgically excised without disrupting normal copulatory function is not known.

To prevent disruption of sutures caused by penile erection, the stallion should be isolated from mares for at least 2 weeks, and application of a stallion-ring to the penis may be necessary. The stallion should be exercised daily

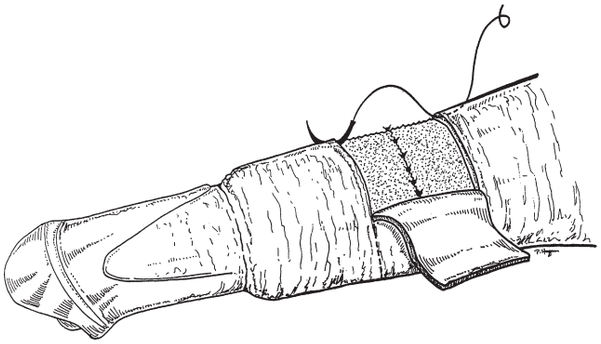

Fig. 4-12 Segmental posthectomy. A cuff of epithelium is removed from the internal lamina of the prepuce.

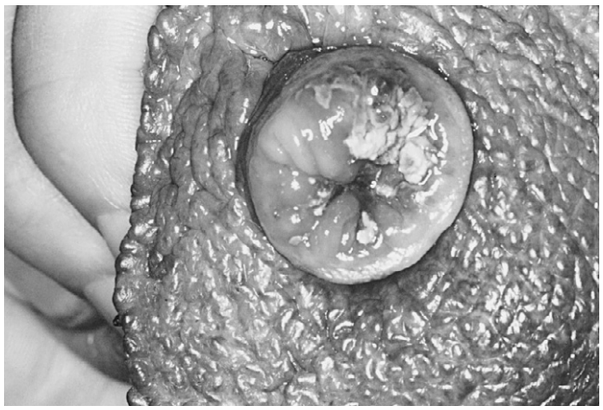

Fig. 4-13 Caseous masses associated with cutaneous habronemiasis at the mucocutaneous junction of the distal urethra. (From Varner DD, Schumacher J, Blanchard TL, Johnson L: *Diseases and Management of Breeding Stallions.* St. Louis, 1991, Mosby.)

to reduce postsurgical edema. Nonabsorbable sutures should be removed at 10 to 12 days.

Phallectomy of stallions may be indicated if neoplasia is extensive or has invaded the tunica albuginea, but phallectomy should only be considered as a salvage procedure. The horse should be castrated at least 2 weeks prior to phallectomy, if possible, and separated from other horses for 2 weeks after phallectomy to decrease the likelihood of sexually induced erection and disruption of sutures.

SUMMER SORES (CUTANEOUS HABRONEMIASIS)

Summer sores are pruritic, pyogranulomatous lesions caused by aberrant, cutaneous migration of the larvae of the equine stomach worm, *Habronema*.[64,65] Summer sores, or cutaneous habronemiasis, can be found anywhere on the integument, and the genitalia, especially the urethral process or preputial ring, are common sites of infestation (Fig. 4-13). Summer sores appear in the warm months of the year when flies, which are the nematode's intermediate host, are prevalent. Summer sores may disappear with the advent of cold weather. Horses that are prone to expose their penises are particularly vulnerable to cutaneous habronemiasis of the genitalia.

Migration and encystment of the larvae of *Habronema* invoke an inflammatory response from the host causing formation of exuberant granulation tissue that is characterized by the presence of small, yellow, caseous granules. Skin surrounding the granulation tissue may be depigmented.[65] Lesions of the preputial ring may interfere with the normal telescoping action of the prepuce, and lesions of the urethral process may involve the corpus spongiosum penis, causing hematuria or hemospermia.[66]

Summer sores may resemble lesions of pythiosis, carcinoma, the fibroblastic form of sarcoid, or exuberant granulation tissue caused by trauma. The presence of small caseous granules in the lesion usually enables the condition to be differentiated from other diseases with similar appearance. When the lesion is squeezed, larvae can occasionally be extruded onto a slide and identified microscopically.[64] A histologic characteristic of lesions is granulation tissue permeated with eosinophils, granules, and larvae. Affected horses often have a marked eosinophilia.

Ivermectin, administered systemically, or an organophosphate, administered systemically or topically, has been effective in resolving lesions by eliminating the migrating larvae. Corticosteroids or diethylcarbamazine, administered systemically, have been successful in resolving lesions by eliminating the horse's response to the larvae.

Lesions of habronemiasis of the internal lamina of the prepuce can be surgically excised. Small lesions can be removed by elliptical excision, but large or multiple lesions are often best removed by reefing. Lesions of the urethral process may necessitate amputation of the urethral process.[64,66] The urethral process can be amputated with the horse anesthetized or with the horse standing and sedated. A male urinary catheter is passed into the urethra, and if surgery is performed with the horse standing, the base of the urethral process is injected with local anesthetic. The urethral process is circumferentially excised proximal to the lesion, and the urethral mucosa is sutured to the epithelium of the stump of the urethral process to close the exposed corpus spongiosum penis (CSP) using 2-0 or 3-0 absorbable suture. Fibrous tissue at the suture site may tear during subsequent breeding, causing hemospermia.

PRIAPISM

Priapism, or persistent erection without sexual arousal, occurs when detumescence of the engorged corpus cavernosum penis (CCP) fails because of disturbances of arterial inflow or venous outflow (Fig. 4-14).[67] Priapism occurs in both stallions and geldings, but stallions are more frequently affected. The condition is economically devastating when a valuable breeding stallion is affected, because impotence is the usual outcome, and phallectomy may be required.

Priapism in human beings has many causes, but in horses, priapism is usually caused by administration of a phenothiazine-derivative tranquilizer.[68,69] Phenothiazine-

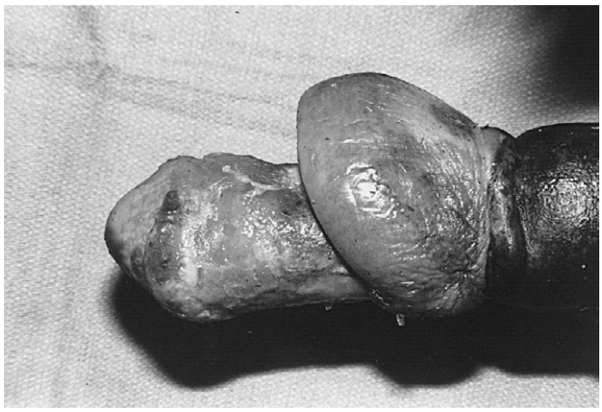

Fig. 4-14 Penis of a horse suffering from priapism. The corpus spongiosum is not involved in the erection. The preputial ring has become edematous.

derivative tranquilizers may cause priapism by blocking sympathetic impulses that initiate detumescence.[70] Other, less frequently reported causes of priapism in horses include tumors of the pelvic canal,[71] general anesthesia,[72] and nematodiasis of the spinal cord.[73]

The precise mechanism by which priapism occurs is not known, but basically, priapism of horses results from a disturbance of venous outflow to the CCP, causing the erect penis to fail to detumesce. The corpus spongiosum penis (CSP) remains uninvolved. When detumescence fails, blood in the CCP becomes stagnant, and partial pressure of CO_2 in the stagnant blood rises, causing erythrocytes to sickle.[74] The sickled erythrocytes obstruct venous outflow from the CCP, and the collecting veins eventually become irreversibly occluded.

Arterial supply to the CCP is still patent in the early stages of priapism, but if priapism persists, it too becomes irreversibly occluded.[74] Eventually, the trabeculae of the cavernosal tissue become fibrotic and lose their expansible capacity necessary for normal erection. In addition to damaging erectile tissue, prolonged erection in the horse may also result in penile paralysis by damaging the pudendal nerves, perhaps by compressing the nerves against the ischium (authors, personal observation). The eventual outcome of unresolved priapism in the horse is impotence caused by loss of both erectile function and sensitivity of the penis.

The primary clinical sign of priapism is prolonged protrusion of a turgid penis. Although the affected horse may not have a full erection, turgidity of the CCP can be detected when the penis is palpated. The penile and preputial epithelium becomes edematous soon after the onset of priapism[75] and, if not protected, becomes excoriated and infected. Dysuria may accompany the condition in some horses.[75] The CCP of a horse with chronically unresolved priapism feels fibrous and appears densely echogenic when examined ultrasonographically. A chronically affected horse may fail to respond to painful stimuli applied to the distal aspect of the penis.[71,76]

Horses with priapism have been treated empirically with diuretics, corticosteroids, general and regional anesthesia, penile and preputial massage, emollient dressings, and slings, but success in resolving priapism using these treatments is poor.[75] Although massage, dressings, and slings are ineffective in resolving priapism, they are important in preventing damage to the exposed organ.[75] Benztropine mesylate, a cholinergic blocker, has been used successfully to treat horses affected with priapism.[72,77] Affected horses of average size have been treated with 8 mg, administered by slow intravenous injection. Alpha-adrenergic agents, such as adrenalin and phenylephrine have been injected into the CCP of human beings to bring about detumescence,[78] and instillation of 10 mg of phenylephrine diluted in physiologic saline solution (10 ml) directly into the erect CCP of horses affected with priapism will usually bring about detumescence This response can be corrective for horses affected acutely by priapism but is usually a temporary response (2 to 4 hours) for horses affected chronically.

If medical therapy is unsuccessful in bringing about detumescence, the horse should be treated by irrigation of the CCP to evacuate sludged blood. Heparinized saline (10 units/ml physiologic saline solution) is injected through a large-bore needle inserted into the erect CCP proximal to the glans penis. Sludged blood and physiologic saline solution are evacuated 10 to 15 cm caudal to the scrotum through a small stab incision or through one or two large-bore needles inserted into the CCP. The CCP is irrigated until fresh hemorrhage appears in the efflux. The stab incision in the tunica albuginea of the CCP should be sutured after irrigation. If arterial blood fails to appear after irrigation, arteriolar supply to the CCP is probably permanently damaged, and impotence is likely. Failure of erection to subside following irrigation indicates that arteriolar inflow is patent and that venous outflow is still occluded.[79]

If erection recurs after irrigation of the CCP, establishing an alternative route of exit for the sludged blood may be necessary to bring about detumescence. The shunt should be created before the corporeal tissue and pudendal nerves are irreversibly damaged, but the time at which damage becomes irreversible has not been established for the horse. Irrigation of the CCP likely postpones the time at which the corporeal tissue becomes irreversibly damaged. The CCP can be anastomosed to the CSP to create a shunt for escape of venous blood trapped in the CCP (Fig. 4-15). The CSP may offer a convenient outlet for trapped venous blood, because its venous outflow differs from that of the CCP, and in contrast to the CCP, the CSP does not act as a closed system during erection. Impotence has occurred after creation of the shunt in human beings from failure to achieve or maintain pressure in the CCP necessary for intromission,[67,79] and this failure can result from damaged cavernosal tissue or from the shunt.[79] The shunt may close as normal venous outflow resumes, but whether closure is necessary for erection to be reestablished and maintained has not been determined.[80] A shunt between the CCP and CSP following trauma to the penis apparently causes impotence in the bull,[81,82] but studies of normal stallions that had a shunt created surgically between the CCP and CSP suggest that a shunt between the CCP and the CSP of

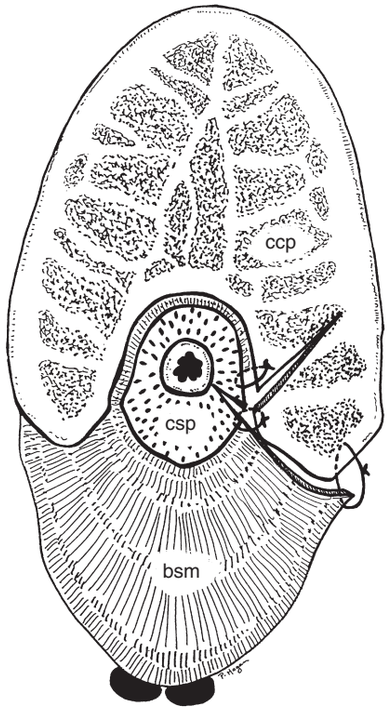

Fig. 4-15 Cross section of penis showing creation of a shunt between the corpus cavernosum penis *(ccp)* and the corpus spongiosum penis *(csp).* The cavernous tissue is exposed by elevation of the bulbospongiosus muscle *(bsm).*

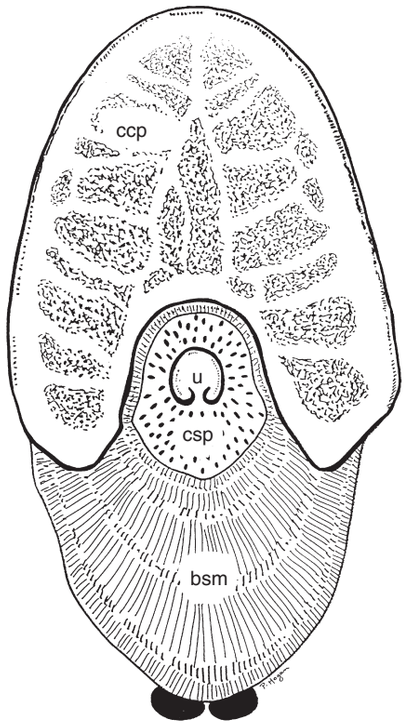

Fig. 4-16 Cross section of penis showing a defect in the urethra. *ccp,* Corpus cavernosum penis; *csp,* corpus spongiosum penis; *bsm,* bulbospongiosus muscle; *u,* urethra.

stallions does not interfere with subsequent erection and ejaculation.[83]

To create the shunt, the horse is anesthetized, positioned in dorsal recumbency, and prepared for aseptic surgery, and a male urinary catheter is inserted into the urethra. A 15-cm, longitudinal midline incision is created 5 cm caudal to the base of the scrotum to expose the shaft of the penis. The right or left edge of the bulbospongiosus muscle is elevated from the underlying tunica albuginea to expose a 5-cm long section of the CSP. A 3-cm, longitudinal incision is made through the tunica albuginea of the exposed portion of the CSP, taking care to avoid penetrating the catheterized urethra, and an identical, 3-cm, longitudinal incision is made through the tunica albuginea of the adjacent CCP. Hemorrhage from the incised CSP is copious, and so to preserve visibility, suction becomes necessary at this point in the procedure.

The inner edge of the incision through the tunica albuginea of the CSP is sutured to the inner edge of the incision through the tunica albuginea of the CCP with 2-0 absorbable suture using a continuous pattern. To complete the vascular shunt, the outer edge of the incision through the tunica albuginea of the CSP is sutured to the outer edge of the incision through the tunica albuginea of the CCP. The bulbospongiosus muscle is sutured to the tunica albuginea of the CCP with 2-0 absorbable suture using a continuous pattern, and the subcutaneous tissue and skin are apposed separately in a routine manner. The stallion should be isolated from mares for a month after surgery to reduce the probability of erection.

Some stallions with permanently damaged erectile tissue and impaired penile sensitivity may be trained to ejaculate into an artificial vagina, and some may be able to achieve intromission if intromission into the vagina of the mare can be assisted. To lower the ejaculatory threshold of stallions, an antidepressive drug, such as imipramine, can be administered before breeding.[84]

HEMOSPERMIA

Hemospermia, a cause of infertility or reduced fertility of stallions, has been attributed to bacterial and viral urethritis, improperly applied stallion rings, habronemiasis or carcinoma of the urethral process, and wounds to the glans penis or seminal vesiculitis.[43,85-88] Hemospermia can also be caused by a urethral rent, the cause of which is unknown.[89] The usual source of voluminous hemorrhage is the CSP (Fig. 4-16). Hemorrhage typically occurs near the end of ejaculation when contraction of the bulbospongiosus muscle causes pressure within the CSP to increase from around 17 mm Hg to 1000 mm Hg.[90]

Hemospermia may occur more commonly in frequently bred stallions.[86,91] Affected stallions are sometimes slow to ejaculate, and ejaculation sometimes appears to cause pain.[86] Hemospermia is usually diagnosed by gross or microscopic examination of semen that has been collected with an artificial vagina. The site of hemorrhage can often be determined by examining the

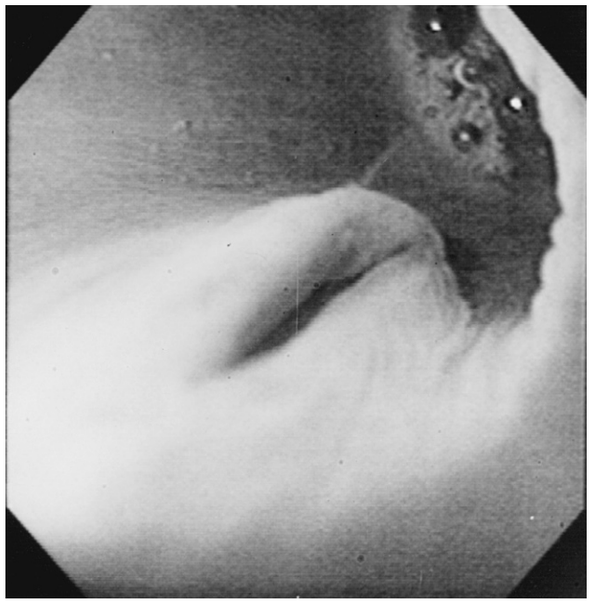

Fig. 4-17 Endoscopic view of a longitudinal defect at the convex surface of the urethra at the level of the ischial arch.

exterior of the penis or by examining the urethra with a sterilized, flexible endoscope that is at least 100 cm long. Endoscopic examination of the urethra of stallions affected with hemospermia often reveals a 5- to 15-mm longitudinal defect on the caudal surface of the urethra at the level of the ischial arch (Fig. 4-17). No gross signs of inflammation surround the defect.

Stallions affected with hemospermia have been treated medically by sexual abstinence and systemically administered formalin, methenamine, or antimicrobial drugs.[87] Enforcing sexual abstinence for a protracted time (exceeding 1 year) is often an unsuccessful treatment of stallions affected with hemospermia associated with urethral rents. Stallions affected with this form of hemospermia seem to be most effectively treated by temporary urethrotomy performed near the level of the ischial arch.[87,89,91] Urethrotomy is performed with the horse standing and sedated after administering epidural anesthesia. To facilitate identification of the urethra during dissection, a urethral catheter or the insertion tube of an endoscope is inserted into the urethra and advanced until it is proximal to the defect.

An 8- to 10-cm longitudinal incision, centered on the ischial arch, is created on the perineal raphe. The incision extends through skin, retractor penis and bulbospongiosus muscles, CSP, and urethral mucosa. Incising the urethral mucosa may be unnecessary, and opening the CSP without entering the urethra may reduce risk of complications associated with urethrotomy, such as a urethral fistula or stricture. The ischial wound is allowed to heal by second intention. Daily instillation of suppositories composed of an antimicrobial drug and a corticosteroid into the urethral lumen has been advocated[91] but is probably not necessary.

Stallions should receive sexual rest for at least 2 to 3 months after surgery. Horses may bleed at the urethrotomy for more than a week after surgery, especially at the end of urination when the bulbospongiosus muscle contracts. The ischial wound generally heals within 3 weeks.

Incising the CSP at the ischium decreases cavernosal pressure at the end of urination, and decreased pressure in the CSP may be responsible for the apparent success of temporary urethrotomy in eliminating hemospermia associated with urethral rents. When the bladder has emptied, the bulbospongiosus muscle contracts to expel urine that remains in the urethra, and these contractions increase pressure within the CSP.[92] Blood may be forced to exit the urethral rent at the end of each urination, because of increased pressure in the CSP, preventing the rent from healing. Incising the CSP converts this semiclosed vascular space into an open space, and during urination, blood flow is diverted from the urethral lesion to the urethrotomy, thus permitting the rent to heal.

Because the urethral defects are typically located at the caudal surface of the urethra near the ischial arch and are accessible through ischial urethrotomy, primary closure of the defect may be possible. Urethral endoscopy aids the surgeon in identifying the exact location of the defect. To confirm the location of the defect, a hypodermic needle can be inserted percutaneously into the lumen of the urethra at the level of the ischial arch during endoscopic examination.

CHAPTER 5

Techniques for Artificial Insemination

JUAN C. SAMPER

Although artificial insemination (AI) in horses can be done with semen collected at the farm for immediate use, maximization of this technology is achieved when mares are bred at considerable distances from where the stallion stands. To achieve this, semen either can be shipped in its liquid state after passive cooling and deposited in the mare several hours (12–36 hours) after collection or can be processed for freezing and maintained in liquid nitrogen until its use several weeks or years later. This chapter will discuss semen collection, handling and processing of cooled shipped and frozen semen, and the factors that affect the success of AI programs.

SEMEN COLLECTION

Breeding stallions that are going to be used for AI should have a semen evaluation performed prior to each breeding season. Because it is virtually impossible to improve the inherent quality of semen from a stallion, it is important for the mare owners as well as the stud farm to be aware of the stallion's semen quality. A veterinarian working for clients that decide to stand a stallion or stallions for AI has the responsibility of overseeing that the clients are properly set up for what they are offering. This preparation includes proper stimulus for the stallion such as, if necessary, the availability of a mare in heat at all times during the breeding season, availability of shipping containers, and a laboratory for the proper evaluation and processing of the semen. It is also important to inform the stallion owner that a proper semen evaluation should be performed to determine semen quality and microbiologic status of the semen including equine viral arteritis.

Stallions can be trained to achieve an erection by conditioning them to certain routines or by exposure to certain objects or animals associated with breeding. A stallion can be stimulated to achieve an erection by exposure to a mare in natural estrus, an ovariectomized mare that has been injected with estrogens, or a phantom or dummy mare where he is normally collected. In addition, stallions can be manually stimulated to drop their penis and then massaging the glans will elicit a full erection and pelvic thrusting movements. The stallion when collected with a properly prepared artificial vagina (AV) will follow a similar pattern of thrusting to that of natural mating.

To ejaculate into an AV it is not necessary for the stallion to jump a mare or a dummy. Collection on the ground can be achieved by teasing the stallion in cross ties, in an open area, or in a stall. Once the stallion has achieved a full erection, his penis is washed with clean water, dried and inserted into a properly prepared AV. The stallion in many instances will vocalize and move forward until the pelvic thrusts start at which time he might lift his front legs slightly or arch his back and have all four limbs on the ground until ejaculation. Most stallions with good libido can be easily trained to ejaculate on the ground.

It is the belief of many horse owners whose stallion(s) breed only by natural cover that a number of stallions cannot be collected artificially. However in the author's experience most stallions can be collected with an AV. Several models of AVs are available on the market, and although each has advantages and disadvantages, each operator should choose a model based on stallion suitability and ease of use. All AVs work under the same principle, which consists of a double rubber liner, usually latex, that will provide space to form a water jacket that at the adequate temperature and pressure will stimulate the stallion to ejaculate. Contrary to what would be expected, the temperature in the water jacket to stimulate a stallion to ejaculate is not body temperature but in general should be at least 42 to 43°C. In addition, older stallions often require temperatures of over 45°C to be properly stimulated. Furthermore, proper lubrication with a nonspermicidal water-soluble lubricant and the proper pressure are critical for adequate stallion stimulation. For stallions that have difficulty ejaculating into the AV, use of hot towels at the base of the penis to provide additional stimulation has been successful.

Although the author prefers the Missouri model AV due to its light weight and convenience of assembly and cleaning, there are other alternatives for semen collection. Condoms provide an alternative for obtaining a semen sample, particularly from stallions that are reluctant to ejaculate in an AV. Other methods of semen collection include the use of pharmacologic agents. These methods to induce ejaculation involve the use of pharmacologic regimens to either reduce the ejaculatory threshold in stallions or to induce extracopular ejaculation. Reduction of the ejaculatory threshold can be achieved with the use of diazepam 0.05 mg/kg IV or imipramine 500 to 1000 mg orally 15 to 30 minutes prior to breeding. Pharmacologic induction of ejaculation is achieved by slow IV injection of xylazine (0.66 mg/kg) with or without prior administration of 2.2 mg/kg of imipramine IV. In general, pharmacologic induction of

ejaculation occurs within a few minutes of the injection and the success rate is about 30 to 50%. It must be pointed out that this method does not always result in ejaculation from the same stallion. Therefore, it is difficult to program breedings if pharmacologic ejaculation is the only method available for semen collection.

Because many stallions breed a reduced number of mares and therefore ejaculate only a few times during the breeding season, it is important to identify stallions that are "sperm accumulators." These stallions in general have large testicles, and if sperm is not collected on a regular basis, they have the tendency to accumulate sperm in their reproductive tract. The accumulated sperm tend to have a lower motility, reduced longevity, and poorer morphology. Therefore, when such a stallion is offered for AI it is important to collect him several times prior to breeding mares, shipping, or processing for freezing. The number of ejaculates necessary to collect to improve the semen quality will vary among stallions. Two consecutive ejaculates of similar quality should indicate that the stallion has voided the accumulated sperm.

SEMEN HANDLING

Raw semen is very fragile and should not be exposed to direct sunlight or sudden temperature changes. Once the stallion ejaculates, the semen should come into contact with a clean and warm container to prevent cold shock. The semen is filtered in line during ejaculation or filtered immediately after collection with nylon mesh or milk filter paper. This procedure is done to remove all extraneous particles and the gel fraction. Immediately after collection the raw semen should be placed in an incubator at 37°C prior to extension. The volume and color of the ejaculate should be recorded. In addition, the other physical characteristics of the ejaculate such as sperm movement, sperm concentration, and sperm morphology should be assessed from a small aliquot (1–2 ml) of raw semen that is removed prior to the addition of any diluents or extender. Once semen is diluted with a prewarmed extender it should be immediately removed from the incubator and cooled down to room temperature (20°C). An accurate assessment of the percentage of progressively motile sperm can only be done when the semen has been diluted to 25 million to 50 million sperm per milliliter.

PRESERVATION OF SEMEN

The processing of semen should be done according to the period of time that the semen is expected to remain viable. It is recommended to always place the semen in an appropriate extender even if it is going to be inseminated within a few minutes. There are several reasons why semen should be extended within a few (<5 minutes) after collection. A proper extender buffers pH changes of the raw semen, maintains the osmolality, provides energy and protein sources for sperm metabolism and membrane stabilization during thermal changes, reduces the detrimental effects of the seminal plasma, and provides antibacterial properties through the antibiotics. Semen can be preserved for varying periods of time. However, the state and the processing technique will be determined by the expected longevity of a given ejaculate. Fresh extended semen can be kept at 20°C, avoiding exposure to direct sunlight, without losing its fertilizing ability. If semen is intended to last 12 hours or more, either because the stallion will not be available or because the semen will be shipped, it should be slowly cooled and maintained at 4 to 8°C. If semen is to be stored longer than 72 hours, freezing is recommended.

It is extremely important to ensure that the extenders that are going to be in contact with the sperm are isothermic with the semen. In other words, extender that will be added to raw semen should be prewarmed. However, extender added to semen that has been cooled to room temperature should be also at room temperature. Failure to do so induces cold shock to the sperm, resulting in irreversible reduction of the progressive motility and membrane damage reducing the fertilizing potential.

FRESH SEMEN

Semen that is collected and used immediately or up to 6 hours after collection does not necessarily have to be cooled and in most cases can be diluted with prewarmed extender at ratios of 1:1 to 1:3, depending on raw semen concentration and ejaculate volume. Immediately after extension, the semen is removed from the incubator and can be cooled to room temperature (15–20°C) without loss of its fertilizing potential.

COOLED SEMEN

AI using cooled semen is still gaining popularity among breeders since more breed registries are accepting registrations of foals resulting from the use of this technology. Although there is a tremendous increase in its use there is also a tremendous variability in the results achieved. In order to minimize the variability in the results it is important that the handling and processing of the semen be standardized.

The semen handling and processing factors that could have the biggest impact of the quality of an insemination dose are (1) cooling rates and containers, (2) dilution rates, (3) and the insemination process.

Although there are several extenders that can be used for preserving semen in its liquid state it appears that most researchers and clinicians favor the use of nonfat, dried milk solids and glucose or the Kenney extender. This is perhaps due to its ease of preparation and handling, as well as its clarity making it easy to evaluate sperm motility.

Cooling Rates and Containers

Spermatozoa suspended in an extender could be rapidly cooled from 37° to 20°C, but require a slow cooling rate of –0.5° to –0.1°C per minute between 20° and 5°C to maximize spermatozoal viability. If sperm are cooled slowly, once they have reached 4° to 8°C, this temperature storage is superior to storage at 20°C. It appears that the ideal storage temperature range for maintaining motility and fertility of cooled equine semen preserved

for more than 12 hours in a Kenney type extender is between 4° and 6°C. However, Magistrini and associates found that a storage temperature of 15°C was superior to 10° or 4°C for maintaining spermatozoal motility when the extender does not contain milk solids. The current industry standard for preparing semen for shipping is to pack 1×10^9 progressively motile sperm in a nonfat dried milk (NFDM) glucose extender containing antibiotics, so that the final sperm concentration is 25 to 50 $\times$ 10^6 sperm/ml. Semen is slowly cooled, maintained, and stored at 4° to 8°C.

There are several containers currently available commercially that are designed for cooling and transport of equine semen. The Equitainer is the most widely used container for passive cooling and transporting of equine semen. Less expensive, disposable semen-transport containers are also available, such as the Equine Express or Expect-A-Foal. These containers are also passive-cooling transport devices, which provide variable rates of cooling. However, the big difference between the Equitainer and other semen transport systems is the effect of environmental temperature on the rate at which the semen is cooled or their ability to maintain their internal temperature. A study conducted to evaluate the effect of storage containers and environmental temperature suggested that sperm motility is adequately maintained in most commercial equine semen transport containers when the outside temperature is between 22°C and 37°C. However, environmental temperature of –20°C for 6 hours resulted in the reduction of progressive motility in most of the disposable containers. This study suggested that the Equitainer was a better container to isolate the semen from the effect of environmental temperatures.

Semen Extender and Dilution Rates

The majority of extenders used for fresh and cooled equine semen in North America are nonfat dried milk solids with glucose and antibiotics. Most of these extenders are variations of the original Kenney extender described in 1975. The variations of this extender are primarily a change in the sugar content or the type of antibiotic added. Two types of sugars are primarily used: glucose or sucrose or a combination of the two. Some of the countries in continental Europe such as France, Holland, and Germany use other types of extenders for routine cooling and shipping. French stallion farms ship semen in an ionic extender supplemented with phosphocaseinate, which does not need to be cooled. On the other hand, Dutch and German stallion semen is centrifuged and the sperm is resuspended in an egg yolk based extender for fresh or cool shipping.

The most common antibiotics include a combination of potassium penicillin and amikacin sulfate, gentocin, and ticarcillin. It is strongly recommended to avoid the use of polymyxin B because it has been shown to have a deleterious effect on sperm motility. The bacterial flora of the stallion and the effect of the antibiotic on the sperm motion characteristics for the individual stallion should be determined, because the most appropriate antibiotic(s) could vary between stallions.

Although the processing and handling of the sperm is tolerated well by the semen from the majority of the stallions, some stallions have a significant and unexplainable reduction of the semen quality when cooled and stored for over 12 hours. It appears that for some of the "problem" stallions, partial or total removal of the seminal plasma is important to maintain the percentage of progressively motile sperm. The ideal dilution rate at which sperm should be extended will vary according to the sperm concentration in the raw semen and the total number of progressively motile sperm. The author has found that semen with 100 million sperm should be diluted at a 1:3 ratio (semen: extender). Every increment of 50 million sperm/ml will increase the dilution rate by 1. So when the concentration of the ejaculate is between 450 million and 500 million per milliliter the dilution rate would be 1:10. Extending the semen using this method will result in a final sperm concentration of 25 million to 50 million per milliliter. The final volume to be shipped will be calculated so that a total of at least 1 billion sperm cells are sent to the mare.

The packaging of the semen when using the skim milk glucose extender should be performed under anaerobic conditions. Semen can be packaged in preloaded syringes, disposable baby bottle liners or whirl pack bags, provided that all the air is removed from the package prior to placing it in the container.

Insemination of Cooled Semen

A considerable amount of controversy exists regarding the number of insemination doses and the number of times that the mare should be inseminated. In the author's opinion there is no clear answer and it would depend on the quality of the stallion's semen and the reproductive history of the mare. If the semen is of good quality and the mare is a young fertile mare, she could be inseminated once or twice at 12- or 24-hour intervals. However, if the semen has poor quality it would be important to breed the mare as close to ovulation with the entire dose. On the other hand, if the semen is of good quality but the mare is a problem mare with a tendency to accumulate uterine fluid, she should be bred only once within 24 hours prior to ovulation. The combination of a problem mare bred with poor quality semen should be avoided because this will be a source of aggravation for the mare owner, the stallion owner, and the veterinarian. However, if there is no other option, these mares should be bred as close as possible to ovulation with all the semen that is available.

FROZEN SEMEN

In general the freezing process involves the collection of semen from the stallion, evaluation of the semen, dilution and centrifugation, and resuspension of the sperm in freezing extender. Unfortunately frozen-thawed sperm appear to have a shorter life than fresh or cooled sperm. This appears to be partially related to changes inflicted on the spermatozoa during the process of freezing and thawing. These changes, collectively called cryodamage, could be lethal if the sperm is rendered infertile or sub-

lethal if the change is reversible. Owing to apparent short lifespan of cryopreserved semen the insemination process with frozen semen requires more infrastructure and is more labor intensive than insemination with fresh semen and often results in reduced fertility compared to other breeding methods.

Facilities

To increase the pregnancy rates with frozen semen it is recommended to breed mares in a central location where the veterinarian is able to examine the mares on a regular basis and has proper equipment for thawing and evaluation of thawed semen. Because it is imperative to breed the mares close to ovulation, accuracy in the prediction of the time of ovulation is critical. Therefore, the availability of ultrasound equipment is required. In addition it is strongly suggested that the facility where the mares are inseminated be equipped with a liquid nitrogen tank for the storage of semen. Thawing, evaluating, and loading the semen requires an incubator, an accurate thermometer, a clean water bath, a good quality microscope, clean slides, coverslips, and a watch.

Pregnancy Rates with Frozen Semen

The success of a frozen semen program will depend on (i) The quality of the frozen-thawed semen; (ii) selection of the mares and stallions; and (iii) management of the mares during the breeding cycle.

Semen Quality

Currently about one fourth of the stallions whose semen is frozen will have pregnancy rates over 60% per cycle. Some of the remaining stallions, although they will have a lower pregnancy rate per cycle, can reach acceptable levels of fertility by the end of the season. The drawback is that the number of breeding cycles to achieve acceptable pregnancy rates is often too high or too expensive for the mare owner. Unfortunately, individuals performing the insemination rarely have control of the quality of the semen that must be used. Because frequently the semen quality is not very good, careful mare selection as well as excellent reproductive management are critical in determining the outcome of that breeding.

Thawing and Evaluation

Temperature at which the semen should be thawed depends on the type of straw in which the semen is packaged. Straws of 0.25 or 0.5 ml are generally thawed at 37° C for a minimum of 30 seconds. Care must be taken if multiple 0.5-ml straws are thawed at once to ensure that the straws will not adhere to each other while thawing, which will create an uneven thawing rate in the straws. Accuracy in the thawing time and temperature are critical when using thawing 0.5-ml straws at 75° C for 7 seconds. Semen could be also frozen in 2.5-, 4-, or 5-ml straws. Sperm packaged in these straws, regardless of volume, should be ideally thawed at 50° C for 45 seconds, although some individuals will thaw them at 37° C for 2 minutes.

There is no standard procedure or protocol to evaluate frozen semen. In addition, none of the tests routinely used to evaluate cryopreserved semen appear to correlate well with fertility. Furthermore, there are no set standards for the minimum quality of an insemination dose. Despite the lack of standardization, it is agreed by most laboratories freezing semen commercially that the minimum criteria required in an insemination dose are 30 to 35% progressively motile, 50% morphologically normal, and greater than 600 million total sperm per dose. Increasing the number of sperm to 800 million total increases the fertility in a linear way, but no further increase was detected when total sperm concentration reached over 800 million. Colorado investigators reported that stallion semen frozen in 0.5-ml straws that had 320 million progressively motile spermatozoa after thawing resulted in higher pregnancy rates compared to semen frozen in straws at lower concentrations. There is still no consensus on the minimum number of progressively motile sperm per dose that are needed to maximize fertility, and perhaps this is a stallion-dependent factor as has been reported for the bull. Vidament and associates have reported that 300 million sperm inseminated every 24 hours resulted in higher pregnancy rates compared to inseminations having 150 million sperm per dose. Semen frozen in The Netherlands is required to have a minimum of 300 million progressively motile and morphologically normal sperm per dose after thawing in order to be sold commercially.

Because the evaluation of post-thawing motility is a fairly subjective measure of quality and is also a poor predictor of fertility, it is recommended that veterinarians using frozen semen routinely evaluate the morphology of the sperm. This is particularly important when the pregnancy results are suboptimal despite apparent good motility.

Stallion Selection

The large variation among stallions' semen to tolerate the freezing and thawing process is poorly understood. Constituents of the seminal plasma or molecules on the sperm itself could be involved in the variability; however, it is important to realize that the selection criteria for stallions rarely, if ever, involves semen quality or fertility. Therefore, colts sired by stallions with inherent good semen quality are more likely to have good semen themselves. Semen from some of these stallions and their sons have consistently resulted in excellent post-thaw quality and pregnancy rates above 60% per cycle. The previous fertility of the stallion with fresh or chilled semen is not necessarily a good indicator of the stallion's fertility with frozen-thawed semen. In order to increase the chances of success it is advisable to inquire regarding the previous fertility of the stallion with frozen semen so that only stallions of proven success are used.

Mare Selection

The average number of cycles per pregnancy is higher for mares inseminated with frozen-thawed semen compared to natural cover or fresh artificial insemination. It is therefore critical that the mare owner is made aware of this potential reduction in fertility so that stallions and mares

with good fertility histories are selected. Even after careful stallion and mare selection proper client communication is imperative so that a nonpregnancy result after the first cycle will not discourage future breedings. Increasing the number of breeding cycles will undoubtedly result in higher pregnancy rates for mares by the end of the season.

Owing to changes in the horse industry, an increasing number of older maiden mares (>8 years), which have had a prolonged sport or show career, are being bred by artificial insemination. These mares and mares with histories of reproductive problems in general have significantly lower pregnancy rates, are potential candidates for disappointments, and are considered poor frozen semen candidates. Mare status has been shown to have a significant effect on the chances of a mare becoming pregnant. First cycle pregnancy rates with frozen semen for young maiden mares (younger than 7 years old) are around 65%; older maiden mares (over 8 years of age) 35%; barren mares 50%; and mares nursing a foal, 51%. Old maiden mares and those that have been barren for more than 2 years appear to have the poorest fertility. When only mares with excellent reproductive histories are inseminated with frozen semen, first cycle pregnancy rates of 100% on the young maiden mares and 75% in barren and foaling mares clearly indicate the importance of careful mare selection when breeding with frozen semen (Metcalf 1995).

Management of Mares

It is important to ensure that mares that are going to be bred with frozen-thawed semen are cycling regularly. Transitional heats should be avoided in order to increase the reliability of ovulation and reduce the use of semen. All mares should have at least a uterine culture and cytologic examination performed. These procedures can be obviated in young maidens (<6 years) with good perineal conformation. However, young maiden mares with evidence of fluid accumulation should also be cultured. A mare with a positive culture and cytologic findings should be infused in the uterus for at least 3 consecutive days when her cervix is dilated. Daily monitoring is necessary to ensure that no fluid accumulation is present in the uterus.

The availability of frozen semen is often limited to one or two doses per cycle or three to five for the entire breeding season. Therefore, it is important to maximize the use of the semen by making sure that the mares have a clean culture and cytologic test and by breeding mares once or no more than twice during one cycle. To achieve this, mares should be examined every other day or daily during the first days of the heat period and more intensively when close to ovulation. When the semen is of good quality every attempt should be made to breed the mares within 12 hours prior to ovulation. Mares that do not ovulate after the first insemination should be examined every 12 hours and inseminated with a second dose immediately after ovulation is detected if semen is available.

Timing of insemination. Sperm that have been frozen and thawed appear to have reduced longevity because of the membrane changes inflicted on them during the process of cryopreservation. Therefore, to maximize fertility, it becomes critical to try to breed the mares as close to ovulation as possible. Unfortunately, this is a more labor-intensive process for the veterinarian and more costly to the mare owners. In the author's experience, mares have a higher pregnancy rate when insemination is performed within 6 to 12 hours prior to ovulation. If mares have not ovulated within the first 12 hours after the AI, then a second dose should be inseminated immediately after ovulation has been detected on rectal examinations performed every 12 hours. In this author's experience fertility of mares that are bred only once after ovulation when rectal examinations are only performed every 12 hours is reduced by an additional 20% compared to those mares bred only once before or before and after ovulation. Although some experienced veterinarians have reported very high pregnancy rates when inseminating only once after ovulation, it seems that that to maximize pregnancy rates with single postovulation breedings, mares should be bred within 2 to 4 hours after ovulation. Because there is no ultrasonographic or palpable parameter to age the corpus luteum in a horse, it is necessary to examine mares at 2- to 4-hour intervals in order to be accurate.

An ovulatory inducing agent should always be used in order to reduce the number of examinations and to reduce the time from breeding to ovulation. Two products are currently available to induce ovulation in mares: human chorionic gonadotropin (hCG) and deslorelin, a GnRH analogue implant (Ovuplant). Both products are effective in inducing ovulation. Typically 2500 IU of hCG are given intravenously when the mare is displaying behavioral estrus, has a follicle of at least 35 mm, and has obvious and distinct edema of the endometrial folds. Ovulation in these mares occurs at 36 ± 17 hours. Because of the range in ovulation timing, mares treated with hCG should be palpated and evaluated with ultrasound every 6 to 8 hours after the injection. If the same criteria are followed to treat mares, Ovuplant induces a reliable ovulation in a narrower window (38 ± 2 hours) after treatment. Even when using an ovulatory inducing agent, the follicular and uterine texture should be evaluated closely and routinely by rectal and ultrasonographic examination in order to determine the ideal breeding time.

Availability and cost of semen is an important factor in determining the timing and number of doses to be used on a per cycle basis. It is encouraged that mare owners purchasing frozen semen be provided with a minimum of two doses per cycle.

Insemination technique. The number of straws per insemination and the thawing procedure should be performed following the instructions from the laboratory processing the semen. In general multiple (4–8) 0.5- or 0.25-ml straws are necessary for one dose and should be thawed at 37°C for at least 30 seconds. However, some laboratories will freeze one insemination dose on one 0.5-ml straw. When semen is frozen in 2.5-, 4-, or 5-ml straws commonly the processor will recommend one straw per insemination dose that should be thawed at 50°C for 45 seconds.

The straw(s) of thawed semen will be removed from the water bath and dried thoroughly. It can be more

practical to cut the straws that constitute an insemination dose at one end and place the entire volume of semen in a dry, warm clean tube, or directly into a warm syringe case. The semen should be evaluated microscopically prior to inseminating the mare. It is not recommended to add any type of extender to the thawed semen prior to insemination because of a high risk of causing an osmotic stress to the sperm. The semen should be slowly deposited into the uterus using a regular insemination pipette. Using the same syringe the pipette is flushed with air a couple of times. After the semen is in the uterus, the pipette is rinsed with 4 to 6 ml of a skim-milk glucose extender and the pipette again is flushed with air once or twice. It is important to perform these procedures slowly to increase the volume of semen deposited into the uterus.

The standard insemination technique is to place the semen in the uterine body. However, recently several groups have reported differences in pregnancy rates when mares were bred with reduced sperm numbers around the oviductal papilla. It seems that higher numbers of sperm reach the mare's oviduct when they are bred deep in the uterine horn ipsilateral to the dominant follicle, and therefore, veterinarians using frozen semen should consider inseminating deep in the uterine horn as an alternative to uterine body insemination.

Postbreeding therapies. The postinsemination examination is a crucial component of the insemination process and should be done not more than 12 hours after insemination. The purpose of this examination is to confirm that the mare has ovulated if she was bred prior to ovulation and to determine the presence of inflammatory exudates or fluid accumulations in the uterus regardless of the time of breeding. This is particularly important in old maidens, mares with delayed uterine clearance, and mares susceptible to uterine infections. Appropriate therapies such as uterine lavage, oxytocin injections, postbreeding antibiotic infusions, and Caslick's procedures should be performed. Blanket therapies such as uterine lavage or postinsemination infusions on all mares bred with frozen semen are not necessary. However, mares should be treated based on their clinical signs and previous reproductive history.

Allergic Reactions to Frozen Semen

There are a number of mares that accumulate excessive amounts of fluid or purulent material within a few hours after the insemination with fresh extended, cooled, or frozen semen. Some mare owners believe that some of these mares are allergic to certain stallions' semen or to components of the extender in which the sperm has been diluted. Several groups have investigated this "problem," and their data indicate that a slight amount of fluid accumulation in the uterus after insemination is a normal process. This reaction appears to be in response to the spermatozoa and does not depend on the type of extender or any of its components such as egg yolk, milk proteins, or glycerol.[1] In addition, no evidence of an allergic reaction has been detected in these mares. Small amounts of uterine fluid can be detected on most mares shortly after breeding and is a transient uterine inflammatory and a normal process in all mares. Seminal plasma appears to be a modulator and delays the physiologic uterine reaction to semen. Since the process of freezing semen involves the removal of most of the seminal plasma, this probably increases the transient inflammatory response in the mare. Small to moderate amounts of fluid are drained through the cervix within a few hours of breeding in the normal mare. Excess fluid accumulation is perhaps the result of poor cervical relaxation coupled with poor lymphatic drainage in the old maiden mare, or poor uterine contractility in mares susceptible to uterine infections. Mares that are in these categories should be routinely checked and a uterine lavage performed. In addition, oxytocin therapy should be implemented to aid in uterine contractility and drainage of the excess amount of fluid.

The number of mares bred artificially is increasing every year. AI in horses results in the birth of thousands of foals every year. Cooled transported and frozen semen breeding, unlike natural cover, does not allow for many errors in the handling of semen or flexibility in the timing of breeding. This results in an increase in labor for the veterinarian and cost for the mare owner that should be clearly discussed before starting the process. Careful selection of the mares and stallions will further increase the chances of success in an artificial breeding program.

CHAPTER 6

Stallion Sexual Behavior Dysfunction

SUE M. McDONNELL

INADEQUATE SEXUAL INTEREST AND AROUSAL; SLOW OR VARIABLE RESPONSE

Common complaints concerning inadequate sexual interest and arousal or slow or variable response include slow starting novice breeders, slow or sour experienced stallions, and specific aversions or preferences.[1] Certain genetic lines tend to be quiet or shy breeders under domestic in-hand conditions. A large portion of inadequate libido in stallions is believed to be the result of domestic rearing, training, or breeding conditions. Most conspicuously, stallion sexual behavior can be suppressed by adverse experience.[2] For example, stallions that have been disciplined for showing sexual interest in mares during their performance career, or are discouraged from showing spontaneous erection and masturbation, or are injudiciously or roughly handled during breeding under halter are at risk of libido and sexual behavior problems. When exposed to a mare for teasing, such stallions may simply stand quietly, may appear anxious and confused, or may savage the mare. Most stallions with experience-related libido problems respond well to behavior therapy alone or in combination with anxiolytic medication.[2] These stallions typically respond well to extended exposure to mares, either in direct contact (turned out together) or in adjacent paddocks or stalls. Some extremely inhibited stallions may not respond in the presence of humans. Once they are responding at pasture, they may require gradual introduction to human handling during sexual interaction with mares. Confident, respectful, patient, positive reinforcement–based handling greatly facilitates the transition to breeding in-hand. These stallions appear to respond favorably to reassurance for even small increments of improvement. Tolerance of minor misbehavior, rather than punishment, is often the most effective initial retraining strategy with low libido stallions. Once these stallions understand and gain confidence with the domestic breeding process, necessary breeding manners can be imposed without suppressing arousal. Some of these stallions appear to demonstrate specific preferences or aversions, which can be for certain mares, colors or breeds of mares, handlers, locations, time of day, etc. The anxiolytic diazepam (0.05 mg/kg slow IV 5 to 7 minutes before breeding) is useful in many such cases, as an adjunct to behavior modification.

For novice breeding stallions in transition from a race career, exposure to anabolic steroids and other medications can be a factor in low libido. Depending upon the duration of treatment and the season in which treatment was discontinued, it may take several months for endocrinology, testicles, or behavior to appear normal. Libido may be more affected than fertility, and vice versa.

Management, as it affects sociosexual environment, can be a significant influence on stallion behavior, endocrinology, and sperm production. For most stallions, sexual and aggressive behavior are subdued when kept together with other stallions and away from mares as compared to being in management when the stallion is away from other stallions and exposed to mares.[3,4]

Spontaneous erection and penile movements, common in all mammals, are known as "masturbation" in stallions.[5] Episodes of spontaneous erection and penile movements occur at approximately 90-minute intervals in all stallions, regardless of age, breed, housing, exercise, sociosexual environment, breeding status, or fertility. Although the penis typically becomes fully erect and the glans penis may fully flare, ejaculation rarely occurs. While most stallions can be easily distracted momentarily from progressing with an episode, it is extremely difficult and likely beyond humane care to significantly inhibit the number of episodes. Accordingly, genital injury as well as fear of humans and suppressed sexual behavior can result when, due to simple misunderstanding of these normal periodic penile erection and movements, aggressive attempts are made to physically inhibit or punish the behavior.

In practice, a small proportion of cases of slow breeding novice or experienced stallions appears to be hormone-related, with androgens on the low side of the normal range. Some cases obviously involve trying to breed outside the natural breeding season in stallions that are especially seasonal. These stallions will likely improve with management aimed at increasing exposure to mares and reduced exposure to other stallions. This will typically increase androgen levels and general confidence, as well as sexual interest and arousal. Gonadotropin-releasing hormone (GnRH) (50 micrograms subcutaneously 2 hours and again 1 hour before breeding) can be useful in boosting libido in stallions, particularly in those with low normal levels.[6] In rare cases when more rapid improvement is required to rescue a breeding career, treatment with testosterone can effectively "jump start" a slow novice without apparent significant adverse effects on spermatogenesis. Current recommendations are 0.1 to 0.2 mg/kg aqueous testosterone subcutaneously every other day for up to 2 weeks, with frequent assay of circulating testosterone not to exceed 4 ng/ml. As described in Chapter 1, stallion testicular function

apparently will respond to artificially increased day light, but the experience has been that if long-day recrudescence is advanced with artificial lighting, so will the following seasonal decline be advanced. In other words, it appears that the stallion has a fixed length of peak seasonal reproductive function. Effects of artificially advanced photoperiod on behavior apparently have not been characterized. In practice managers report that some low libido stallions that must breed in late winter months benefit from 16 hours of light beginning in late fall. The same schedule of lighting that is used to advance seasonal cycling for mares is used.

For diminished libido in an experienced stallion, whether gradual or sudden, changes in general health, nutritional condition, housing, handling, breeding conditions, and breeding schedule should be considered as potential contributing factors. Changes in semen quality and testicular size and consistency often indicate endocrine factors.

SPECIFIC ERECTION DYSFUNCTION

Libido-independent erection dysfunction appears to be relatively rare in stallions. The majority of cases are related to traumatic damage of the corpora cavernosa, resulting in insufficient or asymmetrical tumescence (lateral or ventral deviations) that impairs insertion. In some instances, penile injury appears to impair sensory or proprioceptive feedback from the penis, delaying coupling, organized thrusting, or ejaculation. Common causes include stallion ring injuries, phenothiazine-related paralyzed penis and paraphimosis, kick injuries, and self-serve breeding dummy accidents.

A peculiar and often confusing type of erection dysfunction involves the folding back of the penis within the prepuce as it becomes erect. The behavioral hallmark of this situation is a stallion that appears aroused and ready to mount, without a visible erection. The stallion may also appear uncomfortable or intermittently distracted, pinning the ears, kicking toward the groin, or stepping gingerly on the hind legs. Close observation reveals a rounded, full appearing prepuce, with the skin stretched taut. Resolution usually requires removing the stallion from the mare until the penis detumesces. Once the penis is fully withdrawn, application of a lubricating ointment to the prepuce facilitates subsequent normal protrusion. This situation tends to repeat occasionally over time with particular stallions, particularly in stallions with either profuse smegma production or in stallions in which the penis and sheath are dry from frequent cleansing.

MOUNTING AND THRUSTING DIFFICULTIES

A significant percentage of breeding dysfunction appears to involve neurologic or musculoskeletal problems that affect the stallion's ability to mount and thrust. Stallions vary considerably in the degree of musculoskeletal or neurologic deficit or discomfort that affects breeding performance or libido. Many such stallions can continue breeding with therapy aimed at reducing discomfort and accommodating disabilities during breeding, including adjustments to the breeding schedule aimed at reducing the total amount of work. A detailed discussion of musculoskeletal and neurologic problems in breeding stallions can be found in Martin and McDonnell, 2003.[7] Lameness problems that are not readily apparent in brief ground examinations can in some cases be more apparent during breeding. Direct observation by a breeding lameness specialist or review of video samples of successful and unsuccessful breedings, when possible, can be useful in identifying problems. Playback at various speeds, from very slow or frame-by-frame to fast-forward playback can often draw attention to a specific problem. Figure 6-1 illustrates two standard views we recommend for video analysis of mounting and thrusting difficulties. Stabilization of the video camera on a tripod is strongly recommended for most amateur videographers to obtain satisfactory views that enable meaningful evaluation.

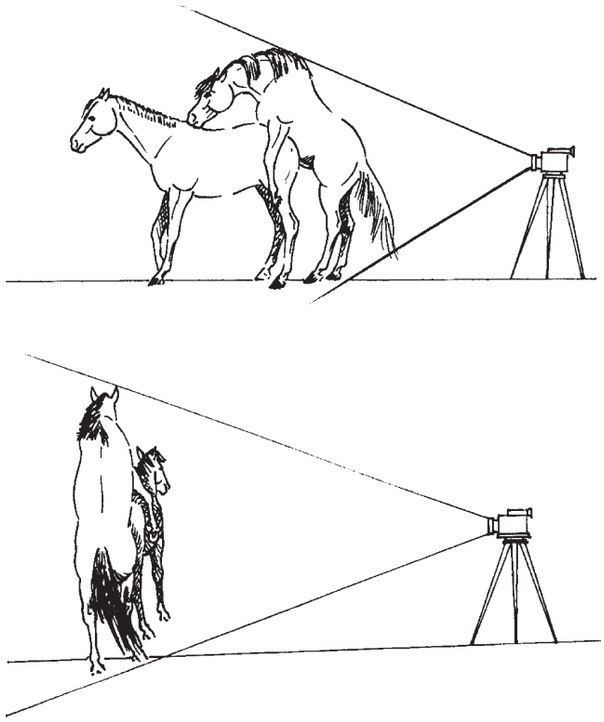

Fig. 6-1 Positioning of video camera on stable tripod for obtaining standard rear and side video views suitable for evaluation of mounting and thrusting difficulties in stallions.

Long-term treatment with oral phenylbutazone (2–3 mg/kg orally twice daily) can be used to maintain adequate comfort for breeding through a breeding season. Exercise programs carefully designed to improve overall stamina and to develop compensatory fitness, as well as weight management to reduce the effort of mounting and thrusting, can be beneficial in many instances. Management changes, including changes in breeding schedule, footing for breeding, housing and turn-out, diet, and handling in the breeding shed, all for optimal general attitude, libido, and performance of the individual stallion, can contribute significantly to extending the career of a stallion. Medications aimed at lowering the ejaculatory threshold can be useful in reducing the amount of work and resulting "wear and tear" on a busy stallion.[8] Imipramine hydrochloride (0.5–1.0 mg/kg orally 2 hours before breeding) can effectively reduce the ejaculatory

threshold. Similarly, xylazine at low levels enhances ability to ejaculate. Also, for stallions breeding by artificial insemination (AI), many can benefit from semen collection while standing on the ground as opposed to mounted.[9]

SPECIFIC EJACULATION DYSFUNCTION

Even though any libido, erection, or mounting and thrusting problem may result in failure to ejaculate, for some stallions the dysfunction seems to be specific to ejaculation. Specific ejaculation problems can include apparent failure of the neural ejaculatory apparatus, physical or psychological pain associated with ejaculation, and genital tract pathology. Common problems leading to ejaculatory delay or failure include occluded ampullae, either unilateral or bilateral, that appear painful and aortic iliac disease; psychogenic disruption of thrusting and premature dismount can result from mishandling, especially at the mouth while mounted. Similarly, stallions that are rushed to dismount, for example, to collect a dismount semen sample, may develop a pattern of dismounting before ejaculation. Therapy includes addressing as many contributing conditions as possible, as well as optimizing handling and breeding conditions and maximizing musculoskeletal fitness and libido to enhance the stallion's ability to overcome ejaculatory difficulty. Imipramine hydrochloride (0.5–1.0 mg/kg up to a total of 20 mg per horse orally 2 hours before breeding) can effectively reduce the ejaculatory threshold for most stallions.[2]

Ejaculation difficulty can be one of the first signs of neurologic disease in a breeding stallion, as well as a last lingering problem of neurologic disease. In addition to hind limb deficits, which are typically more apparent during mounting than during ground work, there are specific signs of pelvic neurologic deficits associated with ejaculatory dysfunction. These include poor anal tone when mounted, for example, anal protrusion, defecation, or flatus with each thrust; weak, irregular, or thready ejaculatory urethral contractions; atypical and variable ejaculatory pattern, for example, sperm poor or gel fraction before sperm rich fraction; wide fluctuations in semen characteristics, including sperm concentration and pH likely reflecting variable contributions from the ampullae and accessory sex glands.

For stallions using a dummy mount for frequent semen collection, a common factor apparently causing or contributing to mounting and thrusting difficulties, as well as specific ejaculatory dysfunction, is poor dummy fit.[8] Our experience is that most problems are related to mounting a dummy that is too low. This may lead to the stallion's advancing up the near side of the dummy rather than remaining squarely behind the dummy. This results in thrusting with the lower back bent rather than straight. Stallions in this condition have been observed to develop sore backs and retarded ejaculation or anejaculation. Raising the dummy mount usually helps to keep the stallion "squared up" and the back straight in a physiologic copulatory position during thrusting. Use of a less bulky model artificial vagina, such as the Missouri model as opposed to a Colorado model, and use of a wedged dummy mount (cut away at the rear to enable a more physiologic positioning of the artificial vagina, for example Breeders Choice, Aubrey Texas, http://www.breederschoiceonline.com/phantoms.asp), typically further enhance the ability of the stallion to maintain a good "squared up" copulatory position.

PHARMACOLOGICALLY INDUCED EJACULATION

Ejaculation can be induced *ex copula* with various pharmacologics.[10] Although none of the protocols developed to date are near 100% reliable, the method can be useful in extending the breeding career of disabled stallions. The most reliable regimen for most stallions is pretreatment with oral imipramine (2.2 mg/kg PO) followed 2 hours later by xylazine (0.4 to 0.6 mg/kg IV).

ROWDY BREEDING BEHAVIOR

Rowdy, misbehaved breeding stallions in most cases represent a human-animal interaction problem and the manner in which stallions are given limited, concentrated interaction with mares. Most rowdy stallions can be handled safely for breeding with retraining in combination with simple modifications of facilities to minimize accidents. Even strong, vigorous, and misbehaved stallions can be brought under control using consistent positive and negative reinforcement, with very little or no severe punishment.[11] Retraining can be done in a safe and systematic manner without abuse or commotion, usually within a few brief sessions. Some of the most challenging rowdy stallions may benefit from vigorous exercise under saddle or ground work, immediately before breeding. Exercise not only fatigues and mellows the stallion, but also establishes a pattern of the stallion's taking direction from a handler. For similar reasons, when retraining a stallion in the breeding shed, we find it helpful to follow an intensive schedule, with up to several breedings per day. With fatigue and reduced urgency to breed, many stallions seem more able to abide direction and learn the routine. With repetition for schooling over a short period of time, many rowdy stallions seem to more readily understand the routine.

Tranquilization of breeding stallions is generally not recommended. It is difficult to achieve levels of sedation that improve controllability without compromising musculoskeletal stability or ejaculatory function. Tranquilizing agents commonly used in stallions, such as xylazine or detomidine, can both facilitate and inhibit erection and ejaculation, depending on levels. Acepromazine is not recommended for use in stallions for any purpose, due to its association with paralyzed penis.

HYPERACTIVE OR FRENZIED BEHAVIOR

Distinct from simple rowdiness, some stallions are hyperactive or even "frenzied." The hyperactive behavior can be either year-round, or more typically, greater during the breeding season. Some will spend nearly their entire time budget frantically "climbing the walls," vocalizing (screaming), or frantically running a fence line. The behavior may include stereotypic weaving, pawing, pacing, or circling. Generally, frenzied breeding stallions

can benefit from more roughage and less grain in the diet, organized physical work and pasture exercise, and consistent housing in a quiet area. Careful observation (particularly video surveillance) can be useful in identifying environmental conditions and events that set off episodes or tend to quiet a stallion. In extreme cases, pasturing directly with mares can effectively quiet or sensibly occupy a frenzied stallion. L-Tryptophan supplementation (1–2 grams twice daily in feed) can have a calming effect on such stallions. Tranquilization for this purpose is not recommended in breeding stallions because of risk of paralyzed penis and paraphimosis.

SELF-MUTILATION

Self-mutilation, while not unique to stallions, is a severe and relatively uncommon fertility-limiting and life-threatening problem. It typically takes the form self-biting of the flank, chest, or limbs, with violent spinning, kicking, and vocalization. Self-mutilation in horses appears to occur in two distinct forms. One form appears to be a severe reaction to irritation or pain, and would be similar in males and females. The self-biting is typically targeted toward the site of discomfort. Another form occurs in males and is reminiscent of stallion inter-male aggression. Sniffing, nipping, and frank biting behavior is targeted at the typically inter-male sites of aggression—the groin, flank, knees, chest, and hocks. The sequence of the behavior follows closely to that of two males fighting, with sniffing and nipping of the groin, vocalization, stamping with a foreleg, kicking out with a hind leg, and then taking occasional larger bites. Episodes often appear to be stimulated by sight, sound, or smell (feces or oily residues) of another stallion. For some stallions, episodes are set off by sniffing their own excrement or oily residues on stall walls or doorways. Current recommendations are to (1) physically protect the stallion from injury by padding walls or limbs, blanketing, and muzzling as effective, (2) aggressively evaluate the housing and social environment to identify exacerbating and ameliorating conditions that may be manipulated for greatest relief, (3) reduce concentrates and increase grass and hay in the diet to increase feeding time and eliminate highly palatable meals (feeding tends to distract and occupy the stallion; concentrate meals tend to increase stereotypic behavior), (4) apply odor-masking agents (Vicks VapoRub or Acclimate) around the nares, and (5) provide as much organized exercise as possible, also to distract the stallion. Housing in a large paddock without solid objects against which to contact kicks may reduce the risk of limb injury.

SAVAGE STALLIONS

Quite distinct from generally or sexually rowdy or unruly stallions, and much less common, are the truly savage stallions. Truly savage stallions are those that attack humans, without apparent provocation, and with the apparent intent to kill. Specific behaviors involve charging with head lowered and mouth opened; grasping onto the shoulder, belt, or limb; and shaking, tossing, and stomping the victim. The attacks are typically intermittent, unprovoked, and unpredictable. Savage stallions are not necessarily high libido or otherwise aggressive stallions, and do not usually respond to violent discipline. These stallions are often described as otherwise especially docile and compliant. Managers may unwittingly attribute the attack to a particular person or circumstance. In practice, our recommendation for stallions that have savagely attacked has been to either euthanize or to manage under "bull stud" conditions, where the stallion is barred from direct contact with humans.

RESIDUAL STALLION-LIKE BEHAVIOR IN GELDINGS

Castration, regardless of the age or previous sexual experience, does not always eliminate stallion-like behavior. If given the opportunity, as many as half to two thirds of geldings will show stallion-like behavior to mares, many will herd mares, and some will even mount and appear to breed. Similarly, although castration does tend to "mellow" most horses, it does not eliminate general misbehavior. Traditional behavior modification is usually much more effective in controlling sexual and aggressive behavior in a gelding under saddle or in-hand than it is with an intact stallion. Also, treatment aimed at quieting sexual and aggressive behavior, such as progesterone (for example, altrenogest 50–75 mg orally daily), is typically more effective in geldings than in intact stallions or cryptorchid "geldings." Elimination of stallion-like herding and teasing at pasture is difficult. Pasturing separate from mares is often the only suitable management.

CHAPTER 7

Clinical Reproductive Anatomy and Physiology of the Mare

TIMOTHY J. EVANS, GHEORGHE M. CONSTANTINESCU, and VENKATASESHU K. GANJAM

The dynamic functions of the ovaries, uterus, embryo, and fetus are beginning to be fully appreciated as mares are evaluated during different stages of the estrous cycle and pregnancy and during various seasons. Anomalies, injuries and age-related changes may occur in mares, necessitating the use of diagnostic, prognostic, and therapeutic procedures, which require a thorough knowledge of equine anatomy. Several references, including the corresponding chapter in the first edition of this text, are currently available and provide a comprehensive discussion of reproduction in the mare, complementing the information presented in this text.[1–4]

REPRODUCTIVE ANATOMY

The organs involved in reproductive function are not only physiologically but also morphologically dynamic. The reproductive tract in the mare consists of the ovaries, uterine tubes, uterine horns, uterine body, cervix, vagina, vestibule, and vulva. These are the organs that produce the oocyte, facilitate its fertilization, provide an environment for embryonic and fetal development, and transport the fetus from the maternal to the external environment. They cannot perform these functions without interacting with other organ systems. The normal development of the reproductive tract of the mare, as well as the physiology of the mare's estrous cycle (upon which there are seasonal influences), depend on the neural and endocrine functions of the epiphysis (pineal gland) and hypothalamus (including the hypophysis or pituitary gland). The interactions of the epiphysis and hypophysis with other structures within the nervous and endocrine systems, the reproductive tract, and the mammary glands affect sexual behavior, pregnancy, foaling, and lactation.[4] Anatomy textbooks by Sisson and Grossman; Nickel, Schummer, and Seiferle; and Dyce, Sack, and Wensing are the foundations of the anatomic knowledge of many veterinarians.[5–7] Every effort will be made to remain consistent with their descriptions as well as with the nomenclature approved by the *Nomina Anatomica Veterinaria* (NAV) and the *Illustrated Veterinary Anatomical Nomenclature*.[8,9] Unless specifically noted, all anatomic discussions will pertain to the postpuberal female.

The Reproductive Tract of the Mare

The female reproductive tract consists of paired ovaries, uterine tubes, and uterine horns contiguous with a uterine body and cervix, vagina, vestibule, and vulva. These organs, with the exception of the ovaries, are collectively termed the tubular genitalia. There is a continuous lumen from the cranial end of each uterine tube and uterine horn, via the uterine body and cervix, vagina, and vestibule to the labia of the vulva. The tubular genitalia provide a connection from the peritoneal cavity to the external environment. For further details, see the references at the end of this chapter.

Suspensory Ligaments

Structure and function. Bilaterally the ovaries, uterine tubes, and uterus are suspended from the lateral sublumbar and pelvic walls by the double-layered peritoneal folds referred to as the broad ligaments, divided into three anatomically nondelineated portions: the mesovarium (attached to the ovary), mesosalpinx (arising from the lateral surface of the mesovarium), and mesometrium (attached to the uterus and a portion of the cranial vagina) (Figs. 7-1 to 7-3).[1,4–7,10] The cranial or free border of the mesovarium is the suspensory ligament of the ovary, which attaches in the sublumbar region.[8,9,11] The ovarian bursa is a duplication of the broad ligament between the ovary and the uterine horn.[4]

The broad ligaments allow for functional as well as physical attachment of the reproductive tract to the rest of the body. They provide an avenue for arteries, veins, lymphatic vessels, and nerves, which supply the ovaries, uterine tubes, and uterus. These ligaments also contain loose adipose and collagenous tissues as well as smooth muscle that is continuous with the outer longitudinal muscle layer in the uterine tube and uterus. The broad ligaments are also dynamic structures. During gestation, the vessels and smooth muscle mass enlarge in the broad ligaments, resulting in an apparent thickening. This suspensory apparatus allows for movement of the ovaries, uterine tubes, and uterus. Embryologically, peritoneal pouches form between the suspensory ligaments of the rectum, uterus, and urinary bladder and the roof and the

floor of the pelvic cavity, respectively. Cranially, these pouches open into the peritoneal cavity, and they end caudally in cul-de-sacs in the pelvic cavity against the pelvic diaphragm. The rectogenital pouch is formed by reflection of the peritoneum from the rectum onto the vagina. The reflection of peritoneum from the urinary bladder onto the vagina forms the vesicogenital pouch (Fig. 7-2).[1,4,7–11]

Clinical aspects. The anatomy of the broad ligaments can be clinically relevant in several situations. Exterior-

ization of the uterine horns or ovaries during surgical procedures is limited by the suspensory ligaments. The mesovarium is located for écrasement and ligation during ovariectomy, and in standing animals, local anesthetics are applied to the mesovarium prior to performing these procedures (Figs. 7-1 and 7-3).[12] As the vagina is rarely involved in uterine torsion in the mare (in contrast to the cow), transrectal palpation of the broad ligaments is necessary for diagnosis of uterine torsion and determination of the direction of torsion. In cases of uterine and ovarian arterial rupture, the mesometrium may contain the hemorrhage, or bleeding may dissect the broad ligament resulting in its rupture and exsanguination of the mare. Hematomas can be found in the mesometrium during routine postpartum examinations, and they may or may not be associated with clinical signs. Rupture of hematomas several weeks following parturition has been recorded.[4] It is important to remember that the anatomic boundaries of the rectogenital and vesicogenital pouches are variable and that this anatomic variability can be of clinical significance when performing an ovariectomy via a vaginal approach (colpotomy) or in assessing whether contamination of the peritoneal cavity has occurred following a vaginal or rectal injury (Fig. 7-2).[1,4,5,12]

The Ovaries

As in other domestic mammals, the ovaries perform exocrine (gametogenic) and endocrine (hormone production) functions in the mare. Exocrine function of the ovaries justifies the existence of the tubular genitalia and allows for the ovaries' hormonal integration and control of the reproductive tract.[1,3,4]

Location. The ovaries are traditionally the landmarks for transrectal palpation of the reproductive tract in mares. The ovaries and uterine tubes are the most cranial structures of the reproductive tract and may be found as far cranially as the third lumbar vertebra or as far caudally as the fifth lumbar vertebra. They are not as freely moveable as cows' ovaries, and, in nonpregnant animals or very early in gestation, they are often located 5 to 10 cm directly cranial to the upper third of the ipsilateral ileal shaft in the sublumbar region. The kidney lies cranial to the ipsilateral ovary by a distance ranging from 5 to 30 cm with the left kidney generally closer to the corresponding ovary. The left ovary is normally situated 2 to 3 cm further caudad than the right. The ovaries may be in contact with the corresponding uterine horn or may be separated by a distance of up to 5 cm. In circumstances in which the uterine horn is readily located, this anatomic relationship may be helpful in locating the ipsilateral ovary (see Figs. 7-1 and 7-3). As discussed previously, the mesovarium allows for variable positions of the ovaries depending on the stage of estrous cycle or pregnancy, seasonal influences, and the location of other abdominal organs. During pregnancy, the ovaries are frequently found pulled cranioventrally and medially. The ovaries frequently lie on top of the intestinal mass and are in contact with the dorsal abdominal wall; however, they may be found among the adjacent viscera.[1,4,5]

External structure. The mare's ovaries are reniform in shape and, in mares of light breeds, range from 5 to 8 cm in length, 2 to 5 cm in width, and 3 to 5 cm in height during the ovulatory season. Ovarian weight varies with age and stage of the estrous cycle, ranging from 30 to 120 g per ovary. The ventral (free) border of the ovary is concave and is indented by the ovulation fossa (ovarian fossa; NAV), which is an anatomic structure specific for the mare (Fig. 7-3).[1,3,4] When the intestinal viscera are removed and the reproductive tract is suspended by the broad ligaments, the ovaries are described as having medial and lateral surfaces, dorsal and ventral borders, and cranial (tubal) and caudal (uterine) extremities or poles. The dorsal (attached) border is convex, and, since this is where the mesovarium attaches and where vessels and nerves enter the ovary, it is correctly termed the hilus of the ovary. The ventral (free) border of the ovary is concave and is indented by the ovulation fossa (Fig. 7-3).[1,4,5,8–11] The caudal or uterine extremity of the ovary is attached to the uterus near the tip of the uterine horn by the proper ligament of the ovary (round ligament of the ovary or utero-ovarian ligament), which is a band of smooth muscle within the broad ligament (Figs. 7-1 to 7-3). In the embryo, this structure is continuous with the round ligament of the uterus and is homologous to the proper ligament of the testis in the male (part of the remnant of the gubernaculum testis).[1,4–6,8–10] Additional details regarding the histology of the external surfaces of the ovary are covered in the corresponding chapter of the first edition of this text.[4]

Internal structure and function. In most domestic mammals the ovaries consist of a peripheral parenchymatous zone (cortex), containing various stages of follicular and luteal gland development, surrounding a central vascular zone (medulla), comprising collagenous connective tissue rich in blood vessels. In the mare, the central parenchymatous zone, which surfaces at the ovulation fossa, is surrounded by the vascular zone.[1,4–7,11] Development of this unusual arrangement of the zona parenchymatosa and zona vasculosa in the mare will be discussed later.

The primary functions of the ovary are oogenesis (production of female gametes, oocytes, or ova) and steroidogenesis (production of estradiol and progesterone). During early gestation, the primordial germ cells arise from the epithelium of the embryonic yolk sac and migrate through the developing mesentery to the gonadal ridge (ovarian anlage) in its position contiguous with the mesonephros. Mitosis and meiosis of the oogonia do not occur beyond the sixth month of gestation and do not commence again until after puberty. There is substantial atresia of oocytes during fetal life, with only a portion surviving to parturition.[1,4,7]

The structural and functional unit of the ovary is the follicle. A primary oocyte surrounded by a single, flattened cell layer is a primordial follicle. There is an intact basal lamina separating the single layer of what will become granulosa cells from the adjacent stromal tissue, which eventually develops into the theca folliculi (theca cells). Mares are born with a finite pool of primordial follicles. It has been estimated that there is a reserve pool of approximately 36,000 primordial follicles in the mare (in contrast to over 120,000 primordial follicles in the cow). At any time during the ovulatory season, 100 (versus 300 in the cow) primordial follicles have left the reserve pool

and have entered the active pool of follicles and are undergoing growth and differentiation (folliculogenesis). At this point in their development, the follicles are called primary follicles. Once a primordial follicle joins this pool, it is destined to become atretic or ovulate. The oocyte grows in size and the zona pellucida is formed. The cells surrounding the oocyte differentiate into granulosa cells. A primary follicle is transformed to a secondary follicle when the single layer of granulosa cells differentiates into several layers. Primary and secondary follicles have traditionally been described as preantral follicles.[1,4]

Fluid exuded from granulosa cells of secondary follicles coalesces to form an antrum, and the follicle is transformed into a tertiary or antral follicle, which is primarily estrogenic. The wall of the follicle is formed by granulosa and theca cells. In the mare, follicles approximately 0.3 mm in diameter begin to form antrums, and these antrums may reach a size of 35 to 50 mm with follicular walls 5 to 6 mm in thickness. Studies in mares have estimated that it may take as long as two estrous cycles (42 days) for a follicle to grow from 0.1 mm to 1 mm. Other research has suggested that in cows the period required for a primary follicle to develop into a preovulatory follicle may be as long as 60 days. In mares, 50 to 75% of follicles greater than 1 mm in diameter present at any time are undergoing atresia, which is irreversible. Atretic follicles demonstrate degenerative changes in the oocyte and follicular epithelium. Fibroblastic remodeling of the remnants of large follicles results in scar tissue (corpus fibrosum atreticum).[1,4]

During each estrous cycle there may be up to two waves of follicular growth during which several follicles attain diameters greater than 15 mm. Usually one follicle ovulates from the primary wave, but occasionally there can be multiple ovulations or ovulation(s) from the secondary wave, as well.[1,3] The small number of follicles that ovulate migrate toward the ovarian fossa as their diameter increases, and they soften as they get closer to evacuation. Granulosa cells cease to divide a few days prior to release of the ovum. Immediately prior to follicle evacuation, granulosa cells undergo further differentiation, theca cells begin to degenerate, and there is a thinning of the follicular wall toward the exclusive site of ovulation in the mare, the ovulation fossa (Fig. 7-3).[1,3–6] At the time of ovulation, the first meiotic division is complete, and a secondary oocyte (arrested in metaphase II) is released.

A short time following ovulation, folds of stromal tissue that are accompanied by distended blood vessels, are formed by the collapsed inner wall of the follicle. Within 24 hours, granulosa cells have begun to undergo further growth and differentiation and are beginning to secrete progesterone. These changes to the granulosa cells constitute the process commonly referred to as luteinization. Proliferating capillaries accompanied by hypertrophied fibroblasts intermingle with luteinizing granulosa cells and replace degenerating theca cells. Nine days after the formation of the luteal gland, two types of luteal cells are evident, large and small. Eighty-five percent of the luteal cell population is composed of large luteal cells, which are almost four times larger than they were at the time of ovulation. The small cells are not derived from theca cells, as in other species, but are most likely granulosa cells in transition to becoming large luteal cells. By the twelfth day of the luteal phase in nonpregnant mares, the large luteal cells have decreased in size and in number. At the time of the next ovulation following luteal regression, the large luteal cells have undergone degeneration and the corpus albicans has been formed.[1,4]

Luteal glands have two distinct appearances when examined by ultrasonography (Fig. 7-4). Approximately 50% of the luteal structures contain a central blood clot that occupies greater than 10% of the cross-sectional area and progress through a corpus hemorrhagicum stage during formation of the mature corpus luteum (CL; Fig. 7-4, *A*). The central clots remain during the life of the CL but decrease in size and become more organized. The other 50% of ovulations result in formation of a solid or uniformly echogenic CL (Fig. 7-4, *B*). There is no significant difference in progesterone secretion by these two differently appearing luteal structures.[1,3,4] In nonpregnant mares, the luteal gland begins to regress approximately 12 to 14 days following ovulation and begins to form a corpus albicans by the start of the following estrus.[1,4]

Prepuberal ovarian development. At birth the ovaries are oval rather than reniform in shape; cuboidal germinal epithelial cells cover their ventral (free) surface, and the ovarian fossa has not yet formed. The fetal gonads at their greatest size during gestation are ten times larger than the foal's ovaries at parturition. By 3 months of age, the cortex (parenchymatous zone) is located beneath the infundibulum suggesting the future site of ovulation. The parenchymatous zone becomes invaginated into the vascular zone causing the ovarian poles to be drawn toward each other. In this manner, the unique anatomic relationship between the zona parenchymatosa and zona vasculosa seen in the ovary of the postpubertal mare begins to develop. As early as 5 to 7 months of age and certainly by puberty, the ovaries are kidney-shaped with a definite ovulation fossa.[1,4,11]

Clinical aspects. Transrectal examination of the ovaries by palpation and ultrasonography is one of the more commonly performed diagnostic procedures in mares. Confidence in locating the ovaries and identifying the normal, pertinent structures allows efficient determination of the mare's suitability for breeding and an accurate diagnosis of ovarian pathology, as well as a decreased risk of rectal injuries. Larger follicles can frequently be palpated as fluctuant structures; however, as the mare always ovulates from the ovulation fossa, smaller preovulatory follicles may sometimes be difficult to assess by transrectal palpation alone.[3,13–15] This certainly may be the case in younger or smaller mares that exhibit some resistance to the procedure. Although recent ovulations can be appreciated by palpation, luteal structures are often difficult to detect, especially if the mare's estrous cycle has not been followed closely by serial palpations. Transrectal ultrasonic imaging of the mare's ovaries allows visualization of follicles, ovulations (during estrus and diestrus), ovarian hematomas, and CLs (Fig. 7-4). In addition, ultrasonography has made possible the detection of multiple ovulations, anovulatory hemorrhagic structures, ovarian abscesses, and tumors.[1,3,4,13–16] Using

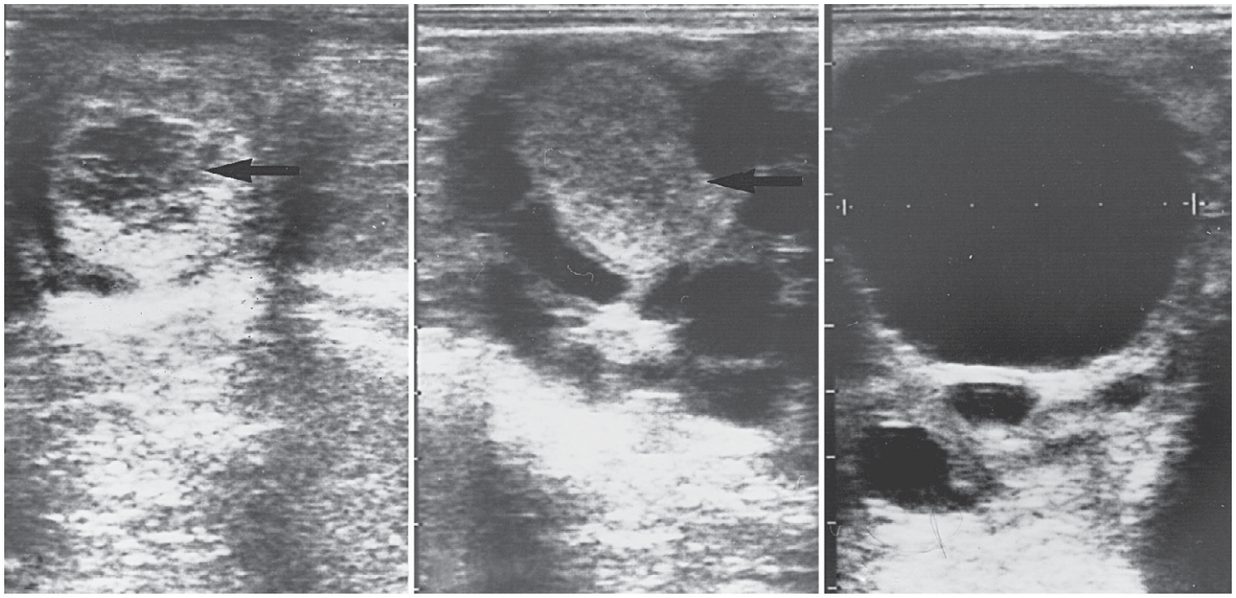

Fig. 7-4 Ultrasonographic appearance of ovarian structures. **A,** Solid arrow points to a centrally nonechogenic CL. **B,** Solid arrow points to uniformly echogenic CL surrounded by small follicular (>50 mm) structures. **C,** Calipers mark a large preovulatory follicle observed in a mare late during the ovulatory season. (Photographs courtesy of Mr. Howard Wilson.)

ultrasonography, it has been documented that there is an increased incidence of left-sided ovulations in maiden mares and that there is no predilection for nocturnal ovulations, as was previously thought.[1] The routine use of cooled, transported, and frozen semen and the performance of embryo and oocyte collection and transfer procedures has necessitated refinement of the ability to pinpoint the time of ovulation using ultrasonic imaging of the ovaries.[4,17–19] Irregularly shaped or flattened follicles with echogenic spots in the follicular fluid, as well as decreased follicular pressure and separation and hyperechogenicity of the follicular wall, are some of the changes noted just prior to ovulation.[3,4,15,20]

Knowledge of normal ovarian morphology and development can be helpful in the diagnosis of a variety of pathologic conditions and is critical for safe and successful oocyte recovery.[1,3,4,17–19] Not infrequently, mares are palpated, and both ovaries are found to be small and inactive. Seasonal influences account for the majority of these cases, but a history of anabolic steroid administration or chromosomal abnormalities (leading to gonadal dysgenesis) can account for some of these cases.[4,13,14] Although subject to some debate, it is generally thought that mares do not experience cystic follicular degeneration, as do other species.[4,13,16] Large ovarian follicles, which might be mistaken for follicular cysts, are often found during the early spring or late fall due to seasonal influences. Mares may develop epithelial inclusion cysts (fossa cysts), which can invade the ovarian stroma, and these cystic structures can potentially be a cause of infertility in older mares. Older mares are also more likely to have abnormal ovulations, which result in defective oocytes and embryos.[4,13–16,21] Ovarian hematomas are frequent occurrences, and although the ovary may be greatly enlarged, the mare continues normal ovarian activity. A number of different types of ovarian tumors have been observed in mares, including granulosa-theca cell tumors, dysgerminomas, teratomas, and cystadenomas.[1,3,4,14,16,21] The most common of these is the granulosa or granulosa-theca cell tumor. These tumors can be very large, and affected mares can exhibit several different patterns of abnormal behavior. The contralateral ovary is usually small and inactive, and the ovulation fossa is normally not palpable. However, exceptions have been observed, and these cases may represent the clinical presentation early in the course of tumor development.[4] It has been reported that excessive adrenocortical tissue can occur on the surface of the ovary and invade adjacent tissues. This most likely represents a pathologic manifestation of the adrenocortical nodules frequently seen in mares.[4,16]

The Uterine Tubes

The uterine tubes are paired structures, each associated with an ovary and uterine horn. Known by a variety of names including oviducts, salpinges, and fallopian tubes, these structures are the initial segment of the tubular genital tract. Like the uterus and vagina, they are derived embryologically from the paramesonephric ducts (müllerian ducts) and perform a variety of functions.[1,4,7]

External structure and location. The external surface of the uterine tube is covered by visceral peritoneum or serosa that is an extension of the squamous epithelium (mesothelium) of the mesosalpinx. This epithelium is contiguous with the mucosal lining of the infundibular portion of the uterine tube.[1,4] When dissected free from the mesosalpinx, each uterine tube, which is located

adjacent to the lateral surface of the ipsilateral ovary, is 20 to 30 cm in length and is divided into three segments—the infundibulum, the ampulla, and the isthmus (Figs. 7-1, 7-3, and 7-5).The funnel-shaped infundibulum has irregular fimbriae along its margins and a centrally located abdominal ostium. The tortuous ampulla, which is of a similar diameter to the abdominal ostium of the infundibulum, gradually decreases in diameter and extends from the infundibulum to a poorly defined point in proximity to the lateral surface of the uterine extremity of the ovary, where the isthmus begins. The isthmus is less tortuous, and its terminus, the uterotubal (tubouterine) junction, consists of a small papilla projecting into the uterine lumen. The oviductal lumen communicates with the lumen of the uterine horn through the uterine ostium in the papilla.[1,4,7–9,11]

Internal structure and function. There is a divergence in the internal structure of the portions of the oviduct and this structural alteration suggests that the primary functions of the uterine tube vary from the ovarian to the uterine extremities. The muscular layer (myosalpinx or tunica muscularis) consists primarily of an inner layer of circularly arranged muscle fibers covered by an outer layer of longitudinally oriented fibers. These longitudinally arranged fibers are continuous with the smooth muscle present in the mesosalpinx. There are very few muscle fibers in the fimbriae, and the tunica muscularis of the ampulla is thin. The muscular layer of the isthmus, however, is very well developed. A sphincter of circular smooth muscle is formed at the uterotubal junction.[1,4]

The mucosa of the infundibulum is highly folded longitudinally and covered by columnar epithelium, which is frequently ciliated. Changes in the estrous cycle are reflected by alterations in ciliogenesis and ciliary action. The mucosa of the ampulla is extremely plicated with primary, secondary, and even tertiary folds. This complexity of folding is more obvious in the mare than in ruminants, but the mucosa of the isthmus has much less folding than that of ampulla.[1,4,7]

The oocyte with its cumulus of granulosa cells is swept into the infundibulum by cilia. Very little, if any, follicular fluid enters the uterine tube following ovulation. The proximal portions of the oviducts provide a conduit for transport of the oocyte to the site of fertilization at the

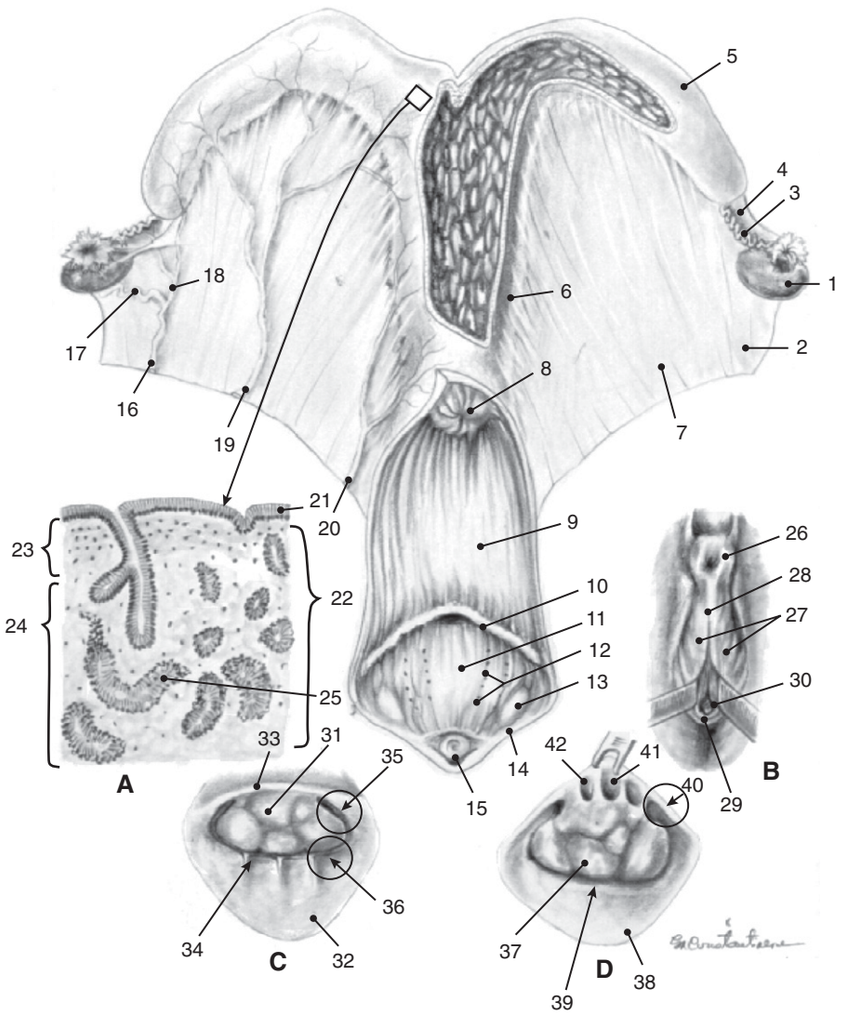

Fig. 7-5 Genital apparatus of the mare (dorsal view); the dorsal wall of the right horn and the body of the uterus, vagina, vestibule, and vulva are removed. *Inset A,* High-power magnification of a section of the endometrium. *Inset B,* The vulva. *Inset C,* The glans clitoridis. *Inset D,* The fossa and sinuses of the clitoris. 1, Ovary; 2, mesovarium; 3, uterine tube; 4, mesosalpinx; 5, uterine horn; 6, uterine body; 7, mesometrium; 8, vaginal portion of uterine cervix; 9, vagina; 10, transverse fold (hymen); 11, vestibule; 12, minor vestibular glands; 13, vestibular bulb; 14, vulvar labium; 15, glans clitoridis; 16, ovarian a.; (17, ovarian branch; 18, uterine branch); 19, uterine a.; 20, uterine branch of vaginal a. *Inset A:* 21, luminal epithelium; 22, lamina propria; (23, stratum compactum; 24, stratum spongiosum); 25, endometrial glands. *Inset B:* 26, anus; 27, vulvar labia; 28, dorsal commissure of vulva; 29, ventral commissure of vulva; 30, glans clitoridis. *Inset C:* 31, glans clitoridis; 32, ventral commissure of the labia; 33, preputium clitoridis (transverse frenular fold); 34, fossa clitoridis; (35, lateral recess; 36, ventral recess). *Inset D:* 37, glans clitoridis; 38, ventral commissure of the labia; 39, fossa clitoridis; (40, lateral recess); 41, medial sinus; 42, lateral sinus.

junction of the ampulla and the isthmus. The uterotubal junction allows spermatozoa to enter the isthmus following breeding, yet there is no reflux of uterine contaminants into the oviduct. The isthmus provides sites for capacitation and storage of spermatozoa while they await an oocyte to fertilize. The nonciliated epithelium of the uterine tube is predominantly secretory in nature and produces proteins and glycosaminoglycans. These secretory products may play a role in mediating capacitation of spermatozoa, fertilization of the ovum, and early embryonic cleavage. Preovulatory follicular fluid has a role in regulating oviductal protein production in vitro and in vivo (uterine tube ipsilateral to ovulation).[4] The mare is unique among domestic mammals in that only fertilized oocytes (developing embryos) enter the uterus approximately 6 days following ovulation. Unfertilized ova are retained in the middle third of the uterine tube for several estrous cycles among collagenous material that may contain cells similar to fibroblasts. Some have suggested this selective transport of fertilized oocytes is the initial step in "maternal recognition of pregnancy" in the mare.[1,4,5]

Clinical aspects. The uterine tube is the one portion of the reproductive tract of mares where functional abnormalities or pathologic changes and their significance are less likely to be appreciated. The myoelectrical activity of the myosalpinx can be influenced by oxytocin and prostaglandin $F_{2\alpha}$ (PGF). The clinical relevance of these modifications in oviductal function is yet to be determined. The presence of debris in the uterine tube has been described and is hypothesized to have an effect on tubal patency. Several techniques have been developed for the assessment of oviductal patency, but controversy exists over the prevalence of nonpatent oviducts and whether the observed debris actually represents a pathologic change.[4,22] Hydrosalpinx is rare in mares, but cases have been reported.[3,4,16,21] Mild to moderate inflammation and adhesions of the uterine tube have been noted in postmortem examinations of the horse; yet, as with other conditions observed in the uterine tubes, it is not known which oviductal changes have a negative effect on fertility and which represent normal variations. Several types of parovarian cystic structures occur in the vicinity of the oviducts. Some of these cysts are of mesonephric origin (epoöphoron and paroöphoron cysts). Although generally small and clinically significant, some of these structures, especially epoöphoron cysts, can become fairly large in the mare.[4,13,16,21] Despite being listed as mesonephric in origin by some references, hydatids of Morgagni are, based on histologic evidence, paramesonephric in origin and represent accessory uterine tubes, which can become quite large and impede proper function of the reproductive tract.[4,16,21]

The Uterus

The uterus is a dynamic organ, which has several diverse functions. The uterus facilitates spermatozoal transport to the uterine tubes, and optimal embryonic and fetal development depend on an appropriate uterine environment. Fetal transport from the maternal to external milieu at the expected time requires coordination of activity between the uterus, fetus, and various neuroendocrine organs. Elimination of contaminants following breeding and rapid postpartum uterine involution require efficient uterine defense mechanisms. The cervix serves as a barrier to foreign materials during pregnancy and allows passage of a foal at parturition. Changes in ovarian steroid production or alterations in uterofetoplacental hormone metabolism can cause uterine anatomy and function to vary.[1,4]

External structure and location. Embryologically derived from the paramesonephric ducts, the uterus of mares is bicornuate with a relatively long body. The uterus consists of paired uterine horns, a single body, and the cervix (see Figs. 7-1, 7-2, and 7-5). The cervix represents the thickened caudal portion of the uterus. The terminal segment of the uterine cervix (portio vaginalis) projects into the vaginal lumen. Externally, it is difficult to differentiate the uterine body from the cervix; however, the cervix can readily be distinguished by palpation. The surface of the uterus is covered by serosa or visceral peritoneum (perimetrium), which is continuous with the mesothelium in the broad ligaments. Viewed from above, the uterus is Y- or T-shaped. In nonpregnant mares, each uterine horn varies in length from 20 to 25 cm. In parous mares the horns may be asymmetrical. The uterine body is approximately 20 cm long. The cervix averages 5 to 7 cm in length and 3 to 4 cm in width. The intercornual ligament is much smaller and less distinct than in cattle. The uterus is capable of wide variations in size, shape, and location depending on the stage of the estrous cycle or pregnancy, seasonal influences, and degree of handling. The uterine horns are generally located entirely in the abdominal cavity. In the nonpregnant mare, the uterine body is found immediately in front of and frequently just ventral to the cranial brim of the pelvis. It can also be partially located in the pelvic cavity where it is continuous caudally with the cervix.[1,4–7,10,11]

Internal structure and function. As discussed previously, at the tip of each uterine horn, there is a small papilla containing a sphincter of circularly arranged smooth muscle fibers where the uterine ostium of the oviduct is located (Fig. 7-5). The dynamic nature and functional significance of the uterotubal junction have already been discussed. Where the uterine horns join the body, there is a short median septum. This septum and the papillae of the uterotubal junctions are important structures to be identified during endoscopic examination of the uterus (hysteroscopy) or nonsurgical deposition of semen within the oviduct.[1,4,12,13,22–24]

In contrast to ruminants, there are no caruncles (permanent elevations) in the mare's endometrium. The endometrial surface is composed of longitudinal folds that range in number from five to fifteen (Fig. 7-5). These endometrial folds in conjunction with the relatively flaccid uterine walls result in the existence of capillary spaces between adjacent folds rather than a central uterine lumen. It has been theorized that capillary action is partially responsible for the movement of secretions and inflammatory cells that collect in these spaces.[1,4,7,10] It seems logical that similar factors may contribute to rapid transport of spermatozoa from the cervix to the uterotubal junction.

The internal uterine ostium is funnel-shaped and is the beginning of the cervical canal. The external uterine ostium is located in the intravaginal segment of the cervix (portio vaginalis). Longitudinally folded like the endometrium of the uterine body and horns, the mucous membrane lining the cervical canal is pale rather than the typical reddish brown (ranges from yellow to reddish brown) observed in the rest of the uterus. The circular folds (plicae circulares or annular rings) present in the cervical canal of ruminants are absent in the cervix of the mare. Folds of mucous membrane extend through the external uterine ostium. The dorsal and ventral folds may continue onto the vaginal wall to form frenulums dorsally and ventrally, respectively (Fig. 7-6).[1,4,11–13]

The uterine wall is divided into the perimetrium, myometrium, and endometrium. The myometrium is composed of an outer layer of longitudinally oriented muscle fibers, a middle vascular layer, and a thick inner layer of circular smooth muscle. The vascular and longitudinal muscle layers are continuous with the vasculature and musculature, respectively, in the mesometrium. The endometrium (mucosa) consists of simple columnar epithelium overlying a lamina propria (Fig. 7-5, Inset A). The height of the cells and the degree of ciliation is dependent on the stage of the estrous cycle. The endometrial folds are formed by aglandular, longitudinally arranged cores of connective tissue that are covered by mucosa. The lamina propria of the endometrium extends from the basement membrane of the epithelium to the inner layer of myometrium. There is no muscular tissue in the lamina propria, which consists of the 1-mm thick stratum compactum (high density of stellate, stromal cells) and the stratum spongiosum (low density of cells with abundant interstitial fluid and prominent tubular branched glands).[4,25] These glands in the lamina propria are a distinguishing feature of the endometrium of the uterine body and horns. The glands open at the epithelial surface and extend to the depth of the lamina propria. Like the luminal epithelium, the lining of the endometrial glands consists of a single layer of columnar cells whose height is dependent on the stage of the estrous cycle and seasonal influences.[1,4,25,26] With regards to the pre- and postnatal development of these endometrial glands, it has recently been shown that the final differentiation and maturation of the secretory portion of the endometrial glands occurs after the first ovulation and requires exposure to progesterone following estrogen priming.[27] Gap junctions exist between adjacent cells in the luminal and glandular epithelium, and this feature of cells in the endometrium may allow for autocrine and paracrine functions of some hormones.[4] Endometrial glands have varying degrees of tortuosity and patterns of distribution depending on ovarian steroid hormone production and the time of the year. Straightened glands and endometrial edema are typically seen during the follicular phase of the estrous cycle (estrus).[1,25,26] During pregnancy, endometrial glandular secretions (histotrophs) and associated carrier proteins may play a role in establishing a normal uterine environment for embryonic and fetal development.[28] The diffuse epitheliochorial placentation (microcotyledonary) observed in the mare reflects the absence of caruncles and underscores the importance of the entire epithelium in supporting fetal maturation.[1,4,29]

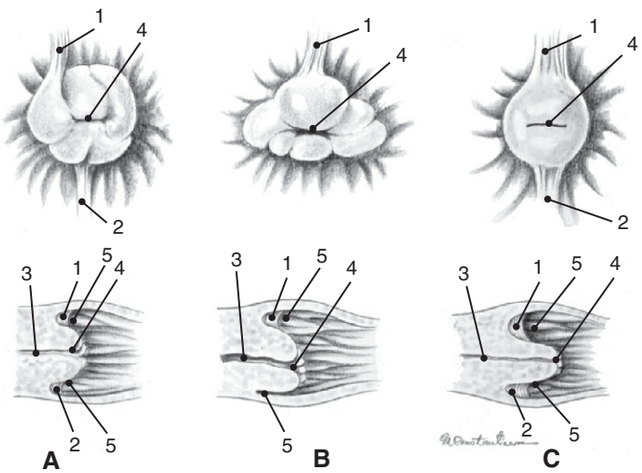

Fig. 7-6 *Upper row:* vaginal portion of the uterine cervix (caudal view). *Lower row:* median section through the vaginal portion of the uterine cervix. **A,** Diestrus. **B,** Estrus. **C,** Pregnancy. 1, Dorsal frenulum; 2, ventral frenulum; 3, cervical canal; 4, external uterine ostium; 5, vaginal fornix.

The endometrium plays an important role in the regulation of luteal function during the estrous cycle and pregnancy in the mare. The uterine mucosa is the source of the luteolysin PGF, and the embryo's ability to prevent endometrial synthesis and release of PGF and facilitate "maternal recognition of pregnancy" will be discussed later in this chapter.[1,4,29] In a process unique to the mare, involving metalloproteinases, chorionic girdle cells (fetal origin) initially attach to and then invade the luminal epithelium beginning at approximately day 35 of gestation. These trophoblastic cells engulf the epithelium, infiltrate the lamina propria, and differentiate into endometrial cups. Endometrial cups, which completely regress by the end of the fifth month of pregnancy due to a maternal cellular response, are specialized secretory structures that play a role in maintenance of the primary CL and the formation of supplementary CLs (also called secondary CLs by some authors) during gestation (second and third luteal response to pregnancy, respectively). The endometrial cups have a functional duration of 60 to 80 days that is independent of fetal viability. There may be a delay in return to normal ovarian and behavioral cyclicity following pregnancy termination if functional endometrial cups are present.[1,4,29]

Histologically, the structure of the uterine cervix reflects its function. There is a large number of mucigenous cells in the cervical epithelium. The cervix produces mucus, which serves as a lubricant or sealant depending on the stage of the estrous cycle or pregnancy. As compared to the uterine wall in the horns and body, there is an increased amount of collagen, as well as a prominent layer of circular smooth muscle containing many elastic fibers in the cervical region. The ability of the cervix to constrict and dilate is critical for successful breeding, pregnancy, and parturition.[1,4]

Clinical aspects. The ability to properly locate the uterus and to recognize the normal size, shape, and appearance of this organ, depending on the hormonal milieu and stage of pregnancy, is necessary to accurately diagnose uterine pathology and to make decisions regarding breeding and therapy. The uterus (including the cervix) is commonly examined using transrectal palpation or ultrasonography for assessment of the stage of the estrous cycle, pregnancy, postpartum uterine involution, and uterine disease. Additionally, examination of the cervix (portio vaginalis) by vaginoscopy provides useful information that complements the findings of palpation and ultrasonography (Figs. 7-6 and 7-7).[4,13,14]

Prior to the availability of diagnostic ultrasonography, uterine and cervical "tone" were the parameters most commonly evaluated to determine the stage of the estrous cycle. Unlike the cow, turgidity of the uterus and cervix increases between estrus and diestrus. During anestrus, the uterus is normally flaccid and nonedematous. The failure of some maiden mares' cervices to soften and dilate appreciably, even under the influence of estrogens, and the edema frequently associated with estrus can lead to inaccuracies in interpretation of palpation findings. Transrectal ultrasonic examination of the mare's uterus (including the cervix) allows visualization of the prominent endometrial folds ("cut surface of an orange" or "spokes of a wagon wheel" appearance), cervical edema, and increased diameters of the uterine horns, body, and cervix observed when the uterus is under the influence of estradiol during estrus (Fig. 7-6, *A*). Likewise, the absence of these features during ultrasonic imaging may suggest that the uterus is under the influence of progesterone secreted during the luteal phase of the cycle (Fig. 7-6, *B*).[1,4,13,14] Pregnancy diagnosis is performed routinely using transrectal palpation or ultrasonography.[1,4,29]

The rapidity of postpartum involution in the mare has been well documented. Mares can conceive and carry a foal to term when bred during the first estrus after parturition (foal heat). Transrectal ultrasonic imaging of the postpartum uterus has been successfully used to detect intraluminal fluid at the time of the foal heat. This accumulation of fluid indicates delayed uterine involution, which has an adverse effect on foal heat conception rates.[1,3,4] Various pathologic conditions can also be diagnosed using transrectal ultrasonic imaging of the uterus, including endometritis with small to moderate amounts of intraluminal fluid, mucometra, pyometra, and endometrial cysts (although there is some debate over the pathologic significance of these cystic structures).[1,3,4,13,14,30]

The mucosal folds of the portio vaginalis of the cervix can have a distinctive appearance during the various stages of the estrous cycle and pregnancy (Fig. 7-6). Their appearance may also change due to seasonal influences. Pink, moist, soft, edematous folds lying on the floor of the vagina with a prominent dorsal frenulum are typically seen during estrus, particularly in pluriparous mares. This "wilted rose" appearance is most apparent a day or two prior to ovulation, and it is at this time that the external uterine ostium appears as a horizontal slit (Fig. 7-6, *B*). During diestrus the folds have a "rose bud" appearance. The mucosa is pale and dry and the dorsal frenulum is less evident than during estrus. The terminal portion of the cervix projects further into the vagina and a ventral frenulum is sometimes observed, especially in maiden mares (Fig. 7-6, *A*). During early pregnancy the

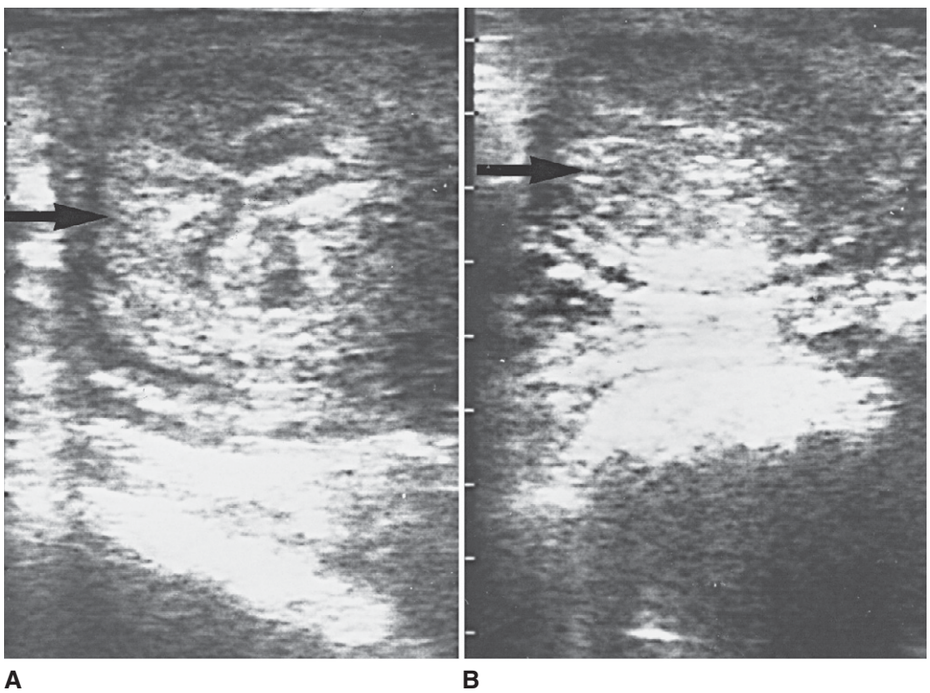

Fig. 7-7 Ultrasonographic appearance of the uterine horns during estrus demonstrating endometrial folds **(A)** and during diestrus **(B).** (Photographs courtesy of Mr. Howard Wilson.)

cervix appears "tight" and is often almost white in appearance. It projects even further into the cranial vagina than during diestrus, and the dorsal and ventral frenula are frequently both evident (Fig. 7-6, *C*). As pregnancy progresses, the cervix is pulled cranioventrad and is more difficult to view. Thick, "waxy" appearing mucus is present in the cervical canal and may be observed at the external uterine ostium and on the vaginal walls during pregnancy. During anestrus the cervical folds are nonedematous, pale, and soft. The cervix may be described as atonic, and it may be possible to observe the uterine lumen through the cervix.[1,4,7] Bruising of the mucosal folds at the external uterine ostium frequently occurs during coitus due to physical contact with the glans portion of the stallion's penis. Observation of bruises during vaginoscopy can suggest recent breeding in instances in which such information has inadvertently been omitted from the reproductive history.[4]

Endometritis, particularly of bacterial origin, is one of the most frequently diagnosed (correctly or incorrectly) abnormalities of the reproductive tract of the mare. It has been hypothesized that "breakdown" of uterine defense mechanisms, possibly related to trauma or abnormalities in anatomic conformation, predispose certain mares to endometritis. Humoral and cellular responses to uterine contaminants have been evaluated, and, most recently, considerable research has focused on the actual physical clearance of foreign material, including microorganisms, from the uterus (uterine clearance).[31] It has recently been proposed that an intrinsic defect in myometrial function predisposes individual mares to delayed uterine clearance.[32] The clinical diagnosis and treatment of endometritis and its underlying cause(s) involve a thorough examination of the mare's reproductive tract and require an understanding of normal reproductive anatomy and physiology. The reproductive tract of the mare may be examined utilizing ultrasonographic, vaginoscopic, histologic, cytologic, microbiologic, and, possibly, even hysteroscopic or scintigraphic techniques.[13,14,22,30,31]

Endometrial periglandular fibrosis is the hallmark of endometriosis, formerly termed chronic degenerative endometritis. The deposition of collagen around individual glands or glandular nests has been linked to recurrent endometritis, embryonic and fetal death, and abortion.[1,4,25] Recent studies have suggested that impaired synthesis or secretion of proteins by endometrial glands may be associated with endometriosis and may contribute to pregnancy wastage. It has also been demonstrated that specific enzyme systems and myofibroblastic transformation may play a role in the pathogenesis of endometrosis.[33–35] The detection of endometrial periglandular fibrosis is accomplished by evaluation of endometrial biopsy samples. Normal variations due to stage of the estrous cycle (edema during estrus or changes in luminal and glandular epithelial height) and seasonal influences (glandular atrophy or nonfibrotic clumping of glands during the anovulatory period) are taken into consideration. Various grading systems have been developed that demonstrate an inverse relationship between amounts of uterine fibrosis and the chances of an individual mare conceiving and carrying a live foal to term.[4,25,35,36]

A variety of other pathologic conditions may occur that require an awareness of normal uterine structure, function, and development. Uterine masses (hematomas and leiomyomas), transluminal adhesions, segmental aplasia, and double cervices (incomplete fusion of the paramesonephric ducts) have been reported in the literature.[21] It has been stated that freemartinism does not occur in the horse; however, asymptomatic XX/XY chimerism has been described in fillies born as twins to colts. Congenitally incompetent cervices and cervical lacerations, which can lead to subfertility when undiagnosed and not repaired, do occur and are diagnosed most accurately by digital and vaginoscopic examinations performed during diestrus.[4,13,14]

Ovarian and Uterine Vasculature

The important hormonal coordination of ovarian and uterine functions and the dynamic morphology of these organs underscores the significance of their blood supply. The CL is reported to be one of the most vascularized structures in the mare. The expansion noted in the uterine vasculature within the broad ligaments during gestation is unrivaled anywhere else in the body. The blood vessels of the ovaries and uterus have been described in detail in several articles and anatomy texts. The vasculature will be reviewed briefly in this chapter with an emphasis on clinically important structures and their functions.[1,4]

Nomenclature and Structure

The arterial blood supply and venous drainage for each ovary are provided by the ipsilateral ovarian branches of the ovarian arteries and veins, respectively, which are located in the mesovarium. Several small vessels form the ovarian branch of the ovarian vein, and these small veins anastomose with each other and with vessels of the uterine branch of the ovarian vein to form a uteroovarian plexus. The arterial supply to the mare's uterus comes principally from the uterine artery (formerly called the middle uterine artery), which arises on each side from the external iliac rather than from the internal iliac artery or one of its branches, as in other species. The uterine branches of the ovarian artery and the vaginal artery (previously referred to as the cranial and caudal uterine arteries, respectively) also contribute arterial blood to the uterus (see Figs. 7-1 and 7-5). The uterine branches of the ovarian and vaginal veins, as well a uterine vein, which is recognized by some authors, provide for uterine venous drainage. These vessels anastomose extensively with each other and with the corresponding structures on the other side of the body.[1,4,7–11]

Functional and Clinical Aspects

The intimate anatomic and functional relationship observed between ovarian arterial supply and uterine venous drainage in ruminants is absent in the mare. In cows and ewes, there is strictly a local (unilateral luteolytic; utero-ovarian) pathway with regard to the circulation of endometrial luteolysin. In the mare, endometrial PGF, secreted in the absence of an embryo or due to inflammation, enters the venous system, circulates

through the heart and lungs, and eventually reaches the ovaries via their arterial supply (systemic pathway).[1,4,29]

The structure, function, and location of uterine and ovarian blood vessels during gestation are relevant from a clinical perspective. Pre- or postpartum rupture of the external iliac, uterine, or ovarian arteries in the mare can lead to exsanguinations. The blood supply to the gravid uterus, the vascular layer of the myometrium, and the diffuse nature of equine placentation require a hemostatic suture the incised uterine wall during cesarean section to prevent excessive hemorrhage. Any conditions adversely affecting arterial blood supply or venous drainage of the ovaries or uterus during pregnancy pose a potential risk to the fetus.[1,4]

The Vagina

The vagina makes up a major portion of the anatomic connection between the uterus and the external environment. Although frequently only a slit due to dorsal compression by rectal contents, the vaginal lumen must be able to expand to accommodate the stallion's penis during breeding, the body of a foal during parturition, and a veterinarian's arm during diagnostic or therapeutic procedures.[1,4]

Location and Structure

For purposes of this discussion, the vagina of the mare represents the caudalmost derivative of the paramesonephric ducts and is sometimes called the vagina proper (see Figs. 7-2 and 7-5). The vestibule will be discussed separately later in this chapter. Located in the pelvic cavity, the vagina is approximately 20 to 25 cm in length and extends from the recess surrounding the terminal segment of the uterine cervix (vaginal fornix) to the prominent transverse fold overlying the external urethral orifice, which is a remnant of the hymen. Only the cranial portions of the vagina are covered by peritoneum. The extent of this coverage is determined by the variations in size of the rectogenital and vesicogenital pouches dorsally and ventrally, respectively. Collagenous connective tissue, fasciae, and muscles surround the portion of the vagina that is not covered by peritoneum.[1,4,6,7,10,11] Like the myometrium, the muscular layer of the vagina comprises a thinner longitudinal layer of smooth muscle and an inner, thicker layer of circular smooth muscle. The lamina propria of the vagina is well vascularized but is aglandular. Stratified squamous epithelium, consisting of basal, middle, and superficial regions, covers the vaginal mucosa, which is arranged in longitudinal folds.[1,4]

Functional and Clinical Aspects

The distensibility of the vaginal walls can be attributed to the muscular layer, the presence of fibroelastic tissue, and the longitudinal mucosal folds. Although variations in the mare's vaginal epithelium have been reported during the estrous cycle, the degree of cornification of superficial squamous cells is minimal compared to that observed during estrus in the bitch. As a result, vaginal cytologic testing is not useful for determination of the stage of the estrous cycle in mares. The vaginal canal can be used as a surgical approach to the peritoneal cavity (colpotomy) or may be a route for peritoneal contamination from coital or parturient trauma. Vaginal vessels, which are branches of the internal pudendal artery and vein, are located in the lateral walls of the vagina and should be taken into consideration when evaluating traumatic injuries or when performing surgical procedures in the vagina.[12] The transverse fold by virtue of its contribution to the vestibulovaginal sphincter is an important barrier to contamination of the more cranial aspects of the reproductive tract associated with pneumovagina or vesicovaginal reflux (urine pooling). The transverse fold is an important landmark to identify in order to avoid the passage of a vaginal speculum, insemination pipette, culturing device, or biopsy instrument into the urethra. Surgical modification of the transverse fold is involved in correction of urine pooling.[12] Persistent hymen occurs occasionally, and rupture during breeding may result in mild discomfort and minor hemorrhage. If imperforate, a persistent hymen can cause accumulation of fluid in the vagina and uterus. Like the uterus, the vagina is frequently bacteriologically sterile, but approximately 30% of mares have vaginal contamination with nonpathogenic bacteria. The vagina can be examined with a speculum or digitally for the presence of traumatic lesions, transluminal adhesions, persistent hymen, or urine pooling.[1,4,13,14]

The Vestibule and Vulva

Frequently described as part of the vulva in English and French textbooks, the vestibule is considered by the NAV to be a portion of the vagina. For purposes of this discussion, it will be considered distinct from the vulva but contiguous, having a common embryonic origin, similar functions, and shared structures. Because of its proximity and close relationship to the vestibule and vulva, the perineum (and related structures) will be discussed as well.[1,4,6,8,9,11]

Location and Structure

The vestibule and vulva represent the portions of the mare's reproductive tract caudal to the transverse fold of the vagina (see Figs. 7-1, 7-2 and 7-5). Originating embryologically from the urogenital sinus, these are the terminal and common segments of the reproductive and urinary tracts. The vestibule has a ventrodorsal slope with the ventral wall (floor) of the vestibule being longer than the dorsal wall, which is covered by the perineal septum. The floor of the vestibule is 10 to 12 cm long and extends caudally beyond the ischiatic arch. The vestibular walls and floor contain the constrictor vestibuli muscle, which consists of circular and longitudinal striated muscle fibers. Smooth muscle fibers, which can either be a continuation of the vaginal musculature or a part of the retractor clitoridis (formerly called the suspensory ligament of the anus), are also present. Medial to the constrictor vestibuli muscles are the vestibular bulbs, which are ovoid masses of erectile tissue measuring 7 cm by 3 cm (Fig. 7-5). The lamina propria of the vestibule is covered by stratified squamous epithelium. The mucosa of the vestibule is folded and is pink to reddish brown. Papillae on the vestibular floor and walls represent the

openings of the branched tubular minor vestibular glands.[1,4,6,7,10,11]

The vulva is just caudal to the vestibule and consists of two labia and the clitoris. The labia are apposed at the vulvar cleft and form a dorsal and ventral commissure (Fig. 7-5, Inset B). The ventral commissure is rounded and forms part of the prepuce of the glans clitoridis. Seventy percent of the vulva is normally below the floor of the pelvis. Each labium has a mucocutaneous junction between an internal, aglandular mucosa and a thin, external layer of skin. The skin is usually pigmented and is abundantly supplied with sweat and sebaceous glands. The constrictor vulvae are located beneath the vulvar skin and are composed of striated muscle fibers that are continuous dorsally with the sphincter ani (Figs. 7-1 and 7-2). Ventrally, the constrictor vulvae surround the clitoris, and a few muscle fibers cover the retractor clitoridis on each side.[1,4]

The clitoris of the mare is homologous to the stallion's penis and, like the penis, contains well-developed erectile tissue (corpus cavernosum clitoridis; Figs. 7-1, 7-2 and 7-5, Insets B, C, and D). The clitoris consists of a body (corpus clitoridis) consisting of two crura, which attach to the ischial arch and a prominent glans clitoridis. The corpus clitoridis lies beneath the vestibule and is approximately 5 cm long. The glans is normally 2.5 cm in diameter. The glans clitoridis is located in a small cavity, the fossa clitoridis, which is surrounded by the prepuce of the glans clitoridis, a portion of which is formed by the ventral commissure of the vulva. The transverse frenular fold, arising from the vestibular mucosa, forms the roof of the prepuce and is attached to the glans clitoridis by a median frenulum. There is a median sinus and, in most mares, two additional, but inconstant, lateral sinuses. These sinuses are located on the dorsal aspect of glans clitoridis (near the median frenulum). Within the fossa clitoridis are frenular, ventral clitoral and labial recesses. Smegma produced by clitoral sebaceous glands can be found in these areas (Fig. 7-5, Insets C and D).[1,4,6,7,10,11]

The portion of the body wall that surrounds the anal canal and vulvar and vestibular portions of the urogenital tract at the pelvic outlet is the perineum. The first few coccygeal vertebrae, the sacrosciatic ligaments, and the floor of the pelvis form the boundaries of the perineum dorsally, laterally, and ventrally, respectively. Embryologically, the perineum is formed by the connective tissue that separates the anal membrane dorsally from the urogenital membrane ventrally. This embryonic structure later develops into the perineal body, which is a node of muscular and fibrous tissue between the anus and the vestibule. The perineal region is distinct from the perineum and the perineal body and represents the cutaneous area between the semimembranosus muscles, extending from the base of the tail to the ventral commissure of the vulva (or base of the udder, according to some texts).[1,4,7,10,11]

Functional and Clinical Aspects

Owing to the upright posture of humans, there is a well-developed pelvic diaphragm consisting of muscle and a rudimentary tail, which supports the weight of the pelvic organs (and to a limited extent, the abdominal organs). The mare is a quadruped and the floor of the pelvis is the structure that bears the weight of the pelvic viscera. However, during urination, defecation, breeding, foaling, and episodes of tenesmus there are forces exerted upon the pelvic outlet that must be counterbalanced to prevent prolapse of the pelvic organs. In the mare, the levator ani and coccygeus muscles and connective tissue compose what is called the pelvic diaphragm (considered by some to be the muscular basis of the perineum). The constrictor vestibuli, constrictor vulvae, and retractor clitoridis, through their association with the vestibule and vulva, function with the pelvic diaphragm to provide for containment of the viscera within the pelvic cavity when expulsive forces are exerted (Figs. 7-1 and 7-2). As a result, uterine and vaginal prolapses are infrequent occurrences in the mare. The constrictor vestibuli, vestibular bulbs, and constrictor vulvae accommodate and secure the penis during breeding. The vestibular walls and labia of the vulva contain elastic fibers that allow for expansion during coitus and parturition. The constrictor vulvae function in the closure of the labia and the eversion of the clitoris ("winking") observed following urination or during estrus.[1,4,7–11]

The vulvar labia along with the transverse fold (as part of the vestibulovaginal sphincter) and the uterine cervix are the three anatomic barriers between the external environment and the uterus. Variations in perineal conformation can predispose mares to reproductive failure. Proper closure of the vulva is necessary to prevent air and feces from contaminating the reproductive tract. Generally, no more than 4 cm of the vulvar cleft should be between the dorsal commissure and the pelvic floor, and the vulvar angle (cranial-to-caudal slope of the vulva) should not vary more than 10 degrees from vertical (Figs. 7-1 and 7-2). Systems for quantifying abnormalities in perineal conformation have been devised, and surgical procedures have been developed to correct these variations.[4,12]

Bacteria, including some potentially pathogenic varieties, can often be cultured from the vestibule and fossa clitoridis of the mare. This bacterial flora has the potential to contaminate more cranial portions of the reproductive tract during the performance of diagnostic and therapeutic procedures. The various sinuses and recesses of the glans clitoridis and fossa clitoridis collect smegma (Fig. 7-5, Insets C and D). The medial sinus of the glans clitoridis may be 1 cm deep and provide adequate anaerobic conditions for growth of *Taylorella equigenitalis,* the bacteria that causes contagious equine metritis (CEM). Surgical removal of the glans and sinuses has been performed in countries where CEM is endemic.[1,4]

Congenital anomalies, traumatic injuries, and drug-induced anatomic abnormalities occur in the vestibular and vulvar region. Equine pseudohermaphrodites have been reported, and a penile structure, protruding from what appears to be labia in the perineal region, may be observed in affected horses. Perineal lacerations of various degrees may occur during foaling or breeding, and surgical procedures have been developed for their correction.[12] Hypertrophy of the glans clitoridis may be a clinical finding in mares to which anabolic steroids have been

administered. It is not uncommon for these mares to exhibit variable degrees of subfertility.[1,4,13]

The Epiphysis (Pineal Gland) and Hypothalamus

In humans and animals alike, the neuroendocrine functions of the pineal gland (epiphysis) and hypothalamus (inclusive of the hypophysis, or pituitary gland in this discussion) play an important role in regulating the body's physiologic processes. These structures facilitate development of the reproductive tract and endocrine regulation of the mare's estrous cycle. Sexual behavior, gestation, parturition, and lactation are all affected by the pineal gland and hypothalamus. Clinicians should be aware of the location of these structures and their interaction with one another and the impact their functions might have on reproductive physiology.

Location, Structure, and Function

The pineal gland is pine-cone shaped in humans (hence the name pineal). In the horse, the pineal gland is an ovoid, reddish brown structure 10 to 12 mm long and 7 mm wide and is a component of the epithalamic region of the diencephalon (Fig. 7-8). It is located caudodorsal to the thalamus, protected in a deep median depression between the cerebral hemispheres and the vermis of cerebellum. The pineal gland is surrounded by a capsule of pia mater from which trabeculae project into the gland, dividing it into masses of epithelial cells of ependymal origin. These cells secrete melatonin, which plays a role in the regulation of reproductive photoperiodicity and possibly puberty. The rete pinealis supplies arterial blood to the pineal gland, and venous drainage is provided by the ventral longitudinal sinuses.[1,4,7,10]

The hypothalamus comprises the portion of the diencephalon that includes the ventral walls of the third ventricle, the mammillary body, the tuber cinereum, and the hypophysis. Cell bodies of neurosecretory cells are organized into discrete foci (nuclei).[1] Magnocellular (large) neurosecretory cells such as those found in the supraoptic and paraventricular nuclei secrete hormones such as vasopressin and oxytocin at their terminal nerve endings in the neurohypophysis.[1,4,7,10] Releasing and inhibitory (hypophysiotropic) factors such as gonadotropin-releasing hormone (GnRH), thyrotropin releasing hormone (TRH), and dopamine (prolactin inhibitory factor; PIF) are synthesized and secreted by predominantly parvicellular (small) neurosecretory cells located in a variety of hypothalamic nuclei. These hormones are carried to the appropriate target cells in the adenohypophysis by the hypothalamic-hypophysial portal system (to be discussed later).[1,4,7]

Although a part of the hypothalamus, the pituitary gland warrants special attention because of its unique origin, structure, and functions. The hypophysis is flattened dorsoventrally and is approximately 2 cm wide. It comprises the neurohypophysis (light-colored "posterior pituitary gland"), which is of neuroectodermal origin, and the adenohypophysis (dark-colored "anterior pituitary gland"), derived from an evagination of oral ectoderm (Rathke's pouch; Fig. 7-8).[1,4,7] The major portion of the gland is covered by dura mater in the hypophysial fossa of the basisphenoid bone. The hypophysis is attached to the rest of the hypothalamus by the infundibular (neural stalk) portion of the neurohypophysis, which is a continuation of the tuber cinereum at the median eminence. The adenohypophysis can be subdivided into the pars distalis (analogous the human "anterior pituitary gland"), pars intermedia, and the pars tuberalis, and, together, these structures almost surround the entire neurohypophysis. The pars distalis contains specific cell types which, with appropriate stimulation, secrete prolactin, the gonadotropins (follicle-stimulating hormone or FSH and luteinizing hormone or LH), thyrotropin (thyroid-stimulating hormone or TSH), or other endocrine products. Cells in the pars intermedia secrete melanocyte-stimulating hormone in some species, and the pars tuberalis contains numerous vessels of the hypothalamic-hypophysial portal system and some secretory cells, such as those which secrete the gonadotropins, which are also referred to as gonadotropes.[1,4,7,10,11,37] The

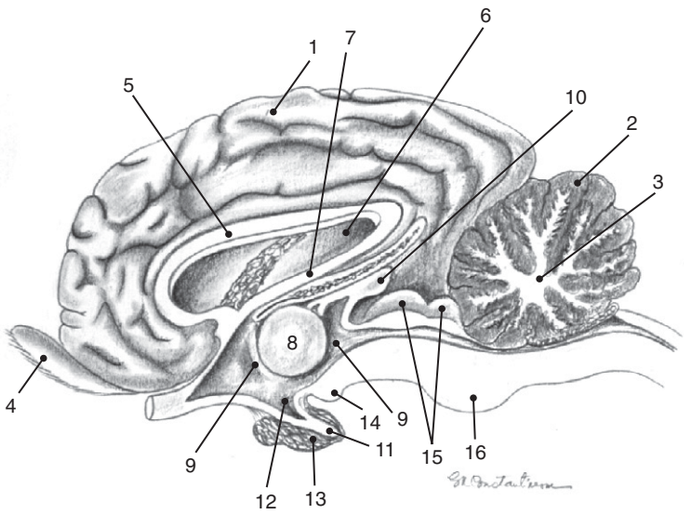

Fig. 7-8 Median section thorough the brain. 1, Cerebrum; 2, cerebellum; 3, vermis; 4, olfactory bulb; 5, corpus callosum; 6, hippocampus; 7, fornix; 8, interthalamic adhesion; 9, third ventricle; 10, epiphysis (pineal gland); 11, neurohypophysis; 12, infundibulum; 13, adenohypophysis with pars tuberalis (covering the infundibulum, pars distalis, and pars intermedia); 14, mammillary body; 15, corpora quadrigemina; 16, pons.

proportion of gonadotropes in the pars tuberalis, unlike that in the pars distalis, appears to be increased in normally cycling, sexually active mares, as compared to seasonally anestrous mares. In addition, although gonadotropes in the equine adenohypophysis frequently produce both FSH and LH, cells that specifically secrete FSH or LH have been shown to differentiate predominantly in the adenohypophyses of cycling mares.[37]

The hypothalamic vasculature contributes to the functional relationships between the hypophysis and the other portions of the hypothalamus. Branches of the internal carotid artery and the rami communicantes caudales supply the capillary plexus in the median eminence. Portal vessels in the pars tuberalis, which terminate in sinusoidal capillaries, transport endocrine products (releasing and inhibitory factors) from the more dorsal parts of the hypothalamus to the adenohypophysis, and may, in fact, represent the sole arterial supply to this part of the pituitary gland. The caudal infundibular arteries supply arterial blood to the neurohypophysis. Venous drainage for the hypothalamus is provided by the cavernous and intercavernous sinuses.[1,4]

Clinical Aspects

Manipulation of the photoperiod to inhibit melatonin production by the pineal gland is commonly utilized in reproductive management of broodmares to facilitate the commencement of normal estrous cycles earlier during the year. Based on research performed in rodent species and validated to some extent in the horse, this neuroendocrine pathway is somewhat complex and appears to be dependent on normal retinal function and the integrities of the optic chiasma, the retinohypothalamic nerve tracts and the suprachiasmatic and paraventricular nuclei. Projections from the median forebrain bundle and pre-and postganglionic sympathetic fibers associated with the superior cervical ganglion must also be intact for the effects of photoperiod on melatonin synthesis and mare reproductive function to be manifested.[38]

What has been traditionally referred to as the hypothalamic-pituitary-gonadal axis during discussions of reproductive endocrinology forms the basis for regulation of the mare's sexual development and estrous cycle. Pituitary adenomas and pars intermedia dysfunction may adversely affect reproductive function in the mare.[1,4] With regards to "fescue toxicosis," ergot alkaloids produced by the endophyte *Neotyphodium coenophialum* (formerly *Acremonium coenophialum*) interact with D_2-dopamine adenohypophysial receptors on maternal lactotropes and possibly fetal corticotropes to mimic hypothalamic suppression of prolactin secretion and delay parturition. Recently, it has also been noted that ergot alkaloid exposure may delay the onset of the ovulatory season and cause irregularities in the seasonal estrous cyclic activity of mares.[39–42]

The Mammary Glands

Adequate secretion of milk (including colostrum) must take place at the appropriate time for normal growth and development of the foal.

Location and Structure

Between the hind legs, closely attached to the ventral abdominal wall, is the mare's udder (Figs. 7-1 and 7-2). In maiden mares it is barely visible and is frequently situated caudal to two folds of abdominal skin, which are effaced during mammary development toward the end of gestation. In maiden mares, the teats are small and flattened laterally, and hair may be present at the orifices on the tips of the teats of young fillies. Removable, dark sebum is present in the intermammary groove between the teats. The halves of the udder (mammae) are supported by lateral and medial suspensory ligaments on each side. The mare has two teats, which generally have two or occasionally three orifices. For each teat orifice, there is a corresponding glandular complex, the largest of which is located cranially. Associated with each orifice is a separate papillary duct (streak canal) lined by stratified squamous epithelium (Fig. 7-2). The papillary duct is continuous with a lactiferous sinus, consisting of a papillary part (teat cistern) and a glandular part (gland cistern). Each lactiferous sinus, lined with bistratified columnar epithelium, leads into a lactiferous duct system and contiguous glandular tissue, lined with columnar epithelium. In addition to glandular tissue and a system of ducts, the udder contains smooth muscle, fibroelastic tissue, and well-developed vasculature. The cranial and caudal mammary arteries, which are branches of the external pudendal artery, supply arterial blood to the udder. Similarly named veins provide for venous drainage.[4]

Functional and Clinical Aspects

Mares can develop mastitis, and the severity of inflammation, the response to therapy, and the proportion of the mammary glands involved will determine the prognosis for future lactations. Galactorrhea in mares is not an infrequent complaint by clients and can have a number of causes, including pituitary adenomas. Ergot alkaloid exposure, such as in cases of "fescue toxicosis" or ergotism, suppresses the typical, periparturient secretion of prolactin resulting in inhibited lactogenesis and agalactia.[4,39–42]

REPRODUCTIVE PHYSIOLOGY

As there is an intimate relationship between organ structure and function, some important physiologic aspects of equine reproduction have already been discussed in conjunction with reproductive anatomy. The purpose of this section is to explain concisely what is presently understood about photoperiod regulation, the estrous cycle, puberty, pregnancy (including maternal recognition of pregnancy), and parturition in the mare. For a detailed description of the classification and description of the hormones involved in equine reproduction, the reader is directed to the corresponding chapter in the previous edition of this text.[4]

Photoperiod Regulation of Reproduction in Mares

It has long been recognized that reproductive function in the mare, specifically normal ovarian cyclic activity, is

governed predominantly by photoperiod, or, in other words, day length. This topic has been covered extensively in other references, but will be discussed briefly in this chapter in order to provide the physiologic basis for some clinically relevant aspects of mare reproductive management. In addition, other endocrine pathways and external factors traditionally considered to have minimal roles in the seasonal onset of estrous behavior and the regulation of equine reproductive function in the mare have recently been shown to play a larger part in these processes.[1,4,43–49]

To varying degrees, mares naturally respond to changes in day length and generally experience autumnal transition, winter anestrus, and vernal transition (collectively termed the anovulatory season), and seasonal polyestrous cyclicity (breeding or ovulatory season) during the late spring and summer. Photoperiod influences ovarian activity, at least in part, through the actions of melatonin. Melatonin is synthesized and secreted in the pineal gland mostly at night and is thought to act by decreasing the synthesis of GnRH in the hypothalamus. Decreasing day length in the fall results in lower hypothalamic GnRH content and reduced secretion of LH and FSH by the adenohypophysis. Clinically, mares may have reduced fertility and persistent, anovulatory follicles and, possibly, prolonged periods of estrus during the autumnal transition (receding phase). During the winter, hypothalamic GnRH is at its lowest concentrations, consistent with short photoperiods and a high level of pinealocyte melatonin synthesis.[1,38] Owing to the absence of GnRH activation of the promoter for the LH β subunit, the adenohyphysial content of LH is minimal during anestrus.[38,43] The concurrent decreases in ovarian activity and size are accompanied by passive sexual behavior in anestrous mares. Increasing photoperiod after the winter solstice (approximately December 22) results in a gradual decrease in melatonin synthesis and an increase in pulsatile secretion of GnRH. FSH secretion is subsequently stimulated and folliculogenesis is initiated. The relative lack of LH secretion is evidenced by the development of multiple, transitional, anovulatory follicles. The ovaries of mares in the vernal transition (resurging phase) are frequently described as resembling "clusters of grapes" by transrectal palpation, and ultrasonographically these ovaries contain multiple nonechogenic follicular structures.[1,15,16,38] Sufficient GnRH stimulation induces LH synthesis and secretion and ovulation. Subsequent to this initial ovulation in a previously anovulatory mare, the sequential and cyclic endocrine and functional reproductive events which characterize the equine breeding season take place.[1,38]

Several photoperiod manipulation techniques have been employed to hasten the onset of ovulatory estrous cycles in mares. Exposing mares to 16 hours of artificial light (10 to 12 foot-candles of light), or increasing day length after sunset for 2 to 3 hours for a total photoperiod of 16 hours have been used successfully to manipulate photoperiod. The introduction of an hour of light 9.5 hours after the onset of darkness has been suggested as another alternative to stimulate mares to cycle earlier in the year. Even with artificial photostimulation, mares will experience a "transitional" phase. Photoperiod manipulation schemes should commence at least 60 days before the desired time of breeding.[1,38]

Recent research has suggested that factors other than photoperiod and endocrine mediators in addition to melatonin may play roles in the commencement of normal cyclic behavior in mares. The tendency of some mares to cycle continuously without respect to photoperiod may reflect the influence of some of these external factors and other hormonal signals. Young mares have been shown to begin anestrus earlier than mature mares, and body weight, percent body fat, and circulating levels of leptin (reflecting energy availability) modify the photoperiod response and determine the propensity of individual animals to cycle continuously throughout the year.[44,45] Endogenous opioid tone is less during the breeding season than during anestrus, and mares cycling throughout the year do not experience such fluctuations.[46] Prolactin has been proposed to play a role in the regulation of seasonal cyclicity, particularly the vernal transition, and melatonin, dopamine, and opioids have been shown to decrease circulating levels of prolactin in the spring.[44,47–49] Ergot alkaloid–exposed, transitional mares have delayed ovulations in association with decreased circulating levels of prolactin.[40,41,47] Lower ambient temperatures appear to adversely affect the ability of D_2-dopamine receptor antagonists to hasten ovulation in anestrous and transitional mares.[40,47,48,50]

A variety of pharmacologic approaches have been developed to advance the onset of the ovulatory season in transitional mares. Exogenous progestins (with or without estradiol) and GnRH-type compounds have been successful to variable degrees in hastening ovulation. Human chorionic gonadotropin (hCG), by virtue of its LH-like activity, has been employed in some transitional mares with persistent follicles.[51] Stimulation of prolactin secretion by lactotropes, through the use of D_2-dopamine receptor antagonists, has also been recommended for use in mares experiencing the vernal transition.[40,41,47,48,50]

The Estrous Cycle

The normal estrous cycle of the mare is approximately 21 days, and the normal lengths of estrus and the interestrous interval range from 5 to 7 days and from 14 to 16 days, respectively. The estrous cycle of nonpregnant mares is characterized by a typical pattern of hormone concentrations in the peripheral blood (Fig. 7-9). Individual variations in estrous cycles exist and are dependent on seasonal influences, body condition, exposure to ergot alkaloids in tall fescue pastures or hay, the number of follicular waves, and the possibility of multiple or diestrous ovulation(s). An understanding of the normal equine estrous cycle and an awareness of the common observed variations are necessary for the efficient reproductive management of breeding programs. This knowledge allows for the identification of mares with irregular reproductive cycles and behavior, which require further examination and therapy. Based on the normal reproductive physiology of the mare, pharmacologic protocols have been developed for the induction and synchronization of estrus and ovulation.[1,4,51]

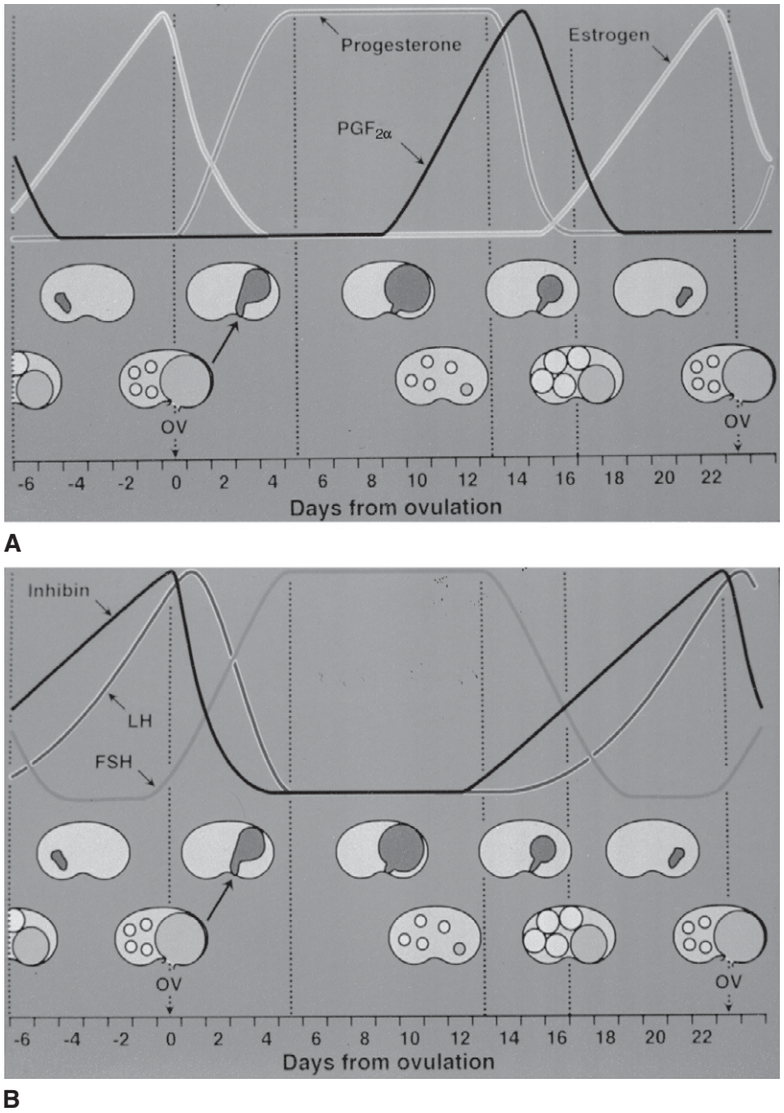

Fig. 7-9 Temporal relationships between circulating hormones and ovarian events. **A,** Progesterone, estrogen, and $PGF_{2\alpha}$. **B,** FSH, LH, and inhibin. (From Ginther OJ: *Reproductive biology of the mare: Basic and applied aspects,* 2nd ed. Cross Plains, WI: Equiservices, 1992. Reprinted with permission of O.J. Ginther. Photographs courtesy of Mr. Don Connor.)

Estradiol of follicular origin is the predominant reproductive steroid in the blood at the beginning of estrus. Progesterone is low at this time (less than 1 ng/ml), and mares should begin to show behavioral signs of estrus when teased (eversion of the clitoris, frequent urination, standing for the stallion, etc.). "Mouth clapping," along a head held low with ears turned back, are consistent signs of estrus in jennies and zebras. The dominant follicle grows in size and produces more estradiol. Subordinate follicles become atretic owing to production of inhibin (induced by estradiol) by granulosa cells of the dominant follicle. Under the influence of estradiol, GnRH pulse frequency increases (after an initial suppression) to favor secretion of LH relative to FSH. LH levels increase, and FSH reaches minimum levels. The preovulatory LH surge is more gradual in the horse, as compared to other species, and actually reaches maximum peripheral concentrations 1 to 2 days following ovulation. As LH levels increase and the follicle approaches ovulation, theca cells begin to degenerate, and estradiol production actually begins to decrease prior to ovulation. Blood levels of follicular estradiol and inhibin return to their basal levels over a 1- to 2-day period following ovulation, and this decline in estradiol coincides with the end of behavioral estrus in the mare (Fig. 7-9).[1,4] hCG and GnRH analogues have been used pharmacologically to induce ovulations in mares.[51]

A common clinical complaint in mares is abnormal prolongation or increased frequency of estrus. The athletic performance of some mares can be adversely affected by estrous behavior, and various therapeutic approaches to this problem have been employed.[52] As mentioned earlier, mares can return to estrus sooner than anticipated (short interestrous interval) because of endometritis and endotoxemia. The large quantities of estrogens synthesized during pregnancy may also result in mares exhibit-

ing prolonged estrous behavior during gestation. Mares with granulosa cell tumors may exhibit signs of persistent estrus, and older mares or mares during vernal transition may fail to ovulate.[1,4,14]

Multiple (predominantly double) ovulations occur in mares, and there seems to be an individual predilection for this phenomenon. There may also be a hereditary propensity for double ovulations as this is a fairly common occurrence in Thoroughbred and draft breed mares (approximately 20–25%) as compared to other breeds (5–10%). Maiden and barren mares are more inclined than foaling mares to have double ovulations, and it is postulated that double ovulations occur because of an increased number of LH receptors on two developing follicles (increased sensitivity to gonadotropins). Double ovulations can result in twin pregnancies, which, if maintained beyond the embryonic period (40 days), are frequently aborted.[1,3,4]

Diestrus begins following ovulation with cessation of estrous behavior. The predominant reproductive hormone during this period is progesterone. During diestrus, mares are generally disinterested in stallions and may pin their ears and kick when teased by stallions. Blood levels of progesterone increase rapidly following ovulation, reaching a maximum (greater than 4 ng/ml) 4 to 7 days after ovulation. Under the influence of progesterone, GnRH pulses are infrequent and FSH pulse amplitude increases relative to LH. Peripheral blood levels of FSH reach a maximum during diestrus, allowing for follicular development. Suppressions of subsequent levels of FSH and LH, as well as prolongation of the interovulatory interval, have been observed with pharmacologic doses of a GnRH analogue (deslorelin) implanted in mares to induce ovulation.[53,54] Recent research has suggested this undesired effect of deslorelin can be avoided with removal of the implant 48 hours after initial implantion.[55]

One (Fig. 7-9) or two waves of follicular growth (primary and secondary) may occur during diestrus. If there is one follicular wave, then this constitutes the primary wave of folliculogenesis. This follicular wave begins approximately 9 days following ovulation, and the granulosa cells of one follicle begin to produce inhibin, which causes a decline in FSH. The theca and granulosa cells of this dominant follicle begin to synthesize small amounts of estradiol, and the subordinate follicles begin to undergo atresia. At about the same time as the primary wave of folliculogenesis is occurring, the progesterone-primed endometrium begins to synthesize and secrete PGF.[1,4] It has been shown in pony mares that oxytocin secretion and endometrial oxytocin receptor density are correlated with endometrial synthesis and secretion of PGF.[56] Peak peripheral blood levels of PGF occur on or about day 14 or 15 following ovulation and coincide with luteolysis and a decline in blood levels of progesterone. Increased secretion of estradiol by the dominant follicle results in the mare's return to estrus 1 to 3 days following CL regression and the beginning of another estrous cycle (Fig. 7-9).[1,4]

Prolonged luteal activity (longer than normal diestrus) is commonly observed in mares, and there are several explanations for this condition in addition to the prolonged interovulatory period associated with deslorelin implants.[53,54] Late diestrous ovulations from secondary follicular waves (also called secondary ovulations) may result in a developing secondary CL (insensitive to PGF) being present at the time of normal PGF secretion by the endometrium, and severe uterine disease may render the endometrium incapable of PGF synthesis and secretion. Exposure of nonpregnant mares to ergot alkaloids in tall fescue pastures or hay has also been associated with prolonged luteal activity. Early embryonic loss after the normal time of maternal recognition of pregnancy (14–16 days) will also result in a longer than expected interestrous interval. Idiopathic persistence of the CL (in the absence of uterine pathology or embryonic loss) has been described, but it is felt by some that further objective documentation of this condition is warranted.[1,4,40] PGF or related compounds can be administered therapeutically to mares in cases of luteal phase prolongation or in order to shorten the interovulatory period for reproductive management purposes.[51]

PUBERTY

The onset of puberty in the equine female is denoted by occurrence of the first ovulation. It is generally thought to occur sometime between 12 and 24 months of age. The prepuberal ovary must undergo changes in morphology prior to ovulation, and these may occur as early as 5 to 7 months of age in the mare. Little research has been done on puberty in the mare because horse owners are generally content to allow mares to develop until the age of 3 prior to breeding. Additionally, some horses are initially trained and shown as yearlings and 2-year-olds and sexual immaturity under these circumstances may be desirable. In prepuberal animals, there is adequate FSH secretion to stimulate the development of small follicles, which secrete some estradiol but are not yet ovulatory. It has been speculated that the endocrine events and alterations in hormonal gene expression that signal the onset of puberty in horses share significant similarities with the factors that regulate the vernal transition and the onset of seasonal ovarian cyclic activity in mature mares.[1,4,38]

There appear to be several external determinants of the timing of the first ovulation in young mares. Prepuberal mares (6 to 8 months of age) exposed to 16 hours of light beginning in December actually ovulated later than control animals. Poor nutrition may delay the onset of puberty by its effect on body fat composition and growth rate. In cases of poor nutrition, it has been demonstrated that LH pulse frequency and amplitude are suppressed when growth rate is retarded.[1,4,44] Based on data collected for mature cycling mares, exposure to *Neotyphodium*-infected fescue hay or pastures, or potentially, other sources of ergot alkaloids might also be expected to delay the first ovulation in young mares.[40,41] Pheromones and exposure to male animals may play a role in puberty in the mare, as it does in other species such as the ewe. Anabolic steroids have been implicated as having a role in delaying normal reproductive cyclicity in young mares, and young mares with chromosomal abnormalities may fail to cycle.[1,4,14]

Pregnancy

The ultimate goal of breeding a mare is the delivery of a live foal. The normal estrous cycle of the mare must be interrupted through embryonic-maternal interactions, and adequate placentation must be established for the metabolic and endocrine support of pregnancy. The length of gestation varies in mares, ranging from 310 to 380 days (average 335–340 days), with male fetuses tending to have longer gestations. Pregnancy begins with conception (fertilization), which takes place within the oviduct of the mare. Approximately 24 hours after fertilization, the first cleavage takes place. On the sixth day after ovulation, the morula stage of the embryo is selectively transported in preference to nonfertilized ova from the isthmus of the uterine tube via the uterotubal junction to the ipsilateral uterine horn. This process is thought by some to represent a form of "maternal recognition of pregnancy" in the mare.[1,4]

Blood concentrations of progesterone (luteal origin) reach their peak by the time the embryo enters the uterus. Under the influence of progesterone, the uterus is prepared to provide the proper environment for early embryonic development. Concentrations of immunoassayable progestins greater than 2.5 ng/ml 12 days after ovulation have been reported to be associated with higher pregnancy rates in mares.[57] Embryonic blastocyst formation occurs with synthesis of the embryonic capsule occurring prior to shedding of the zona pellucida. Other dramatic, metabolic changes take place within the developing embryo, such as the synthesis and secretion of insulin-like growth factor–binding proteins, which facilitate the actions of insulin-like growth factors on the equine conceptus.[58] By virtue of the embryonic capsules' mucin-like glycoprotein structure, the secretion of estrogens by the embryo and maternal myometrial contractions, the horse embryo exhibits mobility within the uterus beginning on day 9 or 10 after ovulation. Coinciding with maximum embryonic mobility (days 11–15 following ovulation) diminished levels of PGF metabolites are observed in pregnant versus nonpregnant mares. It is theorized that the mobile horse embryo produces some anti-luteolysin, which prevents regression of the mare's CL, and this luteostatic mechanism has been termed the first luteal response to pregnancy ("maternal recognition of pregnancy"). The mechanism of this anti-luteolysin's action may involve stimulation of an inhibitor of endometrial PGF synthesis or interference with the oxytocin-PGF interaction within the endometrium.[1,4,56] Because equine embryos do not seem to express the appropriate genes, the anti-luteolysin in the mare is most likely not an interferon, as in the cow and ewe.[1,4]

Equine embryos fix (day 16 after ovulation) and continue in their development following the first luteal response to pregnancy. Blood levels of progesterone in the mare decline slightly from this time (decreasing size of CL) until the secretion of eCG by the endometrial cups on approximately day 40 of pregnancy. Resurgence of progesterone synthesis by the primary CL (resulting from eCG stimulation) has been termed the second luteal response to pregnancy. The formation of supplementary CLs, induced by eCG secretion, constitutes what has been referred to as the third luteal response to pregnancy. Blood levels of progesterone (secreted by primary and supplementary CLs) reach their maximum between days 60 and 100 of gestation (10–20 ng/ml) and plateau until days 120 to 150. By the end of the sixth month of gestation, progesterone levels reach a minimum (less than 2 ng/ml).[1,4]

Lower than expected progesterone levels may occur in the pregnant mare under several different circumstances. Ultradian rhythms of luteal progesterone secretion may be reflected in the timing of sampling. ELISA tests for progesterone will detect very little progesterone after days 120 to 150 of gestation. Endotoxin has been shown to cause PGF production and luteolysis, which can result in pregnancy loss prior to day 70 of pregnancy. Luteal insufficiency has long been thought to be a cause of embryonic and fetal death, although its actual incidence is subject to debate.[1,4]

Production of 5-α pregnanes by the uterofetoplacental unit begins around day 40 of pregnancy and reaches a plateau by approximately mid-gestation. Although the first edition of this text referred to these compounds collectively as "progestins," the fact that 5-α pregnanes include metabolites of pregnenolone, as well as progesterone, makes "progestagens" a more appropriate collective term for these compounds, including instances in late pregnancy where they are being measured by radioimmunoassays for progesterone.[4,57,59] The 5-α pregnanes may be able to maintain pregnancy in the absence of ovarian progesterone (as demonstrated in ovariectomy and endotoxin studies) as early as day 50 in some mares and frequently by day 70 of gestation.[1,4] Between days 90 and 300 of gestation, maternal plasma concentrations of immunoassayable progestagens are reported to range between 4 and 10 ng/ml in healthy pregnancies.[57] Thirty days prior to parturition, there is a dramatic rise in levels of progestagens in the maternal circulation, which peaks (usually at over 25 ng/ml for immunoassayable progestagens) 2 to 3 days prepartum and declines precipitously within 24 hours of parturition.[57,59]

Concentrations of progestagens in the maternal circulation are affected by a number of pathologic conditions. In cases of "fescue toxicosis" or other prolonged exposures of mares to ergot alkaloids, the dramatic increase in maternal immunoassayable progestagens observed during the last 30 days of pregnancy is suppressed or absent.[39–42,57,59] Withdrawal from *Neotyphodium coenophialum*–infected pastures or ergotized grains or grasses (30 days prepartum) or prepartum treatment with D_2-dopamine receptor antagonists prevents this "fescue toxicosis"–associated decrease in maternal immunoassayable progestagen levels.[39–42] Maternal plasma progestagen levels are also reported to be lower than expected in acute conditions not directly involving the fetus, such as uterine torsion and colic.[59] Somewhat surprisingly, circulating progestagen levels in the mare are actually increased rather than decreased in cases of placentitis and other situations in which fetal well-being is compromised.[57,59]

Pregnant mares also have high concentrations of estrogens in their circulation. Beginning on approximately day 40 of gestation, the primary CL and possibly supplemen-

tary CLs, under the influence of eCG, produce large quantities of estrogens.[1,4] Fetal-placental estrogen secretion begins to increase as luteal estrogen production declines. Estrogens of fetal-placental origin increase gradually until day 200 of pregnancy and then decrease very gradually until foaling.[1,4,57,59] The high levels of estrogens in pregnant mares may result in estrous behavior, and mares previously diagnosed pregnant that are exhibiting signs of estrus should be reexamined for pregnancy prior to rebreeding or performing diagnostic techniques such as uterine culture and biopsy.[1,4]

Measurements of estrogens in mares (urine or blood) beginning between days 60 and 90 of pregnancy (timing depends on assay and laboratory) can be used to detect pregnancy and fetal viability in the mare; however, pathologic conditions appear to vary in their effect on maternal estrogen levels.[1,4,57,59] After day 150 of gestation, maternal plasma concentrations of immunoassayable estrogens less than 1000 pg/ml have been reported to be associated with placentitis, and parenteral administration of estradiol derivatives has been reported to increase fetal survival rates in these instances.[57] Maternal estrogen concentrations are frequently higher than normal in mares carrying twins but are often within the normal range in pregnancies compromised by equine herpesvirus 1 infection or severe colic.[59] The effects, if any, of ergot alkaloid exposure on immunoassayable estrogen concentrations in pregnant mares are apparently inconsistent, with both increases and no discernible effects being reported in the literature.[39,42]

Relaxin is produced in large part by the placenta during equine gestation. Circulating relaxin levels increase from approximately day 75 of pregnancy until reaching a peak level at approximately gestational day 175.[1,4,59,60] These blood levels of relaxin are essentially maintained until parturition, and there is a subsequent surge in relaxin during labor.[59] Relaxin has been used as an indicator of placental health and function, and conditions suggesting placental insufficiency such as placentitis, premature placental separation, and the placental thickening seen in "fescue toxicosis" result in decreased systemic levels of relaxin in pregnant mares.[59,60]

Parturition

Parturition constitutes transport of the fetus and its associated membranes from the maternal to the external environment. The fetal hypothalamic-pituitary-adrenal axis initiates the process of fetal maturation and the cascade of endocrine and neural events that lead to parturition in the mare; however, the specific physiologic processes are somewhat different in the mare than other animal species.[1,59] CRF stimulates the release of ACTH from the fetal pituitary, and ACTH, in turn, stimulates secretion of cortisol by the adrenal glands. Elevations in fetal cortisol (fetal LH may be involved as well) appear to modulate uterofetoplacental steroid metabolism (Fig. 7-10).[1,4] Progestagens decrease precipitously approximately 24 hours prior to parturition, and, although total estrogen concentrations decrease in the maternal circulation during late gestation, specific estrogens are thought to be locally active in the uteroplacental tissues during the initiation of equine parturition.[59] Following this change in the relative influences of progestagenic and estrogenic hormones on uteroplacental tissues, several events occur that prepare the uterus for parturition (Fig. 7-10). The cervix softens, most likely facilitated by relaxin and cervical production of PGE_2. Oxytocin receptors in the myometrium increase in number, and PGF is synthesized within the uterus. Blood flow to the gravid uterus and placenta increases, allowing for adequate fetal oxygenation and nourishment, as well as a means of supplying hormones, sources of energy, and oxygenated blood to the uterus. Neural signals caused by fetal movements and myometrial contractions are involved in a complex interaction with slightly elevated basal levels of oxytocin and increased secretion of PGF to bring about the first stage of labor.[1,4,59] There is a short period of uterine quiescence during the first stage of labor, most likely due to a surge in relaxin, which immediately precedes a rapid increase

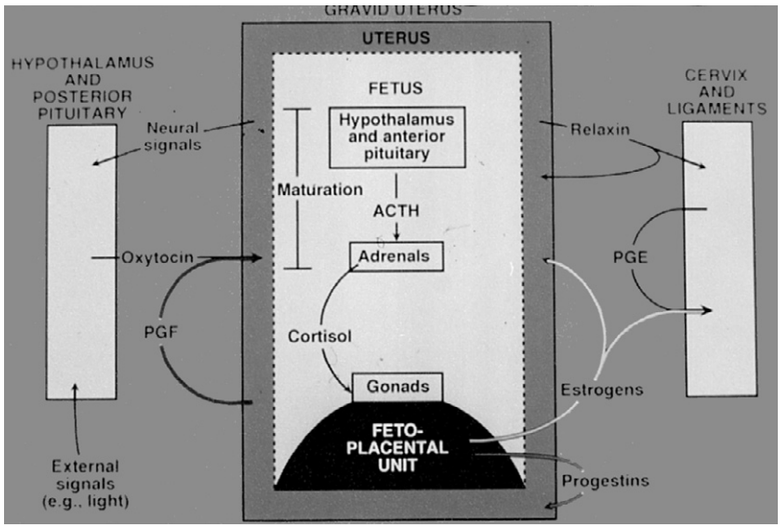

Fig. 7-10 Control of parturition. (From Ginther OJ: *Reproductive biology of the mare: Basic and applied aspects,* 2nd ed. Cross Plains, WI: Equiservices, 1992. Reprinted with permission of O.J. Ginther. Photograph courtesy of Mr. Don Connor.)

in oxytocin and PGF secretion, which leads to rupture of the allantochorionic membrane and commencement of the second stage of labor. Strong myometrial contractions result and the foal is delivered in a very short time (5–45 minutes). This myometrial activity declines after foaling but is maintained at a level sufficient to ensure expulsion of the fetal membranes (Fig. 7-10).[1,4,59,61]

The importance of the fetal hypothalamic-pituitary-adrenal axis, as well as other endocrine and neurologic pathways, in equine parturition is evident from the hormone profiles of foals, as well as mares, in a number of disease syndromes. Blood cortisol levels are decreased in premature, dysmature, and overmature (seen in "fescue toxicosis") individuals as compared to normal foals.[1,4,40,59] Decreased triiodothyronine levels in premature, dysmature, and overmature equine neonates suggest that fetal thyroid hormones may also play a role in fetal maturation and the initiation of the foaling process.[40,42] Maternal levels of prolactin, relaxin, and progestagens are all decreased in cases of "fescue toxicosis" or ergot-associated prolonged gestation, and treatment with D_2-dopamine receptor antagonists, unlike administration of rauwolfian alkaloids (e.g., reserpine), results in reversal of these endocrine trends, along with the onset of apparently normal parturitions.[41,42,62] The mare has more control over the first stage of labor than do other species, and external stimuli (such as lights and noise) can suppress oxytocin secretion and delay foaling.[1,4]

Parturition can be induced in the mare using oxytocin or a combination of prostaglandin and oxytocin. Certain criteria (duration of gestation, quality of mammary secretion, and cervical relaxation) must be met to ensure that foaling induction is safe for the both the mare and foal.[4,63] Equine parturition is a very rapid and powerful event and maternal and fetal survival depend on adequate supervision and prompt and appropriate intervention when indicated.[1,4,61]

CHAPTER 8

Clinical Aspects of Seasonality in Mares

GARY NIE, DANIEL C. SHARP, GILLIAN ROBINSON, BRIAN D. CLEAVER, and MICHAEL B. PORTER

SEASONAL REPRODUCTIVE PATTERNS

Natural selection would seem to logically favor a species delivering its offspring in a season of the year when weather conditions are optimal and food is abundant. Therefore, horses presumably developed their annual rhythm of reproductive competence and incompetence to ensure foals were born in spring and summer. This seasonal mechanism can thus be viewed as a timer of foaling rather than breeding. Breeding season appears timed to occur one gestation length prior to ideal foaling season.

Cueing to an unreliable environmental predictor of season could jeopardize species survival. It seems, then, that regulation of reproductive function in mares was selectively aligned to the most reliable, naturally occurring environmental cue available: photoperiod. It is important to appreciate reasons for seasonality and driving forces behind its development in order to realize that attempts to change the pattern of events quickly or acutely may not yield useful results. As a timer of foaling, this mechanism prepares 11 months or more in advance. Therefore, it is highly probable that a few days of some treatment or inappropriate weather is unlikely to change a course of events set in motion well before the breeding season. With these thoughts in mind, veterinary clinicians should consider the following phases of the annual reproductive cycle in mares.

Breeding (Ovulatory) Season

Equine breeding (or ovulatory) season is a time of reproductive competence occurring from mid spring through summer (Fig. 8-1). Nonpregnant mares experience numerous, repeated estrous cycles, ostensibly for the purpose of providing multiple successive opportunities to become pregnant. In other words, mares are seasonally polyestrous. Ovarian steroids (i.e., follicular estradiol and luteal progesterone) alternate dominance over the reproductive tract and sexual behavior in mares, setting suitable conditions for service, conception, and pregnancy.

Autumnal Transition

Transition from reproductive competence to incompetence occurs during autumn and is poorly understood compared with other annual reproductive phases. Its relative lack of economic importance compared to other phases undoubtedly accounts for some lack of interest in studying this phase. Cultural emphasis on breeding mares during late winter and early spring has made autumn-born foals less attractive in all but a few breeds. Consequently, mechanisms by which mares lose reproductive competence are not well understood, although inferences from what is known about other phases of the year allow some speculation. As mares transition to reproductive incompetence, exemplified by a relative lack of gonadotropin-releasing hormone (GnRH) and consequently reduced secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH), decreasing hormones likely reflect a response to diminishing day length or some other environmental cue(s) experienced earlier in the year. As a result, a repeatable pattern of ovarian steroid production, characteristic of the ovulatory season, is interrupted, setting unfavorable conditions for sexual activity and conception. Timing of autumnal transition is highly variable among mares, occurring from September to as late as November or December. Such variability may reflect a relative lack of importance of the end of the breeding season as a selection criterion for species survival. Regardless of the reason, variability makes autumnal transition difficult to study and therefore contributes to our poor understanding of its mechanisms.

Anestrus

Anestrus is a time of complete reproductive incompetence, marked by reduction in hypothalamic GnRH content[1,2] and secretion[3] with a consequent sharp reduction in LH and FSH secretion from the pituitary.[2,4] Pituitary LH content is also dramatically reduced during anestrus.[2,4] As a result of this hypothalamic-pituitary slowdown, ovaries undergo functional, if not morphologic, atrophy with only a few follicles over 5 to 10 mm observed. Lack of follicular development is echoed by virtual loss of ovarian steroids in peripheral circulation, and progesterone and estradiol become essentially undetectable.[6–8] During anestrus, mares' sexual behavior toward stallions becomes more passive. They may not object to a stallion's presence and may even permit mounting, but intromission is often prevented by holding their tail down.[9]

Vernal Transition

Springtime (or vernal) transition from anestrus into the ovulatory season is economically and scientifically important. Desire, throughout much of the equine industry, for early-born foals conflicts with innate physiologic regulation of reproductive competence. Furthermore, vernal transition is filled with ambiguous signs that disguise the underlying process, confuse breeders, and lead to low reproductive efficiency. Owing to a lack of understanding, breeders often cover mares based solely on behavioral signs of estrus and without regard for their state of reproductive competence. On the other hand, vernal transition has been shown to follow a well-regimented series of steps leading to resumption of reproductive activity (Fig. 8–2). Vernal transition is the most precisely regulated of the annual reproductive rhythms, with relatively little variation among mares in timing of their first ovulation of the year. One of the first events in vernal transition is resumption, albeit at a reduced level compared with the ovulatory season, of GnRH secretion by the hypothalamus. Examination of hypothalamic GnRH content[1,2,10] and secretion[3] indicates the GnRH neural network increases its activity shortly after winter solstice. This increased GnRH secretion appears to be maintained throughout much of vernal transition. In response to increased GnRH, FSH secretion resumes. Though speculative, apparently the gene-regulating FSH subunit synthesis remains functional during anestrus and the lack of FSH secretion reflects a lack of GnRH secretion rather than pituitary FSH content. Nevertheless, an increase in FSH secretion is temporally associated with increased GnRH.

Ovaries, quiescent until this point, respond by developing new follicles. Follicular growth pattern during vernal transition is relatively predictable, with increased size and numbers of follicles. Of major importance, the first several follicles that develop during vernal transition generally do not ovulate, although they may reach normal preovulatory size (>30 mm). This is one of the major events contributing to reproductive inefficiency during vernal transition, as it is difficult to know whether a given follicle is competent and will ovulate. After several (3.7 ± 0.9) of these transition follicles develop and regress without ovulating, a competent follicle develops.[8] Although it is not yet known what factors contribute to eventual development of the first competent follicle, it is clear that this follicle, destined to be the first ovulatory follicle of the year, is reasonably steroidogenically competent. Development of the first ovulatory follicle is accompanied by a surge of estradiol in peripheral plasma followed a few days later by a surge in LH. The first ovulation of the year follows, ending vernal transition.

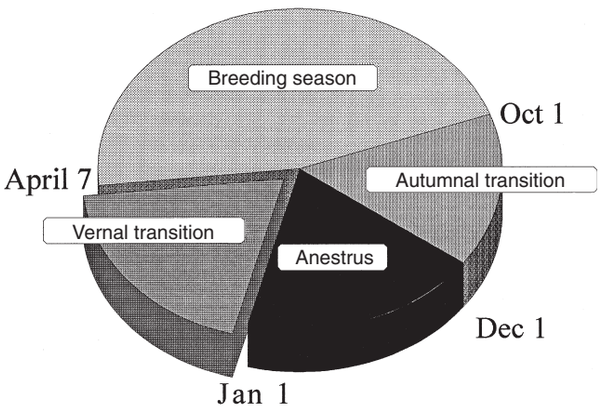

Fig. 8-1 Phases of the annual reproductive rhythm in mares. Vernal transition is emphasized because of its scientific and economic importance.

Events of Vernal Transition

1. Photoperiod response
2. Increased GnRH secretion
3. Increased FSH secretion
4. Initiation of follicular development
5. Little LH secretion = High FSH:LH ratio
6. Abnormal follicles, do not ovulate
7. Follicles do not secrete estrogen
8. Normal follicle develops
9. LH gene activated; LH secreted
10. Ovulation occurs

Fig. 8-2 Events characterizing vernal transition in mares. These events appear to be serially linked and are likely causal.

CLINICAL ASPECTS OF SEASONALITY

Challenges Seasonality Presents to Breeders and Veterinarians

A circannual rhythm in mares entrained by environmental cues ensures foaling during spring and summer. However, many breed associations observe January 1 as the official birth date of foals (in order to be eligible for registration in their respective association) born in the same calendar year. Therefore, seasonality in mares presents breeders and veterinarians with a major challenge to produce foals early. Though other environmental factors may also exert some influence on the annual reproductive rhythm in mares,[11–20] photoperiod is widely accepted as the driving force.[21] Increased photoperiod has long been recognized as a means of returning seasonally anestrous mares to reproductive competence sooner than would occur with natural day length.[22] However, increasing day length with artificial light does not shorten transition but merely causes it to begin earlier in the year.[23] Whether transition is brought about by natural or artificial light, it is a lengthy process lasting 6 to 12 weeks or more and there is considerable variation in interval from start of treatment to first ovulation among mares.[24,25] Horse breeders would benefit from a treatment or management protocol that would not only shift the beginning of the ovulatory season to a point earlier in the year but would also shorten the length of vernal transition.

Though mares in vernal transition proceed through a regimented series of steps leading to resumption of reproductive activity (Fig. 8-2), ambiguous signs characteristic of the phase are difficult to interpret and present considerable challenges for breeders and veterinarians managing transitional mares. Unknowledgeable breeders often equate behavioral signs of estrus with the ovulatory season and cover mares repeatedly during irregular and often lengthy periods of sexual receptivity. Even when follicular growth and development are monitored with behavior, difficulty in predicting the first ovulation of the year can further contribute to low reproductive efficiency.

Photostimulation of Reproductive Resurgence

In 1947, Burkhardt was the first to report early breeding of mares after doubling their daylength by adding artificial light.[22] Since then, a variety of photoexposure regimens have been used in mares to stimulate an early return to reproductive competence.[26–28] Traditionally, horse breeders exposed mares to a 16-hour fixed-length photoperiod throughout transition using a combination of natural and artificial light. Although very effective, such a long photoperiod can involve considerable expense and inconvenience. Other options available today may help breeders reduce overall expense and inconvenience of their photostimulation program. Extending natural day length with as little as 2 to 3 hours of additional artificial light was sufficient to accelerate onset of the ovulatory season.[21,24] Of interest, adding light prior to sunrise was completely ineffective, whereas adding light at sunset, thus extending the day, was very effective.[21,24] Guidelines for providing artificial light in a box stall or paddock setting have been reported.[21,29] Another effective method of providing photostimulation is the so-called "night-interruption" or "pulse lighting" approach.[30] Artificial light is applied for 1 to 2 hours during a photosensitive phase 9.5 hours after the beginning of darkness. The disadvantage of this approach is that "pulse" timing must be adjusted to changing onset of darkness or onset of darkness must be controlled artificially.[25]

Timing the start of a photostimulation program is important to effectively shift transition. Ideally mares enter the ovulatory season 1 or more cycles before intended breeding, thus eliminating the need to predict the first of ovulation and allowing ample opportunity to evaluate and prepare, if necessary, their uteri for conception and pregnancy. To effectively gain an advantage over natural photoperiod, artificial light should begin no later than winter solstice.[30] However, an even greater advantage may be possible when artificial light is applied as soon as 5 to 7 weeks before winter solstice.[24,29] One author's (GJN) clinical experience supports that assertion. Breeders waiting until January to expose their mares to increased day length will not realize any advantage over exposing them to natural photoperiod.[24,31] Traditionally it was recommended that artificial lights be continued until late spring,[28] presumably until natural day length was sufficiently long to prevent an abrupt differential in photostimulation that potentially could interfere with cyclic activity. However, it was recently reported that 14.5 hours of light applied for only 35 days beginning at winter solstice was sufficient to advance the ovulatory season.[28] The mares reached their first ovulation in a similar time as other mares exposed to an extended daily photoperiod throughout the winter and spring. Further, they remained reproductively active after artificial light was discontinued even though natural day length at the time was considerably shorter than the artificial photoperiod.

Dating back to the first report of photostimulation in mares, traditionally a 100 W incandescent light bulb, providing luminal intensity of 10 to 12 foot-candles (approximately 100 lux), has been recommended for use in a 12 × 12 box stall to stimulate onset of reproductive activity.[22,29] However, studies have investigated light intensities down to 10 lux (approximately 1 foot-candle).[21] One report indicated that light intensity of only 10 lux, when applied daily, for 14.5 hours, throughout the winter and spring, was sufficient to advance the onset of reproductive activity.[28] Little work has been done to determine the optimal spectral wavelength of light used for photostimulation in mares. Nevertheless, recognizing the eye as the primary photo receptor and maximal photochemical sensitivity being in the midrange (approximately 550 nm), it was suggested that light sources with emission ranges that include the midrange will work.[21]

Equine FSH and Pituitary Extracts

Crude equine pituitary extracts (EPE) containing eFSH and eLH have been used to stimulate follicular development and ovulation in seasonally anestrous and transitional mares.[32–34] However, EPE is not available commercially. Recently, though, a purified eFSH was used to stimulate follicular development and ovulation in transitional mares.[35] Ovulations occurred in eFSH-treated mares nearly a month earlier than control mares.

Gonadotropin-Releasing Hormone

As GnRH deficiency in mares appears to be a primary cause of reduced reproductive function during anestrus, it seems logical to administer the releasing hormone in an effort to reverse reproductive collapse. Although several studies have reported inducing ovulation in seasonally anestrous mares treated with GnRH or its analogues,[36] a number of factors limit its clinical use including cost of treatment and questions that remain regarding its preferred mode of administration (i.e., dose, frequency, route, and duration). Protocols have typically required 2 to 3 weeks of GnRH administration to induce ovulation, although a recent study induced ovulation in transitional mares with a shorter duration of treatment by repeatedly administering a slow-release subcutaneous implant containing a GnRH analogue, deslorelin.[37]

Estrogen

The positive effect of estradiol administration on LH concentrations has raised some interest and may prove to be a useful tool. However, there is an important caveat

to the use of estrogen. Although estrogen has been shown to stimulate LH secretion[4] during early vernal transition, it was demonstrated that exposure to a stimulatory photoperiod is essential for this effect.[38] Therefore, breeders who administer estrogen during anestrus or very early vernal transition might not realize any benefit from the treatment. Furthermore, estrogen treatment inhibits FSH secretion, resulting in lack of follicular development, a result contrary to resumption of the ovulatory season.

Progestins

Conflicting reports exist about the usefulness of progestins in anestrous mares. Some authors report hastening the onset of ovulation in noncyclic mares,[39,40] but others were not able to demonstrate this effect.[41–44] It appears a satisfactory response may require several conditions be met in mares selected for treatment, such as being in mid to late transition (which suggests prior photostimulation either with natural or artificial light), having considerable follicular development (i.e., multiple follicles >20 mm in diameter), and displaying estrus for 10 or more consecutive days.[39] Progestins have also been combined with estradiol 17-β; however, the suppressive effects of estradiol on follicular development delayed onset of ovulation following treatment.[45] Therefore, the combined steroid treatment did not offer an advantage over progestins alone. The results of one study suggested progestins may best be used to synchronize the first ovulation rather than hasten its onset.[41] In that case, if waiting until a mare ovulates for the first time to begin breeding management is not acceptable, breeders and veterinarians might best utilize progestins to synchronize the first ovulation and reduce the error in predicting its onset. Protocols typically call for administration of progestins for 12 to 15 days with ovulation coming within 12 to 15 days following treatment.

Dopamine Antagonists

Considerable work has recently been reported on the use of dopamine D_2-antagonists in anestrous and transitional mares. The role dopamine plays in seasonal reproductive activity and the level at which it exerts its influence are still unclear.[25] Nevertheless, several studies have demonstrated a shortened time to onset of reproductive activity in mares treated with dopamine antagonists.

In one study, seasonally anovulatory mares exposed only to natural photoperiod and treated with 1 mg/kg of sulpiride IM daily, beginning on January 30, experienced a shortened interval to their first ovulation than did untreated control mares.[46] In a second study the same workers reported treating seasonally anovulatory mares with 200 mg of sulpiride IM daily, beginning on February 5. While being exposed to a natural photoperiod, sulpiride-treated mares again experienced their first ovulation of the year earlier than control mares.[47] When domperidone was administered orally to seasonally anovulatory mares maintained under natural photoperiod at 1.1 mg/kg, they too experienced a shortened interval to their first ovulation of the year than did control mares.[48] It appears from these reports that dopamine antagonists can shorten the interval to the onset of the ovulatory season even when mares are maintained only under natural photoperiod. However, the average interval from the start of treatment until ovulation ranged from 51 to 85 days among the studies.[46–48] Additional findings indicate that prior photostimulation may improve results seen with sulpiride treatment. When mares were exposed to extended day length (14.5 hours of light and 9.5 hours of darkness) beginning on January 10 and were treated with 1 mg/kg of sulpiride IM, twice a day beginning on January 23, the mean interval to their first ovulation was 39.5 days from the start of photostimulation.[49] The interval to ovulation was shorter for sulpiride-treated mares than for their matched control mares. It is also noteworthy that the overall treatment interval required to achieve ovulation in sulpiride-treated mares exposed to an extended photoperiod was considerably shorter than had been reported in the previously mentioned studies in which mares were maintained under natural photoperiod.[46–49] In addition to extended photostimulation it also appears temperature and other environmental factors may affect the results of sulpiride treatment. Mares housed indoors and exposed to extended day length (16 hours of light and 8 hours of darkness) were treated with 0.5 mg/kg of sulpiride IM, twice a day beginning on January 18. Average interval to the first ovulation in sulpiride-treated mares was 14.8 days. The interval was shorter than that for untreated mares maintained indoors under the same photoperiod as well as that for untreated mares maintained outdoors under natural photoperiod.[50] It appears that dopamine antagonists may be most effectively employed to shorten the interval to the first ovulation of the year, when used in combination with photostimulation and moderate temperatures. It seems possible, then, to stimulate the onset of the ovulatory season in the majority of mares by mid-February even when artificial lights are not started until January.[49]

Although the body of work suggests dopamine antagonists may hasten the onset of cyclic ovarian activity in transitional mares, the mechanism is still unclear. Dopamine antagonists have been shown to cause increased endogenous prolactin concentrations in treated mares;[47,51–53] however, their reported effect on gonadotropins in horses is inconclusive.[46–48,50,53] Therefore, it is still unknown whether dopamine influences seasonal reproductive activity in mares through an inhibitory effect at the hypothalamic level or dopamine antagonists increase ovarian responsiveness to available gonadotropins through a prolactin-induced increase in FSH or LH receptors.[25]

CONCLUSIONS

Even though seasonality in mares is the result of a complex endogenous rhythm of neuroendocrine controls entrained by one or more environmental cues, we chose to limit our review to the clinical aspects of seasonality. Readers are referred to the previous edition of this text for a more in-depth review of the neuroendocrine control of seasonality in mares.[54]

The most practical tool for regulating the annual reproductive rhythm of mares remains photoperiod. It is relatively inexpensive and easy to administer. A variety of treatment regimens appear to be effective, allowing breeders choices that fit their own management schemes. Recent work suggests that combining photostimulation with dopamine antagonists may greatly reduce the interval required to stimulate the onset of the ovulatory season.

It seems clear that horses, having evolved in a temperate climate, developed a systematic, predictable schedule for mating to ensure that foaling would occur when survival of the foal was most likely. It is important to remember that the mechanisms regulating the annual reproductive rhythm had to be predictive of events one gestation length in the future. There would have been little selection advantage for regulation of the time of mating, except for its consequence. Therefore, it must be appreciated that the annual reproductive rhythm in mares is a long-term process, guided by reliable environmental conditions in a manner not yet fully understood. Attempts to alter the course of this annual rhythm must be based on a sound understanding of the underlying principles. Although several treatment regimens have shown promise in this regard, expectations of immediate response to treatments must be tempered by knowledge that the system is designed to move slowly in response to events past and in anticipation of events in the future.

CHAPTER 9

Clinical Examination of the Nonpregnant Equine Female Reproductive Tract

CARLA L. CARLETON

COMPONENTS OF THE EXAMINATION

History

It is essential that a thorough reproductive history be taken before a physical examination of a mare's genital tract is performed. Infertility may be the result of a previous reproductive event, such as uterine infection, dystocia, or perineal trauma, or an anatomic deficiency such as poor vulvar conformation. The history should include the number of foals the mare has produced, the years in which she has been bred, and abnormalities at parturition such as dystocia, stillbirth, or retained fetal membranes. If there is a history of retained fetal membranes, how was it resolved (oxytocin or traction, intrauterine therapy)? Is there evidence of early embryonic death, twinning or reduction of twins, or abortion? If the mare has aborted, was the cause determined (twinning, infectious agents, age, etc.)? Could abortion be related to endometrial fibrosis? It is also helpful to collect information regarding the mare's reproductive behavior and the incidence, frequency, and duration of behavioral estrus throughout the physiologic breeding season.

External Evaluation

External evaluation of mares should begin with an examination of the mammae: their size, a comparison of the halves, and the gross appearance of the teats. Attempts should be made to determine whether their appearance can be explained by the age, parity, and lactational status of the mare. Abnormalities of the perineum, including integrity of the anal sphincter and vulvar conformation, can predispose mares to aspiration of air and feces into the genital tract.[1] An assessment of vulvar conformation should include the relationship of the dorsal vulvar commissure to the pubis, the adequacy of the seal formed by the vulvar labia, and the angle of the vulva (Fig. 9-1). A wind-sucking test performed by gently parting the labia and listening for the sound of air rushing into the vagina can identify mares that would benefit from Caslick's vulvoplasty.[1] The examination must evaluate the ability of the three anatomic barriers (vulvar labia, vestibular sphincter, and cervix) to protect the uterus from the external environment and ascending infections. If a mare has foaled previously, an abnormality of the perineum may be evidence of trauma during parturition. Such mares are candidates for detailed vaginal examination to determine whether there is additional internal damage such as rectovaginal fistulae or lacerations of the vagina or cervix. The examiner should record the general appearance of the patient, taking note of body condition and conformation. If a mare has a very flat croup, she may have correspondingly poor vulvar conformation. The normal female phenotype may be altered by certain conditions such as X-chromosome monosomy, chronic use of anabolic steroids, and hermaphroditism.[2–6] If the mare is a maiden, it is important to conduct a vaginal exploration prior to first cover.

Internal Evaluation

The initial evaluation of a mare's genital tract requires a number of examination modalities, the most important of which is a skilled transrectal palpation (TRP) of the ovaries, uterine horns and body, and cervix. Ultrasonography cannot replace competent TRP, but can add information and clarify palpation findings. Manual evaluation of the cervix is an important component of a thorough vaginal examination. Digital palpation of the vagina and cervix provides detailed information on subtle changes within the vaginal vault and permits the most complete assessment of abnormalities of the external cervical os and the cervical lumen. If reproductive failure due to a cervical laceration is suspected, the examination is best conducted during diestrus when the cervix is normally closed owing to the influence of progesterone. A digital examination allows assessment of the ability of the cervix to close and protect the uterus from the external environment. An examination using a vaginal speculum may help identify tears, hematomas, abscesses, and urine pooling.

Invasive examinations of the uterus should never be undertaken before TRP, and in some cases ultrasonography of the tract has been conducted to ensure that the mare is not pregnant. Once it has been established that a mare is not pregnant, vaginal procedures can be accomplished without regard to the stage of the estrous cycle. Care should always be given to placement of a tail wrap and tail tie and thorough cleansing of the mare's anal sphincter, vulva, and perineum to minimize the potential risk of introducing contaminants.

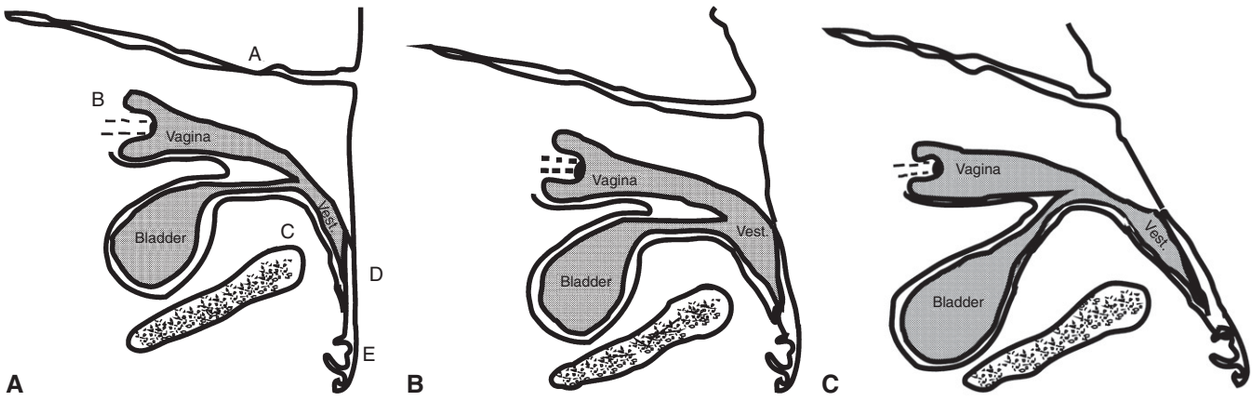

Fig. 9-1 Evaluation of vulvar conformation. Assessment includes the adequacy of the seal of the vulvae, the relation of the dorsal vulvar commissure to the pelvic floor (above, even with, or below), and the degree of forward tipping of the vulvae. The degree of tipping ranges from vertical *(Good, far left)* to an increasingly cranial slant *(Fair, middle; Poor, far right)*. Conformation changes are attributable to increasing parity, loss of vaginal fat, age-related or injury-related changes, and genetics (mother–daughter). A, rectum; B, external cervical os, C, pubis; D, vulvae; E, clitoris.

Additional means of identifying abnormalities in infertile mares are uterine cultures to determine the microbiologic status of the uterine lumen, endometrial cytologic examination to establish the presence of inflammatory cells, endometrial biopsy to detect histologic changes that could inhibit the mare's ability to sustain a fetus to term, and uterine endoscopy to identify gross lesions within the uterine lumen that might prevent conception or interfere with pregnancy maintenance. The incidence of oviductal disease is very low in mares when compared with other domestic species, such as the cow.[7] Although there have been some interesting reports that attach significance to collection of material within the uterine tubes or to inflammation of the uterine tubes, lesions of the oviducts do not appear to be common causes of reproductive failure in mares.[8,9]

Effect of Season

The reproductive activity of both mares and stallions is driven primarily by day length[10–12] and to a much lesser extent by ambient temperature. In normal mares, seasonal and environmental changes are reflected in the findings during TRP. During winter anestrus the ovaries become inactive. The weight of ovarian stroma decreases and ovarian dimensions diminish.[13] This normal change should not be mistaken for a congenital abnormality, but viewed within the context of the season. Ovarian development is a reflection of the activity, or lack thereof, of the hypothalamus and the pituitary gland. Ovarian activity (contrast inactive with the presence of follicles and corpora lutea) affects the balance of the genital tract, and in the absence of progesterone, uterine tone is poor (flaccid) and the cervix relaxed. With the coming of spring, day length increases, pineal gland suppression wanes, and activity of the hypothalamus and the anterior pituitary gland increases.[10–12,14] With consistent photostimulation (increasing day length), the size and activity of the ovaries increase dramatically.[13]

During spring (vernal) transition, there is significant follicular growth, both in size and number.[15] Transition occurs between winter anestrus and the ovulatory season (vernal transition) and again between the end of the ovulatory season and anestrus (autumnal transition).[16]

TRANSRECTAL PALPATION AND THE INTERRELATIONSHIPS OF SEASON, OVARIAN ACTIVITY, UTERINE TONE, AND CERVICAL RELAXATION

Transrectal palpation of the ovaries, uterine horns and body, and cervix is the most important skill needed by practitioners striving for success in equine reproduction. Initial evaluation of every mare must include a detailed evaluation of all components of the genital tract. Absence of a structure may suggest a congenital anomaly or may be the result of a surgical procedure (e.g., ovariectomy). After all structures of the genital tract have been identified, an understanding of their relationship to each other is essential. The examiner should establish whether ovarian activity coincides with the mare's behavior, that is, the relationship between follicular or luteal phase structures and teasing response. The correlation between uterine tone and the degree of relaxation of the cervix is also key in establishing whether a mare is reproductively normal. No portion of the genital tract can be evaluated without regard to its relationship to the whole. All recorded findings should be relayed to the client to help her or him decide on further management of the mare.

The nonpregnant uterus is T- or Y-shaped. The uterine horns approximate the cross-bar or the V of the letters. The uterine horns and ovaries are suspended by the broad ligaments (mesometrium and mesovarium) between the tuber coxae. The ovaries usually lie lateral and slightly ventral to the tips of the uterine horns. The ovaries are moveable within a range of 2 to 5 cm from the cranial border of the broad ligament and, by virtue of the mare's

motions or during palpation, may be brought to lie dorsal and medial to the broad ligament.

After fecal material has been removed and adequate rectal relaxation has been achieved, the examiner can identify the uterine bifurcation by inserting the arm approximately 30 to 40 cm beyond the cranial brim of the pelvis (generally at or slightly beyond elbow depth). With the fingers close together and slightly cupped, the arm is swept downward toward the prepubic tendon (belly wall). By bending the elbow and flexing the wrist, the examiner can lift up the uterine horns and cradle them with this gentle scooping motion. The horns are cradled within the arc formed by the thumb and fingers. Continuing further laterally, the ovaries can be individually isolated and fully palpated between a thumb and fingers. The risk to the examiner and the mare should always be kept in mind. A complete examination is frequently the result of incremental palpation. If the uterine horn findings have been recorded and a peristaltic wave is bearing down on the hand, it is better to retreat, as necessary, and continue from that point. The time lost by careful, but cautious, palpation is insignificant when compared with the value of the mare or the safety and liability of the veterinarian.

Ovarian Palpation

Structures that can routinely be palpated are follicles, ovulation depressions (OVD), corpora hemorrhagica (CH) for up to 5 to 6 days after ovulation (after which time they mature into functional corpora lutea and most are not palpable), and parovarian cysts.[17–20] During *winter anestrus* the ovaries are small and inactive, there is an absence of follicles, and ultrasonographically the ovarian stroma appears uniform and completely unremarkable. With the onset of *spring transition,* follicular activity begins. The size and number of follicles can be highly variable during this period.[21] Transition is associated with persistent follicles, which usually exhibit a slow rate of growth. Transitional follicles are anovulatory and their size and number can wax and wane.[15,21] Unlike cystic ovarian disease in cows, which is a degenerative condition, persistent follicles in mares are normal structures associated with season. Transition ends with the first ovulation and an increase in serum progesterone.[22,23] For the duration of the physiologic breeding season, mares experience an approximate 21-day cycle from one ovulation to the next.[24,25] During the physiologic breeding season, follicles are produced in waves approximately every 10 days. Generally behavioral estrus is exhibited when serum progesterone concentrations fall below 1 ng/ml and is accompanied by a dominant follicle that increases in size at a rate of 5 to 6 mm per day until ovulation.[14,26,27]

All ovulations in mares occur through the ovulation fossa; thus, developing follicles increase not only in width but also in depth as they extend through the ovarian stroma and encroach on the ovulation fossa (Fig. 9-2).[28] Measurements of follicles recorded during an ultrasonographic examination may be larger if depth is measured rather than width. Thus, consistency in records will be achieved if measurements of dominant follicle size represent the width of the follicles, not their depth.[27] Not all follicles soften prior to ovulation. As a follicle nears ovulation, it is possible to feel an irregular ridge around the perimeter of the ovulatory follicle where the ovarian stroma meets the edge of the follicle (Fig. 9-3, *D*).[19] The ultrasonographic appearance of follicular fluid is uniformly black (see Fig. 9-2, *G*).[29]

Immediately after ovulation, the distinct cavity of an OVD can be palpated (see Fig. 9-3, *E*). Although not apparent in all mares, even in mares palpated at 6-hour intervals, when an OVD is detected, its roughened perimeter is palpable level with the ovarian surface, and its deepest point extends through the ovary to the ovulation fossa. In some instances, an OVD may be delineated as long as 18 hours, but in other cases blood fills the space (CH) much more quickly. It is possible to distinguish many follicles from CH during TRP by the angle formed between the edge of the follicle or the CH and the ovarian stroma. Except for some follicles that develop at the extreme poles of the ovaries, the palpable angle between a follicle and the ovarian stroma is approximately 90 to 100 degrees.[19,27] In contrast, the angle between a CH and the stroma is much wider, 100 to 120 degrees (a CH is flatter than a follicle; see Fig. 9-3, *D* and *F*). CH also tend to be smaller than the follicle that preceded them.[3] A CH feels softer and more fluctuant than the surrounding ovarian stroma during the first 1 to 2 days after ovulation. Ultrasonographically, the CH contains echogenic particles that result from blood filling the former follicular space. As the blood clots and organizes, its ultrasonographic appearance becomes more hyperechoic and, over the span of 2 to 4 days, more uniform.[29] Although a mature CL cannot be palpated, it can consistently be distinguished by its uniform gray (more echogenic than the ovarian stroma) appearance during ultrasonographic examination (see Fig. 9-2, *K*).[19,29]

Parovarian cysts are embryologic remnants of the wolffian duct system.[3] Their only significance is that they may be confused with follicles by the novice examiner. A careful transrectal examination can more specifically identify the location of these fluid-filled structures to be only "in the vicinity of ovaries," that is, parovarian. The size of parovarian cysts increases either not at all or very slowly. They can range in size from a few millimeters to that of a modest-sized follicle.

Uterine Palpation

To demonstrate the relationship between ovarian activity and its effect on the uterus, it is necessary first to establish descriptive, user-friendly definitions. For this discussion, the definitions describing uterine tone reflect the tubularity of the uterine horns and the response of the uterine horns to slight digital pressure during TRP. The intent is to avoid the variety of numerical ranges used to define tone, as well as "food pathology" descriptions to describe the genital tract, for example, meaty, liver-like, spongy, and so on. This discussion will be based on the following definitions to follow uterine tone throughout the estrous cycle. The descriptive nature of the definitions should aid in their use and in the interpretation of TRP findings.

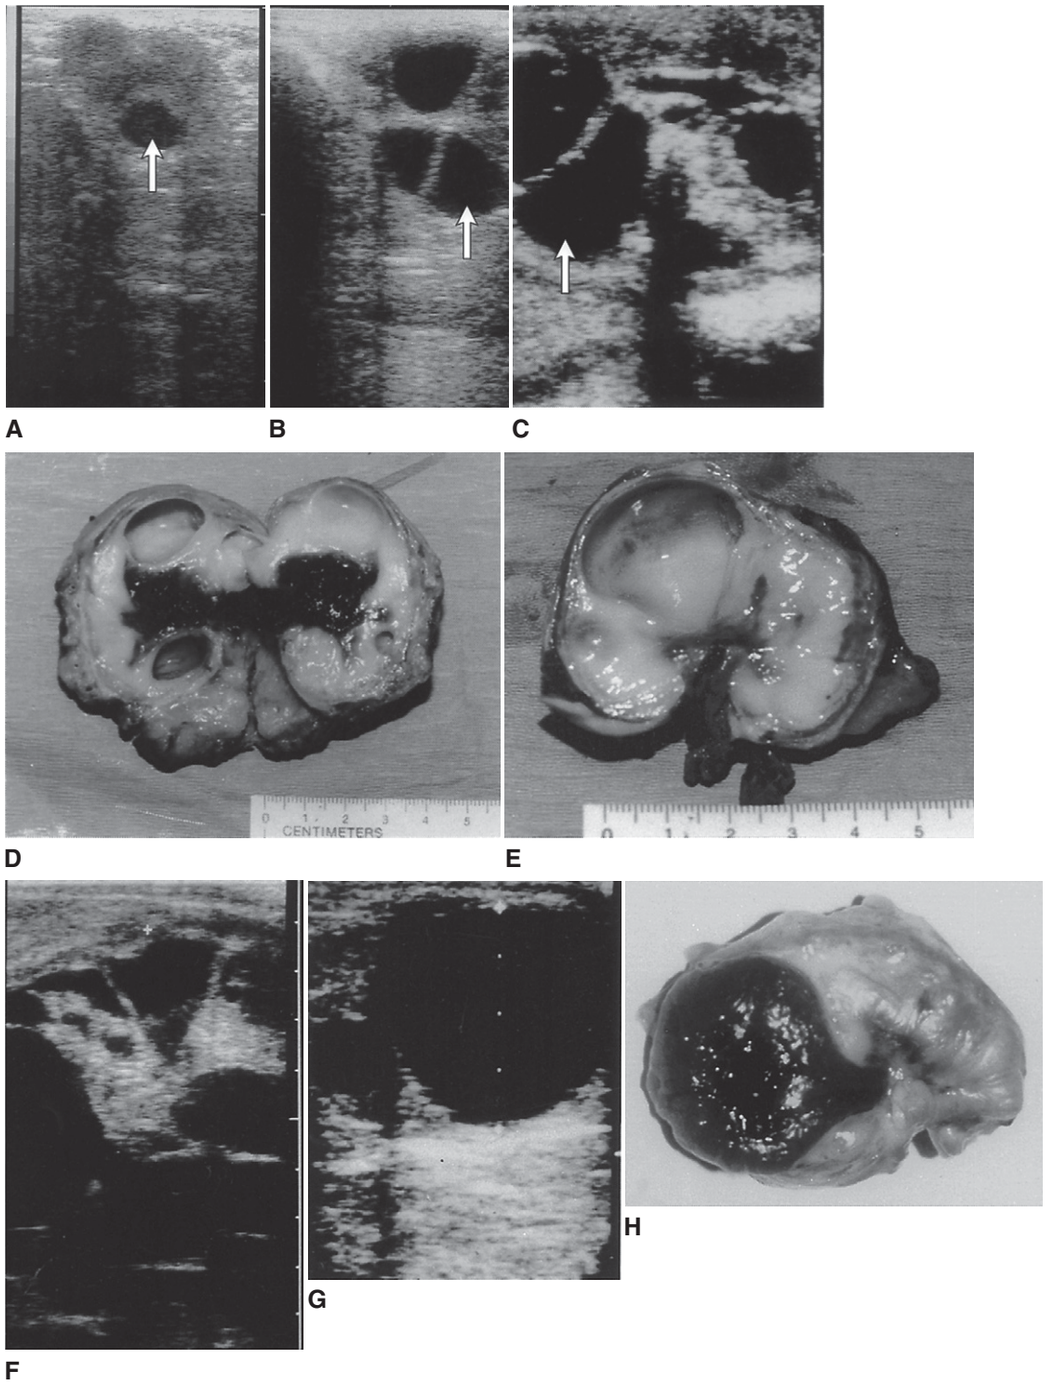

Fig. 9-2 Ultrasonographic (**A** to **C**), and cross-sectional **(D)** views of the progression of follicular development. **A** is view of a small follicle, and **D** is of a small follicle and regressing corpus luteum. The "point" of the developing follicle encroaches upon the ovulation fossa as it nears the time of ovulation. Depending on the orientation of the transducer to the ovary, this point is not always apparent during an ultrasonographic examination (**B** and **C**). **E** to **K,** Distinguishing characteristics, which can be identified in the periovulatory period, between follicles and corpora hemorrhagica: cross-sectional (**E** and **H**) and ultrasonographic (**F, G,** and **I** to **K**) views. The tonicity (firm to very soft) of ovulatory follicles and CH can be similar (**F** and **G,** large follicles; **I,** early CH). Note that **K** was a double ovulation. *Continued*.

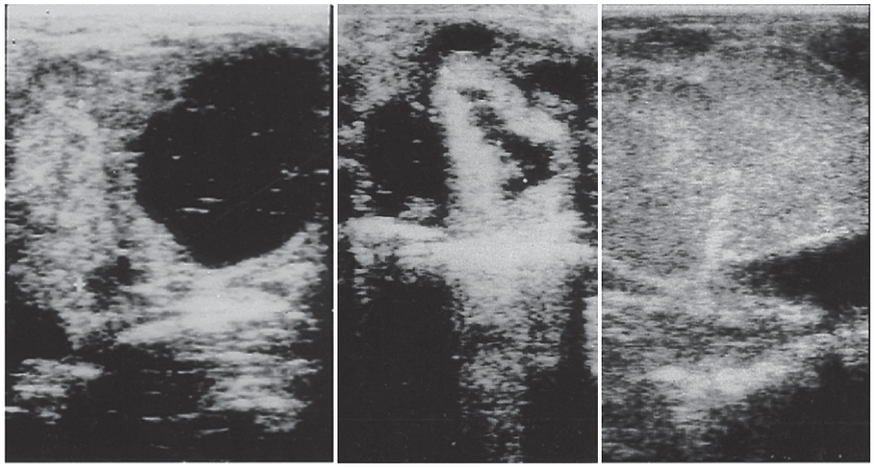

I J K

Fig. 9-2, cont'd **I** to **K** show the progression of luteal development postovulation: **I** recent ovulation; **J,** partial luteal development; **K,** mature corpora lutea.

Excellent tone (ET): Upon palpation, the uterine horns are found to be distinctly tubular. Gentle digital indentation of the cranial ventral border of the uterine horns is met with resistance. The uterine horns feel similar to a rubber hose. ET would accurately describe the uterine tone expected in a heifer during estrus. ET in mares occurs first during early pregnancy (16–20 days of gestation) and occasionally during the first week postpartum (a reflection of optimal uterine involution). As pregnancy continues, the tone of the uterine wall immediately around the conceptus begins to decrease as the amount of fluid increases. ET may persist until 40 to 45 days from the middle to the tip of the nongravid horn.

Good tone (GT): The uterine horns are still distinctly tubular during palpation, but indentation is possible. The area of indentation readily springs back.

Fair tone (FT): The uterine horns are still tubular during palpation, but digital pressure as described above leaves an indentation that remains for variable short periods. The sensation of fair tone is similar to that of pitting edema.

Poor tone (PT): The uterine horns are not tubular, but instead flattened. On initial palpation they are found to be flaccid or atonic.

As a clinician becomes more familiar with this system, intermediate grades of uterine tone can be further defined:

Good to excellent tone (GET): Tubular and very firm, can be indented, but the indentation springs back immediately under the finger.

Fair to good tone (FGT): Tubular, springs back, but more slowly.

Fair to poor tone (FPT): The uterine horns appear initially to be tubular, but with the slightest pressure, they flatten out.

The abbreviations of tone in this sliding scale are as follows (greatest to least tone): ET-GET-GT-FGT-FT-FPT-PT.

Separate notations of tone are made for the left and right uterine horns if they differ by as much as a half grade, and separate values are recorded for diameters of the uterine horns if they differ by more than 5 mm. Individual mares may exhibit either good or fair tone during diestrus, and as they enter estrus, uterine tone begins to decrease. Typically, uterine tone decreases one grade by the time the mare ovulates. The uterus exhibiting good tone during diestrus will decrease to fair tone by late estrus. The uterus with fair tone during diestrus will decrease to poor tone near the time of ovulation. Following ovulation, uterine tone increases by one grade and returns to its former diestrual tone. In a decade of experience with 300 mares, individual mares during the physiologic breeding season tended to maintain similar "highs" and "lows" of uterine tone (GT ↔ FT, or FT ↔ PT) from one year to the next (C.L. Carleton, unpublished observations). As in any population there will be a few mares in which tone alterations between estrus and diestrus are less than one grade. Uterine horn diameter represents the average of approximately four sites between the tip (smallest diameter) and base (largest diameter) of each horn (Fig. 9-4). With practice this determination is quickly accomplished and becomes second nature for the examiner. This degree of detail can be especially useful in monitoring uterine involution in the first 8 to 30 days post partum.

Palpation of the Cervix

The dynamic capabilities of the cervix are quite extraordinary. Its proportions are influenced primarily by the presence (luteal phase) or absence (follicular phase) of progesterone. The cervix closes under the influence of progesterone.[14,17] It relaxes, to a variable degree, during the estrous cycle when serum progesterone is low, by becoming shorter and wider from the beginning of estrus up until the time of ovulation, after which time it again closes. In contrast with the cow, in which the cervix is always palpable, the palpable characteristics of the equine cervix can vary from tightly closed and easily identifiable to not palpable, if it is completely (100%) relaxed.[17,18] Consistent and accurate palpation of the cervix is the most difficult part to master of TRP of the genital tract, but persistence is worth while. To maximize accuracy of the description, cervical palpation is best left until the

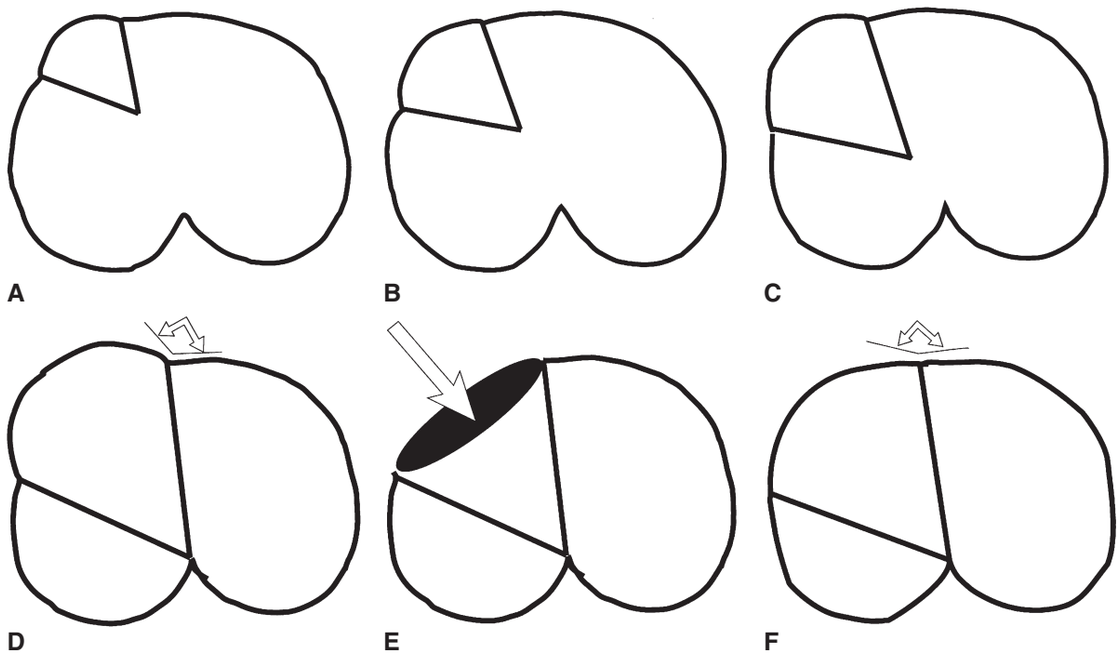

Fig. 9-3 **A** to **C,** Schematic showing the progression of follicular development. **D** to **F,** Schematic of the distinguishing characteristics, which can be identified in the periovulatory period, between follicles and corpora hemorrhagica (CH). CH are usually smaller and flatter **(F)** that the follicles that preceded them **(D)**. There is a more acute angle from the stroma onto a follicle **(D)** than onto a CH **(F)**.

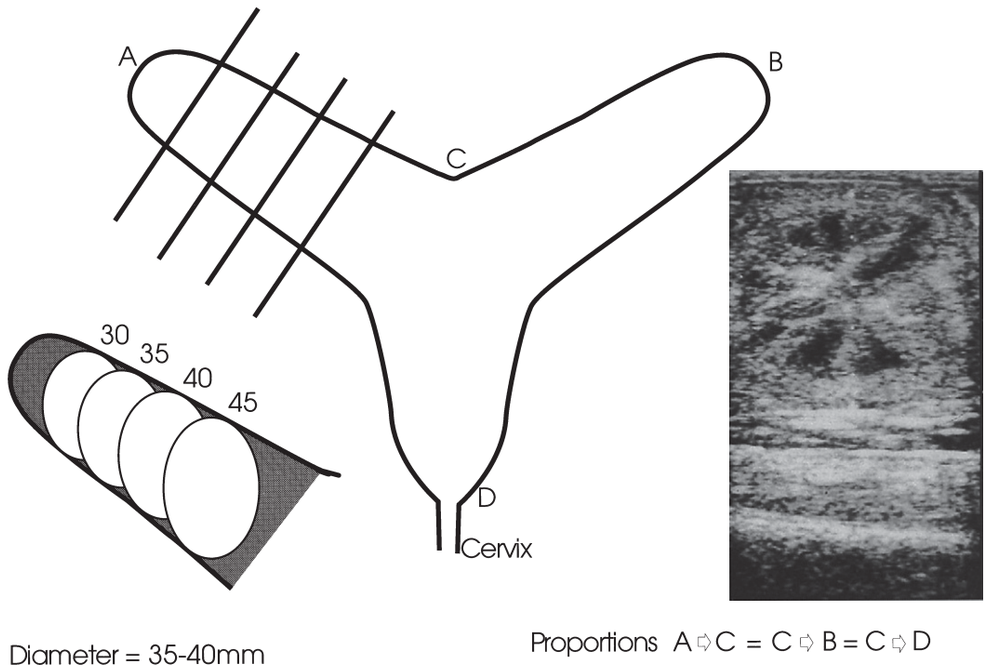

Fig. 9-4 Transrectal palpation of the uterus to establish uterine horn size (diameter). The relationship between the length of the uterine horn (A → C or C → B) and the length of the uterine body (C → D) is used as a guide to locate and facilitate palpation of the cervix. The ultrasonographic appearance of the edematous endometrial folds during estrus has been described as "orange slices" or a "wagon wheel".

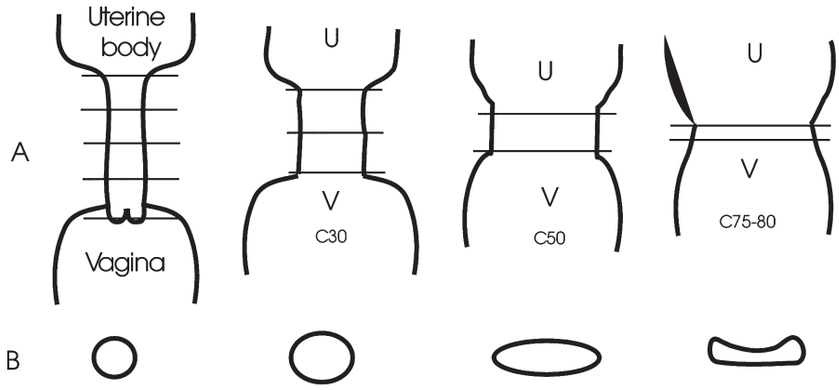

Fig. 9-5 The parameters by which assessment of cervical proportions and percent relaxation are determined (C30 = 30% relaxation). **A,** The proportion of cervical length to width; **B,** tubularity of the cervix in relation to its length:width ratio, in cross section.

Table **9-1**

Sample Transrectal Palpation Record of a Broodmare

*Follicle (F) and corpus hemorrhagicum (CH) size given in mm.
†If records from prior seasons are available, only these palpations are essential.

end of a detailed genital examination. If the palpator has adequately described the ovarian findings and defined the diameter and approximate length of the uterine horns, then the location of the internal cervical os can readily be anticipated. The length of a uterine horn (tip to bifurcation) is approximately equal to the length of the uterine body (the distance from the bifurcation of the uterine horns to the internal cervical os) (see Fig. 9-4). As the examiner's hand is being withdrawn near the completion of a TRP, the caudal extent of the uterine body can be identified. By gently pinning of the uterine body under the outspread fingers and palm, the internal os of the cervix can be identified. There is a subtle inward coning at the transition of the uterine body to the internal os of the cervix (see Fig. 9-4). Except when the cervix is completely relaxed, the external cervical os can be identified transrectally. Using relative proportions of length to width, the closed cervix is described as having a ratio of 4:1. In the author's records, cervical relaxation is routinely recorded in increments of 10% (C.L. Carleton, unpublished observations). Full definition of the cervix requires assessment of three factors: length, width, and tubularity (Fig. 9-5). This combination provides a quick and reasonable means of assessing the degree of cervical relaxation. The percent of relaxation of the cervix is related to the structures on the ovaries. The cervix and the uterus thus are additional predictors of the mare's readiness for mating and ovulation. Most normal mares achieve at least 40% relaxation of the cervix prior to ovulation (C.L. Carleton, unpublished observations).

Prediction of the Time of Ovulation

With serial palpations, an appreciation of the relationship of a dominant follicle to decreasing uterine tone and increasing cervical relaxation can improve the breeding management of mares. Knowledge of follicular size at ovulation in individual mares from records of previous seasons and estrous periods makes it feasible to predict more closely the time of ovulation. Insemination is avoided until the follicle is within 5 to 10 mm of its anticipated ovulatory size, When coupled with evidence of decreasing uterine tone and a relaxing cervix during estrus (Table 9-1), accurate, consistent, multiple-year records are invaluable in predicting the optimal time to breed and, during subsequent ovulatory seasons, result in a decrease in the number of covers per mare. Individual mares tend to ovulate similar-sized follicles year after year. The exception occurs during foal heat, during which the dominant follicle may become significantly larger. Nevertheless, the effect of the follicle on uterine tone and on cervical relaxation is consistent near the time of ovulation. Factors that prevent the cervix from responding to ovarian activity include anabolic steroid administration, induration of the cervix subsequent to chronic pyometra, and chronic cervicitis.[4,5]

Good records permit assessment of trends and recognition of abnormalities of a mare's estrous cycle. Additional structures noted during TRP and ultrasonography may include endometrial folds (see Fig. 9-4, *inset*), uterine fluid, and uterine cysts. During estrus, the endometrial

folds are particularly prominent owing to edema.[17] Notations made of the location and size of lymphatic and glandular cysts will prevent confusion with pregnancy during an early ultrasonographic examination. If fluid is detected during TRP, its nature can be further defined by ultrasonography, microbiology, cytology, lavage, or endoscopy. An early report dealt with grading of luminal fluid and based its severity on its echogenicity.[30] The volume of uterine fluid can be estimated ultrasonographically. Few mares show evidence of gross vaginal discharge even when a large volume of fluid is in the uterus.[3] Once the presence of fluid has been confirmed, a uterine swab should be collected prior to performing other techniques because bacterial contaminants introduced during subsequent procedures could mask the original problem. Intraluminal adhesions, unless extraordinarily large or extensive, are not palpable.

Vaginal Examination

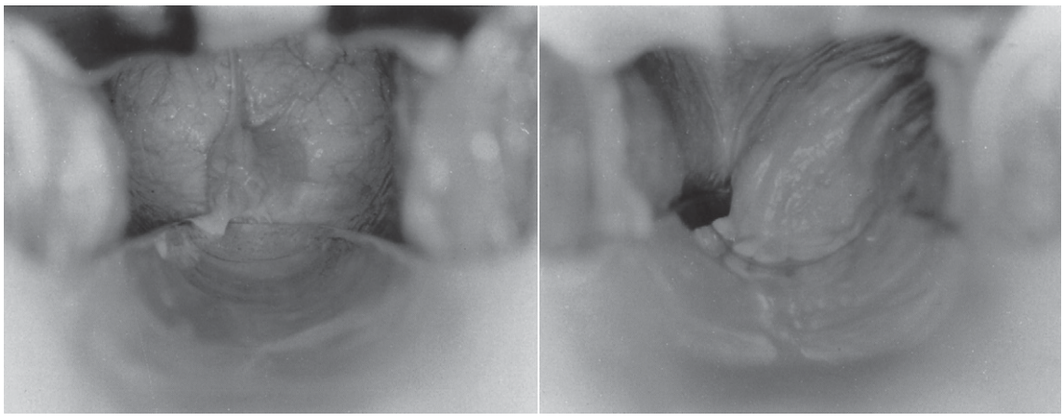
The need to perform routine vaginoscopy to assess readiness for mating should diminish as facility for cervical evaluation by TRP improves. A vaginal examination is a standard part of a breeding soundness examination and is an essential part of the evaluation of a subfertile mare or whenever discharge is noted at the vulvar lips. A *digital vaginal examination* is better suited than vaginoscopy to detect and evaluate subtle irregularities of the mucosa caused by trauma, as well as more obvious adhesions. To rule out cervical tears, it is important to assess cervical integrity during diestrus.[31] With an index finger in the cervical lumen and the thumb on the outside of the external os, it is possible to discern subtle abnormalities of the cervix. The integrity of the cervical lumen can be determined by exploring it for areas of thinning, tears, and adhesions. A digital vaginal evaluation prior to the first live cover or artificial insemination will determine if a persistent hymen is present. The hymen may be imperforate, or only remnants may remain.[4,32] In either instance, the hymen should be eliminated 10 to 14 days prior to breeding to avoid hemorrhage at the time of cover.

A speculum examination can help to further define lesions detected during a digital examination. A *vaginal speculum* requires a bright light source to fully evaluate the vaginal vault. A vaginal speculum examination may aid in determination of the origin of exudate (which may stem from the uterus, cervix, or vagina) noted at the vulvar lips.[19] If an assessment is made immediately upon placement of the speculum into the vagina, a vaginoscopy permits an accurate evaluation of vaginal color. The mucosa is pale pink to salmon in color and glistens during estrus.[33,34] During diestrus, the vaginal walls appear dry and pale. The mucosa rapidly becomes hyperemic following distention of the vagina with air. As the cervix relaxes during estrus, its position drops from the center of the cranial face of the vagina toward the cranial vaginal floor. After ovulation, the cervix closes and regains its former location (Fig. 9-6). Fecal matter may gain entrance to the vagina through a rectovaginal fistula or may be present because of poor vulvar conformation and pneumovaginitis. Dystocia may result in vaginal abscesses and tears.[35,36] A speculum is used to identify mares suspected of urovagina.[37,38] Abnormalities infrequently seen include enlargements of Gartner's ducts, vaginal fibromas, and venous varicosities.[3,39]

ADDITIONAL TECHNIQUES FOR EVALUATION OF INTERNAL UTERINE HEALTH

Culture

A *uterine culture* is an essential tool to determine the etiology of uterine infections.[40,41] A swab is the most accurate means of obtaining samples for identification of the specific bacteria that cause infection. A complete microbiologic work-up includes identification and antibiotic sensitivity of the bacteria and is essential to developing a specific treatment plan. Endometrial biopsy and cytologic



A B

Fig. 9-6 The appearance of the external cervical os during diestrus (closed) **(A)** and estrus (relaxed) **(B),** as viewed through a vaginal speculum.

examination may identify the presence of bacteria or fungal elements or inflammatory cells, but do not identify a specific etiology. A uterine culture is an essential component of a prepurchase examination of a broodmare and may be required prior to presentation of a mare at a breeding farm. Endometrial culture is a routine procedure in the evaluation of mares mated unsuccessfully at two or more estrous cycles during the physiologic breeding season. Additionally, endometrial cultures provide essential information for the evaluation of mares that suffer dystocia, give birth to a weak or dead fetus, experience retained placenta, and are barren at the end of the season.

Technique

To avoid collecting poor-quality swabs and to minimize contamination of the vulvar lips, it is essential to wrap the mare's tail and secure it to one side. The perineum is washed meticulously, including the anal sphincter, the vulvar lips, and the surrounding perineal area. Use of sterile equipment to collect the sample (lubricant, sleeves, and guarded swabs) is mandatory.

Sample quality is improved by the use of a guarded swab. Its quality is further improved by the practitioner's adequately protecting the tip of the guarded swab in the palm and holding it securely under the thumb as it is carried through the vulvar lips, vestibule, and vagina. The cervical lumen is not always straight. Insertion of the index finger through the cervical canal facilitates passage of the guarded swab and reduces the time required to traverse the cervix.

Samples obtained by introduction of a swab through a vaginal speculum frequently become contaminated. The swab cannot consistently and efficiently be directed from the cranial vagina through the cervical lumen. It must be advanced cranially to a point at which one must assume the uterine body has been reached. Resistance within the cervical canal may falsely be interpreted as the swab having come into contact with endometrial folds. Samples obtained through a speculum are of questionable quality and their interpretation is suspect.[3,43,44]

Microbial Flora in the Genital Tract

The number of bacteria in a mare's genital tract decreases cranial to the vulva, with diminishing numbers in the vestibule, vagina, and cervix.[44] There are no normal resident microbial flora of the uterus.[3,45–47] There are reports suggesting the presence of a normal uterine microbial flora, but it is more likely that mares suffering chronic infertility have persistent uterine contamination or infection or both. Bacteria are usually introduced into the uterus during breeding, during foaling, or during other invasive procedures.[3] It is essential that the sample for culture be taken from the uterus and not the cervix. Isolates recovered in pure culture (single organism) are more significant. Ideally the laboratory will determine not only the identity of the organism but the number of colony-forming units as well. Recovery of bacteria from endometrial swabs can be enhanced by gently advancing the swab cranially and allowing it to remain in contact with the endometrial folds for at least 30 seconds, which improves absorption of uterine fluid into the swab.[45] Isolation of more than two bacterial species from a uterine swab often indicates poor collection technique, but may also reflect ascending contamination of the uterus secondary to poor vulvar conformation and pneumovagina. A guarded uterine horn lavage (UHL) technique was developed that was compared with other sampling methods.[45] Seventy-five percent of all aerobic endometrial samples from normal mares collected using UHL yielded no bacterial growth, compared with 35% of those collected using a standard guarded swab. In this project, the few bacterial isolates from both UHL and endometrial swabs were all common contaminants. The numbers of colony-forming units were considered to reflect the rigor with which the mare was prepared for the procedure as well as the degree of protection from contamination provided by each technique and did not reflect a normal uterine microbial flora.[45]

The uterus of normal *resistant* mares has been shown to be able to eliminate bacteria within 96 hours after inoculation.[48] Other mares are unable to overcome bacteria introduced at the time of breeding or foaling and are described as *susceptible* to contamination and reinfection.[48,49] One manifestation of reinfection is luminal fluid identified during TRP and ultrasonographic examination of such mares. Oxytocin has been reported to be a useful treatment to reduce fluid in the uterus at the end of estrus following breeding of subfertile mares.[50–53]

With few exceptions, barren mares are presented for a breeding soundness examination without the luxury of the stage of their estrous cycles being known. There are conflicting opinions concerning the practice of obtaining samples for endometrial culture only during estrus when uterine resistance is greatest and the defense mechanism is most effective in clearing contamination.[54,55] This response is diminished during periods of progesterone dominance, and the number of bacteria, immunoglobulin A, and nonantigenic markers remain elevated for prolonged periods after inoculation.[56,57] If it has been determined that the mare is not pregnant and if preparation of the mare is meticulous and considerable care is taken to minimize introduction of contaminants, endometrial samples for bacterial culture can be taken during either estrus or diestrus. Dilation of the cervix, even when closed during diestrus, is simply accomplished and causes no harm to the mare.[58]

Septic metritis is an infrequent finding in postpartum mares. It is an acute condition and is characterized by depression, anorexia, fever, and laminitis. Predisposing factors include retained fetal membranes, dystocia, and a grossly contaminated foaling environment. Unless a mare is acutely ill, uterine cultures taken during the first week post partum are unlikely to be very useful, especially if taken prior to foal heat (10 days post partum). Isolation of multiple bacterial species and large numbers of colony-forming units reflects contamination introduced during normal parturition.[59] For breeding farms to require a clean, "no growth" culture of mares presented for foal heat breeding is generally an exercise in futility.

Significance of Bacterial Growth

The majority of pathogenic bacteria isolated from uterine swabs are β-hemolytic streptococci *(S. zooepidemicus, S. equi,* and *S. equisimilis).*[44] Other significant pathogens are *Klebsiella* species, *Pseudomonas* species, *Candida* species, and hemolytic *Escherichia coli.*[60] Some laboratories support typing of *Klebsiella* isolates to determine their pathogenicity, but this has not gained wide acceptance.[61] Nonhemolytic *E. coli* is the most common uterine contaminant and with few exceptions is a reflection of poor vulvar conformation and windsucking. Following Caslick's vulvoplasty, *resistant* mares clear bacteria within one or two estrous cycles and do not require treatment with antibiotics.[49] *Staphylococcus,* β-hemolytic streptococci, *Gardnerella,* and other enteric organisms are common contaminants.[62] Uterine infections caused by yeasts and molds commonly follow inappropriate or excessive antibiotic therapy.[63,64] Identification and antibiotic sensitivity testing of isolates are essential to select a proper treatment regimen.

Equipment

A number of guarded instruments are available for obtaining endometrial samples for bacterial culture, including Kalayjian (Kalayjian Industries, Inc., Long Beach, Calif.) and Priority Care (First Priority, Inc., Gilberts, Ill.). Combination rods (Accu-CulShure, Accu-Med Corp., Pleasantville, NY.) are available and can be used to collect a sample for microbiologic culture as well as a sample for endometrial cytologic examination. A cytologic examination can also be performed using the cells collected within the cap of the Kalayjian rod during collection of the bacterial culture.[58]

Most commercially available guarded uterine swabs do not incorporate transport medium within their design. If a sample cannot be immediately streaked onto a selective medium and blood agar, then the swab should be placed into an appropriate transfer medium and refrigerated until it can be processed.[43] One usable system in which a swab can be transported is the Culturette (Becton-Dickinson Microbiology Systems, Cockeysville, Md.). The swab packaged within the Culturette is similar in length to the detachable swab at the tip of the majority of uterine culture rods. The Culturette's swab is discarded and the swab from the guarded culture instrument takes its place. The fluid-filled ampule is crushed to prevent desiccation of the swab. The Culturette is refrigerated until the sample can be placed on artificial medium and incubated.

Therapy

If culture results indicate the need for therapy, uterine lavage can be useful to reduce fluid collection in the uterus. The efficacy of most antibiotics is diminished in the presence of debris.[65,66] Lavage, followed by instillation of an antibiotic, increases the efficacy of treatment by increasing contact of the antibiotic with the endometrial folds. Lavage also provides a clinical gauge of myometrial responsiveness.[67] The author has experienced greater success in treating and achieving pregnancies in barren mares from which at least a 75 to 80% return of the lavage solution was obtained. Serial lavage continues until the efflux is clear (Fig. 9-7). Appropriate antibiotics, selected on the basis of a sensitivity test, can then be instilled in a volume proportional to uterine size.[66]

Endometrial Cytologic Testing

The significance of cytologic examination is a matter of debate among theriogenologists.[69,70] Reports published during the early 1980s recommended taking samples for bacteriologic and cytologic testing during early estrus, 15 to 17 days after the previous ovulation.[42] The intent was to obtain a sample before the uterus came fully under the influence of estradiol and the "increasing bactericidal capacity of the uterine secretions." Circulating neutrophils are recruited to the uterine lumen in response to antigenic material. Their presence is an indication of an acute and active inflammatory process. The usefulness of cytologic testing may be greatest in the mare from which few, but pathogenic, bacteria are isolated. Small numbers of organisms not accompanied by an inflammatory response are less likely to be significant or require treatment.[68,71] Cytologic testing may be utilized late in the breeding season if there is pressure to make treatment decisions before results of uterine cultures and biopsies

Fig. 9-7 Significant amounts of luminal fluid in the uterus preclude effective treatment with antibiotics. A uterine lavage reduces fluid and debris. A successful lavage continues until the color and nature of the return fluid is like that of the instilled medium (saline): left to right.

are available. Although the presence of inflammatory cells is significant, their importance must be kept in perspective. By itself, cytologic testing is not a means to identify the etiologic agent.[31,70]

There are a number of ways in which a cytologic sample may be obtained. Following collection of the microbiologic sample, a second guarded culture swab can be introduced through the cervix and rolled against the endometrium and the swab then gently rolled along a glass slide. If a Kalayjian culture swab has been used, a cytologic sample may be collected from cellular material and fluid that become entrapped within the unseated cap of the swab.[58,60] Recovery of cells can be maximized as the instrument is withdrawn from the uterine body by rotating the swab to facilitate a pick-up of cells from the endometrium. Culture and cytologic instruments have been designed specifically for dual sample collection. Cells can be retrieved with a syringe and pipette by injecting and aspirating a small volume of saline in the uterine body.[72] Curettage was used as a method of treatment for barren mares. A similar or modified technique could serve as a method of harvesting material for a cytologic examination.[73,74]

It is an indication of inadequate sampling of the endometrium if epithelial cells are not present in the sample, and a second cytologic procedure should be done. The appearance of epithelial cells may range from columnar to cuboidal, depending on the stage of the mare's estrous cycle. In addition to epithelial cells and neutrophils, other cells present may include lymphocytes, monocytes, eosinophils, red blood cells, and, after breeding, spermatozoa.[72,75] The speed with which inflammatory cells enter the lumen following any intrauterine procedure must be kept in mind.[47] Normally there are no neutrophils in the lumen.[76] If a cytologic sample has not been collected simultaneously with the sample for bacterial culture, then it should be collected immediately thereafter. If there is a delay, then the significance of the recruited cells may be doubtful. As in endometrial biopsy specimens, lymphocytes, monocytes, and macrophages are usually a reflection of chronic endometritis.[58] Eosinophils are infrequent and are most likely associated with urine pooling and chronic windsucking. Interpretation can be complicated if neutrophils are present without accompanying bacteria. Significance is based in part on the frequency of polymorphonuclear cells (PMNs) observed, that is, when the ratio of epithelial cells to PMNs falls below 10:1.[59] As the number of PMNs increases, fertility decreases.[77] UHL was also compared with standard cytologic technique. The UHL collection technique caused the least disruption to the integrity of cells retrieved. Unlike a standard cytologic sample, UHL revealed no difference in the nucleated cell counts recovered from normal mares in estrus, diestrus, and anestrus.[45]

Interpretation of the cytologic sample is easier when the sample is examined promptly on a wet mount. Diff-Quik (American Scientific Products, McGaw Park, Ill.) stain, with a three-stain procedure, is easy to use.[58] Gram stain is an easy screening stain for the presence of bacteria.[75,78,79] New methylene blue can help identify capsular material of potential pathogens, such as *Klebsiella*.[80] If the laboratory capability allows, a cytospin can facilitate concentration and evaluation of samples that contain low numbers of cells.[45] An aerosol cytofixative (Spray-Cyte, Clay-Adams, Parsippany, NJ) can be sprayed on the sample to prevent cellular distortion that occurs with drying.

Endometrial Biopsy

Endometrial biopsy is an important key to identifying the nature of an infertility problem. When combined with the results of TRP, ultrasonography, and microbiology, it permits a more accurate assessment of a mare's reproductive prognosis. Factors have been defined that provide a prognosis for the mare's fertility.[71] These factors include inflammation, periglandular fibrosis, cystic glandular degeneration, and lymphatic stasis. Candidates and circumstances for which endometrial biopsy is warranted include barren mares bred repeatedly to a known fertile stallion; mares presented for genital surgery (rectovaginal lacerations and cervical tears) that may have already suffered permanent endometrial damage; mares with a history of early embryonic death, abortion, or retained fetal membranes; mares failing to cycle during the physiologic breeding season; or as part of a prepurchase examination of a potential broodmare.

Endometrial tissue is readily obtained with a biopsy punch (Pilling, Fort Washington, Pa.). Ideal sample size for interpretation is at least a 10 to 20 mm × 3 mm sample.[81] Both the epithelial cell layer and the glandular architecture reflect season of the year and the stage of the mare's estrous cycle.[82] The luminal epithelium peaks in height from 30 to 40 μm during early estrus, then decreases to 15 to 20 μm by late estrus or early diestrus. It increases once again slowly through diestrus into early estrus. The luminal epithelium appears atrophic during winter anestrus and is characterized by cuboidal epithelium and straight, rather than tortuous, glands.[81] For proper interpretation, the results of TRP and stage of the estrous cycle should accompany the sample at the time of submission.

Technique

A biopsy can be taken by either a rectovaginal method[71] or a vaginal approach.[83] With the rectovaginal method, once the mare has been properly prepared, the sterile biopsy punch with its jaws closed is carried in a gloved hand through the vagina, gently guided through the cervical canal, and positioned in the uterine body. The hand is then withdrawn from the genital tract and placed in the rectum. The punch is palpable within the uterine body and is advanced to the desired biopsy site. The jaws of the punch are opened and rotated until the flat edge of the biopsy basket is palpable under the fingers as an opened V shape. With slight digital pressure, the endometrium is pushed into the V and the handle of the instrument closed to excise the tissue sample. In the vaginal technique, the closed instrument is carried through the cervix and advanced 2.5 to 3 cm beyond the tip of the index finger into the uterine body. The tip of the biopsy punch is advanced with the basket opened an additional 4 to 6 cm. With the index finger in the cervix

as a fulcrum, the punch is swung laterally to move the tip into the endometrial fold. In this technique, when the veterinarian's right arm is in the mare, the biopsy is most easily obtained from the left side of the lumen; conversely, the left arm in the mare's genital tract makes right-sided sampling easiest. The jaw is closed abruptly and the instrument withdrawn. It is readily apparent if a tissue sample has been obtained as the endometrium trapped within the basket will be tugged caudally and palpated by the tip of the index finger. With a gentle tug, the instrument is withdrawn.

The specimen should be gently teased from the basket with the use of a small sterile needle and placed in either Bouin's solution or 10% buffered neutral formalin.[84] The fixed tissue is trimmed, placed in paraffin blocks, and sectioned. Sections are routinely stained with hematoxylin and eosin. Neutrophils are associated with an acute inflammatory response while lymphocytes, monocytes, and plasma cells serve as indicators of chronic inflammation. An interpretation should indicate the location of the inflammatory cell infiltrates within the lamina propria, for example, stratum compactum (immediately under the epithelial cells, nearer the lumen) or stratum spongiosum (deeper, vicinity of gland branches).[71] Antibiotics and uterine lavage, used appropriately, appear able to reverse endometrial inflammation to some degree.[54,65] Fibrosis is most commonly identified in a periglandular location, and its severity is gauged by the number of layers encircling glands, as well as by the frequency of nesting of groups of glands in a more extensive response (Fig. 9-8). Fibrosis usually occurs secondary to chronic inflammation, and glands lose their ability to function.[71,85] Significant loss of uterine glands appears to be associated with inability to sustain pregnancy beyond the first few months of gestation.[71] There is no known treatment that can reduce fibrosis. Cystic glandular degeneration is usually secondary to severe periglandular fibrosis. Dilated lymphatics can be distinguished from cystic glands by their lining of endothelial cells. Extensive lymphatic stasis can interfere with fertility, and some improvement has been reported following a series of hot saline uterine lavages.[71] Incidental histologic findings can further define ongoing problems or historical events. The presence of siderocytes suggests an episode of intrauterine hemorrhage sometime during the previous 7 months and may be evidence that either an abortion or parturition occurred.

Interpretation

Interpretation of endometrial biopsies provides an estimate of both the frequency and distribution of inflammation and fibrosis, as well as the prognosis for the mare's ability not only to become pregnant but to carry a pregnancy to term. Based on the interpretation, the endometrium is assigned to one of four categories: I, IIA, IIB, or III.[71] The higher the number, the poorer the prognosis.

Category I includes mares that have minimal or no changes in endometrial architecture (Fig. 9-9). These mares have a 70% or greater chance to conceive and to carry a fetus to term. *Category II* endometria exhibit changes that diminish the mare's ability to conceive and carry a fetus to term. The nature, frequency, and distribution of architectural changes will place the biopsy into either a IIA or IIB classification. Any of the factors previously described may be involved, singularly or in combination, such as slight to moderate inflammatory cell infiltration of the stratum compactum, scattered but frequent foci of inflammation and fibrosis throughout all areas of the sample, scattered periglandular fibrosis of gland branches, or nesting of glands up to an average of three per 5.5 mm in at least four fields, or widespread lymphatic stasis noted only by biopsy.[18] Mares with predominantly inflammatory changes (IIA), and cases for which treatment may be beneficial, fare better than those with predominantly fibrotic changes. The latter, for which treatment is either unavailable or which have moderate to severe inflammation and severe fibrosis, are classified as IIB. Correspondingly, the reproductive prognosis for carrying a fetus to term diminishes and is approximately

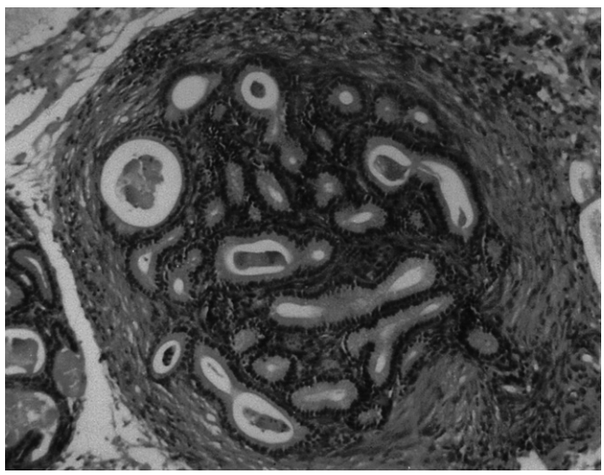


Fig. 9-8 Endometrial section with a fibrotic glandular nest and cystic degeneration subsequent to the fibrosis.

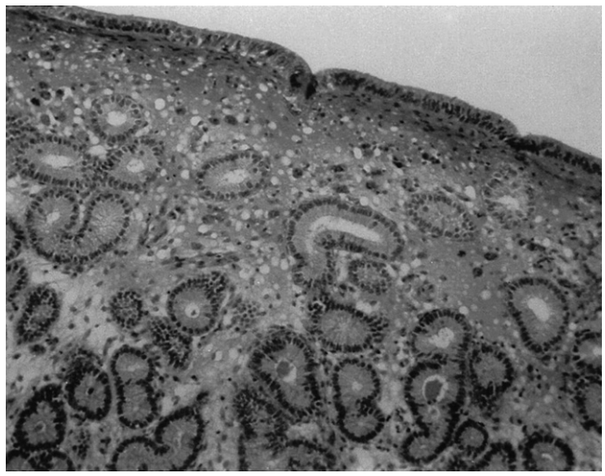

Fig. 9-9 Endometrial section with normal gland distribution and frequency.

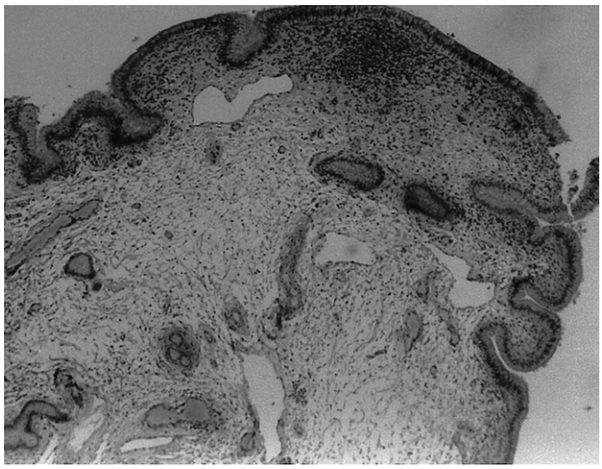

Fig. 9-10 Category III endometrial section lacking normal glands and with a locus of inflammatory cell infiltration in the stratum compactum.

50 to 70% in mares with IIA endometria and 30 to 50% in endometria classified as IIB. Category III endometria exhibit widespread or severe irreversible changes that negatively affect both conception and the mare's ability to maintain a pregnancy to term (Fig. 9-10). Examples include extensive periglandular fibrosis (five or more nests per low power field), widespread and severe inflammation, severe lymphatic stasis that results in a spongy feel to the uterine wall (grossly palpable), chronic pyometra associated with atrophy of the endometrial folds or pervasive inflammation, or endometrial atrophy that persists throughout the physiologic breeding season.[18] Such mares have a less than 10% chance of conceiving and carrying a fetus to term. The expense of attempting to get one more foal from such a mare must be weighed against the value of the mare and her potential offspring.

The cause of uterine infection may be suggested if numerous bacteria or fungal elements are evident in a biopsy sample.[71] Additional sections can be cut from the tissue block and stained to attempt identification of specific bacteria (Gram's stain) or fungal elements (methenamine silver stain).[75,78,79,86]

Endoscopy

Endoscopy is not often used during an initial breeding soundness examination, but is generally reserved as a second tier of examination of mares in which the cause of infertility remains undefined. It is also used to define more completely those abnormalities identified by TRP or ultrasonography. A flexible endoscope permits visualization of the vagina, external cervical os, and lumen of the uterine body and horns up to the uterotubal junctions.[87] During endoscopy, gross lesions can be defined, site-specific biopsies obtained from abnormal-appearing uterine mucosa, and samples of uterine fluid aspirated. Depending on the number and diameter of channels of an endoscope, specialized instruments are available that allow observation of and access to lesions. Available instruments permit site-specific biopsy (though the sample size is very small), aspiration of uterine content, curettage, and laser-guided surgery.

Dilatation of the uterine lumen with either air or fluid may cause discomfort, and problems can be averted by sedating the mare prior to performing the procedure.[87] If fluid is used to dilate the uterine horns, it can be introduced either through the channel of the endoscope or through a separate uterine infusion catheter. Infusion through a catheter is particularly helpful if it is anticipated that large volumes will be required to achieve adequate distention. Endoscopy is more easily accomplished when a mare is in diestrus. A closed, diestrual cervix slows the escape of air or fluid through the cervix and thus facilitates dilatation of the uterine lumen to permit visualization of gross lesions. During estrus or anestrus, when the cervix is relaxed, it is more difficult to distend the uterus because fluid escapes through the cervix.

Sufficient distention may be achieved solely using air in combination with the reservoir attached to the biopsy flush channel. The reservoir can be filled with sterile distilled water. Abnormalities may be difficult to identify if there is exudate or fluid in the uterus. The flush channel can be used, as needed, to remove exudate from the head of the endoscope as it is advanced into the uterus. Cloudiness caused by a mix of flush solution and uterine contents may mask subtle lesions, such as mucosal color changes or small cysts. If the amount of uterine fluid is large, it may be necessary to precede endoscopy with uterine lavage. In this instance, in exchange for better visualization of gross lesions such as transluminal adhesions and cysts, the examiner may be unable to distinguish between hyperemia or inflammation caused by lavage and that associated with infertility.

Particular attention must be paid to preparation of equipment prior to use to avoid contamination of the uterus. Cold sterilization of the endoscope, using either glutaraldehyde (Cidex, Johnson & Johnson Medical, Inc, Arlington, Tex.) or ethylene oxide (EtOH, 3M Animal Care Products, St. Paul, Minn.), is essential. The endoscope channels must also be disinfected to eliminate an additional source of uterine contamination during introduction of flush solution or instruments. This may be accomplished by immersing the flexible portion of the endoscope in a tray filled with glutaraldehyde and aspirating the solution into the channels with 60-ml syringes attached to the proximal ports of the endoscope. Although it is important to comply with the minimum contact time recommended by the manufacturer, the suggested time should not be exceeded. The endoscope and its seals can be damaged by prolonged immersion. Glutaraldehyde is very irritating to both skin and mucous membranes. Upon removal from the disinfectant solution, both the external surface and the channels of the endoscope must be thoroughly flushed with sterile water to avoid placing irritants into the genital tract. One assistant should be available to handle the flexible portion of the endoscope. Aseptic procedures should be followed from the time the endoscope is removed from the disinfectant or the sterile package (if EtOH was used) and throughout placement in the genital tract.

Gross Pathology and Endoscopy

The examination begins as soon as the tip of the endoscope is carried through the vulvar lips. A detailed examination includes observation of the gross appearance of the vestibule, vagina, external cervical os, and the uterine body and horns. The uterine mucosa should be uniform in color (a pale salmon color) and glisten (Figs. 9-11 and 9-12). To avoid confusion between the bifurcation of the uterine horns and a transluminal adhesion, attention should be paid to the length of the endoscope as it is introduced into the uterus and note made of the depth at which the bifurcation of the uterine horns is first observed (Fig. 9-13). Transluminal adhesions can range from very thin and fibrinous in nature, to thick bands, to complete occlusion of a uterine horn. Patience is essential for careful and complete examination of the uterine body and both horns. Identification of the ostium, the small papilla at the apical end of each uterine horn, provides assurance that the entire length of each uterine horn has been traversed (Fig. 9-14). Lymphatic cysts are common in older mares.[18] Their number and size tend to increase with age and they may be pedunculated or broad-based and multilocular.[71] Lymphatic cysts more frequently impinge on the uterine lumen and may be large enough to impede transuterine migration of the

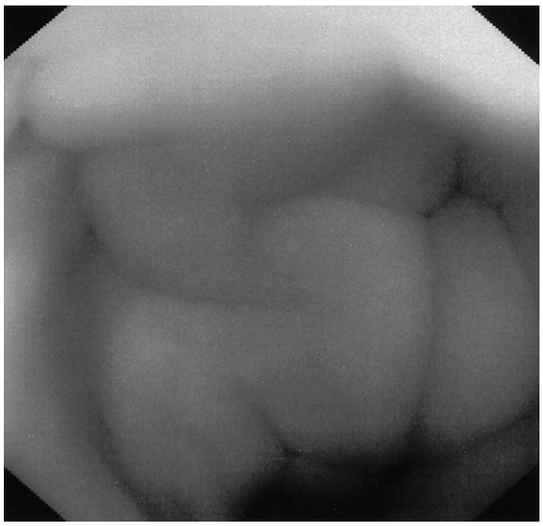

Fig. 9-11 Endoscopy of the uterus: early in the procedure, with prominent endometrial folds and minimal dilatation and expansion of the lumen.

embryo during early pregnancy. Erosions of the uterine wall, exudate, and color changes of the endometrium can be identified. The appearance of the endometrial folds may be misleading if observed during anestrus or vernal transition, as they will appear underdeveloped or atrophic.[18]

Resolution of Problems Diagnosed by Endoscopy

Lymphatic cysts can be very large and occlude the uterine lumen (Fig. 9-15). A variety of techniques have been used to remove them or reduce their size. Methods of cyst reduction include partial removal of the cyst wall with an endometrial biopsy punch, digital removal of pedunculated cysts,[54,58,88] or laser surgery to remove a large portion of the wall of a broad-based cyst (Fig. 9-16). The laser (Nd:YAG contact laser, Surgical Laser Technologies, Oaks, Penn.) is introduced through the biopsy channel of the endoscope, which permits careful and measured ablation of the cyst wall. These procedures may be followed by uterine lavage to remove the contents of the collapsed cysts. If an insufficient portion of the wall is removed, some cysts will seal and refill.

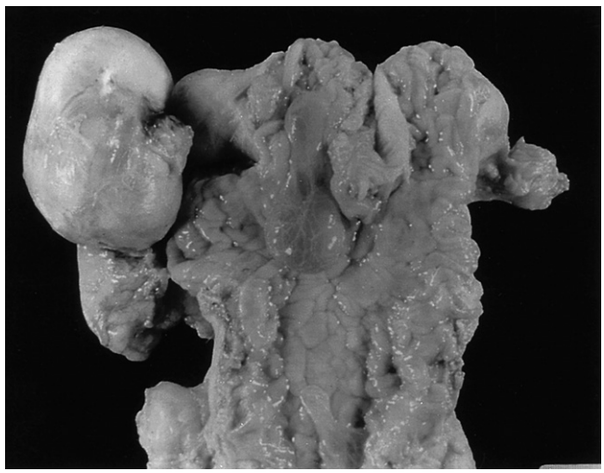

Fig. 9-15 Large lymphatic cyst occluding the lumen of a uterine horn. Note also that this mare consistently ovulated only on the side of the lymphatic cyst, which prevented transuterine migration of the embryo.

Additional gross changes observed during endoscopy may be the result of chronic infection, scars secondary to injury suffered during dystocia such as a cervical or uterine mural tear, a sequela of a postpartum problem such as retained placenta, or poor vulvar conformation and chronic windsucking. A variety of foreign material may be found in the uterine lumen including fecal matter, urine (calcium carbonate crystals), purulent exudate or mucus, tips of culture swabs, or mummified parts of fetuses.[87] After endoscopy, if there is any doubt about asepsis, it may be beneficial to eliminate contaminants by uterine lavage and intrauterine antibiotics.

Problem mares are frequently identified by their inability to mount an appropriate cellular response to contamination of the genital tract. They may accumulate fluid, experience an increased incidence of early embryonic death, or suffer chronic uterine infections. The goal in evaluating a mare's reproductive ability is to determine not only what is normal or abnormal but also the treatment and management techniques that can best take advantage of the mare's remaining reproductive potential.

CHAPTER 10

Control and Synchronization of the Estrous Cycle and Ovulation

CARLOS R. F. PINTO and PATRICK J. MEYERS

Accurate and predictable synchronization of estrus and ovulation is vital to equine breeding. The objectives of controlling the reproductive cycle of mares during the breeding season center on the ability to induce a fertile estrus and ovulation.

Synchronization of estrus has been used successfully as a management tool in the cattle industry. In cows, estrus and ovulation are simultaneously synchronized by hormonal therapies because ovulation predictably occurs shortly after the end of estrus (see Chapter 38). In contrast, synchronization of the mare's estrus and ovulation is more difficult.

The mare's estrus is relatively long, averaging 5 to 7 days; the maturation of the preovulatory follicle until ovulation takes 36 to 48 hours to complete. In addition, ovulation cannot be predicted from the first day of estrus as in cows. Actually, in the mare, behavioral signs of estrus typically cease within 2 days after ovulation; thus, the presumptive day of ovulation can only be determined retrospectively. Even though many effective methods have been developed for inducing estrus with a reasonable degree of synchronization, hormonal therapies that predictably induce estrus and ovulation are limited. In the United States, very few drugs have been approved for control of the equine estrous cycle. Because many horse breed associations are now accepting the use of frozen and shipped cooled semen in artificial insemination programs, the development of synchronization protocols that would allow a single breeding at a predetermined time remains a challenge for veterinarians and a great expectation for horse breeders.

This chapter focuses on methods that are currently available for controlling and synchronizing estrus and ovulation in mares, including induction of cyclicity in anestrous and transitional mares.

INDUCTION AND SYNCHRONIZATION OF ESTRUS

In general terms, synchronization of estrus in mares is currently accomplished in the following ways:

1. Termination of the luteal phase of the estrous cycle with prostaglandin F_2 alpha ($PGF_{2\alpha}$)
2. Lengthening the luteal phase of the estrous cycle with exogenous progestins
3. Combination of both methods

Termination of the Luteal Phase with Prostaglandin F_2 Alpha

The luteal phase of the estrous cycle can be shortened by treatment with $PGF_{2\alpha}$ and its analogues.[1] $PGF_{2\alpha}$ was shown to be luteolytic in mares in 1972 and since then has been widely used in breeding farms that require intensive management of broodmares and stallions and mares.[2] The corpus luteum is not responsive to one single injection of $PGF_{2\alpha}$ until day 5 after ovulation, although daily administration of $PGF_{2\alpha}$ for 2 or 3 days starting on day 3 after ovulation may cause luteolysis. In horse mares, 9 µg/kg of the $PGF_{2\alpha}$ free acid equivalent to 1.2 µg of dinoprost tromethamine prostaglandin (Lutalyse, the only $PGF_{2\alpha}$ approved for horses by the Food and Drug Administration [FDA]) has been shown to be luteolytic, but the manufacturer recommends the administration of 1 mg/100 lb (~22 µg/kg). Recently, a dose as low as 0.5 mg of Lutalyse per horse mare (~1.2 µg/kg) administered twice 24 hours apart caused luteolysis in 100% (21/21) of mares in the study without inducing well-known side effects (sweating, colic) associated with recommended dose.[3]

Most common indications for the use of $PGF_{2\alpha}$ in nonpregnant broodmares include but are not limited to the following: [4]

1. Induction of estrus when the previous ovulation date is known. Specific indications may include a missed breeding, diagnostic or therapeutic considerations, induction of estrus to accommodate the stallion breeding schedule, and embryo transfer. Veterinarians using palpation per rectum and transrectal ultrasonography should determine whether the mare is in diestrus or not and administer $PGF_{2\alpha}$ accordingly; if reproductive examination is not available, horse breeders may be instructed to administer a single dose of $PGF_{2\alpha}$ 5 days after the mare ceases behavioral signs of estrus. If veterinary assistance or teasing information is not available, horse breeders might be advised to administer a single dose of $PGF_{2\alpha}$ at

any given day and to repeat it in 5 days if the mare is not observed in estrus.

2. Fertility of foal heat can be decreased in mares experiencing problems during the peripartum period (dystocia, retained placenta, delayed uterine involution, etc); for these reasons or simply because of a breeding management strategy, some horse owners may choose to not breed a mare during her foal heat. Shortening the first postpartum luteal phase is then recommended and a single dose can be administered as early as 5 days after ovulation during foal heat.

3. Treatment of prolonged diestrus. This irregularity was initially thought to result from a persistent corpus luteum (CL). Prolonged diestrus is often associated with another unique phenomenon of the mare's estrous cycle, the diestrous ovulation. Prolonged diestrus is diagnosed as a diestrous period lasting more than 16 days after ovulation. A single dose of $PGF_{2\alpha}$ is administered at any time after the condition has been diagnosed via reproductive examination (palpation of a firm, tubular cervix; detection of a CL by ovarian ultrasonography) or hormonal assays (detection of >2 ng/ml of serum or plasma progesterone). Mares undergoing early embryonic death after the maternal recognition period may also experience prolonged diestrus. Regardless of the etiologies, concentrations of plasma or serum progesterone greater than 2 ng/ml in mares with spontaneously prolonged interestrous intervals indicate the presence of a functional CL that requires treatment with $PGF_{2\alpha}$. Occasionally, mares with spontaneously prolonged interestrous intervals do not have a functional CL and would not benefit from $PGF_{2\alpha}$ therapy.

4. Estrus synchronization. In this regimen, two doses of $PGF_{2\alpha}$ are administered 14 to 18 days apart. However, for close synchrony of estrus and ovulation in a group of mares, more elaborate schemes of hormonal treatment are required.

5. Induction of estrus following therapy with progesterone (or synthetic progestin) used to suppress estrus and pituitary release of gonadotropins. A single dose of $PGF_{2\alpha}$ is administered on the last day of progestin treatment to ensure that all luteal function is negated.

Other indications for administration of $PGF_{2\alpha}$ include termination of unwanted pregnancies before and after formation of endometrial cups, termination of abnormal pregnancies such as trophoblastic vesicles without an embryo proper, and therapy for mares susceptible to persistent postmating endometritis. Induction of parturition with $PGF_{2\alpha}$ is possible but not recommended because of an increased incidence of premature placental separation and decreased foal viability associated with its use.

Idiosyncrasies of Prostaglandin F_2 Alpha Use in Mares

Without a sound understanding of endocrinology and knowledge of the follicular and luteal structures present in the ovaries at the time of $PGF_{2\alpha}$ administration, some of the clinical responses observed (such as the interval from treatment to display of estrus and time of ovulation) may be confusing to veterinarians not familiar with the mares' reproductive physiology.

Prostaglandin $F_{2\alpha}$ only has a significant effect when a mature CL is present.[5] Maturity of a CL and hence its responsiveness to the action of $PGF_{2\alpha}$ may vary considerably among individual mares. Although the CL of most mares will respond to $PGF_{2\alpha}$ from the fourth day after ovulation, some will respond as early as the first day after ovulation, and others appear to be refractory.[6] Studies in cows have shown that stage of diestrus[7] and follicular status at the time of $PGF_{2\alpha}$ administration[8] have dramatic effects on the interval between $PGF_{2\alpha}$ treatment and display of behavioral estrus. Large and small luteal cells have been shown to differ in their response to luteotrophic and luteolytic agents through regulation of $PGF_{2\alpha}$ receptors.[9] The mare's CL has two distinct populations of luteal cells but it has been reported that the relative proportion of small to large luteal cells increases with the age of the CL during diestrus.[10] The effect of this phenomenon on clinical response to treatment with $PGF_{2\alpha}$ is currently unknown.

Follicular status also has an effect on the interval from treatment with $PGF_{2\alpha}$ to the onset of estrus and ovulation.[4] When a large follicle (30 to 40 mm or greater) is present at the time of $PGF_{2\alpha}$ administration, a number of different clinical responses have been demonstrated.[5] In most cases, mares come into estrus and ovulate within 6 days after $PGF_{2\alpha}$ treatment,[11] but in a few instances ovulation occurs within 24 to 72 hours and the mare shows few or no signs of estrus.[12] In the latter situation, $PGF_{2\alpha}$ may play a role in accelerating ovulation, because analogues of $PGF_{2\alpha}$ have been shown to speed the ovulatory process.[13] On occasion, the large diestrual follicles present at the time of $PGF_{2\alpha}$ treatment may be atretic. Ovulation at the subsequent estrus is the result of growth and maturation of smaller follicles following regression of the larger one. In this situation, an increased amount of time is required for the mare to display signs of estrus and to ovulate.

Spontaneous diestrual ovulations occur in approximately 5% of estrous cycles and may account for apparent failure of luteolysis following treatment with $PGF_{2\alpha}$.[4] If $PGF_{2\alpha}$ is administered shortly before spontaneous ovulation of a large (greater than 35 mm) diestrual follicle, luteolysis of the primary CL may occur, but the CL that develops following spontaneous ovulation of the diestrous follicle (and increased progesterone concentrations) may mask the effects of lysis of the primary CL and the mare may not return to estrus as anticipated.

From this discussion it is clear that the use of $PGF_{2\alpha}$ in mares may not be straightforward. Administration of $PGF_{2\alpha}$ on days 6 to 9 after ovulation will result in the onset of estrus and subsequent ovulation within 3 to 4 days and 9 to 10 days, respectively, following treatment in most mares.[5] It should be emphasized that the behavioral signs of estrus may not be observed and the interval between treatment and ovulation may range from 2 to 15 days.[14]

Appropriate adjustments in the management of individual nonpregnant mares may be required when treatment with $PGF_{2\alpha}$ is anticipated. For example, careful examination of the ovaries by palpation per rectum and

ultrasonography, noting the exact size, location, and texture of follicular structures prior to $PGF_{2\alpha}$ treatment may alert the practitioner to the need to examine the mare more frequently so that short intervals between treatment and estrus and ovulation do not result in missed breeding opportunities.

Lengthening the Luteal Phase with Exogenous Progestins

During the physiologic breeding season when mares cycle regularly, the primary indication for extending the luteal phase is synchronization of estrus and ovulation for embryo transfer and for timed insemination. The administration of progesterone (or synthetic progestin) alone or in combination with estradiol-17β suppresses estrus behavior, thus mimicking an extended luteal phase for as long as the progestins are administered.[14] Progesterone is also used alone to assist in the maintenance of pregnancy and to delay the onset of estrus (e.g., at foal heat). Because progesterone has an inhibitory effect on the release of LH from the anterior pituitary, the rationale is to artificially maintain an elevated concentration of progesterone until the corpora lutea (CL) in all treated animals have regressed. Estrus is delayed by progesterone administration until the onset is desired. Following withdrawal of progesterone, estrus and ovulation should occur at a predictable time. This method is generally successful for estrus synchronization in mares; however, progesterone, as with any other single hormone used to synchronize estrus and ovulation in mares, does not exert complete control over the physiologic events of the mare's estrous cycle. The limiting factor is the degree to which spontaneous follicular growth and ovulation are suppressed.

Treatment with progesterone in oil (50 mg/day IM) initiated before estrus prevents the behavioral signs of estrus but does not prevent ovulation, whereas a dose of 100 mg/day blocks both estrus and ovulation.[15] Neither dose is very effective if started after the first day of estrus. A dose of 200 mg/day is needed to suppress behavioral signs if a mare is in estrus at the beginning of treatment. Also, the dose required to inhibit ovulation once estrus has begun is higher than that required by mares in diestrus. Even the high endogenous concentrations of progesterone that are present during the midluteal phase of the estrous cycle are sometimes not sufficient to suppress gonadotropin release, follicular development, and ovulation. Administration of progesterone in oil (100 to 200 mg/day IM) for 7 to 10 days is followed by estrus 2 to 7 days after treatment ends. Daily injections of progesterone in oil may be painful, are not well tolerated by mares, and have the potential to cause seromas, abscesses, and fibrosis at the injection site.

In attempts to overcome the inconvenience of daily injections, other preparations and routes of administration have been tested; however, none are currently approved for use in horses and are commercially available only through veterinary compounding pharmacies. Intravaginal sponges impregnated with progesterone and synthetic progestins may have some degree of success in synchronizing estrus in mares.[16] Unfortunately, sponges have the potential to adhere to the vaginal wall and induce necrotic vaginitis. Intravaginal devices that release progesterone slowly have been investigated in Europe and Australia and hold promise for future use. Microspheres containing progesterone and progesterone plus estradiol-17β have been injected to control or synchronize the estrous cycles of mares. Some long-acting preparations of progesterone plus estradiol were available by prescription from a pharmacy in Kentucky but the FDA recently seized compounded equine drugs. The FDA understood the pharmacy was illegally manufacturing drug products from bulk ingredients without FDA approval and selling them outside a valid veterinarian-client-patient relationship.

The only progestin approved by the FDA for use in horses is altrenogest (allyl-trenbolone*). Consequently, altrenogest (Regu-Mate) is the most extensively studied synthetic progestin. Altrenogest is widely used because of the convenience of oral administration, safety, and a common belief in its efficacy. Examples of efficacy include the following:

1. A dose of 30 mg altrenogest administered orally to a group of mares for 10 to 15 days resulted in 80% of the mares being in estrus within 2 to 8 days after treatment was suspended and 79% of mares ovulating within 7 to 12 days after treatment was suspended.
2. Oral administration of altrenogest to mares at a dose of 0.044 mg/kg body weight for 15 days resulted in intervals to estrus and ovulation of 5.0 ± 2.4 days and 10.2 ± 3.6 days, respectively.

When altrenogest is fed for 15 days, most mares express estrus within 3.5 to 5 days and ovulate 9 to 11 days after treatment.[17]

Lofstedt and Patel[18] questioned the ability of altrenogest to control the equine estrous cycle. At the recommended dose and duration of treatment, altrenogest failed to suppress follicular development. Ovulation occurred in three of four mares when treatment was initiated during the first 3 days of estrus. Apparently the binding affinity of altrenogest for receptors in the hypothalamus is 60% that of progesterone. Also, LH is only slightly or not at all suppressed by altrenogest.[16] Of the four mares that were treated during estrus in one study, the mean duration of estrus was 4.5 days. Nine of the 12 mares treated with altrenogest ovulated and formed CL during treatment. In four of the mares, the CL persisted between 2 and 10 days beyond the 15-day altrenogest treatment. To ensure closer synchrony, $PGF_{2\alpha}$ should be administered at the end of the progestin therapy. Altrenogest or progesterone in oil given for 9 days in addition to an injection of $PGF_{2\alpha}$ on day 9 or 10 of treatment with progestin has been shown to be an effective method of synchronizing estrus. Oral administration of altrenogest for 8 to 12 days with an injection of $PGF_{2\alpha}$ on the last day of altrenogest treatment will result in most mares exhibiting estrus in 2 to 5 days after withdrawal. If any large follicles exist at the end of treatment, they can ovulate without the mare exhibiting signs

*ReguMate, Hoechst-Roussel Agri-Vet Co, Somerville, NJ.

of estrus, and these ovulations may be missed. However, not all mares with preovulatory follicles present at the end of treatment ovulate within 3 to 4 days. In one study, 4 of 12 preovulatory follicles remained until ovulation occurred 6 to 9 days later.[17] Examination of the ovaries with transrectal ultrasonography at the end of the treatment period and administration of human chorionic gonadotropin (hCG) when a preovulatory follicle has reached 35 mm in diameter will help alleviate this problem and provide tighter synchrony of ovulation. During routine breeding management of the majority of mares at breeding operations, there are few indications for use of progestins to control the reproductive cycle.

INDUCTION AND SYNCHRONIZATION OF OVULATION

Induction of Ovulation with Human Chorionic Gonadotropin

In the mare, when normal estrous cycles have been established it is probable that high-frequency pulses of gonadotropin-releasing hormone (GnRH) from the hypothalamus are responsible for eliciting a preovulatory increase in luteinizing hormone (LH).[19] This increase appears to be directly associated with final maturation of preovulatory follicles and initiation of ovulation. The process of ovulation involves a complex interaction between LH and cyclic adenosine monophosphate, prostaglandins, and proteolytic enzymes.[20] Follicles increase rapidly in size (about 5 mm in diameter per day) before ovulation. In 400- to 500-kg mares, preovulatory follicles average 44 mm in diameter.[1]

The ability to accurately control ovulation in mares and synchronize ovulation with mating has several advantages. The use of an ovulation induction agent effectively minimizes the number of matings required per estrous cycle, thereby conserving stallion power.[21] Administration of a drug to induce ovulation in mares shipped to the stallion for breeding ensures a minimum of transportation during each breeding cycle and reduces the chance of stress-induced anovulation. Mares prone to uterine infection as a result of breeding also benefit from one cover or insemination per estrous cycle.[22]

Human chorionic gonadotropin (hCG) is a hormone that induces ovulation in most domestic animals and humans. The hCG hormone is extracted from the urine of pregnant women and provided as a lyophilized product that must be reconstituted shortly before use because its stability in solution is relatively short (2 to 3 weeks). Although hCG has been used to induce ovulations in mares since 1939,[23] it is not approved by the FDA for use in horses. The hCG is an LH-like hormone and thus has been used extensively to induce or hasten ovulation at a predictable time during estrus.[24] Before the advent of ultrasonography, several studies have indicated that administration of hCG on the second day of estrus can shorten the mean length of estrus by 1 to 3 days.[24,25] Administration of a single dose of 1500 to 3300 IU results in ovulation within 24 to 48 hours and shortens estrus in treated animals compared with untreated control animals.[1] A dose of 2500 IU IV is typically administered when a follicle 35 mm or greater in diameter is detected by palpation per rectum or ultrasonography in an estrual mare and a breeding appointment has been arranged. Mares with two presumptive preovulatory follicles do not need a second injection of hCG during the same cycle. The stage of follicular development at which hCG is administered is very important. Constant monitoring (every 24 or 48 hours) of follicular development throughout estrus by transrectal ultrasonography is essential for a predictable response. Generally, poor responses have been noted when hCG was given before follicles reached 30 mm in diameter or when a large follicle destined to atresia is present in the ovaries. Appropriately sized follicles (35 mm in diameter) are detected on the second or third day of estrus, and ovulation usually occurs before 48 hours after injection. In one trial, 83 of 89 of mares ovulated within 48 hours after injection.[26] Recent reports have shown that efficacy of hCG to cause ovulation was not affected by follicle size, as long as the minimum follicle diameter of 30 mm had been reached. Ovulation rates for follicles measuring 30 to 34 mm, 35 to 39 mm, and over 40 mm were not significantly different.[27] For more accurate control and synchronization of ovulation in a group of mares (e.g., embryo donors and recipients), hCG can be included as part of an estrous synchronization regimen (see later discussion).

Disadvantages of hCG administration are inconsistencies in response between and within mares and antibody formation, which may or may not cause refractoriness and impair fertility.[28] Refractoriness and decreased fertility seems to be associated with elevated doses of hCG (>5000 IU) administered intramuscularly. Although the product insert recommends the intramuscular route, equine reproductive physiologists recommend the intravenous route because, in addition to being a safe route, it is expected to minimize antibody formation. As most hCG products in the United States are sold as 10,000 IU lyophilized vials that must be reconstituted into 10 ml of distilled water before use, it is convenient to administer 2000 to 3300 IU per animal (3 to 5 doses per vial).

Induction of Ovulation with the GnRH Analogue Deslorelin

Gonadotropin-releasing hormone (GnRH), a 10-amino-acid neuropeptide, has recently been shown to induce ovulation in mares.[29] However, treatment with GnRH or its analogues administered as a single injection[25,30–32] or multiple injections[33–35] during estrus in cyclic mares has resulted in variable efficacy. Continuous or multiple treatments were more efficacious than a single treatment.

The nonapeptide deslorelin is a potent (relative potency of 114) analogue of the natural decapeptide GnRH. Recently, studies using deslorelin (6-D-tryptophan-9-[(*N*-ethyl-L-prolinamide]-10-desglycinamide) delivered by a novel release system (Ovuplant)* have shown the effects of deslorelin administration on ovulation.[36,37] Ovuplant is a biocompatible sustained-

*Ovuplant, Fort Dodge Animal Health, Fort Dodge, IA.

release subcutaneous implant and its registration by the FDA was achieved in June 1998 for sales in the United States. Deslorelin (Ovuplant) has become the first hormone approved for inducing ovulation in mares in the United States. Studies in Europe during the 1990 breeding season demonstrated that short-term implants containing deslorelin induced ovulation in cyclic mares comparably to 3000 and 5000 IU hCG.[36] Two dose-response studies, one in Australia[29] and one in the United States,[37] demonstrated that a dose of 2.2 mg deslorelin given as a deslorelin short-term implant was appropriate for reliable acceleration and induction of ovulation. Most recently, deslorelin has been shown to effectively induce ovulation in mares without diminished activity over three consecutive estrous cycles.[38] Recent field trials with deslorelin, delivered by a subcutaneous slow-release biocompatible implant, revealed an ovulation rate (within 48 hours of administration) of 88.2% for deslorelin-treated mares, compared with 37.7% in placebo-treated mares.[39] Ovuplant is currently available in the United States only in implants containing 2.1 mg of deslorelin already preloaded in an implanter designed for subcutaneous administration. Its efficacy in inducing ovulation in mares is comparable to that of hCG; however, the deslorelin implant is relatively more expensive than hCG (hCG costs approximately one sixth of Ovuplant price).

Ovuplant was well received in the market because in addition to being an FDA-approved drug, it was an attractive alternative to mares presumed to be refractory to hCG administration. Deslorelin, as opposed to hCG, does not induce antibody formation. During the second breeding season after Ovuplant was in the U.S. market, anecdotal reports discussed the increased number of mares that would have prolonged interestrous intervals had they not become pregnant in the cycle Ovuplant was used. In 2000 and 2001, Louisiana and Colorado researchers, respectively, reported that deslorelin could indeed induce prolonged interovulatory intervals in cycling mares; this effect was probably caused by a prolonged decrease of FSH plasma concentrations during the luteal phase that followed deslorelin-induced ovulations.[40,41] Soon thereafter, it was recommended to have the implant removed once ovulation was confirmed by reproductive examination to avoid prolonged effects of deslorelin.[42] Because it was relatively difficult to find the 3-mm pellet in the area in which it was applied, veterinarians begun to insert Ovuplant in the vaginal mucosa, just short from the vulvar mucocutaneous junction to facilitate the visualization of the pellet for its removal. Administration of $PGF_{2\alpha}$ to short cycle a mare in the diestrus following administration of Ovuplant is not recommended, especially if the bioimplant has not been removed. The use of Ovuplant is now, in addition to its relatively higher cost, associated with increased labor.

"Ideal Method" of Synchronizing Estrus and Ovulation

The variation in duration of estrus makes synchronization of ovulation difficult. Precise control over ovulation is necessary for success in embryo transfer programs. None of the methods described here is entirely effective for precise control of ovulation. When the above methods are used in combination, synchronization of ovulation is improved. In randomly cycling mares, synchronization of ovulation is improved when mares are treated with a combination of progesterone and estradiol rather than progesterone alone. Combining these hormones exerts a more profound negative feedback on LH and FSH release than progesterone alone, resulting in more uniform inhibition of follicular development. When exogenous progesterone and estradiol therapy is discontinued, a more uniform follicle population begins to develop in the ovaries, resulting in a more synchronous ovulation. Mares treated with this drug combination do not experience decreased fertility.

The protocol, originally developed by Loy and coworkers,[43] involves intramuscular injections of progesterone (150 mg) combined with estradiol-17β (10 mg) in oil for 10 consecutive days with a single injection of $PGF_{2\alpha}$ administered on the tenth day of treatment. After the combined steroid treatment regimen is discontinued, administration of hCG (2500 IU) IV or IM when a 35-mm follicle is detected will further improve ovulation synchrony. No commercial preparations of estradiol-17β are approved for use in horses. Estradiol cypionate and estradiol benzoate as substitutes for estradiol-17β in this synchronization scheme have not been investigated. It is likely that the prolonged action of these formulations would make their effects less predictable and therefore less desirable.[44]

POSTPARTUM MARES

Administration of ecbolic agents (e.g., oxytocin and $PGF_{2\alpha}$) has been advocated to enhance uterine involution and thereby improve fertility during the early postpartum period, but results of studies have been extremely varied and inconclusive.

Two methods are currently employed to postpone breeding during the postpartum period until normal pregnancy rates can be achieved. These methods delay the onset of foal heat or shorten the interval to the second postpartum estrus. Pregnancy rates achieved by breeding during foal heat appear to be higher in mares in which estrus is delayed by hormonal therapy.

In the first method, altrenogest is given orally (0.044 mg/kg/day) for 8 to 15 days after foaling,[45] followed by $PGF_{2\alpha}$ on the last day of treatment. Prostaglandin is given because progestin therapy alone may not prevent ovulation even though estrus is suppressed. If ovulation has occurred during altrenogest treatment, the resulting CL will continue to produce progesterone despite withdrawal of the exogenous progestin. Treatment with $PGF_{2\alpha}$ ensures that progesterone concentration will decrease and permit the mare to return to estrus, usually within 2 to 7 days. A combination of progesterone and estradiol-17β as described earlier also delays the onset of foal heat and ovulation.

Delay of foal heat with hormone therapy until after day 10 postpartum allows more complete uterine involution to occur, as evidenced by a greater proliferation of endometrial glands and increased endometrial gland density and ciliation of luminal epithelium.[46] Delaying

foal heat with progesterone likely improves the uterine environment and endometrial secretions necessary to sustain conceptus development.

One objection to the use of progestins for several days beginning at the time of foaling is that treatment delays the onset of foal heat and foaling intervals are not significantly reduced. If treatment of postpartum mares for 2 or 3 days after foaling would delay ovulation until just after day 10 post partum, hormone treatment might offer the best method for increasing pregnancy rates without significantly extending the foaling interval. There is also concern that treatment of mares with progestins during the early postpartum period might predispose to development of postpartum endometritis. Controlled studies, however, have not proved this premise.

Administration of $PGF_{2\alpha}$ 6 or 7 days after the first postpartum ovulation hastens the onset of the second postpartum estrus, which normally occurs approximately 30 days post partum.[5] Although this management technique is expected to increase the pregnancy rate at the first postpartum breeding, such is not always the case. The interval from foaling to first breeding will also be about 2 weeks longer than that associated with breeding during foal heat. About 1 week is saved by breeding during foal heat compared with waiting and breeding during the $PGF_{2\alpha}$-induced second postpartum estrus.

The ideal method to ensure optimal pregnancy rates at the first breeding regardless of whether it occurs during foal heat or during the subsequent estrus is to monitor postpartum mares by transrectal ultrasonography for ovulation and fluid accumulation within the uterus. Mares can be bred during foal heat if they do not ovulate before day 10 post partum and if normal uterine ovulation occurs; little or no fluid should be present when the mare begins its foal heat. Normal per cycle pregnancy rates can be expected under these conditions for mares bred at foal heat. If ovulation is expected to occur prior to day 10 post partum or if a significant amount of fluid is present within the uterus, the mare should be treated with $PGF_{2\alpha}$ 1 week after ovulation and bred instead during the induced estrus.

HORMONAL MANAGEMENT OF TRANSITIONAL ESTRUS

Since the 1970s, attempts have been made to hasten ovulation during the transitional season with progesterone or combinations of progesterone and estradiol. Although the mechanism of action is not completely understood, it is speculated that progesterone may act by causing a rebound release of LH following withdrawal of treatment.[20] The ability of progesterone to synchronize the first ovulation has been well documented, but the ability of progesterone to stimulate follicular development and hasten the first ovulation during the transitional season is debatable.[47] Administration of progesterone to mares that are on the verge of the first ovulation of the year may block estrus and synchronize the first ovulation, but administration of progesterone to mares earlier during the transitional season may not hasten the first ovulation. Altrenogest has been used frequently in attempts to hasten ovulation in transitional mares. Altrenogest is administered at 0.044 mg/kg/day for 15 days, and it is recommended that therapy not be initiated until the largest follicle exceeds 20 mm in diameter.

A number of preparations of progesterone and estrogen are currently in use but have to be prescribed by a veterinarian and prepared by a compounding pharmacy. Injectable progesterone (150 mg) and estradiol-17β (10 mg) administered daily for 10 to 15 days have been used to hasten ovulation in transitional mares. The addition of estradiol to the preparation results in more profound suppression of follicular development compared with progesterone alone. This therapy is frequently combined with a dose of $PGF_{2\alpha}$ on the last day of hormone administration to remove any luteal tissue that might be present in mares that have had a previously undetected ovulation.

Administration of a single dose of GnRH to anovulatory mares will result in a transient increase in LH and follicle-stimulating hormone release from the pituitary.[48] Thus, the pituitary gland is able to respond to exogenous administration of GnRH during the anovulatory season. A number of studies have demonstrated that administration of GnRH stimulates follicular development and ovulation in mares.[48] Several treatment regimens and GnRH analogues have been used to stimulate follicle development and ovulation during the anovulatory or transitional period in mares.[35] Early trials provided frequent (hourly) pulses of GnRH to stimulate gonadotropin release. Although pulsatile administration of GnRH may improve the response to therapy compared with continuous administration, a number of studies have shown that continuous administration of GnRH or an analogue is effective in stimulating follicle development and ovulation in treated mares. Administration of relatively potent GnRH analogues twice daily has also been effective in hastening the first ovulation in anovulatory or transitional mares.

Administration of GnRH or its analogues to mares during the anovulatory period reduces follicular response and ovulation in some mares. The response to GnRH therapy appears to be more predictable in mares that have entered the transitional period and in which some follicular development is present. Mares in deep seasonal anestrus require longer time to respond to exogenous GnRH, and these mares are more likely to return to an anovulatory state after an induced ovulation. Some mares induced to ovulate with GnRH during the deep anestrus period failed to form a CL. When ovulation was induced with GnRH during deep anestrus (follicles less than 15 mm in diameter), the pregnancy rate at day 11 after ovulation was 64%; however, the rate of pregnancy loss by day 40 was also 64%.[50] These losses appeared to be related to low serum progesterone concentrations and it appears that the CL formed after induced ovulation in mares during deep seasonal anestrus are not functional. When ovulation was induced in transitional mares with active ovaries, there was not an increase in the rate of embryonic loss. Therefore, the use of GnRH to induce follicular development and ovulation appears to have most benefit in mares that have entered the transitional phase and that have detectable follicular development (greater than 20 mm in diameter) at the start of treatment.

A variety of delivery systems have been used for the administration of GnRH.[51] These include the use of continuous delivery from an osmotic minipump implanted subcutaneously, which delivers its content over a number of days. Multiple injections (ranging from hourly to twice daily) have been used successfully, but this type of treatment is too intensive for practical application. Pulsatile delivery systems are available but the equipment is expensive and not used routinely. The most promising delivery system for the administration of GnRH to transitional mares is the use of controlled release implants that deliver a constant amount of the drug for up to a month.

Mares ovulated approximately 18 days after initiation of GnRH treatment during the transitional season. Fertility of mares induced to ovulate during the transitional season with GnRH appears comparable to that of control mares. Pregnancy rates for induced ovulations are high (80% in one study), although more work is required to characterize fertility of mares treated with GnRH during transition. Currently, the only options available for administration of GnRH to anestrous or transitional mares are by injection or an osmotic minipump. The use of multiple implants of deslorelin has been shown to induce ovulation in the early transitional mare; however, this regimen is not recommended because prolonged interovulatory intervals could result from the use of multiple Ovuplants in a short period of time.

Human chorionic gonadotropin may also be effective during the late transitional season to hasten the first ovulation. Administration of 3300 IU hCG to transitional mares with a follicle greater than 40 mm in diameter that have been in estrus for more than 3 days accelerated the first ovulation by approximately 1 week compared with control mares. The function of the CL that developed after ovulation was induced with hCG appeared normal. Because normally several (up to four) follicular waves occur during the transitional season, it may be difficult to determine whether a large follicle present on the ovary of a mare is growing or regressing. If the follicle is undergoing atresia, hCG will probably not induce ovulation. Therefore, it is important that follicular status be known prior to the use of hCG. This may require multiple examinations using ultrasonography to determine that the follicle is increasing in size and softening in texture.

In summary, the use of artificially prolonged photoperiods remains the most effective means available to hasten the onset of the ovulatory season in mares. The use of progesterone or progesterone and estradiol combinations during the late transitional season may synchronize the first ovulation, but it is uncertain whether this therapy will hasten ovulation. Administration of GnRH or its analogues over a 2- to 3-week period is effective in inducing ovulation in anovulatory mares. The response to GnRH therapy depends on the size of follicles present at the start of treatment. Mares with active ovaries (follicles greater than 20 mm in diameter) appear to respond more reliably than mares with smaller follicles. hCG can hasten the first ovulation of the year during the late transitional season if administered during the growing phase of follicle development and a well-developed uterine edema is present.

CHAPTER 11

Pregnancy Evaluation in the Mare

PATRICIA L. SERTICH

Effective management of broodmares requires that their pregnancy status be known so that proper managerial steps can be taken to ensure optimal care. At 14 to 18 days after ovulation, a mare that has been bred should be carefully examined for pregnancy; if the mare is not pregnant, steps can be taken to have her bred prior to the next ovulation. Early detection of twins is imperative for a successful reduction to a single pregnancy by manual crushing of one conceptus. If performed after 30 days of gestation, the procedure is less likely to result in a single, viable fetus. Ideally, mares that have been pronounced in foal should be teased three to four times per week and re-examined at approximately 30, 42, 60, and 120 days and again in the fall to monitor their reproductive status. If pregnancy loss has occurred, they can be rebred expeditiously if no obvious cause is detected that requires treatment. Broodmares that are not pregnant at the end of the breeding season should undergo a breeding soundness examination. Therapy, if indicated, can then be instituted and the mare's reproductive status be re-evaluated prior to the onset of the next breeding season.

Knowledge that a mare is pregnant allows one to make the decision to vaccinate for protection against equine herpesvirus I (rhinopneumonitis) periodically throughout gestation (3, 5, 7, and 9 months) and to administer other vaccines as appropriate for the geographic location 1 month prior to the mare's anticipated due date. Use of anthelmintics should be avoided the first 60 days of gestation during organogenesis, as well as during the last 30 days of gestation, when any abortion/stillbirth that might occur may be attributed to their use. Otherwise, appropriate anthelmintics approved for use during pregnancy (consult the product label and package insert carefully) should be administered periodically throughout gestation. The frequency of anthelmintic administration will be determined by the environment and animal density, but may be as often as every 6 to 8 weeks or even on a daily basis. During the last trimester, pregnant mares may need to be separated from open mares so that additional feed can be provided as necessary to maintain optimal development of the fetus. The pregnant mare herd should be isolated from any transient population to prevent exposure to infectious diseases. Mares greater than 300 days pregnant should be closely observed for signs of mammary gland development and impending parturition.

Several techniques are available to determine the presence of an embryo or fetus and the status of pregnancy. Some techniques are used to directly evaluate the conceptus or fetus; other techniques are used to indirectly assess the conceptus by evaluating changes in the mare's behavior, hormones, or genital tract that are due to pregnancy. The procedure used will be based on factors such as stage of gestation, temperament, size, reproductive or medical history of the mare, examination facilities, equipment available, intensity of management, financial constraints of the owner, value of the mare, and experience of the veterinarian.

BEHAVIOR

Although the absence of estrus may suggest the pregnancy status of some species, it is not a reliable indicator in the mare. Ten percent of pregnant mares may show estrus during pregnancy. Estrus during pregnancy typically occurs around 18 to 21 days after ovulation. Mares that experience pregnancy loss between 40 to 120 days of gestation typically do not come back into estrus until after the endometrial cups have involuted. Nonpregnant mares would likely fail to display estrus during the winter anestrous season.

PALPATION PER RECTUM

Characteristic changes occur in the mare's genital tract during pregnancy. Some changes are due to the response of the genital organs to hormone stimulation. Changes in dimensions of the uterus and the position of the genital tract within the pelvic canal are caused by an increase in size of the growing conceptus and increase in fetal fluid volume. The large size and tolerant nature of most broodmares permit evaluation of changes in the internal genitalia by palpation per rectum.[1] Careful, systematic palpation of the internal genital tract per rectum requires generous lubrication, gentle removal of feces, and adequate restraint of the mare. To prevent damage to the rectal mucosa, the tail should be wrapped or care taken to avoid inadvertently dragging tail hairs into the rectum during the examination. A water-soluble methylcellulose lubricant is recommended because it is not irritating to the rectal mucosa. The lubricant should be rinsed or wiped from the perineum after the examination to prevent chapping of the perineum. The rectum must

be emptied of feces so that the genital organs can be felt. Mares can be palpated per rectum while being held in hand, standing in a stall doorway or in stocks. A nose twitch may be required to more safely restrain restless or difficult mares. As with any exogenous medications, administration of tranquilizers should be avoided during pregnancy. Nonetheless, if the results of the examination are critical for making management decisions and there is risk of injury to the mare or examiner, chemical restraint of the mare may be necessary. Adequate relaxation may be achieved using acepromazine (0.05 mg/kg IV) alone. Xylazine (0.3–0.5 mg/kg IV) combined with acepromazine (0.05 mg/kg IV) has been used clinically to help nervous mares tolerate palpation per rectum. Although xylazine has little effect on fetal heart rate, it causes contraction of the uterus, increases uterine tone, and may induce premature parturition. Therefore, xylazine should be used with caution during the last trimester of pregnancy.

Cervix

As early as 16 to 18 days after ovulation, the cervix of the pregnant mare becomes tightly closed, firm, slender, and elongated. The portio vaginalis assumes a pointed shape. In multiparous mares, the cervix may not assume this character until 21 days after ovulation. These changes are not only due to elevated blood concentrations of progesterone but also due to "embryonic" factors not yet identified but thought to be associated with pregnancy. The cervix of the normal pregnant mare may remain closed until the mare goes into first stage labor, or it may soften and relax during the month prior to parturition.

Uterus

Careful evaluation of the uterine horns between 12 and 25 days of gestation will reveal a marked and gradual increase in uterine wall thickness. The endometrial folds are no longer palpable as folds of tissue rippling through one's fingertips. Instead the uterus becomes tubular, smooth, and firm with tone. This tone is caused by progesterone and embryonic factors. Distinct bends at the base of the uterine horns may be present at 20 to 22 days of gestation. The conceptus becomes positioned at the base of one of the uterine horns near the junction of the uterine body. Both the nongravid and gravid uterine horns on each side of the conceptus maintain a firm, tubular character as the conceptus increases in size. The uterine wall thins over the developing conceptus, which maintains a buoyant, vibrant quality throughout gestation. The uterine horns and body gradually lose the tubular tone after 48 to 55 days.

The conceptus develops in a recognizable pattern of size and shape, allowing an estimation of age based on its palpable characteristics. In maiden and barren mares, a careful, experienced clinician may be able to feel the embryonic vesicle ventrally at the base of one uterine horn at 17 to 25 days, producing a bulge 3.5 cm in diameter. At 30 days of gestation, both uterine horns will be small with prominent tone and the conceptus can be felt as a ventral bulge 4 cm in diameter and positioned at the base of the gravid uterine horn. The uterine wall becomes thinner over the expanding conceptus. At 42 to 45 days, the conceptus occupies approximately half of the gravid uterine horn and is 5 to 7 cm in diameter. The enlargement of the conceptus begins to involve the uterine body by 48 to 50 days and is 6 to 8 cm in diameter and 8 to 10 cm long. At 60 days of gestation, nearly the entire gravid horn and half of the uterine body are filled with conceptus, but the nongravid horn remains small. The 60-day conceptus is 8 to 10 cm in diameter and 12 to 15 cm in length. After 85 days, the turgidity of the conceptus decreases such that the fetus becomes palpable. At 90 days of gestation, the conceptus fills the entire uterus and the cranial portion of the uterus may extend over the brim of the pelvis into the abdominal cavity. After 100 to 120 days, the gravid uterus will be positioned cranial to the pelvic brim in the abdominal cavity. The ovaries will be positioned toward the midline, cranial and ventral to their normal nonpregnant position because of the ventral traction the enlarging uterus exerts on the broad ligament.

Expansion of the uterus is not a gradual filling process but rather alternately proceeds and recedes, apparently in response to transient segmental constrictions of the uterus. These constrictions seem to cause a reallocation of allantoic fluid. Reclosure of the uterine horns first occurs after day 106. Although the placental membranes interdigitate with the endometrium of the uterine horns, little fetal fluid remains in the uterine horns. At 150 days, palpation of the fetus is still possible. Between 5 to 7 months, the uterus is positioned ventrally in the abdomen and it is difficult to thoroughly evaluate the conceptus by palpation per rectum. From 6 to 7 months the horns are approximately perpendicular to the dorsal cranial aspect of the uterine body. As the conceptus continues to grow, it expands in a dorsal direction so that by 11 months the mesometrial surface of the uterine horns move closer to the dorsal surface of the uterine body and the fetus is within reach of the examiner when palpating per rectum.

Normally the fetus is active after 40 days and mobile after 70 days of gestation.[2] Fetal activity or movement of the head, mouth, and limbs and fetal mobility occur throughout the entire fetal stage of gestation. If one fails to immediately detect fetal movement during palpation per rectum in a later stage of pregnancy, it is advisable to be patient in assessing the presence of fetal activity. Several minutes may be necessary for a movement to be noted.

During early gestation (2 to 5 months) the presentation of the fetus changes owing to the fetal mobility. As fetal mobility decreases after 4 months of gestation the fetus is more likely to be in a cranial presentation. During the seventh to eighth month the hind limbs of the fetus enter the uterine horn containing the umbilical cord, and although the limbs remain active throughout gestation, they do not retract from this horn. Distinct parts of the fetus may not be discernible, and thus it is difficult to accurately assess fetal presentation solely by palpation per rectum. Fortuitous visualization of the orbit during an ultrasound examination per rectum or location of the

heart and stomach transabdominally with ultrasonography will permit a more accurate assessment.

Ovaries

The ovaries are active during early gestation. The primary corpus luteum forms from the follicle that ovulated the oocyte of the pregnancy and persists for 160 to 180 days. Numerous medium and large follicles are present on the ovaries between 40 and 60 days. Secondary corpora lutea form from ovulation and luteinization of these follicles. After 180 to 200 days, there is little ovarian activity and evaluation of the ovaries by palpation per rectum after 120 days is difficult because the ovaries are pulled ventrally under the broad ligament because of the weight of the enlarging gravid uterus.

VAGINAL SPECULUM EXAMINATION

Reproductive status can be ascertained without invading the internal genital tract by palpation and ultrasonography per rectum as well as by transabdominal ultrasonography. Nonetheless, reproductive status can be ascertained by evaluation of the cervix of the mare by direct visualization through an illuminated speculum. Speculum examination requires the mare to be restrained as for palpation per rectum. The tail should be wrapped to prevent hairs from entering the vaginal canal. The perineum should be washed with povidone-iodine scrub or mild soap, thoroughly rinsed, and dried. A sterile speculum, lubricated with sterile, water-soluble lubricant, is gently passed through the vulvar lips, vestibule, vestibular ring, and caudal vagina. An external source of light allows one to visualize the cranial vagina and the portio vaginalis of the cervix. It is not possible to prevent air from passing through the speculum, which may allow the introduction of microorganisms or induce straining by the mare. Iatrogenic pneumovagina is particularly a problem in thin mares, older or swaybacked mares, and mares with an incompetent vestibulovaginal ring. Manipulation (stimulation) of the cervix, particularly in late gestation, should be avoided because it may result in prostaglandin release and premature parturition.

The appearance of the cervix is directly related to the hormone milieu. During pregnancy, the cervix will be tightly closed by the influence of progestogens and unidentified substances produced by the conceptus. The portio vaginalis is yellow-gray, dull, dry, sticky, and in a central position in the cranial vagina. During the last month of pregnancy, the normal cervix may be soft or relaxed, so great care must be taken not to initiate an iatrogenic ascending infection.

ULTRASONOGRAPHY

The use of ultrasonography per rectum requires the mare to be handled and restrained as one would for examination by palpation per rectum. Thorough palpation of the genital tract must be performed before an ultrasound scan is made. A real time linear 5 to 10 MHz probe is used for reproductive evaluation per rectum, which produces a rectangular cross section image of the structure scanned. The resolution of a 2.5 to 3.5 MHz probe is less than that of higher resolution transducers, but its increased depth of penetration makes it useful for transabdominal scanning of late gestation mares. The use of the ultrasound transabdominally requires that the mare's abdominal hair be clipped and the skin generously lubricated.

The diagnosis of pregnancy in mares using ultrasonography was first reported in 1980.[3] This technology has increased veterinarians' ability to estimate gestational age and evaluate equine pregnancy considerably. Management of twins has improved and it is recommended that mares be examined for presence of twins by ultrasonography per rectum between 14 and 19 days. Success is good for reduction of a twin pregnancy to a singleton if the manual reduction procedure is performed before 30 days of gestation (Fig. 11-1, *A* and *B*). Comprehensive reviews of the changes in the developing embryo as seen by ultrasonography per rectum are available.[4] Characteristics of the late term fetus and its uteroplacental unit obtained by ultrasonography per rectum and transabdominally allow clinicians to evaluate the status of late pregnancies.

Early Gestation

Although most equine embryos enter the uterus as a morula or early blastocyst 6 days after ovulation, the conceptus is not large enough to be seen by ultrasonography per rectum until day 9 or 10, when it appears as a round (4 mm) nonechogenic structure in the uterine lumen (Fig. 11-2). The conceptus migrates throughout the uterine lumen until day 16, at which point it lodges at the base of one uterine horn. At day 17 or 18, the conceptus has a characteristic triangular shape resembling a guitar pick. The embryo proper can first be seen in the ventral portion of the yolk sac at day 21. The allantois develops from an outpouching of the hindgut and can be seen at day 21 or 22. A comparative increase in size of the developing allantois relative to the regressing yolk sac allows estimation of the age of the embryo. At day 24 or 25, a heartbeat can be seen in the embryo proper (Fig. 11-3). At day 28 to 30, the dorsal regressing yolk sac is nearly equal in size to the developing allantois (Fig. 11-4). This relative change in the fluid cavities continues until day 40, when the allantois occupies the entire fluid cavity surrounding the amniotic vesicle (Fig. 11-5). At this time it appears that the embryo is suspended from the dorsal wall of the uterine horn by its umbilicus. Over the next few days the umbilical cord lengthens and the fetus will come to rest on its dorsum on the ventral wall of the gravid uterine horn (Fig. 11-6). After 40 to 45 days, fetal movement may be detected.

The conceptus grows at a steady rate of 3.4 mm per day from days 11 to 16. A plateau of growth occurs between days 18 to 26, after which growth continues at approximately 1.8 mm per day until day 50. The growth rates of different horse breeds are similar for the first 28 days of gestation, but thereafter, the diameter of the embryonic vesicle of draft breeds will be 1 to 4 mm larger than light horse breeds.

Absence of a heartbeat after 25 days is a reliable sign of fetal death. Impending embryonic death may be

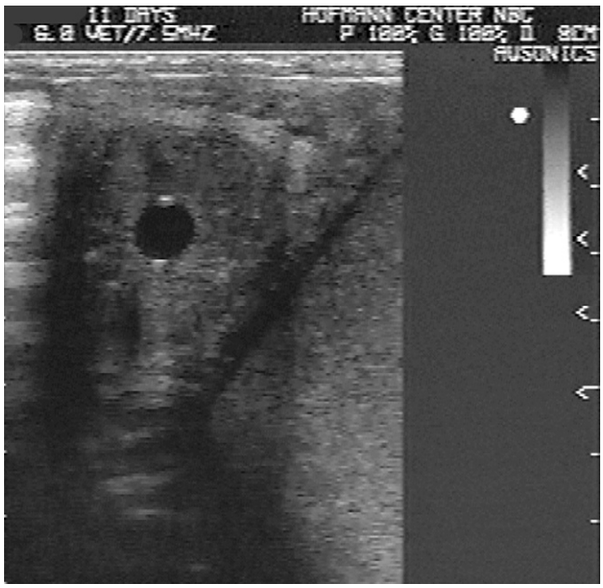

Fig. 11-2 An 11-day-old conceptus seen as a nonechogenic circle bordered by two white lines (specular reflection).

Fig. 11-3 The ventrally positioned allantois develops as a outpouching of the hindgut. The relative size of the dorsally positioned yolk sac continues to decrease as the allantois increases in size. A heartbeat would be obvious in a 25-day conceptus.

Fig. 11-4 At 28 to 30 days, the conceptus appears to contain two fluid compartments of equal size (yolk sac dorsally on left, allantoic cavity ventrally on right).

Fig. 11-5 A 38-day conceptus. The yolk sac is quite small relative to the enlarging allantois.

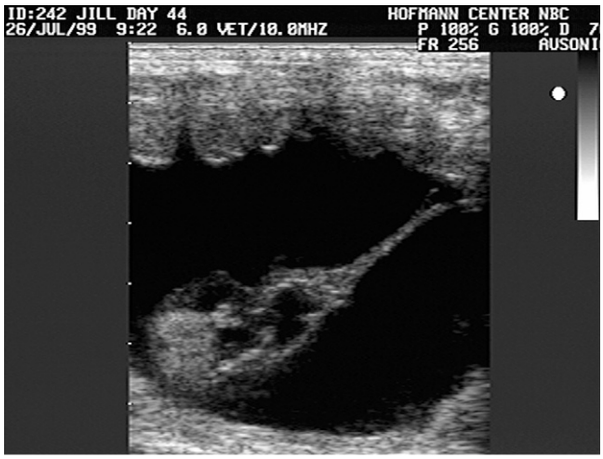

Fig. 11-6 A 44-day conceptus. The fetus has dropped to the ventral portion of the conceptus, and its umbilicus is attached dorsally to the allantois.

predicted by several characteristics seen ultrasonographically. Any increase in echogenicity of the normally nonechogenic early conceptus indicates an increase in the cellular content of the embryonic fluid. Inadequate size for the stage of gestation may indicate impending embryonic death. Subsequent to reduction of a twin pregnancy to a surviving singleton, orientation of the membranes within the conceptus may be atypical with regard to positioning of the developing allantois in relation to the regressing yolk sac. When embryonic shape is abnormal or the outline of the conceptus appears irregular such that endometrial folds can be readily seen, the abnormality is thought to be due to a decrease in surface tension of the conceptus caused by a decrease in embryonic fluid.

Fetal Sexing

Ultrasonography can be used to determine the sex of an equine fetus by imaging the position of the genital tubercle between 55 and 90 days of gestation.[5] The precursor to the clitoris in the female and the penis in the male, the genital tubercle appears as a hyperechoic bilobed structure located on the ventral midline of the fetus between the umbilicus and the tail. Each lobe of the tubercle is oval and elongated. Although the genital tubercle is first visible on examination by ultrasonography per rectum between 40 and 54 days, prior to days 55 to 59 it is in an undifferentiated position between the hind legs that does not allow sex determination. After 55 to 59 days the genital tubercle is positioned just caudal to the umbilical cord in a male and just cranial to the tail in a female. Examinations per rectum are most easily and accurately performed between 59 and 68 days. As the gravid uterus increases in size it becomes more difficult to reach the genital positions per rectum. Between 3 and 5 months of gestation, the external genitalia of the fetus (clitoris and mammary glands of the female, prepuce and penis of the male) may be imaged by ultrasound examinations per rectum (using a 2.5 to 3.5 MHz transducer) if the fetus is in caudal presentation. After 100 to 120 days of gestation the external genitalia may be imaged by transabdominal ultrasonography.

Accuracy of sexual determination can be excellent if an experienced ultrasonographer has optimal visualization of the fetus. Ideal examination conditions should include a high-quality ultrasound machine with at least a 5 MHz transducer on a transrectal probe, low external light, ultrasound monitor positioned at eye level close to the examiner, a cooperative mare that will stand still with minimal rectal straining, and the opportunity to repeat the examination on a later date if necessary. High-resolution ultrasound transducers (7.5 to 10 MHz) with an adequate depth of penetration will enhance the visualization of the fetal parts. An ultrasound machine equipped with a cine feature will allow the operator to review previously scanned images frame by frame. The accuracy of the diagnosis is not only dependent on the examiner confirming the presence of the genital tubercle in the appropriate position for the sex of the fetus, but also on the determination that the genital tubercle is absent from the genital position of the opposite sex. If both of these conditions are not imaged repeatedly during the examination, the accuracy will be less than optimal.

The entire fetus should be observed and the position of the beating heart, anechoic stomach, tail, limbs, and umbilical cord noted. Although a sagittal section is useful to identifying body parts and to determine the orientation of the fetus, it is not particularly useful for identifying the genital tubercle. The presence or absence of the genital tubercle in a frontal plane, and a transverse cross section positioned through the inguinal region of the fetus should be determined (Fig. 11-7). A positive male view and a negative female view must be imaged to confirm that the fetus is a male. Conversely, a positive female view and a negative male view are necessary to confirm that the fetus is a female.

Late Gestation

Assessment of the late gestation conceptus is limited with ultrasonography per rectum because only the cervix and only a small amount of the caudal uterine contents can be visualized. During the first two trimesters of gestation, the fetal fluids tend to be nonechogenic; however, in the last part of pregnancy, it is normal for a slight to moderate amount of echogenic particles to be dispersed throughout the allantoic fluid. After a period of fetal activity, swirls of echogenic material can be seen in the amniotic and allantoic fluids. Excessive amounts of echogenic particles can indicate placentitis, dehydration, or fetal diarrhea.

The uteroplacental unit, which consists of the chorioallantois and the endometrium, tends to increase in thickness as gestation progresses. Normally the uteroplacental unit is less than 12 mm thick even near term. A uteroplacental thickness greater than 12 mm may be associated with placentitis, placental edema, or placental separation. Small areas of separation between the chorioallantois and the uterus can be seen in an uneventful, normal pregnancy. Near term the chorion immediately over the cervix may separate slightly as the cervix relaxes. It is not unusual for the chorioallantois sur-

rounding the insertion of the umbilical cord to be separated from the endometrium. Extensive areas of fetal membrane thickening and separation of the chorioallantois in the uterine body (Fig. 11-8) may signal impending premature separation of the fetal membranes at the time of parturition.

Fortuitous identification of the round anechoic orbit of the fetus during an examination using ultrasonography per rectum indicates cranial presentation. Ranges of orbit diameter, rib diameter, intercostal space, and trunk, stomach, and brain case size in Thoroughbred and Standardbred mares have been established to permit estimation of fetal age.[6]

After 120 days of gestation, transabdominal ultrasonography can be used to assess the intrauterine environment and fetal status.[7] Number of fetuses present, fetal presentation and position in the uterus, fetal heart rate and activity, and character of the fetal fluids and placenta can be determined. Deviations from the normal profile may indicate the pregnancy is at risk and should prompt preparations to be made for management of a compromised neonate at parturition.

ENDOCRINOLOGY

It is critical that the normal endocrinology of pregnancy be understood in order to use endocrine analysis for the diagnosis of pregnancy.[8] Endocrine assays are available, but none are useful at all stages of gestation. One must use these tests at the appropriate stage of gestation and be aware of their specificity so that interpretation of the results will be of clinical value. These tests are most valuable when used in conjunction with other methods of pregnancy detection.

One should check with the laboratory that will perform the assay for their specific guidelines on sample handling. Assays are usually performed using serum or plasma obtained from blood collected in clot (red top) or heparinized (green top) tubes. The sample should be nonhemolyzed and kept cool. Serum or plasma should be harvested from the clotted or heparinized sample shortly after procurement. Samples requiring accurate quantitation should be centrifuged soon after procurement to separate the red blood cells. Aspirated serum or plasma can be frozen and transported on cold packs by express delivery service. Many endocrine laboratories perform equine reproductive hormone analyses. Laboratories experienced with interpreting equine reproductive hormone test results can provide valuable information for the clinical management of broodmares (Box 11-1).

With radioimmunoassay (RIA), serum or plasma samples are mixed with known quantities of radioactive labeled hormone. The amount of radioactivity detected in the sample is measured and that value is compared to a set of known standards of concentrations to determine the unknown concentration in the sample. Radioimmunoassays have specific and accurate results; however, they are time-consuming and require a technician and laboratory capable of handling radioactive materials.

Enzyme-linked immunosorbent assays (ELISA) using highly specific monoclonal antibodies and enzyme-induced color changes allow for fast, easily obtained results. Use of monoclonal antibodies in assays allows for less cross reactivity with related substances than polyclonal antibodies. ELISA may be qualitative or quantitative and simple assay kits are available that can be performed in a veterinary clinic. Expense may be reduced because samples do not need to be transported long distances and laboratories do not need to meet strict regulations regarding use of radioactive materials.

Progestins

Mare blood progesterone concentrations indicate the presence or absence of luteal tissue and are not diagnostic for pregnancy. Progesterone concentrations less than 1 ng/ml at 18 to 21 days after ovulation suggest that a mare is not pregnant. The primary corpus luteum produces progesterone and systemic blood concentrations increase to greater than 4 ng/ml during the first 3 weeks of pregnancy, after which there is a slight decrease. Secondary corpora lutea produce a second rise in plasma progesterone after days 40 to 45, and concentrations plateau in the blood between 65 and 90 days. Thereafter,

progesterone concentrations normally decline so that by 150 to 180 days, plasma progesterone concentrations are negligible (<1–2 ng/ml). At approximately 60 days, the conceptus or fetal placental unit begins to produce progestogens other than progesterone (primarily 5α-pregnanes) that are detectable in the maternal circulation. Results of a specific progesterone assay using gas chromatography/mass spectrometry on pregnant mare blood samples obtained after 60 days of gestation would normally be low.

The antisera used in radioimmunoassay and other immunoassays for progesterone will cross-react with 5α-pregnanes, resulting in an overestimation of progesterone in the blood of mares in late gestation. At present, gas chromatography/mass spectrometry is not available commercially for field use to specifically measure these progestogens. However, less specific assays can measure total progestogens and be of diagnostic value. Any progesterone test should be used in conjunction with other methods of pregnancy diagnosis.

Equine Chorionic Gonadotropin

Chorionic girdle cells of the conceptus invade the mare's endometrium to form endometrial cups. These cups start to produce equine chorionic gonadotropin (eCG) between days 35 and 42. Concentrations of this hormone peak at 55 to 65 days and, as the endometrial cups normally involute, decrease to baseline by 120 to 150 days. If the conceptus dies, the endometrial cups usually maintain their production of eCG until 120 to 150 days of gestation. Accordingly, use of an eCG assay for a pregnancy test has limitations. One must be certain of the breeding date of the mare, and blood should be sampled between 40 and 120 days after ovulation to avoid false negative results. It must be remembered that elevated plasma concentrations of eCG indicate that the mare had endometrial cup formation. False positive results may be obtained if the fetus dies between 40 and 120 days.

Several assay systems have been used to measure concentrations of eCG, including RIA, radioreceptor assay, hemoagglutination inhibition test, polystyrenic agglutination test, ELISA, and direct latex agglutination. The time and technical requirements of the radioimmunoassay and radioreceptor assay preclude their use in clinical veterinary practice. Although only a small amount of eCG is excreted in urine, assays are available for eCG analysis of urine samples. Assay test kits are available to practitioners (see Box 11-1) and may be valuable when used as directed in mares with known breeding dates, particularly in miniature horse mares or fractious mares that will not tolerate palpation and ultrasonography per rectum.

Estrogens

Estrogen is produced by the conceptus as early as day 12, but concentrations of estrogens in maternal blood are not detectable until after 35 days. Estrogens may be bound to sulfates (conjugated) in the serum or plasma or be free (unconjugated). The concentrations of conjugated estrogens are 100 times greater than unconjugated estrogens. Equilin and Equilenin are ring-B saturated estrogens unique to the mare and present in the urine after 4 months of gestation. Estrogens have been measured in feces and urine.

Although serum concentrations of estrone sulfate increase a few weeks after conception, a dramatic increase occurs after 60 days of gestation that can be detected to diagnose pregnancy. After 150 days of gestation, the conceptus produces sizable amounts of estrone sulfate, which are excreted in the mare's urine. Estrone sulfate concentrations not only indicate that the mare is pregnant, but provide information on the well-being of the conceptus. Concentrations of estrogens decrease rapidly if fetal death occurs. Biologic tests have been replaced with chemical assays for estrogens. Radioimmunoassay combined with column chromatography separation was developed to measure low concentrations of estrogens early in pregnancy. Estrogens can be measured in a blood, urine, fecal, or milk sample. Simpler chemical tests are available that can easily measure the high concentrations of conjugated estrogens in urine, including the Cuboni test.

CHAPTER 12

Retained Fetal Membranes

WALTER R. THRELFALL

The functions of the fetal membranes, also referred to as the placenta, and fluids are to supply nutrition to the fetus, remove waste products from the fetus, exchange oxygen and carbon dioxide between the mare and the fetus, and serve as the major source of protection to the fetus.[1,2] The amniotic fluid, which averages approximately 8 L at term, serves to protect the fetus from external mechanical injury and acts as a bactericidal medium in which the fetus can develop. It also serves as a slippery mucous fluid that prevents the fetus from becoming attached to the developing fetal membranes. The primary source of amniotic fluid is fetal nasopharyngeal secretions and saliva.[1] The allantoic cavity stores fetal urine until such time as it can be removed by the circulation to the mare. Urine enters the cavity through the urachus and reaches approximately 18 L by term. This fluid-filled cavity also acts to protect the fetus against external trauma. Hippomanes are generally located in the allantoic fluid and are formed from sediment and debris plus mucoproteins and calcium phosphate found in urine. Generally at least one hippomane is present but frequently two or three may be found. There is no clinical significance attached to their presence.[1,2]

The fetal membranes must be examined following parturition to evaluate the attachment surfaces that existed during gestation and to determine the appearance of all other aspects, which may be normal or abnormal. The attachment surface of the chorioallantoic membrane is an excellent indicator of the endometrial surface during that gestation and possibly future pregnancies. Examination of the fetal membranes during gestation is also possible using ultrasonography and can be used to aid in the diagnosis of placentitis. Routine pregnancy examinations are performed by rectogenital examination at greater than 50 days of gestation unless there is reason to suspect a problem with the pregnancy. Indications of problems include vulvar discharges, premature udder development, edema of the ventral abdominal wall, illnesses or injuries of the mare that may affect the fetus and the pregnancy, extreme enlargement of the abdomen, and in some instances, prolonged gestation. In addition to evaluation of the fetal membranes during ultrasonographic examination, the fetus and fetal fluids should be examined. The thickness of the near-term amniotic membrane is approximately 2 mm.

Postpartum examination of the placenta is an excellent diagnostic aid, because the expense is minimal and the evaluation can be rapidly performed. The membranes can be inspected during the same visit in which the foal is examined. If the environmental temperature is high, the placenta should be refrigerated until it is examined to preserve many important characteristics. The first characteristic to observe is the location of the chorionic side of the membranes. This side should be inverted, with the allantoic side outermost, if the delivery was normal. The chorioallantoic membrane should be examined for thickness, absence of villi, and any area of abnormal color or appearance. The weight of the placenta, although previously stressed as being important, is probably the least significant placental characteristic and the author has chosen to eliminate this portion of the examination because of a lack of correlation of placental weight to any specific problem.

The next part of the examination is to carefully visualize the entire surface of the chorioallantoic membrane and place it in the T shape that normally exists; the gravid horn makes one side of the T much larger than the other. Several small sacculations may be present near the junction of the pregnant horn and body of the uterus on the allantoic surface. These areas contain sloughed endometrial cup material.[1,3] Another sacculation may be attached to the umbilical cord and can be fluid-filled and up to 20 cm in length.[4] The umbilical cord is composed of two arteries, a vein, and the urachus, plus lymphatics. One artery originates from each of the two horns.[2] Twisting of the umbilical cord is normally very common and makes the diagnosis of umbilical torsion and occlusion somewhat more difficult than it is in other species. The normal approximate length of the twisted umbilical cord is 50 to 60 cm.[1,2] It has been proposed that shorter-than-normal umbilical cords can result in umbilical herniation. It has been reported that umbilical cord torsion can result in vascular occlusion and urachal occlusion, which may result in death of the fetus and abortion or previous urachus and predisposition to rupture of the bladder.

The next portion of the examination is the amnion. This is examined to determine whether meconium is present. Meconium presence generally indicates a problem with fetal oxygenation resulting in fetal distress near term or partutrition.[1] The chorionic side of the allantochorionic membrane can be examined in detail following inversion so that the allantoic portion is once again internal to the chorionic surface. This examination provides an evaluation of the mirror image of the attachment surface that existed during gestation and cannot be replaced by any other diagnostic test. The surface should ideally be roughened with the presence of villi except where the papillae of the oviducts enter the uterus, where placental folds exist because of overlapping in the areas adjacent to the endometrial cups, where the yolk sac attachment existed, and where the internal os of the cervix was located.[4] Any abnormal condition such as

endometrial fibrosis, placentitis, or uterine cysts can reduce the attachment surface available and may be sufficient to result in fetal growth retardation or loss.[5] The tips of the chorioallantoic membrane near the apical end of the uterine horns are frequently edematous, with the gravid horn more often affected than the nongravid one.[1,4]

Placentitis caused by infectious organisms may account for up to approximately 16% of equine abortions. Streptococcal organisms were reported to be the most likely cause of placentitis, representing approximately 23% of those diagnosed. *Escherichia coli, Pseudomonas* spp., *Klebsiella* spp., and *Staphylococcus* spp. have also been reported as important causes of bacterial placentitis.[6] Fungal infections of the fetal membranes account for approximately 41% of abortions reported by several investigators. Viruses account for the remainder of the infectious placentitis causes of abortion.[1,2,6] Organisms enter the uterus through the cervix or by hematogenous spread. Organisms that enter by the cervical route include those that enter the uterus prior to or at the time of breeding and do not manifest themselves as a clinical problem until abortion. Ascending infections may result in lesions located near the internal cervical os.[1,6] Less than normal vulvar conformation can result in bacterial contamination of the vagina and cervical inflammation. This may cause the cervix to relax and bacteria or fungi to enter. It has also been suggested that cervical relaxation may also occur during transition of pastures from poor to lush vegetation. Bacterial infections that are acute in onset result in abortion, whereas chronic infectious often result in fetal growth retardation or emaciation.[1] Lesions associated with infections of the placenta include inflammation and thickening. The nature of the amniotic fluid may prevent spread of bacterial organisms directly to the fetus, but entry is possible by invasion through the umbilical vessels and cord.[6]

There was reportedly an increase in mycotic placentitis associated with the use of intrauterine antibiotics and with increased manipulations, which result in entry of these organisms into the reproductive tract. The chorioallantoic membrane may increase in thickness by five to ten times.[6] The amnion is involved in fungal infections in only approximately 10% of cases, and the fetus may have the characteristic appearance of thickened and roughened skin. Severe placentitis accompanying fungal infections restricts nutrient supply to the fetus and reduces fetal size.

Retention of the fetal membranes is reported to be the most common problem in postpartum mares. Authors consider failure of passage of part or all of the allantochorionic membrane with or without the amniotic membrane within a predescribed period of time as retention of the fetal membranes. The length of time varies among authors from 30 minutes to 6 to 12 hours.[2] Retention of fetal membranes has also been described as retained placenta or retained afterbirth. This condition is reported to occur with a frequency of 2 to 10.5%. It is difficult to determine from the literature an exact incidence because variation exists in the point of time post partum at which a placenta is considered to be retained. Retained placenta is more common in draft breeds than in medium- or lightweight breeds. Following dystocia or prolonged gestation, there is also an increase in the incidence of retained fetal membranes. Dropsy of the fetal membranes and cesarean section have been related to an increased incidence of retained fetal membranes. There is disagreement between authors as to whether there is an increased incidence of retained fetal membranes following abortion, stillbirth, or twinning in lightweight horses. It appears that there may be no increase unless these conditions coexist with dystocia.

A more recent study found the following relationships to retained fetal membranes: mares that were bred naturally versus those that conceived by artificial insemination have an increased incidence of retained placentas when the breeding occurred at foal heat.[7] There was no reported difference in placental passage in mares artificially inseminated at foal heat versus mares artificially inseminated at second, third, or later postpartum estrus. In mares that were barren or maiden or had foaled the previous year, there was no difference in the incidence of retained placenta following parturition. In mares older than 15 years of age there was a higher incidence of retained fetal membranes than there was in mares that were younger.

Time of year appeared to influence the incidence of retained fetal membranes only on certain farms, with a higher incidence after March 31. The sex of the foal did not influence the incidence of retained fetal membranes. There was no reported difference in the retention incidence between the birth of weak or diseased foals and that of healthy foals. During normal parturition, separation occurs between the allantochorionic membrane and the endometrium during stage III of labor. The mechanism responsible for separation is believed to involve cessation of blood flow through the umbilical cord and the corresponding collapse of fetal placental vessels and decrease in size of chorionic villi.[2] This is followed by uterine contractions, which enhance reduction of uterine size and separation of chorionic villi. Uterine horn contractions originating nearest the ovary and progressing toward the body of the uterus aid in separation and expulsion of fetal membranes from the uterine lumen. As the placenta enters the cervix, its presence enhances the release of oxytocin and results in increased uterine and abdominal contractions. Once the placenta passes between the vulvar lips, the weight of the placenta aids in expulsion by applying gentle pressure and stimulating separation.

Causes of retained fetal membranes are uncertain at the present time. A variety of situations or circumstances are related to retention of fetal membranes, but no specific single cause has been described. It is known that complete separation of the placenta cannot occur until the microvilli are released from the maternal crypts. These microcotyledons are firmly attached to the endometrium by the seventh month of gestation. It has been suggested that in mares with retained fetal membranes, retention is not necessarily caused by attachment of the fetal membranes in both uterine horns but rather in the previously gravid horn or the nongravid horn. An additional report suggests that attachment and failure to separate does not necessarily occur in either of the horns

but actually occurs in the body of the uterus. It appears, however, that the majority opinion favors the failure of the previously nonpregnant horn to separate from the fetal membranes. Characteristics of the placenta that may account for the difference in horn separation include variations in allantochorion thickness, length of the villi, and the degree of attachment of the fetal membranes in the gravid horn or in the nongravid horn. Furthermore, because of the success of oxytocin therapy in mares with retained fetal membranes, it has been speculated that a hormonal imbalance accounts for membrane retention. It has been suggested that more microvilli are present in the uterine horns than in the body of the uterus and that these microvilli are much more branched and larger than in the nonpregnant horn. Reportedly, folding of the fetal membranes and the endometrium occurs more commonly in the nongravid horn than in the previously gravid horn or body of the uterus. Uterine involution may occur at a slower rate in the nongravid horn than in the previously gravid horn or in the uterine body. It is possibly one of these phenomena, a combination of two or more, or unknown events that are responsible for retention of fetal membranes in mares. Furthermore, the edema of the placenta may be partially responsible for retention. Edema apparently is more prevalent in the gravid horn than in the nongravid horn, which would add support to the hypothesis that the gravid horn is the primary site of fetal membrane retention.

Endometritis or inflammation of the uterine lumen during pregnancy has been suggested as a possible cause of fetal membrane retention. Inflammatory responses could create adhesions between the chorioallantoic membrane and the endometrium and delay separation of the fetal membranes. These infections could be introduced during breeding, could enter the uterus through the cervix during gestation, or could spread to the uterus via the blood. In addition, it has been postulated that air entering the uterus immediately following expulsion of the fetus could be a source of bacteria and other substances that could be responsible for a subsequent inflammatory response.[2] It is difficult to believe, however, that substances entering the uterus at the time of parturition could create circumstances that lead to endometrial inflammation, placental edema, decreased effectiveness of oxytocin, or any of the other possible causes of retained fetal membranes within a few minutes following parturition. The theory that bacteria enter the uterine lumen at breeding and remain dormant for a prolonged period of time appears to have more credibility than that of bacteria that enter at the time of parturition in regard to an effect on fetal membranes. It has been reported that infections occurring between the fetal membranes and the endometrium are much more prevalent near the external os of the cervix and the surrounding area of uterine body than at any other location within the uterine lumen. Because this area is rarely involved in fetal membrane retention, it appears that infection as a cause of fetal membrane retention is not a high probability.

Mares with retained fetal membranes reportedly do not exhibit the usual signs of colic and abdominal straining immediately post partum that occurs in mares that pass the placenta normally. If a hormonal imbalance were responsible for failure of myometrial contractions that normally occur after foaling, this would account for a decreased occurrence of straining and abdominal pain. Furthermore, excellent results have been reported with oxytocin in the treatment of retained fetal membranes.[8] Oxytocin normally increases in the blood during the second and third stages of a normal parturition. Furthermore, oxytocin has been used to induce parturition, and increased doses reduce the time to the second and third stages of labor.

It has also been suggested that uterine inertia can be caused in mares by a decrease in the concentration of blood calcium; overstretching of the myometrium, which is seen in cases of hydrops allantois, twinning, or oversized fetuses; and in cases of myometrial degeneration resulting from bacterial infection. Uterine inertia has also been incriminated following premature deliveries when the proper sequence of hormonal interaction has not been established. In one mare with retained fetal membranes, high concentrations of progesterone persisted, in contrast to the decrease observed in unaffected mares. Relaxin concentration was reported to remain elevated in a mare with retained fetal membranes. It has been suggested that the presence of retained fetal membranes within the lumen of the uterus serves as a continued source of relaxin. The function of prostaglandin $F_{2\alpha}$ remains unknown in the normal physiologic passage of fetal membranes.

Clinical signs of retained fetal membranes primarily consist of a portion of the membrane protruding from the vulvar lips. The degree of membrane protrusion varies from a few centimeters to a situation in which the placenta protrudes from the vulva to the ground. Retained fetal membranes can be present without any visible signs. In affected mares, the entire fetal membrane or a portion thereof is retained within the uterine, cervical, or vaginal lumen. Diagnosis in these cases is more difficult than in those in which the fetal membranes are apparent. Retained fetal membranes that protrude from the vulva generally create no adverse side effects unless the placenta irritates the mare and causes her to kick at the placenta. Some mares unintentionally kick their foals while trying to get the placenta away from their hocks. For this reason it is suggested that the placenta be tied in a knot ventral to the vulvar lips. Another suggestion has been to place the placenta in a plastic sleeve and tie it so that the placenta is included inside the plastic sleeve. This can be done in such a way to keep the placenta from touching the hocks or distal extremities.

The complications most frequently reported following retained fetal membranes include metritis, laminitis, septicemia, and death of the mare.[9] Acute metritis and laminitis appear to be more of a problem in the draft breeds than in the medium- to lightweight breeds. It has also been suggested that the risk of uterine infection and delay in uterine involution increase with the duration of placental retention. This observation resulted in veterinarians removing the retained fetal membranes manually from the mare's uterus. This is no longer a recommended treatment. The relationship between laminitis and retention of the fetal membranes was thought to be the result

of the delay in uterine involution because the environment is suitable for bacteria to multiply within the uterine lumen and result in absorption of bacteria and toxins.

Many types of gram-negative organisms capable of producing endotoxin and causing histamine release have been found in the uterus with retained fetal membranes.[2] In a report of 356 Standardbred mares with retained fetal membranes in which the fetal membranes were not manually removed, there were no reported cases of acute metritis, septicemia, toxemia, or laminitis during or following passage of the placenta.[7] It should also be noted that postpartum laminitis can occur as a result of systemic acute metritis with or without a retained placenta.[10] Septic or toxic metritis can result in systemic signs of elevated body temperature, changes in disposition, and changes in appetite. However, toxic or septicemic metritis can occur in the absence of obvious retained fetal membranes. There may be retention of many microvilli in large areas where they have broken free from their attachments and remained embedded in the maternal crypts of the endometrium. This is the primary reason that manual removal or attempts to separate retained fetal membranes from the endometrium should be avoided.[2] Although a major portion of a retained fetal membrane could be removed manually, the large number of remaining microvilli can serve as foci of infection and inflammation with fluid accumulation within the uterine lumen. It is imperative that following expulsion of fetal membranes the chorionic surface be examined carefully to determine its gross appearance.

Laminitis may occur when large numbers of microvilli remain attached to the endometrial surface, which is followed by systemic involvement from septic uterine contents or related to histamine release by the uterus. Laminitis has been attributed to degenerative changes that occur within the tissue between the third phalanx and the hoof wall. This is in contrast to the normal sequence of events, which include toxic capillary injury and edema. The substances produced within the uterus may also have a direct effect on the sensitive lamina of the hoof. The specific mechanism involved in the development of laminitis following septic metritis is not known. Two possibilities have been suggested that involve a vasoactive component and a coagulation component. The relationship of hormones or toxins acting on digital vessels and thus altering the circulation of blood to the feet has been included in what has been known as the vasoactive component. Furthermore, it has been suggested that peripheral blood circulation increases immediately postpartum because of a reduction in uterine size and increase in uterine tone, thus moving blood from the uterus to the peripheral circulation. It is suggested that this is the vasoactive component of laminitis. The coagulation component is thought to be related to intravascular coagulation and fibrogen degradation products; thus, treatment with heparin has been recommended to reduce the incidence of laminitis.

Laminitis associated with retention of fetal membranes or, more specifically, with toxic or septic metritis, is similar to that which occurs following gastrointestinal involvement. The initial signs of laminitis occur 2 to 4 days following the onset of septic or toxic metritis. At that time, the animal exhibits an unusual gait and unusual stance by attempting to bear more weight on the rear limbs than on the forelimbs; thus, the rear limbs are placed further forward under the animal than normal. In such a case, the hooves of the horse are warmer to the touch than normal and a characteristic pulse may be present in the digital artery. Many affected animals spend the majority of their time lying down or stationary in a standing position.

The literature suggests that any animal with retained fetal membranes be treated to prevent laminitis. This includes the use of ice or cold water foot baths, suitable footing, and intrauterine and systemic antibiotic therapy to prevent septic metritis. Substances such as antihistamines, phenylbutazone, nonsteroidal anti-inflammatory drugs, and tranquilizers have been included in recommended therapy for retained fetal membranes. Antihistamines apparently neither prevent nor cure laminitis following retained placenta and their use is not recommended. It has also been suggested that the quantity of roughage be reduced in animals demonstrating signs of laminitis and that grain be completely eliminated from the diet.[2] Some authors recommend flushing the uterus when septic or toxic metritis is present or manually removing the placenta immediately to reduce the possibility of laminitis.

It is this author's opinion that neither flushing the uterus nor manual removal of the placenta is indicated in mares with uncomplicated retained fetal membranes or in mares affected by septic or toxic metritis. As stated previously, manual removal of the placenta may result in separation of microvilli from the larger portion of the fetal membranes. In such instances, the microvilli then have to liquefy from the maternal crypts and be expelled or be absorbed by the uterus. Whenever manipulation of the uterus is performed, either for the purpose of manual removal of retained fetal membranes or in uterine lavage, there is an increase in blood supply and potentially an increase the absorption of substances from the uterine lumen into the circulatory system. If these substances are of a septic or toxic nature, manipulation of the placenta or flushing of the uterus generally initiates a deterioration in the mare's general clinical condition. Such treatment may be more detrimental than beneficial. Excellent results have been obtained with conservative therapy involving systemic medications, including antibiotics and supportive care when indicated during the first 2 days post partum. The conservative approach in treating retained fetal membranes permits the mare to establish the normal physiologic barrier that is responsible for prevention of septic or toxic signs following parturition in most mares. This supportive care may include systemic antibiotics, anti-inflammatory drugs such as phenylbutazone or flunixin meglumine, and systemic fluids if required. This approach to treatment of retained fetal membranes generally results in improvement in the mare's condition within 24 to 48 hours. Once improvement has occurred, local treatment of the uterus may be initiated. Frequent measurement of body temperature

and complete blood counts in systemically affected mares demonstrates subclinical relapses following manipulation of the uterus for examination, uterine infusion, or uterine lavage.

Treatment of retained fetal membranes varies widely and each has its advantages and disadvantages. The first reported treatment for retained fetal membranes was manual removal. A variety of methods are described in the literature for manual removal of fetal membranes from the uterus of a mare. These methods include grasping the free portion of the fetal membrane protruding from the vulvar lips and applying traction; inserting the hand between the chorion and the endometrium to force separation of the two; placing the hand between the chorion and the endometrium, applying massage rather than simply using the hand as a wedge to separate the two structures; grasping the chorioallantoic membrane and twisting it, thus forcing separation of the fetal membranes from the endometrium; and, possibly the most complex, placing a wooden ring over the fetal membranes and forcing it between the membranes and the endometrium.[2] It has been recommended that the time between parturition and manual removal be anywhere from immediate to 24 hours. The primary rationale for early removal is to avoid delay, thus reducing the time required for uterine involution and reducing the possibility of uterine infection. In the same report, however, the author states that manual removal of fetal membranes delays uterine involution. Several vaginal examinations at 4- to 12-hour intervals may be necessary to manually remove fetal membranes without causing injury to the mare. It was furthermore suggested that the membranes be manipulated no longer than 10 minutes at each visit.

Although manual removal has been reported to be the treatment of choice by many authors, it is accompanied by several undesirable complications, the first of which is severe hemorrhage. Mares can lose large quantities of blood into the lumen of the uterus following manual separation of the fetal membranes. Assuming that the mare survives, this blood serves as an excellent environment for bacterial growth. It has also been reported that pulmonary emboli follow manual removal of the placenta. Manual removal of fetal membranes has been accompanied by invagination or eversion of a uterine horn, as well as a delay in uterine involution. It has been reported that there is an increased amount of fluid accumulation in the uterine lumen following manual removal of fetal membranes. The primary reason for the increase in fluid is that during separation only the central branches of the chorionic villi within the maternal crypts are removed. The remainder of the microvilli are broken off and retained within the endometrium. Furthermore, rupture of the endometrial and subendometrial capillaries occurs adding fluid within the lumen of the uterus. The presence of microvilli remaining within the endometrial crypts has been related to an increased occurrence of endometritis, laminitis, uterine spasm, and delayed involution. One author acknowledged that manual removal should be discouraged because of the possibility of trauma, hemorrhage, and infection. Manual removal was then recommended after other methods failed. It has been postulated that manual removal of the fetal membranes can result in permanent endometrial damage. The author has observed an increase in endometrial fibrosis occurring in a number of mares from 3 to 14 years of age that had normal fertility until manual removal of the fetal membranes. Following manual removal, decreases in fertility and deterioration in endometrial biopsy classification due to an increase in endometrial fibrosis were observed. The cervices of mares in which the fetal membranes have been manually removed remain open longer than those of mares treated with more conservative approaches. It has been suggested that manual removal of the fetal membranes remains as a treatment from a time when draft horses predominated and retained fetal membranes were more of a problem. The use of antiseptics placed into the lumen of the uterus has been suggested as an alternative method of treatment. Povidone-iodine diluted in large volumes of warm water has been placed into the lumen of the uterus or inside the placenta. Another method describes the placement of 2 to 12 L of dilute povidone iodine solution into the allantochorionic space followed-by ligation of the cervical star. This procedure traps the fluid within the allantoic cavity[9] and stretches the uterus and dilates the cervix as the placenta is passed, thus initiating endogenous oxytocin release and separation of microvilli from their attachments. It is suggested that the placenta should be passed within 30 minutes following this procedure. A disadvantage of the use of antiseptics has been their possible depression of phagocytosis by uterine neutrophils. The clinical importance of this phenomenon is unknown. Flushing and siphoning of fluid from the uterus is reported by some authors to be successful in the management of retained fetal membranes but by others to be of questionable value.[2] Infusion of the uterus with warm water (42° C) has been used with beneficial results. Large volumes of intrauterine saline and uterine flushes containing antibiotics have reportedly prevented or cured laminitis. Much diversity with regard to uterine therapy obviously exists. The most conservative treatment for retained fetal membranes in the author's opinion is the use of oxytocin. A variety of doses and routes of administration are described in the literature. The use of oxytocin in a slow intravenous drip with 30 to 60 units placed in 2 L of saline and administered over an hour or of 80 to 100 units added to 500 mL saline and administered over a 30 minutes were both successful. Oxytocin can be administered as a bolus intravenously or intramuscularly. Doses for bolus injection range from 20 to 120 units. The administration of oxytocin can be repeated at 1.5- to 2-hour intervals until the placenta is delivered. Owing to the extremely short half-life of oxytocin, there is no detrimental effect of repeated administration. The only disadvantages of administration of a bolus are the spasmodic myometrial contractions and abdominal straining that may follow. It has also been reported that signs of colic appear more frequently when oxytocin is administered as a bolus.[8] The severe cramping and abdominal straining may be related to dose. This author has not observed colic requiring treatment following administration of 20 units of

oxytocin intramuscularly at 1- to 2-hour intervals. Furthermore, if signs of colic do occur, they can be eliminated with sedatives or analgesics. As the interval between parturition and treatment increases, the dose of oxytocin may be slightly increased. Dosages administered shortly after parturition should not exceed 20 units. Oxytocin is effective up to at least 18 hours post partum. As the animal approaches 15 to 18 hours post partum, the dose of oxytocin may be increased to 40 units per injection. The route of administration does not appear to affect the clinical outcome.

Antibiotics have also been recommended in the treatment of retained fetal membranes. It is probable that antibiotic treatment does not result in a more rapid expulsion of retained fetal membranes but primarily aids in the prevention of metritis. One report indicated the successful use of oxytetracycline hydrochloride in capsule form. In this author's experience, the use of powered antibiotics or antibiotics in capsule or tablet form is undesirable because these antibiotics must be dissolved before they can have contact with the endometrial surface. Liquid preparations are believed to be superior for intrauterine administration. Other antibiotics that have been used in treatment of retained fetal membranes include amikacin, polymyxin, ticarcillin, sulfanilamide, and penicillin. It has been recommended that intrauterine antibiotics be administered at approximately 8 hours post partum if fetal membranes are retained. The primary value of antibiotic treatment is reportedly to control the contaminating bacteria that enter the reproductive tract at the time of parturition. Furthermore, it has been suggested that the fetal membrane attachment to the endometrium be examined prior to each treatment. Mares treated with intrauterine antibacterial agents for placental retention have a significantly higher pregnancy rate at the end of the breeding season than do mares that have not been treated with intrauterine antibiotics.[7] The incidence of abortion, however, is higher in this group than in mares that have not been treated with intrauterine antibiotics. There was no difference in the foaling percentage of mares treated or not treated with intrauterine antibiotics for retained fetal membranes. Another reason not to incorporate intrauterine antibiotic therapy as part of a "routine" treatment for retained fetal membranes is based upon a report indicating that by 5 hours following intrauterine administration of antibiotics, 45% of the mares expelled the fetal membranes, compared with 81% of mares treated with oxytocin alone.[7]

Protection against tetanus must always be a consideration following parturition but especially in cases of retained fetal membranes. The use of tetanus antitoxin or toxoid is recommended. The placement of sutures or metal clips in the dorsal vulva following parturition if indicated has been recommended to reduce uterine contamination.[2] The beneficial aspects of intrauterine therapy or the need to manually remove the placenta rapidly has not been established. It is established, however, that systemic oxytocin treatment for uncomplicated cases of retained fetal membranes is superior to all other forms of therapy. A heavy hunter mare that was treated only with systemic antibiotics following a cesarean section passed the placenta 5 days following delivery with no adverse side effects.[11] The animal was not given intrauterine medication because of her disposition. Another report involving a mare first examined 5 days following parturition indicated that she had passed the placenta on that day without signs of complications, having received no prior therapy. This author treated a mare following an abortion at 9 months of gestation with intrauterine oxytetracycline once daily for 3 days followed by intrauterine infusion of 2% Lugol's solution every other day until passage of the fetal membranes. This mare received phenylbutazone for the first 4 days of treatment. The fetal membranes were passed 13 days following the abortion. The uterus was cultured 34 days following delivery and contained no bacteria. The mare was bred approximately 60 days following abortion and conceived, maintained the pregnancy, and delivered a healthy foal. A careful examination is indicated in all mares with retention of fetal membranes to determine that septic or toxic metritis is not present.

Follow-up examination of mares with retained fetal membranes is mandatory regardless of treatment. It is imperative to be certain that the uterus is involuting normally regardless of whether the mare is to be bred during that breeding season. Transrectal examination of the reproductive tract must be utilized to determine the degree of uterine involution. Additional diagnostic tests may be indicated, including uterine culture, endometrial biopsy, and ultrasonographic examination. Endoscopic examination and endometrial cytology may also be used. Waiting approximately 25 days following placental passage to breed the mare may be beneficial; however, late in the breeding season, mares have been bred at 10 to 20 days post partum following retention of fetal membranes with acceptable conception rates. Examination of the placenta should occur following passage; however, many times it is difficult to determine whether the placenta is complete because of the deterioration of the tissue during retention.

There appears to be no difference in conception rates following the first breeding or at the end of the breeding season. Pregnancy loss rates were similar in normal foaling mares and in mares with retained placenta.[7] This lack of a difference was obvious regardless of the duration of placental retention. Manual removal of the fetal membranes was not attempted. It has been suggested that fetal membranes that cannot be removed easily should not be removed and a more conservative approach should be taken.[12] This author suggests that if fetal membranes have not been expelled by 3 hours post partum, the mare should be treated. The author's treatment of choice is the administration of 20 units of oxytocin intramuscularly every 1 to 2 hours until the mare passes the placenta or until 18 hours post partum. Oxytocin in syringes is dispensed to owners prior to parturition with specific instructions, including contacting the attending clinician at 3 hours post partum so that medication can begin immediately when it is obvious that the placenta is retained. This avoids the delay in the arrival of the veterinarian to the farm, which may not occur until later that day. Mares that foal in the middle of the night should be examined early the following morning to determine if any complications coexist with the retained fetal

membranes or if passage of the membranes has been complete. This examination includes rectogenital palpation and examination of the placenta, if possible. Decrease in uterine tone has been an excellent indicator of potential complications following parturition. If the uterus has good to excellent tone at the time of the examination, no vaginal investigation is made of the vagina or uterus to locate a fetal membrane. If fetal membranes are present within the uterus but good to excellent tone is present, the uterus is infused with 5 to 8 g oxytetracycline in 500 mL of saline. The author is uncertain whether this treatment is necessary. If the uterine tone is diminished, the volume of uterine infusion fluid is increased. In lightweight breeds no other medication is given. In draft breeds or in any mare following correction of a dystocia, systemic penicillin with or without gentamicin and flunixin meglumine is administered. Because mares that have experienced severe dystocias appear to be at a higher risk for developing septic or toxic metritis in conjunction with retained fetal membranes or because of the dystocia itself, systemic medication is continued for 3 to 7 days, depending on the animal's condition. Uterine infusions are changed from oxytetracycline to 2% Lugol's solution on the second to fourth day unless a cesarean section was performed to enhance the contractility of the uterus, thereby increasing tone and decreasing uterine lumen size. The volume of dilute Lugol's solution administered is determined by the size and tone of the uterus and may vary from 500 ml to 4 L. An important consideration regarding the administration of Lugol's solution is to not overdistend the uterus.

CHAPTER 13

Management of Twin Pregnancy

AMANDA C. RAGON

Twin pregnancy in mares is a significant cause of noninfectious abortion and perinatal death. Twins are reported to account for 20% to 30% of fetal and neonatal tissues submitted for necropsy[1,2] but compose only 0.5% of births.[3] Records of Thoroughbred studbooks in the United States and other countries have confirmed that the prevalence of twins in this breed ranges from 1% to 3.8% of births.[1,4,5] Twins are reported to occur frequently in draft breeds, and foal survival rates are said to be higher than in lightweight breeds,[6] but twins are rare in ponies.[7] At least two authors have reported triplets.[5,8]

Several investigators using ultrasonography for early pregnancy diagnosis have reported much higher rates of twin conception. Twin pregnancies were found in 6.1% of Standardbreds and 15.4% of Thoroughbreds,[6] and a twin conceptus rate of 15.3% was calculated in maiden Thoroughbreds and Standardbreds.[9] A study of German Thoroughbred mares indicated that the rate of twin pregnancies increased significantly and continuously as the breeding season progressed, from 0.9% in February to 1.76% in June and July.

The outcome of twin pregnancy in mares is frequently unfavorable. Of 62 mares carrying twin fetuses, 64.5% aborted or delivered dead foals, 21% delivered a single live foal, and 14.5% delivered both twins alive.[7] Of 124 fetuses in this study, only 18 survived beyond 2 weeks of birth. Mares that abort twins are likely to suffer dystocia, retain their fetal membranes, and experience a prolonged interval to next conception. In contrast, when twin pregnancy is diagnosed and treated while yet in the embryonic stage, 60% of mares deliver a single live foal.[10]

ORIGIN OF TWINS

Equine twins are reported to be dizygotic and arise from multiple ovulations.[11] A set of identical, or monozygotic, twins, has been reported but identification was based on a shared chorioallantois, not on blood or DNA type.[12] In contrast to twins in cattle, freemartinism does not occur in equine heterosexual (colt/filly) twins, although blood cell chimerism has been reported.[6,13]

Multiple ovulations are defined as occurring within a single follicular phase of the estrous cycle.[4] They may be synchronous, ovulating within 24 hours of each other, or asynchronous, occurring up to 48 hours apart. When follicles ovulate more than 2 days apart, the mare's estrous status should be critically examined to determine if each ovulation occurred within the same follicular phase. There appears to be little difference in the twin conception rate at the time of fixation between synchronous and asynchronous ovulations,[4] although in one trial, 96.5% (55 of 57) of mares with twin embryos examined between days 13 and 16 were determined to have had synchronous double ovulations.[9]

Not surprisingly, the incidence of multiple ovulations is highest in those breeds in which twinning is the most prevalent. Besides breed, multiple ovulations are influenced by reproductive status. One investigator found a 50% increase in double ovulations in barren mares over foaling mares.[9] Multiple ovulations are reported by some to occur more frequently during the late spring and summer,[4] although solid support for this conclusion is lacking. There is extensive evidence to suggest that double ovulations occur repeatedly in certain individuals,[4] but the heritability of multiple ovulations is not known. Increasing age has also been associated with a higher risk of twinning.[5]

EMBRYO FIXATION AND REDUCTION

Fixation of the embryo is postulated to happen when the embryos become so large and uterine tone so great that transuterine migration ceases, despite continued uterine contractions.[15] Fixation occurs approximately the same time (day 16 after ovulation) for twin embryos as for singletons; however, ultrasonographic studies found that twin vesicles tended to fix together in one uterine horn (unicornual fixation) more frequently than they were found separately (bicornual fixation). When the size of the vesicles was considered, 85% of embryos that differed in diameter by 4 mm or more fixed unicornually. Similarly sized embryos also showed a preference for unicornual fixation, but by a lesser margin.[4]

Size difference between twin vesicles are likely caused by asynchronous ovulations; thus, a difference in the age of the vesicles. Growth rates of single and multiple embryos are similar, as are diameters of single embryos and those resulting from multiple, synchronous ovulations. Although asynchronous ovulations are not more likely to produce twin embryos,[16] the incidence of unicornual fixation is increased over vesicles resulting from synchronous ovulations.[17]

Embryo reduction refers to the biologic mechanism by which one member of a twin set is eliminated.[4] Evidence

indicates that prefixation embryo reduction is negligible; most reduction occurs after day 16.[18] The pattern of embryo fixation greatly influences whether one embryo of a twin set will be reduced before reaching the fetal stage. Approximately 85% of unicornual twin embryos undergo postfixation reduction, more than half before day 20. The day of reduction appears to be later for unicornual vesicles of similar size.

The "deprivation hypothesis" explains the higher incidence of embryo reduction in unicornually fixed twin sets.[19] According to this theory, embryo reduction, as well as the time of reduction, depends on the amount of contact between the endometrium and the vascularized wall of each embryo. Unicornual twins positioned so that one embryo partially or completely prevents contact between the developing vascular wall and embryonic disk of the second embryo underwent rapid reduction that was complete by day 30. Embryo reduction occurs very late in the embryonic stage, or not at all, in bicornual twin sets and unicornually fixed twins that do not compete for endometrial contact. The chance of embryo reduction decreases and the time to complete reduction increases, the longer a vesicle survives after fixation.

BREEDING MANAGEMENT STRATEGIES: DETECTION AND RESOLUTION OF TWIN PREGNANCY

Historically, twin pregnancy was managed by preventing twin conception. Mares with more than one ovulatory-sized follicle (>30 mm) were not bred in the hope that a single dominant follicle would be present during the next estrous cycle. This is not an efficient method of preventing twin pregnancy, especially within the constraints imposed by the operational breeding season, but it was not critically evaluated[4] and became a common practice.

A 1982 survey of veterinarians documented the widespread practice of withholding mating to prevent twins.[20] Almost all (95%) of the veterinarians surveyed attempted to modify the breeding program in some way, especially early in the operational breeding season. However, the majority of veterinarians responding to a 1988 questionnaire had abandoned this practice and had shifted to early detection of twin pregnancy as a more efficient management technique.[15]

A breeding program that minimizes twin pregnancy but maximizes reproductive efficiency begins with breeding of all mares regardless of number of ovulatory follicles. Breed and other risk factors for twinning should be considered in designing such a program, as well as the intensity and goals of the breeding operation. In addition, a strategic management program should schedule timely examination of mares to detect twin pregnancy, prevent development of twin embryos to twin fetuses, and allow mares that have suffered abortion (spontaneous or induced) to be rebred within the same breeding season. Although ultrasonographic examinations to diagnose twin pregnancy may be less cost-effective for mares at low risk for multiple ovulations, every client should be informed of the possible consequences of undetected twin pregnancy.

Prebreeding Considerations

Ideally, twin management begins before conception. Instituting a reliable record-keeping system enables owners and veterinarians to review a mare's reproductive performance during past breeding seasons, as well as previous estrous cycles during the current season. In addition to recording information on the size and tone of the uterus and degree of cervical relaxation, parameters such as number and size of ovulatory follicles will document trends in a mare's reproductive cycle and identify mares that experience multiple ovulations. Because not all multiple ovulations are identified by transrectal palpation, ultrasonography may be used if there is any uncertainty that ovulation has occurred.

A prebreeding ultrasonographic examination of the uterus identifies the presence, location, number, and size of any uterine or endometrial cysts. Although cysts rarely decrease fertility (unless multiple or very large), they are commonly misidentified as early "twin" embryos.

Diagnosis of Twin Pregnancy

Ultrasonographic examination of the uterus is essential for accurate diagnosis of twin pregnancy during the embryonic stage. It is critical to perform a thorough, complete scan of both uterine horns and body; a rapid examination is more likely to miss the second embryo from a multiple ovulation. To this end, the patient should be properly restrained (preferably in stocks) and sedated if necessary. Ultrasonography can also be used to identify two corpora lutea in the ovaries.

The first pregnancy evaluation should be scheduled for 16 days after ovulation. If pregnancy is not established, this time frequently coincides with beginning of the next follicular phase and behavioral signs of estrus. Earlier examination (14 days after ovulation) has been suggested by some authors to facilitate treatment of unicornual twin pregnancies.[4,21] Day 14 (prefixation) embryos may be separated from each other at this time and one embryo manipulated to the tip of the uterine horn for manual reduction.

The mare should be examined again at 25 days. At this time, the embryo proper and its beating heart are visible with ultrasonography. This examination is important because it provides an opportunity to diagnose twin embryos that may have been missed during the initial examination, and it allows assessment of embryo viability and growth. If both embryos of a twin set have a visible heartbeat at this stage of gestation, the pregnancy may still be reduced or aborted prior to formation of endometrial cups (days 33–35).[22]

The identification of twin embryos using ultrasonography is well described in several textbooks. Most postfixation embryos are found at the corpus-cornual junction but can occasionally be located further up the horns or in the uterine body. Bicornual twins are generally easier to identify than unicornual embryos but may be confused with uterine or endometrial cysts.

Embryonic vesicles may be similar in size and shape but can be distinguished from cysts because they grow 3 to 4 mm per day.[23] Unicornual twin embryos may be more

difficult to identify than bicornual twins, but may appear larger in diameter than the normal single vesicle and will frequently have a visible membrane.

Management of Twin Embryos

The treatment method chosen to reduce a twin pregnancy depends on fixation pattern and stage of gestation.

Day 16

At the initial pregnancy examination, bicornual twins are easily treated by manual crushing of one vesicle transrectally. Both yolk sacs are located in the uterus and measured by ultrasonography, and the smaller of the two is then crushed between the thumb and fingers. The uterus is then scanned again to document that the yolk sac has been ruptured. This technique is often easier to perform on the uterine horn contralateral to the veterinarian's palpation arm. Success rates have been reported as high as 96% with this procedure. Treatment of mares with antiprostaglandins and progestogens has not reliably improved the outcome of the procedure, but it is the author's practice to routinely administer both following a twin reduction.[24]

Manual crushing of one of a unicornually fixed twin set is more difficult and likely to result in disruption of both embryos. If fixation has not yet occurred, the embryos may be gently separated and one manipulated to the tip of the uterine horn and crushed. After fixation, separation is difficult; however, the majority of these twins will be naturally reduced.[4]

Day 25

The sizes of the concepti and presence of the embryo proper and its heartbeat at this stage of gestation provide information about the viability of each twin. The majority of unicornual twins will have been reduced to a single embryo, or will be undergoing visible signs of reduction. If both vesicles of a unicornual twin pregnancy contain an embryo with a heartbeat, treatment options include (1) induced abortion with prostaglandin (or other methods described elsewhere), (2) transvaginal ultrasound-guided reduction of one vesicle, or (3) nonintervention, in the hope that elimination of one twin will occur before formation of endometrial cups (approximately day 35). When nonintervention is selected, careful monitoring with ultrasonography is recommended every 48 hours until day 33. If there are no visible signs of embryo reduction (decrease in size, absence of heartbeat) by that time, abortion of the pregnancy can be accomplished before endometrial cups are functional, so that the mare can be mated on the next cycle. Return to estrus may be delayed until after day 120 if abortion is induced after the endometrial cups are functional.[22]

Transvaginal ultrasound-guided twin reduction appears to be most successful when attempted before 36 days' gestation. This procedure utilizes a 5-MHz endovaginal curvilinear transducer introduced aseptically into the cranial aspect of the mare's vagina. Once the pregnancy is identified and is isolated transrectally a sterile, 18-gauge 60-cm spinal needle is passed through a needle channel in the transducer casing to penetrate the vaginal, peritoneal, and uterine walls and the allantoic sac. Care must be taken at this point to disrupt only one embryonic sac. Aspiration of allantoic fluid may increase the likelihood of damaging the remaining embryo. Success rates of 50% have been reported by some authors for the reduction of unicornual twins prior to day 35.[31]

Bicornual twins may be reduced manually at day 25, but this procedure is less successful than when performed at day 16.[4] The decline in success rates at this stage has been attributed in part to fluid released from the crushed embryonic vesicle. The fluid surrounds the remaining vesicle and disrupts contact of the vesicle with the endometrium.[32] The use of transvaginal ultrasound-guided allantocentesis to reduce bicornual twins should be more successful, in theory, because the distance between the two embryos makes needle placement less critical. Complete aspiration of embryonic fluid can be completed with little concern of damaging the other embryo. Because fewer sets of bicornual twins are presented for this procedure, the data regarding the procedure success rates and best time to perform are not as plentiful as with unicornual twins.[31]

Management of Twin Fetuses

Twin pregnancy reduction is difficult after the fetal stage is reached. Twins are more likely to abort than to reduce to a single fetus at this gestation.[4] In one study only 6% of mares carrying twins after 40 to 42 days experienced the loss of a single fetus and carried the other to term.[10] Manual reduction of bicornual twin fetuses is technically difficult and unlikely to have a positive outcome.

Several methods of reduction have been described for fetal stage twins. For twin pregnancies greater than 60 days' gestation, transabdominal ultrasound-guided fetal cardiac puncture and injection of potassium chloride has been successful in some mares.[27,28] Patient selection for this procedure is a concern; gestational age apparently influences the outcome, as do many other unidentified factors. The best candidates seem to be mares between 115 and 130 days of gestation, with a recommended upper limit of 140 days. With this stipulation, the success rate is estimated to be around 50%. Administration of flunixin meglumine and altrenogest after this procedure may be of benefit.[27–29] No adverse effects on the mare's health or subsequent fertility have been reported. Macpherson and Reimer modified this procedure by using procaine penicillin for injection into either the thorax or abdomen. They reported the birth of 8 of 13 live foals following this technique.[30]

Another alternative for managing fetal stage twins may be the use of exogenous progesterone. In three mares, supplemental progesterone reportedly prevented abortion during middle to late gestation even after signs of impending abortion were evident.[31] Although the numbers are small, this may be a useful treatment to attempt when twins are first diagnosed during the latter half of gestation and access to the more sophisticated techniques is limited.

CHAPTER 14
Parturition and Dystocia

WALTER R. THRELFALL

The average gestation length in mares is approximately 340 days. There is considerable variation; gestation length may range from 315 to 400 days and is influenced by season, with pregnancies that terminate in winter longer than those that terminate in summer. When large variation occurs from the average there always should be some concern and the mare should be examined if indicated. The definition of eutocia is a "normal delivery" or as a safe easy delivery without significant injury to either the fetus or the mare.

MARE PREPARTUM CHANGES

Progesterone concentrations in the peripheral plasma are less than 1 ng/ml during the last half of gestation; thus, measurement of this hormone is useless for determining deficiencies or predicting the time of parturition.[1] Other progestogens, 20α-hydroxy-5β-pregnan-3-one and 5β-pregnane-3α,20α-diol, decrease during the last 24 hours prior to parturition.[2,3] Prepartum changes in the mare include enlargement of the udder 4 to 6 weeks prior to delivery. This time varies with the individual animal and is somewhat dependent on the number of previous pregnancies, if any. The udder becomes more rounded as it enlarges. Enlargement and edema of the udder and the abdominal wall immediately anterior to the udder are apparent 2 to 3 weeks prior to foaling. Waxing, or the appearance of a sebaceous-like secretion on the teat ends surrounding the sphincter, should occur as the mare approaches parturition. However, waxing has been observed to occur as early as 4 weeks prior to delivery and may not occur in some mares. Waxing generally occurs with regularity in the same animal at approximately the same time prior to parturition. The teats usually fill and distend 2 to 14 days prior to parturition, but this may not be observed. Some mares leak colostrum prior to parturition. This is undesirable because once the colostrum is lost from the udder it is not replaced. Colostrum should be collected and frozen or substitute colostrum should be made available for the foal following delivery.

Relaxation of the tailhead and pelvic ligaments occurs gradually over several weeks before delivery. During this same period the vulva relaxes and the opening elongates. At 1 to 3 weeks prior to foaling, relaxation becomes apparent in the flank area with the mare appearing somewhat "gaunt" in this area. Approximately 7 to 10 days later, the gluteal muscles and the muscles adjacent to the tailhead relax and appear less evident, with the bones in that area more pronounced. The ultrasonographic character of the fluids within the uterus also changes during the last 10 days of gestation, and echogenic particles appear. The vagina and vulva relax and there is an increase in mucus. The vaginal mucosa may appear reddened; this generally occurs within 24 hours of parturition. The cervix becomes completely relaxed and the uterine contractions increase in frequency and strength. Because some mares foal with only a few of these normal prepartum signs, prediction of the exact time of foaling is difficult without further diagnostic tests. Body temperature has been suggested as a possible method to determine the time of parturition before the onset of stage I of labor.[4,5] Although it has been demonstrated that changes in body temperature measured at 6-hour intervals with an electronic rectal thermometer were not adequate to predict parturition, the use of telemetry with a computerized system to record core body temperatures at 15-minute intervals could be useful in parturition prediction.[6,7]

Several commercial aids are available for use in determining approximately when parturition will occur. These include the Sofchek Test strip, the Titrets Calcium Hardness Test Kit, and the Predict-a-Foal Predictor Kit. The Sofchek Test strips indicate there is a 79% probability of parturition within 24 hours when the hardness test strip exceeds 250 ppm. The Titret Calcium Hardness Test strip indicates a 53% probability of parturition within 24 hours when the hardness exceeds 250 ppm. The Predict-a-Foal Predictor Kit indicates a 59% probability of parturition within 24 hours if the color change is a 4 or greater. These tests are more predictive of indicating when the mare will not foal rather than when parturition will occur.

A number of methods commonly are used to monitor the actual parturition. The most frequently used and oldest method is to stay in the barn with the mare and personally observe. This method obviously has several disadvantages including inclement weather and loss of sleep. This system is not 100% effective, and many people have fallen asleep while supposedly observing the foaling or have gone to the house for a few minutes and have missed the birth. Others systems designed to improve the quality of life of the foaling attendant include video cameras, sound monitors, the Foal-alert system, the Birth Alert system, and other systems designed for the mare at parturition. Video cameras have progressed considerably from the days of the poor image quality requiring a great deal of light and hard wiring. The systems of today require minimal lighting and no wires. The cost of these systems also has been greatly reduced, making them affordable to most horse farms. They permit the person monitoring the mare to remain in a more comfortable environment than would otherwise be possible. The

author has used several video monitoring systems over the past 22 years and has found them to be worth the cost. Sound monitors including baby monitors and intercoms are of limited value because many horse sounds may "wake" a horse owner and not be related to foaling. However, they do work in combination with other systems such as the monitors, which emit an audible signal at the time of parturition. The Foal-alert system is a monitoring device that includes the placement of a transmitter on the vulvar lips such that at the time of parturition the lips spread with passage of the fetus and the transmitter is activated. The receiver is activated and it produces an audible sound, which can be heard within the barn or transmitted by phone or pager to a distant point. An intercom system can also be used to transfer the alarm sound to a house or sleeping area of the foaling attendant. The Foal-alert system works excellently if any portion of the fetus or fetal membranes filled with fluids reaches the vulvar lips and causes activation of the transmitter. The Birth Alert system is another foaling monitoring system that utilizes a transmitter in the anterior vagina and is activated when the transmitter is expelled from the vagina and the temperature sensor signals the decrease in temperature to the receiver. The receiver transmits an audible signal.

Restlessness increases as the mare approaches parturition. Prior to this increase, mares may demonstrate decreased activity that could last for several weeks. Personality changes are obvious as the time of parturition approaches. This is especially true during the 24 hours before birth. Distractions of any kind should be kept to a minimum during this period. Changes in prepartum myometrial activity have been reported.[8,9] Internally, during this period, the mare's uterus begins more active contractions beginning at the end of the uterus near the ovary and progressing posteriorly toward the cervix.

The fetus is in a variety of presentations until approximately the sixth month of gestation when it aligns itself in a cranial presentation (Fig. 14-1). Presentation may change after this stage, however, and therefore cannot be used reliably to determine the presentation of the fetus until parturition actually begins. The fetus assumes a variety of positions, including dorsosacral, for longer durations as term approaches. As parturition approaches, the head and forelimbs can be palpated in the pelvic canal of the mare and may at times be alongside the cervix with pressure on the vaginal wall.

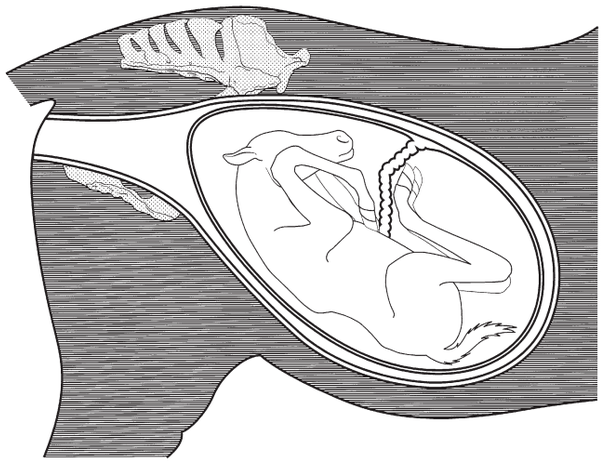

Fig. 14-1 Fetal presentation and posture 2 to 3 months before birth. (From Threlfall WR: *Threlfall's equine obstetrics.* Powell, OH: Global Reproductive Services, 1996.)

There is no need to wrap the mare's tail, wash the perineal area, or wash the udder before foaling. These procedures, although recommended by some, mostly serve to disrupt the mare and have no medical basis. However, cleaning the stall and maintaining reasonable cleanliness are especially important before and immediately post partum. This could include disinfecting stalls between mares but is not practical with most farm facilities. For disinfectants to be effective, all organic material must be removed. This is usually only feasible with a high-pressure sprayer and requires that relatively nonporous material be used in the construction of stalls, including the floor. Stalls should be at least 12 ft by 12 ft or larger and be bedded preferably with large quantities of straw. Other types of bedding material may promote bacterial growth or be too dusty for use with neonates or postpartum mares. If Caslick's procedure has been performed to improve vulvar conformation, the vulva should be opened approximately 14 days prior to the due date or as determined by visual assessment of the mare's preparation for foaling.

Stage I

Sweating initiated in the shoulder area combined with frequent observations of the flank area by the mare are indicators that stage I of labor is occurring. Kicking, biting of the flank, or other signs of mild colic frequently occur during this period. During this stage, final positioning and posturing of the fetus occur. The front feet and the nose make an excellent wedge to aid in cervical dilatation. This is also assisted by pressure of the fetal fluid on the cervical opening. The increase in pressure is first due to increased uterine activity. As the pressure increases and the cervix starts to dilate, oxytocin is released. Oxytocin increases the uterine contractions and indirectly stimulates the abdominal muscles to contract and further increase the uterine pressure. The beginning of stage I of parturition is difficult to determine because its onset is not marked by any single event or change in the mare and is rather vague and variable. As the normal mare approaches foaling, she may have a decrease in activity the day before the night of foaling. It has been reported that approximately 85% of mares foal between 7:00 PM and 9:00 AM, with most mares foaling between 11:00 PM and 4:00 AM.[4] Within 2 hours prior to foaling, the mare may become restless and show signs of colic. She may paw the ground and stop eating for short periods of time as an indication of pain. Increased switching or movement of the tail is also usually observed as the mare approaches parturition. Milk may be seen squirting from the teats. This activity is associated with oxytocin release and apparent uterine pain. Signs of pain are not constant but intermittent and correspond with uterine contractions. These periods may last from 1 or 2 minutes to 20

minutes in length. These events may not be observed in older mares, even though the entire process may take several hours. This explains how mares are able to foal during the 30 minutes an observer may be absent. The mare should be observed but left undisturbed unless problems arise. The average range for this period is 1 to 4 hours. Any disturbances may delay the foaling and result in complications. The chorioallantoic membrane ruptures and the allantoic fluid escapes, marking the end of stage I.

The fetal heart rate prior to the onset of parturition is approximately 76 beats per minute, with elevations occurring with increased activity. Heart rate may increase by as much as 40 beats per minute and the accelerations may average one per minute. The activity of the fetus is most pronounced during the period of 5 to 72 hours prepartum. The fetal heart rate during the 24 hours prior to delivery is approximately 62 beats per minute and during stage I and stage II is between 54 and 60 beats per minute. The heart rate of the neonate averages over 100 beats per minute.

Stage II

Signs of the second stage of labor are more apparent. The mare lies down during most of this period; although she may sit up and lie down several times and is generally sweating. When in the recumbent position, all legs may be extended and the head stretched outward away from the body (Fig. 14-2). She may bite her flank area or chew on hay or straw. During stage II of labor, the mare frequently urinates and defecates because of the pressure applied by the contracting uterus and the abdominal wall and the presence of the fetus and fetal fluids. Some mares may roll in an apparent attempt to lessen the pain or position the fetus. The average time for stage II is 20 minutes, calculated from the time of chorioallantoic membrane rupture until delivery of the fetus. It is abnormal for mares to continue this stage of labor longer than 70 minutes, and prolonged second stage indicates problems are present and fetal death is likely. It is generally recommended that mares be given 20 minutes to complete the second stage before the foaling attendant becomes alarmed. Normal progression in the delivery process should occur during this period.

During stage II, the amniotic membrane protrudes from the vulva (Fig. 14-3). The amniotic membrane should be visible at the vulvar lips within 5 to 10 minutes following rupture of the chorioallantoic membrane if the mare has not been disturbed during the delivery process. Once the amniotic membrane is visible, the fetus has entered the birth canal sufficiently to stimulate strong abdominal contractions. As the foal is pushed caudally by abdominal and uterine contractions, the feet are observed through the amniotic membrane. Rupture of the membrane does not usually occur until the fetus is at least midway or completely through the birth canal. Although most mares foal in lateral recumbency, it is possible for parturition to occur while the mare stands. The major concern in this situation is a ruptured umbilical cord

Fig. 14-2 Mare in stage II of parturition with severe abdominal contraction resulting in all limbs extended. (From Threlfall WR: *Threlfall's equine obstetrics.* Powell, OH: Global Reproductive Services, 1996.)

Fig. 14-3 Mare in stage II of parturition with the forefeet protruding covered by amniotic membrane. (From Threlfall WR: *Threlfall's equine obstetrics.* Powell, OH: Global Reproductive Services, 1996.)

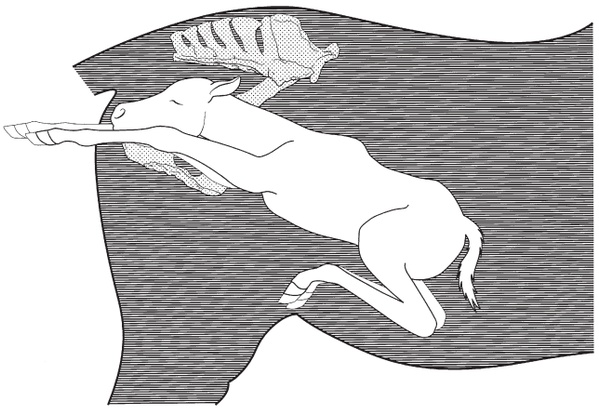

Fig. 14-4 Normal presentation, position, and posture. Anterior longitudinal with dorsosacral position and extension of head, neck, and forelimbs. (From Threlfall WR: *Threlfall's equine obstetrics.* Powell, OH: Global Reproductive Services, 1996.)

close to the abdominal wall and blood loss. If the foal is delivered and the amniotic membrane remains intact as the foal struggles following delivery, the membrane should be incised and removed from the area of the fetal nose and mouth. The normal delivery posture of the fetus is one forelimb extending approximately 4 inches in front of the other and the soles of both feet directed ventrally (Fig. 14-4). This offsetting of the feet results in a slight angling of the shoulders and thereby reduces the width of this area as it passes through the mare's pelvis. While the foal passes through the vulvar lips surrounded by the amnion, the observer can determine the offset position of the hooves and note that the soles are ventral. If the soles are not directed ventrally, immediate attention is indicated. The head should rest on the forelimbs in the area of the carpal joints. The head and neck are extended. If the nose of the fetus has not appeared by the time the carpal joints are observable immediate intervention is indicated. The vertebrae of the fetus are located near to the vertebrae of the mare; the position is close to a dorsosacral but slightly off toward the ileum. This position permits the fetus to take advantage of the greater pelvic diameter. As the fetus is expelled further, the rear limbs are extended so that the hooves are the last part of the fetus delivered. Any variation from this normal position, such as failure to observe one of the feet or the head and neck, indicates a postural abnormality and a difficult delivery. Because the mare's delivery is so forceful, she may severely injure herself by pushing the fetus out and tearing her tissue as the fetus is expelled. Also, anything that slows the delivery process is detrimental because the placenta separates rapidly and eliminates the fetal supply of oxygen. This probably accounts for the poor survival rate of foals when the mare was in need of assistance and none was immediately available.

Stage III

The mare should be permitted to lie quietly in the stall for up to an hour following parturition; however, if she jumps up rapidly following delivery, it is not necessarily a reason to panic. Although it has been suspected, it has not been demonstrated that abdominal wall damage occurs to the fetus when this occurs. The determination of hemorrhage from the umbilicus, although not common, should be made. It was once believed that large volumes of fetal blood could be lost from the placenta and that care should be taken to assure the cord remained attached to the placenta. A more recent scientific study revealed that blood flow through the umbilical vessels ceases by the time the umbilical cord is visible at the vulvar area of the mare.[10] Following delivery of the fetus and after the mare has accepted the foal and is resting, cleaning of the stall and observation of the mare and foal are the two most important managerial tasks. Stage III of parturition begins following expulsion of the foal and ends when expulsion of the placenta is complete. The fetal membranes should be expelled within 3 hours following delivery.

INDUCED PARTURITION

Parturition induction permits observation and professional assistance, if necessary, at the time of foaling. There are primarily two reasons for parturition induction. The first is for medical indications. It is of most value when used for mares that have a history of difficult deliveries or have had injuries or illnesses that could possibly endanger the life of the mare or the foal if not assisted immediately at the time of parturition. Among the clinical indications for induced parturition are ruptures of the prepubic tendon, rupture or weakening of the abdominal wall, following surgical correction of third-degree perineal lacerations or rectovaginal fistulas, previous fracture of the pelvis with narrowing of the birth canal, history of premature placental separation, prolonged gestation, near-term colic, and uterine inertia. Parturition induction also permits opening of Caslick's vulvoplasty immediately prior to delivery and replacement immediately post partum, thereby reducing contamination of the reproductive tract. Furthermore, if an episiotomy is indicated to eliminate vulvar lacerations, it can be performed when indicated. Induced parturition in mares that have previously produced foals with neonatal isoerythrolysis can be easily managed by removal of the foal immediately following delivery.

The second reason for the induction of parturition is for convenience. Induction of parturition is becoming an acceptable method of permitting the owner, manager, or veterinarian to be present at the time of delivery in normal mares. The value of induced parturition in labor savings is brought about by the elimination of "foal watchers," people hired to observe mares near term, or by the elimination of frequent observations throughout the night with the possibility of missing the foaling onset. The labor savings plus the guarantee that capable assistants will be present at the time of parturition easily offset the expenses incurred in parturition induction. The convenience factor also applies to certain research projects involving parturition and neonatal physiology and for the educational value of being able to provide a parturition demonstration. Induction has also been utilized to induce mares to deliver where the primary intention was

to provide a nurse mare for a valuable foal. There is no association between induction and impaired future reproductive efficiency. Owners must be aware of the problems with dysmature or premature foals if delivery occurs prior to the time the foal is mature.

Some of the more general criteria to consider before induction of parturition include knowledge of the gestation length, which should exceed 320 days. The mare's previous gestation lengths can be utilized to some extent to determine term but the effect of time of year should be considered. Mares foaling in the months of January, February, and March have longer gestations than mares foaling in April, May, and June. Prepartum changes such as perineal and cervical relaxation have been used as indicators for predicting parturition but may not be accurate enough to predict the time to induce parturition. Although relaxation of the pelvic ligaments can also be used as an indicator of approaching parturition, it is less noticeable than udder changes and more experience is necessary to detect subtle changes. Mares should be introduced into the foaling environment at least 3 to 4 weeks prior to induction if possible. This permits the mare to be exposed to the organisms in the new environment as well as become accustomed to her new surroundings. The mare should be placed in a clean stall bedded with straw in a quiet area of the barn. Rectal examination of the mare at this time usually permits evaluation of fetal presentation, position, and posture as well as viability of the fetus. Because this is an elective delivery and the time of delivery is predetermined, a tail wrap is applied to the mare and the perineal area is washed prior to administration of the induction agent.

Determination of fetal presentation, position, and posture plus a physical examination of the mare must be performed prior to induction. The fetus should be in cranial longitudinal presentation with slight dorsoileal position and the head and neck extended. Although the final delivery position and posture are determined as the mare enters stage I of parturition, the presentation will have already been predetermined. A caudal presentation would indicate the importance of assistance much earlier in the delivery process than a cranial presentation. If the head and feet are not in the proper posture, it is very probable that correction will occur before delivery without assistance. The author does not advise intervention once delivery has been induced unless it is apparent that the progress is slower than normal or is abnormal. Assistance that is too aggressive or premature may result in cervical lacerations or delay parturition.

Contraindications to parturition induction include conditions that indicate that expulsion of the fetus is not possible through a pelvic canal greatly reduced in size. Any abnormal condition affecting the mare prior to induction should be brought to the attention of the owner and a decision made as to whether to proceed. Conditions such as increased body temperature, abnormal vulvar discharges, and abnormal presentation of the fetus should influence the decision to induce because they may affect the outcome. Fetal extraction following cervical dilation without parturition induction may be indicated in certain instances to provide a better probability of fetal survival.

The most common agent used to induce parturition is oxytocin by intravenous or intramuscular administration.[11] If the cervix is closed, administration of estradiol cypionate (4 to 6 mg) or diethylstilbestrol may be considered 12 to 24 hours in advance of oxytocin administration to aid in relaxation. Oxytocin also has the capability of inducing cervical relaxation in a mare with a closed or nearly closed cervix. The best results are obtained when it is administered as a 10-unit dose intravenously every 15 to 30 minutes by slow intravenous drip. Four to six repetitions of bolus administration may be required. If dilatation occurs without delivery, the dosage of oxytocin can be increased to 20 units. While determining the degree of cervical dilation, one can also determine the position and posture of the fetus by transrectal palpation because disruption of the mare has already occurred.

The dosage of oxytocin administered varies with the degree of cervical relaxation. If the internal diameter of the cervix is relaxed to at least 2 cm, it has been recommended by several authors to administer 40 to 60 units oxytocin as an intravenous bolus. Delivery of the fetus should occur within 90 minutes. In a pluriparous mare, the sequence may be more rapid, with stage II completed within 30 minutes after oxytocin administration. Many veterinarians have traditionally administered oxytocin intramuscularly.[12] Much of the recent literature has reiterated the observation that the mare's response (both in speed and violence) is proportional to the dose of oxytocin given. The higher the dose of oxytocin the faster the delivery of the fetus. Oxytocin has been reportedly used to induce parturition in six mares with all foals normal and healthy within approximately 34 minutes. None of the mares had a retained placenta and all lactated normally. The dose of oxytocin ranged from 40 to 60 units. The author prefers to administer 20 units of oxytocin intramuscularly to mares with a minimum of 2 cm cervical dilation and has not had any of the reported problems described later in this chapter.

In mares with at least 2 cm cervical dilation and other signs of preparedness for delivery, the administration of 20 units of oxytocin is followed in approximately 5 to 10 minutes with restlessness and slight colicky pains, which include tail movements and looking at the flank. Within 20 minutes, the mare will be walking, frequent defecation will be occurring, the tail will be held partially up for long periods of time, frequent urinations will occur, she may repeatedly move from the standing position to the recumbent position, and sweat will appear in the area of the shoulder. The movements will become more pronounced and the sweating will extend to other areas of the body. Rupture of the chorioallantoic membrane will occur approximately 30 minutes following oxytocin administration. Delivery of the fetus through the vulva will commence in approximately 30 to 60 minutes following administration and will take approximately 30 to 40 minutes. The fetal membranes should be passed within 3 hours or the mare should receive additional oxytocin as a treatment for the retained fetal membranes.

Reportedly, oxytocin is dangerous when used to induce parturition because it has the capability to induce delivery whether the fetus is mature or not. The response

of the mare is to release larger quantities of prostaglandin than occurs during a natural parturition and is therefore a pharmacologic not a physiologic induction. Fetal membrane retention occurred as an undesirable effect in two of three mares when oxytocin was given by slow intravenous drip for longer than 3 hours. Four of five mares induced with oxytocin produced foals that were weaker than normal, and one had to be "destroyed." Cases of malposition have been reported following induction with oxytocin. It is recommended to examine the fetus 20 minutes following oxytocin administration to determine the fetal position and to correct any malposture or malposition. The author believes that all these side effects could and do occur in natural deliveries and that some of the effects may be related to dose or route of administration.

Prostaglandin F_2 alpha ($PGF_{2\alpha}$) reportedly failed to induce parturition in the mare.[13] $PGF_{2\alpha}$ can also cause very strong myometrial contractions and may decrease foal survival and increase fetal weakness and risk of death due to early placental separation.[13,14]

Fluprostenol is capable of inducing parturition in mares. Fluprostenol causes less myometrial stimulation than $PGF_{2\alpha}$ and, therefore, has been successfully used for induction. Mares with a closed cervix can be induced with fluprostenol at a dose of 2.2 μg/kg. The time to delivery should be approximately 4 hours. Fluprostenol was administered to 17 ponies, horses, and donkeys to induce parturition. The prostaglandin F metabolites (PGFM) increased after injection in mares that delivered within 90 minutes following injection and peaked during the maximal expulsive efforts of parturition. If parturition required longer than 90 minutes, the PGFM increased at various times following injection and peaked before the maximal expulsive efforts.

Thirty-three mares were induced to foal with prostalene or fenprostalene based on presence of prefoaling mammary secretion. Twenty-three mares served as control subjects and were monitored but not induced. All mares given fenprostalene delivered within 3.9 hours following injection without complication. Seventy-five percent of mares receiving prostalene delivered within 3.7 hours and the remainder delivered within 30 to 56 hours following injection without difficulty. Tests were performed to determine the content of calcium carbonate or the total "hardness" of the colostral secretion. Mares were monitored beginning 10 days prior to the expected foaling date and the secretion checked daily for 3 days and then twice daily until parturition.

Combinations of fenprostalene followed by oxytocin in 5-unit doses at 20-minute intervals has been recommended as a means to reduce the approximate 4-hour time interval following the prostaglandin analogue administration until delivery. Oxytocin was administered 1 hour following the initial injection and the delivery time was more predictable.[12]

Glucocorticoids have reportedly failed to induce parturition in the mare. Dexamethasone, 100 mg at 24-hour intervals until parturition occurs, has been utilized but with less reliability than oxytocin. The average induction time of 4 ± 1.6 days was considered to be undesirable because qualified assistance probably would not be present when required. Because suppression of the immune response is a disadvantage of corticosteroid therapy, it is thought that the use of this substance to induce parturition may be undesirable.[13] Combinations of $PGF_{2\alpha}$ and flumethasone, a synthetic glucocorticoid, have been reported to successfully induce parturition.

Dystocia

Dystocia is defined as an abnormal or difficult delivery that may or may not require assistance. A dystocia may result in injury or death to the mare or the foal or both. Dystocia occurs in fewer than 1% of equine parturitions. Certain breeds or the crossbreeding of animals of extreme size difference when the mare is smaller may increase this percentage. Although mares have fewer problems with deliveries than other domestic species, when difficulties are present they are true emergencies. The reason for this is the rapid and very strenuous nature of the delivery process in this species.

Fetal causes of dystocia account for the majority of difficult deliveries. The primary reason is postural abnormalities of the long fetal extremities. Positional and presentational abnormalities can also occur but to a lesser degree. The fetus should be expelled from the uterus within 30 minutes with a maximum of 70 minutes following the rupture of the chorioallantoic membrane. Caution should be used when assisting in the extraction of a fetus to be certain the uterus, the cervix, the vagina, the vestibule, and the vulvar lips are not lacerated by traction applied too rapidly. Extraction of a fetus in an abnormal posture or position should not be attempted until the abnormality is corrected because of the increased probability of laceration. The round shape of the mare's pelvis compared with that of the cow reduces dystocias caused by large fetuses. Other less frequently encountered fetal causes of dystocia include fetal anasarca, ascites, fetal tumor, hydrocephalic fetus, fetal monster, and mummified fetus. Maternal causes of dystocia include uterine torsion, abnormally small pelvis, uterine inertia, immaturity, constriction of the cervix or vagina, and other causes unrelated to the fetus.

The approach to a dystocia should not be hasty or heroic. A well-planned approach will be far more successful than one that overlooks major points of information critical to a successful delivery. Important aspects of this approach are a complete history and a rapid but complete physical examination. An obstetrician is often under real or perceived pressure from the owner upon arrival and may be tempted to rush the approach. The procedure will be far more successful if a reasonable time is taken for preliminary information and examination.

Notation should be made of the mare's behavior, posture, character of her breathing, ability to rise and remain standing, response to stimulation, and degree and frequency of straining; the condition of the allantoischorion; the presence of the amnion, visceral organs, or fetal extremities protruding from the vulva; and vulvar discharges and the appearance of the vulva. If possible prior to examination, the mare should be placed in a relatively dust-free, quiet area. The mare's tail should be wrapped and secured to her neck with a cord.

Next, the reproductive tract and fetus should be examined. The author prefers to perform this procedure initially via transrectal palpation. This approach permits evaluation of the uterine body more anteriorly than may be possible via the vaginal canal, thus allowing assessment of the existence of uterine torsion, rupture of uterine arteries, or uterine rupture on the dorsal surface. Fetal viability can also be assessed using the transrectal approach. The perineal area is then washed and, with the use of a sleeve and sterile lubricant, the vaginal, cervical, and uterine walls are examined for possible lacerations. This procedure should always be performed before examination of the fetus to eliminate the possibility of missing a significant lesion.

Only after the determination of the absence of lacerations should the fetus be palpated through the vaginal canal to determine its presentation, position, posture, and viability. Several reflexes can be used to determine the viability of a fetus. Depression of the eyes should initiate either movement of the fetal head or, in a depressed fetus, only movement of the eye itself. A finger inserted deeply into the mouth should stimulate the sucking reflex. With a caudal presentation, a finger can be inserted into the fetal anus to detect movement of the entire fetus or simply contraction of the anal sphincter. The skin of the fetus can be pinched or a limb can be flexed or extended maximally to stimulate a response and thus indicate fetal viability. A stethoscope on ultrasonographic examination can also be performed for detection of fetal heart beat or blood flow. The relative size of the fetus and that of the pelvis and birth canal should be approximated during this examination and identification of any abnormalities of the fetus that could compromise the delivery should be made. Following the preceding examinations, the owner should be informed as to the prognosis for the mare and fetus and the cost of the recommended procedure before therapy is initiated.

All genital examinations and obstetric procedures should be performed as sanitarily as is feasible. Obstetric procedures are easiest with the mare in the standing position with epidural anesthesia unless the mare has been anesthetized and is in dorsal recumbency. Lateral recumbency is the most difficult position. Stocks are desirable to reduce side-to-side movement of the mare if one remembers that mares may suddenly go from the standing to the sternal or laterally recumbent position, making removal from stocks difficult. Anesthetized mares can be positioned with the rear quarters higher than the head on an incline or placed in dorsal recumbency with the rear feet elevated using a chain hoist (use caution following epidural). Elevation of the hindquarters permits the mare's abdominal viscera to move away from the pelvic area. The uterus and fetus will also move cranially, permitting more space to manipulate the fetus.

Fetal presentation refers to the relationship of the spinal axis of the dam. Cranial longitudinal presentation is where the fetal head is presented first at the vulva. Caudal presentation occurs when the rear limbs or pelvis are presented first. Transverse and vertical presentations occur when the mid portion of the fetus is the first portion to contact the cervix. Position is defined as the relationship of the dorsum of the fetus to the quadrant of the maternal pelvis. The possibilities that exist in longitudinal presentation are dorsosacral, right dorsoileal, dorsopubic, and left dorsoileal. Posture refers to the relationship of the fetal extremities to the fetal trunk. A normal delivery is defined as cranial longitudinal presentation, dorsosacral position, with the fetal head, neck, and forelimbs extended.

Chemical restraint is often necessary to facilitate obstetric manipulations in the mare. Owing to their potent cardiovascular effects, sedatives (xylazine, detomidine) and tranquilizers (acepromazine) must be used with caution in compromised patients. Prior to administration of any sedative or tranquilizer drugs the cardiopulmonary status of the mare should be evaluated and doses adjusted accordingly. The potential for subsequent general anesthesia should always be considered when administering sedative/tranquilizer drugs to the equine dystocia patient.

Administering a combination of xylazine (0.66–1.1 mg/kg IV) and acepromazine (0.04–0.06 mg/kg IV) generally provides a reasonable degree of patient cooperation and a reduction in the severity of uterine contractions. This combination should provide 20 to 40 minutes of relief and can be repeated. Butorphanol (0.01–0.015 mg/kg IV) may be added to improve the efficacy of the preceding combination. In some cases general anesthesia may be required to facilitate fetal repositioning and removal. When available, inhalation anesthesia is always preferred for obstetric work.

Intravenous general anesthesia can be safely performed in the field setting. The practitioner should review a contemporary veterinary anesthesia text for a more thorough understanding of the procedures involved and the potential risks of equine field anesthesia. Sedation with xylazine (1.1 mg/kg IV) is followed by induction with a combination of diazepam (0.06–0.1 mg/kg IV) and ketamine (2.2 mg/kg IV). This combination should provide approximately 10 to 15 minutes of anesthesia when used alone. The duration of anesthesia can be extended with administration of "triple drip" (also called GKX), which is made by adding 1 mg/ml of ketamine and 0.5 mg/ml of xylazine to 5% guaifenesin solution. Triple drip is administered at a rate of 0.08 to 1.6 ml/kg/hour IV (or 1–2 drops/sec/450 kg). The 1 drop/sec rate will generally extend recumbency, but will often not cover significant surgical stimulation later in the procedure. The 2 drops/sec rate will generally extend complete surgical anesthesia for the duration of the procedure. An infusion rate of 3 drops/sec has been reportedly used without adverse effects. A more stable plane of anesthesia will result if triple drip administration is started immediately following anesthetic induction. If field anesthesia must be extended beyond 1 hour, the second bag of triple drip should be made using half the concentration of xylazine to minimize the accumulation of this drug. Recovery from triple drip is generally very smooth and usually takes 15 to 30 minutes following short anesthetic periods. Expect recovery time to increase as anesthetic duration is extended. α_2-Adrenergic antagonists (yohimbine, tolazoline) may be used to reverse some of the xylazine sedation to shorten these longer recovery times. They should be administered in small increments (0.005 mg/kg for

yohimbine and 0.5 mg/kg for tolazoline) and not until the horse has been in sternal recumbency for some time to minimize the risk of a rough recovery. It is very important to be patient when using smaller doses of reversal agents to produce a titrated response. For best results doses should be given at 3- to 5-minute intervals.

Repeated bolus administration of xylazine-ketamine can be used as an alternative to triple drip for extending the duration of equine field anesthesia. One third to one half of the initial dose of each drug is administered intravenously as a bolus when signs of a lightened plane of anesthesia are observed. Xylazine dose should be systemically reduced when numerous boluses are required. The anesthetic plane achieved using this approach is not an even plane and requires more attention than when using triple drip.[15]

One of the challenging aspects of treating animals in dystocia is that there are only a limited number of methods available for correction. The most difficult decision is to select the method that will achieve the objective of delivering a fetus alive with minimal trauma to the mare and the fetus. The second most important aspect of successful management of dystocia is to have access to the mare early in the delivery process. The possibilities for dystocia correction include mutation, forced extraction, fetotomy, laparotomy, and laparohysterotomy. Although euthanasia of the mare may be selected to terminate the case because of economics or the physical condition of the mare at the time of arrival, it is not included as a treatment for dystocia as it does not fulfill the definition of mare and foal survivability.

The amount of assistance necessary depends on the technique to be employed for correction. The minimal amount of assistance recommended for an obstetric procedure is two persons. One person is at the head of the mare for the entire procedure and one assists the obstetrician with equipment and with traction or fetotomy cuts when required. Generally three or four assistants make the procedure go more rapidly.

Obstetric equipment recommended by the author includes three obstetric chains (60 inch), three obstetric chain handles, fetatome (Utrecht or flat tube model), a Krey-Schottler hook, a wire introducer, two wire handles, a detorsion rod, a fetotomy finger knife, a rope snare, obstetric wire, a Kühn crutch, rubber sleeves, buckets, a stomach pump, a nasogastric tube, and lubricant. The lubricant of choice is polyethylene polymer (J-Lube*), which comes in powder form and is water soluble. It can be mixed at the site and delivered into the uterus with a stomach pump and tube. Although not all of this equipment is essential for every dystocia, its availability will improve the quality of the obstetric manipulation and reduce the work required to obtain desirable results.

Mutation

The most frequently used method of correction is mutation. Mutation is the procedure used to correct malposture, position, and presentation followed by delivery of the entire fetus. This method should be the least traumatic and should be employed prior to the use of forced extraction. Mutation may not always be possible or indicated, depending on the length of time the mare has been in labor, viability of the fetus, and the cause of the dystocia.

Mutation involves returning the fetus to a normal presentation, position, and posture by repulsion, rotation, version, and adjustment or extension of the fetal extremities. It is primarily indicated when the fetus is alive and the procedure can be performed in a relatively short period with a high probability of success. It has been found by the author that in the case of a dead fetus, fetotomy procedures to eliminate a postural abnormality are faster and less stressful to the mare and the obstetrician than attempts to mutate unless the dystocia has been of minimal duration and sufficient area exists within the uterus to permit manipulation. Repulsion of the fetus into the abdominal cavity away from the pelvis aids in creating more space in which to perform obstetric procedures. Lubrication is very important with all obstetric procedures, including mutation, and may make the difference between success and failure of the technique. Extension of a flexed limb is accomplished by repelling the proximal portion while the midportion of the limb (carpus or tarsus) is rotated laterally (Fig. 14-5). Following this, the foot is brought medially and extended into the pelvis. If correction is not possible in 15 to 20 minutes, another method of correction should be selected.

Lateral deviation of the head is a common cause of dystocia because of the relatively long neck of the fetus (Fig. 14-6). The fetus should never be delivered with this postural abnormality because of the potential for injury to the birth canal. The operator's fingers can be inserted into the fetal mouth and traction applied to bring the head toward the brim of the pelvis. Much of the success of this technique depends on the amount of space within the pelvic area. In cases of prolonged labor, there may be no available space for the extension of the neck. The limb on the side opposite the deviation of the neck may need

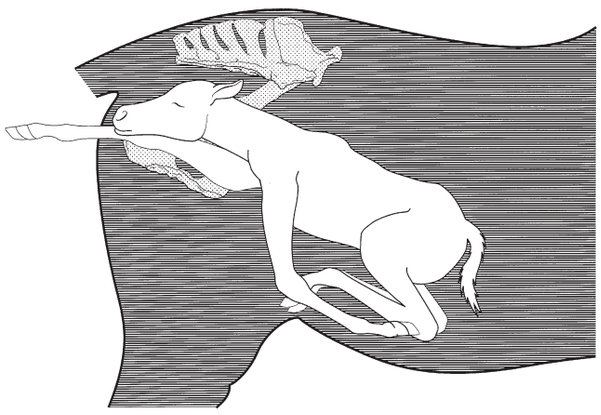

Fig. 14-5 Anterior presentation, dorsosacral position, with the head and right forelimb extended and left shoulder flexed. (From Threlfall WR: *Threlfall's equine obstetrics.* Powell, OH: Global Reproductive Services, 1996.)

*Jorgensen Laboratories, Loveland, CO.

to be placed into carpal or shoulder flexion to permit sufficient space for extension of the head. Attachment of a rope snare to the fetlock area of this limb facilitates postural correction following extension of the neck. A repulsion rod can be used to repel the fetus by placing it in the area of the sternum and pushing gently. The muzzle can be brought into the pelvis by pushing the poll of the head to the opposite side of the pelvis while applying traction to the mouth or muzzle (Fig. 14-7). A rope snare can also be used to facilitate this technique. As traction is applied to the rope snare, the hand is used to guide the neck and head into the pelvic canal. A rope snare placed on the mandible can be used as a method of postural correction but should never be used as a point of traction because the mandible fractures easily and the incisors can be removed in such attempts. If the fetus is alive, anesthetizing the mare and placing her in dorsal recumbency with the rear end elevated early in the correction process may be beneficial. If the fetus is dead, an immediate fetotomy may be the preferred method of correction.

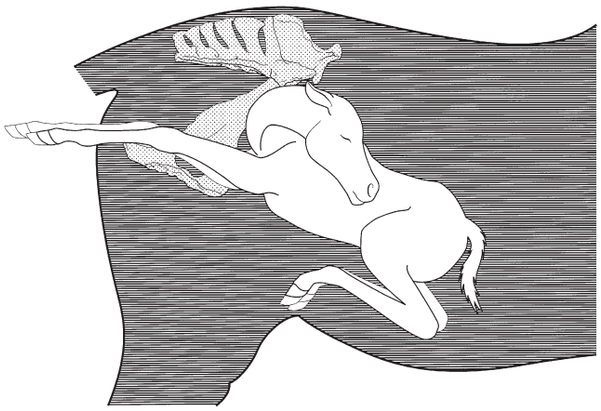

Fig. 14-6 Left lateral deviation of head and neck with extended forelimbs and fetus in anterior longitudinal presentation with dorsosacral position (lateral view). (From Threlfall WR: *Threlfall's equine obstetrics.* Powell, OH: Global Reproductive Services, 1996.)

Cranial longitudinal presentation, dorsosacral position with head, neck, and forelimbs extended and with bilateral hip flexion can be diagnosed following failure of delivery of a fetus that appears to be in proper presentation, position, and posture (Fig. 14-8). Determination is made on vaginal examination that the fetal rear hooves are located in the mare's pelvis near the elbows of the fetus. The first step in correcting this abnormal posture is to repel the rear hooves over the brim of the pelvis and into the abdominal cavity. This may not be possible owing to forced extraction applied before an accurate diagnosis was made or to the time elapsed waiting for delivery of the fetus in what appeared to be a normal presentation, position, and posture. A dead fetus may have to be transected in the lumbar area and, if possible, repelled or the pelvis bisected and removed. If the fetus is alive, it may be impossible to deliver a viable offspring even if the mare's rear quarters are elevated or by cesarean section.

Correction of carpal flexion (Fig. 14-9) by mutation in live fetuses is best accomplished by grasping the limb in the area of the metacarpus with the hand positioned so the thumb and fingers completely encircle the limb. The proximal portion of the limb is then repelled into the uterus. The limb is rotated with the carpus pushed laterally and the hoof moved medially under the neck of the fetus and then pulled cranially with respect to the fetus. Once the hoof can be brought into the pelvis, the limb is extended. If this technique is not possible with the hand alone, a rope snare can be attached to the wire introducer and placed around the flexed carpus and formed into a loop. The loop is moved distally on the limb until the snare is distal to the fetlock if possible. The rope is tightened and traction is applied as the proximal portion of the limb is repelled. The disadvantage of this technique is the loss of control of the direction of the

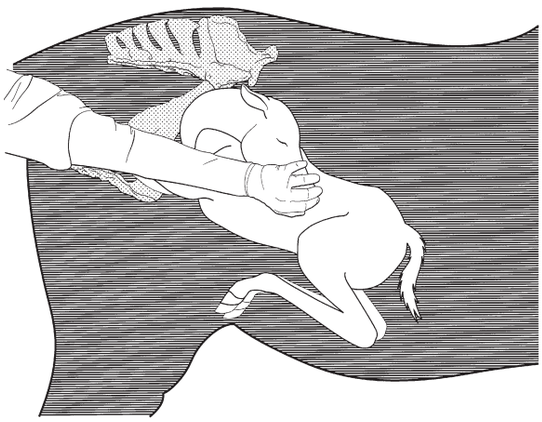

Fig. 14-7 Correction of head and neck lateral deviation by hand alone. Hand is placed around muzzle or fingers are placed in lateral commissure of mouth and a pulling pressure is applied. (From Threlfall WR: *Threlfall's equine obstetrics.* Powell, OH: Global Reproductive Services, 1996.)

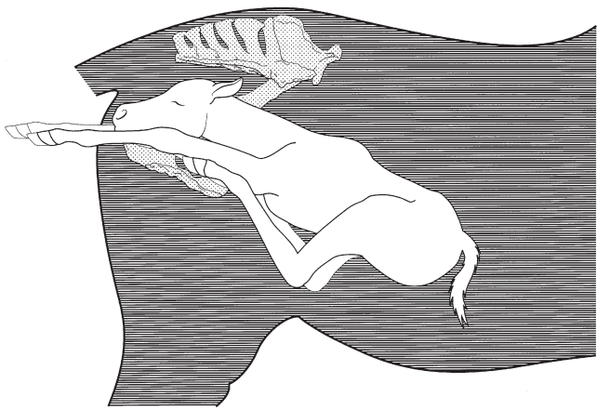

Fig. 14-8 Anterior presentation, dorsosacral position with head, front limbs, and rear limbs extended. (From Threlfall WR: *Threlfall's equine obstetrics.* Powell, OH: Global Reproductive Services, 1996.)

hoof as it clears the brim of the pelvis. However, it is an acceptable and beneficial technique that has application in some dystocias with a live fetus.

Dorsoilial and dorsopubic positions should be corrected before delivery of the fetus to ensure minimal trauma to the birth canal during extraction. Although other methods to rotate the fetus have been described, such as the hand alone to push or pull the fetus in the desired direction, these techniques require more physical work and are not as successful as the use of a detorsion rod. Although techniques have been described using chains without a detorsion rod for correction, there is a higher probability of injury to the vagina of the mare and the limbs of the fetus with this technique.

After determining the viability of a fetus in transverse presentation (Fig. 14-10), the method of correction should be employed immediately. If the fetus is alive, the best possible choices would be to do a cesarean section or attempt to elevate the rear quarters of the mare to provide additional space for manipulation. If possible, an attempt should be made to deliver the fetus in caudal presentation; the reason for this is to eliminate the need to direct the fetal head, and this may make the delivery more rapid. If the fetus is dead, transection of the fetus should be attempted if sufficient space is available. A major problem associated with a transverse presentation is that affected mares have usually been in labor for a much longer period of time than believed by the owner, since there may be no cervical pressure to induce the more visible expulsive efforts of stage II labor.

Forced Extraction

Forced extraction is generally combined with mutation or fetotomy. Forced extraction is not intended to replace other techniques but to aid in the delivery process. If used unwisely, forced extraction results in injury to the fetus or the mare's reproductive tract or both. Extractive force is used with uterine inertia, following corrective mutation, with inadequate cervical dilation, in caudal presentations and in combination with fetotomy. Extreme traction should never be applied in lieu of corrective mutation, a fetotomy or cesarean section because of the possibility of trauma to the mare or fetus. The position and posture of the foal should be as near to normal as possible before traction is applied. Traction placed on the fetus should be slightly dorsal and caudal until the forelimbs, head, and neck are at the vulvar lips. The direction of the traction is then directed more ventrally as more of the fetus is visible. Traction should be directed mostly ventral by the time the shoulders have passed through the vulvar lips.

When the operator is experienced and uses good judgment, forced extraction is relatively safe. It can cause various injuries, however, including damage to the head, limbs, and spinal cord of the fetus; damage to the uterus and cervix and adjacent structures; eversion of the uterus; and lacerations of the vagina, vulva, perineal body, and rectal floor. Aftercare following forced extraction may include uterine stimulants placed into the uterus or administered systemically. The use of antibiotics may be indicated to reduce the number of organisms that were introduced during the procedure. Broad-spectrum antibiotics are generally recommended for this purpose.

If it becomes apparent that forced extraction is not going to be successful, another technique for correction should be attempted. A common mistake made by obstetricians is to continue using a technique beyond a reasonable time in anticipation that eventually it will be successful. Determining the time to abandon one technique for another is gained through experience and is always a challenge.

Fetotomy

Fetotomy is indicated in many instances because the manipulative time and trauma to the mare can be reduced over that of mutation and forced extraction if the fetus is dead.[16] Fetotomy is a reduction in fetal size by removal of the extremities or dissection of the body. Specific indications include the presence of a dead fetus in the absence of excessive uterine contracture; a fetus that

is not overly emphysematous; abnormalities in fetal presentation, position, or posture; the presence of an oversized fetus in relationship to the maternal birth canal; the presence of fetal abnormalities such as ankylosis of joints; and incomplete cervical dilatation. The decision to perform a fetotomy also depends on the veterinarian's opinion that there is sufficient space in the dam's genital tract to perform the procedure and on the experience of the obstetrician. The advantages of a fetotomy include reduction of fetal size, elimination of need for a cesarean section, minimal assistance necessary, decreased trauma to the mare, less infertility than following cesarean section, less aftercare than with cesarean section, shorter recovery time than with cesarean section, greater practicality as a "field" technique than a cesarean section and greater monetary economy to both the owner and the veterinarian. A cesarean section is the preferred approach by many veterinarians over that of fetotomy in cases of a live or dead fetus that cannot be removed by mutation and forced extraction. Reasons given for not using fetotomy include overstretching of the cervix; more physical exertion by the veterinarian; lacerations of the uterus, cervix, vagina, and of the operator; and the procedure being "too hard on the mare." A cesarean section, however, cannot generally be performed under farm situations where no technical assistance or facilities are available, whereas fetotomies can be performed under these conditions. Supposedly to reduce severe injury to the genital tract, it has not been recommended to perform fetotomies that require more than one or two cuts.[17] However, the duration of the fetotomy, the damage to the reproductive tract prior to the initiation of the fetotomy, and the correctness of the cuts have a major influence on the success of the procedure. The other consideration on the farm is what other options are available that will save the life of the mare. Also, most equine dystocias are caused by simple postural anomalies, so only one or two cuts are necessary to permit delivery of the remainder of the fetus following fetotomy in most instances. Also, fetotomy procedures are generally less costly to the owner since aftercare is considerably less and future reproductive capability is better than following a nonelective cesarean section.

One of the primary determining factors in most but not all fetotomies is the quality and type of instrumentation available to the obstetrician and familiarity of the obstetrician with the procedures. Some veterinarians consider fetotomy as the last resort, and such thinking may result in failure. If performed properly, fetotomy requires less aftercare than a cesarean section and there is less probability of systemic infection, parametritis, perimetritis; higher reproductive capability; reduction in laminitis; and a shorter time to rebreeding.

Indications for total fetotomy should be recognized early so that cesarean section can be considered before a large amount of effort and time is expended on fetotomy. When performing a complete fetotomy on a fetus in cranial presentation, the following sequential cuts with some variations are recommended: amputation of the head; amputation of a forelimb; amputation of the opposite forelimb; transverse section through the third thoracic vertebra and removal of the remaining neck and the thorax cranial to the cut; transverse cut through approximately the third lumbar vertebra and longitudinal transection of the thorax; and finally a longitudinal cut through the pelvis. A partial fetotomy with one or more cuts, evisceration, and lubrication may enable simple mutation or forced extraction and delivery of the remainder of the fetus.

Dismembering a fetus in cranial presentation may be indicated for various reasons. Amputating a protruding fetal head in dystocias in which the forelimbs are retained provides more space for repositioning or removing the limbs. Owing to the rapid normal delivery of the fetus in the mare, partial placental separation and death of the fetus frequently occur by the time the obstetrician arrives at the dystocia. This situation plus the available assistance and surroundings may make fetotomy the only method possible to correct the dystocia and save the mare. An extended head is separated through the atlanto-occipital junction with the fetatome head resting against the caudal border of the ramus of the mandible. To do this, a loop of wire that has been threaded through the fetatome is placed around the fetal head and behind the ears in the area of the axis. After proper lubrication, it may be possible to deliver the remainder of the fetus by traction following head removal. The remaining portion of the fetus is within reach; it cannot drop further into the uterus because of pressure against the fetus. It is imperative that following placement of the obstetric wire, the position of the wire be checked one last time before any attempts to dissect the fetus are made. The hand of the obstetrician always covers the head of the fetatome during the amputation procedure. The person doing the sawing must fully understand that he or she is to start only when instructed to do so and to stop immediately when instructed to do so.

Probably the most common indication for amputating the fetal head and neck is lateral deviation. The forelimbs may have to be repelled if possible to provide more space in the birth canal for this fetotomy procedure. If the limbs cannot be repelled with little effort, the limb opposite the direction of the head deviation or opposite to the limb in flexure should be removed to provide additional working area for removal of the head. Neck amputation involves inserting the wire introducer with the obstetric wire attached around the fetal neck and then withdrawing it from the birth canal. The wire is threaded through the fetatome and the head of the fetatome is held tightly against the fetal neck at its greatest curvature. Following this cut, the head and attached portion of the neck of the fetus can be removed with the use of a Krey-Schottler hook.

Another common cause of dystocia in cranial presentation is a flexed forelimb. The limb is usually flexed at the shoulder and extends beneath the fetal body. A wire introducer with wire attached is passed dorsally over the shoulder and between the fetal trunk and the limb. The wire is then grasped ventrally and pulled outside of the genital tract. The fetatome is inserted into the uterus so that the head is approximately 5 cm dorsal and medial to the scapula's spinous process. After the limb has been severed, it is removed. Following amputation of the limb, the area of the scapular attachment is examined for

remnants of cartilage or bone fragments. If these are found, they can be removed with the fingers alone using blunt dissection or with the aid of the finger knife. The fetus can be removed if the flexed limb was the only cause for the dystocia, the opposite limb can be removed in the same manner, and the remaining cervical vertebral bodies used to secure the Krey-Schottler hook. In this instance the single point of traction is sufficient for delivery. If there exists a flexed carpal or, in the case of caudal presentation, tarsal joint, a cut distal to the joint may alleviate the dystocia with a dead fetus and save the mare further discomfort and injury that may occur with attempts to mutate the limb. The limb is amputated by placing obstetric wire around the limb with the wire introducer. The wire is then threaded through the fetatome and the cut is made distal to the joint. This permits the attachment of an obstetric chain to the remaining stump in order for this limb to be used as a point of traction.

A complete fetotomy performed in caudal presentation includes the following cuts: The first may involve either of the rear limbs depending on access. The second cut removes the opposite hind limb. The third cut removes the caudal aspect of the fetus including the remaining pelvis and the majority of the lumbar vertebra. The next cut is made through the area of thoracic vertebra immediately caudal to the scapula. Then the forelimbs can be removed one at a time. The neck and head with the remaining thorax could be removed together or separately. Other modified cuts may be necessary in cases such as hydrocephalus, when the head must be sectioned prior to removal, or in instances in which limbs may need to be sectioned, such as with a tarsal flexion, before delivery is possible.

With a true breech presentation only the tail is in the birth canal and may be observed protruding from the vulva. Both hind limbs are flexed and retained beneath the fetal body. A wire introducer is inserted dorsally over one hind limb between the trunk and the limb, and a hand is slipped under the limb to grasp the wire introducer ventrally and pull the end of the obstetric wire from the birth canal so that it can be threaded through the fetatome. The head of the fetatome is placed adjacent to the tailhead and a flexed hind limb is removed with a cut approximately through the coxofemoral joint. The amputated limb can then be removed. It usually is more rapid and less exhausting for the surgeon to remove the opposite retained limb in a similar manner rather than trying to mutate it. A Krey-Schottler hook can be inserted into the fetal pelvis to serve as a point of traction and deliver the remainder of the fetus after adequate lubrication.

In the case of an extended rear limb amputation, following placement of an obstetric chain on the rear limb with a loop above and another loop below the fetlock, the fetatome threaded with a loop of wire is placed as was described for removal of an extended forelimb. The loop of wire is fixed adjacent to the third phalanx alongside the chain. The head of the fetatome is moved slowly proximally toward the body of the fetus lateral to the limb until the head is 5 cm dorsal and cranial to the tuber coxae and is fixed in this position by attaching the chain to the fetatome. The wire is then moved alongside the medial surface of the limb while maintaining tension on the wire to prevent kinking or twisting. Immediately prior to dissection, the wire is checked to be certain of its placement. If indicated, the opposite rear limb can be removed in a similar manner. Once the limb or limbs have been removed, the fetal abdominal cavity should be incised and the abdominal contents removed to reduce the size of the abdomen. Removal of one or both rear limbs is a fairly common fetotomy procedure employed to permit the removal of an equine fetus due to abnormal posture of the rear limbs. If it is determined that the remainder of the fetus is still too large for forced extraction, a cut can be made through the area of the second lumbar vertebra to remove the pelvic portion of the fetus. If this problem was foreseen prior to removal of the second rear limb, the pelvis could be cut diagonally, thus allowing removal of the remaining rear limb and a portion of the pelvis with one cut. Fetotomy aftercare generally includes the administration of systemic uterine stimulants such as oxytocin and the infusion of antibiotics or antiseptics into the uterus.

Laparotomy is indicated primarily in those cases involving uterine torsion in which other methods of correction via the vagina were unsuccessful. The torsion may be evident months prior to the onset of labor as determined by prolonged colic-like signs that fail to respond to therapy for gastrointestinal pain. The diagnosis can be easily made by transrectal palpation of the uterus and broad ligaments. The finding of one broad ligament traversing the midline to the opposite side dorsal to the uterus with the other broad ligament nonpalpable is sufficient information to make the diagnosis. The correction of the uterine torsion via laparotomy can be achieved by one of several abdominal approaches with the mare standing or recumbent. The author prefers the standing flank approach on the side of torsion origin. For example, a counterclockwise torsion would be approached from the right flank. The author prefers this approach because the uterine horn can be pulled or pushed into normal position.

Laparohysterotomy

Laparohysterotomy is another option for the alleviation of dystocia. Cesarean section refers to delivery of a fetus through incisions in the abdominal wall and uterus of the dam. Cesarean section has its best advantage following repositioning of a uterine torsion or when preplanned and the time and facilities are immediately available to permit delivery of the fetus while alive. Indications for cesarean section include a previously fractured pelvis or other obstruction that reduces pelvic diameter; a small pelvis; an extremely large fetus; abdominal wall or prepubic tendon ruptures; uterine torsion that is not correctable by a vaginal approach or by rolling the mare; malpresentations that are not correctable by other methods; emphysematous fetuses; fetal anomalies; and a live fetus that cannot be delivered by any other way. One complication of cesarean section is rupture of the uterine artery during manipulation. The biggest problems encountered in regard to a cesarean section are mare and foal survival and future reproductive performance of the

mare. An elective cesarean section gives the best prognosis for both.

The considerations involved in selecting a site for a cesarean section include the operative conditions and disposition of the animal. The surgeon's previous experience with operative sites is another major consideration. The possible operative sites include right and left flank with the animal standing using sedation and local anesthesia. This approach, however, is seldom recommended owing to reduced exposure of the uterus, visible abdominal wall scarring, and possible movement of the mare during surgery. The flank approaches under general anesthesia are also options, but the reduced uterine exposure and visible scar following surgery are disadvantages. The primary advantage of the left flank over the right is that the cecum is less of a problem and thus does not obstruct access to the uterus. However, intestines may make the left flank approach difficult. Possible operative sites in a recumbent animal include low approaches through either flank, the paramedian area, or the abdominal midline. The ventral midline incision is most commonly used and has the advantage of providing excellent exposure of the uterus. There is very little hemorrhage when this site is used. There may be one or two large veins in this area that form an anastomosis from the right to left subcutaneous abdominal veins. These veins, if present, should be ligated prior to making the incision in the subcutaneous tissue.

After the fetus is removed through the incision, the placenta is removed if it is free within the uterine cavity. If the placenta is still adhered to the endometrium, it is left in the uterus and an antibiotic solution or boluses are placed into the lumen before closure. If hemorrhage occurs from the subendometrial veins, the veins are ligated independently or a ligature is placed in the area of the hemorrhage, including endometrium, subendometrium, and myometrium. Simple continuous, continuous interlocking, or similar suture patterns can also be used to control hemorrhage. A Cushing suture pattern can be used to infold the incision site. The suture should be placed so that very little if any suture material is apparent on the serosal surface following closure. This will reduce the adhesions that form between the uterine wall and abdominal viscera. The care of mares following a cesarean section should be provided on an individual basis because it is not feasible to treat all animals the same way and achieve good results. Repeated administration of oxytocin is advisable to enhance uterine involution.

Following the correction of dystocia by any method, the uterus should be examined to ensure that another fetus is not present. The tone of the uterine musculature should also be assessed. The birth canal should be palpated for evidence of lacerations.

CHAPTER 15

Abnormalities of Lactation

STEVEN D. VAN CAMP and MARY BETH STANTON

Lactational abnormalities are rarely encountered in mares. Yet when a particular mare is involved and her foal is at risk, these problems are highly significant to the mare's owner. Equine lactational problems may have received so little study or documentation in the veterinary literature because they are often easily corrected and because adequate substitutes for mare's milk are available. Abnormalities of lactation can be classified as functional or infectious. Functional abnormalities include agalactia, galactorrhea, precocious lactation, premature lactation, and eclampsia (lactational tetany). Mastitis is the main infectious abnormality.

To understand these abnormalities, it is important to comprehend lactational physiology and anatomy of the equine mammary gland. These topics have been reviewed.[1]

ANATOMY AND PHYSIOLOGY

The equine udder consists of two flattened, cone-shaped glands, each terminating in a short, laterally flattened teat. Each gland contains distinct lactiferous duct systems, organized into lobes and lobules that are incompletely separated from one another by fascial trabeculae extending into the gland from the medial and lateral suspensory ligaments. The cranial lactiferous duct system is the largest. Each teat has two or three orifices, each connecting to its own lactiferous duct system within the gland. The orifice leads to a streak canal that connects to a cistern within the teat. Each teat cistern opens into a gland cistern above the teat in the lactogenic portion of the gland.[2,3] The small size of the teat orifices and the separate lactiferous duct systems associated with each gland complicate intramammary therapy in cases of mastitis.

During the first gestation the mare's udder changes from two small inguinal skin folds with teats into recognizable mammary glands under the influence of the gestational hormones. Estrogen promotes mammary gland duct development; progesterone facilitates proliferation of the lactogenic epithelial cells and organization of clumps of these cells into mammary alveoli.

The decline in estrogen and progesterone late in gestation is associated with increased prolactin release from the anterior pituitary during the last week of gestation.[1,4,5] It is thought that prolactin release is made possible by suppression of prolactin-inhibiting factor from the hypothalamus. Dopamine is likely the prolactin-inhibiting factor in mares and other animals.[1] Thyrotropin-releasing hormone (TRH) may function as a prolactin-releasing factor.[4] A rise in prolactin is associated with final development of the mammary gland and the onset of lactogenesis. In addition to prolactin, adrenal corticosteroids, insulin, growth hormone, glucagon, and thyroid hormones play a role in mammary gland development and lactogenesis, although their exact functions in mares are poorly understood.[4]

During nursing, milk ejection occurs as myoepithelial cells surrounding the mammary alveoli contract in response to oxytocin released from the posterior pituitary. Oxytocin is synthesized in the hypothalamus and stored in secretory vesicles within the hypothalamic oxytocin neurons. It is released from nerve terminals in the posterior pituitary. Hypothalamic oxytocin neurons are also stimulated to release oxytocin in response to vaginal stimulation, which occurs during parturition.[5]

Abnormal endocrine stimulation may lead to functional lactational abnormalities such as agalactia, hypogalactia, galactorrhea, precocious lactation, premature lactation, or eclampsia.

AGALACTIA

Agalactia must be differentiated from failure of milk letdown. The udder is slack and not engorged with milk in agalactic mares. On the other hand, some maiden mares with tender edematous mammary glands or nervous mares are reluctant to relax and allow nursing and thus retain milk in the glandular alveoli. Phenothiazine tranquilizers and warm towel massages of the udder are helpful in these mares.[6,7] In addition to their calming effect, phenothiazine tranquilizers stimulate release of prolactin and may augment lactation. Oxytocin (10–20 units) has also been used to help stimulate milk letdown once mares are relaxed.[8]

Agalactia at parturition may actually be delayed onset of lactation. This condition has been described in some maiden and multiparous mares that had small udders and only honey-like mammary secretions.[6] Many of these mares start lactating within a day or two but some may have decreased milk output. Phenothiazine tranquilizers, udder massage with hot packs, and repeated stripping of secretions from the udder may help speed the onset of lactation. TRH (2.0 mg SC, twice a day for 5 days) has been used successfully in some affected mares.[9]

Agalactia in mares without udder development is typical of fescue toxicity.[6,7,10] Fescue toxicity occurs frequently when pregnant mares are fed fescue infected with the endophyte fungus *Acremonium coenophialum*. This fungus produces a toxin (thought to be an ergot alkaloid) that suppresses prolactin release.[11] Prolactin levels return to normal by 2 to 3 weeks after the toxin is removed.[11] The endophyte is spread through fescue seeds.

A similar syndrome is seen in mares that ingest *Claviceps purpura* (ergot).[12] Fescue toxicity is most significant during the last 90 days of gestation in mares. In addition to agalactia, affected mares may experience prolonged gestation and thickened placentas, which are associated with neonatal asphyxia. Mares grazing infected fescue may also experience reduced fertility.[13] The mares experiencing prolonged gestation frequently have a history of udder development at their expected due date, but the udder involutes and they are agalactic by the time of delivery.

Treatment of fescue-induced agalactia has been aimed at overcoming suppression of the release of prolactin and possibly TRH. TRH, as well as phenothiazine tranquilizers, has been used as described in some cases.[14] More recently, the use of the dopamine receptor antagonist perphenazine (0.3 mg/kg PO twice a day) has been popular for treating fescue-related agalactia.[15] However, some mares experience severe side effects when treated with this drug, including sweating, colic, hyperesthesia, ataxia, and posterior paresis.[16,17] The dose of perphenazine should be calculated based on the patient's weight, and treatment must be carefully monitored and suspended if adverse effects become evident. The selective DA_2 dopamine receptor antagonist domperidone (1.1 mg/kg PO once a day) prevents the signs of fescue toxicosis without adverse side effects.[17]

Prevention of fescue toxicosis rather than treatment should be the primary objective. The current recommendations include the following: (1) maintain mares on nonfescue pasture when practical; (2) dilute the toxin by overseeding pastures with a palatable legume every 2 years so that 20% of the forage is a legume; (3) kill the infected fescue with herbicides and tillage and reseed with noninfected endophyte-resistant strains of fescue that are not allowed to develop seed heads for at least 2 years; and (4) remove mares from fescue during the last 90 days of gestation and provide nonfescue forage or hay.[7] Prevention of toxicosis may also improve fertility, neonatal survival, and foal growth in addition to eliminating agalactia.

Agalactia may be encountered in mares that have established lactation but prematurely cease milk production. Insufficient energy intake to support lactation must be considered, especially in mares that have experienced excessive weight loss during lactation. If the ration is adequate, the stress of pain or disease must be ruled out as the cause of cessation of lactation. Attempts to reinitiate lactation are unsatisfactory.[6]

INDUCTION OF LACTATION

Lactation may be induced in nonparturient mares that have foaled in previous years. This offers the opportunity to produce nurse mares for orphaned foals. However, the immunoglobulin levels provided by milk from an induced lactation are generally inadequate to achieve successful passive transfer in the foal. There is considerable mare variation in the production of IgG.[18,19] Sulpiride, a dopamine D_2 antagonist, successfully induced lactation in cycling mares but not in ovariectomized mares. Prolactin levels did not increase as much in the ovariectomized mares.[20] Progesterone and estrogen are required for lactation induction and the variability of these hormone levels seems to cause the variability of the amount of milk production.[21] The protocol for lactation induction includes altrenogest (44 mg/day PO), estradiol benzoate (10 mg/day IM), and sulpiride, 1 mg/kg IM, twice a day for 7 days with milking to commence on the seventh day.[18] Reinstituting the administration of sulpiride on day 23 of treatment yielded a 75% increase in milk production at day 30 as compared to an 11% increase in the group that did not receive additional treatment after day 14.[22] There is an initial difference in weight gain for the first 4 weeks between foals nursing mares with an induced lactation but by the time of weaning there was no difference in weight.[18]

HYPOGALACTIA

Hypogalactia, low milk production, may be the result of malnutrition in mares. Lactating mares require 1.7 and 1.5 times as much energy during early and late lactation, respectively, compared with nonlactating mares.[1,23] A sound feeding program is necessary to maintain adequate lactation. The use of body condition scores is a valuable method for determining adequacy of the ration to maintain lactation. Other factors that have been incriminated as causes of hypolactation include restricted water intake, selenium deficiency, and stress.[1]

GALACTORRHEA

Precocious lactation in weanling or yearling fillies and nonpregnant or maiden mares occurs occasionally for unknown reasons.[1] The cause is unknown, so treatment has been empirical and includes prevention of nursing by other animals and restriction of feed and water. Theoretically, this condition may be associated with elevated prolactin levels and thus suppression of prolactin secretion may be helpful.

Premature lactation during middle to late gestation may indicate problems with pregnancy. Impending abortion, death of one twin, placental separation, and placentitis have been associated with this condition; however, premature lactation may occur in the absence of any of these conditions. Although treatment with supplemental progesterone has been attempted in affected mares, its efficacy is unknown. There is no specific treatment.[1] Administration of the semisynthetic ergot alkaloid bromocriptine to suppress prolactin in affected mares is not indicated because it may depress progesterone concentrations during late gestation and lead to placental thickening, dystocia, and reduced neonatal survival.[15] Premature lactation during pregnancy probably has no effect on postpartum lactation with the exception of loss of colostrum in periparturient mares.[24]

LACTATIONAL TETANY

Eclampsia or lactational tetany of mares may be more appropriately discussed as a metabolic disease resulting in hypocalcemia than as a functional disease of lactation.

This rather uncommon condition is frequently associated with early lactation in mares on lush pasture that produce large quantities of milk. It occurs most commonly in the first 2 weeks of lactation, often during foal heat, but may also occur after weaning. It may or may not be accompanied by hypomagnesemia and in some cases may be associated with hypermagnesemia.[25] Eclampsia may be precipitated by heavy work or prolonged transport. Hypomagnesemia with hypocalcemia is usually precipitated by transport.[25]

Clinical signs are those typical of hypocalcemia in other species and include excitability, mild muscle fasciculations and gait stiffness, flared nostrils, profuse sweating, muscle paresis, tachycardia, synchronous diaphragmatic flutter, convulsions, coma, and death. Urination and defecation are usually absent, intestinal motility is reduced, and swallowing is hindered.[25,26] Untreated animals usually die within 24 to 48 hours of onset.[27]

The treatment of choice is intravenous 20% calcium gluconate solution. A dose of 250 to 500 ml diluted 1:4 with saline or dextrose is usually effective for a 500-kg mare. A second dose 15 to 30 minutes later may be needed if signs do not abate.[26,27] Urination or defecation, or both, indicates a positive response.[25] Full recovery may take hours or in some cases days.[26,27] Calcium and magnesium solutions used to treat milk fever in cattle can be used with caution. Hypermagnesemia may already be present. Hypomagnesemic mares may benefit from administration of preparations containing magnesium designed for use in cattle.

The clinical signs may be mistaken for those of tetanus during the early stages, although the third eyelid does not prolapse as in tetanus and mares are not hypersensitive to loud noises.[25] Other causes of hypocalcemia should be ruled out, including blister beetle toxicity, pancreatic disease, renal disease, and exertional rhabdomyolysis.[26]

MASTITIS

Mastitis is rare in mares and occurs as isolated cases rather than as herd problems. It can occur at any stage of lactation but is most often observed after weaning[28] and can occur in mares that have not been pregnant for several years.[29] Clinical signs include a hot, swollen, painful udder; depression; anorexia; fever; ventral edema; rear leg stiffness; and lameness.[1,28,30] The milk is often thick and difficult to express from the udder because of pain. The most common organism that causes mastitis in mares is *Streptococcus zooepidemicus,* although other reported organisms include *Streptococcus agalactiae, Streptococcus equisimilis, Streptococcus viridans, Actinobacillus suis, Actinobacillus* spp, *Pasteurella ureae, Enterobacter aerogenes, Corynebacterium pseudotuberculosis, Klebsiella pneumoniae, Pseudomonas aeruginosa,* and *Escherichia coli*.[29,30] Mycotic mastitis has also been reported in a mare as a result of a disseminated infection. The causative agent was *Coccidioides immitis*.[31] Mares may be affected by gangrenous mastitis similar to that which occurs in cows.[32] Verminous mastitis has been documented in a mare. The nematode identified was a species of *Cephalobus* that multiplied within the mammary gland resulting in mastitis.[33]

Treatment consists of systemic antibiotics, intramammary antibiotics, hot packs, frequent milking, and systemic nonsteroidal anti-inflammatory drugs. Antibiotic choice should be based on culture and sensitivity of the organism. However, trimethoprim-sulfonamide or penicillin and gentamicin are good choices for initial systemic therapy while awaiting culture results.[28] Bovine intramammary infusions can be used in the mare's udder, but the size of the teat orifices and the pain involved in many cases make administration difficult. Both orifices on each teat should be treated if intramammary infusions are used, because each orifice leads to a separate lactiferous duct system within the gland. Treatment can be unsuccessful and result in persistent infection and atrophy of the glandular system.

CHAPTER 16

Immediate Care of the Postpartum Mare and Foal

MICHELLE M. LEBLANC

EXAMINATION OF THE NORMAL POSTPARTUM MARE

The initial examination of the postpartum mare should be simple, as intervention beyond absolute necessity may disrupt the adaptation processes that are under way during this time. The examination should consist of evaluation of the mare's behavior including attitude and interaction with her foal and her general condition including character of pulse and respiration, color of mucous membranes, degree of alertness, and responsive reaction to stimuli. The udder also needs to be carefully examined for consistency of mammary secretions and patency of the teats. Further evaluation of the systemic condition, such as rectal and vaginal examination, blood counts, and clinical chemistry tests, are not indicated unless a specific problem is suspected based on the general examination.

The placenta should be thoroughly examined and weighed once it is passed. A normal equine placenta weighs approximately 14% of the mare's body weight or between 10 and 18 lb. A placenta weighing greater than 18 lb is edematous and indicates that the foal may not have received adequate gas exchange in utero. Foals from excessively heavy placentas need to be considered at high risk for neonatal problems. The chorioallantoic and allantoamnionic surfaces and the umbilical cord need to be examined. Irregularities in color, thickness, length of villi, and the presence of any secretions should be noted. If placental abnormalities are found or the foal is born before 325 days of gestation, a blood sample from the foal should be obtained and a complete blood count performed. Foals that experience in utero stress may have either a low white blood cell count (<5000 cells/μl) and low fibrinogen level (<200 mg/dl) if the stress was of short duration leading to premature delivery, or if the stress was

CHAPTER 16

Immediate Care of the Postpartum Mare and Foal

MICHELLE M. LEBLANC

EXAMINATION OF THE NORMAL POSTPARTUM MARE

The initial examination of the postpartum mare should be simple, as intervention beyond absolute necessity may disrupt the adaptation processes that are under way during this time. The examination should consist of evaluation of the mare's behavior including attitude and interaction with her foal and her general condition including character of pulse and respiration, color of mucous membranes, degree of alertness, and responsive reaction to stimuli. The udder also needs to be carefully examined for consistency of mammary secretions and patency of the teats. Further evaluation of the systemic condition, such as rectal and vaginal examination, blood counts, and clinical chemistry tests, are not indicated unless a specific problem is suspected based on the general examination.

The placenta should be thoroughly examined and weighed once it is passed. A normal equine placenta weighs approximately 14% of the mare's body weight or between 10 and 18 lb. A placenta weighing greater than 18 lb is edematous and indicates that the foal may not have received adequate gas exchange in utero. Foals from excessively heavy placentas need to be considered at high risk for neonatal problems. The chorioallantoic and allantoamnionic surfaces and the umbilical cord need to be examined. Irregularities in color, thickness, length of villi, and the presence of any secretions should be noted. If placental abnormalities are found or the foal is born before 325 days of gestation, a blood sample from the foal should be obtained and a complete blood count performed. Foals that experience in utero stress may have either a low white blood cell count (<5000 cells/μl) and low fibrinogen level (<200 mg/dl) if the stress was of short duration leading to premature delivery, or if the stress was

prolonged, a high white blood cell count (>8000 cells/μl) and a high fibrinogen level (>400 mg/dl).[1] Premature foals or foals that experience in utero stress have a greater chance of survival with appropriate nursing care.

CARE OF THE NORMAL POSTPARTUM MARE

Mares should foal in a clean, dry, draft-free area that has protection from excessive sun and wind. If the climate permits, a small, clean grass paddock is best; otherwise, a well-bedded dry stall that is at least 12 ft by 12 ft will do. Mares housed in paddocks can be grouped with either one or two mares or be left by themselves. The number of mares in the paddock should be minimal to decrease competition among the mares for food and space and to allow the mare to bond with her foal.

During the postpartum period mares need exercise to promote uterine involution and to stimulate appetite and gastrointestinal function. Leaving a mare in a stall for prolonged periods is detrimental, as the mare may accumulate intrauterine fluid leading to metritis or septicemia. If the mare must remain in the stall because the foal is ill, the mare's uterus should be evaluated daily for fluid accumulation. If fluid accumulates, lavaging her uterus with large volumes of warm saline until the efflux is clear followed by administration of 10 to 20 units of oxytocin has been helpful in preventing metritis.

For the first few days after foaling, feeding should be light to moderate, and laxative feeds such as bran mashes are appropriate to reduce the incidence of constipation.[2] Routine care of the mare post partum should include essential preventive medicine procedures. In the ideal situation, mares will have received routine vaccinations for the common infectious diseases during the last month of gestation. This allows maximum protection for the foal by way of colostrum. When vaccination history is vague or absent, the mare should be simultaneously vaccinated with tetanus antitoxin and toxoid, at different sites.

Most broodmares on well-managed farms are on a parasite control program whereby antiparasiticals are given every 45 to 60 days. If the mare is not on a bimonthly program and has not been dewormed during the last 2 months of gestation, she should be dewormed within a few days of foaling. Broad-spectrum antiparasitical compounds such as ivermectin are best. Then, an intensive parasite control program, preferably deworming every 45 days, should be implemented.

Mares with a history of a Caslick's operation as an essential part of infertility management should be resutured as soon as practical. If performed within 15 minutes of parturition, local anesthesia is not required. If the mare tears the dorsal commissure of her vulva and it is not sutured immediately, it is best to keep the area clean until it is sutured in 3 to 4 days. If it is sutured when inflammation is maximal, 24 to 48 hours after parturition, it will likely dehisce.[3]

COLOSTRUM MANAGEMENT

As the foal depends on absorption of adequate quantities of colostral immunoglobulin for protection against disease during the first month of life, the quality and quantity of colostrum needs to be assessed. Colostrum with a high immunoglobulin concentration is thick and sticky with either a yellow- or gray-tinged appearance. Immunoglobulin content can be estimated by measuring the colostral specific gravity. However the equine colostrometer (Lane Manufacturing, Loveland, CO) developed for measuring specific gravity is difficult to obtain commercially. A colostral specific gravity of 1.06 or greater correlates with a colostral IgG content of greater than 3000 mg of IgG/dl (30 G/L). Foals that suckle colostrum with a specific gravity over 1.06 rarely exhibit failure of passive transfer and have serum IgG concentrations above 400 mg/dl at 24 hours of age.[4] Colostral quality can also be estimated with a sugar (Bellingham & Stanley, Inc., 5815 Live Oak Parkway, Suite 2C, Norcross, Atlanta, GA 30093) or an alcohol refractometer.[5] The alcohol refractometer is used to measure the percentage of alcohol in wine by wine makers and is readily available. Colostrum with a level of 6000 mg of IgG/dl (60 g/L) read 16% with the alcohol and 23% with the sugar refractometer.

Colostrum with a specific gravity above 1.07 or with a 16% reading from the alcohol refractometer or 23% with the sugar refractometer may be saved for a colostrum bank. Two hundred fifty milliliters can be collected from the udder after the foal first sucks. The colostrum should be tested for isoantibodies to ensure that the foal that receives the banked colostrum does not develop neonatal isoerythrolysis. Colostrum can be stored in clean labeled containers in a refrigerator freezer (–5° C) for approximately 18 months without degradation of the IgG. Frozen colostrum can be thawed in warm water or in a microwave on the defrost cycle.

TREATMENT OF MARES WITH POSTPARTUM COMPLICATIONS

Postpartum mares that are ill will usually exhibit signs of abdominal pain or depression. Examination of these mares must include a complete physical, transrectal palpation of the reproductive tract and manual vaginal examination. Transabdominal or transrectal ultrasonography can be used to identify a ruptured bowel or uterus, the presence of free blood or feces in the abdomen, or peritonitis. Ancillary clinicopathologic tests should include a complete blood count, serum electrolyte determinations, and in patients in which internal bleeding or compromised bowel function is suspected, abdominocentesis and cytologic evaluation of the fluid obtained.

Diagnosis is often difficult because the clinical signs of many postpartum problems are nonspecific. Abdominal pain is the most common clinical sign of periparturient mares experiencing difficulty. This sign frequently occurs in foaling mares undergoing normal uterine involution and expulsion of the placenta. However, because of the incidence of complications, the following differential diagnoses must be considered in mares showing signs of abdominal pain after foaling: internal hemorrhage from rupture of the uterine artery or uterus; rupture of the cecum, stomach, or right ventral colon; ischemic necro-

sis of the small colon; colonic torsion; uterine torsion; retained placenta; and rupture of the urinary bladder or diaphragm.

Depression may follow a course of abdominal pain and may be the only clinical finding, especially if the mare has ruptured a viscus or has septic metritis.[3] These conditions can usually be differentiated by physical examination, complete blood count, and abdominocentesis.

Postpartum Hemorrhage

Hemorrhage from a uterine artery is common in older mares and is a cause of death in a significant number of aged broodmares.[2] Multiparous mares over 10 years of age are primarily affected; however, postpartum hemorrhage may occur in young mares as well. Hemorrhage from the artery is not always fatal. It may slowly dissect into the broad ligament or between the myometrium and the serosa of the uterus, forming a hematoma. The resulting clot stops the arterial bleeding and the mare may not exsanguinate. If the broad ligament ruptures or the serosal surface of the uterus tears during formation of the hematoma, the mare quickly bleeds to death.

Mares that bleed into the broad ligament display signs of colic. As tension increases on the broad ligament and the uterine serosa stretches, the mare sweats, the pulse rate increases, and the mucous membranes become pale. Signs of colic may go unobserved, if parturition has been normal and it is assumed that the mare is exhibiting pain from normal postfoaling uterine contractions. Many mares with postpartum hemorrhage are not discovered until they are weak or dead.

Hemorrhage into the broad ligament can be diagnosed by transrectal palpation of the uterus and ipsilateral broad ligament and ovary or by transabdominal ultrasonography of the caudal abdomen. Palpation causes extreme discomfort, and the degree of enlargement of the uterus indicates the extent of hemorrhage.

Mares that have uterine artery tears do not always have a low packed cell volume (PCV) early in the course of disease because the spleen may contract and thereby increase the number of red blood cells in the intravascular space. The PCV of peritoneal fluid may range from 15% to 50%, depending on the amount of blood that has leaked into the peritoneal cavity. Mares with a ruptured uterus may also exhibit blood in the peritoneal tap. Over time, these mares exhibit an increase in number of white blood cells and possibly bacteria in their peritoneal fluid.

The most successful treatment consists of confining the mare to a dark, quiet stall, using mild sedation if necessary. Blood transfusions, plasma volume expanders, and fluid therapy do not seem to alter the course of many cases and may even be contraindicated if the mare becomes excited by treatment procedures. Administration of naloxone (8–32 mg) or formalin (10 ml) in 500 ml of saline intravenously has gained popularity as a treatment for controlling hemorrhage in the postpartum mare, but the efficacy of these treatments is not clear. The recommended dose of naloxone is not sufficient to stop hemorrhage but at the low dose mares experience a profound relaxation.

Rupture of the Uterus

Mares that rupture the dorsal aspect of the uterus during second stage labor frequently stop active contractions during the delivery. These mares quickly become depressed, are cold to the touch, and sweat. Some will exhibit signs of colic. If the uterine tear is located elsewhere, as in the tip of the horn, the mare may not show clinical signs for 12 to 24 hours. Again, clinical signs will range from acute colic to severe depression. Unless the tear is located just anterior to the cervix or within the uterine body, it is difficult to find the lesion on manual exploration of the uterus. Abdominocentesis is most helpful in confirming the diagnosis. Mares with a uterine tear will have extracellular or intracellular bacteria, increased numbers of white blood cells and red blood cells, degenerate neutrophils, and increased protein content in the peritoneal fluid.

Immediate treatment for hemorrhagic shock or dehydration is indicated. Antibiotics and nonsteroidal anti-inflammatory drugs should be given to control sepsis. The best treatment for salvaging both the life and breeding potential of the mare is laparotomy and surgical repair of the uterine rupture. Abdominal lavage can be performed to reduce contamination. Following repair the uterus should be massaged every 24 hours to prevent formation of adhesions.[6]

Gastrointestinal Complications

Gastrointestinal complications in postpartum mares include rupture of the cecum or right ventral colon, colonic torsion, and ischemic necrosis of the small colon.

The large bowel may be traumatized during parturition when it is full of ingesta or distended with gas. Abnormal expulsive efforts are strong enough to rupture portions of the large bowel entrapped in the birth canal. The cecum is the most likely organ to be ruptured, apparently by explosive increases in intra-abdominal pressure. The large colon and possibly even the rectum may be damaged during foaling. Rents commonly occur 10 to 15 cm from the ileocecal orifice, ventrally in cecal rupture, or caudally in ventral large colon rupture.

Affected mares appear normal at the beginning of parturition. However, during the second stage of labor, instead of the normal, powerful straining using thoracic and abdominal muscles, straining movements are either weak or absent. Manual examination reveals a large fetus in normal presentation, position, and posture, but the mare appears unable to expel it. Manual delivery of the foal is accomplished without difficulty but subsequent observation shows the mare is not recovering from foaling as expected. Increased pulse and respiration rates, sweating, and shock due to severe peritonitis develop quickly.

Most mares succumb about 4 to 6 hours after delivery of the foal. Abdominocentesis is an important diagnostic tool in such cases; the mare should be destroyed if ingesta is discovered in the peritoneal cavity. The course of those mares in which the large bowel is damaged but not ruptured is less dramatic. The ensuing necrosis results in a

slowly developing peritonitis due to movement of organisms through the damaged gut wall.

Though treatment for rupture or severe trauma to the large bowel is virtually impossible, some preventive measures before foaling are helpful. Though most mares voluntarily restrict roughage intake within a few days of parturition, some do not. This is particularly true when mares are managed in groups that compete for feed. It is a good management practice to reduce the quantity of hay fed to all mares a few days before parturition.[2]

Contusions of the small intestine or small colon or its attaching mesentery can occur during parturition. Contusions may produce mild transitory signs of colic and go unrecognized. More severe trauma may result in mesenteric rupture, leading to possible intestinal incarceration or occlusion of the vascular arcade, which results in segmental ischemic necrosis of the bowel ("bruised small colon"). Signs of abdominal pain are seen at any time, from foaling to 24 hours after parturition. Rectal palpation of abdominal viscera reveals inconsistent and varied findings, from absence of palpable abnormalities to an impacted small colon. Results of peritoneal fluid analysis are consistently abnormal.

Exploratory celiotomy is recommended if mesocolic rupture is suspected. However, resection of the devitalized bowel may be complicated by difficulties in surgical exposure, depending on the anatomic location of the injured bowel. Survival rates following ischemic necrosis of the small colon are poor.

IMMEDIATE CARE OF THE NEWBORN FOAL

The role of the veterinarian in the immediate postnatal period will vary with training and experience of the foaling attendants. As the veterinarian is seldom present for a normal foaling, he or she should review with the foaling attendant normal foal behavior and emergency procedures. Guidelines indicating when veterinary assistance is needed should be discussed with the foaling assistant. If parturition proceeds normally, the first veterinary examination is conducted between 8 and 24 hours after birth. Normal foal parameters are presented in Table 16-1.

A foal that is not breathing at birth needs immediate assistance. The foaling attendant can attempt to resuscitate the foal by clearing the nostrils and mouth, by placing blunt objects into the nostrils to stimulate breathing, and by holding the head upright so that fluid may drain through the nostrils. Mouth-to-nose resuscitation may "buy time." The veterinarian should be contacted immediately. Large farms frequently have a source of humidified oxygen that may be delivered to foals. Farm personnel must be trained in its use.

Immediately after birth and again in 4 to 6 hours, the navel of the foal needs to disinfected to reduce the number of microorganisms that colonize the umbilical stump. For years, an iodine based disinfectant, preferably a 3.5% solution, has been advocated. Stronger solutions such as 7% tincture of iodine cause tissue destruction and should be avoided. Work from California, however, indicates that a 0.5% chlorhexidine diacetate solution is more effective in reducing bacterial numbers than 2% povidone-iodine and does not cause tissue destruction.[7]

Table **16-1**

Parameters of Normal Foals Immediately after Birth

Parameter	Time Frame
Time to suck	Within 2–20 minutes; stimulated by placing finger in mouth
Sternal recumbency	1–2 minutes
Time to stand	1–2 hours; longer than 2 hours is abnormal
Time to nursing	2 hours; longer than 3–4 hours is abnormal
Temperature	99–101.5° F
Heart rate	1–5 minutes post foaling >60 bpm; 6–60 min: 80–130 bpm
Respiration rate	First 30 minutes post foaling: 60–80 breaths/min; 1–12 hours: 30–40 breaths/min
Blood Glucose	>80 mg/dl

Adapted from Madigan JE, DVM, Live Oak Publ, Woodland, CA 95776.

Warm water enemas or soap-based enemas are commonly administered to foals to facilitate passage of the meconium. If used, the enema tube should be lubricated before its placement in the rectum. Small amounts of enema fluid, 60 to 120 ml, should be administered slowly, and repeated until the meconium is passed. If resistance is met during delivery of the enema, the procedure should be stopped until veterinary assistance is available.[8] If the dam has not been vaccinated against tetanus during the last 30 days of gestation, her foal should receive tetanus antitoxin at birth. Tetanus toxoid should be given at 6 weeks of age and repeated at 12 weeks. Antibiotics are not indicated if the foal is normal at birth.

The foal's first veterinary examination is usually between birth and 24 hours. At this time the veterinarian should observe the foal from a distance to determine its behavior, ability to rise, coordination and strength, ability and willingness to nurse, and attitude and response to external stimuli. A brief but complete physical examination should be performed.[9] A serum sample for measuring IgG concentration and, if a problem is detected in either the foal or the placenta, a blood sample for a complete blood count needs to be drawn. Foals with serum IgG concentrations above 800 mg/dl are considered to have adequate transfer of maternal immunity. Foals having serum IgG concentrations below 400 mg/dl are considered to have failure of passive transfer. Serum for measuring IgG can be obtained as early as 8 hours after birth. By measuring serum IgG concentrations in foals at 8 to 12 hours of age the veterinarian has time to supplement orally foals with low IgG concentrations prior to gut closure. Foals younger than 18 hours of age with IgG concentrations between 200 and 400 mg/dl and foals whose dams have colostral specific gravities less than 1.06 (alcohol refractometer reading <16%; sugar refractometer reading <23%) should be supplemented with at least

250 ml of colostrum that has a specific gravity greater than 1.06. Orphan foals, foals whose dams prematurely lactate, and foals with IgG concentrations below 200 mg/dl may need up to 1 L of colostrum. On a weight basis, foals require approximately 1 g of colostral IgG/kg of body weight to attain an IgG concentration of 800 mg/dl serum.[4]

Therapies for foals older than 24 hours of age with failure of passive transfer (FPT) include intravenous plasma, purified IgG products, and antibiotics. It must be remembered that the specificity of IgG administered may be more important in preventing infection than the total concentration of IgG attained in the foal's serum. Therefore, some commercial products may not contain antibodies to the potential pathogens in the foal's environment. The ideal plasma donor is an adult horse with serum IgG concentrations greater than 1500 mg/dl that has been blood typed and found free of isoantibodies to the equine major blood types (universal donor).

CHAPTER 17

Infectious Diseases of the Puerperal Period

CLAIRE CARD and CHERYL LOPATE

The puerperal period is the time between the birth of the foal and expulsion of the placenta. This period is normally brief and is often complete within a matter of hours. Involution of the uterus is extremely rapid and by 12 hours post partum the previously gravid horn of the uterus is 1.5 times the size of its nonpregnant state.[1,2] Infectious diseases may dramatically affect the reproductive system and prolong this period. Major disease entities include endometritis and metritis, endotoxemia, septicemia, and maternal or neonatal illness related to peripartum infection.

ENDOMETRITIS AND METRITIS

Predisposing Factors and History

Endometritis and metritis are inflammatory conditions of the uterus. Endometritis is more superficial and involves only the uterine lining, and metritis is deeper inflammation and extends to the myometrium. Both are significant diseases in mares because of frequent postpartum contamination of the uterus, the general susceptibility of the uterus to infection, the potential life-threatening compli-

250 ml of colostrum that has a specific gravity greater than 1.06. Orphan foals, foals whose dams prematurely lactate, and foals with IgG concentrations below 200 mg/dl may need up to 1 L of colostrum. On a weight basis, foals require approximately 1 g of colostral IgG/kg of body weight to attain an IgG concentration of 800 mg/dl serum.[4]

Therapies for foals older than 24 hours of age with failure of passive transfer (FPT) include intravenous plasma, purified IgG products, and antibiotics. It must be remembered that the specificity of IgG administered may be more important in preventing infection than the total concentration of IgG attained in the foal's serum. Therefore, some commercial products may not contain antibodies to the potential pathogens in the foal's environment. The ideal plasma donor is an adult horse with serum IgG concentrations greater than 1500 mg/dl that has been blood typed and found free of isoantibodies to the equine major blood types (universal donor).

CHAPTER 17

Infectious Diseases of the Puerperal Period

CLAIRE CARD and CHERYL LOPATE

The puerperal period is the time between the birth of the foal and expulsion of the placenta. This period is normally brief and is often complete within a matter of hours. Involution of the uterus is extremely rapid and by 12 hours post partum the previously gravid horn of the uterus is 1.5 times the size of its nonpregnant state.[1,2] Infectious diseases may dramatically affect the reproductive system and prolong this period. Major disease entities include endometritis and metritis, endotoxemia, septicemia, and maternal or neonatal illness related to peripartum infection.

ENDOMETRITIS AND METRITIS

Predisposing Factors and History

Endometritis and metritis are inflammatory conditions of the uterus. Endometritis is more superficial and involves only the uterine lining, and metritis is deeper inflammation and extends to the myometrium. Both are significant diseases in mares because of frequent postpartum contamination of the uterus, the general susceptibility of the uterus to infection, the potential life-threatening compli-

cations of uterine infections, and the negative implications for future fertility.[1–3] Poor perineal conformation may predispose to ascending placentitis, or postpartum uterine contamination.[2,4] Susceptible mares may be predisposed to puerperal complications because of poor anatomic barriers, subsequent increased contamination with bacteria and debris, and impaired uterine contractility. A preexisting maternal infection resulting in uterine or placental disease may manifest as puerperal endometritis-metritis. Uterine inertia resulting from dystocia, uterine torsion, hydrops, abnormalities of the allantoic or amniotic fluids,[1,5–7] or endocrine imbalance may predispose a mare to puerperal infection.[8] Dystocia resulting in maternal trauma or requiring forced extraction or fetotomy may lead to contamination of the uterus with bacteria. Trauma to the uterus, cervix, vagina, or vulva during parturition may create favorable conditions for microbial overgrowth.[38] Unsanitary foaling practices, poor environmental conditions, and retention of a dead fetus, particularly after dystocia or attempted abortion of twins, may predispose to disease. Retained fetal membranes may occur as a primary condition or as a sequel to other abnormalities of parturition.

Diagnosis

The most common clinical signs associated with maternal endometritis-metritis during the puerperal period are an abnormal vulvovaginal discharge and fever. In severe cases, mares are toxemic and endotoxemic and they may exhibit any or all of the following clinical signs: inappetence, depression, fever, tachycardia, tachypnea, injected mucous membranes, ileus, vulvovaginal discharge, and an increase in the height and force of digital pulses. A physical examination should include an evaluation of the horse for signs of laminitis. Abdominocentesis may be indicated in cases in which signs of colic or abdominal pain, peritonitis, severe perimetritis, or uterine rupture and laceration are suspected. A complete blood count may reveal hemoconcentration, elevated white blood cell numbers, and an increase in fibrinogen. The differential white blood cell count often shows neutrophilia or neutropenia with a left shift and toxic changes. Serum chemistry may reveal an increase in muscle enzymes due to recumbency and prerenal azotemia due to dehydration or renal injury due to circulating endotoxins. Urinalysis, especially if done on a free catch specimen, will routinely reveal blood and increased protein due to contamination by the vaginal discharge. An examination of the reproductive tract should be complete and should include visual and digital examination of the perineum, vagina, cervix, uterus, broad ligaments, and ovaries using a combination of vaginoscopy, transrectal palpation, and ultrasonography. The perineum should be examined for bruises and lacerations. A vaginal examination may disclose any of the following: vaginal or cervical trauma including bruises, hematomas, and lacerations (particularly on the dorsal aspect); fluid pooled in the cranial vagina; vaginal hyperemia; wide dilatation of the cervix, which exposes the endometrium; the presence of retained fetal membranes; and a voluminous, watery, and fetid discharge that originates from the uterus. A subinvoluted uterus, which is overly large and soft and extends beyond reach, without palpable rugae, may be identified by transrectal palpation. Ultrasonography of the uterus allows the examiner the opportunity to evaluate the uterus and broad ligaments for hematoma formation; to evaluate the tips of the horns for rupture, inversion, or membrane retention; to determine the character and amount of free intrauterine fluid; and to evaluate the uterus for evidence of retained fetal membranes. Transrectal ultrasonography may be used to confirm the presence of partially or fully retained fetal membranes by observing a dense echogenic core in the uterus, which indicates debris or retained fetal membranes, or free floating pieces or edges of membranes. Hysteroscopy, if required to identify retained fetal membranes, may be used to directly visualize the uterine wall and is best performed after distending the uterus with fluid because it is difficult to achieve full insufflation with air or carbon dioxide in the postpartum uterus.

Examination of the fetal membranes may provide clues as to the cause of the disorder. If available, the entire placenta should be examined; however, membranes that protrude from the vagina should not be overlooked. Both surfaces of the membranes should be examined. Delivered fetal membranes should be examined for completeness and the site of rupture determined. If torn, the completeness of delivery may be assessed by reconstructing the placenta using the large vessels on the allantoic surface as guides. These fetal vessels branch from the umbilicus and encircle both horns of the placenta. A large avillous area on the chorionic surface may indicate placental separation and possibly the presence of a twin. The presence of a large demarcated region, typically green to brown in color, extending from the cervical star inward, is typical of an ascending cervical infection, while the presence of a diffuse or focal thick exudate on the chorionic surface of the uterine body or horns and clumping of the microvilli may suggest a hematogenous infection. Adenomatous hyperplasia, which grossly appears as raised round or oval firm nodules on the allantoic surface, has been associated with bacterial and fungal infection in mares.[9] Smears from an endometrial swab, exudate, or imprints from the tissue can be dried and stained.[10,11] Microscopic examination may yield clues to the nature of the disease process. A Gram stain of the exudate can be performed to determine the type of organism involved. A potassium hydroxide digestion, or periodic acid–Schiff stain with a nigrosin counterstain may be used to identify fungal elements, and a Wright-Giemsa stain is used to identify bacteria, yeast, and inflammatory cells such as macrophages and neutrophils.[11,12] Samples of the discharge should be submitted for culture and sensitivity. Fresh samples are typically more representative of the problem, as secondary opportunistic organisms frequently invade as part of the process of autolysis, may overgrow the primary pathogen, or result in a mixed culture that is difficult to interpret. Fetoplacental infection accounts for the largest proportion of fetal and neonatal losses.[13,14]

Etiology

Bacterial organisms that cause endometritis-metritis during the puerperal period include *Streptococcus equi zooepidemicus, Staphylococcus aureus, Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa, Crossiella equi (nocardioform actinomycete), Leptospira* spp., *Brucella abortus, Salmonella abortus equi,* and *Listeria monocytogenes*. Most authors report *Streptococcus* to be the most common isolate. Gram-negative organisms are commonly isolated from cases of toxic endometritis-metritis. Mixed infections are common and anaerobic bacteria may be involved in some infections. Anaerobes require special sample culture devices for growth. The most common fungal isolate is *Aspergillus*, followed by mucoraceous fungi.[11–14] A positive postpartum uterine culture does not always indicate a clinically significant problem because potentially pathogenic microorganisms are commonly recovered from apparently healthy mares owing to normal contamination of the uterus during stage II and III of labor.[8] Culture results need to be interpreted in light of the clinical findings.

Pathogenesis

The pathogenesis of postpartum uterine infections involves inoculation with organisms through the cervix, by hematogenous spread, or by iatrogenic introduction. Fungal organisms commonly ascend through the cervix. An inflammatory process ensues and results in exudation. Under favorable growing conditions provided by dead or devitalized tissues, or in mares with impaired uterine contractility, the organisms replicate quickly and cause further inflammation with subsequent release of toxins. These toxins, if absorbed into the maternal circulation, create specific responses such as fever. Release of organisms into the circulation of the dam may occur and produce septicemia. Complications of endotoxemia and septicemia include systemic illness that may lead to death of the dam or neonate, lactation failure, impaired fertility, and laminitis.

Treatment

Treatment of endometritis and metritis in mild cases includes systemic antimicrobial therapy and multiple injections of oxytocin to encourage uterine involution. In more advanced cases, the mare's condition should first be stabilized with fluid therapy, nonsteroidal anti-inflammatory drugs (NSAIDs), and systemic antibiotic therapy. The perineum should be thoroughly cleansed and a large catheter or tube introduced through the cervix into the uterus or through the interior of the retained fetal membranes. The uterus is lavaged with saline or dilute tamed iodine solution (<1%) to remove intrauterine fluid and debris until the effluent is clear. Uterine lavage is followed by administration of oxytocin (10–40 units) to effect. Multiple small doses of oxytocin (10–20 units) may be used between lavages to help remove debris and encourage uterine involution. Uterine lavage may be repeated several times a day as long as signs of uterine disease are present. Transrectal palpation and serial complete blood counts may be used to determine the progress of the uterine therapy. Nonsteroidal anti-inflammatory drugs are indicated in cases in which a risk of laminitis is present, when signs of laminitis are present (sawhorse stance, reluctance to move, high resting heart rate that increases with locomotion, bounding digital pulses, hot hooves, extreme solar sensitivity to a hoof tester, and reluctance to lift a leg), or in cases in which endotoxemia or septicemia is present. Currently, phenylbutazone, ketoprofen, vedaprofen, or flunixin meglumine are used to treat signs of laminitis or endotoxemia-septicemia. Vasodilators such as acepromazine may be used to encourage circulation to the hooves. Bilateral palmar digital nerve blocks may be required to encourage some horses to move or to allow their hooves to be trimmed. Special hoof care for laminitic horses is advised and may involve trimming, using shoes or pads to reduce weight borne by the sole and the dorsal hoof wall, and pads to cushion the solar surface and lend frog support. Commercially available pads, shoes, and devices (Thera-Flex pads,* Lilly pads,† Farley boot‡) that can be taped on, glued on, or held in place with straps, or a horseshoe may be recommended. Radiography may be used to obtain additional prognostic information concerning laminitis. Any ventral rotation of the coffin bone relative to the dorsal hoof wall is considered undesirable, and rotation of greater than 5.5 degrees is associated with a grave prognosis. Free fluid and gas may be seen on radiographs to intervene between the coffin bone and the hoof wall in acute cases with deep abscesses in the sole.[15] The clinical signs observed in a particular animal may not relate well to radiographic signs; thus, each case should be treated on an individual basis. Dorsal hoof wall resections and heart bar shoes have been used with mixed success. Tenotomy of the deep flexor tendon has recently been recommended as a treatment for severe, intractable laminitis. Recovery from a severe case of acute laminitis that involves rotation of the coffin bone is prolonged, and athletic function may not be regained. The slow-growing nature of the hoof results in a convalescent period that may exceed 1 year. Regular hoof care is required to prevent pathologic changes seen in hooves of chronically laminitic cases. Lactation failure may be treated by the administration of domperidone (1.1 mg/kg PO once or twice a day). An increase in milk production is expected within 24 hours.

INFECTIOUS DISEASES CAUSING MATERNAL OR NEONATAL ILLNESS DURING THE PUERPERAL PERIOD

History

Pertinent aspects of history in cases of infectious disease might include illness or weight loss in the patient or in a cohort of horses on the farm, a history of new introductions, fever during pregnancy, contact with wildlife or

*Thera-Flex Pads, Thera-Flex Inc., Lawrenceburg, KY.
†Lilly Pads, Therapeutic Equine Products, Indianapolis, IN.
‡Farley Boot, Equine Orthotics Inc., Indian Habour Beach, FL.

rodents, previous episodes of vaginal discharge, premature lactation, results of other necropsy examinations, vaccination practices, exposure to pasture, presence of vectors of disease (such as Eastern tent caterpillars), and nutritional management.

Diagnosis

A complete physical and reproductive examination should be performed. Maternal samples collected when an infectious disease is suspected may include blood for a complete blood count, serology, and serum chemistry; colostrum; urine for culture or darkfield examination; exudate; feces, and examination of the fetal membranes.

Etiology of Diseases Causing Maternal Illness During the Puerperal Period

Diseases that have been reported to cause maternal illness during the peripartum period include brucellosis caused by *Brucella abortus*. Brucellosis has been reported to cause abortion, infertility, systemic illness, lameness (osteoarthritis), and suppurative bursitis in horses pastured with cattle infected with *Brucella abortus*.[16] In North America and elsewhere, infection with *Leptospira* spp. has been linked to herd problems, including poor reproductive performance and multiple cases of periodic ophthalmia.[17–20] Leptospiruria has been reported in mares that have aborted or seroconverted, and has caused outbreaks of abortion after environmental flooding.[19,20] *Leptospira* spp. may be present along with other infectious agents causing abortion.[21] *Salmonella abortus equi* has been reported to cause diarrhea and abortion in mares; however, no outbreaks of abortion have been reported in North America for a number of years.[22,23] Other strains of *Salmonella* have been associated with maternal abortion and diarrhea, particularly after stress such as hospitalization for surgery. Listlessness, weight loss, cough, and pyrexia have been described in some cases of *Mycobacterium avium* infection.[24] Rare systemic mycoses have usually been associated with maternal weight loss and include *Coccidioides* and *Histoplasma capsulatum*.[25,26] *Histoplasma* has been reported to cause abortion and granulomatous placentitis.[26] *Coccidioides immitis* was detected in two mares that aborted.[27] Equine cryptococcal placentitis and neonatal foal pneumonia have been reported.[28,29] *Candida* may infect the endometrium and cause disease.[30] Occasional transient maternal illness (fever and depression ± respiratory disease for less than 48 hours) may occur with equine herpesvirus (EHV-1) abortion. Clinical signs lasting longer than 2 days are unlikely to be caused by EHV-1.

Pathogenesis of Fetal and Neonatal Infection

Infection of the fetus occurs hematogenously or through compromise of the placenta. Perinatal infections result in stillborn or weak foals, foals with septicemia or endotoxemia, and foals with multiorgan failure. Perinatal infections may occur through the birth process *(Salmonella ohio),*[31] and through contact with maternal uterine discharge such as *Klebsiella pneumoniae* capsule type 1 and hemolytic *Escherichia coli* serotype 0101.[32,33] These latter two organisms may have an epizootic manner of transmission.

Diagnosis of Diseased Neonates

Examination of neonates should include assessment of rectal temperature, heart rate, respiratory rate, body condition, maturity (length and nature of the hair coat, stature of the ears, degree of calcification of the carpal and tarsal bones) and an evaluation of reflexes, including the righting reflex and sucking reflex. A database on a sick foal might include the following as indicated by clinical signs and economic constraints: blood for serology, complete blood count, fibrinogen, serum chemistry, blood microbiologic culture, transtracheal wash with cytologic and microbiologic culture, blood gas, urinalysis and culture, nasal and rectal swabs for virus isolation, thoracic radiographs, and thoracic and abdominal ultrasonography. Immunoglobulin levels should be measured in neonates more than 12 hours old. Foals whose dams are diseased may be born weak and thin or may become debilitated from maternal lactation failure.

Etiology of Diseases Causing Stillbirth or Neonatal Loss

It has been reported that certain diseases cause neonatal death and stillbirth. The primary list of differential diagnoses for stillbirth includes birth-related problems not necessarily caused by infectious diseases and consists of premature placental separation, suffocation due to failure of the amnion to rupture, and prematurity.[34] Infectious and noninfectious disease processes may be interrelated; hence, each individual foal should be examined by necropsy when practical. Mares may also deliver live but severely diseased neonates. A history of birth-related problems or maternal illness should be noted. A diseased neonate may come from a diseased uterine environment or dam; hence a complete examination of the mare should also be performed. Commonly encountered perinatal conditions include pneumonia, gastroenteritis, colitis, omphalophlebitis, polyarthritis, meningitis, and endocarditis due to bacteria that invade fetuses and neonates.

Viral Diseases

Viral diseases reported to cause weak or stillborn foals include equine herpesvirus type 1 (EHV-1; rhinopneumonitis).[35] Exposure to the virus may occur weeks to months prior to abortion, making maternal serologic results difficult to interpret. Foals born infected with EHV-1 often suffer terminal multiorgan failure. These foals are characteristically leukopenic and neutropenic, with total white blood cell counts below 3×10^9/L, and some are icteric at birth. They may or may not have serum titers to EHV-1. Immunohistochemical staining, polymerase chain reaction, or viral culture of lymphoid or lung tissue will establish the diagnosis. Equine arteritis virus (EVA) has been isolated from aborted fetuses and neonates.

Gross necropsy findings include edema and rib impressions on the parietal surface of the foal's lungs.[36,37] Outbreaks of EVA have been reported and include stillbirth, sudden death, and respiratory disease due to interstitial pneumonia.[38,39] Aerosol or direct contact with mares acutely infected or stallions acutely or latently carrying the virus, are believed to be a factor. In addition, fomites and bedding have been suggested to be involved in lateral transmission between mature stallions, and fomites and contaminated bedding may be a source of virus for neonates.[40]

Bacterial Diseases

Leptospirosis has become an increasingly recognized cause of neonatal loss. During a 4-year period from 1987 to 1990, the prevalence of abortion or stillbirth associated with leptospira in Kentucky ranged from 0.6% to 5.9%. Serologic studies on fetuses and mares demonstrated that 85% of the infections were caused by serotype *pomona,* with serotypes *grippotyphosa* and *Bratislava* constituting the remainder. Direct fluorescent antibody staining of fetal or placental tissues showed a positive result in 81% of the cases.[11–13,21] Warthin-Starry silver stain showed spirochetes in allantochorion or fetal kidney in all cases. Gross fetal changes ranged from an absence of lesions to an enlarged jaundiced liver, perirenal edema, radiating white streaks in the kidney, and placentitis. Histologic lesions included acute, subacute, or chronic placentitis, and subacute fetal hepatitis and suppurative fetal nephritis. Infected foals may be stillborn or born jaundiced, presumably after in utero leptospiral infection.[18]

There are also reports of isolation of *Klebsiella pneumoniae* (most commonly capsule type 1) from mares with endometritis whose foals developed diarrhea and fatal hemorrhagic enteritis caused by that organism.[32] A hemolytic strain of *E. coli* serotype 0101 was associated with metritis and foal diarrhea.[33] Infection with *Salmonella abortus equi* has been reported to occur in outbreaks and to result in septicemia and polyarthritis in newborn foals. *Salmonella ohio* infections have been reported in outbreaks with diarrhea, septicemia, and septic arthritis in newborn foals.[31] A few cases of abortion, neonatal septicemia, and meningitis caused by *Listeria monocytogenes* and cases of abortion and neonatal diarrhea caused by *Campylobacter* spp. have been reported.[42] Other rare but recently recognized diseases include borreliosis *(Borrelia burgdorferi)* in a stillborn neonate and two live neonatal herdmates;[43] however, exposure to the agent of Lyme disease does not always result in perinatal loss.[43,44] Potomac horse fever *(Ehrlichia risticii)* has been associated with abortion.[45,46] *Mycobacterium avium* has also been shown to be a cause of abortion in horses.[47]

Unknown Etiology

Mare reproductive loss syndrome (MRLS) was first reported in 2001 in Kentucky and the surrounding areas. Similar abortions had been reported in the early 1980s, but not to the extent noted in 2001 and to a lesser extent in 2002.[48,49] It is believed that unusual weather patterns (drought followed by higher than normal temperatures, followed by heavy frost) led to emergence of a higher than normal population of Eastern tent caterpillars (ETC; *Malacosome americanum*) in the region. Studies show that mares spending extensive time on pasture are at greater risk than those housed in barns. Affected farms have cases of early fetal loss, late fetal loss, pericarditis, and panophthalmitis. Mares with late term abortions have been reported to have premature placental separation, placental thickening or edema, and explosive deliveries. Lesions in the fetuses or foals include pneumonia and funisitis. Non-β-hemolytic streptococci and *Actinobacillus* organisms are routinely cultured from the fetuses or foals, but may be opportunistic organisms rather than causative factors in the abortion. Some MRLS foals are born weak with neurologic deficits and signs of neonatal maladjustment syndrome. The pathogenesis of this disease remains to be completely elucidated. The current hypothesis is that the barbed setae present on the cuticles of the ETCs are involved in the pathogenesis. The mare ingests the barbed setae fragments that are covered with or contain bacteria. The barbed setae fragments then penetrate the intestinal tissues including venules and other blood vessels, which then are proposed to embolize and to release septic material that distributes hematogenously throughout the mare. The septic materials and setae emboli spread by the hematogenous route to the placenta and fetus, and other immunologically susceptible sites such as the pericardial fluid and eye.[50] The difficulties with this hypothesis include that the venous drainage of the intestines is through the liver, and the liver has not been reported to have lesions that would be expected if embolic setae fragments were present, and bacteria have not been cultured from the blood of mares experimentally infected with the bacteria, and mares are not reported to have signs compatible with bacteremia. In 16% of the cases, no bacteria are recovered from the fetus, suggesting that bacteria may not be necessary for fetal loss.[50]

Fungal and Yeast Infections

Histoplasma has been reported to cause perinatal granulomatous pneumonia in foals.[26] A yeast organism, *Cryptococcus neoformans,* has been isolated from a fetus following abortion and from the endometrium a month later.[28] Protozoa *(Toxoplasma gondii)* have been identified by polymerase chain reaction hybridization in the placenta of a mare that delivered a healthy foal but grazed on pasture where sheep aborted because of that organism. Interestingly, the amnion had abnormal areas of vascularization and 5- to 9-mm papillae in the area of the umbilicus, similar to lesions reported in sheep.[51] *Neosporum caninum* can cause neonatal death in horses.[52]

Treatment of Diseased Neonates

In milder cases, treatment of diseased neonates includes supportive care such as administration of intravenous or oral fluids, colostrum, plasma transfusions, antibiotics, anti-inflammatory drugs, nutritional supplements, and H_2 receptor blockers. There are some reports that treatment with acyclovir (16 mg/kg PO three times a day) may

Box **17-1**

Microorganisms with Zoonotic Potential That Can Be Spread by Contact with Body Fluids, Placentas, Diseased Neonates, and Abortuses

Leptospira spp.

Neospora caninum

help some of the EVH-1 infected foals survive.[36] Animals with advanced disease should be referred to a neonatal intensive care unit or euthanized. Necropsy is useful to obtain or confirm a diagnosis.

Zoonotic Risk

Many veterinarians view equine abortuses, fetal fluids, and placentas as a low risk for exposure to zoonotic infections. A number of infectious organisms causing puerperal disease in horses commonly infect a number of other mammalian species including humans. Box 17-1 lists pathogenic microorganisms with zoonotic potential.

CHAPTER 18

Irregularities of the Estrous Cycle and Ovulation in Mares (Including Seasonal Transition)

KATRIN HINRICHS

Irregularities of the estrous cycle may be associated with pathology of the ovary (granulosa cell tumor, gonadal dysgenesis) or uterus (shortened luteal activity due to endometritis) or, rarely, may be due to apparent functional abnormalities of the ovarian/hypophysial axis (anovulation with hematoma formation). However, wide variations in cycle length and ovarian characteristics are associated with normal fertility. Abnormalities of endocrinology, cyclicity, and ovulation are uncommon in mares with normal reproductive tracts, and thus other causes of infertility should be ruled out before implicating abnormal cyclicity as a cause of infertility.

Apparent estrous cycle irregularities that are not associated with pathology include prolonged estrus without ovulation during the seasonal transition period, "silent heat" (apparent failure to show estrous behavior), prolonged luteal activity, and anestrus or constant estrus during pregnancy. Additionally, aging of mares is associated with changes in cyclicity.

Abnormal behavior may be related to ovarian pathology, most commonly granulosa cell tumors, in mares. Because this link is known, many other behavioral changes may be attributed to the ovaries by mare owners when in fact they have no association with reproduction.

CHAPTER 18

Irregularities of the Estrous Cycle and Ovulation in Mares (Including Seasonal Transition)

KATRIN HINRICHS

Irregularities of the estrous cycle may be associated with pathology of the ovary (granulosa cell tumor, gonadal dysgenesis) or uterus (shortened luteal activity due to endometritis) or, rarely, may be due to apparent functional abnormalities of the ovarian/hypophysial axis (anovulation with hematoma formation). However, wide variations in cycle length and ovarian characteristics are associated with normal fertility. Abnormalities of endocrinology, cyclicity, and ovulation are uncommon in mares with normal reproductive tracts, and thus other causes of infertility should be ruled out before implicating abnormal cyclicity as a cause of infertility.

Apparent estrous cycle irregularities that are not associated with pathology include prolonged estrus without ovulation during the seasonal transition period, "silent heat" (apparent failure to show estrous behavior), prolonged luteal activity, and anestrus or constant estrus during pregnancy. Additionally, aging of mares is associated with changes in cyclicity.

Abnormal behavior may be related to ovarian pathology, most commonly granulosa cell tumors, in mares. Because this link is known, many other behavioral changes may be attributed to the ovaries by mare owners when in fact they have no association with reproduction.

For this reason, mares with abnormal behavior may be presented for examination of the reproductive tract, and it becomes a diagnostic challenge on the part of the theriogenologist to determine the cause of the change in behavior.

Diagnosis of the cause of estrous cycle irregularities in mares is based on history, teasing records, findings on palpation and ultrasonography per rectum, and determination of hormone concentrations, when indicated.

ASSESSMENT OF THE ESTROUS CYCLE AND OVULATION

The Estrous Cycle

A complete review of mare endocrinology is given in Chapter 7. An important factor to remember when evaluating apparent cycle abnormalities is the normal variation in length of estrus. Estrus length in normal cycling mares can vary at least from 2 to 12 days. Estrus length is generally repeatable within mares, and is longer at the beginning and end of the breeding season (the peak of the breeding season being the first day of summer, June 21 in the Northern Hemisphere). In some mares, estrus becomes so short in midseason that it may be missed if teasing is only performed sporadically. Owners may report that their mare was showing good heat in April and May but that they haven't seen her in heat in June.

Teasing is a major determinant of apparent cyclicity. Individual teasing of mares with an active stallion is the best method of heat detection. To adequately detect cyclical changes in behavior, teasing should be performed thoroughly at least three times weekly, and the mare's behavior scored by a knowledgeable individual. "Silent heat" may occur in mares that have normal ovarian function. The meaning of this term is relative, indicating only that the observer did not recognize estrous behavior. Knowledge of the estrous and diestrous reactions of each individual mare is crucial in heat detection; one mare in heat may be less demonstrative than another mare in diestrus. Some mares may show signs of estrus immediately on contact with the stallion; others—especially young or timid mares—may require teasing for 3 to 4 minutes before they respond. A mare that shows no change in behavior at all during her cycle, as assessed by an experienced observer using good heat detection methods, may present a challenge. Such a mare may need to have the reproductive tract examined regularly by transrectal palpation and ultrasonography to detect estrus (see later discussion). However, assessing the willingness of the mare to allow mounting by a stallion may reveal that she is receptive to him, even though teasing evoked no signs of estrus. Mares that do not show good signs of estrus to a stallion may begin to show estrous behavior if they are bred by natural cover, during estrus, on a few occasions.

Estrous behavior in mares does not necessarily indicate follicular activity. Estrous behavior can be seen in mares in seasonal anestrus, in mares that have been ovariectomized, and in mares with gonadal dysgenesis. This is because sexual behavior in the mare is largely regulated by progesterone; that is, estrous behavior is suppressed by progesterone. In the absence of progesterone, even the small amount of estrogen produced by the adrenals is sufficient to cause the mare to show some signs of estrus. Further stimulation with estrogen does, however, increase the intensity of estrous behavior. This is reflected in the finding that mares in true estrus (during the follicular phase of the cycle) have fewer negative reactions to mounting or intromission than do seasonally anestrous or ovariectomized mares.[1]

The length of diestrus is more repeatable among mares than is the length of estrus, at 15 ± 2 days.[1] When evaluating heat detection records, repeated diestrus intervals of normal length, interspersed with estrous intervals, are a good indication that corpora lutea are forming and being lysed normally. The formation of corpora lutea in turn suggests that normal follicle growth and ovulation are occurring.

Hormone analysis can also be helpful in defining the pattern of cyclicity in a mare; progesterone concentrations are of most value. Reflecting teasing records, a pattern of high progesterone (increasing to >4 ng/ml) for approximately 14 days followed by low progesterone (<1 ng/ml) for 3 or more days is strongly indicative of normal cyclicity.

Ovarian and Uterine Characteristics of Normal Cyclicity

In assessing the normality of follicle growth and ovulation, the large variation in follicle size at ovulation should be recognized. The size of the follicle the day before ovulation is detected is commonly 35 to 45 mm in diameter, but mares can ovulate much smaller follicles (less than 30 mm), or larger follicles, with normal fertility. Follicle size at ovulation is often repeatable for a given mare. Small follicle size at ovulation may be a cause of apparent infertility because, unless this tendency is known, the mare may not be bred at the appropriate time. When double ovulations occur, the follicles ovulate at a smaller size than for single ovulations. Follicle size at ovulation also decreases toward the middle of the breeding season (July and August). Numerous large follicles and corpora lutea are normally present on the ovaries of pregnant mares, especially between 30 and 120 days. These are sometimes mistaken for ovarian pathology.

Transrectal palpation and ultrasonography are indispensable tools in the evaluation of the estrous cycle. Familiarity with the normal appearance of the ovary and uterus on ultrasonographic examination throughout the cycle is a great help when assessing possible abnormalities.[2] Multiple follicles may be present on the ovaries at any stage of the cycle. During estrus, the dominant preovulatory follicle is usually identifiable at approximately 25 mm diameter, when it is about 5 mm larger than other follicles on the ovary. In some mares, however, multiple follicles appear to grow to a large size (>30 mm) from which one or two ovulate; this is associated with normal fertility. On ultrasonographic examination, follicles usually are round and should be echolucent (black) in appearance. In the day or so before ovulation, infrequent small echodensities may be seen within the follicle, and

the follicle may become less round, reflecting a palpable loss of tone. Immediately before ovulation, follicles may appear pointed on ultrasound examination, as they apparently protrude toward the ovulation fossa.

On the first day after ovulation, the collapsed follicle may be difficult to define ultrasonographically. The only finding may be that the follicle seen previously is gone; however, a thick echodense line or mass is usually visible within the ovary. At this time, a depression may be palpable on the ovary, and the ovary may be sensitive to palpation. The normally developing corpus luteum (CL) has two major forms on ultrasonographic examination.[2] Over the first few days after ovulation, the CL may become more and more apparent as an echodense structure within the ovary; then, after about 7 days, it may become less dense and less easily delineated. Alternatively, the ovulated follicle may fill with clotted blood over 1 to 2 days. This corpus hemorrhagicum has a typical ultrasonographic appearance of a round structure with an echodense rim and an echolucent interior, crossed with a lattice of echodense fibers. The echolucent area decreases in size over the next few days as the echodense rim thickens; after 5 or more days this structure is indistinguishable from the CL that did not have an interior clot. A normal corpus hemorrhagicum is typically no larger than was the original follicle; a larger structure with similar appearance on ultrasonography may be a hematoma (see later discussion).

Uterine changes detectable on ultrasonographic examination are also helpful in staging the cycle in mares with questionable estrous behavior. The uterus in estrus becomes edematous. This is characterized on palpation as a heaviness and lack of tone, and ultrasonographically by presence of echolucent areas of fluid within the uterine folds, giving a "wagon wheel" or "orange slice" effect to the cross-sectional uterine image. In diestrus, the uterus is homogenous in appearance on ultrasonographic examination and tends to be more tightly circular in cross section, reflecting increased tone. Changes in palpable cervical tone reflect those of the uterus but may be more influenced by individual variation between mares; cyclical ultrasonographic changes in the cervix are not obvious.

PHYSIOLOGIC ESTROUS IRREGULARITY—THE TRANSITIONAL PERIOD

The mare is a seasonal, long-day breeder, and the majority of mares enter anestrus in the winter. Ten to 25% of mares may cycle through the winter, this percentage being higher in mares having good nutrition and housing. In anestrus, gonadotropin-releasing hormone (GnRH) and gonadotropin secretion is low; follicles reach a maximum diameter of 10 to 15 mm and then regress. The period between anestrus and the first ovulation of the year is termed the transitional period. During this time, pituitary gonadotropin output is sufficient to cause follicular growth, but insufficient to stimulate normal follicle maturation and ovulation. The follicles produced at this time are indistinguishable from normal follicles on palpation and ultrasonographic examination; however, they may be structurally and hormonally abnormal. For this reason, transition follicles will not ovulate in response to one-time administration of gonadotropins or GnRH analogues.

During the transitional period, mares may be presented for examination because of constant or irregular estrus, as they respond to rising and falling estrogen from waves of nonovulatory follicles. Owners may become frustrated at this time with breeding mares over periods of weeks as the mares remain in heat. When estrous behavior does subside, it may recur within days; there is no normal diestrus interval. Unless the mare is bred immediately before the first ovulation of the year, the breedings will not result in pregnancy.

On palpation and ultrasonographic examination, the ovaries have multiple small (in early transition) to large (in late transition) follicles. Extreme cases may have many (5–10) follicles greater than 30 mm in diameter on each ovary. No corpora lutea are present on the ovaries; however, corpus hemorrhagicum–like structures may be present, as these anovulatory follicles sometimes become filled with blood. The structures do not luteinize and so do not progress over time to the normal CL appearance on ultrasonography as described previously. The lack of luteal progesterone (<1 ng/ml in peripheral blood throughout this period) is reflected in poor uterine tone. Some practitioners feel that the presence of uterine edema signals the presence of a functional preovulatory follicle; however, recent studies have not supported this relationship. As gonadotropin secretion reaches functional levels, one of the follicles on the ovary will grow and ovulate; this signals the end of transition and the mare will cycle normally through the season from this point.

Irregular estrous behavior and multiple anovulatory follicles are a normal aspect of the transition period and do not represent an abnormality. Diagnosis of seasonal transition is based on the season of the year (usually February through April in the Northern Hemisphere), lack of evidence of ovulation (no diestrous periods; no corpora lutea; poor uterine tone; low progesterone on assay), and multiple small to large follicles present on both ovaries.

MANAGEMENT OF SEASONAL TRANSITION

Because of the January 1 birthdate imposed by many breed registries, foals born in a given year compete with one another. This has resulted in a demand for foals to be born early in the year. To have a foal born in January, the mare must conceive the previous February, during the period of seasonal transition. Many management methods have been developed to shorten the transitional period or move it to an earlier time of year (December to January). Currently no method is both commercially feasible on a large scale and highly predictable; however, it is likely that in the future this may be achieved using some combination of the treatments currently under investigation.

The most widely used method for management of seasonal transition is increasing perceived day length. This

may be done by housing mares under artificial light (100 lux, or equivalent of a 200-watt bulb 12 ft from the ground in a 12 ft by 12 ft stall) starting approximately December 15. Mares should be exposed to 14.5 to 16 hours of light per day; there is no benefit to increasing the apparent day length slowly, and lengths of light greater than 20 hours may actually reduce effectiveness. Alternatively, it has been shown that a short (1- to 2-hour) burst of light timed to occur at 9.5 to 10.5 hours after dusk is equally effective as having light on constantly for 16 hours. Although this technique saves electricity and may allow large groups of horses to be treated, application is more difficult because the time of the light burst must be correlated with changing day length. Recent studies have shown that reduced lux and reduced treatment periods may be equally as effective as is the traditional regimen.[3] Mares typically ovulate and resume normal cyclicity 6 to 10 weeks after the onset of increased day length.

Use of GnRH administration to induce cyclicity in anestrous or seasonal transition mares has been studied extensively.[4] Infusion of pulses of GnRH (25 to 250 μg/hour) at hourly intervals results in ovulation in essentially all anestrous mares within 11 days. This ovulation may be fertile, but mares may not continue to cycle if not pregnant. Although native GnRH is commercially available, this application requires the attachment and use of a pump. Constant infusion of GnRH or its analogues may also be effective, but responsiveness appears to be greater when the mare has entered transition. Constant infusion of GnRH using an osmotic minipump (an implant that releases drug as it accumulates fluid osmotically), delivering 100 to 200 ng GnRH per kg body weight per hour, induced ovulation in 60 to 70% of mares within 30 days. Injection of long-acting GnRH analogues (e.g., 40 μg buserelin twice daily) induced ovulation in 50% of anestrous mares in 10 to 25 days; however, this compound is not available commercially in the United States. Use of the commercially available implant containing 2.2 mg of the GnRH analogue, deslorelin, administered every other day has been shown to induce ovulation in about 50% of transitional mares. However, recent reports that deslorelin implants suppress pituitary responsiveness to native GnRH after administration suggest that repeated use of the implant may not be advisable. Indeed, when deslorelin was used to induce cyclicity, ovarian suppression was noted in the treated mares that did not ovulate.

Injection of equine pituitary extract (once daily for 14–20 days; dosage is dependent on strength of the preparation) is effective for induction of follicular growth and ovulation in anestrous mares, but this compound is not currently commercially available.

Progesterone and its analogues (e.g., altrenogest) have been used in an attempt to induce early cyclicity with the thought of suppressing luteinizing hormone (LH) release from the pituitary and then having a "rebound" when the progesterone is withdrawn. Progestins are effective in suppressing estrous behavior in transition mares and for this reason may be used simply to reduce the client's concern about whether to breed the mare. The progestin is typically given for 10 to 15 days. Mares return to estrus approximately 3 days after the progestin is withdrawn, because the suppressive action of progesterone on estrous behavior is lost. Administration of progestin is not effective in hastening ovulation if given to mares in anestrus or early transition. In late transition, the first ovulation of the year in mares treated with progestin (e.g., 0.44 mg/kg altrenogest for 12 days) may be hastened by about 10 days.

Other methods for inducing cyclicity during seasonal transition are currently under study. Dopamine antagonists, such as sulpiride (0.5 mg/kg, IM) or domperidone (1.1 ng/kg PO) daily for 10 to 60 days have been shown to induce cyclic activity in seasonally anestrous and transition mares.[3] However, a repeatable method for use of these compounds has not yet been developed, and the response seems to depend on mare, environmental conditions, and stage of transition at the time of treatment. The variability in effect may be due to the mechanism of action of dopamine antagonists in the mare. In contrast to its action in ewes, dopamine antagonists do not appear to directly increase gonadotropin secretion in mares. Dopamine antagonists may work via increasing prolactin concentrations, which sensitize the ovary to circulating gonadotropins;[3] therefore, there must be some native gonadotropin activity for ovarian response to occur.

CYCLE IRREGULARITIES ASSOCIATED WITH AGING

Mares cycle less efficiently after about 20 years of age. There is a delayed entry into the ovulatory season, longer follicular phase (estrus), and fewer ovulations per year.[5] Mares over 25 years of age may cease cycling altogether. These mares may be presented for examination because of erratic or constant heat during the breeding season, or because multiple breedings have not resulted in pregnancy. They may also be apparently anestrous during the breeding season.

Diagnosis is based on the mare's age; these changes are not usually seen until the mare is near 20 years of age. The delay of the first ovulation of the year is associated with a prolonged transitional period in the spring, which extends into the normal breeding season. Breedings during this time will not result in pregnancy because the mare is not ovulating. Findings on palpation and ultrasonographic examination will be similar to those described earlier for the transitional period. Once the mare does ovulate, however, the corpus luteum appears to have normal function and cycles may be regular. Old mares that have ceased cycling will appear to be anestrous (have no follicular activity, no uterine tone, and low progesterone) throughout the breeding season.

Management of old mares that are still intended for breeding would include monitoring the ovaries by palpation and ultrasonographic examination over time to detect follicular growth leading to ovulation. In the case of an old mare that is anestrous, treatment with pulsatile GnRH may be effective in inducing follicular growth and ovulation. It must be remembered, however, that even when cycling normally, old mares have low fertility,

associated with decreased oocyte viability and uterine changes.

Prolonged Luteal Activity

A prolonged luteal phase, that is, greater than 17 days, is a common occurrence in mares. It is estimated that failure of normal return to estrus may occur in 4% to 18% of cycles, and in these cases the luteal phase may be prolonged to over 60 days.[1] The first work in this area was done before ultrasonography, and it was presumed that the primary corpus luteum (from ovulation during the previous estrus) was somehow maintained after the normal time of luteolysis. Work with ultrasonography has shown that a prolonged luteal phase is seen when a diestrous follicle ovulates after day 10 of diestrus. This new corpus luteum is too immature to respond to the endogenous prostaglandin release around day 14. Persistent luteal activity can also be associated with an apparently luteinized hematoma. It is not known whether idiopathic maintenance of the primary corpus luteum can also be a cause of prolonged diestrus.

Another possible cause of prolonged luteal activity is severe damage to the endometrium, as seen in overt pyometra. If the damage is severe enough that prostaglandin production is impaired, retention of the primary corpus luteum results. Inflammation of the endometrium, as seen in endometritis, may result in release of prostaglandin and thus shortening of the luteal phase (see later discussion).

Mares with prolonged luteal activity may be presented because of failure to return to estrus. The other major differential diagnoses for failure to return to estrus are pregnancy, which can happen even if no breeding is recorded; silent heat (the mare that is cycling but does not show behavioral estrus); and poor estrus detection, or short heats that are missed, especially near the middle of the breeding season. Diagnosis of prolonged luteal activity is based on finding a normal-appearing nonpregnant diestrous tract with failure to show estrus or have estrus-type examination findings for more than 17 days after ovulation. Progesterone concentrations will be high (usually >4 ng/ml) for more than 2 weeks.

Treatment of prolonged luteal activity is simple and effective: administration of prostaglandin F2α (10 mg IM). To assure a response, the prostaglandin should be given at least 5 days after the most recent ovulation. The mare should return to heat in about 3 days. It should be verified that the mare is not pregnant before treatment, even if the mare has had a previous negative pregnancy check.

Shortened Luteal Phase

A decrease in the length of diestrus (less than 13 days) may be indicative of premature luteolysis. Primary defects of the corpus luteum have not been confirmed in the mare.[1] The most common factor associated with premature luteolysis is endometritis; prostaglandin production associated with uterine inflammation or bacterial endotoxin production is the causative factor. Some interval of diestrus is seen even if an active endometritis is present, as the corpus luteum is not completely responsive to prostaglandin for about the first 5 days after ovulation. After this, the relatively low but constant production of prostaglandin is sufficient to cause lysis of the corpus luteum over a period of days, typically resulting in a 7- to 11- day diestrus. If a shortened luteal phase is detected, an endometrial culture and biopsy should be obtained to determine if endometritis is present, and, if so, which organism may be responsible. Resolution of the endometritis should result in return of normal diestrous intervals.

CYCLE IRREGULARITIES ASSOCIATED WITH OVARIAN PATHOLOGY

Gonadal Dysgenesis

Gonadal dysgenesis refers to the congenital lack of development of the ovaries. Only a "streak" (small, almost cylindrical) gonad is present, with no follicular activity. The remainder of the tract is intact, as the female tract will form in the absence of gonads, but the tract is juvenile because no ovarian steroids are present to stimulate growth. This abnormality is most commonly associated with defects of the X chromosome, including XO (Turner's syndrome) and XXX; however, it may be seen in XY mares as well as in mares with apparently normal XX karyotypes.

Mares with gonadal dysgenesis may be presented for examination because of anestrus, erratic estrus, or constant estrus. Exhibition of estrous behavior is due to the lack of progesterone. In cases of erratic or constant estrus, the mares may have been bred repeatedly without conceiving. Mares with XO karyotypes may be unthrifty, be shorter than anticipated, or have increased angulation of the hind legs.

Diagnosis of gonadal dysgenesis is based on history, karyotype, and repeated palpation and ultrasonography or progesterone determination. Mares with gonadal dysgenesis have never foaled and have never been pregnant. Palpation and ultrasonography reveal very small or apparently absent ovaries; if ovaries are present, no follicular activity is seen. It should be noted that some normal mares, especially young mares of smaller breeds, can have very small ovaries that function normally (raise follicles and ovulate with normal fertility). For this reason, serial examinations or progesterone determinations at least once weekly for 5 or more weeks during the breeding season may be needed to definitively state that the ovaries are nonfunctional. Presence of nonfunctional ovaries does not necessarily mean that the mare has gonadal dysgenesis: small, inactive ovaries during seasonal anestrus are normal; very old mares (>24 years) may have inactive ovaries in the breeding season because they have stopped cycling altogether; and mares having a severe energy imbalance due to starvation or disease (or, theoretically, mares in extremely hard work) may have inactive ovaries. A chromosomal abnormality on karyotype supports the diagnosis of gonadal dysgenesis. No treatment is possible for mares with gonadal dysgenesis.

Granulosa Cell or Other Functional Tumor

Granulosa cell tumors (GCTs) are by far the most common ovarian tumors in mares. These neoplasms of the sex-cord stroma may also contain thecal cells (granulosa cell–theca cell tumors). They may be found in mares of any age, and are almost invariably benign.

Behavioral changes associated with GCTs include aggressive or stallion-like behavior, constant or erratic estrus, or anestrus, with about equal frequency. These changes are attributed to steroid production by the neoplasm. Theoretically, production of testosterone or high concentrations of estrogen may be associated with aggressive or stallion-like behavior; estrogen with constant estrus; and progesterone with constant diestrous-like behavior; however, progesterone is typically low in cases of GCT. Anestrous behavior (including erratic signs of heat) may be associated with neoplasms that do not produce steroids. The contralateral ovary is typically inactive and small. This is attributed to high concentrations of inhibin or steroids from the tumor, causing suppression of follicle-stimulating hormone (FSH) release. In rare cases, apparently no pituitary suppression is present and mares with GCT cycle normally, ovulating from the contralateral ovary.

Diagnosis of GCT is based largely on the history (abnormal behavior or cyclicity) and findings on palpation and ultrasonography per rectum. The affected ovary is typically large, smooth walled, and spherical. The ovulation fossa is usually not present. The contralateral ovary is usually small and inactive, resembling an anestrous ovary. Ultrasonography is useful for differentiating normal follicular activity from pathologic changes in the ovarian stroma and for confirming the lack of activity of the contralateral ovary. There is no one typical appearance of GCT on ultrasonography, however. The most common ultrasonographic appearance is that of multiple cystic structures ("honeycomb" appearance); however, GCT may also appear as unilocular cysts or may be solid throughout.[6] The honeycomb appearance of a GCT may be confused with that of a clotting hematoma (see following discussion). A hematoma may be differentiated from a GCT by several features: with a hematoma, the activity of the contralateral ovary is normal and the mare has normal cycles; the ovulation fossa is present on the ovary, as the hematoma causes enlargement of only one pole; and the hematoma appears abruptly and regresses over time (usually within 30 days). Serum testosterone concentrations are elevated in 50% to 90% of GCT, and inhibin concentrations are elevated in over 85% of mares with GCT; tests for these hormones may be used as a diagnostic aid.[7] Management is by surgical removal of the affected ovary; approximately 75% of mares resume normal cyclicity from the remaining ovary within 2 years of removal of a GCT.

Teratomas are relatively rare in comparison with GCTs; they may be difficult to diagnose as the ovarian enlargement may not be pronounced, and ultrasonographic findings may be unremarkable. Although not commonly considered to be functional tumors, teratomas may be associated with disruption of cyclicity. Serous cystadenomas of mare ovaries have also been reported; these are associated with multiple large cystic structures resembling normal follicles on palpation and ultrasonography. Serous cystadenomas may be associated with elevated serum testosterone concentrations, but do not appear to affect cyclicity.

INTERSEXUALITY

Conditions in which testicular tissue is present in the gonad such as true or pseudo-hermaphroditism affect cyclicity but usually are suspected early in life because of intersexuality of the external genitalia. However, conditions may occur in which testicles are present but the external genitalia is that of a normal female (some XY sex reversals, including testicular feminization syndrome). These are associated with presence of internal testicles instead of ovaries, absence of cyclicity, stallion-like behavior, and usually failure of formation of the internal female tract, resulting in the vagina ending in a blind pouch. These conditions may be diagnosed on the basis of high serum testosterone levels, abnormal size, shape, consistency, or ultrasonographic appearance of the gonads, and abnormalities of the internal genitalia.

ABNORMALITIES OF OVULATION

Failure of normal ovulation of the dominant preovulatory follicle may occur in mares. This is identified on repeated ultrasonographic examination. Two abnormalities of ovulation have been noted clinically: anovulation with hematoma formation, and apparent failure of the follicle to completely empty at ovulation. The former abnormality has been documented but the latter has only been reported anecdotally among clinicians. No information on the pathogenesis of either abnormality has been reported.

In anovulation with hematoma formation (persistent anovulatory follicles), the preovulatory follicle appears to grow normally, but instead of ovulating, starts to rapidly enlarge. Whereas normal follicles typically grow about 3 mm per day, anovulatory follicles may suddenly increase 10 mm or more in diameter per day, becoming much larger than a normal preovulatory follicle. Echogenic particles become visible within the follicle, and may increase in number over a few days until the follicle may appear to be diffusely echogenic. At this time the contents of the follicle are fluid, and can be seen to swirl on ultrasonography when the follicle is balloted. Aspiration of the follicular contents at this time yields bloody fluid, and so these follicles are considered to be hemorrhagic. Finally, in the majority of anovulatory follicles, the contents of the follicle appear to clot (nonechogenic spaces form, delineated by strands of echogenic material).[6]

Increasing echogenicity over time and apparent clotting, resulting in formation of a hematoma, is not pathologic in follicles that would not normally be destined to ovulate (e.g., diestrus follicles, secondary follicles during estrus, dominant estrus follicles during fall transition [autumn follicles]). Anovulation of the dominant preovulatory follicle during the breeding season is less common and is associated with infertility. A 4.7% incidence of hematoma formation was found in one study,

but it was unclear how many of these were seen in mares that successfully ovulated another follicle at the same time.[1] In a second study, 8% of cycles in mares of varied reproductive history resulted in anovulation. This proportion was age dependent, being 4% in mares 6 to 10 years of age and 13% in mares 16 to 20 years of age.[8]

When anovulation occurs, more than 84% of mares progress into diestrus with progesterone concentrations greater than 1 ng/ml.[8] In these mares, the wall of the follicle surrounding the hematoma appears to thicken, suggesting that it is luteinizing. In one study all such structures responded to prostaglandin administration, but the day of administration was not given.[8] Clinically these luteal structures may appear not to respond to prostaglandin as readily as do normal corpora lutea, and repeated doses of prostaglandin may be needed to cause regression of the structure and return of the mare to estrus. Formation of an anovulatory follicle is associated with failure of conception in inseminated mares.[8]

Mares that experience anovulation and hematoma formation of the dominant follicle tend to do this over repeated cycles.[8] The author observed one Warmblood mare that formed a hematoma instead of ovulating at each estrus, throughout a breeding season. Treatment with human chorionic gonadotropin (hCG), suppression of follicular activity with progesterone and estrogen with subsequent release, and short-cycling with prostaglandin had no effect on hematoma formation. The mare was bred on each estrus but did not get pregnant. The next year, she was bred on an early estrus, ovulated normally, and became pregnant.

Mares experiencing anovulation/hematoma formation of the dominant preovulatory follicle may in fact appear to cycle normally, due to luteinization of the follicle wall. Some cases may be associated with prolonged diestrus; however, the presenting complaint may be simply infertility. Diagnosis entails monitoring follicle growth during estrus daily by ultrasound examination. Findings are those for normal follicle growth up to about ovulatory size (35–40 mm); then these follicles continue to grow, often rapidly, sometimes to a large size (60–90 mm). Echogenic particles usually are seen at the time of follicle enlargement. The echogenicity increases, then apparent clotting occurs. No specific causes or treatment for this syndrome are currently known.

Apparent incomplete emptying of the follicle at ovulation is much less well documented, but has been noted by practitioners. The follicle grows normally and then is seen to be partially collapsed, suggesting that the examination caught the follicle in the process of ovulation (this in fact would be a rare occurrence, as normal ovulation results in follicle emptying within about 5 minutes). Examination the following day shows the follicle to have an unchanged appearance, (i.e., to still be "ovulating"), irregular in outline and containing 15 to 25 mm of fluid within it. This appearance is maintained over the following days, then the fluid regresses slowly. The follicle wall appears to luteinize, and progesterone levels during the ensuing diestrus may be normal. While no hard data is available, the clinical impression is that the pregnancy rate for mares having this follicular appearance at ovulation is low. Again, no specific causes or treatment for this syndrome are known.

FOLLICLE GROWTH AND REGRESSION WITHOUT OVULATION

Follicle growth followed by regression, without ovulation, during the breeding season is extremely rare, but may occur. It is difficult to find documentation of this phenomenon, but it is recognized clinically. The author has observed this syndrome in two 14-hand, 5- and 10-year-old ponies, both pintos. The ponies were obtained from a dealer without knowledge of previous breeding history. Ovarian activity was followed throughout the breeding season by ultrasonography at least three times weekly. The ponies had apparently normal reproductive tracts on palpation and ultrasonography, and the ovaries were of normal size. Multiple follicles smaller than 10 mm were present, and periodically, a follicle would grow to 18 to 20 mm, only to gradually regress. Treatment with prostaglandin to lyse any luteal tissue present, and administration of hCG at peak follicle growth had no effect. No karyotype was done on these mares; however, because of the normal ovarian size and follicle growth, they could not be classified as having gonadal dysgenesis.

BEHAVIORAL PROBLEMS ATTRIBUTED TO THE OVARIES

Persistent Estrus

"Persistent estrus" is a fairly common complaint in working and racing mares. The major factor in the complaint is that the mare is constantly showing a behavior, interpreted as estrus, and it is interfering with the mare's function. Upon investigation, this complaint is usually not associated with any actual abnormality in cyclicity, and it is seldom identified in mares in a teasing program where true estrous behavior (response to a stallion) can be assessed.

When evaluating histories of persistent estrus, the normal variation of estrous length, from 2 to over 10 days, should be considered. The pattern of estrous cyclicity noted by the owner, and exactly what behavior the owner is seeing, should be ascertained. A major confusing issue in these mares is what is considered to be estrous behavior. Such mares may be characterized by their owner as being irritable, kicking when their sides are touched, leaning on the handler, striking, urinating, or wringing their tails. These signs are interpreted as indicating that the mare is in heat; however, they may be simply signs of agitation, discomfort, or submission.

To diagnose the cause of the apparent constant estrous behavior, findings on palpation and ultrasonography of the tract are evaluated with the history, and the mare should be teased with an active stallion. Response of the mare to the advances of the stallion with signs of estrus, such as urinating, raising the tail, winking the vulva, and hesitating to move away from him, accompanied by estrus-type signs on palpation and ultrasonography as outlined earlier, indicate that the mare is in estrus at the

time of the examination. Mares with large follicles (>33 mm) may respond to administration of hCG (2500 IU IV) by ovulating approximately 2 days later and going out of heat in another 1 or 2 days. If monitored, mares in estrus with small follicles will usually show normal follicle growth, ovulation, and entrance into diestrus. The reason for the history of prolonged heat in these mares before the examination is not clear.

Constant or erratic true estrous behavior (response to a stallion) may be seen during seasonal transition (see previous discussion). This behavior may also be related to ovarian pathology such as gonadal dysgenesis or granulosa cell and related tumors, and these possibilities should be investigated as outlined earlier. In addition, pregnant mares may show constant or irregular estrus in response to teasing by a stallion.

In a nontransitional mare with a normal nonpregnant tract showing persistent behavior interpreted as heat, any ovarian basis for the behavior may be determined by establishing whether there is a correlation between behavior and cyclicity. The reproductive tract should be examined two to three times weekly for a month or more while the owner notes the mare's behavior. If the mare cycles normally, and no correlation of cyclicity with behavior is present, the mare's behavior is probably not associated with her ovaries.

Many nonreproductive behaviors may be interpreted as signs of "heat." Mares that have constant agitated behavior, rather than true estrous behavior, may be in any stage of the cycle at the time of examination. Agitated, estrous-type behavior is often seen (or at least complained about) in mares in fairly intense training. This behavior has been termed "submissive, cowering behavior" and has been equated to the urinating behavior of a scared puppy.[9] When mares with this behavior are evaluated critically, although some signs associated with estrus may be present (raising the tail, urinating, leaning), the behavior of the agitated mare is anxious, or guarding.[9] She is resentful of the approach of a stallion when teased, and may lean away from the stallion or appear fearful and attempt to escape. This behavior is in contrast to that shown by the mare in true estrus, which during teasing is typically calm and interested in maintaining contact with the stallion. Mares with cowering behavior may improve given changes in their environment and gentle handling, with the goal of increasing the mare's confidence and decreasing intimidating stimuli while reacclimating her to her training schedule. Long-acting tranquilizers have also been felt to aid in management of these mares.[10]

Signs interpreted as persistent estrus may be attributable to vaginal inflammation due to a foreign body, or to aspiration of air into the vagina when the mare is working. The latter seems to be most common in racing-fit mares (mares with little body fat) in training. These mares lack perineal fat, which affects the tone of the vulvar lips, the angle of the vulva, and the weight of the perineal body, which closes the entrance to the vagina. The affected mare has signs of vaginitis such as frequent urination, hunching the back, dragging the hind feet, and wringing the tail. Racing mares with this complaint commonly have a history of "stopping" part way through training periods; this may be due to pneumovagina incurred during work. Examination of the tract shows the mare in any stage of the cycle; bright echogenic particles representing air may be seen in the uterus on ultrasonographic examination; the vagina may be ballooned with air. Speculum examination of the vagina may reveal an inflamed vagina and the mare may show extreme signs of irritation (hunching the back, attempting to urinate) after the speculum is inserted or removed. This problem may occur even after a Caslick's operation has been performed. A modified Caslick's procedure (perineal reconstruction) may help to prevent pneumovagina by narrowing the vestibule and increasing the bulk of the perineal body.

Abnormalities of the bladder or urethra, such as cystitis or urethral masses, may result in frequent urination that is interpreted as persistent estrus. One mare, presented for examination for "nymphomania," exhibited agitated, pacing behavior, and frequent urination. The cause was found to be neurogenic bladder atony with associated cystitis. The distended bladder constantly ejected urine as the mare moved. When the bladder was kept empty by catheterization, the mare's constant tail raising, posturing, and agitated behavior all ceased; the agitation may have been due to pain from bladder distention. The mare's reproductive tract and cyclicity were normal.

Sometimes stallion-like behavior is interpreted to be estrous behavior by the owner. Assessment of stallion-like behavior may be done by turning the mare out with other mares and observing whether she exhibits courting or mounting behavior, by placing her in a stallion's paddock to observe how she responds to fecal piles (stallion-like behavior includes smelling fecal piles, defecating or urinating on the same pile, and smelling the pile again), and by bringing mares up to the fenceline to see if the mare under study prances up, vocalizes or otherwise behaves in a stallion-like manner. Stallion-like behavior is almost always related to exposure to androgens, possibly from an ovarian tumor or presence of testicular tissue (see previous discussion) or from administration of exogenous anabolic steroids. The effects of exogenous androgens may last for months after the last administration.

Cyclic or Sporadic Behavioral Problems

Some mares do become harder to manage, perform irregularly, or even appear lame when in heat; this behavior is intermittent and corresponds to specific stages of the estrous cycle.[9] Such problems may be due simply to exaggerated exhibition of normal estrous behavior at times that are deemed inappropriate by the owner (e.g., while under saddle). However, there may also be behavioral and physical effects of estrogen, such as increased joint laxity, that affect performance. Some part of this behavior may also be related to pain from the growing follicle stretching the ovarian tunic, or from rupture of the follicle at ovulation. Most mares exhibit signs of pain when the ovary is palpated immediately after ovulation.

Altrenogest treatment (at 0.044 to 0.132 mg/kg orally daily) is commonly used to suppress problem estrous behavior in mares, and is usually effective. Although

progestin-containing implants produced for estrus synchronization in cattle have been used for this purpose, and anecdotally have had some effect, studies have shown that most synthetic progestins do not suppress estrus or interact with equine progesterone receptors. Sometimes owners request ovariectomies for mares that are sporadic or constant "bad actors." This should be reserved only for cases in which the mare has *cyclic* behavioral problems corresponding to a specific part of the estrous cycle when evaluated as described earlier; this behavior should seem to improve over the winter (during anestrus). Mares rarely fall into this category, but when they do, ovariectomy can be an effective cure for the behavior. The mare's tendency to react violently should be considered when making the decision on whether to do the ovariectomy standing (via colpotomy) or under general anesthesia.

As with "persistent estrus," however, owners may attribute objectionable behavior in a mare to ovarian problems when in fact there is no connection. Any type of sporadic behavior (even refusing jumps when under saddle) may be interpreted by the owner as a sign that the mare is in heat. Owners may assign a behavior to 21-day cycles because they are associating it with estrus, and they are aware of the length of the estrus cycle; however, questioning may reveal that the actual duration of the behavior and the period between behavioral episodes is unknown. These cases should be approached with the presumption that the behavior is not related to cyclicity until the association is proved. Examples of this include a mare that was presented for examination with a history that she was in pain during estrus, showing signs of colic and inappetence. The owners had not kept a written record but stated that the episodes occurred about every 21 days. A work-up for recurrent colic was performed, and on gastroscopy the mare was found to have stomach ulcers. Treatment of the ulcers with cimetidine resulted in cessation of the colicky episodes. In another case, a mare was periodically resentful of being handled, to the point of shaking and attempting to lie down; complete examination, including exploratory laparotomy, revealed an abscess in the stomach wall.

Aggressive or Abnormal Behavior

Constant aggressive, quasi-stallion-like or otherwise abnormal behavior may be related to presence of a granulosa cell tumor or testicular tissue (see previous discussion). Interestingly, it appears that some mares may show changes in behavior for a year or more before the detection of ovarian changes indicative of GCT.[10] Therefore, if the reproductive tract is normal on initial examination, but no other cause of abnormal behavior is documented, a repeat examination of the reproductive tract should be performed every 6 months or so.

A warning should be made regarding mares presented for assessment of ovarian causes of abnormal behavior. Occasionally a mare is presented that has vicious outbursts of aggressive behavior—in one case that the author evaluated, the mare broke through a fence to attack a child. These mares may be presented for reproductive examination on the possibility that violent or vicious behavior is related to an ovarian abnormality. Such mares should be approached with caution. Little information is available on the causes of this behavior but it is unlikely to be related to the reproductive tract. In two cases of such behavior seen by the author, pituitary abnormalities were suggested. One mare had preneoplastic changes in the pituitary on histopathologic examination at necropsy, and one mare had adrenocorticotropic hormone (ACTH) concentrations and dexamethasone suppression test results midway between those expected for normal and for Cushing's disease patients.

CHAPTER 19

Infertility Due to Noninflammatory Abnormalities of the Tubular Reproductive Tract

HEIDI IMMEGART

Infertility in mares can result from developmental abnormalities or acquired conditions that cause reproductive failure due to inflammation with or without infection in the reproductive tract, abnormal physiologic events, abnormal reproductive tract anatomy, structural alterations resulting in abnormal function, and neoplasia. This chapter will focus on infertility that is due to congenital or acquired problems of the tubular reproductive tract that are noninflammatory in nature.

REPRODUCTIVE TRACT DEVELOPMENT

Initial development of the reproductive tract is determined by the animal's genetic sex, which is responsible for stimulation of gonadal differentiation. Normal testis determining factor (TDF) genes on the Y chromosome along with the H-Y antigen complex cause development of testes with seminiferous tubules in the undifferentiated gonad of the normal XY male. Sertoli cells within the testis produce müllerian inhibiting substance (MIS), which suppresses development of the paramesonephric (müllerian) ducts while testosterone production from the Leydig cells of the developing testis stimulates development of the mesonephric (wolffian) ducts into the epididymis and vas deferens. Testosterone also stimulates masculinization of the external genitalia following conversion into dihydrotestosterone in those tissues.

The absence of the Y chromosome along with genes on the X chromosome results in differentiation of the fetal gonad into the ovaries in the normal XX female. Without testosterone and MIS, the wolffian ducts regress and the müllerian ducts develop into the female tubular reproductive tract. The nonfused cranial portion of the paired paramesonephric ducts forms the oviducts and uterine horns. The caudal portions of the paramesonephric ducts fuse and develop into the uterine body, cervix, and vagina. The absence of testosterone, and thus dihydrotestosterone, results in feminization of the external genitalia and development of the vulva, clitoris, vestibule, and caudal vagina.

Abnormal reproductive tract development can arise from an abnormal chromosomal/genetic condition or an abnormal hormonal environment as well as from exogenous factors.[1] Many different conditions that result in abnormal development of the reproductive tract in the horse have been reported. The most common genetic condition is X monosomy or (63XO) gonadal dysgenesis, which is the presence of an aneuploid defect of the sex chromosomes.[2] The fetus develops into a female with hypoplastic ovaries and a small underdeveloped tubular reproductive tract with hypoplastic endometrial glands. These animals fail to cycle normally even following hormonal treatment and are considered sterile. Attempts to establish pregnancies via embryo transfer into these mares have not been successful enough to consider these animals appropriate recipients. Affected mares are typically small and weak at birth and remain small in stature as adults. The condition is thought to arise from nondisjunction during meiosis and is sporadic in nature rather than hereditary.

The second most common condition is XY sex reversal.[3] XY gonadal dysgenesis results in a gonadal female with ovaries or streak gonads and a variability in female phenotype from normal to one with hypoplastic or aplastic tubular genitalia. These animals fail to demonstrate normal cyclic estrous behavior despite hormonal stimulation. This author has seen one Thoroughbred mare with the XY gonadal dysgenesis syndrome. This mare would sporadically display estrous behavior, presumably from adrenal steroid production.

The XY testicular feminization condition is associated with a lack of conversion of testosterone to dihydrotestosterone or an insensitivity to dihydrotestosterone. This results in feminization of the external genitalia concurrent with a lack of development of the internal female tubular reproductive tract. The gonads of these animals may contain both testicular and ovarian tissue and behavior is frequently masculinized. XY sex reversal may in some cases be caused by a single gene defect passed through the male or female on the X chromosome.

A multitude of other genetic/chromosomal anomalies have been reported in conjunction with hermaphroditic, pseudohermaphroditic, and subfertile conditions including XX sex reversal, XXY, mosaicism, and chimerism. These animals have displayed varying degrees of gender

ambiguity, associated with the internal and external portions of the reproductive tract, and infertility.

Other developmental abnormalities will be discussed with regard to the structure that is affected.

Oviducts

The oviduct of the mare consists of the infundibulum, which is closest to the ovary, the ampulla, and the isthmus, which is adjacent to the uterine horn. Fertilization occurs in the ampullar region and fertilized ova are transported into the uterus. Unfertilized ova from cycles tend to remain in the oviduct.

Congenital Defects

Although rare, developmental abnormalities involving the oviducts have been reported.[4] Segmental aplasia is the condition in which a portion of the oviduct does not develop. Hydrosalpinx may result from the lack of patency of the oviductal lumen depending on the location of the aplastic segment. Some cysts or series of cysts near the caudal portion of the oviduct are thought to be a persistence of accessory oviducts that may develop at the end of the paramesonephric duct. Large cystic structures may be a cause of infertility.

Acquired Abnormalities

Acquired abnormalities of the uterine tube are usually secondary to disease processes occurring around other structures. For example, adhesions involving the oviduct may develop secondary to salpingitis, which typically arises from severe inflammatory/infectious processes in the uterus or abdomen. Adhesions that obstruct the lumen from external pressure may also cause hydrosalpinx.[4] Fertilization following ovulation from the ipsilateral ovary would be prevented in cases in which complete occlusion of the oviductal lumen is present.

Although globular collagenous masses have frequently been reported to occur mainly in the ampullar isthmic junction area, the clinical significance of these structures remains controversial. Unfertilized oocytes have been located on the up- and downstream aspects of many of these masses, and large collagenous accumulations appeared to fill and in some cases distend the oviductal lumen. Oviductal blockage could prevent oocyte/embryo migration past the mass. One study demonstrated increased pregnancy establishment following surgical intervention to re-establish oviductal patency of previously blocked tubes in a group of mares with a 2- to 4-year history of infertility.[5] Although not easily diagnosed under field conditions, oviductal occlusion should be a consideration in mares in which other causes of infertility have been ruled out.

Sperm capacitation and hyperactivation, fertilization, and early embryonic development all occur within the oviduct. It is possible that functional or secretory abnormalities may affect one or more of these critical steps. Protein secretion patterns have been determined to be different between oviducts from young fertile mares as compared to aged infertile ones. Epithelial cysts in the ampullar region and adhesions in the infundibulum have been described.

Uterus

Developmental Defects

Developmental abnormalities of the uterus include hypoplastic conditions as well as segmental aplasia and uterine body duplication. Hypoplasia of the uterine body and horns is commonly associated with the XO gonadal dysgenesis and XY sex reversal as well as other chromosomal anomalies.

Segmental aplasia is the condition in which a portion of the uterine horn or body does not develop. This author has observed cases in which aplasia has involved one entire uterine horn. The mares involved had a history of being difficult to get in foal and subsequently bearing small offspring. Two other mares were reported to establish pregnancies when the ovary ipsilateral to the existing horn had ovulated.[6] Segmental aplasia involving one uterine horn prevents sperm from contacting the ovum following ovulation from the ovary of the aplastic side. When the aplastic segment includes the uterine body, sperm are completely prevented from passage into the oviduct and fertilization. Depending on the location of the aplastic segment in one uterine horn, this condition may prevent adequate uterine migration by an embryo conceived from an ovulation by the contralateral ovary. Inadequate uterine migration by an embryo will result in a lack of maternal recognition of pregnancy. Decreased functional uterine space may also limit placental growth and result in smaller offspring, premature delivery, or abortion. One mare with repeated abortions was reported to have a short or absent uterine body.[7] Pregnancy loss was attributed to insufficient placental surface.

Uterine body duplication occurs when the bilateral paramesonephric ducts fail to fuse normally. Varying degrees of this abnormality have been observed, ranging from a short septum located at the caudal portion of the uterine body to a complete septum dividing the entire length of the uterine body to the cervix. This aberrant fusion may even involve the cervix as well. One mare was reported to have had a complete division of the uterine body with a separate cervix for each side and a dorsoventral curtain present in the cranial vagina. Lack of sperm transport to the appropriate oviduct and insufficient uterine migration or functional space may be associated with infertility in animals with this abnormality.

Endometrium

The inner lining of the uterus is the endometrium. Within the endometrial epithelium are glands that secrete nutrients necessary for normal embryonic and fetal development. Histologic evaluation of the endometrium of mares has demonstrated changes in the development and secretory nature of the glandular epithelium as well as changes in the luminal epithelium, other cell populations, molecular components, and steroid receptor expression of the uterine lining consistent with normal estrous cyclicity.[8] The changes detected are synchronous with the changes in the hormonal environment encountered during the estrous cycle. The changing local environment of the endometrium at different stages of the cycle has been associated with essen-

tial processes that occur at specific times such as sperm functional changes, embryonic support, fetal support, and placental development. Abnormalities of the endometrium due to abnormal development, secretory function, synchrony, or cellular composition as well as degeneration have been associated with infertility.

Endometrial hypoplasia is the lack of normal development of the endometrial glands. This condition is recognized in association with abnormalities such as gonadal dysgenesis as well as with the normal situation prior to puberty. With puberty and the first ovulatory cycle, endometrial glands differentiate into the adult secretory structures. It has been determined that estrogen is required to prime the uterus for progesterone stimulation of glandular differentiation.[9] With repeated hormonal stimulation associated with normal estrous cycles, the endometrial glands proliferate such that they can provide adequate support to a pregnancy; however, some young mares have been noted to have delayed endometrial maturation and have been categorized as hypoplastic. Increased pregnancy loss rates are observed in 2-year-old fillies and have been associated with the lack of glandular development required to support gestation to term.

Glandular atrophy is the condition in which the endometrial glands, while normal in development, at some point in time are lost.[5] This occurs naturally during seasonal anestrus; however, return to normal endocrine activity may not correlate with return to cyclicity. Endometrial atrophy in cyclic mares can be a cause of early embryonic death. The condition is also observed in older mares and mares undergoing ovarian senescence. Atrophy can be caused by a lack of ovarian steroids. Treatment is not usually productive. Endometrial atrophy and hypoplasia may be difficult to distinguish, however, and history of previous endocrine function and reproductive tract evaluations can help differentiate the two.

Glandular hyperplasia has also been described in mares as a cause of infertility. The hyperplastic condition has been associated with delayed involution following fetal loss or abortion.[10] It can also be seen in conjunction with steroid secreting tumors such as granulosa cell tumors and is reversible in these cases following tumor removal.

Endometrial maldifferentiation has been studied in barren mares. Several patterns of irregular or unequal differentiation of the glandular structures and secretory patterns that did not correspond appropriately with the stage of the estrous cycle from which the biopsy sample was obtained were classified.[11] The prognostic value of these maldifferentiation categories and the abnormal secretory patterns associated with some of them are under investigation. Maldifferentiation is known to cause infertility in other species such as the human. It has also been demonstrated in some species that abnormal endometrial development and glandular differentiation and secretion can be altered if the receptors for the stimulating hormones are deficient or absent.[1,12] In these cases, females undergoing pubertal changes in the hormonal environment do not have concurrent maturation of the uterine lining. Infertility is detected in these individuals. Genetic alterations and chemical encounters at various stages of development have been associated with these cases.

Endometrosis is a syndrome encompassing a group of degenerative changes, typically including periglandular fibrosis, cystic dilation of glands, and glandular necrosis or hyperplasia of the endometrium. These degenerative alterations have long been associated with infertility which may result from damage to the endometrial surface, changes in histotroph components or secretion, retardation of embryonic and fetal development, and delay in placental development. Glandular protein production has been demonstrated to be deficient in some and secretion to be altered, indicating glandular asynchrony, in other mares with endometrosis when compared to normal fertile mares. The pathogenesis of endometrosis is not completely understood; however, associations between the presence of endometrial degeneration and angiotensin-converting enzyme, an enzyme associated with fibrosis in tissues including heart, kidney, liver, and spleen, have been detected in the mare as well as modulations in fibroblasts and collagen IV. This condition has been considered an age-related change that has no consistently functional treatment or prevention in mares.

Microscopic changes of the blood vessels in the endometrium have been noted in aged and multiparous mares. Sclerotic changes have been detected in aged maiden mares and a syndrome similar to pregnancy sclerosis of other species has been detected in multiparous mares.[13] The changes noted included elastosis and fibrosis of the intimal media and adventitial layers. Alterations in endometrial blood flow have been associated with repeated pregnancy failure in older mares.

Endometrial cysts are structures seen typically in mares over 10 years of age and are either glandular cysts or lymphatic lacunae.[8] Glandular cysts frequently are associated with periglandular fibrosis resulting in fibrotic nests that may become just large enough to detect with ultrasonographic examination. Some glandular distentions have been noted without fibrotic change and also have been associated with infertility when the condition persists during the physiologic breeding season. Lymphatic lacunae are dilated lymphatic vessels. These may coalesce and become much larger than glandular cysts and have glandular atrophy associated with the epithelium covering the area. These cysts are typically located at the base of the uterine horns and have been associated with higher biopsy categories. Although single smaller cysts may not affect fertility greatly, large or numerous cysts have been associated with reduced fertility in mares, possibly from increased early embryonic death, reduced embryo migration, and increased embryonic resorption or abortion. Ultrasonography can be used to diagnose the presence of cysts; however, hysteroscopy can be both diagnostic and therapeutic, via cyst ablation.

Changes in the endometrium of mares can be readily detected by histopathologic examination of a biopsy sample. Typically, one sample will be representative of the entire uterus due to the diffuse nature of most abnormalities; however, some focal changes in endometrial structure have been detected. Lymphatic lacunae tend to be localized and are not readily diagnosed with biopsy,

and a decrease in glandular structures has been reported near the internal cervical os. Multiple biopsies may be beneficial if a single tissue sample has been inconclusive or if it is suspected that a lesion is localized or affected by season. The significance of uterine biopsy sampling cannot be overemphasized in aiding the diagnosis of mare infertility.

Uterine Lumen

Adhesions involving the lumen of the uterus may obliterate the glandular surface as well as cross transluminally as bands or sheets. Gross scar tissue formation is typically the result of uterine trauma from dystocia, severe inflammation or infection, or inappropriate administration of caustic substances. Transluminal sheets may cause accumulation of uterine secretions cranial to the blockage. Pyometra may result if the fluid becomes contaminated. Scar tissue may be visible with ultrasonographic examination of the uterus in cases in which fluid accumulation is detected or hyperechoic mottling is present in the lumen. Endoscopy may be used to visualize the presence and degree of adhesion formation or may be blocked by the presence of transluminal sheets. Prognosis for fertility depends on the extent of the adhesions. Although minimal bands may be broken down via endoscopy, generalized uterine insult tends to result in adhesions that are diffusely distributed throughout the uterus.

Mucometra is the abnormal accumulation of mucus in the uterus. As a primary condition, mucometra is rare in mares and is associated with cystic dilation and lymphocytic infiltration.[4] Mucometra may be secondary to the presence of a complete hymen in young cycling mares or cervical adhesions. Unbreached, the mucus remains sterile inside the reproductive tract; however, prolonged exposure to large volumes of mucus may eventually alter endometrial structure or function.

Uterine Wall

Uterine neoplasia is rare in the horse. Tumors reported in equine uterus include benign tumors such as leiomyomas, fibromas, and fibroleiomyomas, as well as malignant tumors such as leiomyosarcomas, rhabdomyosarcomas, lymphosarcomas, and adenocarcinolas.[14] The most common of the tumors reported is the leiomyoma, which is a benign neoplasm derived from the smooth muscle. Neoplasia can be diagnosed utilizing transrectal palpation and ultrasonographic imaging, intrauterine endoscopy, and biopsy. Removal of the tumor mass is indicated for mares being bred; however, large or invasive tumors may require hysterectomy.

Uterine wall hematomas and hemorrhage into the lumen of the uterus typically arise at delivery and usually resolve given time.

The abnormal location of the uterus, tilting ventrally in relationship to the pelvis, has been associated with a lack of normal uterine clearance.[15] Decreased capacity to clear the uterus of fluid and debris results in decreased fertility. Increased uterine clearance is evident following oxytocin treatment of both normal mares and mares with decreased uterine clearance. Ventral sacculations of the uterus, located at the uterine horn and body junction, have also been associated with infertility. These are seen in infertile older mares and may be focal areas of mucosal atrophy or myometrial atony, which accumulate bacteria, fluid, and debris.[16] Treatments including postbreeding oxytocin have been used with variable results, and uterine lavage remains controversial.

Cervix

Developmental Defects

Cervical hypoplasia is the condition in which the cervix is underdeveloped. This has been reported in one mare with normal ovarian activity; however, it is more frequently seen with conditions such as XO gonadal dysgenesis as well as other genetic/chromosomal abnormalities. Typically other reproductive tract anomalies exist concurrently. Cervical hyperplasia was reported in one mare with tissue protruding through the vulva; however, it was not determined whether the benign mass was congenital or acquired.[17] The mare was also noted to have ventral sacculations of the uterus and endometrial atrophy. Double cervix is the condition in which fusion of the caudal paramesonephric ducts is not completed. This condition may exist alone or in conjunction with uterine body duplication or dorsoventral vaginal curtains. Both, or only one, of the cervical canals may be patent. Congenital absence of the cervix through segmental aplasia of the paramesonephric duct is rare in the horse, but it was reported once in a pony mare.[18] Accumulations of uterine secretions were evident due to complete blockage of outflow at the aplastic segment.

Acquired Abnormalities

The cervix is a dynamic organ that must be able to close tightly in order to protect the uterus and early pregnancy as well as relax appropriately during estrus and fetal delivery. Damage to the cervix typically occurs at delivery and may or may not be associated with dystocia. Cervical lacerations may be gross tears of the epithelial and muscular layers of the body or os or they may be microscopic breaches of the muscular layer only. Damage to the cervix may be inflicted by direct trauma at delivery or breeding or may be due to inadequate cervical relaxation for delivery of the fetal shoulders or pelvis. The latter type of trauma is frequently a result of forced fetal retraction prior to adequate cervical relaxation for normal fetal passage. Damage involving only the external os of the cervix may not hinder fertility if the cervical body is capable of achieving adequate closure for pregnancy protection. Gross or microscopic lacerations that render the cervix incapable of closure (cervical incompetence) will result in infertility. Cervical competency can be determined by digitally examining the cervix when the mare is under the influence of progesterone. Surgical repair of cervical lacerations has been attempted with variable results. Suture failure, scar tissue formation, and the potential for reinjury at subsequent foaling may confound treatment.

Cervical adhesions may also result from trauma to the cervix. These adhesions may be intramural or transluminal or they may extend from the external os to the cranial

vaginal wall. Scar tissue formation can result from trauma to the cervix or overwhelming uterine inflammatory disease. Depending on the location of adhesion formation, the cervix may not be capable of normal closure, resulting in infertility. Alternatively, the cervix may scar closed either by cervical wall or by transluminal adhesion formation. Fluid accumulation may be noted in these cases. The capacity of the cervix to close as well as luminal patency and the presence of scar tissue is most accurately determined by palpation of the cervix manually through the vagina. Gross adhesions may be broken down digitally or with long-handled scissors; however, recurrence typically follows.

Cervical neoplasia is rare in the mare; however, two recurrent leiomyomas were reported in half-sibling mares.[19] One fibroma, which interfered with normal function of the cervix, was removed and normal cervical competence was restored.[20]

Vagina

Congenital Defects

Persistent hymen in the mare is the condition in which the opening between the caudal vagina and the vestibule is not complete. A partial persistent hymen may present as a band or bands of tissue stretching across the opening of the vagina and typically has no effect on fertility. A complete hymen is a sheet of tissue that occludes passage into the vagina from the vestibule. These are typically diagnosed in young postpubertal mares in which fluid accumulation cranial to the hymen causes protrusion of the hymen through the vulva. Excision of the hymen tissue corrects the condition; however, chronic distention of the uterus may cause infertility due to endometrial atrophy, or bacterial contamination of the fluid may cause pyometra. One case of vestibular-vaginal hypoplasia was reported in a pony mare in which the caudal vaginal/vestibular area had a diameter of only 4 cm.[21] The cranial vaginal diameter was normal, and no evidence of trauma was apparent at the strictured area.

Acquired Abnormalities

Infertility due to vaginal abnormalities is most commonly associated with adhesion formation after trauma due to delivery or, less frequently, breeding accidents. Scar tissue formation within the vaginal canal can be extensive following dystocia and may nearly obliterate the vaginal canal. This author has seen two mares in which vaginal penetration was made impossible by extensive adhesions in the caudal vagina following dystocia.

CHAPTER 20

Inflammation of the Tubular Reproductive Tract of the Mare

KAREN WOLFSDORF and A.B. CAUDLE

A broodmare needs to produce consistently viable foals to be economically successful. In order to achieve this she needs to be in good physical condition, have regular estrous cycles, mate, conceive, maintain pregnancy, give birth, and raise a foal. If there is a breakdown in any of these areas, she will become considered a "problem" mare. Consideration of management practices and fertility of the stallion is therefore important before all the blame of subfertility or infertility is placed on the mare. The tubular part of the reproductive tract is composed of the vulva, vestibule, vagina, cervix, uterus, and oviducts. All work together to provide the most conducive environment for fertilization, embryonic development, and the birth of a healthy foal. Inflammation of one of these components affects the others.

VAGINITIS AND CERVICITIS

The mare's reproductive tract resides in the caudal portion of the abdomen suspended from the body wall by the broad ligaments. As the number of estrous cycles and foals produced increases so does the laxity of these ligaments causing the reproductive tract to lie more cranial and ventral to the pelvis. Three major anatomic barriers protect the uterine environment: the vulva, labia, vulvovaginal fold (hymen), and the cervix.[1,2] Fertility problems begin to arise in the mare when these anatomic barriers are compromised or fail. This leads to contamination of the reproductive tract by air, urine, or particulate matter, causing pneumovagina, vaginitis, cervicitis, and endometritis.

The vagina and uterus are believed by some investigators to have a normal bacterial flora considered to be nonpathogenic, whereas others assume that the uterus of the clinically normal mare is bacteriologically sterile.[3] Whichever the viewpoint, clinical vaginitis and cervicitis is most commonly due to irritation from air, urine, particulate matter (bacteria), or chemicals including antibiotics and antiseptics and are usually associated with endometritis.[4–6] The vulvovaginal fold, rather than the cervix, has been indicated as the major barrier to ascending bacterial contamination of the mare's reproductive tract.[3] Speculum examination reveals a hyperemic mucosa of the vaginal vault and cervix with or without exudate or urine crystals on the ventral aspect, depending on the cause. Treatment is focused on reconstructing the physical barriers to include Caslick's procedure, perineal body reconstruction, repair of perineal lacerations and rectovaginal tears, and urethral extensions.[1,4] These steps will remove the offending source of irritation or organisms allowing for the vaginitis and cervicitis to resolve. If the underlying problem is endometritis, intrauterine or systemic treatment with an appropriate antibiotic or discontinuation of uterine treatment of irritating antibiotics (enrofloxacin, ceftiofur) or antiseptics (Nolvasan, concentrated iodine solutions) resolves the secondary vaginitis as long as permanent damage such as adhesions has not occurred.[7]

Trauma to the vagina and cervix during breeding or parturition can also be a source of inflammation. Bruising of the mucosa of the vaginal vault and cervix can occur when the stallion is overzealous during mating, especially in maiden mares. This can be alleviated with the use of a breeding roll so that penetration can be controlled and restricted. During parturition, the foal's feet can damage the mucosa, or if assistance is necessary, chains and fetatomes can cause injury. Necrosis of the vaginal mucosa can occur if the trauma is excessive. Unfortunately, clinical observation but not documentation of this ailment has been made. The vaginitis or cervicitis produced will in most cases resolve with time.

ENDOMETRITIS

After fertilization occurs in the oviduct, it takes 5 to 6 days for the embryo to descend into the uterus.[8] Therefore, in order for the embryo to continue to develop, the uterus needs to provide a conducive environment for growth, free of inflammation and contamination. Endometritis is an inflammation of the endometrium of the uterus. It has been described as being the third most important clinical problem in equine practice after colic and respiratory tract disorders.[9] As previously described, endometritis is often seen in conjunction with vaginitis and cervicitis, when compromise to the physical barriers or contamination during breeding occurs,[10–12] and is associated with infertility in the mare.[13,14] Mares have been classified depending on their ability to clear their uterus in a certain amount of time when challenged with infection as susceptible or resistant.[15] Normal/resistant mares are able to clear their uterus from infection or inflammation by three mechanisms: uterine contractions, lymphatic drainage, and an open cervix.[16–19] Antibody-mediated uterine defense appears to be functional in susceptible mares, and although polymorphonuclear neutrophils (PMNs) are not dysfunctional, susceptible

mares were found to have impaired phagocytosis as a result of insufficient opsonization in uterine secretions.[10,20] The breakdown in uterine physical clearance mechanisms is currently believed to play a major role in susceptibility to persistent endometritis.[16] Further identification of these mares has been established by using scintigraphy and ultrasonography in which impaired or reduced myometrial contractility in response to acute inflammation results in an accumulation of fluid and inflammatory products within the uterine lumen.[10,21–24] Additional factors including vascular degenerative changes and dependent position of the mare's uterus have also been implicated in interfering with effective clearance of the uterus.[10,21,25]

Based on the current literature, persistent endometritis can therefore be divided into (1) sexually transmitted diseases (STDs), (2) chronic infectious endometritis, (3) persistent breeding-induced endometritis, and (4) chronic degenerative endometritis (endometriosis).[10]

SEXUALLY TRANSMITTED DISEASES

Sexually transmitted diseases are acquired after mating mares with stallions that inapparently carry pathogenic organisms on their penis or within their semen. Such bacteria as *Taylorella equigenitalis,* certain serotypes of *Pseudomonas aeruginosa,* and *Klebsiella pneumoniae* can produce an acute endometritis.

Taylorella equigenitalis is the causative organism of contagious equine metritis (CEM). *T. equigenitalis* is a gram-negative coccobacillus that is transmitted venereally and is highly contagious in equines. CEM was first documented 25 years ago in Newmarket, England. CEM has now been reported in horses worldwide. In July 1977, CEM was reported on 28 breeding farms in the Newmarket area, with approximately 200 Thoroughbred mares and 23 stallions affected.[26] By the conclusion of the 1978 breeding season, CEM was diagnosed in numerous countries, including the United States and Australia.[27] *T. equigenitalis* has now been isolated in 14 countries, infecting both Thoroughbreds and non-Thoroughbreds.[28]

In 1978, two strains of the organism were isolated from Kentucky Thoroughbreds.[29] One strain was sensitive to streptomycin and the other was resistant. In 1979, Missouri reported an outbreak of CEM in non-Thoroughbreds involving the streptomycin-sensitive strain.

Mares diagnosed with CEM reportedly exhibit shortened diestrous periods and copious mucopurulent vulvar discharges lasting up to 14 days. Stallions covering infected mares were asymptomatic. Numerous cultures were taken without isolating *T. equigenitalis* until fresh cultures were placed in transport medium and grown on chocolate blood agar incubated at 37°C in 5% to 10% carbon dioxide for 48 hours.[30] *T. equigenitalis* was found to be sensitive to a wide range of antibiotics and antiseptics, including benzyl penicillin, ampicillin, and chlorhexidine, but was resistant to streptomycin.[27]

A code of practice was issued in 1977 to control the spread of CEM. The code was published in the United Kingdom and similar measures were taken in Ireland and France. The code stipulated a mare as high risk if she cultured positive for CEM, was covered by an infected stallion, or if she arrived from outside the United Kingdom. The code mandated that high-risk mares should have a negative clitoral culture before and after arrival at stud and a negative endometrial and clitoral culture during estrus prior to breeding. Low-risk mares were required to have a negative clitoral swab taken before or after arrival at stud, providing there was agreement with the stud farm manager.[31] The code further stipulated that stallions should be cultured from pre-ejaculatory fluid, the penile sheath, the urethra, and the urethral fossa, and that all cultures should be sent to designated laboratories and incubated under microaerophilic and aerobic conditions. As a result of this code of practice, the incidence of CEM has decreased. Owing to strict importation regulations in the United States, CEM has not been reported in this country since 1983.[32]

Etiology

In 1978, the initial bacteriologic examination of swabs from the genitourinary tracts of infected animals revealed the CEM organism to be *Haemophilus equigenitalis* strain NCTC1/184 (61717/77). The organism was renamed *Taylorella equigenitalis* in 1984.[33]

Samples from animals suspected of CEM are shipped to the laboratory in Amies transport medium supplemented with charcoal. Upon arrival, specimens are transferred to chocolate blood agar, which is incubated in 5% to 10% carbon dioxide at 37°C. Pinpoint-sized, grayish colonies with a smooth outline appear by 48 hours. After 72 hours, the colonies can reach 1 to 2 mm in diameter and appear raised and shiny.

Transmission

Spread of CEM is primarily by venereal contact. Contaminated equipment, instruments, and personnel that contact the genital tracts of mares and stallions contribute to the spread of the disease. A carrier state exists because *T. equigenitalis* persists indefinitely in the clitoral sinuses of mares and urethral fossae of stallions. *T. equigenitalis* has been isolated from foals born to infected mares.[34] *T. equigenitalis* has been isolated also from an aborted fetus and placenta, but a repeated culture of the dam did not reveal the organism.[35]

Diagnosis

Diagnosis of CEM is confirmed by isolation of *T. equigenitalis* from the appropriate sites in the mare and stallion. It is imperative that samples be placed immediately in transport medium and shipped to a laboratory that is familiar with culture techniques for CEM.

Cultures should be taken during early estrus from the endometrium or cervix. Cultures from the clitoral fossa and the three clitoral sinuses should be submitted. The clitoral sinuses are small and can be visualized when the clitoris is partially extruded and held downward. A small swab moistened with sterile saline can be used to sample the sinuses. Clitoral cultures can be obtained at any time during the estrous cycle and from pregnant mares. A stallion's penis must be extended and samples taken from the

urethral fossa, urethra, preputial folds, skin of the penis, and pre-ejaculatory fluid.[28] Three negative cultures should be taken before the stallion is considered free of the disease.

Serology

Numerous serologic tests have been developed to detect antibodies to CEM in serum. The enzyme-linked immunosorbent assay (ELISA) and passive hemagglutination tests are superior for detection of infected mares.[28] Antibodies can be detected within 40 days of infection. The tests are useful in identifying mares with active infections. Carrier mares and infected stallions have no humoral response, and serologic tests are of little value as screening tests. *Taylorella asinigenitalis* and *B. ureolyticus* have shown such similarity in morphology and phenotype that there have been problems in the identification and conformation of *T. equigenitalis*.[36,37] The culture LightCycler PCR eliminates the confusion because it does not amplify *B. ureolyticus* DNA and discriminates from *T. asinigenitalis*.[38] Therefore, it can be used in conjunction with culture to fulfill export criteria and improve specificity and sensitivity.

Control

The code of practice instituted in 1977 for the control of CEM has dramatically reduced the incidence of the disease. Sporadic outbreaks have occurred that can be traced to carrier animals.[39] Carriers are considered high-risk animals and are treated and followed with extensive bacteriologic cultures until they are found to be negative. Continued vigilance against inapparent carrier animals has prompted countries, including the United States, to institute strict import regulations. Mares and stallions imported from countries not declared free of CEM must undergo quarantine and extensive testing at a designated quarantine station.[39]

Treatment

Intrauterine infusion of antibiotics combined with thorough cleansing of the clitoris, clitoral fossa, and clitoral sinuses is the treatment of choice in mares. Daily intrauterine infusions for 5 to 7 days with penicillin (5 to 10 million U), ampicillin, neomycin, and nitrofurazone have been reported to be successful.[28] The clitoral body, the fossa, and the sinuses must be thoroughly scrubbed daily for 5 days with 4% chlorhexidine solution and packed with nitrofurazone or chlorhexidine ointment. Clitoral sinusectomy might be recommended in mares that continue to harbor CEM in the clitoral area following treatment.

In stallions, the penis should be extended and then both the penis and prepuce thoroughly washed in a 4% chlorhexidine solution. The fossa glandis, urethral fossa, and prepuce are packed with nitrofurazone, penicillin, or chlorhexidine ointment. This should be repeated daily for 5 days. This treatment has been found to be highly successful.

ENDOMETRIOSIS

Endometriosis is a chronic degenerative condition of the endometrium.[40,41] It occurs in older mares that have been exposed to repeated inflammatory conditions or aging.[41] These severe changes can be a sequela of vesicovaginal reflux (urine pooling), chronic bacterial contamination, or delayed uterine clearance with inflammatory byproducts remaining in the uterine lumen. Unfortunately, the process has been found to be irreversible and untreatable and those mares that do get in foal have a harder time maintaining the pregnancy to term.

CHRONIC INFECTIOUS ENDOMETRITIS

Chronic endometritis is a major cause of equine infertility in older and multiparous mares. These mares become contaminated either during breeding or due to anatomic defects of the perineal and vulvar region leading to pneumovagina and fecal aspiration.[42] The most common organisms found in persistent endometritis are *Streptococcus zooepidemicus, Escherichia coli,* yeasts (*Candida* spp. and *Aspergillus* spp.), *Klebsiella pneumoniae,* and *Pseudomonas aeruginosa*.[43,44] Anaerobes have also been described as possibly playing a role.[45] In addition, the unique property of *S. zooepidemicus* enables it to physically adhere to the endometrium in susceptible mares with an increased appearance noted in mares with category 3 endometria.[46]

It is thought that in some mares with delayed uterine clearance, defective uterine immune defense mechanisms may contribute to persistence of infection.[47] Neutrophils need to migrate from the blood into the uterine lumen, phagocytose, and kill bacteria appropriately. Defects in the migration of blood-derived neutrophils have not been found in susceptible mares and factors in uterine secretions of susceptible mares have been determined to interfere with neutrophil phagocytosis rather than an innate phagocytic failure.[17,48] Opsonization by uterine secretion is dependent on both complement and specific antibody; and although a deficiency in complement was suggested to contribute to uterine defense failure, hemolytic complement was recognized to be elevated in flushings from susceptible mares.[49–52] Specific endometrial antibodies are important in the elimination of bacterial infection with their opsonic activity differing between susceptible and resistant mares.[53–55]

Cellular immunity has not received much attention in the equine uterus, although susceptible mares have normal macrophage function and no deficiency of T lymphocyte subsets.[15] A deficiency in antigen processing and handling at the uterine level may be due to a lack of an appropriate increased response of macrophages.[15]

Diagnosis of uterine inflammation due to persistent infection is based on history, physical examination, speculum examination, uterine cytology, uterine culture, and uterine biopsy. It is imperative that the practitioner use all available tests and not rely on only one.

Documentation of inflammation in the uterine lumen and accurate proof of an infectious organism is imperative.[56] In mares with infectious endometritis, the vaginal

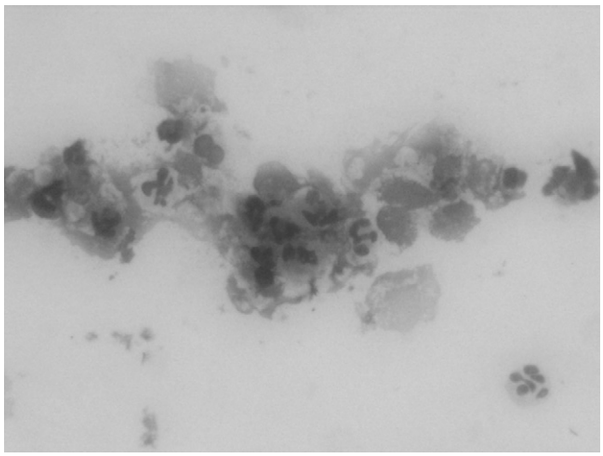

Fig. 20-1 Cytologic examination of endometrial cells with over 5 neutrophils per high-power field representing inflammation.

vault and cervix appear hyperemic on speculum examination with or without the presence of exudate. Rectal palpation may reveal a large relaxed uterus, and transrectal ultrasonography may show flocculent intraluminal fluid accumulation, the extent of which is dependent on the causative agent and severity. Endometrial cytologic examination is the diagnostic test of choice because it provides direct evidence of the presence of neutrophils in the uterine lumen. Any mare that has more than 5 neutrophils per high-powered field confirms active inflammation[56] (Fig. 20-1). Cytologic samples can be acquired by a guarded endometrial swab; collecting cells from the cap of a calajan culturette; or a small sterile guarded atraumatic brush or small volume uterine flush. Care must be taken to roll, not smear, the cells so as not to damage them. A representative sample contains both endometrial and inflammatory cells, with the best results obtained from centrifugation of a small volume uterine flush.[57] Blood contamination can produce a false positive cytologic finding. A guarded uterine culture confirms the causative organism and the antibiotic sensitivity patterns help to direct the treatment. The course of therapy undertaken will be determined by the cause of inflammation.

The goal of therapy for bacterial endometritis is to remove the offending bacteria and enhance uterine defense mechanisms, thereby decreasing the inflammatory process within the uterus. This has been accomplished with intrauterine infusions of antibiotics, antiseptics, and plasma; uterine lavage; ecbolics; and systemic antibiotic therapy. Therapy can be completed before or after breeding, depending on the severity of the infection. It is important to tailor the therapy to the individual case and to remember that no single treatment can be effective in all cases. With severe infections, multiple therapeutic approaches can be used to control the infection. This discussion attempts not to define a course of treatment but to illustrate successful and commonly used treatments. Every mare is an individual and the routine treatment of all mares with the same medication will not result in the best treatment.[58]

Intrauterine Therapy

A common form of therapy is intrauterine infusion of antibiotics, chemicals (antiseptics), and plasma.[59] Intrauterine infusion concentrates medication locally in the infected endometrium as opposed to systemic treatment, which relies on blood concentration of the drug.

For intrauterine antibiotic therapy, a drug should be selected on the basis of sensitivity tests. Broad-spectrum antibiotics might not be as effective as bactericidal antibiotics. Bacteriostatic drugs require assistance from the mare's defense system, which is likely compromised as indicated by the presence of infection.[59] Drug combinations should be avoided because incompatibility often renders the drugs ineffective. The same is true of drug and antiseptic combinations.[58]

The antibiotics most commonly used for intrauterine therapy are penicillin, gentamicin, ampicillin, nitrofurazone, polymyxin B, Timentin, ticarcillin, the sulfonamides, and amikacin.[58,60] Gentamicin, amikacin, ampicillin, and Timentin are the most effective against the majority of pathogenic organisms. Penicillin is thought to be one of the most effective antibiotics available for treating equine uterine infections.[58]

Antibiotics infused into the uterus are dissolved or suspended in sterile water or saline solution and infused directly into the uterus daily for 3 to 5 days or more during estrus.[56]

The size of the uterus, determined by transrectal palpation, should be used to determine the volume infused. The antibiotic can be suspended in volumes between 60 and 100 ml based on the assumption that this volume is optimal for coating the endometrial surface; however, the effects of such dilution on antibiotic efficacy are unknown. Present evidence suggests that most of the antibiotic introduced in this manner is expelled through the cervix soon after treatment.[56,59,61]

Intrauterine antibiotic therapy is not without risk. Indiscriminate use of antibiotics may alter the normal uterine flora and result in development of resistant strains of bacteria, yeast, and fungi.[58,62] Some mares are sensitive to particular antibiotics.[56] Caution must be used to ensure that therapy does not pose a greater threat than infection. The use of products not approved for intrauterine infusion can cause harmful effects in mares.[58]

Immunostimulants have been implicated in aiding the immune system to combat chronic endometritis. Studies are under way to try to objectively prove if they are in fact beneficial.

Uterine Lavage

For uterine lavage lactated Ringer or saline solutions are infused into the uterus via gravity and then allowed to drain. This should be repeated until the flush solution returning from the uterus is clear. A Bivona catheter with balloon and extension tubing can be connected directly

Fig. 20-2 Bivona balloon catheter with extension tubing to connect to lavage fluids.

to the fluid flush bottles (Fig. 20-2). Inspection of the recovered fluid provides immediate information concerning uterine health or the success of uterine treatments. The degree of cellularity and concentration of other inflammatory components correlates well with the appearance of the recovered fluid.[63] Note should be taken that older, multiparous mares have a larger uterus and therefore greater volumes are needed to be infused to fully distend and completely lavage the uterus (4–6 L of lactated Ringer solution). The rationale for this therapy is enhancement of cellular and mechanical aspects of uterine defense mechanisms.[63] The therapeutic effects of lavage are mechanical removal of bacteria and debris from the uterus; stimulation of uterine contractions, thus aiding expulsion of foreign material; and mild endometrial irritation resulting in migration of neutrophils and perhaps serum-derived opsonins to the uterine lumen.[64,56] Uterine lavage has also been reported to stimulate blood flow, improve tone, and decrease uterine size.[65] This procedure in combination with uterine ecbolics such as oxytocin or cloprostenol further enhances uterine clearance.[66] When the fluid is heated uterine lavage has proved beneficial in increasing myometrial tone and uterine circulation in older, multiparous mares with thick-walled or pendulous uteri.[56,63,65,67] Care must be taken, however, not to make the fluid too hot, causing endometrial scalding and adhesions.

Antiseptics

Antiseptics used historically for treatment of uterine disease included acriflavine, bismuth subnitrate, boric acid, charcoal, chlorine, iodine and iodine solutions, iodoform, perboric acid, silver oxide, hot saline and hypertonic saline, sodium hypochlorite, gentian violet, and hydrogen peroxide. Weak solutions of hydrogen peroxide have been used as treatment for acute endometritis and also appear helpful when exudate has been found in the uterine lumen.[59] After phagocytosis by neutrophils, bacteria are destroyed in part by oxidative metabolism, which includes hydrogen peroxide.[59] Lugol's solution (10%) has been reported to be successful for chemical curettage of the endometrium.[60,68]

Extreme care should be taken when infusing antiseptics not to inflict further damage with harsh or concentrated chemicals. A mare's uterus is sensitive to irritating substances.[56,60] Chlorhexidine suspension should be avoided because it causes tissue necrosis.[59,60,69] Oxytetracycline powder can also induce severe tissue necrosis. The endometrium can recover from some irritants, but repeated use may leave a fibrotic endometrium and possibly adhesions.[69] Additionally, hypertonic saline has been viewed by the author to cause severe endometrial adhesions on hysteroscopic examination.

Systemic Antibiotics

Antibiotics for treatment of uterine infections can be administered systemically. Opinions are divided on the success of systemic administration compared to intrauterine therapy. The majority appear to favor intrauterine infusion, especially for treatment of endometritis. Infused antibiotics are believed to be more effective because of direct contact of drugs with the infected endometrium. Systemic therapy has its supporters, and there are reports of success in treating endometritis systemically.[58,68,70] However, objective comparison between systemic and local antibiotic therapy is difficult without controlled trials.[70]

The main question to be addressed when considering antibiotic therapy is which tissues are involved. If the infection includes deeper layers of the uterus or other genital organs, then systemic therapy might be indicated. Some researchers believe that systemic administration results in higher antibiotic concentrations in infected tissues. Metritis, pyometra, and perimetritis would warrant systemic treatment.[58,59,68]

Systemic antibiotic therapy does have advantages. It can be conducted without invading the reproductive tract and treatment can be continued into the diestrous phase of the cycle, whereas postbreeding intrauterine therapy must stop before the embryo enters the uterus. Systemic therapy also enjoys an ease of application.[56,71] A disadvantage is the cost. Systemic therapy requires a higher dose to achieve effective blood concentrations.[56,69]

Based on satisfactory results reported by practitioners, antibiotics suitable for systemic treatment include amikacin sulfate, ampicillin, gentamicin, procaine penicillin, and trimethoprim sulfa.[56] Ciprofloxacin and probenecin has been used successfully by the author and co-workers to combat difficult cases of endometritis due to *Pseudomonas* spp.

Plasma Therapy

Plasma or colostrum augmentation of a mare's natural defense mechanism is another avenue of uterine disease treatment. Plasma therapy is often indicated when no causative agent is identified, when sensitivity tests indicate impractical drugs, or when previous therapy has been unsatisfactory.[56] The goal of plasma therapy is to

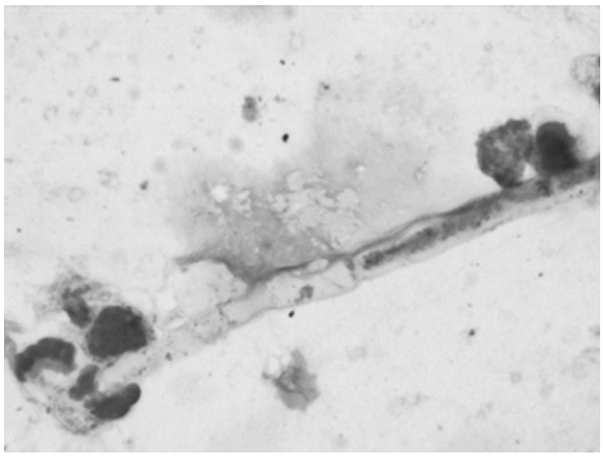

Fig. 20-3 Fungal hyphae with neutrophils.

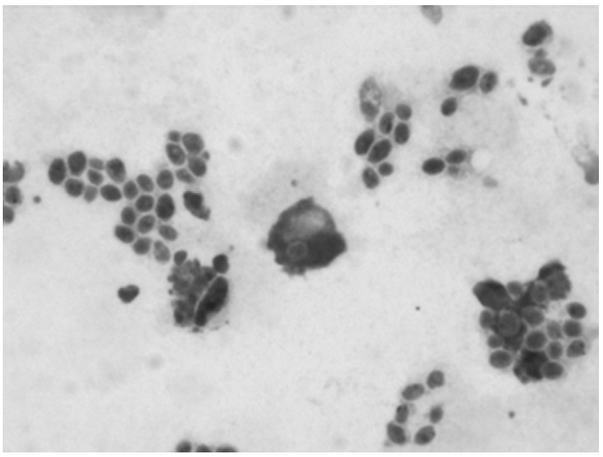

Fig. 20-4 Extra- and intracellular yeasts.

enhance the local uterine immune response and natural defense mechanism. Failure or incompetence of these responses probably accounts for mares that are unable to cope with contaminating organisms.[65] Since plasma is the major source of proteins involved in opsonization of bacteria in the uterus, it has been suggested that a practical method to overcome ineffective uterine defense mechanisms is to infuse plasma or colostrum, substances that contain antibodies, into the uterine lumen.[56,65]

Studies have utilized both homologous and heterologous plasma. The use of heterologous plasma would be convenient, but the possibility of uterine sensitization to foreign protein cannot be ruled out.[67]

Antibiotic and plasma therapy can be used in concert, but some antibiotics are more compatible with phagocytic processes than others. Studies have found that in concentrations commonly used for intrauterine infusion, amikacin sulfate and gentamicin sulfate inhibit neutrophil phagocytosis, and potassium penicillin and ticarcillin do not.[56,67] Further work is needed in this area.

The topic of chronic infectious endometritis would not be complete without the mention of fungal endometritis. The treatment of endometritis due to fungus or yeast is far more difficult than bacteria. *Candida* spp. and *Aspergillus* spp. are the most common fungal organisms associated with fungal endometritis. Poor conformation allowing contamination of the reproductive tract from the environment, repeated or lengthy intrauterine antibiotic treatment, and excessive reproductive manipulation have all been implicated as potential causes of fungal invasion of the uterus.[72] Diagnosis can be made most successfully by endometrial cytologic examination revealing branching fungal hyphae or budding yeast in the presence of inflammatory cells (Figs. 20-3 and 20-4). Endometrial cultures plated on blood or Sabouraud's agar can also aid in identification. Ultrasonography can reveal large amounts of intraluminal flocculent fluid. Endometrial biopsy is recommended in recurrent infections to ascertain the extent of endometrial invasion and inflammation. A white purulent vaginal discharge may also be noted. Treatment has been attempted using uterine lavage to decrease fungal numbers in conjunction with DMSO, vinegar (2%), or dilute Betadine (0.05%). Antifungal agents such as clotrimazole (500–700 mg), amphotericin B (100–200 mg), fluconazole (100 mg) and nystatin ($0.5–2.4 \times 10^6$) can also be used.[44]

Unfortunately studies to determine the necessary length of treatment for a successful outcome have not been done, and therefore, therapy failure may be due to inadequate treatment duration due to cost inhibition. New research has advocated the use of Lufenuron (540 mg) in fungal endometritis.[73]

Lufenuron is a benzoylphenyl urea derivative and is classified as an insect development inhibitor that prevents the synthesis, polymerization, and deposition of chitin.[74] Fungal organisms are surrounded by chitin-rich cell walls, and it is therefore speculated that disruption of this cell wall inhibits fungal growth.[73] In a practical situation the jury is still out concerning whether or not Lufenuron adequately alleviates fungal endometritis. Correcting underlying conformational defects is advised to prevent recurrent infection. Prognosis for reproductive performance is unfortunately poor, due to endometrial invasion of organism and attachment in endometrial folds; treatment only affects certain stages of fungal development, reinfection, delayed uterine clearance, and inadequate duration of treatment. At this time, early diagnosis and treatment is our best defense.

PERSISTENT MATING-INDUCED ENDOMETRITIS

A normal inflammatory response occurs after mating in which there is an influx of PMNs into the uterine lumen due to a chemotactic effect of spermatozoa.[11] It has been speculated that this chemotactic role of spermatozoa may be necessary to clear the uterus from excess spermatozoa and seminal plasma.[10,12] However, this inflammatory process is normally delayed due to the suppression of phagocytosis and migration of PMNs by seminal plasma, therefore allowing spermatozoa to reach the oviduct for fertilization to take place.[75] Seminal plasma has therefore

been suggested to modulate the inflammatory response to spermatozoa, explaining why mares inseminated with frozen/thawed semen containing minimal seminal plasma develop marked and prolonged postbreeding endometritis.[12] During the activation of PMNs, $PGF_{2\alpha}$ is released, causing myometrial contractions.[76] These myometrial contractions are regulated by $PGF_{2\alpha}$ with oxytocin.[11] Uterine contractions are needed to remove contaminants and inflammatory products, thereby preventing persistent inflammation and endometrial damage. If there is a sustained inflammatory process after ovulation, luteolysis will occur and the uterine environment will not be conducive for embryo development. This can cause a substantial reduction in fertility. Susceptibility to persistent mating-induced endometritis (PMIE) is defined as the inability of the estrous mare to clear intraluminal fluid accumulation within 12 to 48 hours after breeding.[16,77] The primary mechanism responsible for the continued presence of intraluminal fluid is impaired physical clearance due to reduced myoelectrical activity and motility.[23,78] Not only has evacuation of the uterus after mating been shown to be defective in mares with PMIE, but sperm transport to the oviduct is also affected.[15] In addition, volume of inseminate may also influence persistence of uterine inflammation, and a recent study has shown that larger volumes decrease the inflammatory response.[79] Intraluminal fluid, which in most cases is indicative of inflammation when seen after mating, can be detected by transrectal ultrasonography.[80,81] The incidence of intrauterine fluid 1 to 2 days after natural breeding has been reported to be between 15% and 43% in the general mare population, with pregnancy rates being significantly lower in these mares.[24,82]

Diagnosis of PMIE should be considered when a mare retains intrauterine fluid for more than 12 hours after breeding.[83] This fluid can be revealed with transrectal ultrasonography in the absence of bacterial contamination. However, mares that are suspected of having this problem should have a complete history obtained, a complete evaluation prior to breeding to include vulvar and perineal anatomy, normal cervical relaxation and closure, cytologic testing and culture, transrectal ultrasonography, and a uterine biopsy. Severe histopathologic changes in the uterine biopsy correlate well with susceptibility to PMIE.[17]

Treatment is aimed at assisting the uterus to physically clear contaminants and inflammatory products. This can be done using large volume uterine lavage 6 to 12 hours after mating in susceptible mares in conjunction with oxytocin 3 to 12 hours after mating.[84,85] $PGF_{2\alpha}$ has also been suggested to help with uterine clearance, with increased myoelectrical activity occurring for 5 hours after 10 mg $PGF_{2\alpha}$ while 20 units of oxytocin causes only 1 hour of increased activity.[83,86] Further studies have revealed that dose and interval between treatments has an effect on efficacy with peak intrauterine pressures occurring in the first 5 to 10 minutes after oxytocin administration and a reduced effect on contractile activity in subsequent treatments if given at intervals of 2.4 hours.[87,88] Decreased pregnancy rates have been shown when treatment consisted of 25 units compared with 15 units of oxytocin after breeding.[89] Therefore, it is the recommendation of the authors to combine uterine lavage in combination with oxytocin or cloprostenol within 6 to 12 hours after breeding. Practically speaking, however, this may not be possible, in which case oxytocin or cloprostenol can be used followed by uterine lavage when the mare is checked the following day. Oxytocin may be used two to three times daily with the authors preferentially using cloprostenol at night when the mares are stabled with less activity. Care must be taken not to use cloprostenol after ovulation because some evidence suggests that it may have a transient effect on corpus luteum formation and progesterone production. Additionally, acupuncture in conjunction with the preceding therapies has been shown to be successful in reducing intraluminal fluid and increase pregnancy rates in mares with PMIE.[90] Regimens used by the author incorporate treatment initiated at the onset of estrus with a treatment delivered every other day until 2 days after ovulation.

METRITIS

Metritis is an inflammation or infection of the deeper layers of the uterus. Systemic signs of metritis are not seen with any degree of regularity but occur most frequently in postpartum mares and mares that have a retained placenta. Draft mares seem to be particularly susceptible to septic metritis. Septic metritis may extend to the peritoneal surface of the uterus (perimetritis) and into the peritoneal cavity (parametritis). Clinical signs of septic metritis include depression, increased temperature (>39.4° C), loss of appetite, and laminitis. Septic metritis can be life-threatening and requires prompt treatment. Large volume uterine lavage with broad-spectrum systemic antibiotics, anti-inflammatories, and preventives for laminitis are imperative for successful results.

Pyometra is characterized by accumulation of purulent exudate in the lumen of the uterus with a closed cervix. The uterus is distended as in pregnancy, and the cervix usually has adhesions due to previous trauma or surgery that prevents drainage. Progesterone concentrations are elevated as a result of a retained corpus luteum, and the endometrium is unable to release prostaglandin F_2 alpha ($PGF_{2\alpha}$). Mares do not show systemic signs. The majority of pyometra cases are diagnosed during routine examination. Treatment can be discouraging because of the permanent damage that may have occurred to the endometrium as well as the inability to resolve cervical adhesions or deformation. Prognosis can be aided by uterine biopsy.

Prevention of uterine disease necessarily precedes any consideration of uterine disease treatment. The importance of a sound prevention and management program cannot be overstated. This is crucial even for mares with normal uterine defense responses because continual contamination debilitates the uterus. Older, multiparous mares and postpartum mares recovering from foaling difficulties have ineffective or compromised uterine defense responses. These mares are particularly susceptible to infection. A sound prevention program begins with sanitary breeding, foaling, and examination procedures. Care must be taken to minimize contamination. Mares prone to infection from organisms introduced at breeding

should be bred near the time of ovulation to reduce unnecessary breedings.[56,58,60] These mares often warrant postbreeding uterine treatment. Surgical correction of anatomic defects also precedes uterine therapy, because abnormal conformation permits bacterial contamination. Caslick's operation corrects poor vulvar conformation that results in pneumovagina.[58–60,67] Third-degree perineal lacerations, rectovaginal fistulas, cervical lacerations, and urine pooling can be corrected with surgery, thus improving fertility.[56,58,59,61]

SALPINGITIS

Salpingitis, or inflammation of the oviduct, is a lesion of principal importance because minor inflammatory changes are incompatible with successful passage of spermatozoa to the ovum and journey of the embryo to the uterus. Conception is rendered impossible (1) by occlusion of the lumen through acute or proliferative swelling, (2) by the lethal effect of toxic inflammatory exudates upon spermatozoa, and (3) by destruction of stretches of ciliated epithelium or contractile muscle that propels the ovum to the uterus.[91] The incidence of salpingitis, however, is low due to the disposition of sphincter muscle around the uterine ostium.[82] This tight uterotubal junction appears to prevent the ascent of endometritis. The special anatomic position of the uterus of the mare in which the oviducts are in the dorsal part of the abdominal cavity above the uterus, rather than lying ventrally, also aids in the prevention of inflammation.[93] Salpingitis in the mare appears to be a widespread infiltrative, nonocclusive, and generally nonexudative process.[94] Past studies, of which there are few, revealed that there is a much higher incidence of ampullitis than isthmitis, as well as twice as great a chance for the two conditions to be bilateral.[93]

In 80% of cases, isthmitis has been associated with endometritis.[93] This could be due to the fact that the highly folded mucous membrane of the ampulla is more sensitive and an inflamed isthmus could recover more easily and rapidly than the ampulla.[93] Infundibulitis may be explained by the presence of the larval form of *Strongylus edentatus,* which migrates over serosal surfaces. Follicular fluid and blood released at ovulation may contribute to the formation of infundibular adhesions. The blood clots could become organized into adhesions, which could then become secondarily infected by hematogenously derived organisms.[93] A hypersensitivity reaction in the infundibulum has also been suggested.[93] Unfortunately, evidence is still lacking concerning how salpingitis, whatever the origin, affects fertility. Additionally, inflammation of the oviduct does not seem to be synonymous with oviductal blockage, and therefore, care should be taken to diagnose infertility due to salpingitis until further evidence and tests can be utilized to determine significance.[93] Flushing of the oviducts appears to be a solution to some, when no other cause of infertility is found; however, care must be taken because this procedure is not without consequences, and adhesions can be produced at the uterotubal junction, causing occlusion and further problems. Therefore, this procedure should be used judiciously.

CHAPTER 21

Bacterial Causes of Subfertility and Abortion in the Mare

T. W. SWERCZEK and A. B. CAUDLE

Bacterial infections of the uterus are the leading cause of subfertility and infertility in mares and represent a major economic loss to the equine industry.[1] The equine breeding industry depends on the health of the uterus, and without a healthy uterus a mare cannot successfully conceive or carry a foal to term. The industry's demand for early foaling dates is largely responsible for equine infertility. The mare's natural breeding season is late May, June, July, and August. In the early spring mares are in reproductive transition and therefore estrus periods are irregular and prolonged. Ovulation is irregular and difficult to predict, and repeated examinations are required to detect it. More than one breeding is usually necessary, which results in added contamination of both the mare and stallion. Frequent uterine contamination and disease occur if a breeder does not implement a meticulous preventive management program to minimize uterine contamination. This program must include immediate recognition and treatment of infected mares.

Bacteria enter the uterus at foaling, breeding, during routine genital examinations, and through vulvar defects (pneumovagina). The uterus of a healthy mare is able to respond to contamination and evacuate transient bacterial contamination. If the uterus is contaminated at breeding, normal defense mechanisms eliminate bacteria without treatment and re-establish a normal environment before the embryo descends into the uterus. Older, multiparous mares and postpartum mares often require special attention and management because their natural defenses have been compromised, and uterine contamination in these susceptible mares often results in infection.[2–6]

CLINICAL SIGNS

Endometritis, which is inflammation of the endometrium, can occur with or without bacterial infection and can be acute or chronic. Most young mares normally resolve uterine contamination within 96 hours, and these mares are considered to be resistant to endometritis.[7] Mares unable to clear bacterial contaminants from their uterus become susceptible, and this results in persistent inflammation. Susceptible mares may have other conformational defects, such as pneumovagina, urine pooling, and foaling injuries, that predispose them to endometritis.

Metritis is an inflammation or infection of the deeper layers of the uterus. Systemic signs of metritis are not seen with any degree of regularity but occur more frequently in postpartum mares. Draft mares seem to be particularly susceptible to septic metritis. Septic metritis may extend to the peritoneal surface of the uterus (perimetritis) and into the peritoneal cavity (parametritis). Clinical signs of septic metritis include depression, increased temperature (>39.4°C), loss of appetite, and laminitis. Septic metritis can be life-threatening and requires prompt treatment.

Pyometra is characterized by accumulation of purulent exudate in the lumen of the uterus with a closed cervix. The uterus is distended and the cervix usually has adhesions that prevent drainage. Progesterone concentrations are elevated as a result of a retained corpus luteum, and the uterus is unable to release prostaglandin F_2 alpha ($PGF_{2\alpha}$). Mares do not show systemic signs. The majority of pyometra cases are diagnosed during routine examination.

PATHOGENESIS

Many different bacteria have been isolated from mares with uterine disease, but *Streptococcus zooepidemicus* followed by *Escherichia coli, Pseudomonas aeruginosa,* and *Klebsiella pneumoniae* are the most frequently isolated pathogens.[8–10] *Corynebacterium* spp., *Proteus* spp., and *Staphylococcus* spp. are considered pathogenic when isolated from mares with cytologic evidence of uterine disease. *Gardnerella vaginalis,* an organism reported to cause vaginitis in humans, has been documented in mares[11,12]; however, biopsy samples indicated only mild endometritis, and the mares conceived and carried foals to term without antibiotic therapy, so the clinical significance is questionable.[12] *Taylorella equigenitalis* is a pathologic, microaerophilic, gram-negative organism transmitted venereally and is the cause of contagious equine metritis (CEM). *Bacteroides fragilis* is an anaerobic organism that has been associated with acute endometritis at foal heat and in barren mares.[13]

DIAGNOSIS

Diagnosis of uterine disease is based on history, physical examination, vaginal examination, uterine cytologic examination, uterine culture, and uterine biopsy. It is imperative that the practitioner use all available tests and not rely on only one. Diagnosis of infectious endometritis is based on documentation of inflammation in the uterine lumen and accurate proof of an infectious

organism.[14] Endometritis may escape detection with vaginal examination, transrectal uterine palpation, and uterine ultrasonography. In these cases, the uterus is not enlarged and there is only a small amount of accumulated fluid or exudate. Endometrial cytologic examination is the diagnostic test of choice because it provides direct evidence of the presence of neutrophils in the uterine lumen. Any significant number of neutrophils confirms active inflammation.[14] A uterine culture confirms the causative organism and the antibiotic sensitivity helps direct the treatment. The Accu-CulShure (ACCU-MED Corp., Pleasantville, NY) swab is an efficient tool for obtaining endometrial specimens. When culturing the endometrium, it is important to obtain a sample uncontaminated by the vestibule and vagina caudal to the urethral orifice because this area is usually heavily contaminated with normal flora. The Accu-CulShure swab is sealed inside the guard tube and resealed immediately following sample collection, so there is no contamination or exposure to air during entry or egress. When the instrument has been removed from the genital tract following specimen collection, the swab is slowly pulled into the self-contained transport medium. The protected swab can be snapped off at the score on the instrument, placed in a transport tube, and sent to a diagnostic laboratory. Metritis and pyometra are associated with uterine enlargement and fluid (purulent exudate) accumulation in the uterus. The fluid may extend to the cervical or vaginal area. Therefore, vaginoscopy, transrectal uterine palpation, and uterine ultrasonography clearly aid in diagnosis. A uterine culture identifies the causative organism, and a biopsy identifies the extent of the disease.

THERAPY

The goal of therapy is to remove or reduce the offending bacteria and enhance uterine defense mechanisms, thereby decreasing the inflammatory process within the uterus. This has been accomplished with intrauterine infusions of antibiotics, antiseptics, plasma, sugars, uterine lavage, and systemic antibiotic therapy. Therapy can be completed before or after breeding, depending on the severity of the infection. It is important to tailor the therapy to the individual case and to remember that no single treatment can be effective in all cases. With severe infections, multiple therapeutic approaches can be used to control the infection. This discussion attempts not to define a course of treatment but to illustrate successful and commonly used treatments. Every mare is an individual and the routine treatment of all mares with the same medication will not result in the best treatment.[15]

Intrauterine Therapy

A common form of therapy is intrauterine infusion of antibiotics, chemicals (antiseptics), plasma,[16] and sugars.[17,18] Medications are infused by gravity directly into the uterus, thus contacting the entire surface of the endometrium. Intrauterine infusion concentrates medication locally in the infected endometrium as opposed to systemic treatment, which relies on blood concentration of the drug.

For intrauterine antibiotic therapy, a drug should be selected on the basis of sensitivity tests. Broad-spectrum antibiotics might not be as effective as bactericidal antibiotics. Bacteriostatic drugs require assistance from the mare's defense system, which is likely compromised as indicated by the presence of infection.[16] Drug combinations should be avoided because incompatibility often renders the drugs ineffective. The same is true of drug and antiseptic combinations.[15] The antibiotics most commonly used for intrauterine therapy are penicillin, gentamicin, ampicillin, streptomycin, chloramphenicol, nitrofurazone, polymyxin B, neomycin, the sulfonamides, and amikacin.[15,19] Gentamicin, amikacin, ampicillin, and chloramphenicol are the most effective against the majority of pathogenic organisms. Penicillin is thought to be one of the most effective antibiotics available for treating equine uterine infections.[15]

Antibiotics infused into the uterus are dissolved or suspended in sterile water or saline solution and infused directly into the uterus daily for 3 to 5 days or more during estrus.[20] Antibiotic treatment after service is advised for mares with impaired uterine resistance that cannot cope with microorganisms introduced at breeding. Antibiotics can be instilled into the uterus up to 3 days after ovulation, but treatment may be wasted if the mares require a second breeding.[21] The size of the uterus, determined by transrectal palpation, should be used to determine the volume infused. The uterine capacity of maiden mares is approximately 35 ml, and that of older mares may be between 60 and 150 ml.[16] Traditionally, the antibiotic is suspended in large volumes of fluid (100–500 ml) on the assumption that this volume is optimal for filling the uterus and coating the endometrial surface; however, the effects of such dilution on antibiotic efficacy are unknown. Present evidence suggests that most of the antibiotic introduced in this manner is expelled through the cervix soon after treatment.[16,20,21] Intrauterine antibiotic therapy is not without risk. Indiscriminate use of antibiotics may alter the normal uterine flora and result in development of resistant strains of bacteria, yeasts, and fungi.[5,15] Some mares are sensitive to particular antibiotics.[20] Caution must be used to ensure that therapy does not pose a greater threat than infection. The use of products not approved for intrauterine infusion can cause harmful effects in mares.[15]

Uterine Lavage

For uterine lavage, large volumes of saline solution or sterile water are infused into the uterus and then allowed to drain. The rationale for this therapy is enhancement of cellular and mechanical aspects of uterine defense mechanisms.[2] The therapeutic effects of lavage are mechanical removal of bacteria and debris from the uterus; stimulation of uterine contractions, thus aiding expulsion of foreign material; and mild endometrial irritation resulting in migration of neutrophils and perhaps serum-derived opsonins to the uterine lumen.[4,20] Uterine lavage has also been reported to stimulate blood flow, improve tone, and decrease uterine size.[6] When the fluid

is heated to 40° to 50° C, lavage has proved beneficial in increasing myometrial tone and uterine circulation in older, multiparous mares with thick-walled or pendulous uteri.[2,6,20,22] Lavage solutions are infused into the uterus in 1-L increments either by gravity or mechanically and then siphoned into a clear, graduated container.[20] Inspection of the recovered fluid provides immediate information concerning uterine health or the success of uterine treatments. The degree of cellularity and concentration of other inflammatory components correlates well with the appearance of the recovered fluid.[2]

Antiseptics

Antiseptics used historically for treatment of uterine disease included acriflavine, bismuth subnitrate, boric acid, charcoal, chlorine, iodine and iodine solutions, iodoform, perboric acid, silver oxide, hot saline and hypertonic saline, sodium hypochlorite, gentian violet, and hydrogen peroxide. Weak solutions of hydrogen peroxide have been used as treatment for acute endometritis and also appear helpful when exudate has been found in the uterine lumen.[16] After phagocytosis by neutrophils, bacteria are destroyed in part by oxidative metabolism, which includes hydrogen peroxide.[22] Lugol's solution (10%) has been reported to be successful for chemical curettage of the endometrium.[6,23]

Care should be taken when infusing antiseptics not to inflict further damage with harsh or concentrated chemicals. A mare's uterus is sensitive to irritating substances.[6,18] Chlorhexidine suspension should be avoided or used cautiously because it causes tissue necrosis.[6,16,24] Oxytetracycline powder can also induce severe tissue necrosis. The endometrium recovers well from some irritants, but repeated use may leave a fibrotic endometrium and possibly adhesions.[24]

Systemic Antibiotics

Antibiotics for treatment of uterine infections can be administered systemically. Opinions are divided on the success of systemic administration compared to intrauterine therapy. The majority appear to favor intrauterine infusion, especially for treatment of endometritis. Infused antibiotics are believed to be more effective because of direct contact of drugs with the infected endometrium. Systemic therapy has its supporters, and there are reports of success in treating endometritis systemically.[8,15,23] However, objective comparison between systemic and local antibiotic therapy is difficult without controlled trials.[8] The main question to be addressed when considering antibiotic therapy is which tissues are involved. If the infection includes deeper layers of the uterus or other genital organs, then systemic therapy might be indicated. Some researchers believe that systemic administration results in higher antibiotic concentrations in infected tissues. Metritis, pyometra, and perimetritis may warrant systemic treatment.[15,16,23]

Systemic antibiotic therapy does have advantages. It can be conducted without invading the reproductive tract and treatment can be continued into the diestrous phase of the cycle, whereas postbreeding intrauterine therapy must stop before the embryo enters the uterus. Systemic therapy also enjoys an ease of application.[20,25] A disadvantage is the cost. Systemic therapy requires a higher dose to achieve effective blood concentrations.[20,24] Based on satisfactory results reported by practitioners, antibiotics suitable for systemic treatment include amikacin sulfate, ampicillin, gentamicin, procaine penicillin, and trimethoprim sulfa.[20]

Plasma Therapy

Plasma or colostrum augmentation of a mare's natural defense mechanism is another avenue of uterine disease treatment. Plasma therapy is often indicated when no causative agent is identified, when sensitivity tests indicate impractical drugs, or when previous therapy has been unsatisfactory.[20] The goal of plasma therapy is to enhance the local uterine immune response and natural defense mechanism. Failure or incompetence of these responses probably accounts for mares that are unable to cope with contaminating organisms.[6] These natural mechanisms are defined as cellular (phagocytes) and noncellular (opsonins, thermal stabile factors, and the leukocytic tide).[6] The uterus of resistant mares contains opsonins, which function to allow efficient phagocytosis of contaminating bacteria by neutrophils. It is believed that susceptible mares are deficient in opsonins, which allows bacteria to become established.[8] Plasma is the major source of proteins involved in opsonization of bacteria in the uterus.[20] It has been suggested that a practical method to overcome ineffective uterine defense mechanisms is to infuse plasma or colostrum, substances that contain antibodies, into the uterine lumen.[6]

Studies have utilized both homologous and heterologous plasma. The use of heterologous plasma would be convenient, but the possibility of uterine sensitization to foreign protein cannot be ruled out.[22] Antibiotic and plasma therapy can be used in concert, but some antibiotics are more compatible with phagocytic processes than others. Studies have found that in concentrations commonly used for intrauterine infusion, amikacin sulfate and gentamicin sulfate inhibit neutrophil phagocytosis, and potassium penicillin and ticarcillin do not.[14,22] More work is needed in this area.

Intrauterine Sugar Solutions

Because of an emergence of bacteria becoming resistant to multiple antibiotics, it. will be imperative to seek alternatives to antibiotic therapy in the future. Monosaccharide sugars have been shown to be effective in inhibiting bacteria that commonly infect the genitourinary tract of mares. One of the benefits of sugars is that they can be used alone or with antibiotics to treat uterine infections in mares. Specific sugars can inhibit bacterial adherence to the equine endometrium in vitro. Mannose and *N*-acetyl-D-galactosamine inhibited adhesion of *Escherichia coli* and *Pseudomonas aeruginosa* to epithelial cells, whereas only mannose inhibited adhesion of *Streptococcus zooepidemicus*. In horses with uterine infections, use of sugars to competitively displace bacteria from attach-

ment sites on cells may provide an adjunct to antibiotic treatment.[17]

Bacterial adherence to cell surfaces and phagocytosis of bacteria have become important in relation to pathogenicity of various strains of bacteria that are common causes of uterine infections, including *Escherichia coli, Pseudomonas aeruginosa, Streptococcus zooepidemicus, Salmonella* spp., and other bacteria. The adherence of bacteria is inhibited by sugars such as L-fructose and D-galactose, which suggest that sugar-mediated adherence is widespread. The intercellular recognition is thought to be mediated by sugar residues such as D-mannose on the surface of cells to which bacteria attach by sugar-binding substance of their surface. The nature of the receptors is unknown, but there is evidence that bacteria such as *E. coli* produce lectin-like substances specific for D-mannose, by which it binds to the cells.[18]

Management and Prevention

Prevention of uterine disease necessarily precedes any consideration of uterine disease treatment. The importance of a sound prevention and management program cannot be overstated. This is crucial even for mares with normal uterine defense responses because continual contamination debilitates the uterus. Older, multiparous mares and postpartum mares recovering from foaling difficulties have ineffective or compromised uterine defense responses. These mares are particularly susceptible to infection. A sound prevention program begins with sanitary breeding, foaling, and examination procedures. Care must be taken to minimize contamination. Mares prone to infection from organisms introduced at breeding should be bred near the time of ovulation to reduce unnecessary breedings.[15,19,20] These mares often warrant postbreeding uterine treatment. Surgical correction of anatomic defects also precedes uterine therapy, because abnormal conformation permits bacterial contamination. A Caslick operation corrects poor vulvar conformation that results in pneumovagina.[15,16,19,22] Third-degree perineal lacerations, rectovaginal fistulae, cervical lacerations, and urine pooling can be corrected with surgery, thus improving fertility.[15,16,20,21]

CONTAGIOUS EQUINE METRITIS

Taylorella equigenitalis is the causative organism of contagious equine metritis (CEM). *T. equigenitalis* is a gram-negative coccobacillus that is transmitted venereally and is highly contagious in equines. CEM was first documented almost 30 years ago in Newmarket, England. CEM has now been reported in horses worldwide.

History

In July 1977, CEM was reported on 28 breeding farms in the Newmarket area, with approximately 200 Thoroughbred mares and 23 stallions affected.[26] By the conclusion of the 1978 breeding season, CEM was diagnosed in numerous countries, including the United States[29] and Australia.[27] *T. equigenitalis* has now been isolated in 14 countries, infecting both Thoroughbreds and non-Thoroughbreds.[28]

In 1978, two strains of the organism were isolated from Kentucky Thoroughbreds.[29] One strain was sensitive to streptomycin and the other was resistant. In 1979, Missouri reported an outbreak of CEM in non-Thoroughbreds involving the streptomycin-sensitive strain. Mares diagnosed with CEM reportedly exhibit shortened diestrous periods and copious mucopurulent vulvar discharges lasting up to 14 days. Stallions covering infected mares were asymptomatic. Numerous cultures were taken without isolating *T. equigenitalis* until fresh cultures were placed in transport medium and grown on chocolate blood agar incubated at 37°C in 5% to 10% carbon dioxide for 48 hours.[30] *T. equigenitalis* was found to be sensitive to a wide range of antibiotics and antiseptics, including benzyl penicillin, ampicillin, and chlorhexidine, but resistant to streptomycin.[27]

A code of practice was issued in 1977 to control the spread of CEM. The code was published in the United Kingdom and similar measures were taken in Ireland and France. The code stipulated a mare as high risk if she cultured positive for CEM, was covered by an infected stallion, or if she arrived from outside the United Kingdom. The code mandated that high-risk mares should have a negative clitoral culture before and after arrival at stud and a negative endometrial and clitoral culture during estrus prior to breeding. Low-risk mares were required to have a negative clitoral swab taken before or after arrival at stud providing there was agreement with the stud farm manager.[31] The code further stipulated that stallions should be cultured from pre-ejaculatory fluid, the penile sheath, the urethra, and the urethral fossa, and that all cultures should be sent to designated laboratories and incubated under microaerophilic and aerobic conditions. As a result of this code of practice, the incidence of CEM has decreased. [32] However, recently three bacterial isolates of *Taylorella asinigenitalis* sp. *nov.* were isolated from the urethral fossa from one male donkey in California and from two male donkeys in Kentucky; these isolates were identical to each other, but different from *Taylorella equigenitalis*. The isolates were phenotypically indistinguishable from *Taylorella equigenitalis,* but sequence analysis of DNA encoding the 16S rRNA revealed that the gene sequences of these isolates were virtually identical to each other (>99.8% similarity), but different (97.6% similarity) from those of several confirmed isolates of *T. equigenitalis*. Based on these findings, a new different species named *Taylorella asinigenitalis* sp. *nov.* was proposed.

Mares bred to infected donkeys did not show clinical signs of disease, even though infection with the organism was established in those bred naturally, but did produce antibodies that reacted in the complement fixation test utilized to identify mares recently infected with *T. equigenitalis*.[33]

Etiology

In 1978, the initial bacteriologic examination of swabs from the genitourinary tracts of infected animals revealed the CEM organism to be *Haemophilus equigenitalis* strain

NCTC1/184 (61717/77). The organism was renamed *Taylorella equigenitalis* in 1984.[34]

Samples from animals suspected of CEM are shipped to the laboratory in Amies transport medium supplemented with charcoal. Upon arrival, specimens are transferred to chocolate blood agar, which is incubated in 5% to 10% carbon dioxide at 37°C. Pinpoint-sized, grayish colonies with a smooth outline appear by 48 hours. After 72 hours, the colonies can reach 1 to 2 mm in diameter and appear raised and shiny.

Transmission

Spread of CEM is primarily by venereal contact. Contaminated equipment, instruments, and personnel that contact the genital tracts of mares and stallions contribute to the spread of the disease. A carrier state exists because *T. equigenitalis* persists indefinitely in the clitoral sinus of mares and urethral fossa of stallions. *T. equigenitalis* has been isolated from foals born to infected mares.[35] *T. equigenitalis* has been isolated also from an aborted fetus and placenta, but a repeated culture of the dam did not reveal the organism.[36]

Diagnosis

Diagnosis of CEM is confirmed by isolation of *T. equigenitalis* from the appropriate sites in the mare and stallion. It is imperative that samples be placed immediately in transport medium and shipped to a laboratory that is familiar with culture techniques for CEM.

Cultures should be taken during early estrus from the endometrium or cervix. Cultures from the clitoral fossa and the three clitoral sinuses should be submitted. The clitoral sinuses are small and can be visualized when the clitoris is partially extruded and held downward. A small swab moistened with sterile saline can be used to sample the sinuses. Clitoral cultures can be obtained at any time during the estrous cycle and from pregnant mares. A stallion's penis must be extended and samples taken from the urethral fossa, urethra, preputial folds, skin of the penis, and pre-ejaculatory fluid.[28] Three negative cultures should be taken before the stallion is considered free of the disease.

Recent molecular advances utilizing the polymerase chain reaction (PCR) amplification and nucleotide sequencing of the 16S ribosomal DNA sequence have been confirmed to be effective for identification of *T. equigenitalis*. These new analytical methods at the genomic DNA level also enabled the discrimination of the newly discovered donkey-related *T. asinigenitalis* from *T. equigenitalis*.[37] A culture-LightCycler PCR assay has been developed for the detection of *T. equigenitalis,* the causative agent of CEM in horses. The culture-LightCycler PCR assay is specific, sensitive, and reproducible, and can be used effectively for the detection of *T. equigenitalis* infections and can also detect *T. asinigenitalis* isolates.[38]

Serology

Numerous serologic tests have been developed to detect antibodies to CEM in serum. The enzyme-linked immunosorbent assay (ELISA) and passive hemagglutination tests are superior for detection of infected mares.[28] Antibodies can be detected within 40 days of infection. The tests are useful in identifying mares with active infections. Carrier mares and infected stallions have no humoral response and serologic tests are of little value as screening tests.

Control

The code of practice instituted in 1977 for the control of CEM has dramatically reduced the incidence of the disease. Sporadic outbreaks have occurred that can be traced to carrier animals.[28] Carriers are considered high-risk animals and are treated and followed with extensive bacteriologic cultures until they are found to be negative. Continued vigilance against inapparent carrier animals has prompted countries, including the United States, to institute strict import regulations. Mares and stallions imported from countries not declared free of CEM must undergo quarantine and extensive testing at a designated quarantine station.[39]

Treatment

Intrauterine infusion of antibiotics combined with thorough cleansing of the clitoris, clitoral fossa, and clitoral sinuses is the treatment of choice in mares. Daily intrauterine infusions for 5 to 7 days with penicillin (5 to 10 million U), ampicillin, neomycin, and nitrofurazone have been reported to be successful.[28] The clitoral body, the fossa, and the sinuses must be thoroughly scrubbed daily for 5 days with 4% chlorhexidine solution and packed with nitrofurazone or chlorhexidine ointment. Clitoral sinusectomy might be recommended in mares that continue to harbor CEM in the clitoral area following treatment. In stallions, the penis should be extended and then both the penis and prepuce thoroughly washed in a 4% chlorhexidine solution. The fossa glandis, urethral fossa, and prepuce are packed with nitrofurazone, penicillin, or chlorhexidine ointment. This should be repeated daily for 5 days. This treatment has been found to be highly successful.

BACTERIAL ABORTIONS

The rate of abortion in mares is between 5% and 15%. Abortions that occur early in gestation, between conception and 90 days, often go undetected and are frequently confused with infertility. The incidence of abortion between 20 and 90 days ranges from 7% to 30%.[40–43] Most observed abortions occur after the fourth and fifth months of gestation. The incidence of abortions after this period is approximately 2% to 12% of all pregnancies.[44] The causal agents involved in equine abortions at all stages of gestation have been divided into infectious, noninfectious, and unknown.[45,46] Infectious causes can account for as many as 47.5% to as few as 16.2% of abortions.[40] Bacteria are the major cause of abortions in mares.

Bacterial Causes of Abortions

Bacteria can cause abortion at any stage of gestation.[42,47] Bacteria associated with equine abortion are: *Streptococcus zooepidemicus; Streptococcus equisimilis* and other streptococci; *Escherichia coli; Pseudomonas aeruginosa; Staphylococcus aureus* and other staphylococci; *Klebsiella pneumoniae* var *genitalium; Leptospira* spp.; nocardioform actinomycetes; and *Salmonella abortus equi*.[43–46,48] The highest incidence of bacterial abortions occurs between the fifth and tenth months of gestation. Bacteria have been implicated in early abortions, but this theory is based on the isolation of organisms from uterine cultures following abortion.[49] Bacteria cannot be implicated merely by their presence; there must be evidence of autolysis and inflammatory changes determined by examination of fetal tissue and the placenta.[43] Organisms enter the fetoplacental unit through the maternal circulation as a result of systemic infection; by ascent through the cervix and infection of the placenta and fetus[44,47]; or possibly, although there is no conclusive evidence, from deep-seated endometritis.[50] The majority of clinicians and researchers agree that the cervix is the most common route.[40,44,47,50]

Streptococcus zooepidemicus is a common cause of abortion at any gestational stage. *S. zooepidemicus* is found on the external genitalia of mares and stallions and is the most common organism associated with vaginitis, cervicitis, and metritis. *S. zooepidemicus* usually ascends through the cervix and causes placentitis.[44] Streptococcal placentitis is a frequent cause of fetal abortion. Gestation continues until the infection compromises the placenta and the pregnancy can no longer be maintained. Abortion occurs after fetal distress or death. The infection can also spread to the fetus and cause septicemia, death, and abortion.[44,50] Streptococcal infections occur most frequently on poorly managed farms that utilize unsanitary breeding, foaling, and examination procedures; excessive breeding of older mares; and frequent services at foal heat.[44] *E. coli, P. aeruginosa, S. aureus,* and *K. pneumoniae* can also ascend through the cervix owing to pneumovagina and result in placentitis associated with progressive placental insufficiency and abortion.[50] Nocardioform actinomycetes are gram-positive, non–acid fast, filamentous branching bacteria.[48] The bacteria do not belong to any of the four recognized species of *Nocardia*. Recent studies have further classified one of these nocardioform actinomycetes, which appears to cause the majority of cases of nocardioform placentitis, as *Crossiella equi,*[51] and similar actinomycete strains have also been further classified.[52] These bacteria cause characteristic placentitis that results in late-term abortions, stillbirths, and premature birth of near-term foals.[48] The characteristic lesions are distributed at the base of the gravid and nongravid horns or at the junction between the body and horn of the placenta. The affected areas are thickened, and the chorionic surface is covered with brown, sticky, mudlike material and dotted with white granular structures. The exposed chorionic surface is red and white, mottled, and roughened. These nocardioform actinomycetes induce extensive chronic placentitis, which grossly mimics mycotic placentitis.[48,53] Mares that abort a fetus with these nocardioform organisms seem to clear of infection fairly rapidly without therapy.

The prevention of bacterial abortions caused by agents ascending through the cervix begins with sanitary breeding and examination procedures, pre- and postbreeding uterine therapy when necessary, and careful management of problem mares (Caslick's procedure).

Salmonella abortus equi was infamous during the late 1800s as the cause of contagious equine abortions, but except for two small isolated outbreaks, *Salmonella* abortions have not been reported in the United States since 1932.[44] The organism is transmitted by ingestion of feed and water contaminated by feces or genital discharges.

Leptospira spp. have also been identified with increasing frequency as a cause of abortion, stillbirth, and premature live birth.[54] Abortion results from fetal infection. The highest incidence of leptospiral abortion occurs during the seventh through eleventh months.[40,48,54] The serotypes commonly associated with equine abortions are *pomona, grippotyphosa,* and *bratislava*.[54–56] *Leptospira* infect the fetus hematogenously, usually after a mild 1- to 3-week maternal illness. Clinical signs include elevated body temperature, anorexia, jaundice, and slight depression.[44,56,57] *Leptospira* have zoonotic potential and are spread by accidental infection. Flu-like symptoms, meningitis, and hepatorenal failure have been reported in infected humans.[56]

Most horses have antibodies against a wide range of serotypes with *pomona, grippotyphosa,* and *bratislava* being the most common. In the horse, serotype *bratislava* is considered to be host-adapted, and *pomona* and *grippotyphosa* are non–host-adapted.[56] Horses infected with a host-adapted serotype can serve as reservoir hosts (persistent shedding in urine), whereas a non–host-adaptive serotype is transmitted as an accidental or incidental disease. Host factors, not the organism itself, determine how long the serotype can be maintained.[56] Mild clinical signs are associated with host-adapted serotypes, and more severe signs are associated with non–host-adapted serotypes. Most abortions are the result of non–host-adapted serotypes *(pomona)* in mares.[56] Clinical signs are rarely observed but include pyrexia, icterus, anorexia, and depression.[58] Abortions occur 1 to 3 weeks after the clinical signs. Abortions occur at any time but most often after the sixth month of gestation. A high percentage of abortions occur in November and December, an observation that has been attributed to wet climatic conditions, horse management conditions, contamination from feral animals, or a combination of these factors.[59] An aborted fetus can display no gross lesions, but it may have a swollen yellow liver, perirenal edema, or white radiating streaks in the kidney, pneumonia, and placentitis. The placenta can have gross lesions, which include slimy exudate, cystic allantoic glands, and a thickened allantochorion. Histologically, the placental lesions consist of focal necrosis of villi, mild perivasculitis, cystic allantoic glands, and infiltration of neutrophils and mononuclear cells in the stroma and villi. Spirochetes can be confirmed by Warthin-Starry stain from the kidney or placenta.[55]

Leptospiral antibodies can be detected in the aborted fetus and in maternal blood. Fetal antibodies are detected

in body fluids or blood or both. Titers range from 1:50 to greater than 1:638,400. Affected mares have antibody titers greater than or equal to those found in the fetus (1:200 to 1:3,276,800).[55] A second voided urine sample (following intravenous administration of furosemide) collected from mares with a two- to fourfold increase in antibody titer should be examined by culture and fluorescent antibody tests to demonstrate leptospires.[60]

Transmission is thought to occur by contact with sources of environmental infection. Animals should be fenced away from low-lying or swampy areas, stagnant water, and runoff water from other animals (cattle, pigs, dogs, or wildlife).[55] Horses can shed the organism for up to 3 months (2 to 3 weeks is normal) and should be isolated (D. Williams, personal communication, 1994).[56] Control of the disease consists of isolation of shedder animals and urine testing until three negative fluorescent antibody tests are completed (D. Williams, personal communication, 1994). A *Leptospira* vaccine approved for use in mares does not exist. Vaccination of horses with cattle vaccine produces extremely high titers (>1:50,000), but these vaccines are not currently approved and do not contain all the appropriate serotypes.[56,60] Vaccines may also pose a threat of anaphylactic reactions in horses.[60] Mares shedding the organism can be treated with procaine penicillin G (20,000 IU/kg IM twice a day) or oxytetracycline (5 mg/kg, IV twice a day) to decrease the shedding period.[58] One trial found that antibiotics administered for 5 days did not eliminate shedding of *Leptospira* in the urine. Administration of antibiotics for longer periods of time may be effective. Antibiotics are thought to be useful in preventing fetal infections in mares with high titers during late pregnancy, thus facilitating the delivery of healthy foals.[56] Leptospiral abortions occur during the wet months and usually affect only one or two mares in a herd. It is important to prevent contamination by isolating infected animals and instituting strict sanitation measures. Contact with infected urine, aborted fetuses, or contaminated feed and water must be eliminated. Stalls, water buckets, and feed troughs should be thoroughly disinfected.

CHAPTER 22
Equine Herpesvirus Infections

T. W. SWERCZEK and STANLEY M. DENNIS

Herpesviral infection is most commonly a mild disease of the upper respiratory tract of young and adult horses caused by three related herpesviruses that are widespread throughout the world. Equine herpesvirus 1 (EHV-1) is most commonly diagnosed as a cause of abortion during late pregnancy.

ETIOLOGY

Equine herpesviruses are classified as EHV-1 to EHV-5.[1–3]

1. EHV-1 is the most important cause of abortion as well as the cause of respiratory disease, neonatal death, and neurologic disease in the mare.
2. EHV-2 (equine cytomegalovirus) causes mild long-term respiratory infection in foals.[4]
3. EHV-3 causes coital exanthema.
4. EHV-4 causes respiratory disease throughout the year, and sporadic abortion (rhinopneumonitis).
5. EHV-5 has unknown pathogenicity.[5]

EPIDEMIOLOGY

Since the first report of equine herpesviral abortion in 1932,[6] EHV-1 and EHV-4 have been widespread in the United States, Canada, Japan, Australia, and Europe. Although horses of all ages are infected, signs of upper respiratory disease are usually observed in young horses. The viruses are highly infectious, and infection originates directly or indirectly from other horses. Transmission occurs by inhalation of infected droplets or by ingestion of food or water contaminated by nasal discharges or aborted fetuses. EHV-1 can survive for 14 to 42 days outside horses.[7] Up to 80% of horses in the United States have serologic evidence of exposure to EHV-1 infection. Cattle and donkeys have been reported to be possible reservoirs of the virus, and infection by EHV-1 has been reported in llamas, alpacas, deer, antelope, and gazelle.[8]

Carriers are necessary for EHV-1 to persist from year to year. Being a typical herpesvirus, infection may persist in a latent state and be reactivated subsequently by various stressors, for example, corticosteroids.[9] As immunity to EHV-1 infection is short and transient, horses may be clinically infected a number of times. Cell-mediated immunity is important in the resistance to herpesviruses.

The EHV-1 causes inflammation of the respiratory tract characterized by coughing and nasal discharge. The initial viral infection is most severe, secondary viral infections are less severe, and subsequent infections tend to produce few or no clinical signs. Fatalities in uncomplicated cases are unlikely.

Most outbreaks of abortion are associated with outbreaks of respiratory disease in foals and yearlings several weeks earlier, commonly in the fall and winter. Separation of weanlings and yearlings from pregnant mares is important in the control of EHV-1 abortion. "Storms" of abortions may occur in bands of broodmares, with up to 90% at risk of either aborting or losing their foals during the first day of life. Most herpesviral abortions occur sporadically in a herd, with maiden mares most often affected. Multiple abortions may occur in closed herds or in open herds with additions or transients from other farms or racetracks.[10] Multiple abortions are most common on farms where pregnant mares are crowded and where there are additions during the final months of the foaling season. Such conditions produce stress and favor epidemic spread of EHV-1 virus. The prevalence of abortion is higher in mares transported during late pregnancy and in those that have gone through sales. Multiple abortions in all age groups usually indicate a lack of immunity in a closed herd that was recently exposed to the EHV-1 virus by a new addition. Abortion is rare in mares kept in a group with no new mares added after the first trimester of pregnancy.[10]

As the majority of breeding mares are clinically immune to the respiratory but not to the abortigenic infection, spread of EHV-1 infection occurs commonly in a herd without obvious clinical signs. Although pregnant mares abort 60 days or more after intranasal exposure, most abort within 30 days. Spread of infection within a group of pregnant mares exposed to a mare that aborted from EHV-1 infection depends on the status of their immunity to respiratory tract infection. The most dangerous source of infection to pregnant mares is an infected aborted fetus. Aborting mares do not shed virus from either the respiratory or reproductive tract at the time of abortion.[10]

Neurologic signs associated with abortion were observed in the 1940s, but isolation of EHV-1 from nervous tissue was not recorded until 1966. It has been reported with increasing frequency since.[7]

PATHOGENESIS

Infection with EHV-1 is responsible for at least four distinct syndromes in horses: respiratory, abortigenic, neonatal death, and neurologic.[2,7,10,11] EHV-1 is highly contagious, and transmission is by inhalation of infectious aerosols or by direct contact with infectious secretions or contaminated drinking water.[6,11] EHV-1 replicates in the epithelial cells of the nasal, pharyngeal, and tonsillar mucosae and then spreads to the regional lymph

nodes. That stage is followed by leukocyte-associated viremia and infection of vascular endothelium in a number of organs.[6,11,12] From that point, invasion of lungs, endometrium, chorioallantois, fetus, and nervous tissue may occur.[11–15] It is surmised that EHV is acquired as a respiratory disease leading to latency and that abortion occurs as an unpredictable sequela to reactivation in a carrier mare.[16]

Spread of EHV-1 occurs transplacentally to fetuses by infected leukocytes, and abortion occurs within 120 days, with the majority occurring in 7 to 20 days.[6,11,15] The longer period may result from persistence of EHV-1 in leukocytes in the endometrium or chorioallantois before it invades the fetus and causes death and abortion. The virus damages the endometrium and the chorioallantois. Local edema occurs at the fetomaternal junction, leading to separation of the chorioallantois from the endometrium and the fetus dies from anoxia; near-term fetuses may be expelled alive but are nonviable. The fetus is usually infected and lesions include massive lymphocytic destruction in the thymus and spleen. Experimental studies have revealed that extensive damage to the endometrium from widespread vasculitis, thrombosis, and ischemia, with replication of EHV-1 in endothelial cells, may occur without evidence of infection in aborted fetuses.[15] EHV-1 has been isolated from fetuses aborted by mares with high levels of serum-neutralizing antibodies to EHV-1.[17]

Abortions usually occur between 7 months of gestation and term, with no maternal illness evident at that time.[10] Respiratory disease before abortion may not be observed in mares, as EHV-1 infection may have been mild, subclinical, or latent; latent disease may have been reactivated by stress-induced immunosuppression.[6,9,11,16–18]

Prenatal infection with EHV-1 without concurrent abortion or respiratory disease has been reported from Australia and resulted in stillbirths or weak, nonviable foals that died within a few hours to 24 hours of birth, and foals apparently normal at birth that developed severe respiratory distress within 18 to 24 hours and died within 24 to 72 hours.[19–21] A different prenatal EHV-1 infection resulting in neonatal death in older foals was reported from Kentucky and was characterized by respiratory disease, diarrhea, and weakness during the first weeks of life.[22] The foals were normal at birth, were agammaglobulinemic, and survived for a few weeks before succumbing to a variety of secondary bacterial and viral infections.

The pathogenesis of the neurologic form of EHV-1 infection is complex and uncertain. The relationship to reinfection and the microscopic changes in the central nervous system suggest an immune-mediated vasculitis typical of a type III hypersensitivity reaction.[11,13,14] Infection is considered to spread to the central nervous system (CNS) through EHV-1-infected leukocytes. Outbreaks of EHV-1 myeloencephalitis appear to be caused by certain strains of EHV-1.[13,16] Originally thought to be confined to pregnant mares, the EHV-1 paralytic syndrome has been observed in barren mares, stallions, geldings, and foals.[23–25] Experimentally, only pregnant mares in early or midpregnancy, not the last trimester, could be infected.[11,13,14,25] The outcome of EHV-1 infection of the spinal cord and brain varied from recovery to permanent locomotor impairment or death.

CLINICAL FINDINGS

Respiratory Disease

Severity of EHV-1 respiratory disease is age-related, with acute upper respiratory tract infection occurring mainly in foals, weanlings, and yearlings. After an incubation period of 2 to 20 days, signs include fever (39° to 40.5°C), conjunctivitis, leukopenia (largely neutropenic[26]), serous to mucopurulent nasal discharge, and cough. The lymph nodes of the throat may be slightly enlarged. The course of illness is usually 2 to 5 days, but the nasal discharge and cough may persist for 1 to 3 weeks.[6,7,11,18,26] Inapparent EHV-1 infections are common. Infection in older horses previously infected is mild to subclinical with few or no clinical signs. Secondary bacterial infection may result in pneumonia. Young horses may develop viral pneumonia.

Abortion

Prevalence of EHV-1 abortion in a group of mares varies from 1% to 90%, depending on management, degree of immunity, virulence of the virus, various stress factors, and number of exposed susceptible mares in advanced pregnancy. Although abortion storms may occur, most herpesviral abortions today tend to be sporadic. Abortions occur over a period of 2 weeks to 3 months, with the majority occurring within 60 days. Mares may abort up to 4 months after respiratory infection, which may be mild and unobserved. The incubation period following natural infection is usually 15 to 30 days. The incidence of abortion is highest in the last trimester, particularly at 8 to 10 months, but may occur as early as 5 months.

Mares usually abort suddenly without any premonitory signs, and the aborted fetus is normally fresh and usually attached to the fetal membranes. Some infected foals are born dead at term, and others may be liveborn and nonviable.[6,10–12,17] Aborting mares recover rapidly and their fertility is not compromised.[27]

Neonatal Mortality

Some infected foals are apparently normal at birth but become weak and depressed and die within 3 days with severe respiratory distress.[19,20] Other infected foals may survive for a few weeks before succumbing to a variety of secondary bacterial or viral infections.[22] They may have respiratory distress, diarrhea, and weakness during that period.

Neurologic Disease

Although EHV-1 myeloencephalitis is usually associated with respiratory disease and abortion,[23,26] it has been reported separately.[7] Outbreaks may involve up to 90% of mares, foals, stallions, and geldings on a breeding

farm.[23,25] Neurologic disease is more common in horses being reinfected with EHV-1. Modified live-vaccine virus may be involved, as nervous signs often occur soon after vaccination or natural or experimental infection.[18] The incubation period for both natural and experimental infection is about 7 days.[14,23,24]

Clinical signs vary from slight ataxia with recovery to severe ataxia followed by paresis that may last for weeks and is followed by recumbency leading to death or euthanasia. Recumbent horses are usually euthanatized within a month. Some horses die acutely after an illness of only 2 days. Urinary incontinence may also occur.[14,23–25]

LESIONS

Abortion

Fetal lesions in EHV-1 abortion vary greatly and depend on the stage of gestation. Before 6 months' gestation, the fetuses are autolytic with diffuse scattering of intranuclear inclusions without local inflammatory response. Later fetuses are usually aborted fresh with their fetal membranes. Fetuses affected at 7 to 10 months of gestation have widespread lesions in liver, lungs, thymus, adrenals, and lymph nodes, and toward term, the lesions are more severe in the lungs.[6,10] In general, the gross fetal lesions include mild icterus, subcutaneous edema, scattered petechiae, hydrothorax and hydroperitoneum, pulmonary edema, heavy and firm lungs, numerous, small, grayish white necrotic foci (1 to 2 mm) in the liver, and focal areas of necrosis in thymus, adrenals, spleen, and lymph nodes. Rarely are all these gross lesions found in the same fetus; the most consistent are pulmonary edema and hydrothorax and hepatic necrotic foci. Microscopically, the lesions are characteristic and diagnostic: viral eosinophilic intranuclear inclusions in necrotic foci in the liver and also in lung, thymus, adrenals, and lymph nodes. Necrosis of lymphocytes occurs in the thymus, the spleen, and the lymph nodes.[6,10,12] There is bronchiolitis and focal pneumonitis in aborted fetuses, and a diffuse pneumonitis in term foals.[10] These lesions do not resemble those found in any other cause of equine abortion.

Neonatal Mortality

Gross lesions in neonates dying within 3 days of birth include voluminous, firm lungs, often "plum purple" with massive atelectasis, submucosal hemorrhagic striations in the trachea and bronchi, and bronchial lymph nodes that are often enlarged, congested, and edematous. Microscopic changes include extensive nonsuppurative alveolitis, mild to severe acute focal necrotizing bronchitis, and bronchiolitis with eosinophilic intranuclear inclusions. Inclusions are frequently observed in the thymus but rarely in the liver. Focal adrenocortical necrosis and depletion or degeneration of thymic and splenic lymphocytes were observed in fewer than 50% of the affected foals.[21]

Neonates surviving for 2 weeks before succumbing had destructive lesions in splenic lymphocytes and massive necrosis of the thymus.[22] EHV-1 intranuclear inclusions were not observed.

Neurologic Disease

Neurologic effects include acute disseminated myeloencephalitis with widespread vasculitis of small blood vessels in the spinal cord and brain and thrombosis that results in hypoxic degeneration and hemorrhage in adjacent tissues and foci of malacia. Microscopic lesions are prominent in both natural and experimental EHV-1 myeloencephalitis.[13,14,25] Vascular changes are generally more prominent in the spinal cord than in the brain, and spinal cord lesions are more prominent in the white matter than in the gray matter.[14] Hemorrhages in the spinal cord and brain are associated with disseminated vasculitis as evidenced by extensive endothelial immunofluorescence and thrombosis within 4 days following experimental infection.[13]

Respiratory Disease

Equine herpesviral respiratory disease is rarely fatal and deaths result from secondary bacterial infections, especially streptococcal. Young horses may develop bronchopneumonia. The main lesion is rhinitis with extensive necrosis of the epithelial cells.[7,12]

DIAGNOSIS

Signs of upper respiratory tract infection in young and adult horses and late abortion with characteristic lesions in aborted fetuses are highly suggestive of EHV-1 infection.[6,10,11,16] Diagnosis can be confirmed by serology, virus isolation, and histopathology. Bacteriologic examination should be negative. Equine herpesviral infection must be differentiated from equine viral arteritis, equine influenza, and strangles. All equine abortions should be considered to be caused by EHV-1 until proved otherwise.

Serologic tests for detecting EHV-1 and EHV-4 include immunofluorescence, serum virus neutralization, enzyme-linked immunosorbent assay, polymerase chain reaction, and indirect immunoperoxidase.[28,29] Respiratory infection can be confirmed by isolation of the virus from nasal swabs submitted in virus transport medium or from blood samples. Polymerase chain reaction is a sensitive and rapid technique for detecting EHV-1 and EHV-4 in nasopharyngeal swabs.[28] A rising titer in virus-neutralizing antibodies in acute and convalescent blood samples is necessary to confirm a recent EHV-1 or EHV-4 infection.[8] A single positive sample confirms previous infection, as herpesvirus-neutralizing antibodies persist for over a year.

Abortion caused by EHV-1 can be confirmed by immunofluorescence, virus isolation, or histopathologic examination. Although histopathologic lesions are frequently pathognomonic, it is prudent to combine histopathologic testing with virus isolation and immunofluorescence.[25] Fluorescent antibody tests have been found to be highly specific and correlate closely with virus isolation and histopathologic findings.[25,30,31] Samples of fetal lung, liver, thymus, and adrenals should

be submitted frozen for virus isolation and immunofluorescence and fixed in 10% buffered neutral formalin for histopathologic examination. Immunostaining for EHV-1 can be performed on formalin-fixed paraffin-embedded sections. Rapid and effective diagnosis of EHV-1 can be provided by an indirect immunoperoxidase technique applied to frozen and paraffin-embedded sections of fetal liver.[29] Fetal and neonatal serologic findings may assist in the diagnosis of EHV-1 abortion, as serum from aborted fetuses, stillborn foals, and weak neonatal foals before colostrum ingestion may have significant virus-neutralizing antibody titers.[32] EHV-1 can be isolated from the brain and spinal cord of affected mares but not consistently.[8]

CONTROL

Sound management practices in conjunction with hygienic procedures to prevent spread of disease and a vaccination program offer the best means for prevention and control of EHV-1 infection.[27] Early recognition of an aborted fetus or a sick newborn foal is important in preventing spread of EHV-1. Aborted fetuses present the biggest risk to susceptible pregnant mares in the transmission of this highly contagious and infectious disease. Sick foals should be prevented from having contact with pregnant mares, the surroundings should be thoroughly disinfected, and all bedding should be burnt. Any aborted fetus and its membranes should be removed in a plastic bag or container for disposal, preferably to a diagnostic laboratory. If this is not possible, then a necropsy should be performed in a suitable, safe location that can be easily cleaned and disinfected. Samples should be collected, packed safely, and sent to a laboratory for diagnosis.

Aborting mares should be isolated and the contaminated area cleaned and disinfected. Attendants must take precautions not to infect other pregnant mares by carrying virus on their clothing, equipment, and utensils. That will require disinfecting boots and changing clothing before attending to other pregnant mares. Mares and foals should be observed closely for signs of abortion and illness. When abortion occurs, no mares should be allowed to enter or leave a breeding farm until EHV-1 infection is eliminated from the diagnosis.[6,11,27]

Management practices such as crowding of pregnant mares, visiting broodmares, indiscriminate mingling of horses of various age groups, the environment of sales, and other factors that produce stress can significantly influence the occurrence of EHV-1 disease.[8,27] Pregnant mares on a breeding farm with EHV-1 infection can leave, provided that they have been strictly isolated from aborted mares for a month after the last abortion. They should be kept isolated from pregnant mares at other breeding farms for an additional 2 months. Pregnant mares returning from an infected breeding farm to their home farm must be kept in isolation until they have foaled.

Vaccines are currently used in conjunction with good management to prevent outbreaks of EHV-1 respiratory disease, abortion, and neurologic disease. The principal objective with broodmares is to protect against abortion. Vaccines currently available are modified-live and inactivated EHV-1 vaccines, but the resulting immunity is of short duration.[6,7,27] The vaccines should contain EHV-1 and EHV-4, although some cross-protection occurs. Two sequential injections of EHV-1 vaccine protect against challenge with EHV-4, but two injections of EHV-4 vaccine do not protect against EHV-1.[33] The limited effectiveness of available vaccines is demonstrated by the continual outbreaks of herpesvirus abortion, respiratory disease, and neurologic disease despite intense vaccination programs.[8] New and more effective vaccines such as a living subunit vaccine and a thymidine kinase–negative EHV-1 deletion mutant vaccine are being tested and may become available in the near future.[7,27]

Cell culture–adapted modified live-virus vaccines are widely used on breeding farms. They do not spread among horses or cause respiratory disease or abortion. Frequent vaccinations are necessary to maintain immunity.[7,27] Broodmares should be vaccinated twice during the latter half of pregnancy, or at the fifth, seventh, and ninth months of gestation to maintain immunity during the period of maximum risk for abortion. Foals and yearlings should also be vaccinated if they are running with the mares or are on the same farms at the critical time of pregnancy when EHV-1 infection is likely to occur. Passive immunity wanes around weaning and this is when foals contract EHV-1 infection. It is recommended that foals should be vaccinated 2 weeks before weaning, followed by two subsequent injections at 4- to 6-week intervals, and a booster injection every 3 months. The level of protection against fetal and foal deaths is low, and other forms of protection such as management must be provided.[4]

CHAPTER 23

Equine Viral Arteritis

T. W. SWERCZEK and STANLEY M. DENNIS

Equine viral arteritis (EVA) is an acute systemic to subclinical respiratory viral disease of horses characterized by generalized vascular necrosis and by abortion.[1–3] EVA usually occurs as a mild and often unrecognized infection of the anterior respiratory tract.[4] Initially a disease of Standardbreds, it now also affects Thoroughbreds.[5,6] It is apparently worldwide in distribution.

ETIOLOGY

The causal agent is an *arterivirus,* an RNA virus of the family Togaviridae. It is the sole member of the genus.[5] Several strains of the EVA virus with varying degrees of virulence have been reported, with only one antigenic type.[6–8] The prototype is the Bucyrus strain from the originally diagnosed outbreak,[1] and its virulence contrasts sharply with the clinically inapparent infections transmitted by many long-term carrier stallions.[6,9]

EPIDEMIOLOGY

Equine viral arteritis was first recognized in 1953 following an outbreak of severe respiratory disease and abortion in Bucyrus, Ohio, and additional outbreaks occurred in Ohio, Indiana, California, and Kentucky.[1] From then to 1984 there were relatively few reports of EVA, although infection appears to be widespread.[5,10,11] Outbreaks of clinical disease are infrequent and occur mainly in mares on breeding farms where up to 50% abort.

A serologic survey revealed 70% to 90% of Standardbred mares and less than 3% of adult Thoroughbreds to be EVA seropositive.[10] The first recorded outbreaks at racetracks in Standardbreds were reported in 1977. The outbreak of EVA in Kentucky in 1984 was the first reported occurrence in Thoroughbreds in North America.[5] There was considerable variation in severity in the 1984 outbreak, with affected mares exhibiting a variety of clinical signs from commonly reported EVA lesions to inapparent infection.[5,6] There were no associated deaths or confirmed cases of abortions. All affected mares made complete, uneventful recoveries. In confirmed outbreaks of EVA since 1984, abortion occurred infrequently.[6]

Horses are the only host of EVA virus, and all ages are susceptible. EVA spreads rapidly in groups of susceptible horses. Mortality rate is low in natural outbreaks, and after recovery, affected horses have prolonged immunity. Currently, the EVA virus is so avirulent that clinical signs are not obvious or are mild when sporadic outbreaks occur.[2,6,10]

TRANSMISSION

Susceptible mares can be infected by inhalation of aerosols from infected horses, and respiratory spread is a major method of transmission of EVA virus in barns, at pasture or sales, and at racetracks.[1,11] Droplets from nasal exudate of infected horses remain infectious for up to 10 days in the environment. Abortion from natural or experimental infection occurs 23 to 57 days after exposure and from 6 to 29 days after the onset of fever.[12]

Venereal transmission from infected stallions to susceptible mares played a significant role in the widespread dissemination of EVA during the 1984 outbreak.[6,9,13] Sexually infected mares transmitted EVA virus to susceptible mares by contact.[6,12] Virtually 100% transmission of EVA virus occurred in susceptible mares bred to long-term shedding stallions during the 1984 outbreak, so clinical infection must have been mild and undetected. Venereal transmission was a major method of spread of EVA on breeding farms.[5,6]

The role of indirect contact with virus-contaminated fomites varied with outbreaks.[6] The role of teaser stallions and nurse mares, although a potential risk, was apparently insignificant in the 1984 outbreaks.[6]

The EVA virus is present in fluids and tissues of aborted fetuses and placentae, which could potentially result in indirect lateral spread of infection.[1] Foals of immune mares are resistant to infection until the loss of colostral antibodies at 2 to 6 months of age.

Carriers of EVA virus are important in perpetuating infection in horse populations. The duration of the carrier state in stallions shedding the virus in semen can vary from weeks to years.[6,9] The frequency of long-term carriers is approximately 30% to 35%. Following experimental infection with EVA, the virus is shed in semen for months, and the ampulla and bulbourethral glands appear to be preferred sites for viral infection.[13] There is little evidence, however, to indicate that mares are EVA carriers with any appreciable frequency. Evidence of congenital infection in foals is lacking.[6]

PATHOGENESIS

The virus of EVA is pathogenic to endothelial cells and causes panvasculitis. In clinical EVA, the inhaled virus replicates initially in lung macrophages and spreads to the local lymph nodes. Viremia is followed by replication in endothelial and medial cells of small arteries and severe vascular damage, especially in the intestinal tract, visceral lymph nodes, and adrenals. That results in

increased permeability, generalized edema, and hemorrhage. Pulmonary edema and hydrothorax are manifested by dyspnea. Hemorrhagic enteritis results in diarrhea and abdominal pain. Petechiae of mucosae and conjunctivae, and edema of limbs also occur. Arterial damage peaks at day 10 after infection when edema has largely disappeared. The vascular lesions resolve if the horse survives. In severe cases, death may occur from dehydration, hypotension, and severe hypoxia.[2,3,14]

Abortion apparently results from severe necrotizing myometritis, placental detachment, decreased progesterone, and local prostaglandin release.[14] Aborted fetuses may be alive or dead but rarely have lesions attributable to EVA. Virus may be isolated from the placenta and fetal spleen and lung.[14]

CLINICAL SIGNS

Infections associated with EVA may vary from acute to mild to subclinical; most are subclinical with sporadic abortions.[2,6,12] Clinical EVA has an incubation period of 3 to 14 days followed by fever (39–41°C), leukopenia, a serous nasal discharge, conjunctivitis, lacrimation and purulent ocular discharge, keratitis, palpebral edema, photophobia, and skin rash, commonly on the neck. Petechiae of nasal mucosa and conjunctivae may occur, along with moderate to severe anorexia and depression, weight loss, and in severe cases, abdominal pain and diarrhea. Respiratory signs, coughing, and dyspnea are seen less frequently. Edema of limbs, especially the hindlegs, and ventral abdomen, scrotum, and prepuce occurs. Secondary bacterial invasion is manifested by rhinitis and infection of the respiratory tract. Naturally infected horses usually have uneventful recoveries, and death is usually confined to experimental infection following dehydration, muscle weakness, and prostration. The course of infection is usually 3 to 9 days, and recovered horses have prolonged immunity.[1–3,5,6,12]

Abortion usually occurs within 7 to 10 days after the onset of maternal illness. The aborted fetus is often autolytic but may be fresh. Most abortions occur between 5 and 10 months' gestation and the prevalence of abortion is up to 50%. It is estimated that 40% to 80% of EVA-infected pregnant mares abort or deliver stillborn foals.

LESIONS

Gross lesions in horses with clinical EVA are mainly due to hemorrhage and edema from generalized vascular necrosis and include petechiae of the upper respiratory tract, lungs, gastric mucosa, adrenals, and all serous surfaces. Hemorrhagic enteritis is present and is usually more severe in the large intestine. Hemorrhage and infarction of the spleen are also observed. There is moderate to severe pulmonary edema, severe hydrothorax and hydroperitoneum, and edema of the mesentery and connective tissue and often of the intestinal wall, eyelids, limbs, ventral abdominal wall, prepuce, and scrotum.[1–3]

Characteristic microscopic lesions occur in the media of small muscular arteries in many organs, especially the intestine and adrenals. There is multifocal necrosis of myocytes in the media with fibrinoid replacement, edema of the vessel wall and adventitia, and infiltration of leukocytes, mainly lymphocytes. Thrombosis may occur in the intestine and lungs with infarction commonly occurring in the intestine, particularly the cecum, the colon, and the spleen. Massive necrosis occurs in lymph nodes and adrenals.[1–3,14]

Acute multifocal necrotizing myometritis occurred in the uterus of experimentally infected mares and may occur in the absence of generalized vasculitis.[14] The lesion is more severe in the internal part of the inner circular layer of the myometrium. The placentae were hyperemic but the blood vessels were histologically normal.[14]

Aborted fetuses may be fresh or autolyzed, and gross and microscopic lesions are rarely observed, although EVA virus may be recovered.[1–3,12,14] Lesions have, however, been observed in a few aborted fetuses and their membranes and included necrotizing vasculitis, especially of allantochorion, and inflammatory foci in various fetal organs.[4]

DIAGNOSIS

Clinical EVA is more severe than the other respiratory diseases and needs to be differentiated from equine herpesvirus infections, equine influenza, equine infectious anemia, and possibly leptospirosis by complement fixation, serum neutralization, and enzyme-linked immunosorbent assay tests.[7,10,12] Characteristic histopathologic changes can be confirmed by immunofluorescence.

The EVA virus can be isolated in equine kidney and rabbit kidney cell cultures.[1,12] Specimens for isolation include nasopharyngeal swabs, heparinized blood, urine, lung and spleen of aborted fetuses, allantochorion, and semen of affected stallions.[6,12,15] EVA is a significant cause of equine abortion and can present a diagnostic dilemma if respiratory signs are minimal.[5,12] Equine herpesviral, bacterial, and fungal causes should be eliminated by serologic and cultural procedures. Definitive diagnosis of EVA abortion can be provided by immunofluorescent tests on aborted fetal tissues and by serum neutralization tests on sera of infected aborting mares.

CONTROL

Sufficient data and an effective live, attenuated vaccine[8,16] are available for prevention and control of EVA.[6] Stallions should be vaccinated annually before the breeding season. Infected virus-shedding stallions can be mated to seropositive or vaccinated mares, provided that strict isolation is maintained between infected and noninfected horses. Mares should not be vaccinated during the last 2 months of pregnancy.[6] Vaccination of foals from nonimmune mares results in good protection, and foals from seropositive mares should be vaccinated at 6 months of age.

Kentucky instituted an effective EVA control program in 1985 based on serologic testing of stallions and mandatory annual vaccination of Thoroughbred stallions.[6] Carrier stallions are kept isolated and bred only to mares that were vaccinated more than 3 weeks previously or are EVA seropositive; the bred mares are isolated from

unvaccinated or seronegative horses for 3 weeks. The same general principles and hygiene for handling equine herpesviral abortion should be used for EVA abortions.

CHAPTER 24

Bacterial Diseases of the Fetus and Placenta Associated with Fetal Loss in the Mare

T. W. SWERCZEK

Fetal lesions and placentitis associated with abortions and stillbirths are major causes of economic loss in mares in many countries throughout the world.[1–4] Before the mid-1980s the majority of pathogenic bacteria associated with equine placentitis and abortions were reportedly due to a group of bacterial microorganisms including *Streptococcus zooepidemicus, S. equisimilis* and other streptococci including non-beta-hemolytic *Streptococcus* spp., *Staphylococcus aureus, Escherichia coli, Pseudomonas aeruginosa, Klebsiella pneumoniae,* and *Actinobacillus equuli.*[1,2,4–6] However, since the late 1980s and early 1990s other microorganisms have dramatically emerged as very significant causes of fetal loss in mares.[7–9] These agents include leptospires, nocardioform actinomycete group of organisms,[10] and microorganisms associated with early and late fetal loss in mares.[11] This chapter will review the emerging bacterial diseases currently causing equine fetal loss in mares.

The most common bacterial group currently being diagnosed is categorized as a group of organisms belonging to the nocardioform actinomycetes, of which there are several,[12] followed by the streptococcal group of bacteria including *Streptococcus zooepidemicus, Streptococcus* spp., and *Streptococcus equisimilis*. Other commonly isolated bacteria include *E. coli, Pantoea* spp., *Pseudomonas* spp., and *Leptospira* spp. In addition, several less commonly isolated bacteria are associated with fetal septicemia. The largest number of fetal losses are free of known pathogens, but are infected with a group of bacteria referred to as nonpathogens and saphrophytes.[11]

unvaccinated or seronegative horses for 3 weeks. The same general principles and hygiene for handling equine herpesviral abortion should be used for EVA abortions.

The most common bacterial group currently being diagnosed is categorized as a group of organisms belonging to the nocardioform actinomycetes, of which there are several,[12] followed by the streptococcal group of bacteria including *Streptococcus zooepidemicus, Streptococcus* spp., and *Streptococcus equisimilis*. Other commonly isolated bacteria include *E. coli, Pantoea* spp., *Pseudomonas* spp., and *Leptospira* spp. In addition, several less commonly isolated bacteria are associated with fetal septicemia. The largest number of fetal losses are free of known pathogens, but are infected with a group of bacteria referred to as nonpathogens and saphrophytes.[11]

Most gross and microscopic lesions affecting allantochorion fall into three categories: diffuse placentitis associated with a hematogenous origin, an ascending placentitis originating from vaginal tract and cervix, and a focal mucoid placentitis located in the anterior body of unknown origin.[13] It is not uncommon to find overlapping of placental lesions when multiple etiologic syndromes simultaneously affect the fetus. In the umbilical cord and amnion, the primary lesions are edema and hemorrhage, and secondary inflammation apparently is associated with secondary opportunistic and pathogenic bacteria. Seemingly, lesions in umbilical cord and amnion are emerging as a significant cause of fetal death associated with midterm and late-term fetal losses.

LEPTOSPIROSIS

Leptospirosis is a zoonotic bacterial disease of worldwide distribution that infects many species, including humans. In horses as well as other species, clinical responses range from inapparent to severe infections. Pregnant mares exposed to infected animals may abort.[14–16] Most infections are caused by leptospires in the Pomona serogroup, and less frequently by the servor grippotyphosa, and rarely other strains.[1,7,18–20] The horse is seemingly an incidental host for these and other serovars, with the possible exception of bratislava.[15,16]

Fetal Lesions

The most dramatic pathologic changes in the fetus are seen in the liver, which is enlarged, mottled, and pale to yellow. The microscopic changes consist of hepatocellular dissociation, hepatocellular vacuolar degeneration, and focal to multifocal fibrosis and necrosis of individual hepatocytes and Kupffer cells. There is intrahepatic bile stasis. Some of the hepatocytes develop into giant hepatocytes with abundant cytoplasm and binucleated to multinucleated nuclei. There is a mixed leukocytic infiltration in the portal trials.[21]

The kidneys are grossly enlarged and edematous with pale white radiating streaks in the cortex and medulla. The microscopic lesions consist of multiple focally extensive microabscesses with few to several giant cells, and multifocal nonsuppurative interstitial nephritis. The tubules may be dilated.[21]

The changes in the lungs and heart are occasionally present and include varying degrees of bronchopneumonia and subpleural, interlobular, and alveolar hemorrhages. The pneumonic changes are usually minimal to mild and consist of focal neutrophilic infiltrations. The microscopic changes in the heart are occasionally found and consist of multifocal infiltrations of mixed leukocytes in the myocardium. The lymphoid organs may have a mild lymphoid necrosis with neutrophilic infiltration and the reticuloendothelial cells proliferate in the sinuses.[21]

Placental Lesions

The placental changes occur in the allantochorion where there are patchy areas of necrotic mucoid exudates on the chorionic epithelium. There may be lesions of nodular cystic hyperplasia in the allantois. Microscopic changes in the chorion consist of thrombosis, vasculitis, mixed inflammatory cell infiltration of the chorion, and villous necrosis and calcification. There is cystic adenomatous hyperplasia of allantoic epithelium.[9,21] The spirochetes can be demonstrated in the majority of cases with immunofluorescent microscopic examination and in histologic sections stained by the Warthin-Starry method for spirochetes.[9,21,22]

For serologic testing, heart blood and pericardial fluid are ideal for testing fetuses and stillborn foals, and blood from the aborting mares can be tested for leptospiral antibodies by the microscopic agglutination test (MAT). The most common serovar found in affected fetuses and aborting mares are *Leptospira interrogans* serovars *pomona, grippotyphosa, copenhageni, hardjo, canicola, and bratislava*. The majority of cases react to only one serovar, but a few cases show cross-reactivity to more than one serovar.[9,21,22]

Epidemiology

Horses appear to serve as maintenance host for the serovar *bratislava* due to the high seroprevalence of *bratislava* antibodies in various horse populations throughout the world.[15] If in fact serovar *bratislava* is host adapted, transmission would be by direct contact with infected urine or by the venereal route from infected horses. *Bratislava* may be localized in the kidneys of horses and may be shed in the urine for the duration of the horse's life.[15]

In North America most horses seemingly are infected with serovars maintained in other animal species, and mares are considered incidental hosts. In the central Kentucky area and likely other areas in North America, *kennewicki, grippotyphosa,* and *hardjo,* found in skunks, raccoons, and cattle, respectively, are the nonhost-adaped serovars associated with equine abortions. [10] These species are commonly found on or around horse farms. Once horses are infected on a farm, horse-to-horse transmission is likely to occur as infected mares may shed high numbers of the nonhost-adaped leptospires for several weeks.[10]

Prevention and Control

Attempts should be made to prevent pregnant mares from coming into direct contact with the urine of maintenance hosts as well as indirect contact with contaminated environmental drinking water, feed, and bedding contaminated with urine from maintenance hosts. Various antibiotics have been used to treat infected and carrier mares with mixed results with apparent success in some mares, but not in others.[10]

MUCOID PLACENTITIS (NOCARDIFORM PLACENTITIS)

Bacteria that induce lesions of mucoid placentitis are categorized as a group of organisms belonging to the nocardioform actinomycete strains of bacteria, of which there are several [12] The causative organisms associated with these lesions are gram-positive, non-acid-fast, filamen-

tous bacteria. The bacteria were previously deemed to be nonpathogenic when they were found in lesions of mucoid placentitis. However, when the numbers of cases became more numerous in the early 1980s[23,24] and subsequently increased dramatically in the late 1990s, these previously called nonpathogenic bacteria are now considered emerging opportunistic pathogens and a significant cause of abortions and premature foals.[10]

Mucoid placentitis is a chronic form of placentitis that is focally extensive, affecting the junction of the horns and body of the allantochorion. Typically, the exudate on the surface of the chorion is mucoid and mimics a mycotic placentitis. Unlike mycotic infections of the placenta, the cervical area of the allantochorion is not affected, which suggests a hematogenous route of infection. The causal organisms induce extensive lesions on the chorionic surface that result in a mild to marked placental insufficiency, depending on the extent of the placental lesions. Affected fetuses either abort, or are born prematurely and typically resemble a twin due to the placental insufficiency. Affected fetuses are usually alive when aborted and lesions are restricted to the liver, which is enlarged and discolored due to the placental insufficiency.

Unlike mycotic organisms,[25] the causative bacteria are not easily demonstrated upon histopathologic examination with hematoxylin and eosin (H&E) staining, but can be demonstrated with the Gram stain.[24] The organisms are easily cultured on blood agar using routine bacteriologic techniques but may require more time to grow than other bacteria or contaminating organisms.[10,26]

Using molecular techniques and comparing the sequence of the 16S rDNA gene against the public databases indicated a relationship to members of the suborder Pseudonocardineae. One of the causative organisms has been further classified as *Crossiella equi*.[27] Other nocardioform bacteria, recently classified as *Amycolatopis* spp., are less commonly found in affected placentas.[28,29] It is likely that other similar nocardioform bacteria are also associated with mucoid placentitis lesions.

Also inducing lesions of mucoid placentitis is a bacterium identified as *Cellulosimicrobium (Cellumonas) cellulans* (formerly *Oerskovia xanthineolytica*).[30,31] This bacterium was first reported as causing abortion in Australia[31] and later in Kentucky.[30] Fetuses affected with *C. cellulans* have lesions in the chorion similar to those caused by *Crossiella equi,* but unlike *C. equi,* in some cases the lesions affect the cervical star area of the chorion, although in other cases the cervical star is not affected.[30] The chorionic epithelium is necrotic, thickened, and tan, and sharply demarcates the normal adjacent chorionic epithelium. The lesions in the body of the placenta are focally extensive, irregular, and very demarcated from adjacent normal chorionic epithelium. The villi in the center of the lesion are absent and covered by a brown, mucoid exudate. The amnion may be discolored yellow.[30,31]

The microscopic changes in the chorionic epithelium include short, blunted villi lined by hypertrophic trophoblastic epithelial cells. There is an infiltration of large numbers of lymphocytes and plasma cells, and fewer numbers of macrophages and neutrophils. There is an increase in vascularity and fibroplasia in the affected area of the chorion. There may be a squamous metaplasia of the trophoblastic epithelial cells. The chorionic surface is frequently covered with an amorphous eosinophic material that contains neutrophils and bacteria. Also, lesions may be present in the allantois and amnionic portion of the umbilical cord, but are less severe than the chorionic lesions and consistent with a nonsuppurative inflammation.[30]

The placental lesions in the chorion resemble those found with *Crossiella equi,* except that the cervical star area may be affected. In addition, fetuses with *C. equi* infections generally have no lesions, other than enlarged pale livers.[10] Fetuses infected with *C. cellulans* are usually emaciated and have gross lesions in the lungs and occasionally the liver. The lungs are firm and mottled red-tan. The liver is enlarged and mottled and may contain multiple 1- to 5-mm pale foci visible on the capsular surface and in some cases distributed throughout the hepatic parenchyma. The microscopic lesions in the liver are multifocal and there are mixed inflammatory cells in the portal triads.[30,31]

The microscopic lesions in the lungs include cellular debris, granulocytes, macrophages, and multinucleated histiocytic giant cells in the lumens of the alveoli and bronchioles. The pneumocytes are frequently hypertrophied, and the alveolar walls may be infiltrated with mononuclear inflammatory cells. Low numbers of gram-positive bacillary to filamentous bacteria can be seen in the pulmonary cells and in the cytoplasm of the multinucleated giant cells.[30,31]

The syndrome is not new, as it was first reported in 1982 in Australia.[31] Earlier, fetuses with identical lesions were seen in an outbreak of abortions on a Thoroughbred farm in central Kentucky in December 1970 (Swerczek, TW, unpublished data). Multiple abortions occurred in a herd of 25 pregnant mares. Two 10-month-old fetuses were submitted for necropsy examination, and the gross and microscopic lesions in the chorion, amnion, umbilical cord, lung, and liver were consistent with those subsequently described in 1982 in Australia[31] and in 2004 in Kentucky.[30] Multiple mixed bacteria were isolated from the placentas and fetuses. Gram stains of lungs with fetal pneumonia revealed bacteria in the alveolar macrophages and multinucleated giant cells that were morphologically consistent with those reported in fetuses in 1982[31] and 2004.[30]

There were no other fetuses with similar lesions submitted for necropsy examination during the 1970 and 1971 foaling season from other area farms (Swerczek, TW, unpublished data). An unconventional feeding program was given to the affected pregnant mares that aborted. The affected mares were being fed haylage starting in November 1970, and approximately 3 weeks later mares aborted. It was suspected that the causative bacterium may have been present in the haylage that was being fed to cattle as well as the pregnant mares on the farm. The farm did not experience similar abortions in subsequent years, but because haylage was the suspected as harboring the bacterium at that time, it was no longer fed after the mares aborted in the fall of 1970.

The source of infection of *Cellulosimicrobium (Cellumonas) cellulans* is most likely the environment. In

light of the cases in which haylage was suspected as early as 1970, these bacteria that are commonly found in soils may be also associated with the oral consumption of the causative bacteria in forages.

Prevention and Control

Until more is known on the distribution of the group of causative organisms in the environment, predisposing factors, and how these bacteria enter the reproductive tract of pregnant mares no recommendations can be made.

EARLY AND LATE FETAL LOSS SYNDROME

History

A dramatic spike in fetal losses, commonly referred to as mare reproductive loss syndrome (MRLS), was first recognized as a significant cause of fetal loss in the spring of 1980 and 1981 in the central Kentucky area.[32] However, retrospective analysis of breeding and pathology records of cases from area farms revealed similar losses to a much lesser extent in the late 1970s (Swerczek, TW, unpublished data). Many mares that were bred in February and March in 1980 later aborted in May and June. During May and June of 1980 late-term mares also aborted at the same time mares early in pregnancy aborted.[32] At that time, unusual climatic and environmental conditions occurred, including severe late spring frosts, which damaged lush grass and clover pastures at late as May 9, 1980. The syndrome was also seen during the 1981 foaling season, but to a lesser extent. During the subsequent years the syndrome was seen each spring, as well as the fall of the year (Swerczek, TW, unpublished data), but there were no drastic spikes in abortions until the breeding season of 2001 when massive early and late fetal losses occurred similar to 1980, but to a much greater extent.[33–36] Again in 2001, climatic and environmental conditions, similar to those that occurred in 1980 and 1981, occurred but to greater extremes. A series of late frosts and freezes affected area pastures during the late spring. Also, extremes of unseasonal high climatic temperatures occurred before and after the late severe frosts and freezes for 1 week starting on April 17, 2001.[37]

The abortions seem to cluster during a brief period of time in the late spring seemingly associated with simultaneous environmental exposure.[33–35,37] Risk factors associated with late-term abortions include increased amount of time at pasture and less time in the stall; feeding concentrates and hay, especially alfalfa, on the ground; access to pasture after midnight during the 4-week period prior to abortions; and drinking water from a water trough or not having access to water buckets or automatic water devices. It was concluded that exposure to pasture during critical environmental conditions similar to those seen in 1980 and 1981 seem to predispose mares to having late-term abortions and stillborn foals.[33,34]

Abortions seemingly occur 9 to 10 days after frost or freeze to lush grass and clover pastures in the late spring and early fall.[37] Retrospective analysis of pathology records between 1980 and 2001 also revealed that spikes of abortions also occurred 9 to 10 days following severe frost and freezes to pasture forages in the late spring and fall (Swerczek, TW, unpublished data). It was found that mares that had access to pasture after midnight were more likely to abort.[34] This was likely associated with frosts and freezes to pastures during the early morning hours when temperatures are the lowest of the day and when frosts and freezes to pastures are most likely to occur in the late spring. Potassium will increase in forages during the early morning hours and will spike during and after a frost.[38] It is suspected that high-potassium frost-damaged forage may be involved in the pathogenesis of the abortions. The high potassium in affected forages would favor the overgrowth of endophytic and saprophytic bacteria in frost-damaged forages. Also, sugars, primarily fructans, will increase in frost-damaged cool season grasses and forages.[37,38] Increase in sugar levels, in addition to elevated potassium levels, would dramatically favor the overgrowth of endophytic and saprophytic bacteria, many of which are found in fetuses and placentas of affected aborted fetuses.

Bacterial Findings

The most common bacteria isolated from aborted fetuses include non-beta-hemolytic *Streptococcus* spp., followed by an *Actinobacillus* species and numerous other bacteria classified as nonpathogens.[11] In addition, plant bacterial endophytes, including *Microbacterium* spp., *Cellumonas* spp., and *Proteoa* spp. were commonly found in affected fetuses (Swerczek TW and Allen GP, unpublished data, 2001–2005). It is suspected that these endophytic plant bacteria, which are present and increase in numbers in stressed pasture forages, may be associated with the pathogenesis of the early and late fetal loss syndrome.[37]

Fetal and Placental Lesions

In early fetal losses there are no characteristic inflammatory lesions. Bacterial are present in the placental membranes and fetal tissues. In midterm fetuses, inflammatory lesions may be present in the amnion and amnionic portion of the umbilical cord. In midterm affected fetuses, the fetus may die from a twisted cord caused by the ongoing developing lesions in the amnionic portion of the umbilical cord. In late-term fetuses there may be a unilateral or bilateral hemorrhagic endophthalmitis. The lungs contain squamous epithelial cells in the alveoli with or without concurrent infiltration of inflammatory cells including neutrophils, macrophages, and monocytes in the alveoli and interstitium. In the heart there may be a focal myocarditis and pericarditis. The placental lesions are characteristic in late-term fetuses and in placentas from foals that are affected but do not abort and are born alive. There is a hemorrhagic, edematous amnionitis and funisitis affecting primarily the amnionic umbilical cord, and to a lesser extent the allantoic umbilical cord and the surface of the allantoic portion of the allantochorion (Swerczek, TW, unpublished data). The chorionic epithelium is usually free of lesions. However, occasionally, there are mixed bacterial infections with

concurrent bacteria, like *Cellulosimicrobium cellulans,*[30] and in these cases the chorionic epithelium is also affected.

In late-term fetuses, like midterm affected fetuses, the amnionic portion of the umbilical cord often becomes constricted and sacculated. The affected umbilical cord may become excessively twisted owing to the ongoing inflammatory lesions, and the fetus may die because of circulatory compromise to the developing fetus (Swerczek, TW, unpublished data).

The early and late fetal loss syndrome is not restricted to mares. At the same time mares were aborting during the spikes in abortions in 2001, other herbivores were also aborting, including cattle, goats, sheep, llamas, and buffalos. Abortions in cattle were seen after pregnant cows consumed haylage harvested after the forage was severely affected by frost and freezes. Affected bovine fetuses had the same lesions of hemorrhagic and edematous amnionitis and funisitis affecting the amnionic umbilical cord, as were present in affected equine fetuses. Myocarditis and endophthalmitis were also present in bovine fetuses. In bovine fetuses, like equine fetuses, plant bacterial endophytic bacteria, including *Microbacterium* spp., *Cellumonas* spp., and *Proteoa* spp. were commonly found in affected fetuses (Swerczek TW and Allen GP, unpublished data, 2001–2005).

Prevention and Control

The early and late fetal loss syndrome seemingly is associated with environmental factors and conditions that affect pasture forages.[34] The use of the terms early- and late-term fetal loss syndrome seemingly is a misnomer. Rather than the stage of pregnancy, abortions are associated with simultaneous environmental exposure to an unknown factor(s) during certain times of the year, usually spring and fall. However, the majority of pregnant mares are either in early or late gestation in the late spring when spikes of abortions are more likely to occur. Fetal losses also occur at midterm, usually in the fall of the year.

Epidemiologic studies suggest that the amount of time, especially after midnight, pregnant mares spend in pastures during periods of environmental and climatic stress are risk factors for fetal losses.[34] Until more is known about the specific etiologic factor(s) in pastures and forages, no preventive measures can be suggested.

CHAPTER 25
Fungal Abortion

T. W. SWERCZEK and STANLEY M. DENNIS

Fungi are important causes of sporadic abortion and are responsible for up to 10% of reported abortions in mares.[1,2] The fungi include *Aspergillus fumigatus, Mucor* spp., and *Allescheria boydii,* with *Aspergillus* being the most common.[2–5] Rarely reported fungi include *Coccidioides immitis,*[6] *Cryptococcus neoformans, Candida albicans,* and *Histoplasma capsulatum.*[2]

MATERNAL SIGNS

Mares may display signs of estrus early in pregnancy and abort later at 8 to 11 months of gestation, usually without any premonitory signs.[7] Infected mares may run milk for days before abortion and occasionally have a thick, brownish, adherent vulval discharge.[1] A purulent vulval discharge may be evident for some days after abortion but resolves spontaneously.[1] Infection with *Aspergillus* and *Mucor* spp. does not persist in the uterus and does not interfere with subsequent fertility.

PATHOGENESIS

Although fungal invasion of the pregnant uterus may be hematogenous or transcervical, it primarily ascends from the vagina via a patent cervix. Initially, infection begins in the chorion adjacent to the cervical star, then progresses cranially up the uterine body.[1,2,7] The resultant chronic ascending chorionitis causes progressive placental insufficiency that interferes with fetal nutrition and growth and results in intrauterine growth retardation.[1] Infection eventually results in abortion or premature expulsion of a dead or nonviable fetus.

CHAPTER 25
Fungal Abortion

T. W. SWERCZEK and STANLEY M. DENNIS

Fungi are important causes of sporadic abortion and are responsible for up to 10% of reported abortions in mares.[1,2] The fungi include *Aspergillus fumigatus, Mucor* spp., and *Allescheria boydii,* with *Aspergillus* being the most common.[2–5] Rarely reported fungi include *Coccidioides immitis,*[6] *Cryptococcus neoformans, Candida albicans,* and *Histoplasma capsulatum.*[2]

MATERNAL SIGNS

Mares may display signs of estrus early in pregnancy and abort later at 8 to 11 months of gestation, usually without any premonitory signs.[7] Infected mares may run milk for days before abortion and occasionally have a thick, brownish, adherent vulval discharge.[1] A purulent vulval discharge may be evident for some days after abortion but resolves spontaneously.[1] Infection with *Aspergillus* and *Mucor* spp. does not persist in the uterus and does not interfere with subsequent fertility.

PATHOGENESIS

Although fungal invasion of the pregnant uterus may be hematogenous or transcervical, it primarily ascends from the vagina via a patent cervix. Initially, infection begins in the chorion adjacent to the cervical star, then progresses cranially up the uterine body.[1,2,7] The resultant chronic ascending chorionitis causes progressive placental insufficiency that interferes with fetal nutrition and growth and results in intrauterine growth retardation.[1] Infection eventually results in abortion or premature expulsion of a dead or nonviable fetus.

FETAL MEMBRANE LESIONS

Grossly, the affected chorioallantois is diffusely involved; is yellowish, thickened, and leathery; and is clearly demarcated from the normal, reddish chorioallantois.[7,8] The chorionic surface is necrotic and usually covered with thick, adherent, mucoid exudate.[9] The amnion may have irregular necrotic plaques in about 10% of *Mucor* spp. infections.[1,10] Amnionitis is not normally associated with aspergillosis.[3] Microscopically, there is marked squamous metaplasia and widespread necrosis of chorionic villi and numerous hyphae are present.[3,4,7]

FETAL LESIONS

Fetuses aborted because of mycotic placentitis are usually fresh, emaciated, and small for their gestational age.[3,7] Affected fetuses are usually aborted dead but may be expelled alive but nonviable. Scattered areas of mycotic dermatitis are rare.[11] The liver is usually pale, enlarged, and mottled.[7] Grayish white granulomas, 1 to 3 mm in diameter, scattered throughout the lungs are not common and are associated with *Mucor*-induced amnionitis.[10] Microscopically, the liver has fatty change, portal hepatitis, and bile ductule proliferation.[7] Multifocal, granulomatous pneumonia with giant cells, macrophages, and hyphae is present in fetuses with grayish white pulmonary granulomas.

DIAGNOSIS

The specimen of choice for diagnosing mycotic abortion is the chorioallantois; it should be submitted to the diagnostic laboratory fresh and in 10% buffered neutral formalin.

Diagnosis of mycotic abortion is confirmed by demonstrating fungal hyphae by smears, histopathologic examination, or culture. Lesions of chronic mycotic placentitis must be differentiated from chronic bacterial placentitis, especially streptococcal.

CONTROL

Control depends on good management and hygiene procedures. Care must be taken to avoid the use of moldy hay and straw. Aborting mares should not be bred on foal estrus.

CHAPTER 26

Evaluation and Management of High-Risk Pregnancy in the Mare

CHARLES T. ESTILL

DEFINITION

A high-risk pregnancy is one in which a condition or multiple conditions exists that are potentially serious or life threatening to either the mare or foal.[1] Those conditions may be the culmination of physical, infectious, endocrinologic, or behavioral abnormalities. Maternal conditions are generally more easily recognized and assessed than fetal abnormalities[1] and may either be limited to the genital tract or involve any other body system such as the gastrointestinal tract or musculoskeletal system. Not only is fetal well-being generally difficult to evaluate but potentially helpful intervention is limited.

PRESENTING CLINICAL SIGNS

The majority of high-risk pregnancy cases are presented because the owner observed a vaginal discharge, noted premature mammary gland development and lactation, or suspects twin pregnancy, or because there is a serious medical or surgical condition in a pregnant mare. Mares with larger than normal abdominal size or overdue pregnancies should also be considered high-risk pregnancies. Mares in which fescue toxicosis is known or suspected are frequently presented for lack of mammary development in late gestation or for prolonged gestation. In other situations there may not be any clinical signs to indicate a mare is experiencing high-risk pregnancy other than historical information from previous pregnancies or parturitions.

OBJECTIVES OF INTERVENTION

In nearly all cases, the primary objective of managing a high-risk pregnancy should be to allow the foal to develop in the uterine environment as long as possible. This objective may be accomplished by: providing antimicrobial therapy when indicated, promoting uterine quiescence, countering the adverse effects of endotoxin, and maintaining adequate fetal gas exchange and nutrition. In mares with an underlying medical or surgical condition, the ideal objective of intervention should be to correct the condition in order that the mare will be able to carry the pregnancy to term. Therefore, the clinician's goal is to maintain the intrauterine environment in a state as close to normal physiologic health as possible. Extrauterine survival of premature foals is unlikely because the final stages of fetal maturation necessary for extrauterine life occur within the last 5 days of in utero development.[2] Even an abnormal uterine environment is often more conducive to maintaining the life of the foal than neonatal intensive care. Premature delivery is indicated only in situations in which extrauterine survival is more likely than continued survival in utero. Exogenous corticosteroids are not effective for induction of fetal maturity owing to their inability to cross the placenta. However, foals that are chronically stressed in utero have the ability to respond by maturing precociously and may be delivered after a relatively short gestation but thrive and develop normally after birth.

ASSESSMENT OF FETAL WELL-BEING

Clinicians presented with sick, pregnant mares must determine if the fetus is affected, how severely it is affected, and the stage of fetal physiologic maturity.[3] Clinical procedures for determination of fetal condition and maturity include palpation per rectum, transrectal and transabdominal ultrasonography of the fetus and placenta, examination of the vagina via speculum, serial blood sampling for hormone assay, amnio-/allantocentesis, fetal electrocardiography, and measurement of mammary secretion electrolytes. Guidelines for an equine biophysical profile based on fetal ultrasonography are available. A low score is a definite indication of an impending negative outcome; however, a high score does not assure a positive outcome.[4]

Palpation per rectum may be used initially to determine fetal viability. A foal with spontaneous movement can be considered alive, but one must bear in mind that stressed foals may demonstrate frequent bouts of hyperactivity and normal foals have periods of intermittent quiescence. Therefore, an unresponsive foal should not be immediately declared nonviable but must be assessed further by repeated examination per rectum or by ancillary procedures described in the paragraphs that follow.

Transabdominal ultrasonography is useful for evaluating fetal position, size, heart rate and rhythm, aortic size, fetal breathing movements, fetal fluid depths and echogenicity, uteroplacental thickness, and fetal move-

ment. Because of the large variation in normal fetal heart rates, fetal heart rate monitoring is not a particularly sensitive method to determine well-being. Fetal heartbeat is easily evaluated by transabdominal ultrasonography and can be monitored continuously via a Doppler heart rate monitor,[5] but fetal electrocardiography is widely available and is more suitable for long-term monitoring. An electrocardiographic (ECG) lead is placed just in front of the mare's udder and another lead is placed on her back in the lumbar area. The fetal tracing is recognized superimposed on the maternal tracing by its rapid rate and low amplitude. In normal equine pregnancies, fetal heart rate decreases progressively with advancing gestation and has a regular rhythm. Prior to day 160 of gestation fetal heart rate exceeds 120 beats per minute but gradually decreases to 60 to 80 beats per minute just prior to parturition. Periodic accelerations are generally associated with fetal activity and suggest fetal health.[6] The frequency of cardiac accelerations associated with fetal activity increases with gestational age.[6] Normal fetal movement can usually be detected a minimum of every 5 minutes. It is normal for heart rate to increase to up to 110 beats per minute for short periods of time in association with fetal activity during late gestation, but persistent tachycardia is pathologic and associated with maternal fever or dehydration, fetal hypoxia, or fetal/placental infection.[6] Bradycardia is an indication of fetal asphyxia. Fetal bradycardia may be present as an adaptive heart rate pattern suggesting either cardiovascular efficiency or early stage hypoxia.[6] The fetus adapting to hypoxic stress will have a slow heart rate and appear inactive with no fetal breathing and few spontaneous movements and cardiac accelerations. If the foal fails to adapt, tachycardia develops in attempt to maintain perfusion and there is no concomitant increase in fetal movement. Finally, with progressive disease, as the myocardium becomes affected, terminal bradycardia may be observed.[6] The disappearance of beat-to-beat variation is an ominous sign. The clinician should be aware that maternal medications, such as detomidine or butorphanol, transiently reduce fetal heart rate variability.

Placentitis, the cause of nearly one third of all equine abortions, is associated with an increase in uteroplacental thickness (Fig. 26-1). Mares with placentitis rarely show signs of systemic illness. Ultrasonographic evaluation per rectum is the established method for measuring uteroplacental thickness. Measurement is made just cranial to the cervix on the ventral wall of the uterus. In normal pregnancies, the combined thickness of the uterus and placenta (CUT) does not change between 4 and 8 months of gestation, but increases significantly each month between 10 and 12 months of gestation.[7] A CUT greater than 1.5 cm at any time (normal is 1.0–1.2 cm at term) is direct evidence of placental or uterine edema and is usually due to placentitis. Separation of the allantochorion from the uterus with accumulation of hyperechoic (purulent) exudate is another indication of placentitis (Fig. 26-2). Large or progressively enlarging areas of placental detachment are abnormal and contribute to fetal compromise and eventual death.[8] Increased echogenicity of either amniotic or allantoic fluid can also be regarded as an indication of placental disease.

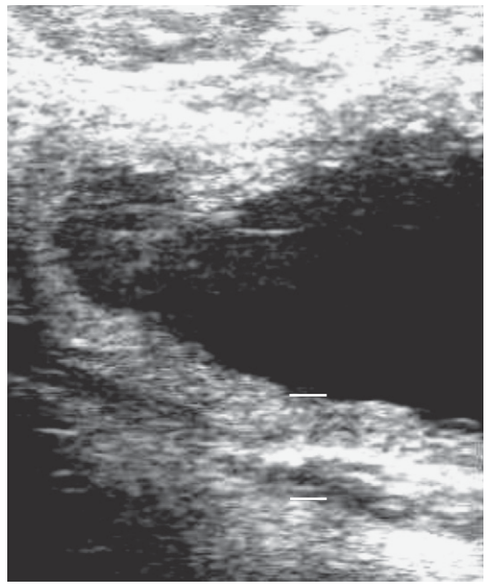

Fig. 26-1 Transrectal ultrasound image (5 MHz linear) demonstrating placental thickening associated with placentitis in a late-term mare. Uteroplacental thickness, as measured between the white bars, greater than 1.5 cm, is considered abnormal. (Courtesy MHT Troedsson.)

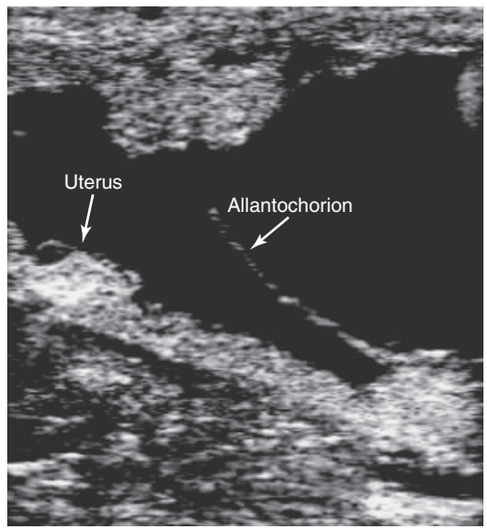

Fig. 26-2 Transrectal ultrasound image (5 MHz linear) demonstrating separation of the allantochorion from the endometrium in a mare. Mares with placental separation are treated similar to mares with placentitis. (Courtesy MHT Troedsson.)

Visual examination of the vagina and cervix is readily accomplished through a sterile cylindrical speculum. It should be performed in all mares with a vaginal discharge and in mares with premature mammary development and lactation. Cases of suspected placentitis should also be examined vaginoscopically. A careful examination provides information on the presence and character of uterine discharges as well as the competency and integrity

of the cervix. Culture specimens of discharges or placenta, which may be seen bulging through a partially dilated cervix, are readily obtained at the time of examination.

Serum hormone analysis can provide useful diagnostic and prognostic information. After about 90 days of gestation, maintenance of pregnancy is dependent on steroid hormones produced by the fetoplacental unit. The endocrine patterns in periparturient mares are characterized by increasing concentrations of progestagens and decreasing estrogens. These hormones are produced from precursors of fetal origin, metabolized by the fetoplacental unit or endometrium, and act primarily locally on the uterus. The mare is unusual in showing an increase rather than a decrease in circulating progestagens before delivery. Maternal serum or plasma concentrations of a number of progestagens, including 5α-dihydroprogesterone, escalate gradually in the last 3 to 6 weeks of gestation and peak 24 to 48 hours prior to parturition[9] (Fig. 26-3). This pattern is evidence of fetal maturity and readiness for birth because the source of the prepartum rise in progestagens is fetal adrenal steroidogenesis. Progesterone is often undetectable (<1 ng/ml) in plasma of late gestation pregnant mares but metabolites of progesterone (progestagens) are present in high concentrations.[10] Whether maternal serum progesterone concentrations are high or low in normal mares depends on the specificity of the testing procedure. Many test kits for progesterone cross-react with metabolites of progesterone such as 5α-dihydroprogesterone making interpretation of laboratory testing in high-risk mares difficult unless one is aware of the specificity of the testing procedure. The maternal endometrium metabolizes progesterone and pregnenolone to 5α-dihydroprogesterone.[11] A rise in maternal plasma progesterone concentration, when the foal is at least 290 days of gestational age, has been associated with birth of premature but viable foals. This scenario is most likely to occur in cases of slowly developing placentitis or partial premature placental separation, which stresses the foal but provides ample time for the foal to respond to the stress and mature precociously to the point at which extrauterine survival is possible. Induction of precocious maturity takes approximately 3 weeks. Abnormal trends in maternal plasma progesterone are associated with fetal compromise. Increased concentrations of plasma progesterone during mid- and late gestation are suggestive of placentitis; however, therapeutic decisions should not be made on the basis of a single sample, and serial determinations are required to detect a clinically useful trend.[12] Maternal plasma progesterone concentration determinations should be made at 48-hour intervals for a minimum of three sampling periods. Rising and elevated progesterone concentrations are associated with a good prognosis for fetal viability in late gestation. Consumption of endophyte-infected tall fescue grass may prevent the dramatic rise in progestagens prepartum.[13] A rapid and sustained decline of progesterone concentrations to less than 2 ng/ml for more than 3 to 4 days is associated with impending abortion. An investigation of hormonal profiles of pregnant mares treated either medically or surgically for colic revealed that progesterone concentrations in mares that subsequently aborted either dropped rapidly or were low at the time of admission and decreased to below 2 ng/ml.[14] If progestagens drop

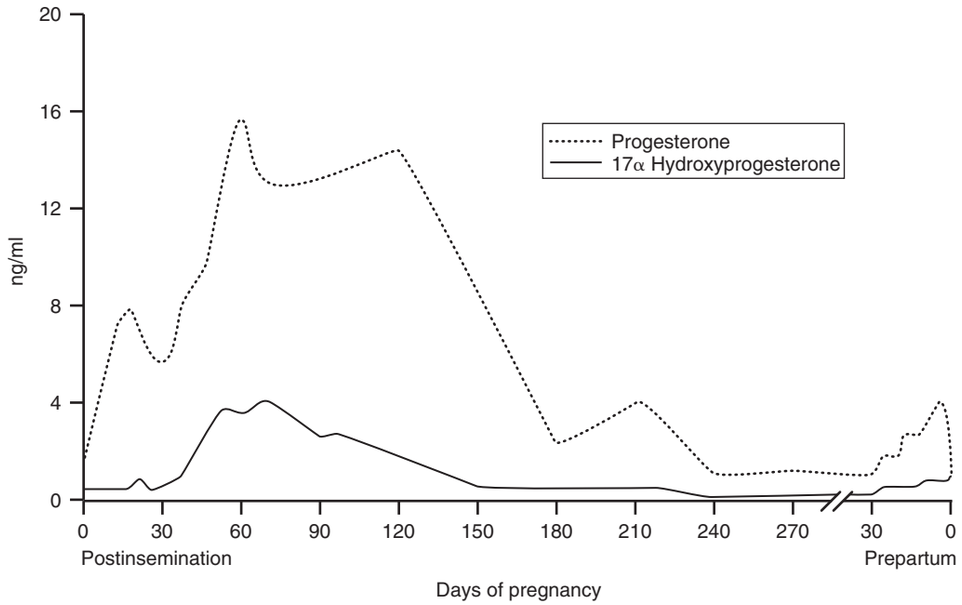

Fig. 26-3 Concentrations of progesterone and 17-hydroxyprogesterone during pregnancy in mares. Note the gradual rise in progestin concentrations during the last month of gestation, culminating in a sharp peak just before parturition. This rise is associated with maturation of the fetal adrenal glands and readiness for birth. (From Holtan DW, Nett TM, Estergreen VL: Plasma progestagens in pregnant mares, *J Reprod Fertil* 1975;Suppl 23:419.)

rapidly, owing to infection with equine herpes virus,[15] mares invariably abort.

The fetoplacental unit is the major source of estrone sulfate after day 70 of gestation. Maternal plasma concentrations are highest between 160 and 280 days of gestation. Concentrations decline during the last month concomitant with a reduction in size of the fetal gonads. Declining estrone sulfate concentrations prior to day 280 may be an indicator of fetal compromise but are of limited predictive value because of wide variation in concentrations in normal pregnant mares. Estrone sulfate concentrations are not a reliable indicator of pregnancy or fetal well-being in the last 2 weeks of gestation. Estrone sulfate concentrations after foaling or abortion may overlap the concentrations seen in the last month of gestation.[14] However, a series of estrone sulfate concentrations obtained from a sick pregnant mare may be useful in determining fetal well-being. A sharp decline in estrone sulfate concentration, which does not rebound within a few days, may be an indication of fetal compromise and help differentiate a viable fetus from one that has died in utero. On the other hand, estrone sulfate concentrations may not decline to nonpregnant levels until several days after fetal death so that it is not always possible to determine fetal viability on the basis of estrone sulfate concentrations.[15]

The assay of serum relaxin has been found to be a sensitive indicator of placental dysfunction in the late-term mare.[16] In a population of mares with normal pregnancies and deliveries, serum relaxin concentrations ranged from 45.0 to 85.0 ng/ml, with a mean value of 63.0 ng/ml during the last 7 weeks of gestation. Relaxin concentrations declined markedly in mares with placentitis during the same period (Fig. 26-4).[16] In the future, exogenous relaxin may be incorporated into the treatment protocol for placentitis in late gestation mares.

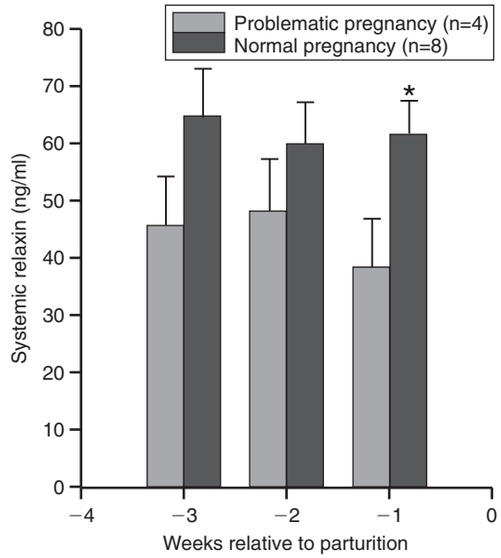

Fig. 26-4 Circulating relaxin in gravid pony mares grazed on endophyte-infected pasture and experiencing normal or problematic pregnancies associated with fescue toxicosis. Plasma relaxin was consistently lower in mares having pregnancy complications regardless of treatment. This difference was significant ($P = 0.03$) the week before delivery. (From Ryan PL, Bennett-Wimbush K, Vaala WE, et al: Systemic relaxin in pregnant pony mares grazed on endophyte-infected fescue: effects of fluphenazine treatment, *Theriogenology* 2001;56:471.)

Although amnio- and allantocentesis are not widely practiced in equine clinical medicine, in some instances valuable information may be obtained with these procedures. In cases of placentitis, fluid obtained by allantocentesis can be evaluated cytologically and cultured to determine infectious etiology and direct appropriate antimicrobial therapy. Experimental work indicated that analysis of phosphatidylglycerol concentrations in fluid obtained by amniocentesis may be useful for determination of fetal pulmonary maturity in the equine.[17] Unfortunately, pulmonary maturity standards have not been established for the equine, and there is a high degree of overlap between values obtained at various stages of gestation.[18] These procedures present some risks, particularly the introduction of bacterial contaminants into the allantoic or amniotic spaces. Another possible complication is tearing of the fetal membranes, permitting mixing of amniotic and allantoic fluid followed by abortion.

Measurement of prepartum mammary secretion electrolytes is a valuable diagnostic aid in determining fetal readiness for birth but must be interpreted with caution. Several commercial kits are available to the practitioner for measuring calcium concentrations in prefoaling mammary secretion. Dramatic changes in calcium, sodium, and potassium concentrations occur just days prior to parturition, and these changes appear to be correlated with fetal maturation.[19,20]

A progressive increase in mammary secretion calcium concentration normally occurs over the last 6 days of pregnancy, and parturition is associated with concentrations exceeding 40 mg/dl.[20] However, mares carrying normal pregnancies that were induced after mammary secretion calcium concentrations rose above 16 mg/dl delivered mature foals, and mares with concentrations less that 12 mg/ml produced dysmature foals that rarely survive.[20] Three to 5 days prior to foaling there is an inversion of the sodium and potassium concentrations such that potassium, which is initially significantly lower than sodium, becomes higher than sodium.[19] In a sick pregnant mare, mammary secretion calcium and potassium concentrations may rise prematurely due to disease-induced hormonal changes.[21] For this reason, in cases of high-risk pregnancy, the mammary secretion electrolyte concentrations cannot always be relied on to predict readiness for birth because fetal maturation may not be synchronous with maternal preparation for birth. Occasionally, when a mare recovers from the underlying disease the electrolyte concentrations return to values consistent with the stage of gestation. Udder development may regress and then resume as parturition approaches. For example, mammary secretion electrolytes and udder development may increase prematurely in cases of placentitis but then return to normal following successful treatment.

MANAGEMENT OF FETAL AND PLACENTAL DISORDERS

Placentitis is one of the few causes of high-risk pregnancy that may be amenable to treatment. Approximately 75% of placentitis cases are associated with *Streptococcus zooepidemicus*.[22] When possible, antimicrobials should be chosen based on sensitivity testing and administered systemically. However, trimethoprim sulfadiazine (25–30 mg/kg/day PO[23,24]) has been used empirically based on its ability to cross the placenta and enter fetal fluids and the fetus.[25] Potassium penicillin G (22,000 IU/kg every 6 hours IV) and gentamicin (6.6 mg/kg every 24 hours) may also reach therapeutic concentrations in fetal fluids.[26] Instillation of antibiotics directly into the allantoic space has not been widely tested but can be considered when culture and sensitivity results indicate that trimethoprim is unlikely to be effective. Antibiotics should be administered until the vaginal discharge and premature lactation cease.

Several other pharmacologic agents may be administered to mares with placentitis or other causes of high-risk pregnancy, but their effectiveness has not been conclusively demonstrated. Nonsteroidal anti-inflammatory agents have been administered to reduce prostaglandin (PG) production, although their effectiveness in altering the overall outcome has not been demonstrated. Experimentally, pretreatment with flunixin meglumine was effective in preventing endotoxin-induced PGF secretion and abortion[27] but is ineffective at modulation of uterine PGF production and prevention of endotoxin-induced abortion when given 1 or 2 hours after endotoxin administration and, therefore, cannot be considered reliable therapy for conditions that are likely to result in increased uterine PGF secretion.[28] Pentoxiphylline (8.5 mg/kg every 12 hours PO) can be added to the treatment regimen for its potential inhibition of proinflammatory cytokines.[29,30] Tocolytics may be useful in cases of endotoxemia or placentitis. Clenbuterol, due to its β_2-adrenergic agonist effect, is capable of inducing uterine relaxation. Experimental evidence suggests clenbuterol is ineffective at delaying parturition, at least in normally foaling mares, when given once a day.[31] Clenbuterol can be given to typical sized mares as an IV bolus (300 μg), which will provide uterine relaxation for 2 hours, or incorporated into an IV drip or for mares at high risk for impending abortion.[32] Low-dose aspirin therapy, as used in horses with laminitis, might provide protection for placental circulation by inhibiting platelet aggregation and vasoconstriction.[33] Synthetic progestins (altrenogest 0.088 mg/kg PO every 24 hours) may be used empirically to induce uterine quiescence and reduce PGF release[34] and for its possible effect of blocking cytokines.[35]

Chronic placental separation may occur concomitantly with placentitis and frequently involves a relatively small area in the vicinity of the cervical star. If the fetus is mature, induction of parturition should be performed. If the fetus is not mature, a mare with placental separation is treated as one with placentitis. In the future, protocols may be developed to induce precocious maturation of fetal foals by injecting the mare with adrenocorticotropin hormone (ACTH) or by intrafetal or intrauterine injection of betamethasone, ACTH, or corticotropin-releasing hormone (CRH).

MANAGEMENT OF MATERNAL DISORDERS

Although several maternal disorders may have an adverse influence on pregnancy, the equine fetus is amazingly resilient in the face of maternal disease. Some examples of maternal conditions that may potentially threaten fetal well-being include colic, endotoxemia, proximal enteritis, colitis, peritonitis, pleuritis, laminitis, chronic painful musculoskeletal disorders, fescue endophyte toxicosis, abdominal tunic hernia, uterine artery rupture, and dystocia. In general, a single episode of uncomplicated colic has no observable effect on the fetus. When colic is accompanied by endotoxemia or requires surgical intervention, abortion is more likely. Endotoxemia appears to have the greatest direct effects on the fetus during the last 60 days of gestation.[36] Mild to moderate medical colic did not appear to have an effect on fetal survival, but severe medical colic cases, especially when accompanied by endotoxemia, have a poorer prognosis for fetal survival.[36] In a retrospective analysis of 74 cases of surgical colic in pregnant mares, it was observed that the stage of gestation at initial examination, type of surgical lesion, duration of anesthesia, and degree of intraoperative hypoxia or hypotension was not associated with increased rate of abortion even though there was a 20% abortion rate overall.[36] However, severe intraoperative hypoxia (arterial oxygen pressure <80 mm Hg, repeatedly) during the last 60 days of gestation was associated with either abortion or delivery of severely compromised foals that failed to survive.[36] In early pregnancy (<60 days), endotoxemia may be associated with luteolysis and embryonic loss.[37] In mares experimentally infused with endotoxin, luteal activity was compromised within 9 hours.[37] Therapy for endotoxemia includes correction of the inciting cause, administration of cyclooxygenase inhibitors such as flunixin meglumine, and if the gestational age is less than 90 days, oral altrenogest.[35,38] Therapy can continue until the mare is greater than 90 days pregnant or endogenous production of progestins can be demonstrated.

When surgical intervention for colic is required in pregnant mares it should be performed as soon as possible after the decision is made. For mares undergoing surgery during the last 60 days of gestation, arterial oxygen should be maintained at 80 mm Hg or greater and adequate perfusion pressure maintained during anesthesia. Although no particular anesthetic protocol has been shown to be clearly superior, it has been recommended that intravenous anesthesia using a combination of detomidine, ketamine, and guaifenesin with oxygen administered via tracheal catheter be used and that anesthesia time be less that 2.5 hours. Alternatively, propofol, although very costly, may be safely used.

Pregnant mares presented for gastrointestinal disturbances are often fasted, a practice that may adversely affect pregnancy. Fasting mares for 24 hours caused a surge in PGFM concentrations as well as a dramatic decline in glucose and an increase in free fatty-acid con-

centrations in peripheral plasma.[39] Elevations in PGFM concentrations may be associated with adverse effects on uterine blood flow and myometrial activity, and prostaglandins may stimulate oxytocin release and the onset of uterine contractions. Refeeding the mares or administering glucose IV induces a rapid decline in PGFM concentrations.

Uterine artery rupture is usually associated with parturition but occasionally occurs prepartum. If hemorrhage is confined within the broad ligament control of pain is the mainstay of therapy. If hemorrhage escapes the confines of the broad ligament, the mare is likely to die acutely from hypovolemia. Therapy includes correction of hypovolemia by administration of fluids or whole blood, anticoagulant therapy, and pain management.

Hernias or rupture of the abdominal tunic are an occasional cause of high-risk pregnancy with rupture of the prepubic tendon the most common form. When a mare is observed to have a cranial displacement of the udder, it is an indication of previous prepubic tendon rupture. Pregnancy in these mares may either be aborted or an attempt made to manage the pregnancy to term, realizing that further damage may result and rebreeding would be very risky. The mare should be confined, given analgesics as needed, and have supportive abdominal wraps applied. Parturition should be induced when the criteria of fetal and maternal readiness are met so that delivery can be assisted.

SUMMARY AND CONCLUSIONS

High-risk pregnancy in the mare can result from a wide variety of maternal and fetal conditions. In nearly all cases, maintenance of the foal in the uterine environment is preferable to premature delivery of a compromised foal. Fetal maturation proceeds rapidly during the last 5 to 7 days of gestation, but the maturation process may actually begin about a month prior to parturition. Foals do have the ability to respond to intrauterine stress by maturing precociously in utero and may be delivered as viable foals after this process has taken place. Unlike other species, exogenous corticosteroids do not induce precocious fetal maturation in foals so reliance on the natural process generally results in improved likelihood of a favorable outcome.

Ultrasonography has greatly improved our ability to diagnose and monitor conditions that may compromise pregnancy in late-term mares. Development of fetal biophysical profile parameters has permitted clinicians to quantify fetal development and offer a prognosis based on repeatable measurements.[4,5] Evaluation of fetal fluids is a relatively new development in equine fetal perinatology and holds promise for more precise diagnostic and therapeutic intervention.[17,18] Assessment of readiness-for-birth using endocrine testing and prepartum mammary secretion electrolyte concentrations has allowed improved prediction of the likelihood of extrauterine survival.

Therapeutic intervention strategies are available to treat conditions such as placentitis that will permit maturation of a fetus to the point where extrauterine survival is possible. Pharmacologic compounds including hormones, tocolytics, antibiotics, antiinflammatory agents, and mediators of vascular permeability and cytokine activity all have a role in management of selected cases of high-risk pregnancy.

CHAPTER 27
Induced Abortion

AMANDA C. RAGON

In mares, elective termination of pregnancy is performed for several reasons, including mismating, change in ownership, age or health of dam, abnormal gestation, and twin pregnancy. Many methods may be used to induce abortion, and care should be taken to select a procedure that is safe and effective and that minimizes damage to the mare's reproductive tract and future breeding health. When terminating pregnancy, the clinician should consider the following factors: stage of gestation, presence of endometrial cups, expected time of return to estrus, presence of twin fetuses, and physical condition of the mare. In every case of elective abortion, the patient should be re-examined at an appropriate time after the procedure to ensure that pregnancy has been effectively terminated.

INDUCED ABORTION BEFORE FUNCTIONAL ENDOMETRIAL CUPS (DAYS 0–33)

The earlier pregnancy termination is attempted, the more likely it is to be safe and successful; however, no method has been shown to reliably terminate pregnancy before

CHAPTER 27
Induced Abortion

AMANDA C. RAGON

In mares, elective termination of pregnancy is performed for several reasons, including mismating, change in ownership, age or health of dam, abnormal gestation, and twin pregnancy. Many methods may be used to induce abortion, and care should be taken to select a procedure that is safe and effective and that minimizes damage to the mare's reproductive tract and future breeding health. When terminating pregnancy, the clinician should consider the following factors: stage of gestation, presence of endometrial cups, expected time of return to estrus, presence of twin fetuses, and physical condition of the mare. In every case of elective abortion, the patient should be re-examined at an appropriate time after the procedure to ensure that pregnancy has been effectively terminated.

INDUCED ABORTION BEFORE FUNCTIONAL ENDOMETRIAL CUPS (DAYS 0–33)

The earlier pregnancy termination is attempted, the more likely it is to be safe and successful; however, no method has been shown to reliably terminate pregnancy before

day 5 after ovulation.[1,2] After the corpus luteum (CL) is fully functional (days 5–6 after ovulation), elective abortion is easily accomplished by causing luteolysis. The simplest method is intramuscular injection of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) or a $PGF_{2\alpha}$ analogue.[1–4] The two products commonly used in mares, dinoprost tromethamine and cloprostenol, have similar efficacy, but the common side effects of sweating and mild colic are avoided with the administration of cloprostenol. Before maternal recognition of pregnancy (approximately by days 12–14) a single injection of either product (10 mg of dinoprost or 500 µg of cloprostenol) has been shown to cause lysis of the CL and effectively terminate pregnancy. After pregnancy recognition, two or more consecutive injections may be necessary to lyse diestrual, or secondary, corpora lutea.[3] Mares can be expected to return to estrus within 3 to 5 days.

Intrauterine infusion or lavage performed after day 6 also terminates pregnancy in mares. Abortion is likely caused by embryotoxic effects or release of endogenous $PGF_{2\alpha}$ as a result of cervical and uterine manipulations.[1] Sterile saline (2–3 L divided into 500- to 1000-ml aliquots) is the preferred solution for uterine lavage because it is relatively nonirritating, but infusions of Lugol's solution, dilute povidone-iodine, or nitrofurazone have been used successfully. These antiseptic solutions are potentially irritating to the genital tract and should be used with care. Chlorhexidine solution should not be used for intrauterine infusion.[5] Any technique that necessitates invasion of the cervix can result in bacterial contamination and endometritis.

Manual crushing of the conceptus can be performed easily between days 16 and 25 after ovulation. After day 25, this technique is more difficult and less efficacious. Transvaginal ultrasound-guided pregnancy reduction has been successful in terminating pregnancies between days 20 and 45.[6] Ovariectomy, although not a practical technique, consistently results in abortion during this period.[3]

INDUCED ABORTION WHILE ENDOMETRIAL CUPS ARE FUNCTIONAL (DAYS 34–120)

During days 34 to 120 of gestation, mares may not return to normal estrous cycles after pregnancy termination. Multiple doses of $PGF_{2\alpha}$ or an analogue have been shown to effectively terminate pregnancy in several studies.[5–7] Mares injected once or twice daily aborted 3 to 5 days after treatment.

Intrauterine infusion or lavage can also be employed to induce abortion, but it is more successful prior to chorioallantoic attachment to the endometrium (at approximately 80 days of gestation).[1,4] After attachment, manual invasion of the cervix, rupture of the chorioallantois, and manual extraction of the fetus and membranes are more expeditious.[4] A sterile saline lavage, following manual abortion, aids in removal of any remaining fetal membranes, blood clots, or fibrin tags.

Manual crushing of the conceptus after day 34 is technically difficult because of the size of the vesicle and the position of the uterus in some mares. Transvaginal ultrasound-guided allantocentesis, with aspiration of allantoic fluid, has successfully terminated pregnancy between days 40 and 65.[6,9,10]

INDUCED ABORTION AFTER 4 MONTHS OF GESTATION

Elective termination of pregnancy beyond the first trimester may be complicated by dystocia, retained placenta, and trauma to the genital tract. A variety of techniques are described in the literature, but there appears to be no consensus on which technique is the most efficacious.

Multiple injections of $PGF_{2\alpha}$ have resulted in abortions in mares between 100 and 245 days of gestation.[3,11] Abortion was induced using $PGF_{2\alpha}$ in two mares at 150 days' gestation; abortion occurred 37 hours after treatment in one mare and after 61 hours after treatment in the other.

A more reliable technique for the termination of late pregnancies is manual disruption of the fetal membranes and removal of the fetus. This is more easily accomplished if cervical dilation is enhanced by methods other than manual distention. Success has been reported with estrogen treatment (6–10 mg estradiol) 24 hours prior to induction of abortion.[4,11] Cervical dilation can also be achieved using intracervical application of PGE_2.[12] Oxytocin treatment (especially following estradiol therapy) may hasten the expulsion of the fetus and fetal membranes. Infusions of large volumes of saline have been recommended by many authors to aide myometrial contractions and expulsion of the fetal membranes.[1–4]

Transabdominal ultrasound-guided fetal cardiac puncture, followed by injection of potassium chloride, has been successful in reducing twin pregnancies in midgestation[13] and could be used for single pregnancy termination.

Intra-allantoic injection of dexamethasone (administered transcervically) induced abortion within 3 days in treated mares.[14] In contrast to other species, systemic dexamethasone (dose of 10 to 80 mg administered parenterally for 4 consecutive days) does not appear to cause abortion in mares.[15]

CHAPTER 28

Surgical Correction of Abnormalities of the Female Reproductive Organs

JEAN-PIERRE HELD and JIM BLACKFORD

SURGICAL CORRECTIONS FOR ABNORMAL PERINEAL CONFORMATION

Types of Abnormal Conformations

Uterine contamination following a breakdown of the anatomic barriers that protect the uterine environment is a common cause of subfertility in mares. In normal mares, uterine contamination is prevented by three anatomic structures: vulvar lips, vulvovaginal sphincter, and cervix.

Vulvar Lips

Ideally, over 80% of the labia should lie in a vertical plane below the ischiadic arch of the pelvis. The Caslick index (La, where L = vulvar length and a = the angle of declination of the vulvar lips) has been developed to enable objective evaluation of the need for corrective surgery.[1] Mares with an index above 100 may benefit from surgery and those with an index above 150 should definitely show improved fertility following surgery (Fig. 28-1).

Vulvovaginal Sphincter

The tightest seal is formed at the junction of the vestibule and the caudal vagina, near the urethral opening. Integrity of the seal depends on the paravaginal connective tissue and a thin muscle layer.

Cervix

Infertility may result due to loss of cervical integrity, with infections manifested as a secondary complication. The cervix represents the last protective barrier between the uterus and the caudal portion of the tubular reproductive tract. A physiologic loss of integrity occurs during estrus, when the cervix dilates under the effects of estrogen.

CHAPTER 28

Surgical Correction of Abnormalities of the Female Reproductive Organs

JEAN-PIERRE HELD and JIM BLACKFORD

SURGICAL CORRECTIONS FOR ABNORMAL PERINEAL CONFORMATION

Types of Abnormal Conformations

Uterine contamination following a breakdown of the anatomic barriers that protect the uterine environment is a common cause of subfertility in mares. In normal mares, uterine contamination is prevented by three anatomic structures: vulvar lips, vulvovaginal sphincter, and cervix.

Vulvar Lips

Ideally, over 80% of the labia should lie in a vertical plane below the ischiadic arch of the pelvis. The Caslick index (La, where L = vulvar length and a = the angle of declination of the vulvar lips) has been developed to enable objective evaluation of the need for corrective surgery.[1] Mares with an index above 100 may benefit from surgery and those with an index above 150 should definitely show improved fertility following surgery (Fig. 28-1).

Vulvovaginal Sphincter

The tightest seal is formed at the junction of the vestibule and the caudal vagina, near the urethral opening. Integrity of the seal depends on the paravaginal connective tissue and a thin muscle layer.

Cervix

Infertility may result due to loss of cervical integrity, with infections manifested as a secondary complication. The cervix represents the last protective barrier between the uterus and the caudal portion of the tubular reproductive tract. A physiologic loss of integrity occurs during estrus, when the cervix dilates under the effects of estrogen.

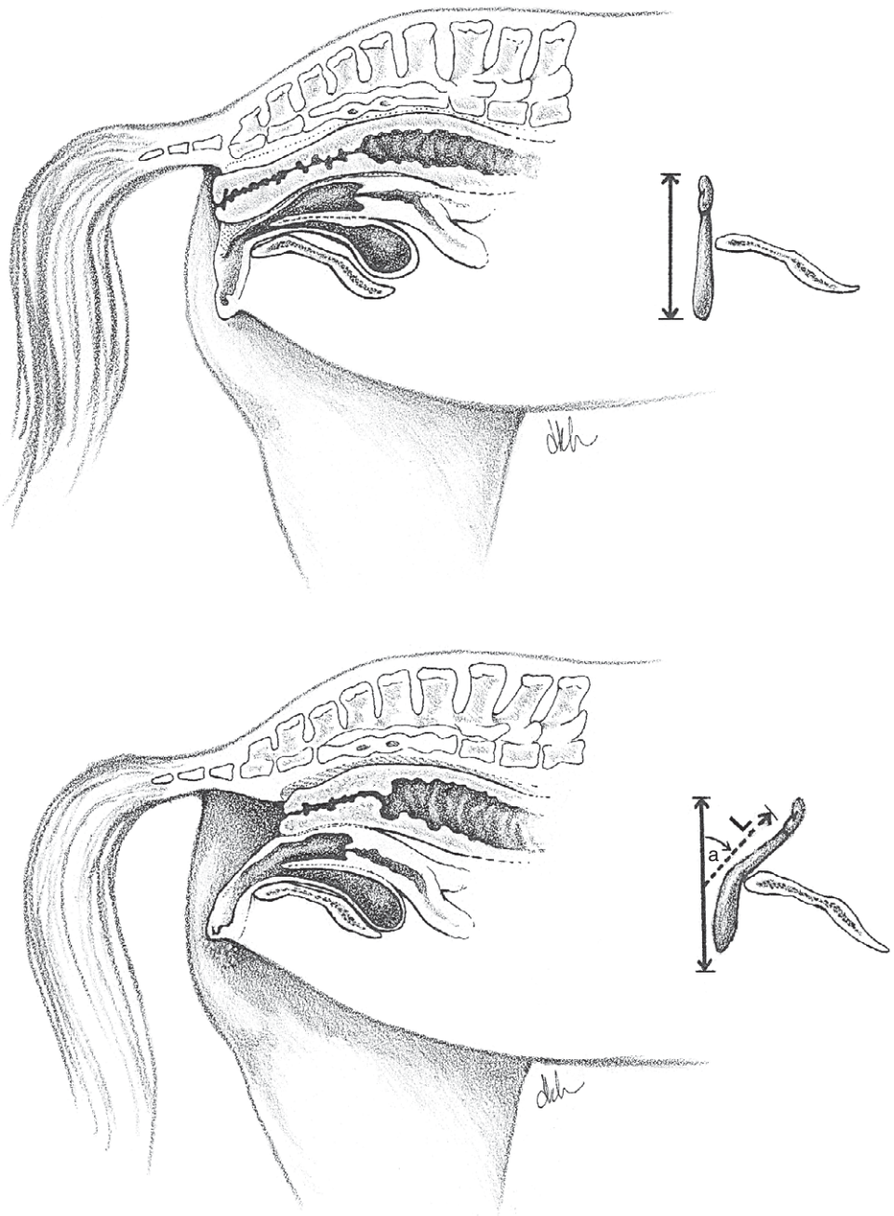

Fig. 28-1 Caslick index determination. *Upper,* normal conformation. *Lower,* abnormal conformation.

Etiology of Poor Perineal Conformation

Dorsal displacement of the vulvar lips in relation to the ischiadic arch predisposes to pneumovagina, particularly in multiparous mares. With each pregnancy, the labia are pulled further dorsocranial, predisposing to aspiration of air and fecal contaminants into the vagina. Effective vulvar length also increases with age. *Poor body condition* reduces the amount of paravaginal fat and paravaginal muscle tone, drawing the anus cranially, thus predisposing to windsucking. *Dystocia* may stretch the perineal body, thereby disrupting integrity of the cranial vaginal seal. Perineal lacerations that disrupt the integrity of the vaginal wall and paravaginal tissue increase the risk of pneumovagina. Multiparous mares with poor vulvovaginal sphincter tone may aspirate air in the absence of a recessed anus, particularly during estrus. *Cribbing* mares with marginally normal perineal conformation may need episioplasty because negative pressure created in the abdominal cavity during cribbing pulls the anal sphincter cranially, predisposing to windsucking.

Surgical Procedures

Episioplasty (Caslick's Surgery)

Episioplasty[2] is the surgical procedure used to reduce the length of the vulvar opening. Following is a summary of the steps involved:

1. Determine the amount of vulvar closure required: A finger should be introduced into the dorsal commissure of the vulva and moved ventrally until the ischiadic arch is palpated. The vulvar lips should be closed to a point 1 to 2 cm ventral to that point, leaving a 3- to 4-cm opening.
2. Anesthesia of the vulvar edges: A 22-gauge needle is introduced along the planned incision line at the mucocutaneous junction of the labia. Lidocaine or Carbocaine is deposited while the needle is withdrawn. Approximately 5 to 10 ml of anesthetic solution is needed on each side. Special attention should be given to adequately block the tissue proximal to the dorsal commissure.
3. Excision of vulvar lip edges: After placing traction on the vulvar lips in a ventral direction, scissors are used to remove a narrow strip of tissue at the mucocutaneous junction. No more than 0.5 cm of tissue should be removed (Fig. 28-2, *A*).
4. Suture the cut edges: Absorbable suture material should be used to avoid the need for suture removal. A continuous or interrupted suture pattern can be used to appose the tissues (Fig. 28-2, *B*).
5. Tetanus prophylaxis should be administered in nonimmunized mares. In instances in which a mare is to be mated after undergoing an episioplasty, a breeding stitch may be indicated. This is a simple interrupted suture of 0.6 mm polypropylene loosely placed 0.5 to 1 cm dorsal to the ventral edge of the sutured lips. Its purpose is to prevent separation of the vulvar labia during intromission. If the breeding stitch is placed too far ventrally, it may cause abrasions to the stallion's penis (Fig. 28-2, *C*).

Episiotomy

Owners should be instructed to have the episioplasty opened approximately 1 month prior to foaling, at the time the mare is vaccinated and dewormed. Opening of the episioplasty is accomplished by incising the sutured vulvar lips up to the dorsal commissure. A local anesthetic may be necessary.

Perineoplasty

In mares that have a very loose vulvovaginal sphincter along with a cranially displaced vulva, episioplasty may not prevent pneumovagina. For these mares, perineoplasty may be performed by resecting a portion of the dorsal vaginal wall and apposing the denuded tissue, resulting in narrowing of the caudal vagina.[3]

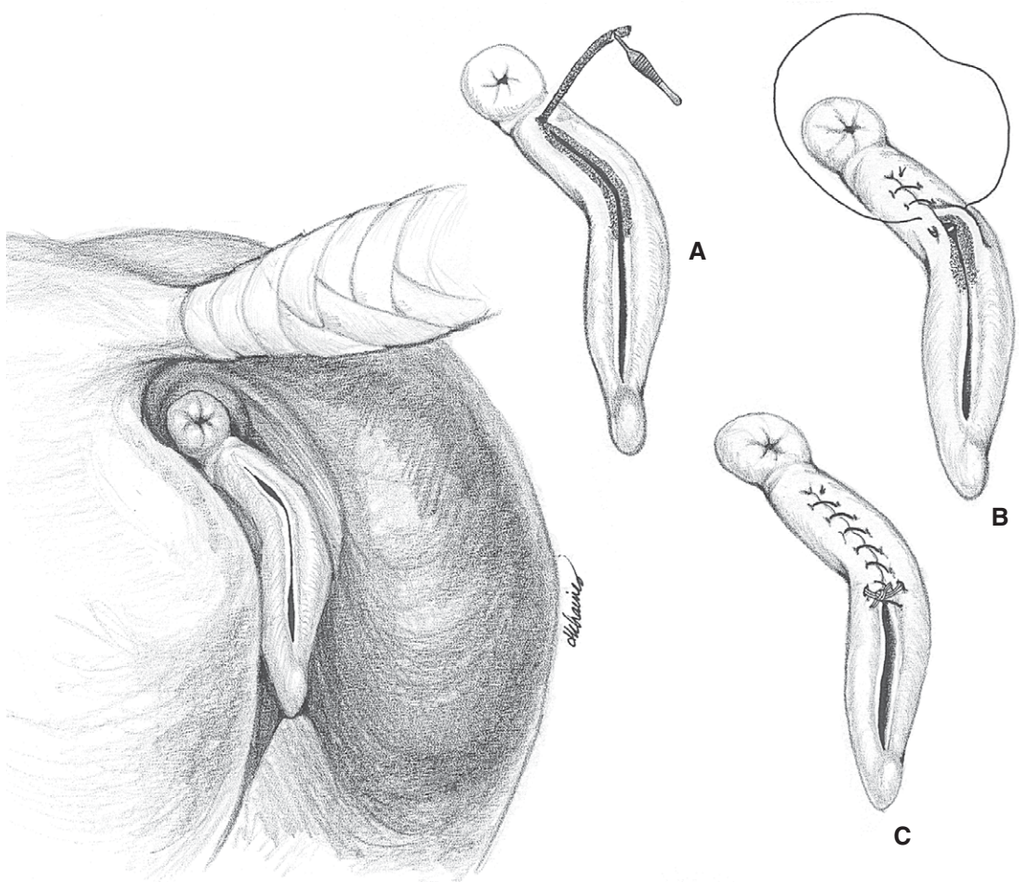

Fig. 28-2 Episioplasty.

1. Analgesia: Epidural anesthesia is preferred over local infiltration due to the large surgical area.
2. Exposure of the surgical site: Adequate exposure may be achieved with stay sutures or towel clamps placed at the 10, 12, and 2 o'clock positions of the vulvar opening.
3. Tissue resection: A triangle-shaped section of mucosa is resected from the dorsal vaginal wall. The base of the triangle is at the mucocutaneous junction of the vulvar lips, at the 10 and 2 o'clock positions. The apex lies on the dorsal midline, above the urethral opening (Fig. 28-3, *A*).
4. Perineal sutures: After the towel clamps are removed, evenly spaced horizontal mattress sutures (No. 1 or 2 polypropylene) are used to appose the edges of the vaginal mucosa, narrowing the caudal vagina. To achieve even tension along the suture line and prevent tissue necrosis, rubber tubing can be used under the exposed suture loops on the perineum (Fig. 28-3, *B*). The perineal and vulvar skin is closed with a No. 0 polypropylene suture in a simple continuous pattern (Fig. 28-3, *C*).

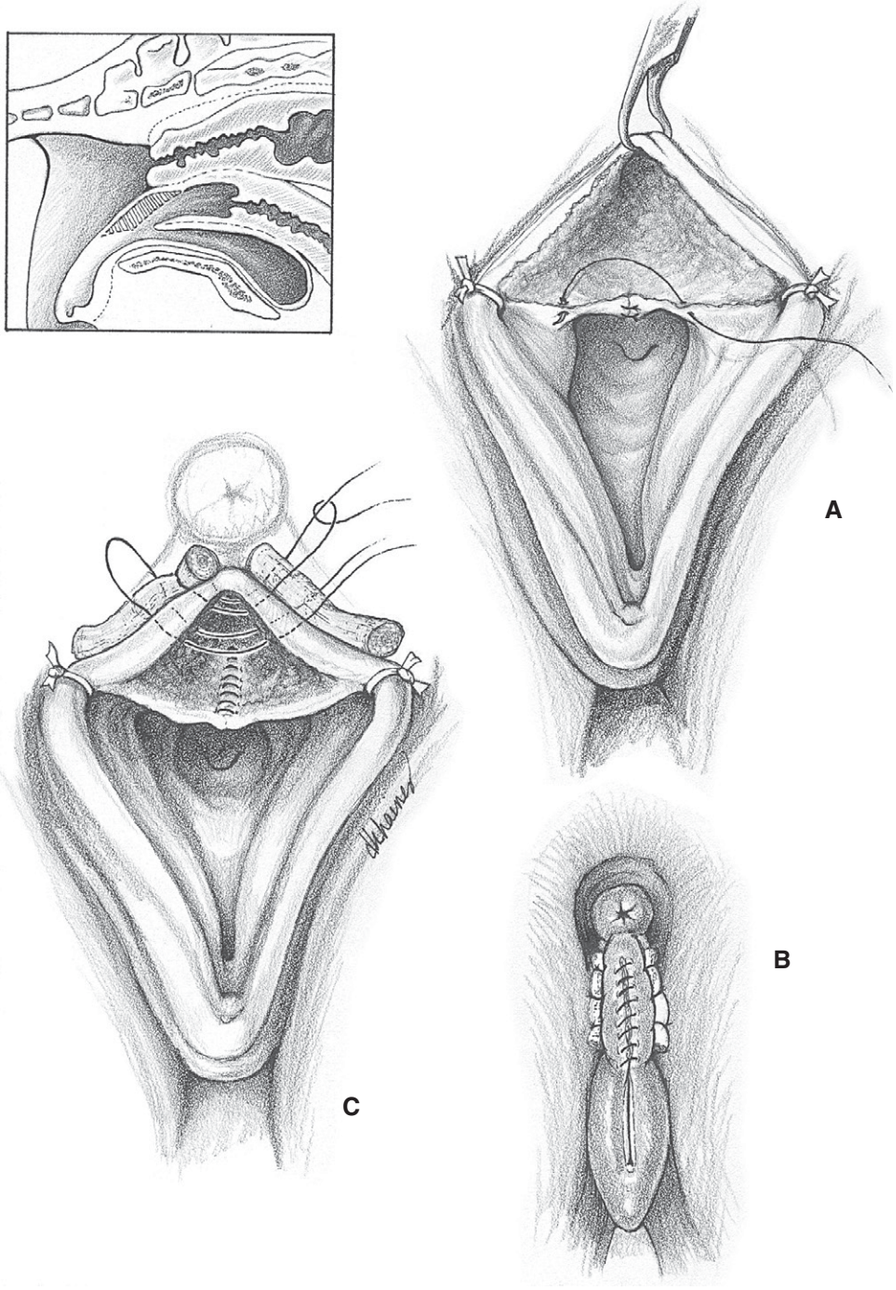

Fig. 28-3 Perineoplasty.

5. Suture removal: All sutures should be removed 10 to 14 days after surgery.

SURGICAL CORRECTION OF URINE POOLING IN THE MARE

Urine pooling (vesicovaginal reflux) is a well-known cause of infertility. It is commonly encountered in multiparous mares because of relaxation of the ovarian and uterine ligaments. Other predisposing factors for urine pooling are weight loss, abnormal perineal conformation (recessed anus), and the combination of edema and relaxation of the reproductive tract that occurs during estrus or the early postpartum period. Mares that experience urine pooling due to poor perineal conformation should have Caslick's surgery. Mares may pool urine only during estrus and suspect mares should be examined during standing heat. Several techniques have been described for surgical correction of the condition. The goal is to extend the existing urethra caudally. Three surgical approaches are described here; however, surgical corrections often fail postoperatively and must be repeated.

Presurgical Preparation

The mare is restrained in stocks, with or without tranquilization. Analgesia is achieved with epidural anesthesia. The rectum is emptied, and the tail is wrapped and tied out of the way with a rope attached around the mare's neck. The vagina is cleaned with sterile lactated Ringer's solution.

Surgical Procedures

Posterior Fixation of Transverse Fold

This technique is among the first described to extend the urethra.[4] The urethral fold is pulled caudally, and its edges trimmed and sutured to incisions in the vaginal wall with No. 0 absorbable material. In most cases, caudal traction on the fold creates excessive tension and results in failure of the suture line. Additionally, it is difficult to achieve good apposition between the edges of freshened urethral fold and the vaginal wall (Fig. 28-4).

Urethral Extension (Shires Technique)[5]

After placement of a 30 French Foley catheter in the urethra (Fig. 28-5, *A*), interrupted horizontal mattress sutures (No. 0 synthetic absorbable material) are placed in the vaginal mucosa, sparing the catheter. As the sutures are tightened, folds of mucosa close over the catheter. Adequate mucosa must be present on the formed crest to allow mucosal tissue to be trimmed. Following excision, a simple continuous suture pattern is used to appose the cut edges. After completion of the procedure, the catheter is removed (Fig. 28-5, *B* to *F*).

Urethral Extension (McKinnon Technique)

With this technique, the urethra is extended using vaginal mucosa. In contrast to other techniques, the denuded tissue present after forming the tunnel is not oversewn but is allowed to heal by second intention (Fig. 28-6, *A* to *D*).[6]

Postoperative Management

When a urethral catheter has been placed, it should be removed upon completion of the surgery because its presence may lead to excessive straining by the mare. Catheters tend to become rapidly obstructed by urinary crystals. Postoperative treatment should include administration of procaine penicillin G (20,000 IU/kg) for 5 days and tetanus prophylaxis. Mares should not be bred for at least 3 weeks. Thereafter, breeding management should include artificial insemination or hand breeding to prevent injury to the extended urethral fold during intromission.

PERINEAL LACERATION REPAIR IN THE MARE

Perineal lacerations associated with parturition represent a significant cause of infertility in mares. Lacerations are most common in primiparous mares, and the injury appears to be more prevalent in mares than in other species. This may be because of the rapid onset and completion of parturition in the horse. Perineal lacerations are divided into four categories:

First degree: Tear of the vulvar lips only.
Second degree: Tear of the perineal body including the connective tissue and paravaginal muscle at the level of the vulvovaginal sphincter.
Third degree: Cloaca formation from a tear extending through the rectovaginal shelf, perineal body, anal sphincter, and vulvar lips.
Rectovaginal fistula: Communication between rectum and vagina without disruption of the perineal body, anal sphincter, or vulvar lips.

Repair of First-Degree Lacerations

Vulvar lip lacerations may occur from insufficient opening of an episioplasty before foaling or overstretching during foaling. When these lacerations are limited to the dorsal commissure, adequate repair is usually attained with an episioplasty to prevent windsucking and pneumovagina.

Repair of Second-Degree Lacerations

Tears involving the perineal body, including the vulvovaginal sphincter, may predispose to urine pooling, pneumovagina or both. These tears require surgical repair of both the perineal body and vulvar lips. In addition, urethral extension may be required to correct pooling of urine in the cranial vagina.

Third-Degree Lacerations and Rectovaginal Fistulae

Presurgical Management

Immediate repair of third-degree lacerations is not recommended. Edema and contaminated and devitalized tissue make immediate repair difficult, if not impossible. The initial injury may require 3 to 6 weeks to heal. Mares

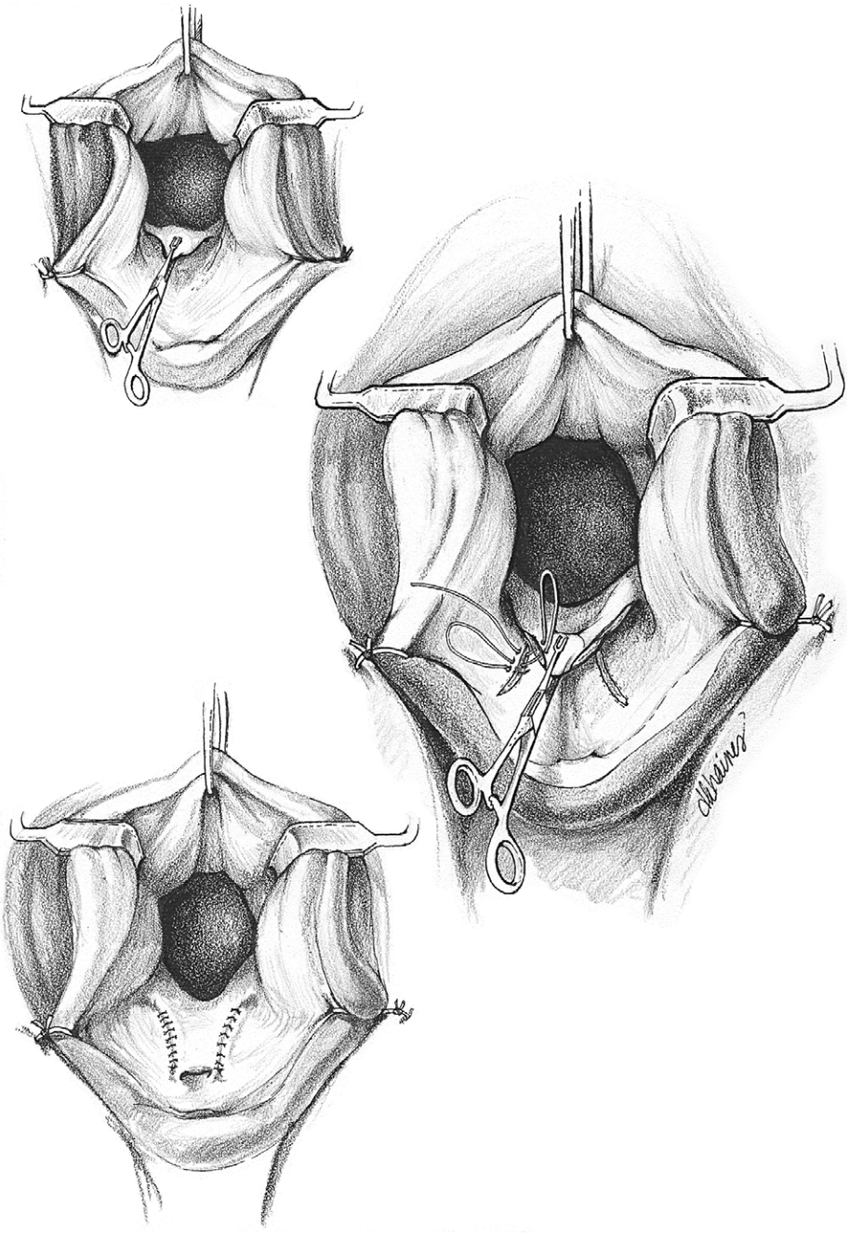

Fig. 28-4 Posterior fixation of transverse fold.

that deliver a dead foal may be repaired at that time. In the case of delivery of a live foal, it is recommended to delay repair until the foal is weaned. Presurgical preparation is critical for a successful surgical repair.

Presurgical Dietary Management

Soft to pasty fecal consistency is critical to prevent suture dehiscence. Firm to normal fecal consistency places excessive tension on the suture lines and predisposes to dehiscence. Fluid feces increase the risk of introducing contaminants into the suture line, predisposing to rectovaginal fistulation. Ideally, feces should have a consistency similar to that of cattle, with no formed fecal balls. Several methods have been used to control fecal consistency. A lush pasture usually keeps feces soft but the quantity passed is high. When alfalfa pellets or complete feed pellets are fed, they should be soaked in hot water for approximately 6 hours, and mineral oil (2–4 L per feeding) should be mixed in the mash (if the mare tolerates it) or given by nasogastric tube. Some mares with very dry feces may respond favorably to magnesium sulfate (Epsom salt) or sodium sulfate (Glauber's salt). The latter is more palatable and, therefore, 100 to 200 g/day can be added to the mash. The use of cathartics is not recommended as they may cause fluid feces. During the 1- to 2-week period prior to surgery, bedding should be

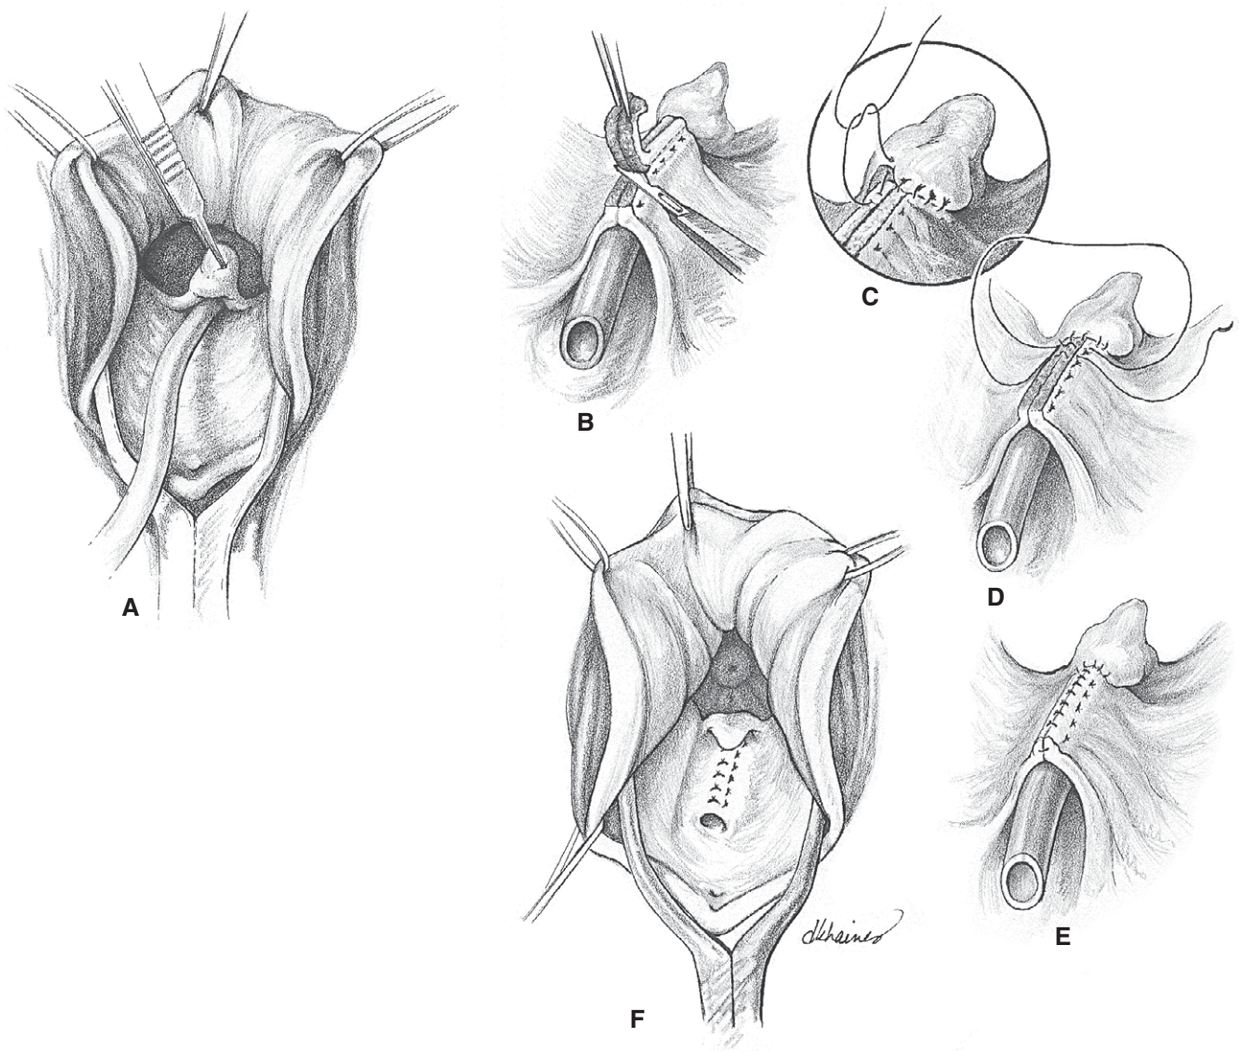

Fig. 28-5 **A,** Urinary catheter placement. **B** to **F,** Urethral extension (Shires technique).

avoided. Withholding feed for 2 days preceding surgery will reduce the chance of fecal contamination during surgery.

Repair of Third-Degree Lacerations

Mare preparation. The mare is placed in a stock, and epidural anesthesia is administered. The use of xylazine for epidural anesthesia is preferred because tone in the anal sphincter remains unaffected by this compound. Acepromazine maleate may be beneficial in fractious mares. Intravenous xylazine should be avoided because of its diuretic effect. The wrapped tail can either be tied overhead or pulled to the side and anchored around the patient's neck. Fecal material is manually removed from the rectum, and the perineal area is thoroughly scrubbed.

First-stage repair. Adequate exposure of the surgery site is achieved by vulvar retraction with stay sutures, towel clamps, or modified Finochietto retractors (Aanes Retractors, Scanlan Instruments, Englewood, Col.). Visualization is improved with a head lamp.

The initial surgery reconstructs the rectovaginal shelf. A No. 15 blade is used to incise and separate the rectovaginal shelf approximately 2 to 3 cm cranial to the defect (Fig. 28-7, *A*). This incision is continued caudally on each side of the common vault, following the margin between the rectal and vaginal mucosa. Scar tissue should not be removed, as tissue loss increases tension on the suture line. Dissection should continue through the mucosa, submucosa, and connective tissue. Care must be taken not to injure the deep (and large) paravaginal vessels.

The rectovaginal shelf is reconstructed using a modified Goetze[7] or Aanes[8] technique. A continuous horizontal mattress or simple continuous pattern is used to close the vaginal mucosa (Fig. 28-7, *B*). An interrupted 6-bite pattern is used for the rectal shelf (Fig. 28-7, *C*). Care must be taken to prevent placement of sutures through the rectal mucosa. The simple continuous vaginal suture can be either sutured first or alternated with the suture approximating the rectal shelf. The suture material used

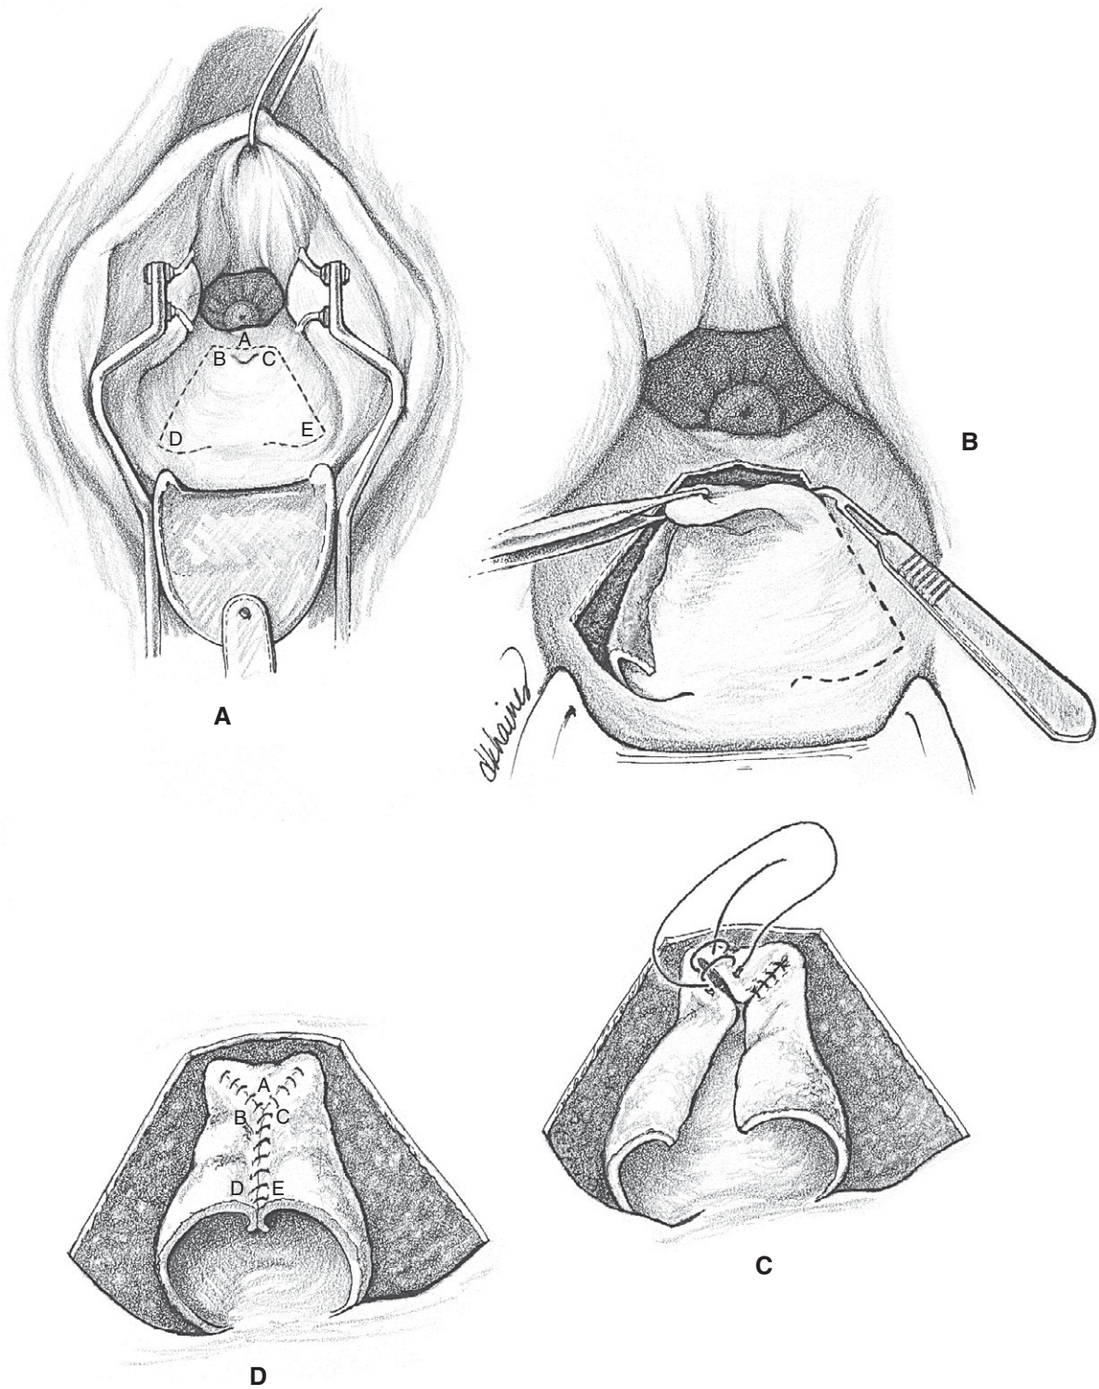

Fig. 28-6 Urethral extension (McKinnon technique).

can be either No. 1 polyglactin (Vicryl, Ethicon, Somerville, NJ) or polydioxanone (PDS, Ethicon, Somerville, NJ) for rectal shelf reconstruction and No. 0 polyglactin for the continuous vaginal suture. The perineal body is not repaired during the initial surgery so as to decrease tension on the sutures when the mare defecates. Diet management as described previously is of prime importance in the postoperative phase because excessive tension placed on the sutures may result in dehiscence. A broad-spectrum antibiotic should be given for 4 to 5 days and appropriate prophylaxis for tetanus is administered as indicated.

Second-stage repair. Three to 4 weeks following reconstruction of the rectal shelf, the perineal body is

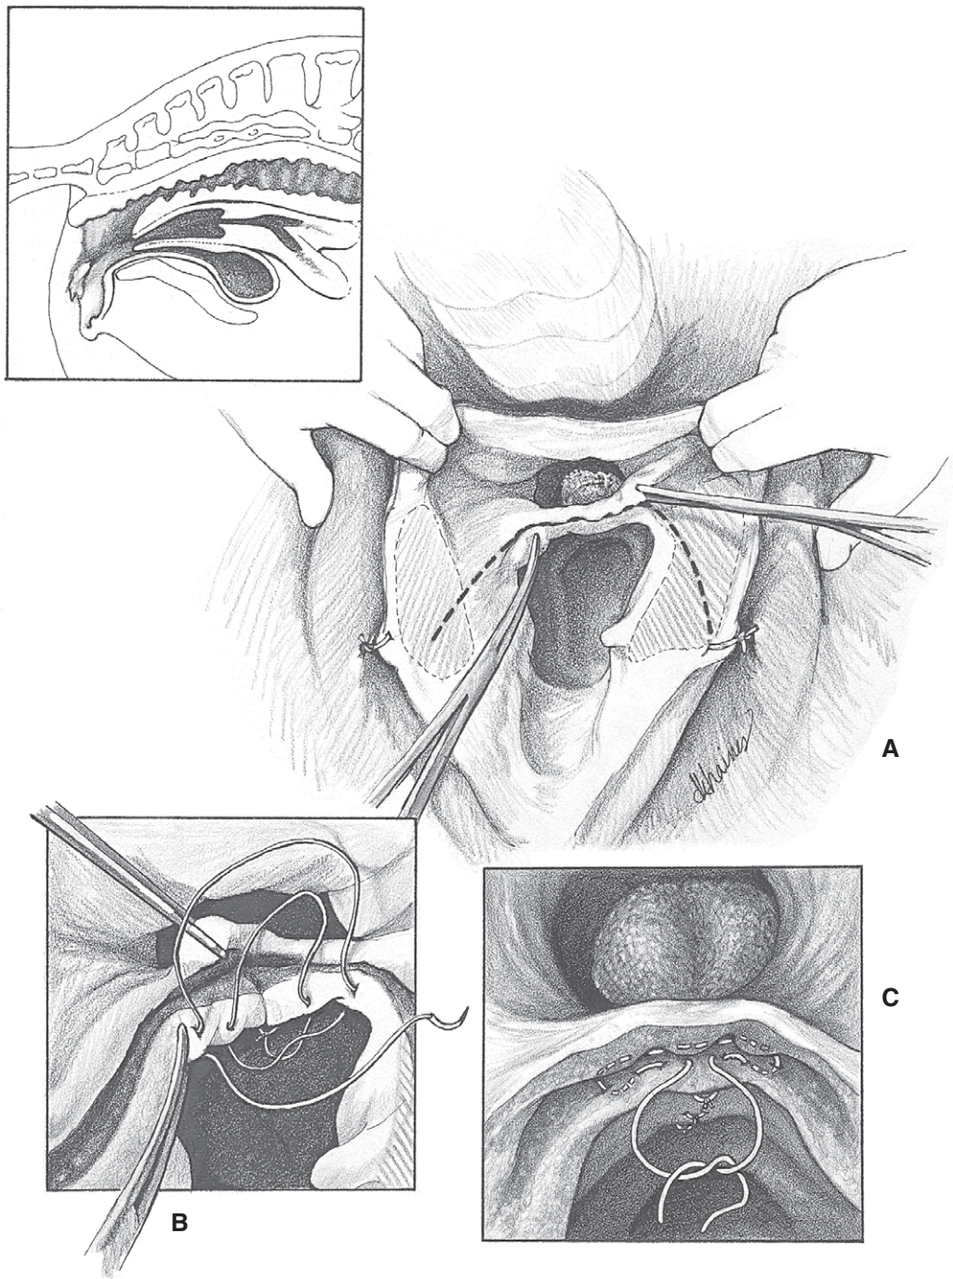

Fig. 28-7 Perineal laceration: first-stage repair.

repaired. The mare is prepared for surgery as described for the first stage. The procedure consists of removing the epithelium on the ventral aspect of the torn anal sphincter. The dorsal vulvar lips are trimmed as for Caslick's surgery. Deep sutures of No. 1 polyglactin or polydioxanone are placed to reconstruct the perineal body and anal sphincter. Special attention must be given to the amount of anal closure achieved. The skin of the vulva and the anus may be closed with either absorbable or nonabsorbable suture material.

Postoperative care. It is advisable to maintain the mare on the laxative diet described earlier for an additional 10 to 14 days.

Alternative Technique for Repair of Third-Degree Lacerations

In mares with substantial loss of perineal tissue, the operative technique described previously can result in excessive tension and predispose to dehiscence.

Surgical technique. The mare is prepared as described previously. A No. 15 blade is used to incise and separate the rectovaginal shelf. The rectal shelf is reconstructed with a simple continuous or interrupted Lembert pattern using No. 1 polyglactin or polydioxanone suture. The vaginal shelf is repaired with a simple continuous or continuous horizontal mattress pattern. The rectovaginal space is left exposed to granulate and heal by second intention. The perineal body and anal sphincter can be reconstructed as described previously. If wound dehiscence occurs, additional surgery is usually easier because of the increased amount of tissue present after healing.

Repair of Rectovaginal Fistulae

The traditional way to repair rectovaginal fistulae is to convert them to third-degree lacerations and repair them as described previously.[9] Retraction of the vulva is accomplished as previously described. The edges of the fistula (vaginal side) are prepared for closure as depicted in Figure 28-8. An interrupted vertical mattress or Lembert pattern is used for the deep layer of sutures that appose the rectal mucosa. An interrupted or continuous horizontal mattress pattern is used to close the vaginal mucosa. The suture material should be either No. 1 polyglactin or polydioxanone. Sufficient vaginal mucosa should be removed around the fistula to provide adequate tissue apposition when the everting rectal sutures are placed. The rectal mucosa should not be penetrated. Postoperative care is similar to that described for third-degree laceration repair. An alternate surgical method is to position the mare in dorsal recumbency under general anesthesia.[10]

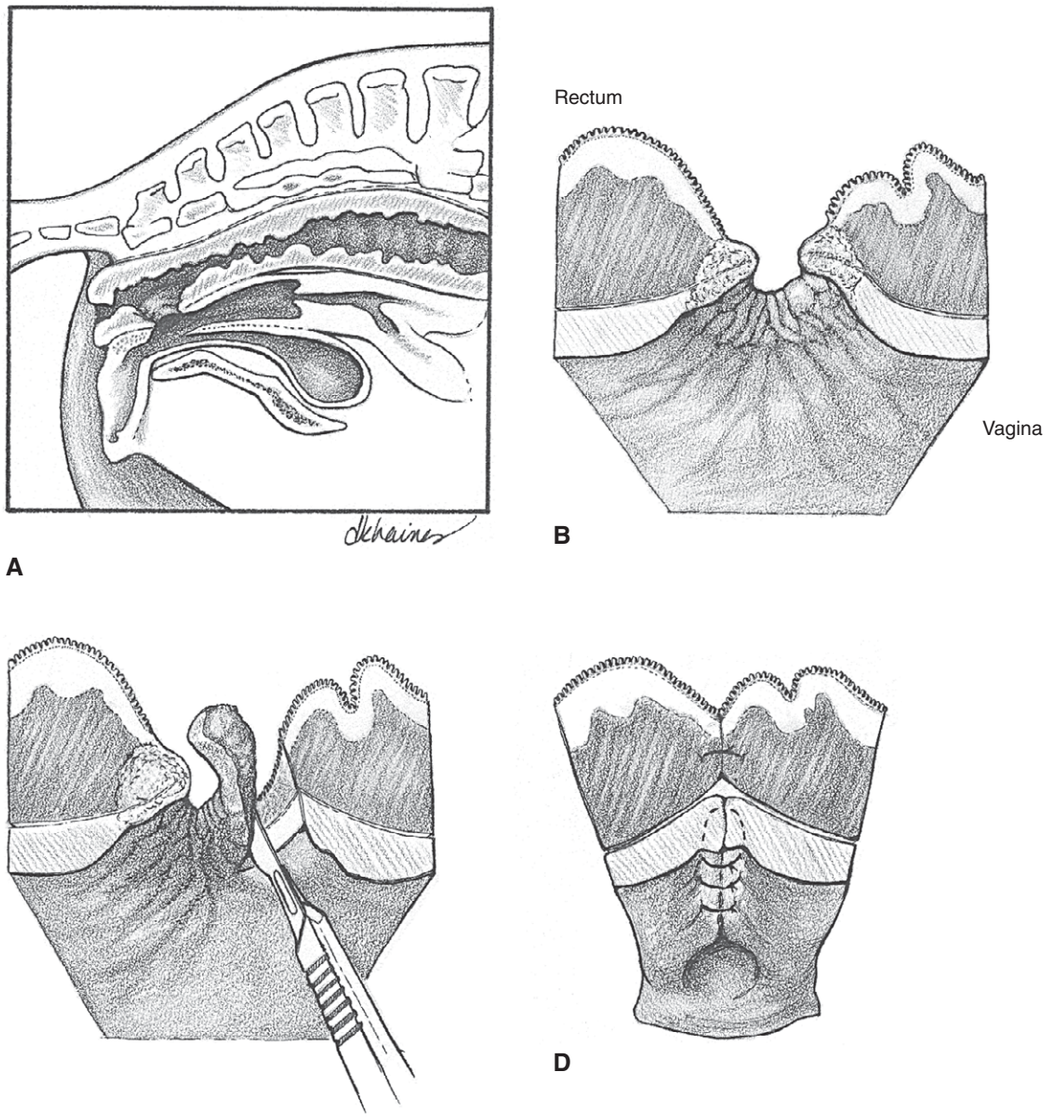

Fig. 28-8 Rectovaginal fistula repair.

The most important factors for successful repair of rectovaginal fistulae and third-degree lacerations are as follows:

1. Assessment of tissue available to build the rectovaginal shelf
2. Avoidance of removal of any tissue during shelf preparation
3. Avoidance of excessive tension on suture line
4. Building a shelf of adequate thickness
5. Adequate fecal consistency

OVARIECTOMY

Two common indications for ovariectomy in mares are neoplasms, such as granulosa cell tumors, and the desire for permanent control of objectionable behavior during estrus in performance horses. The three surgical approaches available are through the ventral midline, the flank, and the vaginal wall. Selection of the most appropriate approach depends on ovarian size.

Ventral Midline Approach

When ovaries are greater than 15 cm in diameter, a ventral midline approach is preferred because of the limited space available in the flank to exteriorize the ovary. Heavy, large tumors are generally easier to exteriorize through a ventral midline approach, as the weight of the mass stretches the ovarian pedicle.

Flank Approach

This technique is appropriate for unilateral removal of ovaries up to 15 cm in diameter. The combination of thick abdominal musculature and the small space between the last rib and the tuber coxae makes flank removal of large ovaries difficult. Care is taken to avoid the cecum if a right flank approach is used.

Preoperative Management

Food should be withheld from the mare for 24 to 36 hours to reduce distention of the gastrointestinal tract. The surgical site is clipped and shaved in a routine manner. The ventral border of the shaved area should allow extension of the incision if needed.[11]

Analgesia

The mare is restrained in stocks and sedated with detomidine hydrochloride (20 µg/kg IV). Analgesia of the surgical site is achieved using the inverted L block technique with 2% lidocaine solution.

Surgical Technique

A vertical or slightly oblique incision is started at a point centered between the tuber coxae and the last rib (Fig. 28-9). For ovaries greater than 10 cm in diameter or in mares with a small paralumbar fossa, the incision is initiated 10 to 15 cm ventrally, as in a low flank approach. The external oblique, internal oblique, and transverse abdominal muscles are manually separated from the center of the incision outwardly (grid pattern). With

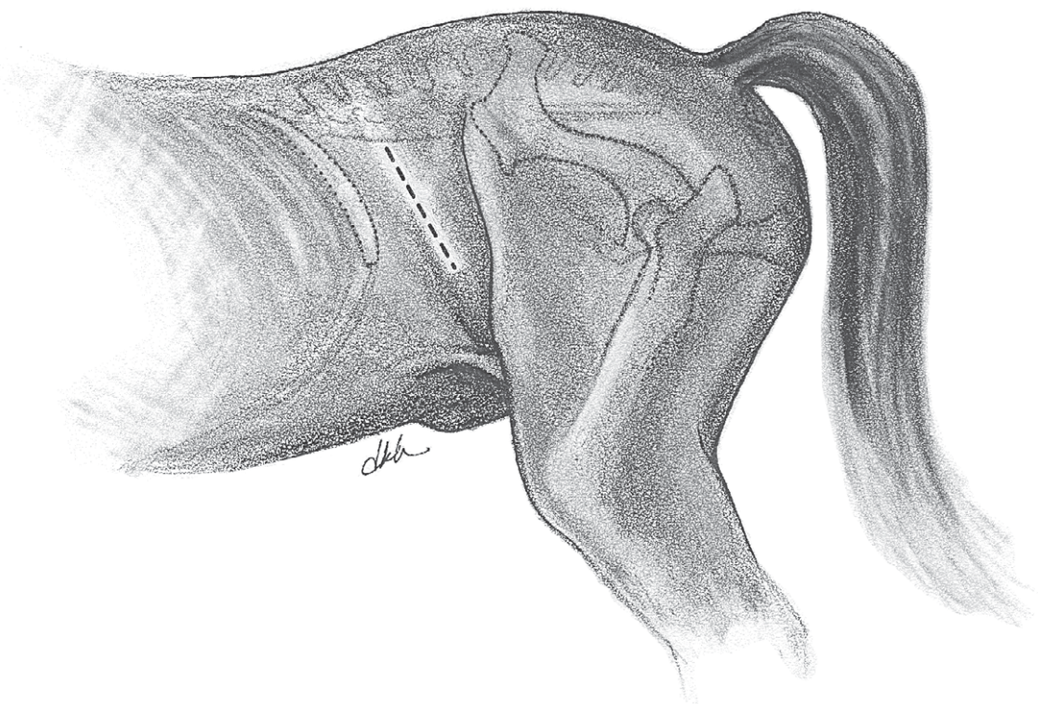

Fig. 28-9 Ovariectomy: flank approach.

larger ovaries (10–15 cm), part or all of these muscles may have to be transected. Before the abdomen is entered, the peritoneum is sprayed with 5 to 10 ml of lidocaine. This decreases the mare's discomfort when the peritoneum is penetrated. Blunt Mayo dissecting scissors are used to perforate the peritoneum, and the opening is enlarged manually. A gloved hand is extended in a caudal direction to locate the ovary. If it cannot be located, the uterus is palpated at the pelvic brim and the uterine horn followed laterally until the ovary is isolated. A lidocaine-soaked gauze sponge attached to umbilical tape (to prevent accidental loss of the sponge in the abdomen) is wrapped around the ovarian pedicle to desensitize it. This procedure is important to minimize pain that may cause the mare to collapse. The surgeon exteriorizes the ovary by placing fingers behind the ovary and pushing it through the incision. If this method fails, an assistant palpating transrectally can push the ovary toward the abdominal incision, enabling the surgeon to place one or two nylon stay sutures into the tunica albuginea of the ovary. The combination of rectally pushing the ovary toward the abdominal opening, and pulling on the nylon sutures helps in the exteriorization of larger ovaries. To prevent postoperative hemorrhage, enlarged vessels should be individually ligated and the ovarian pedicle transfixed with No. 2 polyglactin, avoiding injury to the larger blood vessels. This is particularly important for congested blood vessels associated with granulosa cell tumors. As the pedicle is transected, the stump should be observed for hemorrhage. When the ovarian ligament is short and does not allow sufficient exposure to ligate the vessels, a chain écraseur (Fig. 28-10) can be used as described later, or surgery can be postponed until the ovarian ligament is elongated enough under the tumor's weight to allow proper exteriorization. Alternatively, an automatic stapling device (TA-90, United States Surgical, Norwalk, Ct.) can be used to place two rows of stainless steel staples around the ovarian pedicle. Care must be taken to avoid inclusion of omentum or intestine during the stapling process and to evenly distribute the tissue in the stapling jaws.[12] If the tissue is too thick, the staples will not close properly. Individual muscle layers are apposed with a simple continuous pattern using No. 0 polyglactin or polydioxanone. The fascia of the external abdominal oblique muscle is carefully closed using an interrupted or simple continuous pattern of No. 1 polyglactin or polydioxanone. The skin is closed with nonabsorbable material. Because seromas at the surgery site are a frequent occurrence, a Penrose drain can be inserted under the skin sutures.

Postoperative Care

The use of a broad-spectrum antibiotic such as trimethoprim/sulfonamide for 4 days, and flunixin meglumine (Banamine, Schering Corporation, Kenilworth, NJ) for visceral pain is recommended. The Penrose drain should be removed 3 days postoperatively and the skin sutures removed 10 days postoperatively. The mare should be kept in a stall for 48 hours and observed for any signs of shock or depression that could indicate hemorrhage from the ovarian stump.

Colpotomy Approach

A colpotomy is the surgical approach of choice for bilateral ovariectomy of normal mares. To minimize the risk of postoperative hemorrhage, surgery is performed during seasonal anestrus. If surgery is done during the breeding season, the mare should be in diestrus.

Preoperative Care

Food is withheld from the mare for at least 24 hours. The rectum is evacuated, as a full rectum can be easily penetrated when the vaginal incision is made. The perineum is surgically prepared and the vagina flushed with 1% povidone-iodine solution (Betadine, Purdue Frederick Co, Norwalk, Ct.).

Analgesia

The mare is sedated and epidural anesthesia is performed to paralyze the tail and prevent straining during surgery. Pronounced analgesia is important because any unexpected reaction from the mare during the vaginal incision may result in injury to the rectum or iliac artery.

Surgical Technique

The vaginal lips are spread, which allows the vagina to dilate with air and facilitates the vaginal incision. Incision of the vaginal fornix is usually made at the 2 o'clock position, 2 to 4 cm dorsolateral to the cervix. This position is preferable to the 10 o'clock location because it provides more direct access to the right ovary, which is located further cranially. The incision is made with a No. 15 Bard-Parker blade (Becton-Dickinson, Rutherford, NJ) protected by the thumb and fingers, limiting forward thrust. Only the vaginal mucosa should be incised in

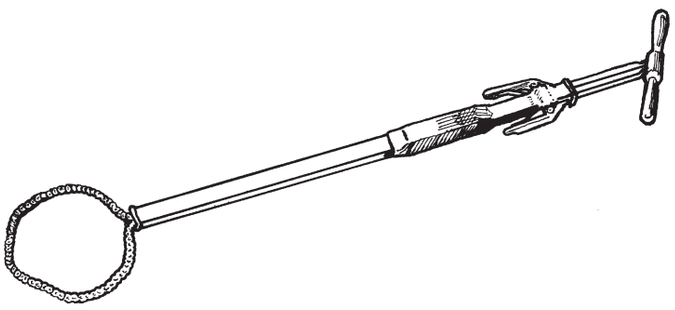

Fig. 28-10 Chain écraseur.

order to minimize trauma to the iliac artery and the rectum. Penetration of the abdomen is done with blunt dissecting scissors; the opening is then manually enlarged. Excessive pain is prevented by slowly stretching the peritoneal opening. After the ovary is located, ovarian ligament analgesia is performed as previously described. An écraseur (see Fig. 28-10) is introduced into the abdomen with the chain slightly slack, allowing one finger through the loop. The ovary is identified and the chain looped around the base of the ovary. Edges of the chain should be carefully examined for trapped intestine or mesentery after initial tightening but before crushing and cutting of tissue. An assistant then gradually tightens the chain while the surgeon holds the ovary. To prevent excessive pain and provide for optimal crushing, the chain is tightened one click every 10 to 15 seconds until the stump is transected. The instrument and the ovary are then removed. During the procedure it is important to keep the instrument as far cranial as possible, preventing tension on the ovarian ligament.

Postoperative Care

Antibiotics and flunixin meglumine are administered as previously described. The mare should be confined to a stall with daily exercise (hand walking), for 5 to 7 days. After that time, the combination of swollen tissues and wound contraction makes herniation of abdominal organs into the vagina unlikely.

CERVICAL LACERATION REPAIR[13]

Cervical lacerations occasionally occur, primarily during dystocias in older, multiparous mares or with inappropriate fetotomy techniques. Less commonly, these tears can occur during normal parturition. Examination of mares with suspected cervical tears should be made during diestrus. The variability in cervical relaxation present during estrus makes a determination of the extent of cervical muscle disruption difficult to determine. However, this relaxation is advantageous for the surgical procedure.

Diagnosis

A gloved hand is used to vaginally palpate the cervix. The location, extent of the tear, and amount of scar tissue that should be removed is accurately determined. Caudal retraction of the cervix for surgery will distort the tissue and make such an evaluation difficult. Defects of the external os of the cervix or tears not affecting over one third of its length generally do not require surgical repair.

Preoperative care and analgesia may be done as described for ovariectomy, colpotomy approach.

Surgical Repair

Surgical repair is best performed during estrus, because of the easier access to the body of the cervix. The vulvar lips are retracted and secured to the perineum with towel clamps or stay sutures. The cervix is retracted caudally using three No. 3 nylon or umbilical tape stay sutures placed deep into the external os or cervical body. The suture ends are left long enough to allow for retraction by helper(s). The use of instruments with long handles, similar to the ones used in third-degree perineal laceration repair is essential. A full-thickness incision is made starting 2 cm cranial to the defect and extending caudally to the external os. Excessive scar tissue is removed and the cervix closed in a two- or three-layer closure. In the three-layer closure, a No. 0 resorbable monofilament suture material such as PDS is used to close the cervical musculature in a simple interrupted or continuous suture pattern. The cervical and vaginal mucosa are closed with a No. 2-0 PDS suture in a simple continuous pattern.

Postoperative Care

Postoperative care should include antibiotic and anti-inflammatory medications for 3 to 4 days. The use of progesterone (300 mg IM daily) for 10 to 14 days may increase cervical tone more rapidly. The mare should be rechecked 30 days following surgery. If healing is adequate, she may be inseminated at that time. Natural breeding should be avoided for 6 months to prevent further cervical injury.

CHAPTER 29

Embryo Transfer and Newer Assisted Reproductive Techniques for Horses

DIRK K. VANDERWALL and GORDON L. WOODS

Embryo transfer has been the most widely utilized assisted reproductive technique for mares; it has been used to (1) obtain foals from performance mares, (2) obtain multiple foals from individual mares each year, (3) obtain foals from 2-year-old mares, (4) obtain foals from reproductively unsound mares, and (5) obtain foals from mares with nonreproductive health problems. In addition, embryo transfer has served as an important research tool for studying early pregnancy in the mare. Although embryo transfer was initially proposed as a promising method for obtaining foals from aged, subfertile mares, experiments utilizing oocyte transfer[1] and embryo transfer[2] have documented that many oocytes/embryos produced by aged, subfertile mares are inherently defective and have low survival rates after transfer to recipient mares; therefore, aged, subfertile mares are not optimal candidates for embryo transfer.

Although embryo transfer provides a means of obtaining pregnancies from some mares that might not otherwise be capable of producing offspring, some mares cannot provide embryos for transfer. Mares in which embryo transfer may not be successful include those with (1) ovulatory failure, (2) chronic endometritis, or (3) anatomic problems (e.g., cervical adhesions). However, these mares could be used as oocyte donors and continue to produce foals through newer assisted reproductive techniques such as oocyte transfer, in vitro fertilization, and intracytoplasmic sperm injection. In addition, stallions with low sperm numbers or poor semen quality could also benefit from some of these newer technologies. This chapter will review current embryo transfer procedures and provide an overview of the current status of several newer assisted reproductive techniques for horses.

EMBRYO TRANSFER

The first successful equine embryo transfer was reported in 1972[3]; however, it was not until the early 1980s that embryo transfer became an accepted clinical procedure in the equine breeding industry. At that time, widespread utilization of embryo transfer was limited by the need to maintain recipient mares at the site of embryo collection, or ship donor mares to a centralized embryo transfer facility. In the late 1980s, a technique for cooling equine embryos was identified[4] and led to the development of a practical method of short-term (≤24 hours) storage and transportation of equine embryos. That development allowed embryos to be collected in the "field" and then shipped to a centralized facility for transfer to suitable recipient mares. The ability to transport cooled embryos provided veterinarians with the opportunity to offer embryo transfer service without the onerous task of maintaining recipient mares and eliminated the need to ship donor mares to a centralized facility.

Mare Management

Donor Mare

If indicated, a complete breeding soundness examination of the donor mare should be performed to assess her suitability for use in an embryo transfer program. If abnormalities are identified that warrant treatment (e.g., bacterial endometritis), appropriate therapy should be completed before embryo transfer procedures are performed. Breeding management of the donor involves teasing to monitor reproductive behavior; use of transrectal palpation and ultrasonography to monitor ovarian follicular activity and ovulation; and use of exogenous hormones to synchronize estrus and ovulation. When in heat, the donor is examined daily to monitor follicular growth, which allows optimal timing of insemination with fresh, cooled, or frozen semen. The day of ovulation is detected is designated as Day 0. Historically, a practical and efficacious means of superovulating mares has not been available; however, a commercially available formulation of equine follicle stimulating hormone (eFSH) has recently become available. Mares treated with eFSH had an average of 3.9 ovulations and 1.9 embryos recovered during a treatment cycle compared to 1.0 ovulation and a 0.5 embryo recovery rate for control mares.[5] Work is continuing to develop an optimal eFSH treatment protocol for superovulation in mares.

Recipient Mares

Proper selection and management of recipient mares may be the most important factor affecting the success of an embryo transfer program. Recipient mares should have normal estrous cycles, and must be free of uterine or ovarian abnormalities. The optimal age of recipient mares is 3 to 10 years. Synchronizing estrus between donor and recipient mares can be accomplished with routine protocols using prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) alone or in

combination with exogenous progesterone.[6] When in heat, recipients are examined daily with transrectal palpation and ultrasonography to monitor follicular growth and detect ovulation. The "window" of synchrony between ovulation in recipient and donor mares is +1 to –3 days (i.e., the recipient mare can ovulate 1 day before to 3 days after the donor mare).[7] In an effort to eliminate the need for synchronizing recipient and donor mares, progestin-treated, ovariectomized mares have been used as embryo recipients[8–11]; however, the success with their use has been variable, and the practice has not been widely adopted.

Embryo Recovery

Equine embryos are selectively transported through the oviduct into the uterus between days 5 and 6 after ovulation,[12] at which time they are at the compact morula to early blastocyst stage of development. After entering the uterine lumen, the size of the embryo increases dramatically as it develops into an expanded blastocyst (Table 29-1).[13] Although embryos can be recovered on days 6 to 9 (Table 29-2),[14–20] the optimal time of embryo collection is day 7 or 8; currently, our preference is to perform embryo recovery on day 8. The primary indication for recovering embryos on day 6 is for freezing embryos.[7] Embryos are not routinely collected on day 9, because their transfer success rate is generally lower than day 7 or 8 embryos.[7]

Embryo collection is performed using transcervical uterine lavage (Fig. 29-1). We currently use an 80-cm silicone balloon-tipped catheter (VEUF-80, Bivona, Inc., Gary, IN 46406) with an inside diameter of 8.0 mm (French size 33); however, other styles of flushing catheters are available. After placing the catheter, the uterus is flushed three to four times with warm (30° to 35° C) flush medium. Historically, the most widely used flush medium has been Dulbecco's phosphate buffered saline (DPBS) containing 1% (v/v) fetal or newborn calf serum, penicillin (100 units/mI), and streptomycin (100 μg/ml); however, more recently, many practitioners have begun to use a zwitterion-buffered flush medium containing antibiotics and bovine serum albumin (emCare Complete Flush Solution, Professional Embryo Transfer Supply, Inc., Canton, TX 75103-0188) or polyvinyl alcohol (ViGro Complete Flush Solution, AB Technology, Pullman, WA 99163).

Table **29-1**

Diameter of Equine Embryos Recovered From the Uterine Lumen

Regardless of which medium is used, using gravity flow, the uterus is filled with 1 to 2 L of medium during each flush (4 to 8 L used during entire procedure). After filling the uterus, the fluid is allowed to flow back out through the catheter and is passed through a 0.75-μ embryo filter. It is important that the embryo filter not overflow or run dry; filters are available that are designed to prevent both from occurring. The fluid passing through the filter is collected to monitor its recovery. After the first flush, the uterus is massaged per rectum during subsequent flushes, which may aid suspension of the embryo(s) in the medium and enhance fluid recovery. The majority (>90%) of fluid infused into the uterus should be recovered, and should be free of cellular debris or blood. Recovery of cloudy fluid indicates the mare had an active endometritis at the time of the embryo recovery and warrants further diagnostic evaluation. When present, blood contamination is often associated with vigorous massage of the uterus or manipulation of the catheter.

At the completion of the flush, the filter cup is emptied into a sterile search dish with grid and the filter is rinsed with approximately 50 ml of flush medium. The fluid is then examined for the embryo(s) using a stereomicroscope at approximately 15× magnification. Larger embryos (e.g., day 8) are generally visible with the naked eye. When an embryo is identified, it is washed by transferring it sequentially through several (3 to 10) 1-ml drops of "holding medium," which consists of an enriched formulation of flush medium; after washing, the embryo is placed into a small petri dish containing the same medium. The embryo is then examined at high magnification (40 to 80×) and graded on a scale of 1 (excellent) to 4 (poor).[21] Embryos can be handled using a 0.25- or 0.5-ml semen-freezing straw, 25-μl glass capillary pipette, or other suitable instrument attached to an appropriate syringe. Whenever an embryo is drawn into a handling instrument, the medium containing the embryo should be surrounded on each side by an air bubble and blank medium. This prevents the embryo from accidentally being pulled out of the instrument should the tip touch something absorbent.

Once embryos are placed into the holding medium, they should either be expeditiously processed and packaged for transport (or frozen) or be transferred into an appropriate recipient mare.[22] While awaiting packaging for transport or immediate transfer to a recipient, equine embryos appear to be quite tolerant of temperatures between room temperature (25° C) and body temperature (37° C). However, efforts should be made to prevent rapid or extreme changes in temperature.

Packaging Embryos for Transport

Since the late 1980s, equine embryos have been cooled and transported using methods developed by Carnevale and associates,[4] which utilizes Ham's F-10 nutrient mixture as the holding/cooling medium. Prior to use, Ham's F-10 medium must be buffered by diffusing a mixture of 90% N_2, 5% O_2, and 5% CO_2 gas through the medium for 3 to 5 minutes, after which it is supplemented with 10% (v/v) fetal or newborn calf serum, penicillin (100 units/ml), and streptomycin (100 μg/ml). Because Ham's F-10 medium must be "gassed" prior to use, it requires having an appropriate compressed gas cylinder and regulator. In addition, once gassed, Ham's F-10 has a limited shelf-life; therefore, many practitioners choose to have the embryo transfer facility that will receive the embryo provide Ham's F-10 just before the embryo collection as part of an embryo shipping kit. More recently, equine embryos have been successfully cooled and transported using the complete medium holding solutions described above,[22] which eliminates the need to prepare the special Ham's F-10 solution.

To package an embryo, the transport medium is filter-sterilized into "snap-cap" tube, leaving a small air gap at the top of the tube. The embryo is then carefully transferred into the medium, the cap is securely snapped onto the tube, and the tube is wrapped with Parafilm. A 50-ml centrifuge tube is then filled with transport medium (unfiltered), and the 5-ml tube containing the embryo is placed into the 50-ml centrifuge tube. The cap of the 50-ml centrifuge tube is closed, eliminating as much air as possible, and it is wrapped with parafilm. The packaged embryo is then placed into an Equitainer, which passively cools the embryo to 5° C. Under those conditions, embryos can remain viable for at least 24 hours, during which time they can be transported via commercial airline or priority overnight delivery to the embryo transfer facility.

Freezing Embryos

The primary advantage of freezing embryos is that it obviates the need to have a synchronized recipient mare available at the time of embryo collection, since the embryo can be frozen and then transferred at a later date when a recipient mare is available. In addition, it would facilitate the international movement of equine embryos. Although "conventional" embryo freezing procedures using glycerol or other cryoprotective agents have been reasonably successful for equine embryos, to do so requires expensive and specialized equipment, as well as approximately 90 minutes to complete the freezing procedure. In addition, after thawing, embryos are generally moved through a series of solutions to dilute the cryoprotectant and other components of the freezing medium before transfer, which makes the post-thaw process laborious. In contrast to conventional freezing procedures, vitrification is a process that utilizes high concentrations of cryoprotectants that can be completed rapidly (<15 min) without specialized equipment using a commercially available vitrification kit.[23] After thawing, vitrified embryos can be directly transferred from the straw into the recipient mare, since further dilution or handling of the embryo is not necessary.

To vitrify an embryo, after "washing" the embryo with a standard embryo holding medium, the embryo is moved sequentially through three separate vitrification solutions (VS1, VS2, and VS3), and then it is loaded into a 0.25 ml polyvinyl chloride straw.[23] The embryo is held in VS1 for 5 minutes and then transferred to VS2 for an additional 5 minutes, after which it is transferred to VS3.

The embryo should remain in VS3 for less than 1 minute, which includes the time to load the embryo into the straw and initiate freezing. The embryo is loaded into the straw in approximately 30 ul of VS3; the embryo (in VS3) is "sandwiched" in the straw between an air bubble on either side and approximately 90 ul of a 0.5 M galactose solution beyond that (on both sides of the embryo). The galactose solution will be mixed with the embryo in VS3 *after* thawing. Once the straw is loaded, the open end is sealed, and the straw is placed into liquid nitrogen vapor for 1 minute before it is plunged into the liquid nitrogen, after which it is moved to a storage tank. A straw is thawed by holding it in room temperature air for 10 seconds, and then it is placed into a room temperature (20° to 22° C) water bath for an additional 10 seconds, after which the contents of the straw are mixed by "flicking" it five to seven times (like a thermometer). The straw is then allowed to lay flat for 6 to 8 minutes at room temperature, after which the tip of the straw is opened and then loaded into a standard transfer gun for transfer into a suitable recipient mare. Using this vitrification technique, Carnevale et al.[23] reported a 62% (16/26) pregnancy rate at day 16 after transfer of embryos. However, like conventional freezing procedures, only small (<300 micron) embryos tolerate vitrification procedures suitably. Therefore, embryos that will be vitrified should be collected on day 6 to very early on day 7.

Surgical and Nonsurgical Embryo Transfer Procedures

Regardless of whether embryos are transferred immediately after recovery; cooled and transported; or frozen prior to transfer, the transfer procedure can be performed surgically or nonsurgically. Historically, surgical transfer has provided the highest pregnancy rates and most consistent results, generally resulting in pregnancy rates of approximately 70% to 75% 1 week after transfer[24]; however, recent reports of nonsurgical transfer have demonstrated the success rates can be equal to, or greater than, those obtained with surgical transfer.[20,25]

At this time, nonsurgical has become the standard method of transferring equine embryos and has generally been performed using (1) a standard artificial insemination pipette, (2) a disposable plastic "insemination gun," or (3) a reusable stainless steel insemination gun. Regardless of which instrument is used, an outer guard is generally placed over the transfer instrument. When performing a nonsurgical transfer, the recipient mare is placed in stocks and sedated, and the perineal area is cleaned and prepared using standard procedures. The operator places a sterile plastic sleeve over his or her arm, and a sterile surgeon's glove is placed over the plastic sleeve. A small amount of sterile lubricant is placed on the back of the operator's hand and applied to the vulva. The tip of the transfer instrument (covered by the outer guard) is placed in the palm of the hand and protected by placing the operator's thumb over the tip. The instrument is introduced into the vagina, and the tip of the outer guard is introduced approximately 0.5 cm into the external cervical os, at which point the instrument is advanced through the outer guard and passed through the cervical canal into the uterine body. The embryo can be deposited in the uterine body or in one of the uterine horns; to deposit the embryo in the uterine horn, the tip of the instrument is guided into the horn using transrectal manipulation. Currently, there is no evidence that the site of embryo placement (uterine body versus horn) during nonsurgical transfer influences the outcome. Once the transfer instrument is positioned appropriately, the embryo is expelled as the transfer instrument is withdrawn slightly, so the tip is not pushed up against the endometrium as the embryo is deposited into the uterus.

NEWER ASSISTED REPRODUCTIVE TECHNIQUES

The successful application of new assisted reproductive procedures requires that equine gametes are collected and handled appropriately. For successful fertilization, the oocyte must be viable and at the correct stage of maturation (meiotic and cytoplasmic). Oocytes "resting" in the ovary are in prophase of meiosis I and contain a distinct nucleus (germinal vesicle). During in vivo maturation, which occurs during the 36 hours prior to ovulation, the nuclear membrane breaks down, and meiosis resumes and progresses to metaphase II. At ovulation, the oocyte has reached, and is arrested in, metaphase II,[26] the stage at which it is fertilizable. Metaphase II oocytes are characterized by the presence of the first polar body.

For commercial application of these new assisted technologies, oocytes are primarily collected by transvaginal ultrasound-guided follicle aspiration (TVA). Oocytes can be collected from mature preovulatory follicles or from immature follicles. Oocytes collected from small, immature follicles must undergo maturation in vitro. The development of successful culture systems for routine in vitro maturation of equine oocytes is currently an area of considerable research interest.

Oocyte Transfer

Oocyte transfer involves collection and surgical transfer of a donor mare's mature oocyte into a recipient mare's oviduct so that fertilization and subsequent embryonic development occur within the reproductive tract of the recipient. This procedure has been referred to as gamete intrafallopian transfer (GIFT), which implies that both gametes (oocyte and spermatozoa) are transferred into the oviduct; however, as it is currently being performed in the mare, this procedure involves only the transfer of an oocyte, for the recipient mare is inseminated with semen from the desired stallion using standard insemination procedures. Because the recipient mare is inseminated, her oocyte must be removed to prevent it from being fertilized.

Oocyte transfer does not require ovulation to occur in the donor and completely bypasses all of the tubular genitalia of the donor mare; therefore, it may be especially well suited for donor mares with ovulatory failure and those with chronic problems associated with the tubular genitalia (pyometra, etc.). In addition, oocyte transfer has been proposed as an alternative method of obtaining pregnancies from any mare in which embryo transfer

has been unsuccessful, regardless of the underlying reason.

Although the first equine oocyte transfer resulting in the birth of a foal was reported in 1988,[27] only recently has the procedure been performed as a clinical procedure. In an initial report, Carnevale and associates[28] described their results using oocyte transfer in a commercial breeding program involving 38 mares (mean age 21 years) with reproductive problems. Donor mares consisted of those with a wide range of reproductive abnormalities including persistent endometritis, pyometra, cervical fibrosis, repeated development of anovulatory hemorrhagic follicles, and idiopathic reproductive failure. Oocytes were collected from donor mares using transvaginal ultrasound-guided follicle aspiration, which was well tolerated by the donor mares without any complications. Oocyte collection rates were high, with oocytes recovered during 80% of cycles. Oocyte collection was performed approximately 24 hours after administration of human chorionic gonadotropin or the gonadotropin-releasing hormone agonist delorelin acetate in an effort to recover oocytes that were in the process of nuclear and cytoplasmic maturation. At the time oocytes were collected, cumulus cell expansion was evaluated to assess the degree of oocyte maturation; oocytes with a fully expanded cumulus were transferred as soon as possible into a recipient mare's oviduct, while oocytes with less cumulus expansion were incubated in culture medium for 12 to 26 hours prior to transfer. Of a total of 90 oocytes recovered from these donor mares during 99 cycles, 75 were transferred into 64 recipient mares, which resulted in 20 mares becoming pregnant (31%).

Carnevale and associates[28] noted that the success of oocyte transfer in their study was affected by oocyte and semen quality. The most important factor affecting oocyte quality was mare age. Reduced fertility in mares at or over 20 years old has been associated with poor oocyte quality; embryo development rates were significantly reduced when oocytes from aged mares, compared to young mares, were transferred into young recipient mares.[1] In addition, morphologic evaluation of oocytes from aged and young mares using light and electron microscopy demonstrated that although some oocytes from aged mares are morphologically similar to oocytes from young mares, more oocytes from aged mares had morphologic anomalies such as large vacuoles and oblong shapes.[29] Because semen quality also affected the success of oocyte transfer, the authors recommend the use of stallions with high-quality semen to maximize the success of the procedure.

In a subsequent report, Carnevale and associates[30] further described the various factors that affect the clinical success of oocyte transfer. Like the initial report,[28] their experience clearly demonstrates that oocyte transfer can be used to obtain pregnancies from mares with a wide range of reproductive problems that otherwise would probably not be able to produce offspring.

In Vitro Fertilization

In vitro fertilization (IVF) has been used successfully for many years in the treatment of human infertility, and techniques are now available for producing large numbers of IVF embryos from several domestic species. Although the first foal produced by IVF was reported by Palmer and associates in 1991,[31] a repeatable method for successfully performing IVF in horses has not been developed. The primary biologic barrier to IVF appears to be an inability to effectively capacitate equine spermatozoa in vitro, a process that is necessary in order for spermatozoa to be capable of fertilizing an oocyte. Because of the lack of progress in this area, recent research has focused on alternatives to traditional methods of IVF.

Intracytoplasmic Sperm Injection

Intracytoplasmic sperm injection (ICSI) is one of the modified forms of IVF being developed for use in horses that involves using a micromanipulator to inject a single spermatozoon into the cytoplasm of a mature metaphase II oocyte. By mechanically fertilizing an oocyte by placing a spermatozoon into the oocyte, ICSI eliminates the need for the spermatozoon to bind to and penetrate the zona pellucida and oocyte plasma membrane, which appear to be the aspects of spermatozoon-oocyte interaction that fail to proceed appropriately during standard IVF procedures.

The first foal produced using ICSI was reported in 1996,[32] and since that time there have been further reports of the success of the ICSI procedure.[33,34] In a recent report,[35] Hinrichs reviewed the current status of the ICSI procedure, focusing heavily on their extensive work in that area. Currently, the blastocyst development rate is 23% to 44% following ICSI and in vitro embryo culture, with a 50% pregnancy rate after transfer of those in vitro–produced embryos to surrogate mares. Unfortunately, approximately 50% of the embryos that establish pregnancy in recipient mares are lost during early gestation, which currently limits the overall efficiency of the procedure. Although ICSI must still be considered an experimental procedure, it holds great potential for assisted reproduction in the mare. In addition, because ICSI requires only a single spermatozoon, it has tremendous potential application for stallion management (e.g., subfertile stallions, frozen semen).

Sexed Semen

There is considerable interest in developing methods of separating X- and Y-chromosome bearing spermatozoa, to produce "sexed" semen that when inseminated allows gender selection of the resulting offspring; insemination of X-bearing spermatozoa will result in female offspring, and insemination of Y-bearing spermatozoa will result in male offspring. The first foal (a filly) conceived with "sexed" semen was born during the summer of 1998 (E.L. Squires, personal communication).

Semen is "sexed" using a flow cytometer, an instrument that physically separates X- and Y-bearing spermatozoa; however, using current instrumentation, only 1000 to 1500 viable, sexed spermatozoa can be sorted per second.[36] Although that appears to be an extremely fast rate of sorting, at that rate, it would require 4 to 5 days of continuous operation to produce enough "sexed"

spermatozoa for one insemination dose using the standard number of spermatozoa required for conventional insemination of fresh semen (i.e., 500 million progressively motile spermatozoa). That limitation has been responsible for stimulating research to develop new insemination methods that are successful when a limited number of spermatozoa are used. In addition to use with sexed semen, low-dose insemination techniques may be beneficial when inseminating thawed frozen semen of low quality or limited quantity, or when inseminating semen from subfertile stallions.

Three methods of "low-dose" insemination have been investigated: (1) surgical insemination into the oviduct,[37] (2) transcervical endoscopic insemination at the uterotubal junction or into the oviduct,[38–40] and (3) deep intrauterine insemination near the uterotubal junction.[41] Although surgical oviductal insemination can achieve pregnancies with extremely low numbers of spermatozoa (50,000 to 150,000), it has limited practical application at this time. Compared to oviductal insemination, endoscopic insemination is more practical and can achieve pregnancies with a slightly higher number of spermatozoa (~1 million), but requires expensive equipment that is not well suited to field use. Currently, deep intrauterine insemination is the most practical method of low-dose insemination because it can be performed in the field with readily available equipment, but it requires more spermatozoa (5 to 25 million) than oviductal or endoscopic insemination. Continued research is needed to further refine low-dose insemination techniques before "sexed" semen can be widely utilized.

Nuclear Transfer (Cloning)

When Dolly the sheep was cloned using somatic cell nuclear transfer,[42] it was recognized as a major scientific milestone because it conclusively demonstrated that a fully differentiated somatic cell can be genetically "reprogrammed" back to the undifferentiated state of a one-cell zygote (embryo), which can then initiate and undergo complete embryonic/fetal development resulting in the birth of an animal that is genetically identical to the original cell donor. Although the specific methods used for cloning using nuclear transfer can differ, it is generally performed by micro-manipulating and fusing two cells. One cell, referred to as the nuclear donor or "karyoplast," is derived from the animal to be cloned; typically, donor cells are maintained in tissue culture, from which one cell is selected for each nuclear transfer procedure. The other cell, referred to as a "cytoplast," is a mature unfertilized oocyte from which the genetic material (polar body and metaphase plate) has been removed. The cytoplast contains numerous cellular factors (e.g., mRNA, proteins, etc.) that play an important role in the "reprogramming" of the genetic material (i.e., genes) of the donor cell that enables the cloned embryo to initiate the complex sequence of events leading to embryonic and fetal development. The reconstituted embryo uses the donor cell DNA as the template for subsequent gene expression, which results in a genetic clone of the donor animal.

Equine cloning was first successful in 2003, when we reported the live birth of three mule foals cloned from a fetal fibroblast cell line[43] and Galli et al.[44] reported the live birth of a horse foal cloned from an adult fibroblast cell line. Since then, several more cloned horses have been produced.[35,45] Despite these successes, like other species, the current efficiency of equine cloning is very low, as evidenced by the fact that only 0.7%[35] to 2.7%[43] of reconstructed cloned equine embryos result in the birth of live offspring. In addition, similar to other species, there is evidence the individual cell donor can influence the success of equine cloning.[44,46] Clearly, further work is needed to increase the efficiency of equine cloning.

For the equine industry, potential uses of equine cloning include (1) preservation of genetics from individual animals that would otherwise not be able to reproduce, such as geldings, (2) preservation of genetic material of endangered and/or exotic species such as the Mongolian Wild Horse (Przewalski's horse), and (3) because of the companion animal role that horses fill for some individuals, it is likely that some horse owners will have individual animals cloned for emotional fulfillment. Of these, cloning geldings to produce intact males for breeding purposes has been the first direct application of equine cloning.[45] Although some breed associations (e.g., The Jockey Club, American Quarter Horse Association) do not currently allow the registration of cloned animals, for some equine sporting activities (dressage, show-jumping, etc.) breed registry status is irrelevant, which eliminates that regulatory impediment to the utilization of cloning technology.

Veterinarians can assist their clientele prepare for cloning of individual animals (if so desired) by "banking" tissue from those animals. There are currently several commercial companies that will isolate and store cells from tissue samples collected from animals for subsequent cloning purposes. These companies typically provide the veterinarian with a tissue collection and transport kit; the procedure involves aseptically collecting a small skin biopsy, which is placed in tissue culture medium and returned to the company, where cells are grown in tissue culture. Once the cells have grown in culture, they can be used immediately for cloning or they can be harvested and stored frozen in liquid nitrogen for use in the future. Ideally, tissue should be collected from a live animal; however, in an emergency it may be possible to collect a suitable sample post mortem. To maximize the likelihood of recovering viable cells, tissue from the deceased animal should be kept refrigerated between and 3° and 8°C (37° and 47°F); the chance of recovering viable cells diminishes when the tissue has been frozen or stored at temperatures above 10°C (50°F).

SUMMARY

Embryo transfer is a valuable assisted reproductive technique in the mare. Although the use of embryo transfer in commercial breeding programs was initially hampered by the need to provide suitable recipient mares at the site of embryo collection, or transport donor mares to a centralized embryo transfer facility, the development of methods for successfully transporting cooled embryos eliminates the need of maintaining recipients on site. That, coupled with the fact that the materials necessary

for embryo collection and transport are well suited to a field setting, more veterinarians can now provide embryo transfer service to their clientele who wish to utilize this technology.

For mares in which embryo transfer cannot be performed successfully, newer assisted reproductive techniques such as oocyte transfer, IVF, or ICSI may provide a means through which offspring can be obtained. In addition, sexed semen and nuclear transfer procedures will provide horse owners with new options for the reproductive management of their animals. Although these new technologies are just beginning to have clinical application at this time (primarily oocyte transfer), with continued development, they will offer new alternatives to our approach of managing subfertile and infertile mares and stallions.

CHAPTER 30

Clinical Reproductive Physiology and Endocrinology of Bulls

PETER J. CHENOWETH and JOHN P. KASTELIC

The bull exerts major influences on herd fertility and production whether he is bred with many females, using assisted reproductive technologies, or with relatively few via natural service. Despite this, relatively little selection pressure for reproductive traits has been placed on most bull populations. Furthermore, multiple-sire breeding, as practiced routinely by commercial cattle producers, makes it difficult to identify subfertile bulls. For example, it is estimated that 20% to 40% of unselected beef bulls in North America are subfertile.[1] Because of this, there is increasing demand for breeding soundness evaluation, particularly for bulls destined for natural service. Knowledge of the anatomy, physiology, and behavior of bulls is necessary for veterinarians to conduct an adequate breeding soundness evaluation, investigate reproductive problems, and advise on reproductive management.

PRENATAL DEVELOPMENT

Sex determination in mammals occurs in three stages: the establishment of chromosomal sex, the development of primary sex characters (the gonads), and the subsequent development of secondary sex characteristics under the influence of gonadal hormones.

During embryogenesis, the gonad first arises from the mesonephros as undifferentiated tissue, which has the capability to subsequently develop in either male or female form. The precursors to the male reproductive tract system (i.e., the wolffian duct system) and the female tract (the müllerian duct system) are both present. Subsequent sexual differentiation is decided, in mammals, by the presence or absence of the Y chromosome, with females being XX and males XY. The presence of a Y chromosome results in male development, regardless of the number of X chromosomes present. Thus, the Y chromosome must contain the dominant inducer of testis formation; the testis determining gene (TDF or SRY). SRY is activated early in embryogenesis to commit the undifferentiated genital ridge to the testicular pathway. The early testis produces both testosterone (T; from the Leydig cells) and müllerian inhibiting substance (MIS; from the Sertoli cells). The latter induces the müllerian ducts to regress. Subsequent hormonal production induces male sexual differentiation. In the bovine, the differentiating gonad may be identified as a testis by 41 days after conception, with testosterone production (from fetal Leydig cells) evident soon thereafter.[2] By 3 to 4 months following conception, the testes have generally passed through the inguinal canal and entered the scrotum, which is derived from the urogenital folds. Although the basic components of a functional male gonad are present at birth, the spermatogonia do not undergo meiosis until the onset of spermatogenesis at puberty. Thus, the basic structure of the testis (seminiferous cords and interstitial tissues) remains much the same from early fetal life until the onset of puberty.

REPRODUCTIVE ANATOMY

The reproductive organs of the mature bull include paired testes, each with a spermatic cord, an epididymis, and a deferent duct (ductus deferens), which culminates in an ampulla.[3] In addition are paired vesicular glands, a prostate gland, paired bulbourethral (Cowper's) glands, and a fibroelastic penis, which incorporates a sigmoid flexure (Fig. 30-1).[4] The vesicular, bulbourethral, and prostate glands are often referred to as the accessory sex glands.

The testes are suspended within the scrotum, a feature that is important for testicular thermoregulation, as discussed subsequently. Within the testis, most (70% to 90% by weight) of the parenchyma is composed of seminiferous tubules (Sertoli cells and layers of germ cells). The remainder consists of interstitial tissue (Leydig cells, blood and lymph vessels, and connective tissue). The mediastinum, an area of connective tissue extending lengthwise in mid-testis, contains blood vessels and tubules of the rete testis. The testicular parenchyma is encased in a thick, connective tissue capsule (tunica albuginea), which is, in turn, covered by a thin, serous membrane (tunica vaginalis propria).[3]

In general, the spermatogenic efficiency of healthy testicular parenchyma in bulls is remarkably consistent (approximately $10–12 \times 10^6$ spermatozoa per gram daily). As testes weight is highly correlated with scrotal circumference ($r = 0.91$ to 0.98 in young beef bulls[1]), this highly repeatable measure has gained wide acceptance as an estimate of sperm-producing capability, especially as testicular size is heritable in beef bulls ($h^2 \sim 0.5$).[1] Although breed and environment may also influence testicular development, most variation in daily sperm production can be

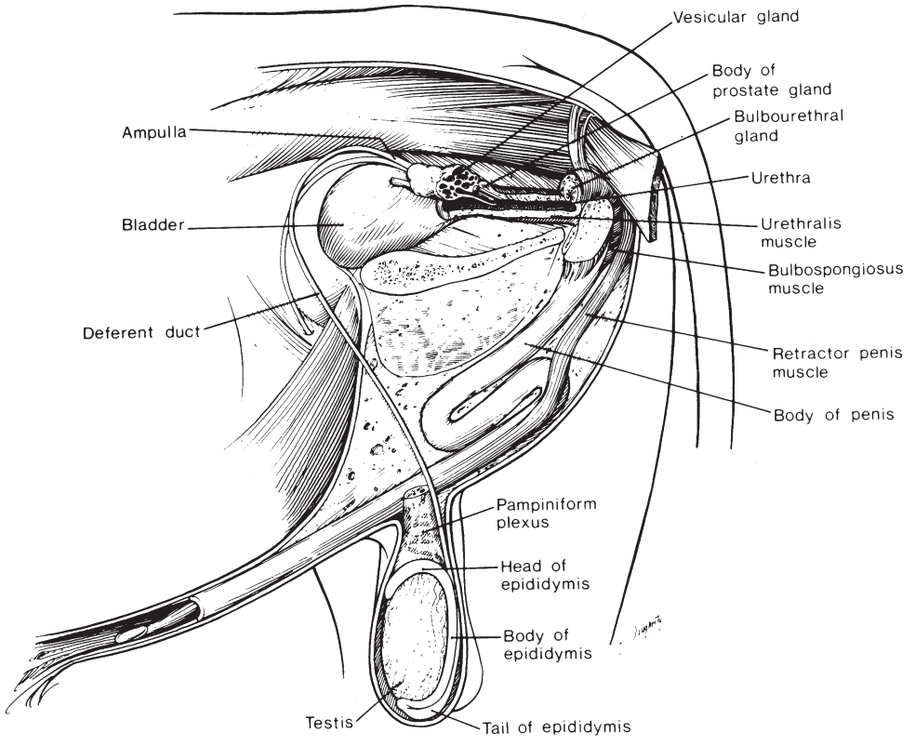

Fig. 30-1 Reproductive organs of the bull. (From Amann RP: How a bull works. Proceedings of the 11th Technical Conference on A. I. and Reproduction (NAAB), 1986, p 7.)

attributed to testicular size (represented by scrotal circumference), at least in younger (<4–5 years old) bulls.

Sertoli cells are amorphous, nucleated somatic cells that span the seminiferous epithelium and play a critical role in supporting and controlling germ cell development.[4] Specialized junctions between adjacent Sertoli cells form the blood-testis barrier, dividing the seminiferous epithelium into basal and adluminal compartments.[5] Spermatogonia lie between Sertoli cells and the tubule basement membrane, and other germ cells are located either in cytoplasmic crypts within Sertoli cells or sandwiched between adjacent Sertoli cells.

Spermatozoa are produced within the seminiferous tubules. Both ends of each tubule form tubuli recti (straight tubules), which join the rete testis (a complex of anastomosing spaces within the mediastinum testis). Spermatozoa pass from the rete testis to the head of the epididymis via the efferent ducts (n = 6–20). The epididymis, an elongated, torturous duct extending from the rete testis along the medioposterior border of the testis, comprises the head (caput), body (corpus), and tail (cauda) regions. Epididymal functions include sperm transport and maturation, as will be discussed.

At birth, the bull penis is short and slender and lacks a sigmoid flexure, and its apex is fused to the inner lining of the prepuce. With time (and under the influence of androgens), penile and preputial tissues separate, the penis elongates, and a sigmoid flexure develops. Tissue separation proceeds irregularly and in many bulls is completed only after the onset of erectile activity. Thereafter, incomplete separation is defined as a persistent penile frenulum (otherwise known as a persistent raphe or tied penis). This condition, most commonly present in Angus, Beef Shorthorn, Hereford, Polled Hereford, and Beefmaster bulls, probably has a genetic basis in many cases.[6] Although this condition is usually correctable with minor surgery, the consequences of perpetuating a genetic defect should be considered when this is done.

The prepuce is a double invagination of skin, with its internal lining everting upon penile erection to constitute much of the penile surface.[3] A fan-shaped protractor prepuce muscle raises and lowers the distal portion of the prepuce and also controls the size of the preputial opening. Retraction of the membrane lining the inner prepuce is under the control of the retractor prepuce muscle. Lack of development of this muscle (a condition genetically linked with the polled gene in bulls), predisposes to chronic eversion of this membrane with increased risk of traumatic injury.

The development and normal function of the accessory glands depend upon the effects of androgens. Castration results in marked depression of both development and secretory functions of these glands.

EPIDIDYMAL FUNCTIONS

The epididymis is far more than a passive organ, with functions including both sperm transport and maturation. Spermatozoa leaving the testis lack both the ability to survive in the female tract and to achieve unassisted fertilization. These capabilities are acquired in the epididymis. Other epididymal functions include the (1)

energy-efficient storage of sperm while maintaining sperm fertility; (2) intermixing of recently formed and older spermatozoa to provide a temporal spectrum of optimal sperm function, and (3) changing sperm attributes and environment to permit survival and ensure fertilizing capability within the female tract.[7]

Immotile spermatozoa are carried into the lumen of the seminiferous tubule following separation of their connections to Sertoli cells. Most of the residual cytoplasm is retained by the Sertoli cell, although some remains attached to the spermatozoa (as cytoplasmic droplets). Initial transport into the rete testis and caput epididymidis seems to be dependent upon fluid secreted by Sertoli cells. Once into the efferent ducts, sperm movement is facilitated by ciliated epithelial cells (within the ducts) as well as by smooth muscle contractions. The efferent ducts and initial segment of the caput epididymidis resorb most fluid and protein emanating from the testis and secrete new compounds.

Sperm maturation occurs within the caput and corpus of the epididymis with this process requiring the coordinated secretion of specialized enzymes and proteins. During this process, changes occur in the sperm DNA-protein complex, plasma membrane, mitochondria, axonemal complex, plasma and acrosomal membranes, and sperm surface characteristics.[7]

As spermatozoa progress through the epididymis, they achieve progressive motility, the cytoplasmic droplet migrates from the proximal to the distal position on the sperm midpiece, and seminal fluids are resorbed and exchanged. Heat stress can adversely affect epididymal function. The epididymis, particularly the tail region, acts as a storage region for sperm, such that a mature Holstein bull may have epididymal reserves representing the equivalent of 6 or 7 days of daily sperm output. Most sperm that are not ejaculated are voided in urine, with a small proportion resorbed by the male tract. Some evidence exists for selective resorption of spermatozoa within the epididymis.

Sperm are transported from the cauda epididymis to the urethra in the ductus deferens (vas deferens) via muscle contractions that are strongest during precoital stimulation. The terminal portions of the ductus deferens expand to form the ampullae (each approximately 10 × 1.5 cm in adult bulls). These ampullae act as minor sperm storage areas and they also secrete fructose and citric acid into the seminal plasma. The ductus deferens open (via the ampullae) into the cranial portion of the pelvic urethra. The vesicular glands (or seminal vesicles) also open into the pelvic urethra. These glands provide much of the fluid component of the bull ejaculate, as well as sperm nutrients and semen buffers. The vesicular glands are lobulated organs, approximately 10 to 15 cm in length and 2 to 4 cm in diameter in mature bulls. The prostate gland, consisting of a relatively small body and larger disseminate region, produces 25% to 40% of seminal volume as well as semen odor. The bulbourethral glands of the bull each open into the pelvic urethra at the ischial arch. The urethra is an elongated tube extending from the bladder to the tip of the penis. It is surrounded by the urethralis muscle, which contracts strongly during ejaculation.

SCROTAL TESTICULAR THERMOREGULATION

Scrotal testicular thermoregulation has been recently reviewed.[8] Testicular temperature in bulls must be 2 to 6°C cooler than core body temperature for effective production of fertile spermatozoa. Several mechanisms act to regulate the testicular temperature. Of major importance is the pampiniform plexus, a complex venous network that surrounds the highly coiled testicular artery within the neck of the scrotum. This entire structure (vein and artery) is properly called the testicular vascular cone.[8] The cone functions as a countercurrent heat exchanger whereby heat is transferred from arterial to venous blood. Scrotal skin is thin and relatively hairless, with extensive blood vessels that can dilate to increase heat loss. The testes and scrotum have complementary temperature gradients that result in a nearly uniform intratesticular temperature.[8] Other mechanisms that help to cool the testes include relaxation of scrotal muscles, scrotal sweating, and whole-body responses (e.g., panting and peripheral vasodilation). Spermatogenesis occurs in an environment that verges on hypoxia. When testicular temperature increases, spermatogenic metabolism increases faster than does blood flow, and hence the testes become hypoxic.[8] Therefore, testicular function is very susceptible to temperature increases due to either endogenous or exogenous factors (e.g., fever or high ambient temperatures, respectively). Increases in testicular temperature cause increased production of defective spermatozoa. The proportion of defective spermatozoa and the time required for recovery depend upon the nature and duration of the thermal insult.[8] Severe insult may cause irreversible spermatogenic damage.

ENDOCRINOLOGY

The function of male reproductive organs is under the control of both the nervous and endocrine systems. The latter includes the hypothalamus, anterior pituitary, and the Leydig and Sertoli cells. The hypothalamus plays a pivotal role in the control of reproduction, acting as the interface between the nervous and endocrine systems. It works within a complicated feedback system (the hypothalamic-pituitary-gonadal complex or axis), which is ultimately controlled by the inputs from the higher nervous system. In turn, this can be influenced by many factors, both environmental and behavioral.

Gonadotropin-releasing hormone (GnRH) from the hypothalamus travels (via the portal system) to the anterior pituitary gland where it stimulates the synthesis and release of both LH (luteinizing hormone) and FSH (follicle-stimulating hormone). Leydig cells, located within the interstitial tissue (in close apposition to lymph and blood vessels), produce episodic bursts of T (testosterone) in response to LH release. T is concentrated in the seminiferous tubules, testicular lymph, and venous blood via a vascular-concentrating mechanism situated within the scrotal cord.[2] T is necessary for Sertoli cell function, and both androgens and FSH maintain spermatogenic function.[2] In addition, T is necessary for the development and function of accessory glands as well as epididymal

function, secondary sex characteristics, and mature sexual behavior. Although libido is apparently not quantitatively associated with resting T concentrations, it appears that a threshold level is necessary for activation. In response to FSH, Sertoli cells secrete fluids and androgen-binding-protein (ABP) (thereby indirectly influencing spermatogenesis).[2] Sertoli cells also produce inhibin and activin, which inhibit and stimulate FSH secretion, respectively, as well as proteins that preferentially target spermatocytes and early spermatids. Leydig cells also produce estradiol (E), which acts in a similar manner to T by causing negative feedback on both the hypothalamus and anterior pituitary, thus suppressing the release of GnRH, LH, and FSH (Fig. 30-2).

Recently, the role of growth factors has been investigated in relation to male reproductive processes. Such factors act by stimulating target cell proliferation and regulate growth of reproductive organs. They include cytokines, interferons, insulin, insulin-like growth factors (IGFs), and others such as platelet-activating-factor (PAF) and epidermal growth factor (EGF). In the male, such factors have been associated with epithelial and interstitial cell development and function, puberty, LH modulation, and sperm motility. This represents a dynamic research area, with new findings appearing regularly to improve our understanding of the fine tuning of male reproduction.

PUBERTY

Puberty in bulls is a process that implies the attainment of functional sexual organs and behavior. Sexual maturity occurs when the development of both spermatogenesis and reproductive behavior allow effective coordinated service and subsequent fertilization. However, such definitions obscure the fact that puberty is a continuous and dynamic process, which commences prior to birth and is mediated through the hypothalamic-pituitary axis.

At birth, the testes are small, solid, and composed of cords of gonocytes and undifferentiated supporting cells. In prepubertal bulls, there is an early rise in gonadotropins (in particular LH and less consistently FSH) between 10 and 20 weeks of age.[9] The earlier this rise in gonadotropins occurs, the earlier the onset of puberty.[9] Spermatogonia start to appear in tubules within approximately 8 to 14 weeks after birth, with spermatocytes appearing shortly afterward. Seminiferous tubules form lumens between 15 and 40 weeks. Sequential maturation of spermatogonia through primary and

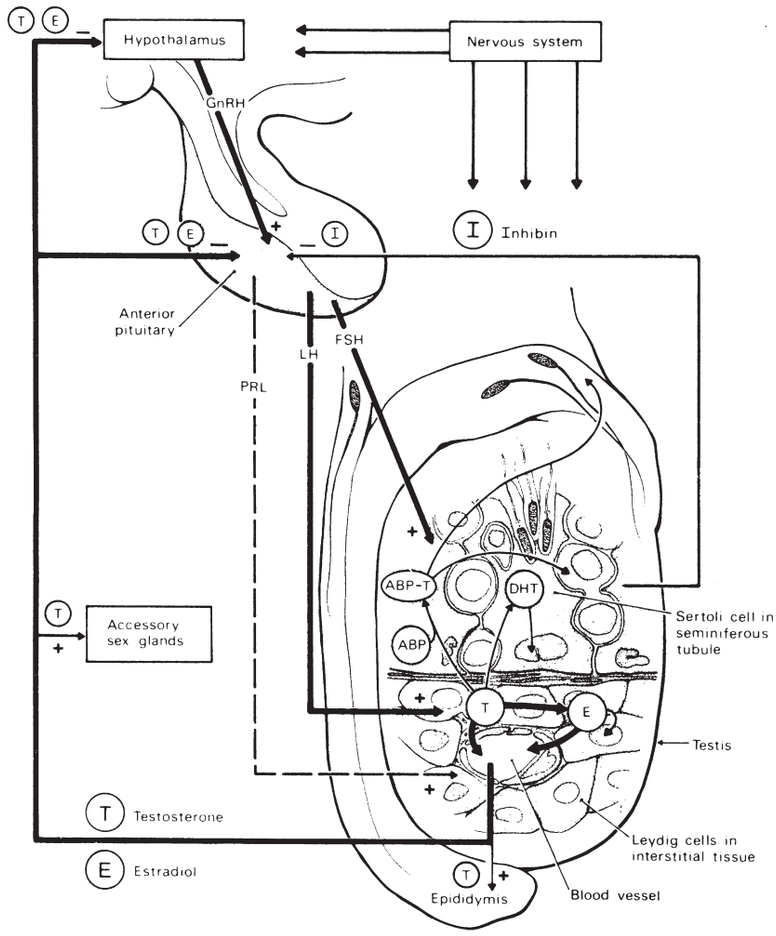

Fig. 30-2 Endocrinology of bull reproduction, showing the interrelationship of hormone production in the Leydig cells and seminiferous tubules and the feedback control of gonadal hormones on the hypothalamus and anterior pituitary glands. ABP, androgen binding protein; E, estradiol or other estrogens; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; I, inhibin; LH, luteinizing hormone; PRL, prolactin; T, testosterone. secondary spermatocytes to spermatids and spermatozoa is achieved between weeks 32 to 44 in well-fed *Bos taurus* breeds.[10] Testicular growth is very rapid between 7 and 10 months of age. Blood concentrations of androgens (initially androstenedione and then testosterone) start to increase at about 6 months of age and continue to rise through puberty (until at least 13 months of age).[10] Puberty is often defined as the first time a bull produces an ejaculate with at least 50×10^6 spermatozoa per milliliter with at least 10% progressive motility.[1] Increases in sperm concentration and the proportion of morphologically normal spermatozoa occur in conjunction with decreasing proximal droplets for at least 4 months after puberty.[5] Although breeds vary in both testicular development and body weight, puberty is quite consistently achieved when scrotal circumference reaches approximately 25 to 27 cm.[1] Therefore, scrotal circumference is generally a better predictor of puberty than either age or body weight, regardless of breed.[10] However, breed differences do occur in the pattern of testicular development. Bull age strongly influences scrotal circumference in young well-grown *Bos taurus* breeds, whereas body weight tends to be more predictive in *Bos indicus* breeds, especially when nutrition is suboptimal. Postweaning average daily gain does not appear to be highly related to scrotal circumference in bulls.[1] However, high-energy diets may depress both libido and spermatogenesis in young bulls, and an association has been reported between excessive backfat and lowered fertility.[1] Prepuberal scrotal circumference measures in bulls have not proved to be reliable predictors of subsequent postpuberal testicular size, although use of minimum thresholds show promise. For example, one study estimated that, to obtain a 30-cm scrotal circumference by 365 days of age, Angus, Simmental and Zebu-derived bulls needed to have a scrotal circumference of 23 cm at start of a 140-day growth test, while other continental breeds and Polled Herefords required 26 cm.[1] Favorable associations with scrotal circumference in beef bulls include age at puberty in related heifers[1] and improved semen quality.[1]

SPERMATOGENESIS

Spermatogenesis is the sum of cellular transformations that occur within the seminiferous epithelium and result in the production of spermatozoa (Fig. 30-3). The process of cellular differentiation commences with spermatogonial stem cells and proceeds through several mitotic divisions, a meiotic division, and numerous cytologic transformations, before culminating as elongated

Fig. 30-3 Spermatogenesis in the bull. Baltimore: Williams & Wilkins, 1987.)

spermatids.[2–5] Knowledge of the structures, processes, and temporal relationships of spermatogenesis is essential for informed diagnosis and prognosis of problems. Some relevant terms and definitions are as follows:

- **Seminiferous (germinal) epithelium**—the cellular constituents within the seminiferous tubule, comprising Sertoli cells, spermatogonia, primary and secondary spermatocytes, and spermatids. The spermatogenic cells become more highly differentiated as they move from the basement membrane toward the tubular lumen.
- **Stages of the seminiferous epithelium**—a series of discrete cellular associations within the seminiferous epithelium (8 to 12 stages are commonly described in domestic animals) that recur in a consistent sequence and under strict temporal regulation. In bulls, 12 stages are often described, with the duration of each stage ranging from approximately 2 hours to 2 days.[2,5]
- **Cycle of the seminiferous epithelium**—the complete sequence of stages appearing at any given site within the seminiferous epithelium.
- **Duration of the cycle**—interval required for one complete cycle of the seminiferous epithelium (time required for one stage to recur at a given site). The duration of the cycle in bulls is approximately 13.5 days.[2]
- **Duration of spermatogenesis**—interval required for a stem spermatogonium to transform into an elongated spermatid, ready for release (spermiation) into the tubular lumen (approximately 61 days in bulls).[5]
- **Epididymal transit time**—the interval between release and ejaculation. In bulls, the duration of this interval averages 8.3 days (range, 7 to 13 days), with shorter periods occurring in response to frequent ejaculation.[2]
- **Daily sperm output (DSO)**—number of sperm harvested per day from a bull. DSO is not only a function of sperm production, but it is also influenced by ejaculation frequency, bull stimulation, and collection method.
- **Daily sperm production (DSP)**—the total number of sperm produced per day by the testes.[2] DSP is usually assessed by histologic examination of testicular tissue or by preparing a homogenate and counting cells. A less invasive approach is to determine total sperm in ejaculates obtained from males in which extragonadal sperm reserves (EGR) have been stabilized by frequent ejaculation. Under these conditions, DSO can approximate DSP, which is typically 7 to 9×10^9 spermatozoa for mature Holstein bulls and somewhat less for beef and *Bos indicus* breeds.

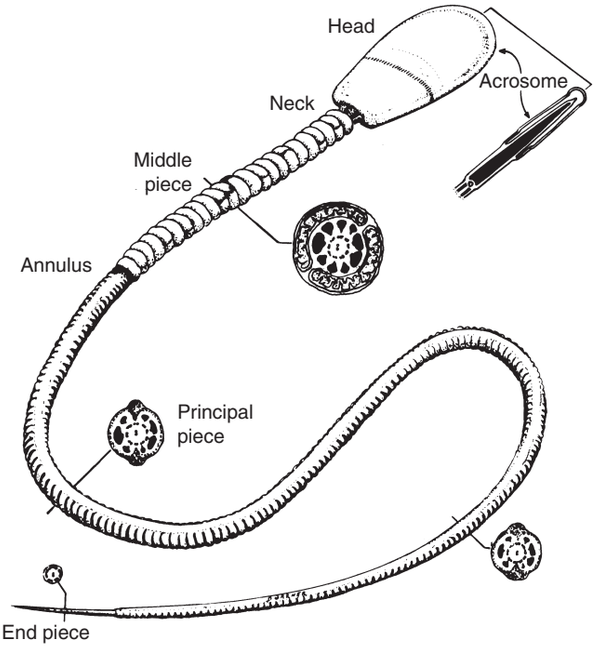

Fig. 30-4 The major regions (head, midpiece, and tail) of the bovine spermatozoon. Sagittal sections show the relationship between the acrosome and sperm head as well as structural details of the principal piece and its relationship to the mitochondrial sheath of the midpiece. (From Hafez ESE (ed): *Reproduction in farm animals,* 5th ed. Baltimore: Williams & Wilkins, 1987.)

SEMEN AND SPERMATOZOA

Bovine semen consists of spermatozoa suspended in seminal plasma. The latter is derived from multiple sources, including the testes, epididymides, and accessory glands (with a substantial proportion being provided by the vesicular and prostate glands). Seminal plasma contains sperm metabolites (including fructose, citric acid, sorbitol, glycerylphosphorylcholine and inositol), amino acids, enzymes, antimicrobials, hormones, and immunoglobulins.[11]

Bull spermatozoa are similar in structure to those of other domesticated mammals (Fig. 30-4). They consist of a flattened head, midpiece, and tail (with principal and end pieces).[5,11] The sperm head is a specialized package of condensed chromatin containing DNA, surrounded by a nuclear membrane, with an acrosome on its anterior aspect. The presence of an intact acrosome is an essential prerequisite for fertilization as it is the site of capacitation and the acrosome reaction. The equatorial region and the anterior border of the postacrosomal region (postnuclear cap) represent the sites of sperm fusion with the oocyte.[11] Sperm motility derives from movement of microtubule doublets within the axonemal complex, with energy supplied mainly by oxidative mechanisms within mitochondria, which form a helical mitochondrial sheath (known as the sperm midpiece) that surrounds the proximal portion of the axonemal complex.

SPERM TRANSPORT AND EJACULATION

Immotile spermatozoa are carried into the lumen of the seminiferous tubule following separation of their connections to Sertoli cells within the spermatogenic epithelium. Most of the residual cytoplasm is retained by the

Sertoli cell, although some remains attached to the spermatozoa (as cytoplasmic droplets). Initial transport into the rete testis seems to be dependent upon fluid secreted by Sertoli cells. Once into the efferent ducts, sperm movement is facilitated by ciliated epithelial cells (within the ducts) as well as by smooth muscle contractions. The efferent ducts and initial segment of the caput epididymidis resorb most fluid and protein emanating from the testis and secrete new compounds.[2]

Transportation of spermatozoa within the epididymis is primarily due to smooth muscle contractions. As spermatozoa progress through the epididymis, they achieve the ability to be progressively motile, the cytoplasmic droplet migrates from the proximal to the distal position on the sperm midpiece, and fluids are resorbed and exchanged. Through these and other changes, the epididymis plays a pivotal role in preparing sperm for fertilization.[2] The availability of testosterone, particularly in the initial and middle segments of the epididymis, is an important factor in sperm maturation. Heat stress can adversely affect epididymal function. The epididymis, particularly the tail region, acts as a storage region for sperm, such that a mature Holstein bull may have epididymal reserves representing the equivalent of 6 or 7 days of daily sperm output. Most sperm that are not ejaculated are voided in urine, with a small proportion resorbed by the male tract. There is some evidence for selective resorption of spermatozoa within the epididymis.

Sperm are transported from the cauda epididymidis to the urethra in the ductus deferens (vas deferens) via muscle contractions that are strongest during precoital stimulation. The terminal portions of the ductus deferens expand to form the ampullae (each approximately 10 × 1.5 cm in adult bulls); these act as minor sperm storage areas as well as secreting fructose and citric acid into the seminal plasma. The ductus deferens open (via the ampullae) into the cranial portion of the pelvic urethra. The vesicular glands (seminal vesicles) also open into the pelvic urethra, providing much of the fluid component of the bull ejaculate, as well as sperm nutrients and semen buffers. These lobulated glands are approximately 10 to 15 cm in length and 2 to 4 cm in diameter in mature bulls.[3] The prostate gland, consisting of a relatively small body and larger disseminate region, produces 25% to 40% of seminal volume as well as semen odor. The bulbourethral glands of the bull each open into the pelvic urethra at the ischial arch. The urethra is an elongated tube extending from the bladder to the tip of the penis. It is surrounded by the urethralis muscle, which contracts strongly during ejaculation.

The penis of the bull is fibroelastic with erection causing relatively little increase in penile diameter.[3] Retraction of the penis into the sheath is controlled by the retractor penis muscle. Ejaculation coincides with the penis reaching its maximal length and momentary peak pressure within the corpus cavernosum penis (CCP) as high as 14,000 mm Hg; the pressure is due to vascular engorgement of the CCP caused by rhythmic contractions of the ischiocavernosum muscle, forcing blood anterior from both crura. Ejaculation lasts approximately 1.3 seconds and is often accompanied by coiling of the penis. The ejaculatory thrust of the bull is achieved primarily through abdominal muscle action and is triggered by vulvar stimulation of nerve endings located just posterior to the glans penis.[12]

SEXUAL BEHAVIOR

Reproductive behavior in the bull has been recently reviewed.[13] In the breeding herd, the female plays a major role in the solicitation of sexual partners and also in controlling sexual activity. Females in proestrus or estrus congregate to form a sexually active group, which usually stays within visual contact of the bull (or bull group). The bull is attracted by the sight of mounting activity, particularly if the mounted female displays immobility.[12] Here, visual cues are usually of greatest importance to the bull, with olfactory cues playing a secondary role. The bull may test the female for immobility by chin resting and sham mounting attempts.[13] When more than one female is receptive, the bull will often preferentially mount the one that most recently came into estrus. Bulls may service an estrous female repeatedly, depending upon his libido (sex drive), stimulus pressure, and the length of time that the female remains receptive.[13]

Bulls can vary considerably in libido and breeding capability (ability to successfully mount and breed), with both traits having strong genetic influences. Modern management systems, whether employing natural or artificial breeding, may perpetuate deficiencies in bull libido and mating ability. Breeding capability also has a learning component, some of which is apparently acquired via mounting activity by juveniles. Despite such juvenile behavior, young bulls raised in bachelor groups often show signs of sexual inexperience when first placed with females. In multi-sire breeding pastures, the sexual activity of bulls can be strongly influenced by their social position in the bull group. Here, more dominant males may monopolize estrous females even though they might have poor libido, mating ability, or semen quality. This situation can result in reduced herd fertility.[13]

Bull libido is subject to various influences including physical problems such as lameness, obesity, presence of a hernia, penile abnormalities, and illness.[12] High-energy diets may reduce bull libido, whereas underfeeding is probably deleterious only when severe enough to affect the physiologic well-being of the bull.[12]

Serving capacity is a measure of the number of services achieved by a bull under defined conditions and thus includes aspects of both libido and mating ability. Testing methods have been developed to quantify both libido and serving capacity.[12,13] Although secretion of steroid hormones initiates sexual motivation, good relationships between circulatory levels of these hormones and quantitative estimates of sexual behavior in bulls have proved to be elusive.[13] Bull age and sexual experience can influence relative mating efficiency and hence libido scores and rankings.[13] A learning component for breeding capability of young bulls has been described in some studies, although inexperience is usually rapidly overcome following adequate exposure to females. More research is needed to differentiate the effects of age and inexperience on bull libido and breeding capability from environmen-

tal and managerial influences. Test scores for libido or serving capacity have generally shown poor relationships with breeding soundness scores, scrotal circumference, semen quality, size of vesicular glands, dominance rank, average daily gain, and resting blood concentrations of either testosterone or LH.[13] This indicates that, with the current state of knowledge and technology, comprehensive bull evaluation will require assessment of physical soundness, internal and external genitalia, semen quality and libido, as well as his breeding capability.

CHAPTER 31

Evaluation of Potential Breeding Soundness of the Bull

ALBERT D. BARTH

It is estimated that at least one in five bulls in an unselected population would be subfertile owing to inability to serve cows efficiently or to poor semen quality. Although some bulls have such serious impediments to fertility that low pregnancy rates result, many bulls that are less than satisfactory achieve acceptable pregnancy rates under low breeding pressure and over a prolonged breeding season. Disastrously low pregnancy rates are very noticeable and can be financially devastating to the individual producer. In the beef industry, the greatest economic loss that is attributable to subfertile bulls is delayed conception (low first-service pregnancy rate)—which may not be noticed by the producer. It has been estimated that for every 21 days of the breeding season during which a cow remains open, a loss of 50 to 60 pounds of weaning weight can be expected the following year for the calf she finally conceives. Therefore, a subfertile bull could be the cause of economic losses in the range of $1500 to $3000 due to reduced weaning weights a year later, depending on the degree of subfertility, bull-to-female ratios, and weaned calf prices. Additional losses will accrue with the culling of open cows and cows that conceived late. Cows that calve late tend to do so perpetually in following years.

In multiple-sire pasture breeding, a great deal of breeding overlap will occur. As many as 80% of cows may be bred by two or more bulls during one estrous period. Thus, bulls with high fertility can compensate for bulls with poor fertility. Because of the common use of multiple-sire breeding and low bull-to-female ratios, inept bull evaluation often is masked by the excellent performance of highly fertile bulls in a group. Nevertheless, as the

tal and managerial influences. Test scores for libido or serving capacity have generally shown poor relationships with breeding soundness scores, scrotal circumference, semen quality, size of vesicular glands, dominance rank, average daily gain, and resting blood concentrations of either testosterone or LH.[13] This indicates that, with the current state of knowledge and technology, comprehensive bull evaluation will require assessment of physical soundness, internal and external genitalia, semen quality and libido, as well as his breeding capability.

CHAPTER 31

Evaluation of Potential Breeding Soundness of the Bull

ALBERT D. BARTH

It is estimated that at least one in five bulls in an unselected population would be subfertile owing to inability to serve cows efficiently or to poor semen quality. Although some bulls have such serious impediments to fertility that low pregnancy rates result, many bulls that are less than satisfactory achieve acceptable pregnancy rates under low breeding pressure and over a prolonged breeding season. Disastrously low pregnancy rates are very noticeable and can be financially devastating to the individual producer. In the beef industry, the greatest economic loss that is attributable to subfertile bulls is delayed conception (low first-service pregnancy rate)—which may not be noticed by the producer. It has been estimated that for every 21 days of the breeding season during which a cow remains open, a loss of 50 to 60 pounds of weaning weight can be expected the following year for the calf she finally conceives. Therefore, a subfertile bull could be the cause of economic losses in the range of $1500 to $3000 due to reduced weaning weights a year later, depending on the degree of subfertility, bull-to-female ratios, and weaned calf prices. Additional losses will accrue with the culling of open cows and cows that conceived late. Cows that calve late tend to do so perpetually in following years.

In multiple-sire pasture breeding, a great deal of breeding overlap will occur. As many as 80% of cows may be bred by two or more bulls during one estrous period. Thus, bulls with high fertility can compensate for bulls with poor fertility. Because of the common use of multiple-sire breeding and low bull-to-female ratios, inept bull evaluation often is masked by the excellent performance of highly fertile bulls in a group. Nevertheless, as the

economic pressure for highly efficient beef production increases, including the use of short breeding seasons, high bull-to-female ratios, and single-sire breeding groups, the need for thorough, unbiased breeding soundness evaluations also will increase.

Veterinarians often feel pressured to compromise their standards by clients who wish to obtain a "satisfactory" classification for breeding soundness of certain bulls (discussed later in the chapter under "Breeding Soundness Classification"). A veterinarian's fear of jeopardizing client relationships and lack of self-confidence regarding ability to evaluate bulls may result in approval for use of bulls of questionable fertility. In the long term, taking chances on cow herd fertility is of benefit to no one. Although it may be difficult to be sure that cow fertility will actually be depressed by allowing mating with questionable bulls, only bulls with the potential for high fertility should be classified as satisfactory.

In addition to freedom from disease, a bull requires three attributes to be fertile: (1) good libido, (2) physical soundness, and (3) good semen quality. These three attributes must be held in the forefront of all decisions regarding herd sire selection and breeding soundness evaluations.

LIBIDO AND SERVING CAPACITY

Serving capacity describes the number of matings a bull is willing and able to perform in a test situation. In spite of extensive research showing the importance of libido and serving capacity to fertility, the use of standardized tests has not become part of routine bull evaluation in North America. Furthermore, methods of bull evaluation have in the past almost totally ignored this part of breeding soundness, and producers often have been lulled into a false sense of security by a satisfactory test result. Veterinarians must inform producers when this critical component of bull fertility remains unassessed. It is particularly important to assess libido and serving capacity in yearling and 2-year-old bulls that have had no previous breeding experience. Many factors, however, including injuries and the development of penile deviations, can incapacitate older bulls that have been sound breeders in the past.

It may be necessary to advise producers on how to assess bull libido and serving capacity. For example, the mere presence of an older dominant bull may completely suppress the expression of libido in younger bulls. Yearling bulls often require some time after exposure to estrual females to develop their instincts and learn how to become efficient breeders. Studies have shown that libido or serving capacity tests do not provide reliable results in yearling bulls. Therefore, observations for libido and serving capacity must be diligently undertaken at the beginning of the breeding season and continued for its duration to ensure that estrual females are being bred.

Under certain circumstances, whether to assess the libido and serving capacity of individual problem bulls or for selection of a bull battery for a producer's herd, practitioners may wish to become involved in libido and service capacity testing. Various testing methods have been investigated, including pasture versus corral settings, use of restrained versus unrestrained cows, use of estrual versus nonestrual cows, test durations ranging from 5 minutes to days, and testing each bull individually versus four or five bulls simultaneously. In Australia, a 3-hour corral test with restrained heifers had a correlation of 0.92 with a 19-day pasture test, but because the first hour of that test had a correlation of 0.91, 1 hour was considered satisfactory. Further testing demonstrated that a 40-minute test had a correlation coefficient of 0.99 as compared with 1 hour. Reduction to a 20-minute test period lowered the correlation to 0.91. Twenty-minute tests seem to be the most practical and are of sufficient accuracy for most purposes.[1]

Methods of Testing Libido and Serving Capacity

Bulls to be tested are exposed to restrained cows in a small paddock or pen and observed for expression of sex drive, ability to serve cows, and the number of services completed in a given time period. Strong cows in good body condition are preferred as mount animals. One or more mount cows are restrained in short-sided breeding crates and sedated with xylazine (0.03 mg/kg IV). Cows need not be in estrus, and some practitioners believe that bulls spread out their services more evenly if cows are nonestrual and restrained at least 20 meters apart. When only one or two bulls need to be tested, it usually is advantageous to have an estrous cow to ensure sexual stimulation of the bulls to be tested. The vagina of each mount cow should be lubricated with approximately 30 ml of a sterile lubricating jelly to reduce tissue trauma from repeated breedings.

Bulls to be tested must first receive 10 minutes of sexual stimulation by allowing them to watch another "stimulator" bull serving the mount cow. The stimulator bull may be a test bull himself, and if he performs well initially, without prior sexual stimulation, further testing may not be necessary for him. Generally it is best to select an older, experienced bull to be the stimulator bull. Depending on available human assistance, one or two more bulls than mount cows are turned into the pen with the mount females. For example, with two mount cows, three bulls may be turned into the test pen at one time. Personnel can encourage serving by moving individual bulls to a different cow, separating bulls that are interfering with each other, or removing bulls that appear to be a threat to more timid bulls. Younger bulls should be tested separately from older bulls to prevent social dominance factors from invalidating test results. Some bulls are afraid of people and will not perform in a test situation. Bulls that give questionable results should be retested under different conditions or on different days to ensure that good bulls are not culled erroneously owing to spurious test results. Provided that bulls do not develop health problems, serving capacity test results are highly repeatable. Even after a period of 6 months, bulls had remarkably similar serving capacity scores.

In a 20-minute test, a serving capacity of 0 to 1 is considered low, 2 to 3 is medium, and 4 or more services are considered to indicate high serving capacity. When large numbers of bulls need to be tested, and only bulls of low

serving capacity will be culled, bulls that serve a cow twice within the first few minutes can be removed immediately, to conserve the mount cows and speed up the testing process.

PHYSICAL SOUNDNESS

General Health

Breeding soundness examinations are not meant to be health examinations. It is taken for granted that bull health, like the health of all other herd members, is the concern of the producer, who is responsible for detecting any signs of health problems. By virtue of their training, however, clinicians should intuitively be alert for abnormalities in a bull's attitude, general appearance, body condition, and fecal characteristics that may warrant further investigation into the health of the animal presented for fertility evaluation. Because bulls rely mostly on vision to detect cows in heat, and because the development of squamous cell carcinoma or corneal opacity due to pinkeye is common, special emphasis is placed on examining the eyes. Furthermore, some evidence suggests that squamous cell carcinoma has a heritable basis, and selection against it may be well worthwhile to reduce the incidence of this problem in a cow herd.

The Musculoskeletal System

A great deal of emphasis must be placed on sound conformation of the feet and legs of a bull. Bulls must travel long distances in order to detect females in heat and breed them. During the mating act, the full weight of the bull (commonly 900 to 1100 kg [1980–2420 lbs]) is borne on the hind legs and feet. Clearly, then, any unsoundness in this region will drastically interfere with breeding ability. Many producers fail to realize that although a bull with a conformation defect of the feet or legs may get by for 2 or 3 years, the more serious danger is that the defect will be passed on to offspring. Replacement heifers carrying conformational defects will propagate these problems in the cow herd, reducing longevity, increasing labor in herd management, and increasing veterinary expense. Common foot and leg problems that have a hereditary basis include the corkscrew claw defect, interdigital fibromas (corns), weak pasterns, post-leggedness, and sickle hocks. An effort must be made during the breeding soundness evaluation to watch the bull walk. Too often bulls are seen only standing in a chute, and although most of the onus is on the breeder to cull bulls with poor conformation and on the producer to procure physically sound bulls, it is not uncommon for them to disregard or fail to detect serious abnormalities.

The Scrotum and Testes

Examination of the Scrotum and Its Contents

Bulls must be adequately restrained to allow comfortable and thorough palpation of the scrotum and its contents. If a clinician does not feel safe behind the bull, a careful examination cannot be completed. For most *Bos taurus* bulls, a strong pole placed at the proper height tightly against the bull's lower buttocks will allow examination of the scrotum and yet prevent injury from kicking. A height of 30 inches (76 cm) from the floor to the bottom of the pole is most practical and works well for most sizes of bulls. *Bos indicus* bulls generally require more secure restraint systems.

Letting the bull become aware of the veterinarian's presence behind him by talking to him and touching him on the rump and thighs before touching the scrotum usually will prevent the bull from reacting to scrotal examination. In general, bulls do not resent palpation of the testes and rarely kick; however, it is common for them to lift their legs at the beginning of the examination. With such movements, the bull's hock may catch the veterinarian's arm and knock it against the post above. To prevent this, one arm should be introduced between the bull's hind legs parallel to the bull's longitudinal axis at the start of palpation until the bull settles down. When both arms are placed between the bull's hind legs, the elbows should be held together. Bulls also are likely to flinch or lift their feet during forceful pressing of the testicles to the bottom of the scrotum. If large numbers of bulls must be examined, padding the veterinarian's wrists and forearms may be helpful. Some bulls are very fractious, and palpating the scrotum may be dangerous because of continuous balking at restraint in the chute. If semen collection is planned, it often helps to do the semen collection first. After the procedure of electroejaculation, fractious bulls usually stand quietly for the scrotal examination.

A visual appraisal of the shape of the scrotum in a warm environment, while the bull is relaxed, reveals valuable information about the thermoregulatory abilities of the scrotum, as well as giving an indication of testis size. Presence of a scrotal "neck" above the testes is of critical importance because this region contains the countercurrent heat exchange mechanism of the testicular cords. In cooler temperatures, the scrotal shape cannot be determined, because the dartos muscle in the scrotal wall and the cremaster muscles will hold the testes closer to the body wall. In cool conditions, the testes must be manually pushed down into the scrotum, stretching the puckered scrotal wall to allow an assessment of scrotal shape. Nevertheless, it is often difficult to reliably assess scrotal shape in cool temperatures. Short scrotums or excess fat in the scrotal neck will prevent normal heat exchange, resulting in abnormal spermatogenesis and possibly testicular degeneration. Less commonly, abnormal scrotal shape may be due to a short caudal frenulum of the scrotum, unilateral testicular hypoplasia, orchitis, scrotal hernia, rotation of the testis, displacement of the cauda epididymidis, or rotation of the scrotum so that the testicles are held in tandem. The scrotum also should be examined for thickness of the scrotal wall, the amount of fat in the neck of the scrotum, and lesions in or on the scrotum.

The testicular cords should be palpated from the body wall down to the top of the testes to detect abscesses, variceles, or a scrotal hernia. The caput epididymidis, located primarily craniodorsally on the testis, usually is palpable and may feel more prominent in some bulls than in others. It is not uncommon to find enlargements

in this area due to inflammation or sperm granulomas, which may prevent sperm transport and result in a small, flaccid, empty cauda epididymidis. The body of the epididymis can be palpated on the medial aspect of the testis by first sliding the opposite testis upward; however, it is extremely rare to detect abnormalities in the corpus epididymidis. The cauda epididymidis of a normally functioning testis is turgid and prominent. Differences in size and consistency between the left and the right cauda epididymidis may indicate inflammation on one side or may result from a blockage of sperm transport on the side of the smaller cauda. Segmental aplasia of one or both epididymides probably is an inherited condition.[2] Occasionally, the ligament that attaches the cauda epididymis to the bottom of the testis is absent or very long, so that the cauda is separated from the bottom of the testis. This condition does not necessarily interfere with semen quality and may not be of concern to a commercial cow-calf producer.

The testes must move freely within the scrotum. Careful palpation of the testes must be done to detect possible abscesses, tumors, hematoceles, or calcification. In some cases, ultrasonography or infrared thermography may be helpful for diagnosis of testicular abnormalities. The consistency of the testis often is difficult to ascertain by subjective palpation. Although the use of tonometers for measuring consistency of testes removes much of the subjectivity, tonometer measurements have not been strongly correlated with semen quality and are not commonly used. In general, yearling bulls have very firm testes compared with those of older bulls. Testes that are obviously soft are most likely to indicate testicular degeneration. This usually can be confirmed by semen analysis.

Scrotal Circumference

The relationship of scrotal circumference to fertility. Scrotal circumference (SC) measurements are highly correlated with paired testis weight, which in turn is directly and highly correlated with daily sperm production and high semen quality traits.[3] Considerable evidence also indicates that SC measurements between 1 and 2 years of age are moderately to highly heritable.

Studies have shown that SC is a more accurate predictor of age at onset of puberty than either age or weight, regardless of breed. Among breed groups, negative correlations greater than 0.9 have been observed between SC and bull age at puberty, age at puberty in half-sibling heifers, and age at puberty in heifer offspring. Good evidence indicates that heterosis in cattle for traits related to size and age at puberty in females and SC of males is due to dominance effects of genes. Furthermore, correlations of 0.66 and 0.97 have been found between breed mean SC and fertility of female offspring.[4]

Strong genetic correlations were reported between SC and age at first breeding (–0.77), age at first calving (–0.66), and pregnancy rate (0.66). Because age at puberty in females is favorably associated with subsequent reproduction, selection for larger SC should improve the reproductive potential of the cow herd.

There is no question that small testes are undesirable. Histologic studies in 14-month-old bulls and in 2- to 3.5-year-old bulls showed that the proportion of seminiferous tubules with normal seminiferous epithelium is significantly lower in small testes (SC less than 32 cm). Yearling bulls with small testes do not exhibit catch-up growth over time and will have small testes at 2 years of age as well. Therefore, yearling bulls with SC below the recommended minimum should be culled.

Effects of nutrition. In young bulls, scrotal circumference measurements are affected by breed, body weight, and age at onset of puberty. Testis growth rate is maximal during puberty, and the level of nutrition in young growing bulls has a great influence on the age at onset of puberty. High-energy diets with adequate protein, vitamins, and minerals hasten the onset of puberty in bulls.[5] The early attainment of puberty improves the opportunity for early postpubertal development. This implies greater numbers of and higher-quality spermatozoa available when the bull is first used for breeding.

High-energy intakes up to about 12 months of age in beef bulls usually do not impair future semen quality, provided that their rations from 1 to 2 years of age do not result in fattening. This probably is because young, rapidly growing bulls can put the excess energy into growth, rather than fat. Nevertheless, Angus and Hereford bulls fed a high-energy diet of 80% grain and 20% forage from weaning to 15 months of age showed significantly lower sperm outputs than those in bulls on a medium-energy diet of 100% forage. Bulls in high-energy diet groups had a greater mean SC at 12 months, but not 15 months, of age, than that in bulls in medium-energy diet groups. Furthermore, excessive energy intake in young bulls may result in abnormal foot growth and conformation because of laminitis and possibly epiphysitis. In addition, high-energy diets increase the risk of rumenitis and liver abscesses, which may lead to the development of vesicular adenitis and epididymitis.[6]

Twelve-month-old Hereford and Angus bulls fed high-energy diets (80% concentrate) until 21 months of age had reduced epididymal sperm reserves, lower percentages of progressively motile sperm, and higher percentages of sperm abnormalities compared with bulls fed a medium-energy diet. Furthermore, Hereford bulls on the high-energy diet demonstrated a decline in testicular size that began at approximately 19 months of age, probably from testicular degeneration brought on by obesity.

Effect of breed. The spermatogenic rates in normal postpubertal bulls of different breeds are similar, and each gram of functional seminiferous tissue contains a similar amount of seminiferous tubule epithelium. Different studies have shown that each gram of normal functioning testicular tissue produces approximately 17 million sperm per day. Testicular shape is remarkably uniform among all breeds. To date, it has not been proved that some breeds with longer, narrower testes can produce larger numbers of sperm than other breeds with equivalent SC measurements.

Significant genetic variation exists among breeds of beef cattle for age at puberty.[7] In general, faster-gaining breeds of larger mature size reach puberty at a greater weight than that observed for slower-gaining breeds of smaller size. Breeds historically selected for milk

Aberdeen Angus	37.2
Charolais	36.3
Horned Hereford	36.1
Polled Hereford	35.6
Shorthorn	34.9
Limousin	32.2
Texas Longhorn	34.6

Data (for 6 studies in the United States and Canada) from Barth AD: Breeding soundness evaluation of bulls. The Western Canadian Association of Bovine Practitioners. Continuing Education, Western College of Veterinary Medicine, Saskatoon, Canada, 2000.

production (e.g., Braunvieh, Gelbvieh, Red Poll, Pinzgauer, Simmental) reach puberty at significantly younger ages than those typical for breeds not selected for milk production (e.g., Charolais, Limousin, Hereford). Great differences are recognized between breeds of bulls in average testicular size at any given age. In general, the large milk-producing beef breeds have an earlier onset of puberty and develop larger testicles at an earlier age and at maturity than smaller breeds of cattle that have lower milk production. Double-muscled breeds such as Piedmonte, Belgian Blue, Parthenaise, Blonde d'Aquataine, and Limousin have a later onset of puberty and smaller average testis size at puberty and at maturity. Few breeders have made an effort to select for larger testis size in these latter breeds; consequently, the breed averages for SC are small. Some breeders, however, have capitalized on the high heritability of testicle size and have made remarkable progress selecting for that trait. Breeders and producers alike are encouraged to select for average or above-average SC, just as they would select for calving ease, weaning weight, or yearling weight. SC data for yearling bulls and 2-year-old bulls are available for many of the common beef breeds (Tables 31-1 and 31-2).

Technique of scrotal circumference measurement. After the testes and epididymides are palpated to ensure that they are normal, the testes are positioned firmly into the lower part of the scrotum so that they are side by side, and scrotal wrinkles that may inflate the measurement are eliminated. This maneuver is particularly important in cool temperatures if accurate results are to be obtained. The testes are held down within the scrotum by placement of the fingers and thumb at the sides of the scrotal neck; however, if the testes are forced down too strongly, softer testes will compress and expand horizontally, resulting in an inflated measurement. The examiner's fingers or thumb must not be placed between the testes, because this will force them apart, also falsely increasing the measurement. A looped tape measure is placed around the greatest diameter of the testes and pulled snugly so that the tape is firmly in contact with the entire circumference. Measurements must be done carefully and repeated to ensure accuracy and repeatability.

Sources of error and reduced repeatability in scrotal circumference measurements. The amount of tension applied by different practitioners can be a source of error in spite of the fact that normal testicular tissue compresses only slightly. The development of spring-scale attachments on scrotal tapes should reduce the variability in SC measurements between veterinarians. When large groups of sale bulls are measured under similar conditions by the same person, the use of a spring-scale scrotal tape is likely to increase producer confidence in SC measurements. Nevertheless, bull weight changes, differences in ambient temperatures at the time of SC measurement, and other factors will still cause variation in reported results on the same bull. For example, in cool temperatures, even if the testes have been carefully pushed down into the scrotum, a larger measurement probably will be obtained than when the scrotum is fully relaxed in warm temperatures.

It appears that fat bulls consistently have larger SC measurements than those obtained after a period of weight loss. In one experiment, 251 bulls of Horned Hereford, Polled Hereford, Aberdeen Angus, and Charolais breeds were evaluated at the time of sale and again just before the breeding season approximately 2 months later. Horned Hereford, Polled Hereford, Angus, and Charolais bulls lost weight over the interval from sale to prebreeding at a mean rate of 2.02, 1.82, 1.71, and 0.94 kg per day, respectively. The rates of loss in backfat and in SC corresponded with the rates of loss in body weight. The loss in SC over the interval from sale to prebreeding was 2.31, 1.95, 2.16, and 1.83 cm for Horned Hereford, Polled Hereford, Aberdeen Angus, and Charolais bulls, respectively.

The cause of the loss in SC most likely was due to weight loss between March sales and May breeding soundness evaluations. The cooler sale barn temperatures in March, however, also may have contributed to the differences in SC measurements.

Changes in testicular tone due to testicular degeneration can occur very rapidly. Within a period of 2 weeks it is quite possible for SC to decrease 2 to 4 cm or even more in severe cases. Subsequently, regeneration and regaining 2 to 4 cm in SC may be observed over 1 to 3 months. These changes will be reflected by changes in testicular tone and semen quality. In such instances, without monitoring of seminal quality, the differences in measurement may be erroneously assumed to be due to differences in technique among veterinarians.

Transrectal Internal Examination

The main focus of the transrectal internal examination is on the accessory sex glands and the inguinal rings. The accessory sex glands of the bull include the prostate, bulbourethral, and vesicular glands. The vesicular glands are lobular structures 8 to 15 cm long, 3 to 5 cm wide, and 1 to 2 cm thick. They lie lateral to the ampullae and neck of the bladder. Congenital defects of the vesicular glands have been reported. These defects usually are unilateral and include aplasia, hypoplasia, cysts, and duplication of the gland. These abnormalities characteristically are associated with anomalies of the mesonephric duct system, which gives rise to the epididymis, ductus deferens, ampullae, and vesicular glands. The bulbourethral glands are embedded in the urethralis muscle caudally near the anal region and are not palpable.

The urethra usually is the first structure palpated. It is a firm tubular structure that usually becomes pulsatile on transrectal palpation as a result of the contractions of the urethral muscle surrounding it. The prostate gland is palpated as a transverse, smooth band surrounding the cranial extremity of the urethra. At this point, the vesicular glands can be palpated craniolateral to the prostate. The vesicular glands vary a great deal in size between bulls. They are smallest in yearling bulls and increase in size with age. They should be uniform in size, lobulated, turgid, and mobile. The ampullae are not very distinct on palpation but can be found by pressing the fingertips over the floor of the pelvis cranial to the prostate gland and moving the fingers back and forth in a lateral direction. The ampullae normally are 10 to 15 cm long and 5 to 8 mm in diameter and can be followed forward to the ductus deferens, which leaves the abdomen through the inguinal rings. Disease of the ampullae often is not clinically detectable. The internal openings of the inguinal canals may be palpable per rectum 15 to 20 cm ventral to the pelvic brim and 5 to 15 cm lateral to the midline. Enlarged inguinal rings are uncommon and are, in most instances, unilateral. A bull with an enlarged inguinal ring will be predisposed to development of a scrotal hernia during breeding. Some evidence suggests that enlarged inguinal rings have a heritable basis.

The most common abnormal finding on rectal palpation is enlargement, excessive firmness, or loss of lobulation of the vesicular glands. Vesicular adenitis occurs in 2% to 4% of yearling and 2-year-old bulls, but the incidence has been reported to be as high as 49%. The incidence in older bulls is less than 1%. Unilateral and bilateral cases of vesicular adenitis have been reported, but unilateral cases are more common. Enlargement with loss of lobulation is the usual finding; long-standing cases, however, may be characterized by adhesions, abscessation, and occasionally, the development of a fistulous tract draining into the rectum, or rarely, the development of peritonitis. In early infections, the glands may not be noticeably enlarged, but neutrophils may be found on examination of semen smears.

In semen smears stained with eosin-nigrosin or eosin–aniline blue, neutrophils with intact membranes appear as white, somewhat irregular bodies with a diameter approximately three times the length of a sperm head. If the neutrophil cytoplasmic membrane is damaged, eosin will enter the cell, staining it pink. To see the characteristic lobulated nucleus of neutrophils, the semen smear must be stained with Wright-Giemsa stain or new methylene blue. Normally, semen smears do not contain any neutrophils. A finding of one or more neutrophils per three microscope fields at 1000× magnification has been suggested as indicative of a significant inflammation somewhere in the reproductive tract. Inflammatory cells usually clump together, however, so large numbers of neutrophils may be found in 1 or 2 fields and none in the next 10 fields. Often, the presence of purulent material in an ejaculate is first indicated by the presence of mucoid streaks and clumps grossly visible on the semen smear. Some caution must be used in interpreting the finding of neutrophils in a semen smear. The source of inflammatory cells may not be the accessory glands or the epididymis. Superficial irritation or injury of the penis and prepuce often results in an abundance of neutrophils on the surface, which may serve as a source of contamination of the semen sample.

The examiner can obtain bacterial pathogens for culture and antibiotic sensitivity testing by collecting semen in a sterile manner with electroejaculation or by passing a long sterile catheter up the urethra and aspirating while massaging the glands. A wide variety of organisms have been isolated from infected vesicular glands; however, in areas in which brucellosis is controlled, *Arcanobacterium pyogenes* is the most common bacterial pathogen found.

SEMEN QUALITY

Methods of Semen Collection

Electroejaculation

Equipment. Currently at least six types of electroejaculators are available on the North American market. Differences between models include how the device is operated and how the bull responds. The kind of electroejaculator used is largely a matter of personal preference.

Rectal probes are available with various diameters and with differences in orientation of the electrodes. Large-diameter probes produce a stronger response to stimuli of a given electrical output than do probes of small

diameter. For most bulls weighing 1200 to 2000 lb (550 to 900 kg), a probe with a diameter of 6.5 to 7.5 cm seems ideal. In larger, older bulls, use of a 9-cm-diameter probe increases the likelihood of adequate stimulus to achieve penile erection and ejaculation. Modern probes have three electrodes spaced about 1 cm apart and are placed completely into the rectum with the electrodes facing ventrally. A U-shaped extension on the back of the probe fits around the tail, ensuring proper orientation of the electrodes during electroejaculation. These probes result in good penile protrusion and electroejaculation with minimal extraneous muscle stimulation. By contrast, the older probes with four electrodes spaced equally around the circumference result in excessive stimulation of the large muscles of the back and hindquarters.

More recently developed probes have three longitudinal ventral electrodes divided into three segments. The segments of the electrodes can be activated separately. The caudalmost segment is used to produce erection and protrusion in all bulls, as well as ejaculation in most yearling bulls. In older bulls, the middle segment and occasionally the cranial segment are used to stimulate ejaculation. The relative effectiveness of segmented probes, or whether they reduce extraneous muscle stimulation or stress in bulls, needs to be evaluated.

Stimulation technique. After examination of the internal organs and inguinal rings by transrectal palpation, the pelvic urethra should be massaged for 30 to 60 seconds in preparation for the collection of semen. The area over the ampulla, prostate, and urethra is massaged by moving the clinician's fingers back and forth in a longitudinal direction. Stimulation will become evident by pulsation of the urethral muscle. In addition, the testes usually will be drawn up, and some clear fluid will drip from the prepuce. Sexual stimulation of the bull by massage seems to facilitate semen collection by electroejaculation. The rectum must be evacuated of feces, and care must be taken to prevent air from entering the rectum. Insertion of the rectal probe is facilitated by lubrication of the probe and rapid massage of the anal region to promote relaxation of the anal sphincter.

The amount of electrical stimulation should be gauged at all times by the response of the bull, rather than by the reading of the meter on the machine. The first stimulus should be applied slowly until the bull gives a minimal response. Each successive stimulus should then be increased slightly in intensity. Stimuli should last 1 or 2 seconds and then be discontinued for about 0.5 second before the next is applied. When the fluid emitted begins to get cloudy, the collection cone is placed over the penis and a sample is collected. If the bull fails to protrude the penis, an assistant should push on the sigmoid flexure behind the scrotum. The operator should be ready with a gauze sponge to grasp the penis when it protrudes. Stimulation usually is continued until 2 to 5 ml of semen is collected.

Bulls usually emit semen without a great deal of stimulation; however, if maximal stimulation has been reached without ejaculation, a total of four or five maximal stimuli should then be given, followed by a 1- to 2-minute rest. The penis should be grasped with a gauze sponge and held during the rest period, because once the penis is retracted, it often will not be protruded during a second attempt at semen collection. Often semen is emitted as the bull begins to relax during the rest period, and the operator must be ready to collect it. As soon as the bull has had a short rest, a second attempt can be made to collect semen. In most instances, semen will be ejaculated on the first few stimuli after the rest period. A similar rest period can be given to a bull that ejaculated easily on the first attempt when a second sample is desired. Frequently, the second sample will be more concentrated than the first.

Difficulty in obtaining semen samples by electroejaculation may be due to several factors. Insufficient electrical stimulus may be due to presence of an excessive amount of air or feces in the rectum, inadequate probe size, a buildup of varnish on the probe electrodes, or weak batteries in the electroejaculator. Electroejaculation seems to be more difficult in fractious, frightened bulls; however, tranquilization of bulls with acepromazine, but not xylazine, is likely to increase the difficulty in obtaining a semen sample. Bulls that have ejaculated repeatedly in the previous 24 hours (e.g., bulls in breeding use) often are difficult to stimulate to ejaculation by this method and produce samples of low sperm density.

Semen cannot be collected by electroejaculation from 1% to 2% of normally fertile bulls despite every effort. Several alternatives to electroejaculation that may be considered are semen collection by massage, use of an artificial vagina (AV), and retrieval of semen from the vagina immediately after breeding.

Massage

Semen can be collected from many bulls by transrectal massage. Sexually rested, quiet mature bulls that have been handled calmly are good candidates for this technique. The hand of the operator is introduced into the rectum, and after the inguinal rings and accessory sex glands have been examined, a longitudinal back-and-forth massage is applied mainly over the ampullae and prostate and periodically over the urethra. Stimulation of the vesicular glands by this method appears to be of minor importance. Massage should be continued until a semen sample is collected, but if no semen is collected within 2 to 3 minutes, usually further massage will be unsuccessful.

Semen collection by transrectal massage carries some disadvantages and may not be practical in all situations. Some of the disadvantages include rectal mucosa irritation, incomplete penile protrusion, the necessity of a second person to collect the semen sample, and difficulty in stimulating excited or fractious bulls. Also, the number of bulls in which this method can be applied at one session is limited, because the procedure is very tiring for the person doing the massage.

Use of an Artificial Vagina

Semen collection with an AV is performed almost exclusively in artificial insemination centers. The method is not used routinely in breeding soundness evaluations but may be considered in bulls that have normal testes and epididymides but produce poor semen samples or no semen at all by electroejaculation. The AV method of

collection sometimes is preferred in prepurchase examinations by artificial insemination centers and by personnel from foreign countries interested in importing bulls.

Bulls considered for collection by AV should be halter-broken and nose ring–trained. The mount animal should be restrained in a short-sided breeding chute. Bulls that are not accustomed to serving an artificial vagina may need a female in estrus in order for the procedure to be successful. The female may need to be sedated (xylazine, 0.03 mg/kg IV) to facilitate collection. The AV is prepared by filling the water jacket with water hot enough to result in a final AV temperature of 42° to 50° C. Air can be added to increase the pressure until the AV liner bulges out of the end slightly. Finally, the AV is lubricated with a sterile nonspermicidal gel. When the bull mounts, the collector must be ready to step in immediately and direct the penis to the opening of the AV. The penis is never handled directly; rather, the operator directs the penis by grasping it through the sheath. The AV is not shoved onto the penis; the bull will make seeking motions and must be allowed to thrust into the AV. The thrust may be extremely vigorous, so that an unwary collector may be knocked off balance or the AV knocked out of the hand.

Collection of semen with an AV from untrained range bulls by conventional means often is unsuccessful. In my experience, however, approximately 85% of untrained range bulls will mount a restrained estrous female and serve an AV if the person handling the AV cannot be seen by the bull. This can be accomplished by fixing a canvas tarp beside the mount cow as a blind. In addition, a triangular piece of tarp must be fashioned to extend perpendicularly across the cow's rump to prevent the bull from seeing behind during mounting.

An alternative to the conventional AV is the recently designed intravaginal AV. Nearly all bulls that normally will serve a cow will readily serve an intravaginal AV.

Finally, a bull may be allowed to breed an estrual female whose vagina has been flushed with saline to remove mucus. After the female is bred, it usually is easy to aspirate a small amount of semen from the cranial vagina.

Evaluation of Semen Quality

Semen Density and Volume

Unlike semen evaluation in the stallion, boar, and dog, in which the total number of spermatozoa in an ejaculate often is used to estimate potential sperm output, the capacity to produce sperm in bulls is determined by measurement of SC. With a regular schedule of semen collection using an AV, as in artificial insemination centers, ejaculate volume and density (sperm output) provide meaningful information about a bull's capacity to produce sperm. With electroejaculation of bulls, however, many factors may affect the volume and density of semen samples, making these characteristics unreliable for evaluation of semen quality. Nevertheless, when several milliliters of concentrated semen are collected with reasonable ease, it provides some assurance that the bull is capable of producing good ejaculates.

The seminal traits of sperm density and motility (described next) usually are described as very good (VG), good (G), fair (F), or poor (P). These descriptors have been in use for longer than 30 years and have specific meanings. The following descriptors are used for sperm density:

VG = creamy, grainy semen with 750 million to 1 billion or more sperm per milliliter
G = milk-like semen with sperm counts of 400 million to 750 million/ml
F = skim milk–like semen with sperm counts of 250 to 400 million/ml
P = translucent semen with sperm counts of less than 250 million/ml

Sperm Motility

Spermatozoa are in a quiescent state within the cauda epididymidis. In order to be motile, spermatozoa are dependent on a normal pH, warm temperature, an osmotically balanced medium, and adequate concentrations of ions and nutrients in seminal fluid.

It is very easy to inhibit motility by contamination of the semen sample or improper handling procedures. For example, glassware used in motility estimates may be contaminated by soap residue from washing, or small amounts of soap may be splashed onto slides from nearby sinks, and chemicals present on the fingers may be transferred to slides during handling. Semen samples may become contaminated by urine during electroejaculation or may contain pus. Cold or hot test tubes, glass slides, or microscope stages, as well as rapid drying or cooling of a drop of semen on a slide exposed to wind, will quickly destroy sperm motility. Seminal fluids do not maintain sperm viability for very long, and spermatozoa quickly lose their vigor of forward progression in semen samples that are not examined soon after collection. Repeated ejaculations may result in improved sperm motility in a few bulls that have not ejaculated for a long time.

Gross motility. Gross motility is determined from a 5- to 10-mm-diameter, non-coverslipped drop of semen placed on a warm slide under brightfield microscopy at 40× to 125× magnification. To increase contrast, the condenser diaphragm should be closed, or in microscopes with no diaphragm, the condenser should be lowered. The following descriptors are used for gross motility:

VG = rapid dark swirls
G = slower swirls and eddies
F = no swirls, but prominent individual cell motion
P = little or no individual cell motion

Mass motion is dependent on three factors: concentration, percentage of progressively motile cells, and the speed of progression of spermatozoa. When any one of these factors is depressed, the rapid swirling expected will be severely depressed or eliminated. Semen with fair concentration may have 80% rapidly progressively motile sperm but show no wave motion, whereas highly concentrated semen may have only 50% motile sperm and still show some slow wave motion. On the other hand, semen with very good concentration and a high percentage of progressively motile sperm may have little or

no wave motion if the speed of sperm progression has been diminished by cold temperature or a prolonged interval from collection to examination. Therefore, gross motility must be carefully interpreted. Wave motion is expected when semen samples have good concentration. If wave motion is present, no further examination for motility usually is necessary. If it is absent, a wet mount must be examined for individual progressive motility. When semen samples are dilute, wave motion is not expected, and wet mounts must be prepared for evaluation of individual motility.

Individual motility. New, perfectly clean, warm slides and coverslips are necessary in the preparation of wet mounts. Dust particles on the slide will prevent even fluid dispersion under the coverslip. With well-made wet mounts, semen dilution is often not required to make an estimate of the percentage of progressively motile sperm. A drop of semen 3 to 4 mm in diameter usually is large enough for the fluid to spread barely to the edges of the coverslip, forming a very thin layer of fluid in which individual spermatozoa are all within the same focal plane. Wet mounts should be examined at 200× to 500× magnification, preferably under phase-contrast microscopy. It is difficult to see individual sperm motion under brightfield microscopy even with the diaphragm closed or the condenser lowered. Many modern student microscopes that find their way into clinical practice can be fitted with phase contrast adaptors for 400× magnification at a cost of $600 to $800. For individual progressive motility, the following descriptors are used:

VG = 80% to 100% motile
G = 60% to 79% motile
F = 40% to 59% motile
P = less than 40% motile

Observation of individual motility and estimation of the percentage of progressively motile sperm will provide information about sperm membrane integrity, as well as the morphologic integrity of spermatozoa. For example, if a high percentage of spermatozoa has normal progressive motility, then a finding of a high percentage of bent midpieces, or dead sperm will indicate mishandling of the semen, rather than an inherent abnormality. Similarly, poor motility is consistent with abnormal sperm morphology and dead spermatozoa. If inconsistencies in motility and morphology observations arise, the cause should be established. It may be necessary to repeat the semen collection and evaluation procedure.

Sperm Morphology

Preparation of semen smears. Spermatozoa are translucent and virtually invisible on brightfield microscopy. Visualization therefore requires staining of spermatozoa or provision of a dark background for highlighting the sperm. For example, rose bengal stains all spermatozoa pink against a clear background, whereas India ink provides a dark background and all spermatozoa remain unstained and appear white. The so-called live-dead stains use nigrosin or aniline blue to provide background and eosin as a vital stain. Eosin penetrates damaged cell membranes, staining injured or nonviable sperm pink (dead), while viable sperm repel eosin and appear white (alive). When normal semen has been handled properly and staining is carried out correctly, the percent of sperm staining alive is highly correlated with individual progressive motility. One-step stains, such as eosin-nigrosin, that can be mixed with semen on the slide are preferable because everything that is in the semen will be visible. Staining techniques that require several steps, including washing, are more damaging to spermatozoa, with greater potential for some elements in semen to be washed off, resulting in less reliable differential counts.

Commonly used formulations of eosin-nigrosin and eosin–aniline blue stains are very hypotonic, having an osmolality of 90 to 100. Some buffers cannot be added to these stains, because the salts precipitate and obscure the spermatozoa when the smears are made and dried. Hypotonic shock is easily induced in living spermatozoa by these stains; risk of such injury must be minimized by drying smears as quickly as possible. Fast drying is possible only when glass slides are warm. Blowing air over the smear speeds up drying. The artifact of hypotonic shock is easily recognized as a whipped-around appearance of the terminal portion of the sperm principal piece. Less commonly, the midpiece bends distally. Because the distal droplet usually would be shed before the occurrence of hypotonic shock, no droplet material would be included in the bend. From 5% to 30% of spermatozoa within the cauda epididymidis do not have a distal droplet, however, so the finding of a distal midpiece reflex without a trapped droplet does not necessarily imply hypotonic shock. Observation of sperm motion under a coverslip is very useful to distinguish between tail defects caused by epididymal malfunction and artifactual causes of bent tails.

The addition of glucose or TES-Tris to eosin-nigrosin, raising the osmolality to 266 mOsm/kg, was shown to decrease membrane damage due to staining in boar sperm. This formulation may be useful in preventing hypotonic shock in bull semen.

In preparation of semen smears, a 5- to 6-mm droplet of live-dead stain should be placed at one end of a warm slide. A 3- to 5-mm droplet of semen is then placed beside the stain to control its size before mixing with the stain. The size of the semen droplet depends on the sperm cell concentration. After the stain and semen are mixed on the slide, the mixture is spread slowly from one end of the slide to the other by drawing along the drop with the edge of another slide or with the side of a wooden applicator stick.

Differential counts of sperm morphology must be done using oil immersion plates at 1000× to 1250× magnification. Lower magnifications simply do not reveal a multitude of possible serious defects. With only a few sperm abnormalities in an individual sample, counting 100 sperm is sufficient. When many abnormalities are present, however, a count of 300 or more sperm will provide a more accurate differential count.

Classification of sperm abnormalities. Although the primary and secondary sperm defect classification system has been widely accepted, this system of classification often means different things to different practitioners. By definition, a *primary defect* is one that originates within

the testis during spermatogenesis. A *secondary defect* is one that originates within the epididymis. All head defects such as knobbed acrosomes, pyriform heads, microcephalic sperm, and nuclear vacuoles are therefore primary defects. Most tail defects, including the Dag defect, mitochondrial sheath defects, and coiled principal pieces also have their origins in spermatogenesis and are primary defects. The **Dag defect**, which results from abnormal development of the axoneme and mitochondrial sheath, expresses itself as a shattered midpiece within the epididymis and has therefore been called secondary by some investigators. By definition of origin, however, the Dag defect would be a primary defect.

Some defects can be either primary or secondary. Proximal droplets may be the result of either a disturbance of spermatogenesis (primary) or a disturbance of epididymal function (secondary). Similarly, detached heads may be due to a defect of the basal plate, which connects the sperm head to the midpiece capitellum (primary), or it may be due to abnormal epididymal function (secondary). The **distal midpiece reflex defect**, which develops in the epididymis, appears not to have its basis in spermatogenesis and would thus be a secondary defect. Sperm with distal droplets have never been reported to be associated with infertility and probably should not be classified as defective. This sperm aberration does not appear to originate in the testis or epididymis but rather (when found in large numbers) results from a lack of a hemolytic factor in seminal fluid.

An important point is that the definition for primary and secondary sperm defects denotes the origin and not the severity of a defect. Furthermore, because adverse conditions that cause both types of defects can affect epididymal function and spermatogenesis simultaneously, primary and secondary defects are equally important as indicators of a disturbance of reproductive function. The first sperm defects to appear in semen after the onset of a disturbance of spermatogenesis are epididymal in origin, and these are followed by primary defects. Therefore, the concept that primary defects have a more important effect than that of secondary defects on bull breeding soundness may be questionable in many instances.

Blom attempted to improve the method of classifying sperm defects with the "major" and "minor" defect system.[8] In this system, major defects are those that have been associated with infertility. Minor defects are those sperm aberrations that were not associated with infertility at the time the system was devised. Some defects considered to be minor involved obvious structural abnormalities, and fertilization or embryonic development probably would be impossible using affected sperm. Some examples are small heads, giant heads, and simple bent tails (distal midpiece reflexes). At the time the major-minor system was proposed, these defects had never been identified in large numbers in semen, even though many bulls had been examined at Blom's laboratory. Therefore, these defects were considered to be minor. As Blom predicted, however, with the development of new information, flaws in the system became evident. For example, distal midpiece reflexes that initially were considered to be minor may be found as a heritable defect in Jersey bulls affecting up to 100% of spermatozoa.

Accordingly, it probably would be appropriate to cease classifying sperm defects. Instead, the prevalent sperm defects should be considered in regard to the current understanding of their significance. Because some sperm defects seem more important to fertility than others, a differential count of the defects should be done. In general, a minimum number of normal, live spermatozoa must populate the oviduct to optimize the possibility of a sperm cell's finding the ovum, penetrating the zona pellucida, fertilizing the ovum, and initiating and sustaining embryonic development. Sperm numbers in the oviduct are affected by sperm transport mechanisms within the female reproductive tract and by the dosage of spermatozoa delivered. Once in the oviduct, spermatozoa require normal membrane receptors to bind to the zona pellucida, a normal acrosome and tail in order to penetrate the zona, and a normal nucleus for fertilization.

A great deal remains to be learned about the various sperm abnormalities in regard to sperm transport through the cervix and the uterotubal junction. Progressive sperm motility evidently is essential for transport through the cervix. Once sperm have passed through the cervix, uterine transport mechanisms move both defective and normal sperm into the oviduct; however, the uterotubal junction also may filter a proportion of sperm abnormalities.

It has been shown that spermatozoa with nuclear vacuoles—the diadem defect—are transported normally in the female reproductive tract and that they may penetrate the ovum. This is a very important finding because zona penetration would be expected to result in the cortical reaction, rendering the zona pellucida impervious to other spermatozoa. Increasing sperm numbers in the oviduct would not improve the chances of normal fertility. For example, if a semen sample had 20% diadem defects, it would make no difference to fertility whether 100, 1000, or 10,000 sperm were present in the oviduct; the chance of a vacuolated sperm cell's penetrating the zona pellucida and initiating a zona reaction would always be 20%. On the other hand, spermatozoa unable to penetrate the zona pellucida, such as those with knobbed acrosomes or bent tails, would be unable to induce a zona reaction and thus not prevent normal sperm from fertilizing the ovum. In such instances, increasing the insemination dosage would increase the probability of fertilization. This has led to the concept of **compensable** (by dose) versus **noncompensable defects**.[9]

Abnormal sperm that are not transported to the oviduct, and those that are transported but are not capable of penetrating the zona pellucida may be compensated for by increasing sperm dosage (compensable defects). Abnormal sperm that are not filtered and that are capable of penetrating the zona pellucida, causing a zona reaction, cannot be compensated for by increasing the sperm dosage (noncompensable defects). Although this may be an oversimplified view of aberrant sperm function, it is helpful for the clinician to think of defective spermatozoa in this way when trying to determine whether a bull's fertility may be affected by a given level of specified sperm defects. Recent in vitro fertilization

studies have shown that although diadem sperm will penetrate the zona pellucida, they are less efficient in doing so than sperm without the defect. Therefore, the diadem defect potentially may be partially compensable. Normal sperm coexisting in semen with a high percentage of proximal droplets were found to be less efficient in attaching to, and penetrating, the zona pellucida than normal sperm from unaffected bulls. Proximal droplet sperm, then, cannot be compensated for by simply increasing dose size. The most common abnormal morphologic forms are depicted in Figure 31-1. More information about abnormal sperm morphology may be found in other sources.[10,11]

Tolerance levels of sperm abnormalities. Many experiments have shown a correlation between sperm defects and infertility. Because of the wide variety of factors that affect herd fertility with both natural breeding and artificial insemination, however, few studies have had sufficient sensitivity to establish the tolerable levels of various sperm defects that would be compatible with good fertility. The tolerable levels that are widely accepted today were established by early workers and have been confirmed by more recent work. Generally, the upper limit for sperm nuclear (head) defects is in the range of 15% to 20%, whereas acrosomal and tail defects in up to 25% of sperm may be tolerated. At least 70% of spermatozoa should be normal.

Interpretation of sperm morphology counts. For many veterinarians, the evaluation of sperm morphology is viewed only as a means to determine whether a bull is capable of causing high conception rates. In fact, however, spermatozoa are in a sense a sample of testicular tissue and as such provide information about the health of the seminiferous epithelium and the epididymis. An abnormal spermiogram, when interpreted in light of the bull's history and findings on the physical examination, may suggest the cause of abnormal testicular and epididymal function, a possible course of treatment, and a prognosis for recovery to normal sperm production.

An understanding of normal and abnormal spermatogenesis greatly facilitates the interpretation of a spermiogram. Abnormal spermatogenesis has many possible causes; in most instances the disturbance can be

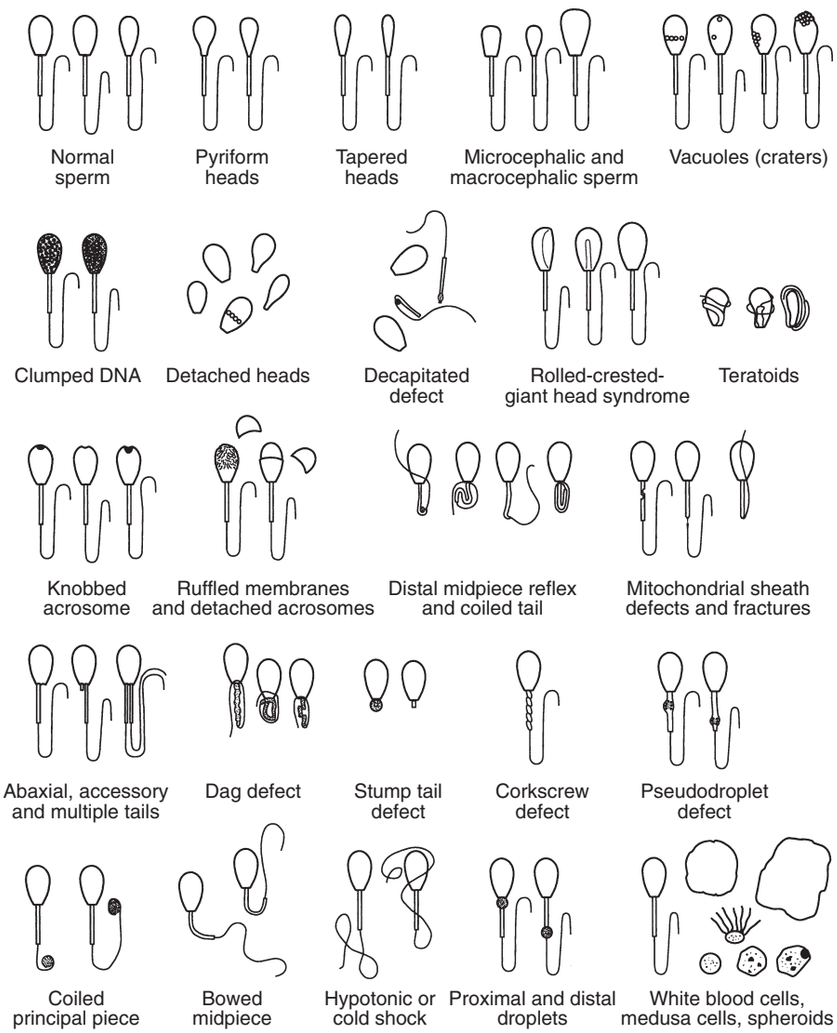

Fig. 31-1 Common abnormal morphologic forms of spermatozoa.

categorized as heat related or stress related. Other, less common causes include genetic, toxic, and perhaps nutritional deficiency. An increase in the temperature of the testes of a bull by 0.5° to 1.0°C maintained for a few days is sufficient to cause a noticeable disturbance of spermatogenesis. It appears that the mechanism of heat damage is through tissue hypoxia. Normally, because of the peculiar anatomy of the blood supply to the testis, the tissue operates on the brink of hypoxia. Raising testicular temperature increases the metabolic activity without a corresponding increase in oxygen supply, and tissue hypoxia ensues.

Normal functions of the epididymis and the seminiferous epithelium are dependent on very high levels of testosterone. Some evidence suggests that hypoxia (heat) also results in reduced testosterone available to the developing germ cells. For example, the Sertoli cells concentrate testosterone by producing androgen-binding protein (ABP). Impaired Sertoli cell function or Leydig cell function may result in reduced testosterone levels.

Stress due to illness, injury, severe and prolonged low ambient temperatures, starvation, transport and environmental changes (e.g., show circuit stress), and pain (e.g., sole abscesses, laminitis, arthritis, dehorning) affects testicular function through an endocrine mechanism. Stress results in excess adrenal cortisol production, which in turn decreases pituitary luteinizing hormone secretion, resulting in reduced testosterone production by the Leydig cells.

Some cells are less susceptible to damage than others; the spermatogonia and Sertoli cells are the least susceptible. The cells in meiosis are quite sensitive to insults and subsequently degenerate, leaving empty spaces in the germinal layer, with reduced sperm output consequent to the decrease in number of cells. The spermatids also are quite sensitive and respond to insults by forming abnormal spermatozoa. For example, a disturbance of spermatogenesis may result in poor condensation of the nuclear chromatin, vacuolation, abnormal head shapes, malalignment of mitochondria in the midpiece, or lack of cementum between fibers of the sperm tail.

Severe disturbances of spermatogenesis result in sloughing of cell layers into the tubular lumen, leaving only Sertoli cells and spermatogonia. This is known as **degeneration.** The empty tubules lose turgidity; thus, testes that have undergone degeneration become softer and smaller. After the insult to spermatogenesis is removed, the spermatogonia repopulate the tubules, the testes may return to normal size and consistency, and normal quantities and quality of semen can be produced. When there is a disturbance of spermatogenesis, usually not all tubules are affected to the same degree. Within a histologic section, completely normal tubules and tubules with cellular damage can be seen; therefore, ejaculates usually have varying proportions of normal and abnormal sperm.

Although heat and stress apparently affect testicular function through different mechanisms, no difference in the types of resulting sperm abnormalities have been observed between the two. A more detailed discussion of spermatogenesis and sperm abnormalities can be found in other sources.[10,11]

BREEDING SOUNDNESS CLASSIFICATION

The four categories of breeding soundness are **satisfactory, questionable, decision deferred,** and **unsatisfactory.** Bulls classified as satisfactory potential breeders are those that have met the minimum requirements for physical soundness and semen quality. Bulls that have unknown sex drive and mating ability may be classified as satisfactory, but documentation of the animal's breeding soundness must mention that this aspect needs to be examined by the producer. The questionable category is for bulls likely to perform adequately in mating but with below-normal fertility, or with an undesirable trait with the potential for genetic transmission to offspring. Some examples follow:

- Bulls with scrotal circumference below the recommended minimum, but with satisfactory semen quality.
- Bulls with conformational abnormalities. A bull with corkscrew claws may be highly fertile, but because the claw defect is heritable, selection of offspring (replacement heifers) from such a bull would eventually lead to foot problems in the cow herd.
- Bulls with high percentages of compensable sperm defects, or a little less than 70% normal sperm at the beginning of the breeding season. Although such bulls may recover normal sperm production at a later date and therefore could be assigned to the category of decision deferred, they would be questionable for immediate use.
- Bulls with a hereditary sperm defect. A defect such as the knobbed acrosome defect affecting 25% of sperm may not reduce fertility significantly. Because the affected bull is likely to carry a recessive gene for the defect, however, it is questionable whether he should be used by a purebred breeder.
- Bulls with an abnormal accumulation of senescent sperm. Such bulls probably would fail to impregnate females for approximately the first week of the breeding season. After repeated ejaculations, however, the accumulation of senescent sperm from the ampullae and cauda epididymidis would be replaced by "new" spermatozoa, and fertility would be expected to become normal.

The decision deferred category is intended primarily for pubertal bulls with poor semen quality. Poor semen quality is expected in pubertal bulls; however, whether normal semen quality will be produced at sexual maturity is unknown. Therefore, the decision on breeding potential should be deferred. The decision deferred category also may be appropriate for mature bulls that have suffered a recent disturbance of spermatogenesis from which recovery is expected before the onset of the breeding season. For example, bulls with mild scrotal frostbite often have poor semen quality in early March, but recovery usually occurs before the May/June breeding seasons.

The unsatisfactory classification should be used for bulls whose use is expected to result in poor fertility in

the cow herd during the impending breeding season. If recovery to normal fertility is possible, this can be stated in the appropriate document.

CHAPTER 32

Diseases of the Reproductive System of the Bull

FRED M. HOPKINS

Conception failure may be associated with female factors, male factors, or both. Too often, it is assumed that infertility is a female problem, and few bulls are examined for breeding soundness before the breeding season. Most bulls are examined because of reproductive failure discovered during or after the breeding season. Estimates of the proportion of bulls having significant reproductive problems range from 5% to 25%. Very often the most cost-effective way of dealing with reproductive diseases of the bull is culling and replacement.

COMMON PENILE PROBLEMS

The lesions of **penile fibropapillomatosis** are warts. Fibropapillomas are the most common mass seen on the bull's penis and have a viral etiology. The causative virus is believed to gain entry into the preputial epithelium through abrasions of the penis associated with mating activity among bulls. This problem usually is seen only in young bulls and is not associated with warts on other parts of the body.

Clinical signs may not be evident in penile fibropapillomatosis, and the problem may be recognized only during a breeding soundness evaluation. Bleeding from the preputial opening may be seen, along with reluctance to mate. Phimosis or paraphimosis may result from the presence of larger masses.

Penile fibropapillomas may occur as single or multiple masses. The mass usually is pedunculated, but sessile lesions with a diffuse distribution also are possible.

Fibropapillomas sometimes will regress without treatment. Surgical removal of pedunculated masses is straightforward. Commercial wart vaccine has been used in treatment, with variable results. Commercial autogenous wart vaccine may be more useful in preventing recurrence of the problem, which may occur in up to one third of affected animals.

the cow herd during the impending breeding season. If recovery to normal fertility is possible, this can be stated in the appropriate document.

CHAPTER 32

Diseases of the Reproductive System of the Bull

FRED M. HOPKINS

Conception failure may be associated with female factors, male factors, or both. Too often, it is assumed that infertility is a female problem, and few bulls are examined for breeding soundness before the breeding season. Most bulls are examined because of reproductive failure discovered during or after the breeding season. Estimates of the proportion of bulls having significant reproductive problems range from 5% to 25%. Very often the most cost-effective way of dealing with reproductive diseases of the bull is culling and replacement.

COMMON PENILE PROBLEMS

The lesions of **penile fibropapillomatosis** are warts. Fibropapillomas are the most common mass seen on the bull's penis and have a viral etiology. The causative virus is believed to gain entry into the preputial epithelium through abrasions of the penis associated with mating activity among bulls. This problem usually is seen only in young bulls and is not associated with warts on other parts of the body.

Clinical signs may not be evident in penile fibropapillomatosis, and the problem may be recognized only during a breeding soundness evaluation. Bleeding from the preputial opening may be seen, along with reluctance to mate. Phimosis or paraphimosis may result from the presence of larger masses.

Penile fibropapillomas may occur as single or multiple masses. The mass usually is pedunculated, but sessile lesions with a diffuse distribution also are possible.

Fibropapillomas sometimes will regress without treatment. Surgical removal of pedunculated masses is straightforward. Commercial wart vaccine has been used in treatment, with variable results. Commercial autogenous wart vaccine may be more useful in preventing recurrence of the problem, which may occur in up to one third of affected animals.

Persistent penile frenulum is a congenital band of tissue extending from the median raphe of the prepuce to the ventral side of the penis near the glans. Penile erection and extension in affected animals results in a ventral bowing of the penis. In bulls with longer prepuces, the prepuce may be pulled over the glans penis by the band. In either case, successful intromission is unlikely. This condition is believed to be heritable, and affected animals should be used only as terminal sires.

Surgical correction of persistent penile frenulum requires that the penis be extended and secured. Local anesthetic injection is given at each end of the band. Blood vessels and the band are ligated, and the band is transected and removed. Healing occurs rapidly.

Inflammation of the penis and prepuce occurs occasionally in younger bulls. Pain resulting from this inflammation may be severe enough that the affected bull mates less often or not at all. Most frequently, this condition is associated with abrasions occurring at mating or infection with bovine herpesvirus type 1 (BHV-1) (i.e., infectious bovine rhinotracheitis–bovine virus diarrhea [IBR-BVD]). BHV-1 infection causes small areas of focal necrosis, resulting in 1- to 3-mm-diameter ulcers. Inflammation of the penis and prepuce may be severe enough to produce adhesions, with limitation of future fertility. In most cases, however, the problem is self-limited and will resolve after 2 weeks of sexual rest.

Hair rings encircling the penis may be seen, especially in younger bulls that are housed in groups. It is believed that these hair rings result from mating activity during which the penis is rubbed across loose body hair. Eventually, a ring of hair may accumulate on the penis, resulting in discomfort, necrosis, and occasionally, urethral fistula or penile amputation. Removal of the hair ring and local wound therapy should result in the resolution of reversible pathologic changes.

DISEASES OF ACCESSORY SEX GLANDS

The most commonly recognized disease of the internal genitalia of the bulls is **vesiculitis.** Inflammation of the vesicular glands most frequently is diagnosed in bulls younger than 2 years of age or older than 9 years. The incidence of vesiculitis usually is low but can be quite high in some groups of young bulls. Inflammation of other parts of the reproductive system often is seen with vesiculitis. The effect of vesiculitis on fertility is variable. Although it is not uncommon for no infectious agent to be identified as the cause of vesiculitis, a number of bacteria and viruses have been associated with this problem. *Brucella abortus, Arcanobacter pyogenes, Haemophilus somnus,* and others have been described as bacterial causes of vesiculitis. The IBR virus and enteroviruses have been incriminated.

The pathogenesis of vesiculitis has not been clearly established. A number of risk factors for this condition have been reported. Young bulls that are housed in contained groups and fed high-energy rations seem to be more susceptible. Slaughterhouse studies have shown an association between vesiculitis and other infectious diseases such as pneumonia, liver abscesses, and navel ill.

Most affected bulls do not show visible signs of vesiculitis. Occasionally, signs of abdominal pain or rear leg lameness may be noted. More often, this disease is diagnosed during a routine breeding soundness evaluation or during examination of the bull as a part of a herd infertility investigation.

Considerable variation in vesicular gland size, consistency, and texture is normal in bulls. Consequently, the interpretation of findings on rectal examination may be difficult. Inflamed vesicular glands are enlarged, painful, and firm. Loss of lobulations may be noted. The vesicular glands may be adherent to adjacent structures. Abscessation can occur. Changes may be unilateral or bilateral. The ejaculate of affected animals may be darker than normal in color and contain clumps. Microscopic examination characteristically reveals an increased number of polymorphonuclear cells. These cells cannot be identified using the usual eosin-nigrosin sperm stain, and a white blood cell stain is necessary. Sperm motility generally is lower in affected bulls.

Bulls older than 9 years of age seldom recover from vesiculitis. Usually, these bulls are culled. Bulls younger than 2 years often recover within 6 months with no treatment at all. Medical treatment of this condition is based on long-term antibiotic therapy. The culture of routinely obtained semen samples is not useful, because gross contamination is the rule. A procedure for the collection of fluid for culture has been described. After cleansing of the ventral abdomen, the penis of a suitably tranquilized bull is extended and secured. A catheter is passed up the urethra and fluid is collected during rectal massage. Even with favorable laboratory results, treatment with appropriate antibiotics often is disappointing. Treated bulls often improve during treatment, only to relapse after the course of therapy is complete. Macrolide antibiotics and flunixin often have been recommended for cases of seminal vesiculitis. Surgical removal of diseased glands is difficult, but a newly described ventral pararectal approach shows promise. Culling of affected bulls probably is the most cost-effective approach. It has been reported that the incidence of vesiculitis in high-risk groups has been reduced by feeding of chlortetracycline.

EPIDIDYMAL DISEASES

Epididymal inflammation, or **epididymitis,** in the bull most commonly is unilateral and involves the tail of the epididymis. Epididymitis may be diagnosed alone but often is seen associated with vesiculitis or orchitis. Infection with bacteria including *A. pyogenes* and *B. abortus* is the most common cause of epididymitis in the bull. Epididymitis often results in infertility secondary to obstruction of the lumen. Thermal injury to the testicle also may result. Inflamed epididymal tails are hot, swollen, and painful early in the course of the disease but chronically become small, hard, and misshapen. Treatment generally is of little value, and most affected animals are culled.

Congenital absence of part or all of the epididymis usually is unilateral in the bull. This segmental aplasia may be hereditary, and affected animals should not be

used for breeding. Segmental aplasia may be accompanied by enlargement of the duct system proximal to the missing area due to sperm stasis. Often, the corresponding vesicular gland or ampulla will be found to be absent.

TESTICULAR DISEASE

Orchitis is infrequently diagnosed in the bull. Generally, only one testicle is affected, but the opposite testicle can quickly undergo degeneration as a result of thermal injury from inflammation. Orchitis generally is considered to be due to infectious causes. Infectious agents may reach the testicles by hematogenous spread from other loci of infection within the body. Infections in other parts of the reproductive or urinary system may extend to involve the testicles. Orchitis may result from wounds that penetrate the scrotal skin. Bacteria, including *B. abortus, Arcanobacter,* and others, are most frequently isolated in cases of orchitis. Certain viruses also may initiate testicular inflammation. The swelling associated with inflammation coupled with an inelastic tunica albuginea leads to pressure necrosis of the testicles. Thrombosis of blood vessels and heat produces degeneration. The testicle rapidly loses its ability to function normally.

The diagnosis of orchitis in the bull is straightforward. Observation of the scrotum shows one testicle larger than the other. On palpation, the scrotal contents will be painful, hot, and edematous. Ultrasound examination and thermography are useful aids in diagnosis. Medical treatments of orchitis may not be completely successful in returning the testicle to normal function. The contralateral testicle is at risk for degenerative changes if resolution of the inflammation is delayed. Antibiotics are of limited value in most cases. Cold water hydrotherapy may be of help. Often, bulls of moderate value are culled. If the bull is more valuable and the rest of his reproductive system is normal, surgical removal of the affected testicle will allow the other testicle to eventually compensate. The remaining testicle probably will produce more than one half of the sperm produced by two.

It is likely that the most common reproductive abnormality of the young bull seen by veterinary practitioners is small-sized testicles. **Testicular hypoplasia** has been defined as testis size smaller than normal for age; one or both testicles may be affected. The definition also presumes that the problem is congenital, with some derangement of germinal cells.

Testicular hypoplasia generally is considered to have a large heritable component. Bulls with small testicles have reduced sperm motility, a lower percent of sperm with normal morphology, and less concentrated semen with fewer total sperm numbers per ejaculate. Affected animals may be subfertile or infertile. Libido is unaffected.

The diagnosis of hypoplastic testicles is based on scrotal circumference measurements and analysis of semen samples. The problem usually is not recognized until after puberty. The Society for Theriogenology has published minimum standards for scrotal circumference in bulls. Scrotal circumference measurements of less than 30 cm, or 32 cm in postpubertal bulls, have been suggested as being diagnostic of testicular hypoplasia in the bull. This problem cannot be corrected, and affected animals should be culled.

Failure of normal testicular descent is referred to as **cryptorchidism.** This problem is relatively uncommon in bulls and usually is unilateral. Because of the possibility that cryptorchidism is inherited, affected animals should not be used for breeding.

Testicular degeneration is an acquired condition in which testicles that were once normal undergo pathologic changes, resulting eventually in small testicular size and abnormal function. Testicular degeneration may affect one or both testicles, and the changes may be temporary or permanent.

A number of factors have been shown to result in testicular degeneration in the bull. Increased temperature of the scrotal contents, even for a relatively short period of time, has been shown to result in testicular degeneration with a higher percentage of abnormal ejaculated sperm or even azoospermia. Fever, high environmental temperature, inflammation of the scrotal skin, and excessive scrotal fat all have been shown to have an adverse effect on testicular function, presumably secondary to increased testicular temperature. Extreme cold resulting in scrotal frostbite is reported to lead to testicular degeneration. Orchitis, testicular trauma, and zeranol implants can result in degeneration of the testicles. Degeneration can result from blockage of parts of the excurrent duct system, such as the epididymis. Bulls seem to undergo testicular degeneration associated with advancing age earlier in life than other animals. Most bulls will undergo changes by 8 to 10 years of age.

Diagnosis of testicular degeneration most often is based on the history, a careful examination of the scrotal contents including scrotal circumference measurements, and semen analysis. Ultrasound examination also has been used.

Treatment is limited to removal of the cause of the degeneration when it can be determined. Re-examination at 45- to 60-day intervals will determine if the changes are temporary or permanent.

OTHER REPRODUCTIVE DISEASES

Penile hematoma occurs as a result of rupture of the tunica albuginea associated with injury at breeding. Affected bulls most often are Polled Hereford and show reluctance to mate, a prolapsed prepuce, and a swelling anterior to the scrotum, which cannot be separated from the penis. Paracentesis should not be used for diagnosis because 60% of the cases progress to abscess formation. Approximately 70% of bulls with hematoma smaller than 20 cm in diameter will recover if given antibiotics and 6 months of sexual rest. About 70% of bulls with hematoma greater than 20 cm in diameter will recover with suturing of the torn tunica albuginea and 3 months of sexual rest. About 50% of bulls with hematomas larger than 20 cm will recover with antibiotics and sexual rest.

Preputial lacerations usually are the result of tearing during breeding and occur most often in Brahma, Brahma-cross, or polled bulls. Affected bulls show reluc-

tance to mate, and on examination, prolapse of the preputial membrane and inflammation with swelling of the cranial one half of the penis and sheath can be seen. Treatment includes local and parenteral antibiotic therapy, along with hydrotherapy and bandaging. The prolapsed portion of the prepuce should be replaced and held in with a pursestring suture as soon as possible. Medical therapy should continue for 10 days to 3 weeks and until infection is controlled and healing is well under way. Surgery (circumcision) is indicated if the prolapsed prepuce cannot be replaced or if the healed laceration produces a stricture so that the bull's penis cannot be extended. Approximately 75% of bulls can be returned to service with some combination of therapy. It is difficult to justify surgical intervention in bulls worth less than $2000.

Lack of libido is difficult to measure or diagnose. Lack of libido may be due to inheritance, inexperience, or back, feet, leg, or joint abnormalities. Lack of libido is not treatable unless a primary medical cause is identified.

CHAPTER 33

Surgical Correction of Abnormalities of the Reproductive Organs of Bulls and Preparation of Teaser Animals

GREGOR MORGAN

Surgical procedures commonly are performed on the reproductive organs of bulls. Although some procedures such as castration are quite simple, when they are performed improperly, the outcome can be costly. Not all surgical failures can be attributed to poor surgical technique, however. Often they are the result of the surgeon's having to perform under less than ideal circumstances (environmental conditions and available facilities, in particular).

In a practice situation, an economic conflict frequently exists between the ideal facility and equipment to perform certain procedures and the number of procedures that can be performed over time. In addition, some procedures are quite difficult, and unless they are performed on a regular basis, familiarity and skill with the technique are not acquired. These factors should be considered when a more difficult procedure is required and referral of the case may be more appropriate. The patients of food animal practitioners have an economic value at slaughter, and this consideration must always be weighed when a costly procedure is considered that may result in loss of the bull's services for the current breeding season. With regard to facilities, most routine procedures performed on the reproductive organs of bulls can be accomplished in a squeeze chute. Other surgical procedures require the animal to be in right lateral or dorsal recumbency, either on a clean ground surface (uncomfortable for the surgeon) or on a surgery table. Anesthesia is required for most procedures, and various local blocks and general anesthesia techniques available for use in bulls have been described.[1,2]

Some surgical procedures are performed to correct a condition that is or is suspected to be heritable.[3] It is the responsibility of the surgeon to be cognizant of the possibility of transmission of undesirable traits and to insist on bilateral castration if the condition is of a potentially serious nature.

SURGERY OF THE TESTES

Castration

Castration is the most common surgical procedure performed on bulls. Despite the relative simplicity of the procedure, many factors contribute to success or failure, including bull size, facilities, location, weather condi-

tance to mate, and on examination, prolapse of the preputial membrane and inflammation with swelling of the cranial one half of the penis and sheath can be seen. Treatment includes local and parenteral antibiotic therapy, along with hydrotherapy and bandaging. The prolapsed portion of the prepuce should be replaced and held in with a pursestring suture as soon as possible. Medical therapy should continue for 10 days to 3 weeks and until infection is controlled and healing is well under way. Surgery (circumcision) is indicated if the prolapsed prepuce cannot be replaced or if the healed laceration produces a stricture so that the bull's penis cannot be extended. Approximately 75% of bulls can be returned to service with some combination of therapy. It is difficult to justify surgical intervention in bulls worth less than $2000.

Lack of libido is difficult to measure or diagnose. Lack of libido may be due to inheritance, inexperience, or back, feet, leg, or joint abnormalities. Lack of libido is not treatable unless a primary medical cause is identified.

CHAPTER 33

Surgical Correction of Abnormalities of the Reproductive Organs of Bulls and Preparation of Teaser Animals

GREGOR MORGAN

Surgical procedures commonly are performed on the reproductive organs of bulls. Although some procedures such as castration are quite simple, when they are performed improperly, the outcome can be costly. Not all surgical failures can be attributed to poor surgical technique, however. Often they are the result of the surgeon's having to perform under less than ideal circumstances (environmental conditions and available facilities, in particular).

In a practice situation, an economic conflict frequently exists between the ideal facility and equipment to perform certain procedures and the number of procedures that can be performed over time. In addition, some procedures are quite difficult, and unless they are performed on a regular basis, familiarity and skill with the technique are not acquired. These factors should be considered when a more difficult procedure is required and referral of the case may be more appropriate. The patients of food animal practitioners have an economic value at slaughter, and this consideration must always be weighed when a costly procedure is considered that may result in loss of the bull's services for the current breeding season. With regard to facilities, most routine procedures performed on the reproductive organs of bulls can be accomplished in a squeeze chute. Other surgical procedures require the animal to be in right lateral or dorsal recumbency, either on a clean ground surface (uncomfortable for the surgeon) or on a surgery table. Anesthesia is required for most procedures, and various local blocks and general anesthesia techniques available for use in bulls have been described.[1,2]

Some surgical procedures are performed to correct a condition that is or is suspected to be heritable.[3] It is the responsibility of the surgeon to be cognizant of the possibility of transmission of undesirable traits and to insist on bilateral castration if the condition is of a potentially serious nature.

SURGERY OF THE TESTES

Castration

Castration is the most common surgical procedure performed on bulls. Despite the relative simplicity of the procedure, many factors contribute to success or failure, including bull size, facilities, location, weather condi-

tions, pre- and postsurgical environment, surgical method including speed and cleanliness, and other pre- and postsurgical stresses. The most common postsurgical complications include severe hemorrhage, wound infection with cellulitis and potentially fatal septicemia, inadvertent damage to the penis, and, rarely, intestinal herniation through the inguinal ring.

Two factors are important to consider in castrating bulls: (1) timing of the procedure and (2) selection of the method to be used. Bulls should be castrated early in life (at 1 to 3 months of age) because performing the procedure then is less stressful and more humane and better addresses animal welfare concerns. When given a growth-promoting implant, steers will reach market size about the same time as do intact bulls.[4] On ranches with a defined calving season, early castration is more easily coordinated. On those farms where calving occurs year round, however, castration at the ideal time necessitates performing castration in groups of animals several times a year. This approach is rarely used, and bulls tend to be castrated at weaning or sold as bulls and castrated at the feedlot or stocker operation. In the purebred industry, castration is purposely delayed to allow consideration of the better bulls for sale as breeding animals. Bulls can be castrated by open or closed techniques. Closed methods involve the use of rubber bands or the Burdizzo method (emasculatome). Open methods require surgical opening of the scrotum to remove the testicles. An economic evaluation of methods of castration has been reported.[4]

The objective of surgical castration is to remove both testes quickly in the cleanest environment possible. Depending on their size, bulls can be castrated while standing or recumbent and held by an assistant(s) or confined to a squeeze chute. Because of time constraints, the procedure usually is performed without anesthesia. Nevertheless, injection of 2% lidocaine directly into each testis will provide some analgesia. In the not-too-distant future, veterinary practitioners may well be compelled to provide analgesia for some procedures in cattle routinely performed without anesthesia for literally thousands of years.

To free the testes from the scrotum, a castrating knife* (Newberry knife) can be used. The knife is applied transversely across the base of the scrotum, closed, and pulled ventrally to open both scrotal sacs without removing any scrotal tissue, thereby preserving the scrotum (cod). An alternative method is to grasp the apex of the scrotum with one hand, stretch it ventrally, and with a scalpel in the other hand, excise the distal one third of the scrotal sac in one swift cutting motion. In both techniques, the tunica vaginalis should not be incised, and the testes are removed in a closed fashion. Once the testes are freed, the "one clean hand, one dirty hand" technique is used to free the spermatic cords from the surrounding fascia. The "dirty" hand grasps the testis (both testes, if small enough) and maintains ventral traction while the "clean" hand strips the fascia free by pushing the skin proximally. The testes are then removed by application of an emasculator proximal to each testis. Tension on the testis should be minimal at the time of emasculation. After the testes are removed, excess scrotal adipose tissue is trimmed from the wound and clostridial vaccines are administered if the patient was not immunized before the procedure.

An alternative to emasculation is ligation of each spermatic cord. Closed castration with a rubber band has been popular in smaller bulls for a number of years. A latex band (commonly used in sheep) can be applied proximal to both testes around the neck of the scrotum. It is important not to place the band so high on the scrotum as to risk injuring the penis. In recent years, castration of large bulls with rubber bands has become more popular with the development of newer equipment designed for the purpose. This method is particularly popular in feedlots. This closed technique uses an instrument* that allows rubber tubing to be stretched and clamped very tightly around the scrotal neck. Avascular necrosis of the scrotum and testes results. Done properly, this is a very effective castration method, and the animals are reported to undergo minimal stress.

All castrated animals should be immunized against clostridial organisms, particularly those causing blackleg and malignant edema. In addition, if rubber bands are used, protection against tetanus must be considered, particularly in large bulls in feedlot situations. Tetanus antitoxin can be used but is relatively expensive; vaccination with products containing tetanus toxoid at the time of castration have proven effective. After castration, animals should be placed in a clean environment, given the opportunity to exercise, and observed periodically over the subsequent 24 hours.

Epididectomy

Epididectomy is discussed later under "Preparation of Teaser Animals" later in the chapter.

SURGERY OF THE PENIS

The surgical procedures most commonly performed on the penis of bulls are for tumor removal, correction of penile deviations, closure of ruptures of the tunica albuginea, and separation of persistent penile frenulum.

Tumor Removal

The most common neoplasm found on the penis of bulls is a viral fibropapilloma. Such growths are common in young bulls housed together and undoubtedly are associated with the homosexual activity this management practice encourages. The lesion is caused by the bovine papillomavirus, which enters the skin through abrasions.

Affected young bulls frequently are presented with the complaint of hemorrhage from the preputial orifice, usually after coitus. Fibropapillomas also may be inci-

*EZE Bloodless Castrator, Wadsworth Mfg., Dublin, MT.

dental findings when a breeding soundness examination is performed. On rare occasions, the bull may be presented with the complaint of phimosis and swelling in the sheath. This can result when the papilloma is of sufficient size to cause pressure necrosis and swelling within the preputial cavity, which prevents penile extension.

Papillomas can be single or multiple and frequently are located on the free end of the penis and less commonly on the preputial skin. They tend not to be invasive, and although the tumor may appear large, the area of attachment often is relatively small. Blood supply to the fibropapilloma is significant, and removal of the tumor may require ligation or cautery.

The procedure can be performed with or without mild tranquilization, depending on lesion size, location, and the bull's demeanor. A pudendal nerve block may also be considered. Tail-stand restraint is sufficient to complete the surgery in most cases, however. To maintain extension of the penis, a cotton gauze bandage is used to get a firm grasp on the glans penis, and another is tied around the penis proximal to the tumor to act as a tourniquet and to assist in keeping the penis extended.

The penis is prepared for surgery with a surgical scrub. Local anesthetic is infiltrated to block the dorsal penile nerves by injection beneath the preputial skin on the dorsal surface of the penis at the level of the external preputial orifice.

The objective in removing a fibropapilloma is to excise it at the base of the lesion. To obtain adequate access to the base of an extensive tumor, a large portion of the mass can be simply cut away. At the base, an elliptical incision is made in the epithelium, leaving a stalk attached to the fibropapilloma. The stalk is ligated with size 0 polyglycolic acid* to prevent postsurgical hemorrhage. The stalk is severed, and the epithelium is closed over the wound. If the tumor is close to the urethra, it is advisable to insert a catheter as a guide to avoid accidental incision of the urethra.

In my experience, laser technology has proved to be a very effective method of removing penile warts, and as the costs of laser equipment decline in the future, it is hoped that this technology will become an economically viable alternative to standard surgical management.

Postoperative complications are rare after fibropapilloma removal. The bull should be withheld from breeding for 2 to 3 weeks, however, and examined before return to service. Regrowth of fibropapillomas occurs occasionally, and vaccination with a commercial or an autogenous wart vaccine may reduce the recurrence rate. Under certain management systems or in particular environments, penile fibropapillomas can affect a significant number of bulls. In these instances, management practices should be changed to avoid co-mingling large numbers of young bulls. A wart vaccine may be administered in an effort to reduce the incidence, although in my experience, vaccines have not been very effective.

*Dexon, Davis and Geck, American Cyanamid Co., Pearl River, NY.

Correction of Persistent Penile Frenulum

A persistent penile frenulum is recognized during a breeding soundness examination or when a young bull is placed in service for breeding. The condition arises when the penis fails to separate completely from the prepuce by 12 months of age. The penis and prepuce are fused at birth in the bull and separate as a result of testosterone stimulation beginning at 4 to 6 months of age. Persistent penile frenulum is suspected to be a heritable condition, and clients should be informed before corrective surgery is performed.

In most cases, a fibrous band extends from the prepuce and attaches to the ventral median raphe immediately caudal to the glans penis. On rare occasions, more than a single attachment point may be present, or the attached area is several centimeters long. The surgical procedure entails extension of the penis, surgical preparation of the area, and ligation of the frenulum with absorbable suture material at the preputial and penile extremities. The tissue is then severed between the ligatures. In those cases in which more than a single point of attachment is present, the other points are ligated and severed in a similar manner. Usually, hemorrhage is minimal. An antibiotic ointment can be applied postoperatively and the bull withheld from breeding for approximately 2 weeks. In cases characterized by a broad area of attachment between the penis and prepuce, corrective surgery must be discouraged.

Rupture Repair in Penile Hematoma

The classic penile hematoma is the result of rupture of the tunica albuginea and subsequent escape of blood from the corpus cavernosum penis (CCP) into and around the elastic layers surrounding the penis. During erection, very high blood pressures in the CCP have been measured.[5] Severe downward deviation of the erect penis during mating may cause a transverse tear through the tunica albuginea into the CCP and permit the release of blood. The injury in the tunica albuginea frequently is on the dorsal surface of the penis opposite the attachment of the retractor penis muscles; however, other rupture sites have been reported.[6,7]

The objective of the surgical procedure is to close the rent in the tunica albuginea, rather than allowing the injury to heal spontaneously. The view of some clinicians is that surgical closure of the rent results in a stronger union and a reduced likelihood of recurrence or shunt formation. This is a controversial point, however, and the decision to perform surgery should be based on elapsed time since the injury occurred, the economic value of the bull, and whether or not the owner places sufficient value on the bull to consider collecting and storing frozen semen after surgery. If semen preservation is not a course the owner wishes to consider, then surgery is not indicated. This recommendation is based on the fact that greater than 50% of bulls with this injury that are treated medically (with 10 to 14 days of systemic antibiotic therapy) successfully return to service.

The typical presenting signs include a swelling of variable size located immediately cranial to the scrotum. The

location alone often constitutes sufficient evidence to differentiate a penile hematoma from a peripreputial abscess. Preputial prolapse and swelling of the sheath frequently accompany penile hematomas and are the result of compromised venous drainage and development of dependent edema. The prolapsed prepuce may be traumatized, necessitating appropriate treatment. It is extremely rare for a peripreputial abscess to be located immediately cranial to the scrotum. These lesions typically are located in the mid-sheath area. In addition, the clotted blood in and around the elastic layers that surround the penis and adjacent tissue makes identification of the penis within the swelling difficult. If doubt still exists as to the contents of the swelling, aspiration (using a 16-gauge, 4-inch needle) after aseptic skin preparation and ultrasonography are alternative diagnostic procedures. If surgery is elected, it should be performed within 7 days of the injury, after which organization of the clot makes exteriorization of the penis, removal of the clot, and access to the tear in the tunica albuginea more difficult. Antibiotics should be administered as soon as the decision for surgery is made.

With the bull in right lateral recumbency and under general anesthesia or heavy tranquilization and local anesthesia of the incision site, the skin over the swelling cranial to the scrotum is shaved and prepared for surgery. The surgical area is draped, and an incision is made through the skin over the most prominent part of the swelling. This incision should be made in a cranioventral direction through the skin and subcutaneous tissue into the hematoma. Occasionally, the penis may be displaced and located just beneath the capsule of the hematoma, and care must be exercised in making the incision. This incision should be large enough to allow the surgeon's fingers into the cavity to remove the clotted blood. If little organization of the hematoma has occurred, the penis can be grasped and easily exteriorized. The area of the attachment of the retractor penis muscles is identified. Careful dissection through the elastic layer of the penis dorsal to this area usually reveals the rent in the tunic. Dissection of the elastic layer must be in a longitudinal direction to avoid damage to dorsal penile blood vessels and nerves. In fresh cases, dissection is relatively simple. In instances in which significant organization of the clot has already occurred, careful dissection and retraction are required to free the penis and facilitate exteriorization. Further careful dissection through the elastic layer is necessary to clearly expose the rent.

The edges of the rent are débrided and sutured with size 1 polyglycolic acid in a simple interrupted or cruciate pattern. It is not necessary to suture the elastic layer around the penis. The hematoma cavity should be thoroughly flushed with an antibacterial solution (5,000,000 IU potassium penicillin in 1 L sterile saline) before closure. The subcutaneous tissue can be sutured with a continuous pattern using size 0 polyglycolic acid. The skin is sutured with 0.6-mm nylon* in a continuous interlocking, cruciate, or horizontal mattress pattern. Postoperative care must include 10 days of systemic antibiotic therapy.

Complications are rare after aseptic surgery, but occasionally a seroma forms at the surgery site. This should not be drained, because abscess formation could follow. Within 7 to 10 days after surgery, the swelling will subside. The skin sutures can be removed at 12 to 14 days. The bull must have complete sexual rest for 60 days. After this period, the bull should be examined for the ability to successfully extend the penis and attain and maintain a normal erection. Sensitivity of the glans penis can be checked by application of a mild pain stimulus. If the bull's reproductive function appears normal, semen can be collected and frozen, or he can be returned to service at 60 to 90 days after surgery.

Four sequelae are possible after this procedure. The first is abscess formation, which requires drainage and usually results in peripenile adhesions and permanent inability to extend the penis. The second is desensitization of the glans penis due to damage to the dorsal penile nerves at the time of injury, during surgery, or after healing and return to service, when adhesions involving the nerves may break down, allowing the nerves to be severed during erection. Third, peripenile adhesions can develop, resulting in fixation of the penis; in the absence of postsurgical infection, however, this is rare. The fourth possible sequela is development of vascular connections (shunts) between the internal blood supply of the CCP and the external vasculature of the penis and prepuce. With formation of such shunts, the CCP is no longer a closed system, and sufficient pressure for normal erection cannot be maintained. The shunts can be identified by contrast radiography, and an attempt can be made to surgically excise them. Vascular shunts are quite rare, and the method for surgical correction has been described.[8]

Correction of Penile Deviation

Three forms of penile deviation are described in bulls. All three involve abnormalities of the apical ligament (AL) of the penis: The AL may be too short, resulting in an S-shaped deviation, which is rare; it may be too long, resulting in ventral deviation; or it cannot be maintained in its normal position when the penis is erect, resulting in a corkscrew or spiral deviation. Spiral deviation occasionally is observed in normal bulls during electroejaculation. Furthermore, the condition is known to occur in some bulls after intromission at the peak of erection. Only if the deviation is seen during natural mating attempts and intromission fails can an association between the deviation and subfertility be made.

The AL of the penis is an extension of the tunica albuginea that begins just proximal to the distal attachment of the prepuce. A band of collagen fibers extends forward on the dorsal midline of the penis and fans out laterally to encapsulate the distal portion of the penis where the ligament inserts back into the tunica albuginea. This ligament provides dorsal strength and support to the erect penis and maintains it in a straight profile, rather than allowing curvature downward and to the right, which is the natural tendency during erection. The ligament is not

*Braunamid, Jorgensen Laboratories, Loveland, CO.

fixed to the underlying tunica albuginea but is separated from it by a fascial layer. Thus, should the ligament be lengthened, a ventral deviation is possible. If it is too short or the bull has an unusually long penis, then an untreatable S-shaped deviation may occur. A spiral deviation occurs when the ligament slips off the dorsal surface to the left side and the distal penis becomes retracted into a spiral position.

Surgical attempts to correct either a spiral or a ventral penile deviation should be reserved for bulls of considerable economic value that must be used for natural service. If artificial insemination is an option, then surgical correction is not required. The objective of surgery is to provide dorsal strength and support in a longitudinal plane in the case of ventral deviation and to prevent lateral movement of the ligament in the case of spiral deviation. A single surgical procedure that utilizes an implant to provide support is used to correct both types of deviation. Other approaches to correct only spiral deviations have been reported, including the AL strip technique.[9]

The **implant technique** uses an autogenous or homologous strip of fascia lata from the cranial border of the biceps femoris muscle or carbon fiber material[10] to provide dorsal reinforcement of the apical ligament and fixation of the ligament to the tunica albuginea. Homologous strips of fascia lata can be harvested from freshly dead cattle and stored in 70% ethyl alcohol until used. All muscle, fat, and other loose connective tissue must be removed before preservation. Before use, the strip should be soaked in normal saline for 30 minutes. I much prefer this approach over harvesting autogenous fascia.

Two techniques are used to correct this condition in the bull, but only my preferred approach is described here. General anesthesia is induced and the penis fully extended. The penis and prepuce are prepared for aseptic surgery. A skin incision is made on the dorsal surface of the penis beginning just caudal to the glans penis and is extended proximally for 20 cm or to just before the point of attachment of the prepuce to the penis. In the proximal portion of the incision, a thin layer of elastic tissue is incised to expose the AL beneath. The thin subcutaneous fascial layer is then incised to expose the AL. The AL is incised along its dorsal midline to expose the tunicalbuginea. The edges of the AL are reflected to allow the implant material to be positioned beneath it. It is important to suture the implant as far proximally as possible and to keep it positioned on the dorsal midline. Simple interrupted size 0 polyglycolic acid sutures are placed in the proximal portion of the implant and into, but not through, the tunica albuginea. Sutures are placed similarly along the lateral borders of the implant for about one half the distance. The distal end of the implant is then sutured while under mild tension, and the remaining sutures are placed in the lateral borders. The objective is to "stretch" the implant into position when suturing. The implant should be trimmed when necessary to ensure a perfect fit. The AL is then closed over the implant with size 0 polyglycolic acid, with each simple interrupted suture passing through the implant. Proximally, the incised elastic layer should be sutured with size 3-0 polyglycolic acid in a closely spaced continuous pattern. The skin is closed with size 0 polyglycolic acid in a closely spaced interrupted pattern.

SURGERY OF THE PREPUCE

Repair of Preputial Injuries

Injuries of the prepuce frequently are encountered in bulls. Preputial injuries are more common in range bulls and may be the result of increased *Bos indicus* influence in the general cattle population. These injuries most often occur during the breeding season when the penis is extended. The outcome of the injury is greatly influenced by its location, depth of the laceration, interval between the insult and examination, and whether serious bacterial infection develops. Bulls with preputial injuries are presented with preputial prolapse with or without paraphimosis, swelling within the sheath, or phimosis without obvious swelling. Rarely are injuries of the prepuce discovered soon after they occur. Consequently, edema, infection, and fibrotic healing frequently are in progress when the patient is first examined. It is important to realize that except in cases of very minor injuries, the affected bull is unlikely to be capable of natural service for the remainder of the current breeding season. Even lacerations that heal without subsequent surgery need 45 to 60 days to heal sufficiently for the bull to return to service. Injuries that require surgery necessitate complete sexual rest for a period of at least 60 days after the surgery. This is in addition to 1 to 4 weeks that may be required for the prepuce to heal sufficiently for surgical intervention to be successful. Many bulls that appear initially to have grave injuries with a guarded prognosis can be successfully returned to service. The practitioner must weigh all of the costs required for treatment, including feed and maintenance, however, before embarking on an intensive and costly treatment protocol. Even in the face of a poor to fair prognosis, many clients will elect treatment when it is difficult to justify economically. Therefore, the practitioner must have a good understanding of the clinical management of preputial injuries to maximize the odds of success.[11]

Briefly, when bulls are presented with preputial injury and prolapse, the objective is to return the prepuce as quickly as possible to its normal position. Fresh lacerations are rarely seen, but when encountered they should not be sutured but rather managed medically and allowed to heal by second intention. At presentation, the prepuce frequently is affected by marked dependent edema. Reduction of the edematous swelling is best achieved by soaking the prepuce in a warm Epsom salt solution for 30 minutes, after which the tissue is dried and an antibacterial ointment is applied to the prolapsed tissue. A stockinette is then applied over the prolapsed portion of the prepuce. A soft plastic tube with smooth ends is inserted into the preputial cavity to facilitate drainage of urine. Beginning at the distal end of the prolapse, elastic tape is applied over the stockinette and continued proximally onto the hair of the sheath. Tape is then used to secure the tube within the preputial lumen. In bulls with pendulous sheaths, a sling of suitable

material is made and tied around the abdomen of the bull to attempt to keep the bandaged prepuce in a more horizontal position. Daily therapy (lavage with a nonirritating antibacterial solution) is administered through the tube. Initially, the bandage is changed every 48 hours. In a majority of cases, the prepuce can be returned to its normal position within 2 to 6 days. Once the prolapse has been reduced, the prepuce is maintained in position by wrapping the sheath with tape and inserting a tube into the preputial cavity. Lavage of the prepuce with antibacterial solutions can be continued by infusion through the plastic tube. A less preferred alternative is a purse-string suture placed in the preputial orifice to retain the prolapsed tissue. In those cases in which induration of the prepuce is so severe that the tissue cannot be returned to its normal position, amputation of the prolapsed portion is indicated.

When bulls are presented with distention of the sheath and phimosis, the swelling may be due to cellulitis or abscess. In those cases in which an abscess is not yet present, preputial lavage along with administration of systemic antibiotics often results in marked decrease in the swelling within a few days. No attempt should be made to extend the penis until healing is complete (which takes 4 to 6 weeks). Repeated attempts to extend the penis do not improve the likelihood of normal erection and protrusion after the lesion has healed but in fact may delay healing and increase scar formation.

When the laceration is deep into the elastic layers of the prepuce, with severe inflammation and abscess development, the prognosis is guarded. This is because even after the abscess is drained and healed, extensive fibrosis results in adhesions within the elastic layers and between the elastic layers and the subcutaneous tissue. The elastic layers are prevented from sliding over one another to allow penile extension. In my experience, attempts to surgically remove the scar tissue in such cases have largely been unsuccessful.

When an abscess does not extensively involve the elastic layers or the subcutaneous tissue and drainage through the preputial orifice occurs, systemic antibiotic therapy along with preputial lavage will eventually result in healing. Normal penile extension may be possible in rare instances, but usually surgical intervention is required to restore normal function.

Two surgical procedures have been described that can be used to remove excessive preputial tissue to prevent chronic prolapse, to remove chronically prolapsed preputial tissue that cannot be replaced within the preputial cavity, or to excise scar tissue in an attempt to restore normal preputial function: circumcision and definitive repair.

Circumcision

Circumcision is the surgical procedure utilized to electively remove excessive preputial tissue as a prophylactic measure or to remove badly injured and prolapsed preputial tissue that cannot be returned to its normal position. It is a procedure that, when performed properly for prophylactic purposes, is quite successful; however, when it is performed to remove seriously injured prolapsed tissue, postsurgical scarring and phimosis are common despite presurgical management as previously described. These cases often require subsequent surgery to remove scar tissue by resection and anastomosis (reefing). The circumcision procedure selected for a particular case depends on facilities available, cost, bull genotype, and the extent of the preputial lesion.

Amputation of the Prepuce

Amputation of the prepuce requires less stringent asepsis than that needed for resection and anastomosis and can be used as a prophylactic procedure to prevent preputial prolapse and to correct chronic preputial prolapse. The preferred technique is to place the bull in right lateral recumbency under moderate tranquilization or general anesthesia. The preputial hairs are clipped and the skin of the sheath shaved approximately 10 cm proximal to the orifice. The prepuce and sheath are prepared for surgery. The largest-diameter plastic tube that will fit is placed within the lumen of the prolapsed prepuce to the depth of the fornix. A 16-gauge, 4- to 6-inch needle is passed through the healthy preputial tissue proximal to the prolapse, to retain the tube in position. A tourniquet is tied around the prepuce proximal to the portion to be amputated. If necessary, 2% lidocaine is infiltrated around the prepuce just distal to the tourniquet.

Commencing distal to the tourniquet, a circumferential, full-thickness incision is made through the prepuce. This incision is made in an oblique plane so that the resultant orifice will be somewhat larger and reduce the risk of postoperative phimosis. The amputated portion of the prepuce is removed. Horizontal mattress sutures of size 2 polyglycolic acid are placed around the amputation line. These sutures should overlap one another around the entire circumference to control postoperative hemorrhage. It is imperative that the surgeon incorporate both layers of the prepuce in each suture. If the surgeon prefers, the amputation can be done in stages—that is, one third of the circumference can be incised and then sutured, then the next third, until the amputation is completed. The edges of the wound are then apposed with a simple continuous pattern of size 0 polyglycolic acid. The tourniquet and the plastic tube are then removed and a smaller tube is placed into the preputial cavity and secured with tape for 7 to 10 days as previously described.

Postoperative treatment with antibiotics is indicated for 5 days. Healing is complete in approximately 6 weeks, at which time the bull should be examined to determine ability to extend the penis. When this procedure is performed on relatively healthy tissue, the success rate is good; however, when it is performed on a badly injured, enlarged, and inflamed prepuce, the subsequent healing process often results in significant scarring, which will require removal by resection and anastomosis at a later date.

Resection and Anastomosis of the Prepuce

The combination of resection and anastomosis differs from preputial amputation in that the objective is to excise the fibrotic tissue that restricts normal extension of the penis. The fibrosis often is confined to a relatively

small area and usually is the result of healed lacerations. Resection and anastomosis may be required after preputial amputation when the procedure is performed under less than ideal conditions. This technique also is preferred in bulls with limited amounts of preputial tissue, in which amputation would severely restrict penile extension.

This procedure is performed when the healing process is complete or at least when the surgical field is healthy. Surgery must not be performed when obvious inflammation, edema, or exudate draining from the laceration is present.

The surgery must be performed under strict aseptic conditions. Careful dissection and hemostasis are essential to success. Ideally, general anesthesia is used after feed has been withheld for 48 hours and water for 24 hours. With the bull in right lateral recumbency, the skin of the sheath is shaved and prepared for surgery. The penis is manually extended as far as possible. Frequently, extension of the penis is impeded by the cicatrix. A pair of towel clamps is placed through the distal end of the penis, avoiding the glans penis and the urethra, and used to maintain traction on the penis. The portion of the penis and prepuce that is exposed is prepared for surgery. Complete extension of the penis requires that the restricting band of scar tissue be incised in a direction parallel to the penis. This is done with the scalpel while applying considerable traction on the penis. As the restriction eases, the penis and prepuce will eventually extend completely. This incision should be made with care to avoid incising deep into healthy elastic tissue. After the penis and prepuce are fully extended, a tourniquet is applied at the junction of the prepuce and the sheath. The previously unexposed portion of the prepuce is then prepared for surgery.

The extent of the scar tissue in the prepuce is now determined, and the locations for two circumferential incisions, one above and one below the cicatrix, are identified. Two interrupted sutures are placed in the preputial skin, one above and one below the intended incision sites, to assist in aligning the two preputial portions when the incision is closed. With the penis extended, the circumferential incisions are made through the preputial skin to expose the elastic layer. A longitudinal incision is then made that connects the two incisions that encircle the prepuce. The isolated section of prepuce is then dissected free and removed. The depth of dissection should be sufficient to remove as much scar tissue as possible. During dissection, several large blood vessels will be encountered. If they cannot be preserved intact, they must be ligated. When the dissection is complete and the scar tissue removed, the tourniquet is loosened. At this point, other significant bleeding must be controlled with ligation or electrocautery. Ligation of larger vessels is preferred, and it is essential that all bleeding be controlled before the two ends of the prepuce are sutured together. The surgical field is then lavaged with saline-antibiotic solution.

Closure can be accomplished with a single layer of horizontal mattress sutures using size 1 polyglycolic acid or catgut if the dissection was not deep into the elastic layers. Initially, three interrupted sutures are placed equidistant around the circumference of the prepuce. Frequently, the circumference of the proximal portion is greater than the circumference of the distal portion. To overcome this disparity, smaller bites are made in the distal wound edge compared with the proximal wound edge to compensate for the difference. The sutures must be placed close together in order to ensure that the wound is sealed.

To prevent urine irritation of the suture line, a clean plastic tube is inserted into the prepuce and bandaged in place to provide protection for the wound and allow passage of urine.

The bull must be confined for 7 days, after which the preputial bandage can be removed. Postoperative administration of antibiotics is indicated for 5 days. The bull must be isolated from all cycling females for 6 weeks, at which time the bull should be examined to determine ability to extend the penis and to evaluate the surgery site. If healing is complete and the penis can be extended normally, the bull can return to service after an additional 3 weeks of sexual rest.

The most common postoperative complication is wound dehiscence, which may be minor and without serious consequence or serious with return of scarring and phimosis. If the bull is of a *Bos indicus* breed, a second attempt at anastomosis and resection may be possible. It is unlikely that sufficient healthy preputial tissue will remain to allow the surgery to be performed a second time on bulls of the *Bos taurus* breeds.

Resection and anastomosis of the prepuce constitute an alternative to amputation of the prepuce. This procedure is readily performed on bulls as a prophylactic measure for preputial prolapse. In estimating the amount of preputial tissue to remove, a rule of thumb is that the remaining prepuce should be twice the length of the free end of the penis for the bull to attain normal penile extension.

Repair of Avulsion of the Prepuce

Avulsion of the prepuce usually is seen after use of an artificial vagina (AV) to collect semen from a bull. The injury involves partial separation of the prepuce from its attachment to the free portion of the penis. It usually occurs at the time of the ejaculatory lunge when the AV is excessively tight and restricts forward movement of the prepuce but not the free end of the penis, or when the caudal edge of the AV strikes the distal attachment of the prepuce.[12] This injury should be repaired immediately. The bull is restrained in a chute and tranquilized if necessary, and the penis extended. After the prepuce is cleansed, a local anesthetic is infiltrated in a ring block around the prepuce. If hemorrhage is significant, a tourniquet can be applied. The injury site is surgically prepared and examined. If significant separation of the elastic layers of the prepuce is seen, a closely spaced, simple continuous suture pattern using size 3-0 polyglycolic acid is completed first, and then the skin edges are brought into apposition with size 0 polyglycolic acid using a horizontal mattress pattern. If a tourniquet was applied, 15 minutes can be allowed for the blood to clot, after which the tourniquet should be removed.

Antibiotic ointment can be infused into the preputial cavity and gently massaged over the lesion daily for 5 days. The bull is withheld from service for 30 days.

PREPARATION OF TEASER ANIMALS

The successful use of artificial insemination in large beef and dairy herds can be enhanced by the use of estrus-detection (marker or teaser) animals. Steers, freemartins, or cows can be used after a period of androgen treatment (currently not legal in the United States). Intact bulls can be used after ensuring that their fertilizing capacity has been nullified through vasectomy or, more commonly, epididectomy. Surgical procedures can be performed to prevent intromission, which not only further safeguards against fertilization but decreases the possibility of transferring venereal diseases—in particular, trichomoniasis and campylobacteriosis.

The importance of preventing intromission in a group of cows or heifers depends on the management practices within that herd (e.g., consideration of bull size with heifers). In cases in which the female herd is closed and the teaser bulls are young, properly vaccinated (for immunization against infectious bovine rhinotracheitis/bovine viral diarrhea/parainfluenza type 3 [IBR/BVD/PI3], *Campylobacter,* trichomoniasis, leptospirosis, and *Haemophilus*), and free of brucellosis and tuberculosis, simple epididectomy is sufficient. Furthermore, teaser animals that are allowed intromission may perform over a longer period of time because of the absence of the "frustration factor" sometimes reported by cattlemen in bulls in which intromission is prevented. On the other hand, in herds with frequent introduction of animals with unknown or incomplete histories, intromission by the teaser bulls should be prevented. These bulls also should be vaccinated.

Nonsurgical Methods

Hormonal Induction

As stated earlier, no hormonal induction protocols are approved in the United States. Therefore, such protocols are not discussed further.

Epididectomy

Epididectomy is a relatively simple and safe procedure and can be performed more quickly than a vasectomy. The tail of the epididymis is located distally in the scrotum, and the objective of the procedure is to remove it. The surgery can be performed with the bull in either the standing or the recumbent position. The skin of the distal one third of the scrotum is shaved and prepared for surgery. Both testes are forced to the bottom of the scrotum and local anesthetic solution is infiltrated into the scrotal skin over the epididymal tail and into the epididymis. One testis is then released and the other is held in position ventrally in the scrotum. An incision is made over the epididymal tail, which must not be so long and deep as to accidentally allow complete prolapse of the testicle. The incision is made through the skin, tunica dartos, and the tunica vaginalis until the tail protrudes from the incision. The epididymal tail is then dissected free from its testicular attachments. With traction applied to the epididymis, two pairs of forceps are forced through the "loop" of the epididymal tail; one is then clamped across the vas deferens and the other across the most proximal part of the epididymal tail. Although not essential, it is preferable to ligate above both forceps with an absorbable suture material (size 1 polyglycolic acid). The tail of the epididymis is then removed by cutting below each forceps. An antibiotic preparation is applied to the site, and the incision may or may not be sutured. The procedure is repeated on the opposite testis. It is recommended that the teaser bull not be used for heat detection for approximately 3 weeks, to ensure that sperm remaining in the duct system have lost their capacity to fertilize.

Methods That Prevent Intromission

Several surgical procedures are described that in one way or another prevent the bull from gaining intromission.[13] Each procedure has its advantages and disadvantages in terms of cost, reliability, potential postsurgical complications, and technical ease. Intromission is prevented in one of three ways: (1) by translocation or deviation of the penis, (2) by adhering the penis or the prepuce in the retracted position, and (3) by prevention of erection.

Penile-Prepuce Translocation

Two techniques are described that translocate the entire penis and prepuce to the flank area of the bull: the tunnel and the Z-plasty techniques. Each procedure is best performed well in advance of the breeding season and should be limited to use in bulls that weigh 500 to 600 pounds. The surgery is performed with the bull in right lateral or dorsal recumbency under heavy tranquilization or general anesthesia. The skin of the caudal ventral abdomen from the left flank to the right side of the midline is shaved and prepared for surgery. My preferred technique is the tunnel technique, so only this method is described.

Two percent lidocaine is infiltrated around the preputial orifice and caudally on the ventral midline of the sheath to a point just cranial to the scrotum. Lidocaine also is injected into a circular area immediately above the fold of the left flank to which the prepuce will be translocated. It is important not to get this translocation site too high in order to avoid postoperative urine scalds on the skin nor too low, as the bull may learn to gain intromission.

The first incision is made completely around the preputial orifice approximately 3 to 4 cm from the cutaneous junction. The incision is then extended caudally for about 25 cm along the midline of the sheath. The incision is deepened, and by dissection the prepuce is freed completely from the abdominal wall. Care should be exercised to preserve the caudal blood supply to the prepuce. Hemorrhage may be extensive, particularly when the preputial orifice is dissected, and all bleeding vessels must be ligated. It also is critical not to incise into the preputial cavity. To avoid this, a small-diameter tube can be inserted into the prepuce to act as a guide.

After the prepuce is freed, a circular incision approximately 6 to 7 cm in diameter is made through the skin, and the cutaneus truncus muscle above the fold of the flank and the abdominal tunic is exposed. A long pair of forceps (e.g., Knowles cervical forceps) is then passed subcutaneously from the flank incision to the caudal end of the ventral midline incision to emerge cranial to the scrotum. The forceps are partially opened, and the fascia between the jaws is incised to allow the forceps to pass through. A subcutaneous tunnel is created through which the preputial orifice and the prepuce will be pulled. To avoid contaminating the tunnel with debris, a sterile obstetric sleeve is placed over the freed prepuce before it is grasped with the forceps and pulled through the tunnel. It is important to ensure that the prepuce is not twisted while being translocated.

Closure consists of suturing the cutaneus truncus muscle to the subcutis of the relocated preputial orifice with size 0 polyglycolic acid using a simple interrupted pattern. The skin surrounding the preputial orifice is apposed to the skin of the flank with nonabsorbable suture (0.6-mm nylon) in a cruciate or horizontal mattress pattern. The midline incision is closed with nylon using a continuous pattern and periodically suturing deeper to include the abdominal wall fascia, in an attempt to obliterate space where fluid might accumulate. The original circular preputial incision may be left open for drainage provided that the animal is returned to a clean area.

To render bulls infertile and reduce the liability of the surgeon for unwanted matings, a bilateral epididectomy should be performed after completion of the penile translocation procedure. Postoperative administration of antibiotics is indicated, as well as daily application of petroleum jelly around the preputial orifice for 3 to 4 days. Complications include dehiscence, abscess formation, and severe urine scalds.

Penile or Prepuce Fixation

Several fixation techniques have been described that are reportedly successful for prevention of intromission[13]; however, with these fixation techniques, it seems reasonable to expect that bulls may experience some degree of pain when mating is attempted. Information is lacking regarding the comparison of longevity of effectiveness of the various teaser surgery techniques that involve some alteration of normal penile function. On the basis of limited experience with this technique, I believe that teaser bulls with penile or preputial fixation tend not to be as functional over time as are bulls with penile deviations.

The fixation technique described here involves suturing the tunica albuginea of the penis to the abdominal tunic. Fibrosis and adhesions result, preventing penile extension. With the bull tranquilized and in right lateral recumbency, a clean plastic tube is passed into the preputial orifice and used to identify the caudal limit of the cavity. The skin of the abdomen between the scrotum and the preputial orifice is shaved and prepared for surgery. Lidocaine is infiltrated along a line parallel to the penis. An 8- to 10-cm skin incision is made over the penis beginning just caudal to the posterior limit of the preputial cavity. The incision is deepened through the subcutaneous tissue and the elastic layer to expose the tunica albuginea. The dorsal lateral surface of the penis is débrided, as is the adjacent abdominal tunic, and three or four nonabsorbable sutures are placed through the dorsolateral aspect of the tunica albuginea and the abdominal tunic. The subcutaneous tissue is closed in a continuous pattern with size 0 polyglycolic acid and the skin is apposed with 0.6-mm nylon. A bilateral epididectomy is performed to ensure that the bull is not capable of a fertile mating. Postoperative edema is expected, but recovery usually is uneventful. A period of 30 days is allowed for healing before the bull is returned to service.

A similar technique has been used successfully to adhere the prepuce to the abdominal tunic. In this procedure, the bull is tranquilized and cast in right lateral recumbency. The skin over the sheath is prepared for surgery and lidocaine is infiltrated along the left dorsolateral aspect of the sheath beginning 6 cm from the preputial orifice and extended posteriorly for 20 cm. A 15-cm skin incision is made along this line and with blunt dissection the prepuce is freed to allow it to be pulled from the incision. A significant portion of the elastic layer of the prepuce is excised without penetrating into the cavity. After excision of a portion of the elastic layer, three or four sutures are placed through the prepuce and into the abdominal fascia using 0.6-mm nylon. A continuous suture can be placed in the subcutaneous tissue using absorbable material, and the skin is closed with nylon. The fibrous tissue formed as the prepuce heals in the absence of an intact elastic layer in a portion of the prepuce results in adhesions between the prepuce and the body wall, so that penile extension is not possible. Again, as an added precaution, an epididectomy should be performed. In approximately 30 days the bull will be ready for service.

Other Techniques

Other procedures have been used in the past to produce teaser bulls but are not discussed here in detail because they have, for various reasons, not become as popular as those previously described. These include the corpus cavernosal block, penectomy, and preputial ring techniques.[13]

SURGERY OF URINARY STRUCTURES

Calculi occasionally lodge in the urethra of both steers and bulls. Steers are diagnosed with the condition more frequently than are bulls because of the smaller diameter of their urethras. Several factors play a role in the development of urinary calculi, including diet, water intake, and urine pH. The calculi found in feedlot steers are mostly phosphates and are multiple, soft, and smooth, whereas those recovered from steers at pasture are oxalates or silicates and are rough-surfaced and hard. Urethral blockage can occur at any level of the urethra, but the most common site for initial blockage is the distal curve of the sigmoid flexure.

When the diagnosis is made early, the calculus or calculi can be removed from the urethra through a low

urethrostomy. More often, however, the diagnosis is made after significant periurethral urine leakage with inflammation and possibly rupture of the urinary bladder. Subcutaneous edema and cellulitis often are encountered at this stage, and the objective of surgery is to restore urine flow as quickly as possible to salvage the steer for slaughter. Because this is the most common scenario, only a technique for high urethrostomy is described.

The preferred site for urethrostomy in these animals is the ischial area. The procedure can be performed on the animal standing with epidural anesthesia. An area of skin is shaved and prepared for surgery beginning at the level of the ischium and continued ventrally for 30 cm. The skin and subcutaneous tissue are incised on the midline beginning at the level of the tuber ischii, and the incision is continued ventrally for 15 to 20 cm. The penis is located deep in this area, and considerable dissection is required to free the penis and allow it to be grasped. The penis is then pulled out through the incision and transected so that a 4- to 5-cm stump will protrude from the ventral commissure of the skin incision. A frequent mistake in transection of the penis is to leave a stump of insufficient length. In transection of the penis, the dorsal penile vessels should be isolated and ligated before the penis is severed. The proximal portion of the penis is then anchored to the skin with nonabsorbable horizontal mattress sutures placed through the skin, tunica albuginea, and corpus cavernosum penis on both sides of the stump. It is important that the stump is not sutured to the skin in such a manner as to create an acute bend, which would restrict the flow of urine. The urethra can be incised longitudinally and its edges sutured to the skin with 2-0 polyglycolic acid in a simple continuous pattern. The skin above the penile stump is apposed with 0.6-mm nylon.

Postoperatively, animals should be observed for normal urination. Treatment with antibiotics is indicated for animals not destined for immediate slaughter. Ventral accumulation of urine can be relieved with several deep skin incisions made parallel to the prepuce.

CHAPTER 34

Techniques for Artificial Insemination of Cattle with Frozen-Thawed Semen

RAYMOND L. NEBEL

In the modern commercial dairy herd, management of the artificial breeding program is a major responsibility. It requires constant attention and expertise by personnel responsible for semen handling and insemination. Whether the responsibility is contracted to a professional artificial insemination (AI) technician or is assigned to employees of the farm, the requirements for success are the same. The artificial breeding program depends on the inherent fertility, health, nutrition, and management of both the cows and the bulls, as well as on the ability of the handlers to preserve, store, and deliver an adequate dose of viable semen to the cow at the proper time during the estrous cycle.

The primary objective in handling semen properly is to conserve the fertile life of sperm until deposition in the female. This is accomplished by minimizing exposure of semen to injurious conditions, which have additive effects that lower the viability and fertile life of sperm. With frozen semen, the storage temperature of liquid nitrogen stops the life processes, allowing semen to be stored indefinitely if it is maintained at very low temperatures. The critical temperature appears to be –80°C. A point of paramount importance is that although it is easy to maintain frozen semen at a safe temperature, it also is easy to destroy its quality in a few moments of carelessness.

High conception rates require proper insemination techniques. The highest-quality semen placed in the healthiest cow at the proper time before ovulation will not produce a calf if the breeding techniques are not up to par. The mechanics of passing the insemination pipette through the cervix necessitate practice and should be periodically reviewed with the aid of professionals. Sanitary methods are critical to good insemination technique. Good technique also means that each insemination is performed within a reasonable amount of time. Consistently following a step-by-step procedure will assist in achieving good conception rates.

SEMEN TANK MANAGEMENT

The semen storage tank is actually a large metal vacuum-sealed liquid nitrogen refrigerator encased within an extremely efficient insulation system. With proper attention and handling, most liquid nitrogen semen storage tanks give years of trouble-free service, but all storage tanks eventually fail. The semen storage tank consists of two separate chambers. Layers of aluminum foil and specially designed paper fill the space between the two chambers. Air is removed and a partial vacuum is created in the area between the two chambers. This vacuum aids in the insulation and is the major effective property of the storage tank. A specially designed stopper plugs the tank's neck tube, insulating liquid nitrogen and semen from outside air. The tank is not airtight, however. Because liquid nitrogen cools by slowly boiling and releasing gases, a tightly stoppered tank might explode. The specially designed plug allows nitrogen gas to safely escape from the inner chamber. Storage tanks keep semen indefinitely at –196°C as long as any liquid nitrogen is present, but a depth of at least 5 cm of liquid nitrogen should always be maintained as good insurance against possible service delays. The normal field holding time or time allowed between liquid nitrogen refills varies according to the tank model and the number of times it is opened. The liquid nitrogen level should be monitored weekly with a measuring stick.

Technical advances in design and construction have produced storage tanks with liquid nitrogen holding times of 6 to 9 months. Although semen tanks are well constructed, they are still susceptible to damage from mishandling. Damage to the liquid nitrogen tank is most likely to occur when the tank is moved, so excessive movement of the tank should be avoided. The inner chamber of the tank, which contains the liquid nitrogen, is actually suspended from the outer shell by the neck tube. Any abnormal stress on the neck tube, which can be caused by sudden jarring or any excessive swinging motion, can crack the neck tube, resulting in vacuum loss and tank failure. Failure to secure the tank in a moving vehicle can result in not only increased probability of damage to equipment but also increased risk of injury to the driver or passengers if liquid nitrogen is spilled inside the passenger compartment of the vehicle.

To ensure maximum holding time, the tank should be kept in a cool and dry location away from direct sunlight, in a clean and well-ventilated area. The tank should be located in an area where it can be observed frequently to detect excessive nitrogen evaporation and development of frost around the outside neck of the storage tank. Drafts from milk coolers and furnaces should be avoided, but ventilation should be sufficient to prevent possible

user suffocation, which can be caused by too high a proportion of nitrogen gas in the air. The tank should be protected from corrosion by being elevated above concrete or wet floors. A wooden dolly equipped with wheels so that it can be moved easily is ideal for tank storage. The tank should be located where it will be safe from children and vandals or locked to secure and protect semen. Particular attention must be paid to the neck and vacuum fitting. Accumulation of frost on these fittings indicates that the vacuum insulation has been lost and liquid nitrogen has been evaporating rapidly. If frost build-up is observed, a functional tank must be located and the semen transferred to it immediately. The viability of semen in the tank should be evaluated before extensive use.

As with any well-managed business, an accurate inventory of location and quantity of the semen stored in the liquid nitrogen tank is important. This is necessary not only for accounting and audit purposes but, more important, to avoid any unwanted exposure of semen during searching for the desired sire's semen before removal for thawing. A simple semen tank inventory log enables the exact location and quantity of semen remaining to be determined quickly.

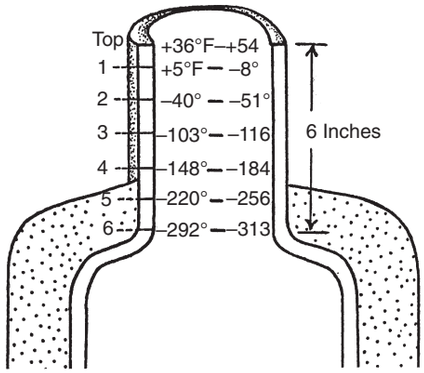

Fig. 34-1 Temperature range found in the neck of the semen storage nitrogen tank. (From Saacke RG: Concepts in semen packaging and use. Proceedings of the Eighth Conference on Artificial Insemination in Beef Cattle of the National Association of Animal Breeders, 1974, p 15.)

Storage of Frozen Semen

Maintenance of low temperatures is important to the successful storage of frozen semen. In 1957, Van Demark and coworkers[1] compared the motility of semen frozen to and stored at –79°C, –65°C, –51°C, –37°C, and –23°C. After 1 day of storage, the motility of semen stored at –37°C and –23°C was basically zero. Semen stored for 1 day at 79°C had 38% motility, compared with 29% and 14% motility for 65°C and 51°C storage, respectively. In studies in which –79°C storage was compared with –96°C[2] or –92°C and –196°C 79°C was inferior to the lower temperatures when judged by maintenance of sperm motility as measured on thawing.

The reasons that subzero temperatures of –79°C and above cannot adequately preserve sperm are unclear and probably are quite complex. Rapatz,[2] however, has proposed that rearrangement in the crystalline structure of frozen semen (recrystallization) may be one cause. This phenomenon has been observed to occur in frozen semen down to a temperature of –80°C. Below –80°C the structure of ice is more stable, and below –100°C it is very stable. Although no direct evidence exists for recrystallization, a correlation has been found between storage injury of spermatozoa and recrystallization.

In addition to the obvious error of permitting a liquid nitrogen storage tank to go dry, stored semen also may be exposed to adverse high temperatures when straws are being removed for thawing. Figure 34-1 shows the temperature gradient that exists in the neck of a typical liquid nitrogen storage tank. As may be noted, dangerously high temperatures prevail in the upper third of the neck of the tank where canes and goblets are raised for removal. When straws are exposed to these temperatures the semen temperature rises quickly. The thermal response of semen in 0.5-ml straws exposed to temperatures of –22°C (2 inches from the top of the tank) and 5°C (1 inch from the top of the tank) is shown in Figure 34-2. The time required to reach –100°C to –80°C, which is the beginning of ice recrystallization, is approximately 10 to 12 seconds for both temperatures. Thermal injury to sperm is permanent and cannot be corrected by returning semen to the liquid nitrogen. For optimal maintenance of sperm viability, canisters and canes containing semen should be raised into the neck of the tank only for

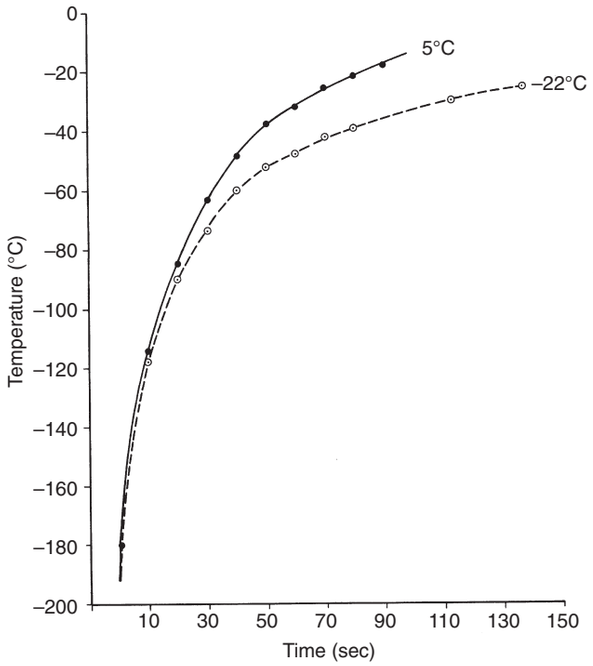

Fig. 34-2 Thermal response of semen in 0.5 mL French straws when exposed to 5°C and –22°C (temperature found in the *upper portion* of the nitrogen storage tank). (From Saacke RG, Lineweaver JA, Aalseth EP: Procedures for handling frozen semen. Proceedings of the Twelfth Conference on Artificial Insemination in Beef Cattle of the National Association of Animal Breeders, 1977, p 49.)

the time required to retrieve a single straw. This time should not exceed 5 to 8 seconds.

SEMEN-THAWING PROCEDURES

The recommendation for thawing of semen frozen in straws is not the same for all AI organizations. For optimal results, the recommendations of the semen processor should be followed. All U.S. semen processors recommend warm-water thawing of straws for periods ranging from 10 to 60 seconds. The situation on most farms is that dairy producers purchase semen from many AI organizations, but only one thawing procedure is performed. The National Association of Animal Breeders (NAAB) has recommended that when specific thawing requirements are in doubt, the straw should be immersed in 30° to 35°C water for a minimum of 40 seconds. Most U.S. AI organizations are members of the NAAB. Based on the scientific literature, warm-water thawing of semen at 35° to 37°C seems most appropriate and safest for vapor-frozen semen packaged in 0.5-ml straws.[3–8]

It has been reported that using a nonthermostatically controlled water bath allows batch thawing of straws (up to 20 at a time) without compromising semen quality when the ambient temperature is approximately 20°C.[9] As many as 10 straws can be thawed simultaneously in a thermostatically controlled thawing bath without significantly decreasing sperm viability. Of note, sperm that remain in a nonthermostatically controlled bath tend to cool over time; this finding may explain the slightly better sperm viability in comparison with that of semen thawed with a thermostatically controlled bath, because the metabolism of cells is lower in the nonthermostatically controlled bath. Thermostatically controlled water baths are designed to maintain a temperature of approximately 35°C.

Regardless of the number of straws thawed simultaneously, straws should be agitated immediately after being plunged into the water, to prevent them from freezing together during the thaw. Duration of incubation time in the bath should be minimized but also depends on the ambient temperature. Ambient temperatures below 20°C dictate that straws remain in the bath until immediate insemination is possible. By contrast, high ambient temperatures allow the immediate removal of straws once thawed; thus, holding time occurs in the insemination rod.

SEMEN HANDLING AFTER THAWING

Regardless of what type of water bath is used, all water should be thoroughly removed from the straw before it is cut. Osmotically, exposure of the 0.5-ml dose of semen to as little as one drop of water results in irreversible cell injury. Rarely, a straw may be defective and leak, permitting water to enter during thawing. If this is suspected, that straw should not be used.

A major concern with warm-water thawing is the danger of cold shock caused by mishandling of the semen after thawing. **Cold shock** is the irreversible injury to sperm caused by a rapid decrease in semen temperature above freezing after thawing. Cold shock occurs when semen is thawed and then subjected to cold environmental temperatures before insemination. The severity of damage depends on rate and span of temperature drop. It results in loss of motility, metabolic activity, and fertilizing potential and is believed to involve irreversible changes in the outer plasma membrane.

Cold shock occurs most frequently when breeding is undertaken in cold weather and particularly when warm-water thawing is used. As might be expected, the high surface-to-volume ratio of the straw makes it vulnerable to cold shock. Saacke and coworkers,[10] using the 0.5-ml French straw, measured the effect of static ambient temperatures—21°C, 4°C, and 16°C—on rate of temperature drop in semen after thawing during preparation of the inseminating rod (Figs. 34-3 to 34-5). Preparation of the inseminating rod, from thawing of the straw at 35°C to the protection of the loaded rod by tucking it against the body, required approximately 1 minute. At each ambient temperature, the rod was prepared at that temperature or warmed by being rubbed quickly with a paper towel several times over the length of the rod. As is illustrated in Figure 34-3, the temperature drop was only 3° to 6°C for a 21°C ambient temperature, and warming the rod was effective in minimizing the temperature drop. At 4°C and –16°C (see Figs. 34-4 and 34-5), the drop in semen temperature was approximately 15°C and 20°C, respectively. Because severity of sperm injury due to cold shock is related to the rate of cooling, warming the rod would be of little value for the two coolest ambient temperatures because it would only

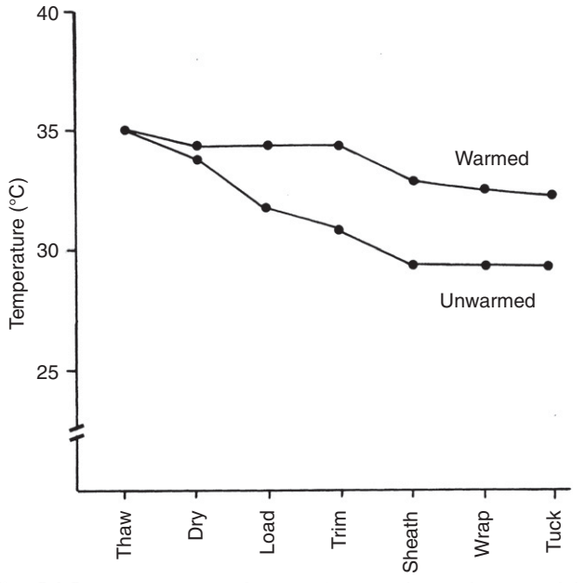

Fig. 34-3 Temperature of semen in 0.5-ml French straws following a 35°C warm-water thaw during preparation of the artificial insemination rod at a 21°C ambient temperature. Preparation of the rod from thaw to tuck required approximately 1 minute. The rod was warmed by being rubbed rapidly with the hand *(warmed)* or was kept at ambient temperature *(unwarmed)*. (From Saacke RG, Lineweaver JA, Aalseth EP: Procedures for handling frozen semen. Proceedings of the Twelfth Conference on Artificial Insemination in Beef Cattle of the National Association of Animal Breeders, 1977, p 55.)

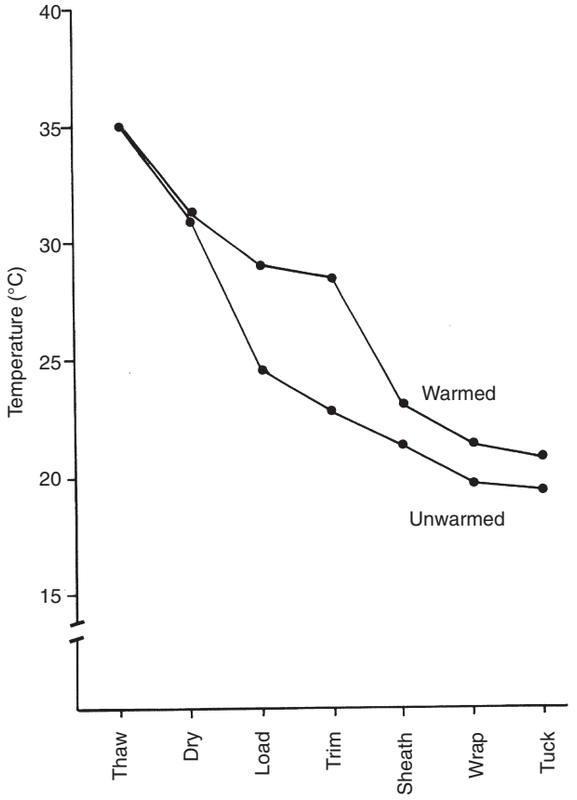

Fig. 34-4 Temperature of semen in 0.5-ml French straws after a 35°C warm-water thaw during preparation of the artificial insemination rod at a 4°C ambient temperature. Preparation of the rod from thaw to tuck required approximately 1 minute. The rod was warmed by being rubbed rapidly with the hand *(warmed)* or was kept at ambient temperature *(unwarmed).* (From Saacke RG, Lineweaver JA, Aalseth EP: Procedures for handling frozen semen. Proceedings of the Twelfth Conference on Artificial Insemination in Beef Cattle of the National Association of Animal Breeders, 1977, p 55.)

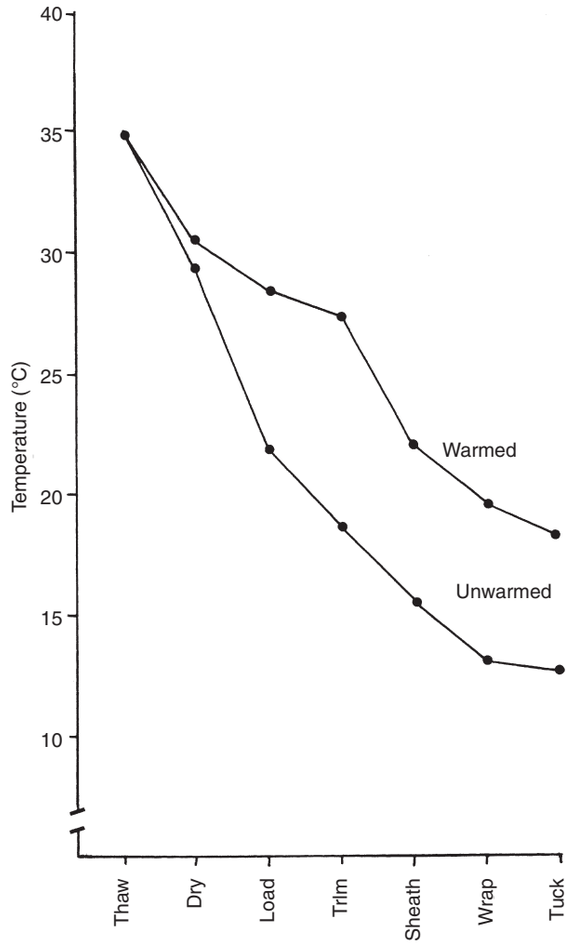

Fig. 34-5 Temperature of semen in 0.5-ml French straws after a 35°C warm-water thaw during preparation of the artificial insemination rod at a 16°C ambient temperature. Preparation of the rod from thaw to tuck required approximately 1 minute. The rod was warmed by being rubbed rapidly with the hand *(warmed)* or was kept at ambient temperature *(unwarmed).* (From Saacke RG, Lineweaver JA, Aalseth EP: Procedures for handling frozen semen. Proceedings of the Twelfth Conference on Artificial Insemination in Beef Cattle of the National Association of Animal Breeders, 1977, p 55.)

postpone the temperature drop. It is clear that in cool weather, precautions against cold shock must be implemented during preparation of the inseminating equipment.

Because of potential cold shock, many investigators have questioned the wisdom of the warm-water thaw, particularly when breeding will take place during cold weather. Fleming and co-workers,[11] using the 0.5-ml French straw, studied the effect of different thaw rates on motility and acrosomal integrity of sperm after 3 hours of incubation after thaw. In their comparison, they included a 35°C thaw followed by immersion of the straws in a 5°C water bath. This treatment achieved a maximum cold shock. Their results (Table 34-1) show that both motility and acrosomal integrity are adversely affected by cold shock, when compared with a 35°C thaw without cold shock; however, air thaw and 5°C water thaw were still inferior to the 35°C thaw followed by cold shock.

In cold weather, either of the following precautions seems warranted: (1) provide a sheltered heated area for breeding, or (2) provide a sheltered heated area for semen thawing and loading of the insemination pipette near the animals to be bred; then insulate the inseminating equipment and carry it to the breeding chute. Freezing weather brings the possibility of refreezing thawed semen. This can be classified as a disaster with regard to semen quality. Regardless of the thaw procedure recommended, conditions causing a sudden drop in the temperature of the semen should be avoided.

SEMEN THAWING AND HANDLING TIPS

It is essential that frozen semen be handled and thawed carefully and properly to maintain sperm viability for

Table **34-1**

Effect of Thaw Bath Temperatures and Cold Shock on Recovery by Spermatozoa in 0.5-ml French Straws

optimal results. Insemination equipment should always be kept clean, dry, and warm. A thermometer should be used to obtain the proper water temperature. The thermometer should be checked for accuracy at least every 6 months with a reference mercury thermometer.

When removing the straw from the nitrogen tank, the handler should gently shake the straw to remove any liquid nitrogen that may be retained in the cotton plug end of the straw. The thaw should be timed with a watch to avoid guessing. While the semen is thawing, the handler warms the insemination rod by rubbing it briskly with a paper towel. Once it has been warmed, the handler places the insemination rod within his or her clothing so that it will be close to the body to maintain warmth. After the semen is thawed, the straw is dried thoroughly with a paper towel and protected from rapid cooling. The air space in the straw should be adjusted to ensure that no semen will be lost when the end of the straw is cut off. This can be done by slightly flicking the wrist while holding the straw at the crimp-sealed end. Only sharp scissors or a specially designed straw cutter should be used to cut the straw. The straw is cut "square" at a 90-degree angle to achieve a good seal with the sheath. The assembled insemination rod is wrapped in a clean, dry paper towel and tucked within clothing for transport to the cow. Finally, the cow should be inseminated within minutes after the semen has been thawed. The period of time between removing the straw from the tank and depositing the semen in the cow should not exceed 15 minutes.

SEMEN DEPOSITION

To reiterate, high conception rates require proper insemination techniques. The highest-quality semen placed in the healthiest cow at just the right time will not produce a calf if the breeding technique is not performed properly. The mechanics of passing the inseminating rod through the cervix are not covered here; for further information, AI organizations or other institutions that provide training in this technique should be consulted. Practice is required to develop the skill, which should be learned and periodically reviewed with the assistance of professionals.

One of the most critical parts of the insemination technique is depositing the semen anterior to the cervix. A majority of sperm deposited by natural service is lost from the reproductive tract shortly after being deposited. The major reason why sperm numbers can be markedly lower in each dose of semen used in AI is that the cervix, which is the major barrier to sperm transport, is bypassed in correct semen deposition with AI. Senger and co-workers[12] reported a significant increase in fertility when bilateral cornual insemination was performed. Seguin,[13] Zavos and co-workers,[14] and Williams and co-workers[15] all reported improved fertility when cornual insemination was performed. Marshall and co-workers[16] reported a slight but not statistically significant negative effect on conception when bicornual insemination was performed (54% versus 50%, respectively). A tendency for improvement was observed, however, when inseminators who were achieving low conception rates by attempting to deposit semen in the uterine body were retrained to deposit semen in both uterine horns. Overall, agreement on the effect of bicornual insemination is still lacking, because neither a consistent benefit nor significant negative effect has been demonstrated at this time.

Gallagher and Senger,[17] using a vaginal sampling technique, showed that sperm retention by the female reproductive tract did not differ when cornual insemination was compared with uterine body insemination; sperm movement into the vagina from the uterus was about the same in both cases. When sperm were deposited in mid-cervix, retrograde sperm loss was almost twice the loss observed after cornual deposition. If cornual insemination has any advantage in terms of fertility, it probably is due to the elimination of errors associated with attempting to deposit the semen in the uterine body but, instead, depositing a portion or all of the inseminate in the cervix. Anterior cornual insemination does not appear to result in greater retention of sperm than that achieved with insemination into the uterine body. Although the factors that control sperm transport and retention are still poorly understood, it is clear that retrograde transport of sperm occurs regardless of the site of deposition. Also, deposition of sperm in the anatomic vicinity of fertilization does not enhance fertility.

SUMMARY

Many livestock producers are breeding their own cows, and others are contemplating such a change in management. The level of success ranges from excellent to frustratingly low. Like many technologies of today, AI requires both skill and management ability. Through conscientious effort and attention to detail, the herd manager–inseminator can be successful. A thorough knowledge of the risks and pitfalls avoids problems and helps to ensure satisfactory results.

CHAPTER 35

Clinical Reproductive Physiology of the Cow

JEFFREY S. STEVENSON

Reproduction drives the production cycle in both beef and dairy enterprises and is of major economic consequence. Maximizing the reproductive potential in cattle requires the understanding and application of many principles basic to the various disciplines of animal and veterinary science, including genetics, nutrition, physiology, and theriogenology, as well as management intervention.

This chapter reviews the most current information on the major endocrine and physiologic events that are known to be associated with the onset of sexual maturation or puberty; the physiology of the estrous cycle, pregnancy, parturition, and periparturient period; and the postpartum transition from anestrus to the onset of estrous cycles. Because of the extent of literature covering these topics, the reader is referred to several key articles and major reviews for further in-depth information.

ONSET OF SEXUAL MATURATION

Increasing reproductive efficiency in beef and dairy herds depends on the timely introduction of replacement heifers into the breeding herd. Heifers should have their first calf by 2 years of age. Maximizing the proportion of

beef heifers that calve early in the calving season leads to heavier calf weaning weights, allows for timely rebreeding, and increases their herd longevity. To maximize lifetime milk production in a dairy operation, replacements also must calve as 2-year-olds in order to recoup rearing costs. Achieving this goal in either type of production unit requires appropriate heifer development and timely onset of puberty and first conception.

Puberty generally is defined as the onset of the first estrus associated with a potentially fertile ovulation that is followed by a luteal phase of normal duration. Prepubertal heifers may have at least one anovulatory estrus that precedes their first normal cycle (13% to 22% of heifers at an average of 3 months before puberty), often called a nonpubertal estrus. Puberty represents only the onset of sexual maturation, which actually is not achieved until the female reaches the maturity characteristic of her breed. This is recognized more easily in a litter-bearing species as the time when maximum ovulation rate or litter size is achieved.

Factors Influencing Onset of Puberty

The onset of puberty, as well as of nonpubertal estrus, is influenced by several factors, including age, genotype, season, body weight, nutrition, and social rearing environment.[1]

Genotype

The breed composition of heifers alters age at puberty, because size at puberty is determined genetically. Numerous studies have demonstrated differences in age and weight at puberty among various breeds. In general, European *(Bos taurus)* dairy and beef breeds attain puberty earlier than do those of Zebu origin *(Bos indicus)*. Breed of sire and dam alters age at puberty, and crossbreeding reduces age at puberty in heifers.

Although timing of puberty is altered by many factors, as discussed later, age at puberty is influenced by selection. Breeds selected for milk production as well as for size (dairy and beef breeds) reach puberty earlier than do breeds of similar mature size and retail product growth potential but not selected for milk yield. Inbreeding delays puberty in heifers by retarding rate of growth. Estimates of heritability for age at puberty range from 0.41 to 0.64, two- to threefold higher than the estimates of heritability of milk production. With such relatively high heritabilities, practices of selection for earlier puberty in genotypes with traditionally later sexual development could prove beneficial, particularly in some beef breeds in which puberty often is delayed. Heifers sired by bulls with large scrotal circumferences reach puberty at younger ages and rebreed sooner after their first parturition than do heifers sired by bulls with small scrotal size. Studies also have demonstrated that heifers that are heavier at 6 months of age (before puberty) reach puberty at younger ages and also are heavier at calving. Although beef heifers that are heavier at weaning reach puberty at younger ages, these same heifers experience longer intervals to estrus after their first parturition than do their lighter-weight contemporaries.

Season

Although cattle are not considered to be seasonal breeders, evidence indicates that season of birth may alter timing of puberty. When heifers were fed similarly in controlled environmental chambers, those born in the autumn reached puberty earlier than those born in the spring.[2] Heifers born late within a spring calving season, however, were younger and lighter at puberty, probably because of improved forage quality and its effects on milk availability from their dams and digestibility of forages obtained by their grazing.

Body Weight and Nutrition

Although age and weight are correlated somewhat with the onset of sexual maturity, body weight is the major factor affecting age at puberty in cattle. Generally, the onset of puberty occurs when the heifer reaches approximately 40% to 50% of her mature weight. Unintended pregnancies may be initiated in heifers younger than 6 months of age when they are maintained in the presence of breeding bulls. Initiation of puberty normally occurs in yearling heifers, but age at puberty may range from 4 months to more than 2 years. Puberty is delayed in heifers that are maintained on low planes of nutrition during the prepubertal growth phase. Onset of puberty is dictated by body weight for the breed. Although age at puberty is influenced by nutritional factors, body weight at puberty is unaffected by nutrition. Correlations between gain in body weight and age at puberty indicate that increased growth rate of heifers results in younger age at puberty. In short, heifers on various planes of nutrition will reach puberty at different ages, but at similar relative stages of physical development. Furthermore, subsequent adequate weight gains are required once heifers reach puberty to ensure that they continue to have normal estrous cycles.

Underfeeding or overfeeding heifers has significant consequences on their development. Underfeeding of growing heifers may result in delayed puberty, subnormal conception rates, underdeveloped mammary glands, and greater incidence of calving problems.[3] Overfeeding often results in weak expression of estrus, subnormal conception rates, high embryonic mortality, decreased mammary gland development, and reduced milk production.[3] Dairy heifers fed 115% of all 1989 National Research Council nutrient requirements for heifers to gain 0.7 kg/day from 3 to 24 months of age were younger at puberty, were heavier at calving, had larger heart girth, were longer, were not excessively fat at calving, and calved at younger ages. Nutrient requirements suggested by the National Research Council should serve as minimum guidelines.

Social Rearing Environment

In some feral mammalian species, the physical presence of the male decreases age at puberty in contemporary females. Presence of mature bulls and adult cycling cows has altered age at puberty of heifers in some but not all studies. Increased proportions of prepubertal beef heifers treated oronasally with bull urine reached puberty earlier than water-treated controls.[3]

Endocrine Mechanisms

The events necessary to initiate the first pubertal estrus occur by an organized and interdependent cascade of changes in the central nervous system, hypothalamus, pituitary, and ovaries during maturation.[4] These events are summarized in Figure 35-1. As early as 4 months of age, the pituitary is capable of releasing luteinizing hormone (LH) in response to injections of gonadotropin-releasing hormone (GnRH). Likewise, the ovaries respond to exogenous and endogenous (GnRH-induced) gonadotropins by increasing the production of ovarian steroids.[4]

Early ovarian follicular development is evident. In fact, intrarectal ultrasonography shows that groups of follicles develop in regular repeating patterns (waves), beginning as early as 2 weeks of age, similar to what is observed in adult females during the estrous cycle and pregnancy[4] (see discussion of follicular dynamics below). The largest follicle, or dominant follicle, within each follicular wave of developing follicles progressively increases in maximal diameter from 2 to 34 weeks of age, parallel to increasing numbers of follicles detected in each follicular wave.[4] The combined evidence of early established pituitary and ovarian competence suggests that hypothalamic inactivity (lack of GnRH pulses secreted into the hypophyseal portal vessels) is responsible for maintaining the prepubertal status. The mechanism by which the hypothalamus remains relatively inactive has not been elucidated in cattle. Maturation of the GnRH pulse system (pulse generator) in the hypothalamus may necessitate other central nervous system involvement. Increased hypothalamic turnover and decreased sensitivity to various neurotransmitters occur in rodents as puberty is imminent. Specifically, increased turnover of norepinephrine and dopamine normally accompanies pulses of LH in the rat. Endogenous opioids may be involved in inhibiting the requisite LH pulse frequency, because administering an opioid receptor antagonist (naloxone) to 4-week-old heifers induced LH pulses, with the response decreasing as heifers approached 32 weeks of age.[4]

Evidence in ewes and heifers suggests that the prepubertal GnRH pulse generator is highly sensitive to the negative feedback of ovarian estrogens, such that estradiol inhibits secretory pulses of LH and probably those of GnRH as well (see Fig. 35-1). This phenomenon was described earlier in rats and is known as the gonadostat theory of puberty.[4] This theory suggests that the threshold to the negative feedback of estrogen increases as puberty approaches, accounting for a decreased sensitivity of the hypothalamus to the negative feedback of estrogen. Thus, the inhibitory mechanism modulating pulsatile release of GnRH and LH decreases, resulting in an increasing frequency of pulses, which normally are observed as puberty approaches (see Fig. 35-1). The pulse frequency of LH gradually increases between day 126 and day 14 before puberty, whereas concentrations of estradiol receptors within the hypothalamus decline.

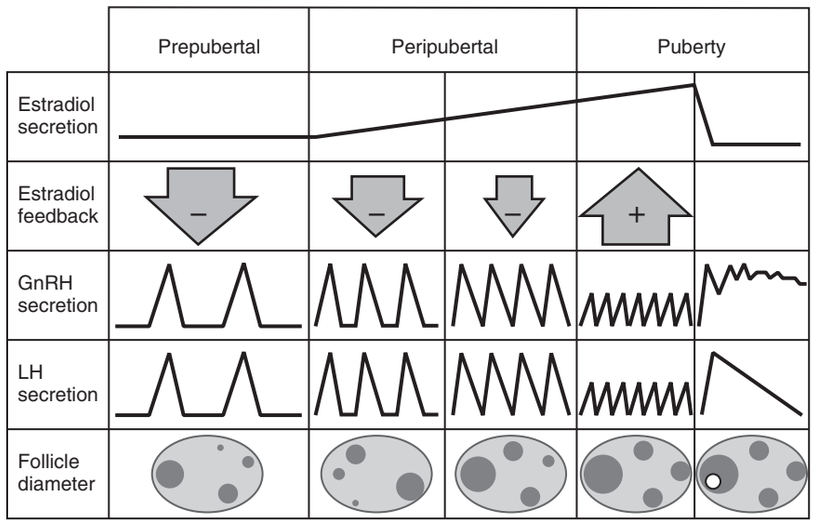

Fig. 35-1 Conceptual model for endocrine changes responsible for the onset of puberty in heifers. The peripubertal period includes approximately the 50 days preceding puberty in heifers. The *sign within the arrows* representing estradiol feedback indicates negative (–) or positive (+) feedback on secretion of luteinizing hormone (LH), and *width of the arrows* indicates relative degree of negative feedback. Secretion of gonadotropin-releasing hormone (GnRH) is highly sensitive to estradiol negative feedback during the prepubertal period. As the peripubertal period and the associated decline in estradiol negative feedback begins, secretion of GnRH, and hence LH, increases resulting in increased growth and estradiol secretion by dominant ovarian follicles. As a result of the progressive decline in estradiol negative feedback and increase in LH pulse secretion during the peripubertal period, estradiol eventually attains concentrations sufficient to induce the pubertal preovulatory surge of LH. (From Day ML, Anderson LH: Current concepts on the control of puberty of cattle. *J Anim Sci* 1998;76:1 Suppl3.)

Endogenous LH pulses occur at a frequency of one to four per 24 hours during the prepubertal period. As during the estrous cycle, the frequency of LH pulses sufficient to "drive" follicular maturation to ovulation must increase to approximately one pulse per hour. For 3 weeks before puberty, blood concentrations of progesterone seldom rise above 0.5 ng/ml (indicative of significant luteal tissue in the ovaries and little or no negative feedback of progesterone on LH secretion). Therefore, the frequency of LH pulses seems to be insufficient to support follicular maturation and ovulation during this period.[4]

The transition into puberty occurs for 2 to 4 weeks before first ovulation. This transient stage is characterized by an increased frequency of LH pulses and ovulation, as determined by a significant increase in blood concentrations of progesterone. In most cases, heifers in this transitional period exhibit one or two short-lived (duration of 2 to 5 days) elevations in blood progesterone of lower magnitude than what is observed in the normal estrous cycle. These transient increases in progesterone are preceded by LH pulses, the source of which may be luteinized ovarian follicles, and may be involved in preparing the uterus for the possibility of pregnancy and/or the establishment of normal patterns of GnRH and LH pulses characteristic of cycling females. The first major preovulatory LH surge occurs only after earlier prepubertal rises in progesterone, with a behavioral estrus observed in some heifers at this time. Puberty has been induced by administering a progestin as an ear implant containing norgestomet for 9 days,[3] in addition to an intramuscular injection containing both norgestomet and estradiol valerate, or as a progesterone-releasing intravaginal insert. Similar success has been reported when melengestrol acetate was fed for 7 to 16 days.[3] The effectiveness of these treatments depends on attainment of adequate body weight in heifers, characteristic of that necessary at normal puberty for their genotype.

PHYSIOLOGY OF THE ESTROUS CYCLE

General Traits

Once puberty occurs, estrous cycles generally continue unabated unless pregnancy is established or nutritional conditions are limited severely. Estrous cycles typically are 3 weeks in duration but normally may range from 17 to 25 days. The period of estrus may range from 2 to 50 hours in duration but averages 12 to 18 hours under most conditions. Ovulation occurs approximately 24 to 30 hours after the onset of estrus, with the first signs of estrus usually coinciding with the beginning of the preovulatory surge of LH and follicle-stimulating hormone (FSH). Durations of estrous cycles are often 1 to 2 days shorter in heifers than in cows. High seasonal temperatures do not seem to alter duration of cycles but may reduce the duration of estrus and decrease blood flow to the reproductive tract and may alter concentrations of various reproductive hormones.[2]

The estrous cycle is divided into two distinct phases—follicular (day 19 until estrus occurs) and luteal (days 1 to 18)—or into four stages—estrus (day 0), metestrus (days 1 to 3), diestrus (days 4 to 18), and proestrus (day 19 until behavioral estrus occurs). Estrus is characterized by sexual receptivity of the female (standing behavior) to a bull or to mounting activity by other females, in addition to follicular growth in preparation for ovulation. Metestrus is characterized by final follicular maturation and ovulation, formation of the early corpus luteum, and its subsequent ability to secrete progesterone. Once significant concentrations of progesterone are observed in peripheral blood, the luteal phase or period of diestrus begins and continues until the corpus luteum starts to regress at the onset of luteolysis. As concentrations of progesterone in blood begin to decline rapidly with the demise of the corpus luteum, the follicular phase is initiated, leading to the selection and accelerated growth of another ovulatory follicle.

Some important differences in these basic traits of estrus have been observed between *Bos taurus* and *Bos indicus* breeds. Specifically, *Bos indicus* females are reported to have periods of estrus of shorter duration, shorter intervals from the onset of estrus to ovulation, reduced magnitude of the preovulatory concentration of the LH surge, smaller corpora lutea, and lower luteal-phase concentrations of progesterone.[1,3]

Endocrine Patterns

For purposes of describing the interactions of hormones secreted by the hypothalamus, pituitary, ovaries, and uterus that are involved in the orchestration of sexual behavior and normal endocrinology of the estrous cycle, the cycle can be divided into three endocrine periods: (1) pregonadotropin surge, (2) postgonadotropin surge, and (3) luteal phase.[5]

Pregonadotropin Surge

The period of the pregonadotropin surge begins with the demise of the corpus luteum and ends with the preovulatory surge of LH and FSH, which initiate ovulation of a mature follicle 24 to 30 hours later (Fig. 35-2). Concentrations of progesterone rapidly decline as those of estradiol begin to increase concurrently with the accelerated growth of the preovulatory follicle. As progesterone declines, the baseline concentration of LH increases,[5] the frequency of LH pulses increases from about one pulse every 4 to 6 hours to one pulse every hour, but the amplitude of LH pulses declines[5] (all because of reduced negative feedback by progesterone on the hypothalamus and pituitary). This change in LH secretion, which coincides with a parallel pulsing of estradiol secreted into the venous effluent of the ovary bearing the preovulatory follicle, can be monitored in jugular blood by frequently collected blood samples (see Fig. 35-2). Although follicular growth may be stimulated by FSH alone, a combination of LH and FSH has been shown to induce maximal synthesis of estradiol in vitro.[6] Thus, both gonadotropins influence follicular development and subsequent secretion of estradiol. Estradiol appears to exert inhibitory effects on FSH release, because when it is administered to ovariectomized heifers, FSH is reduced to precastration concentrations. Furthermore, when titers of estradiol are

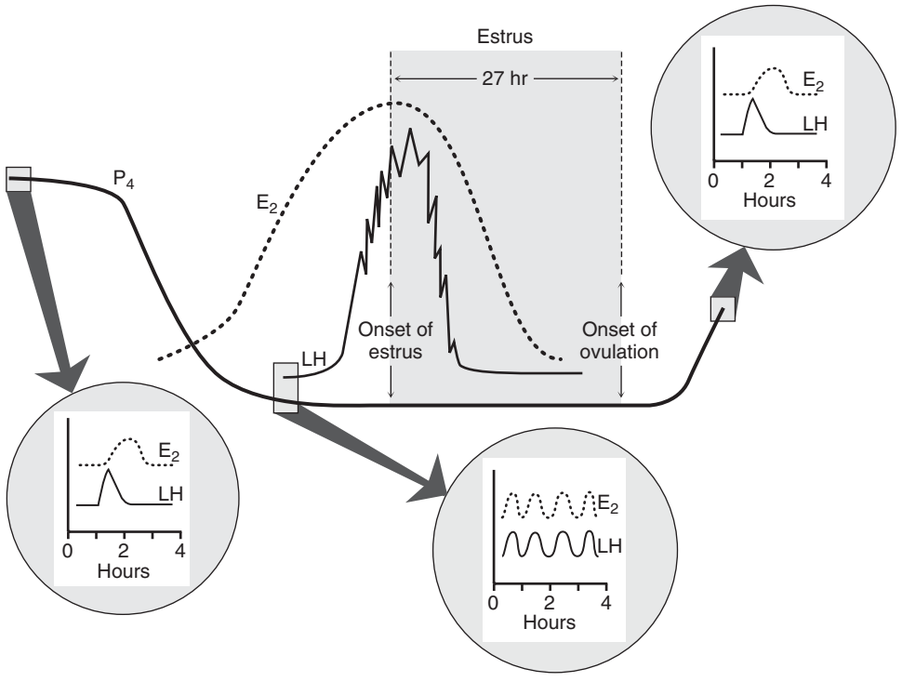

Fig. 35-2 Concentrations of progesterone (P_4), estradiol (E_2), and luteinizing hormone (LH) during the pre- and postgonadotropin surge period of the bovine estrous cycle. During diestrus (because of high concentrations of progesterone secreted by the corpus luteum), the frequency of LH pulses in jugular blood is low (approximately one per every 4 to 6 hours) and pulse amplitude is high, similar to that of estradiol in the ovarian venous effluent. As the corpus luteum dies and progesterone declines to baseline concentrations, the pulse frequency of LH increases to approximately one per hour (decreased amplitude) followed by correlated secretion of estradiol. The LH surge results from increased LH pulse frequency sufficient to sustain a peak (surge) of 8 to 12 hours induced by maximal titers of estradiol. These two events are coincident with the onset of estrus, which is followed by ovulation in approximately 27 hours.

at their peak just before the preovulatory surge, concentrations of FSH are lowest.[5]

A carefully orchestrated cascade of increasing LH pulses and elevated titers of estradiol eventually culminates in the onset of estrus, with estradiol triggering the initiation of both estrous behavior and the preovulatory surge of LH (see Fig. 35-2). Estradiol apparently triggers more frequent pulsatile GnRH secretion by the hypothalamus and enhanced pituitary responsiveness to each priming GnRH pulse. Blocking the rise in estradiol by chemical or immunologic means can block the occurrence of the gonadotropin surge.[5] Likewise, concentrations of progesterone must be low before estradiol can induce the gonadotropin surge, because administering progesterone during the period before the surge can block it. The elevation of LH and FSH (surge) usually endures for 8 to 10 hours. Termination of the surge is due to refractoriness of the pituitary to GnRH (decreased concentration [down-regulation] of pituitary GnRH receptors) and depletion of the releasable pool of pituitary gonadotropin. This hypothesis is substantiated by two observations: (1) When heifers are ovariectomized shortly after the onset of estrus and the preovulatory surge, a delay in the classic postcastration rise in LH is observed, and (2) injections of GnRH within 12 to 16 hours of the onset of the surge result in the release of only marginal amounts of gonadotropin.

Postgonadotropin Surge

The postgonadotropin surge period is characterized by declining titers of estradiol in blood, after their peak at the onset of estrus, as follicular luteinization ensues (Fig. 35-3). The process of ovulation has been likened to mechanisms associated with an inflammatory reaction.[7] The process of follicular rupture is regulated by a host of intrafollicular mediators. For example, ovulation can be blocked by intrafollicular administration of various prostaglandin enzyme inhibitors or antiserum to various prostaglandins or their regulatory enzymes.[5] Inter–theca cell capillaries and the basement membrane of the follicle are disturbed at ovulation, accounting for some hemorrhage, and thus allowing both capillaries and theca cells to pervade the ruptured follicle. Follicular content of estradiol declines rapidly as progesterone content begins to increase, because both theca and granulosa cells differentiate into luteal cells (luteinize) that form the corpus luteum. Theca cells appear to develop into smaller-diameter cells, known as small luteal cells, and the granulosa cells become large luteal cells as the corpus luteum develops.[8]

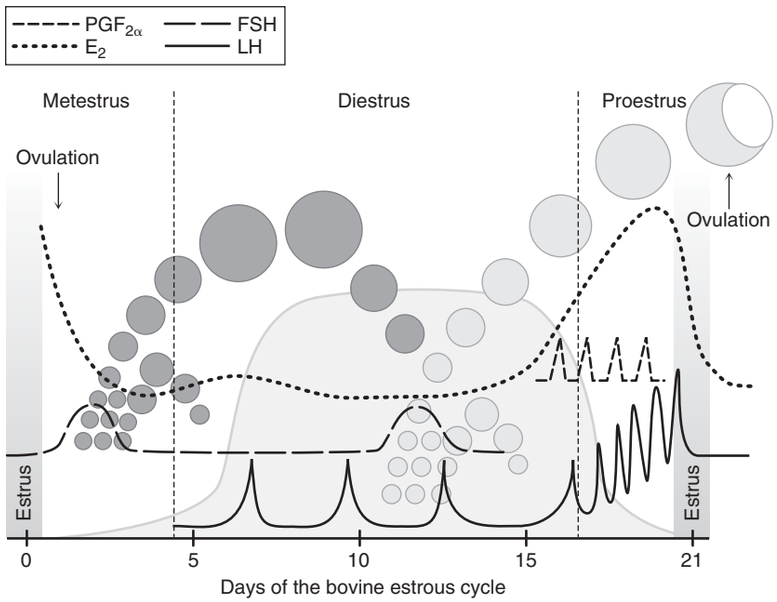

Fig. 35-3 Diameters of two dominant follicles and their respective subordinate follicles from each of two cohorts of follicular waves during the bovine estrous cycle. Peak concentrations of follicle-stimulating hormone (FSH) are detected 1 to 2 days before the recruitment of each follicular wave. The first peak is nearly coincident with ovulation during metestrus. During diestrus, when elevated concentrations of progesterone (P_4) are secreted by the corpus luteum, pulses of luteinizing hormone (LH) are sufficient to allow selection of dominant follicles but insufficient to allow maturation of a dominant follicle until progesterone returns to basal concentrations after spontaneous luteolysis (increased uterine-secreted prostaglandin $F_{2\alpha}$ [$PGF_{2\alpha}$]) or in response to exogenous injections of $PGF_{2\alpha}$. After luteolysis, during proestrus, LH pulse frequency and estradiol (E_2) increase sufficiently to induce behavioral estrus and the LH surge. (Adapted from Thatcher WW: *Fundamentals of dairy reproduction. The 100-day contract: Fundamentals for achieving reproductive efficiency CD-ROM.* Pharmacia Animal Health, Kalamazoo, MI.)

The remainder of what is called metestrus (days 1 to 3) is characterized by low blood concentrations of LH, estradiol, and progesterone (see Fig. 35-3). A secondary rise in FSH of lower magnitude than that observed during the surge often is reported just before ovulation, or about 24 to 30 hours after the onset of the preovulatory surge. This secondary rise may be a consequence of the loss of follicle-derived inhibin production during the ovulatory process. This increase in FSH probably is critical to the recruitment of the first wave of antral follicles that becomes visible by intrarectal ultrasonography during early metestrus[11] (see Fig. 35-3; see also subsequent section on follicular dynamics).

Luteal Phase

The luteal phase (days 4 to 18) begins when the corpus luteum secretes significant concentrations of progesterone, which generally exceed 1 ng/ml by day 4 or 5 of the cycle (see Fig. 35-3). As progesterone establishes itself again as the dominant negative feedback hormone of the luteal phase, patterns of LH secretion are modified once again to a lower frequency (one pulse every 4 to 6 hours) but with higher-amplitude pulses. Progesterone reaches maximal concentrations by days 8 to 10, which is nearly coincident with the maximum weight of the developing corpus luteum. Both cell types of the corpus luteum secrete progesterone, but the small luteal cells seem to have nearly all of the LH receptors and are six times more responsive to LH in vitro than the large luteal cells in terms of progesterone secretion.[8] The small luteal cells represent about 20% of the total luteal cell population and contribute approximately 15% of the progesterone secreted by the corpus luteum, whereas the remainder is derived from the large luteal cells. The large cells, however, have nearly all of the receptors for prostaglandin E_2 (PGE_2) and prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$). Concentrations and affinity of highly specific $PGF_{2\alpha}$ receptors in the bovine corpus luteum are similar on days 2, 4, 6, and 10 of the estrous cycle, failing to explain the lack of luteolytic response of the corpus luteum to $PGF_{2\alpha}$ before day 5 or 6 of the cycle. Large luteal cells also produce neurophysin and oxytocin, identical to those produced in the hypothalamus and stored in the posterior pituitary.[8] Early in pregnancy, about 20 days after conception, the original large cells disappear, leaving the small luteal cells, some of which expand into larger-diameter luteal cells in the corpus luteum of pregnancy.[8] The major luteotropin in cattle is thought to be LH, because if antiserum to LH is administered during the luteal phase, regression of the corpus luteum ensues.

Marked pulses of $PGF_{2\alpha}$ secreted by the uterus, in absence of a viable embryo, cause regression or death of the corpus luteum, thereby ending the luteal phase (see Fig. 35-3). After about 14 days under the influence of progesterone secretion, the endometrium secretes pulses of $PGF_{2\alpha}$, each lasting about 6 hours, for a total of approximately 36 hours. Prostaglandin $F_{2\alpha}$ causes an immediate decline of progesterone and oxytocin to basal concentrations within 6 to 10 hours in the peripheral circulation and in the content of the corpus luteum. Uterine involvement in the process of luteolysis is supported by the prolonged maintenance of the corpus luteum when the uterus is removed during the luteal phase. Furthermore, cattle with a congenitally absent uterine horn that is ipsilateral to the ovary bearing the corpus luteum have prolonged cycles with an extended luteal lifespan. Such observations, as well as surgical preparations in sheep, have provided evidence of a local utero-ovarian control of luteal lifespan. Current observations suggest that $PGF_{2\alpha}$ produced by the uterine horn adjacent to the ovary bearing the corpus luteum is transferred from the uterine venous effluent into the ovarian artery via a countercurrent transfer mechanism.

Some controversy remains concerning the mechanism by which $PGF_{2\alpha}$ induces luteolysis. Luteolytic effects of $PGF_{2\alpha}$ are thought to occur in part through its direct inter-

vention with luteal cells and, indirectly, via a reduction in luteal blood flow. Although $PGF_{2\alpha}$ has vasoconstrictive properties, it has not been determined whether the marked decrease in ovarian and luteal blood flow that occurs in spontaneous or $PGF_{2\alpha}$-induced luteolysis is a cause or consequence of luteolysis. Recent evidence indicates that luteal oxytocin is involved in luteolysis, probably through its ability to elaborate more secretion of $PGF_{2\alpha}$ from the endometrium as the corpus luteum begins to regress and oxytocin is released during luteal demise. Oxytocin given exogenously on days 5 to 8 of the cycle causes regression of the corpus luteum only if the uterus is present.[5] Estradiol produced by the dominant large follicle late in the cycle is thought to initiate the process of luteolysis by inducing production of uterine $PGF_{2\alpha}$. Estradiol induces uterine endometrial receptors for oxytocin, which, when occupied by oxytocin, activate phospholipase A_2 and release arachidonic acid and the arachidonic acid cascade, leading to production of uterine $PGF_{2\alpha}$ and eventual luteolysis. Administration of exogenous estrogens initiates luteolysis and can stimulate uterine production of $PGF_{2\alpha}$. Conversely, removal of ovarian follicles after day 10 of the cycle will extend luteal function for several days beyond the duration of a normal cycle. Therefore, the positive feedback cascade of oxytocin from the corpus luteum to the uterus and of $PGF_{2\alpha}$ from the uterus to the corpus luteum probably serves as a fail-safe mechanism to ensure luteolysis. The process of luteolysis and actions of $PGF_{2\alpha}$ can be monitored by measuring a major blood serum-stable metabolite of $PGF_{2\alpha}$, 15-keto-13,14-dihydro-$PGF_{2\alpha}$ (PGFM). Luteolytic pulses of $PGF_{2\alpha}$ (peripheral PGFM) are observed with concurrently detectable increases in estradiol and declining concentrations of progesterone (see Fig. 35-3).

Follicular Dynamics

Waves of follicular growth develop throughout the bovine estrous cycle. In each cycle, either two, three, or four waves of follicular growth can occur, with two waves being most common in adult cows.[6,9] An example of one cow with two follicular waves is illustrated in Figure 35-3. Each wave consists of a cohort of follicles that begin to increase in diameter from their original 1- to 2-mm size (recruitment), the largest of which becomes the dominant follicle by continuing to grow (selection), whereas others degenerate and undergo atresia.[9] Once dominant, the dominant follicle undergoes three phases of development: growth (increasing diameter); stasis (little change in diameter); and regression (decreasing diameter [atresia]). The first wave consistently begins around day 1 of the cycle. The second, third, and fourth waves begin at more variable times, with more waves occurring in cows with longer estrous cycles. Any dominant follicle can mature and ovulate, if the corpus luteum is forced to regress by exogenous injections of $PGF_{2\alpha}$ at the appropriate time. In other words, if $PGF_{2\alpha}$ were given and the corpus luteum regressed during the growing or early static phase of the dominant follicle, it could proceed to ovulation. Otherwise, if the dominant follicle has begun to become atretic, a new dominant follicle will develop from a new cohort of follicles, accounting for a longer follicular phase.[9] In retrospect, atretic follicles can be identified histologically by the presence of pyknotic nuclei in the granulosa cell layer or by the decreased ratio of estrogen to progesterone in the follicular fluid.

Emergence of each follicular wave is initiated by an increase in FSH[9] (see Fig. 35-3). The first wave is initiated by the secondary rise in FSH that follows its preovulatory surge. All other waves are initiated by detectable transient increases in FSH that precede the ultrasonographic appearance of each wave by 1 to 2 days. Increased estradiol in blood is observed shortly thereafter, as the largest follicle becomes dominant and estrogenic.[9] The largest follicle apparently dominates its subordinate cohort of follicles by producing various substances, including inhibin. Because of this orchestrated regular occurrence of follicular waves, at least one dominant follicle (codominance of two large follicles can occur) is always present in the pair of ovaries at any stage of the cycle. This phenomenon guarantees great difficulty in accurate prediction of stage of the cycle or impending estrus by palpation of the ovaries alone, even when a palpable corpus luteum is identified. Accurate diagnosis of a functional corpus luteum by palpation per rectum is difficult. Studies in which the presence or absence of functional luteal tissue was validated by concurrent measurement of progesterone in serum indicated that when a corpus luteum was identified by palpation, only 82% of the time was its presence validated by high concentrations of progesterone. When a corpus luteum was not palpated, progesterone concentrations were low 70% of the time, indicating that a corpus luteum was present but missed in 30% of the cases.

Follicular maturation follows coordinated actions of LH and FSH through receptors in theca and granulosa cells, respectively (Fig. 35-4). LH binds to theca cells and stimulates production of androgens, which subsequently diffuse through the basement membrane and into granulosa cells. Binding of FSH to granulosa cells increases aromatase activity, which converts androgens to estradiol. Increasing concentrations of estradiol and FSH also up-regulate receptors for LH in granulosa cells in maturing preovulatory follicles (<10 mm in diameter). Binding of LH and FSH by granulosa cells is necessary for regulating final follicular maturation and eventual ovulation in response to these hormones.[6] These two cell types and the associated gonadotropins are regulated by finely tuned mechanisms because estradiol also can inhibit the production of progesterone in both theca and granulosa cells, thus ensuring that androgens are produced via a parallel enzymatic pathway in both cell types (see Fig. 35-4). This system of regulation of theca and granulosa cells by LH and FSH often is referred to as the "two-cell, two-gonadotropin model."[6,8]

PREGNANCY

Pregnancy is defined as the period from fertilization until parturition. Gestation in cattle is approximately 280 days in duration, with a normal range of 270 to 292 days. Variability in the duration of pregnancy is influenced by fetal sex; number of fetuses; breed; genotype of the sire, dam, or fetus; plane of nutrition; and environmental factors.[1]

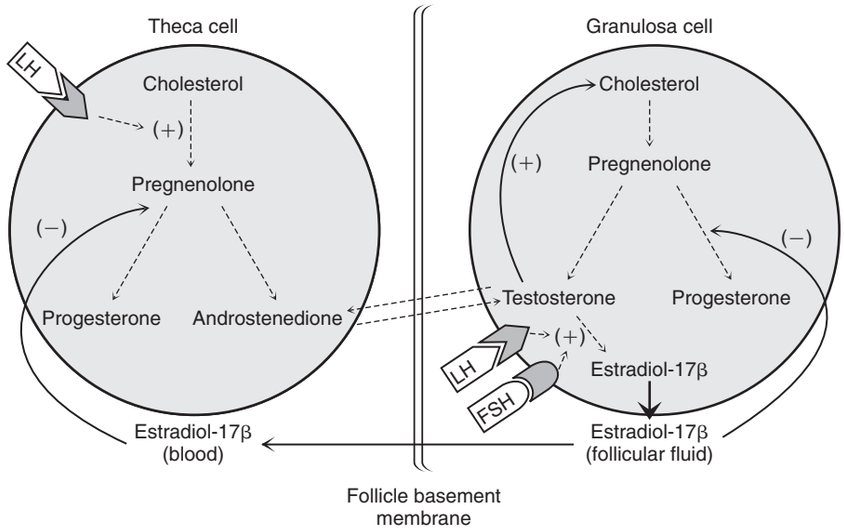

Fig. 35-4 Suggested two-cell, two-gonadotropin model for regulation of estradiol by preovulatory follicles. Theca cells provide androgen precursors in response to luteinizing hormone (LH) stimulation of cholesterol (derived mostly from low-density lipoprotein [LDL]-cholesterol) conversion to pregnenolone and androstenedione. Androstenedione crosses the basement membrane into the granulosa cells and is converted to testosterone in response to follicle-stimulating hormone (FSH) in small follicles and in dominant follicles in response to LH. Increased supply of testosterone leads to synthesis of estradiol, which is transferred into the follicular fluid or back across the basement membrane to increase blood concentrations of estradiol. Concentrations of estradiol inhibit the conversion of pregnenolone to progesterone in both follicle cell types.

Male fetuses are carried longer than female fetuses, whereas presence of twin fetuses results in shortened periods of gestation. Undernutrition and heat stress can shorten gestation, retard fetal growth, and result in weak calves.

If conception occurs at a given estrus, blood or milk concentrations of progesterone rise within 3 to 4 days, as in the normal cycle. Instead of declining at about day 17 or 18, however, they remain elevated for the duration of pregnancy (Fig. 35-5). The functionality of the corpus luteum must be spared (i.e., luteolysis must be prevented) to allow pregnancy to continue. Progesterone stimulates the glandular epithelium of the endometrium to proliferate and become secretory (histotroph or "uterine milk"), providing the only source of nutrients for the growing conceptus before placentation occurs and a minor portion even afterward. In addition, progesterone decreases uterine tone and myometrial contractility by increasing the threshold of sensitivity to various myometrial stimulants, thus allowing free expansion of the conceptus and placenta without expulsion from the uterus.

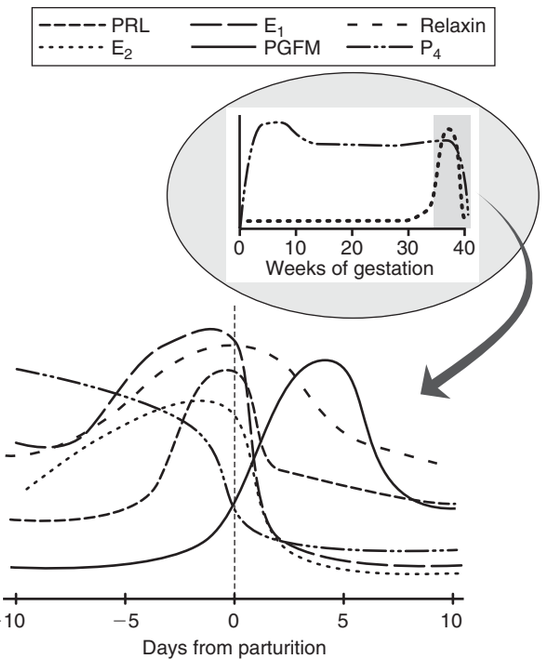

Fig. 35-5 **Upper panel,** Concentrations of progesterone (P_4) and estradiol (E_2) during gestation in the bovine. **Lower panel,** Relative acute changes in various hormones during late gestation before parturition are illustrated: P_4, E_2, estrone (E_1), relaxin, prolactin (PRL), and 15-keto-13,14-dihydro-$PGF_{2\alpha}$ (PGFM).

Maternal Recognition of Pregnancy

At about day 16 or 17, the conceptus appears to signal its presence to its dam, an event known as **maternal recognition of pregnancy.**[10] The timing of this recognition was determined by an experiment in which embryos were transferred into the uterus at various times; it was

observed a viable embryo must be present in the uterus by day 16 or 17 to prevent luteal demise. If the embryo dies before day 16, then the cow will recycle in 18 to 24 days, as if conception never occurred. If the embryo dies after the demise of the corpus luteum is prevented, then the cow may have a delayed return to estrus (prolonged cycle). Up until this time, the hormones of the estrous cycle and pregnancy are effectively similar (see progesterone [P_4] and estradiol [E_2] in Figs. 35-3 and 35-4), and changes in the oviductal and uterine environments occur regardless of pregnancy status. Beyond this point, a viable conceptus in the uterus plays an active role in securing its survival there. Consequently, luteal maintenance, which is characteristic of pregnancy, reflects responses of the uterus and ovary to physiologic conditions initiated by one or more signals from the conceptus and its products.

Several hypotheses have been presented to explain the mechanism by which the embryo signals its presence and prevents luteolysis.[10] The embryo actively secretes a host of steroids, prostaglandins, and proteins into the lumen of the uterus beginning on day 13. Between then and day 16 or 17, noticeable conceptus-altered maternal physiology is not observed, but during this critical period, the normal cycle of events associated with luteal regression is modified to accommodate the existing pregnancy.

Embryos may produce an antiluteolytic substance that prevents luteolysis either directly or indirectly by inducing a uterine luteotropic substance. Prostaglandin E (PGE), when infused directly into the uterus beginning in the late luteal phase of the estrous cycle, has delayed luteolysis in some experiments. Furthermore, administering homogenates of day 10 to 12 bovine embryos into the uterine lumen also has delayed luteolysis.[10] Experiments have demonstrated that bovine blastocysts (obtained at days 13 to 19) produce progesterone, testosterone, estradiol, PGE, and $PGF_{2\alpha}$. A bovine-produced conceptus protein known as interferon-tau may signal changes in endometrial production of various prostaglandins in the presence of the embryo, thereby preventing luteolysis and maintaining the corpus luteum.[10] Therefore, the embryo probably produces a luteotropin that prolongs luteal life span. Around days 10 to 12 of the cycle or pregnancy, blood flow to the ovary bearing the corpus luteum increases markedly and remains elevated throughout pregnancy.[5,8]

Presence of the ovary bearing the corpus luteum is essential to maintain pregnancy in the cow until about day 200 of gestation. In one study, nearly all pregnant cows that were subjected to bilateral ovariectomy maintained their pregnancy, so long as their adrenal glands remained intact. Elevated concentrations of progesterone and placental estrogens during pregnancy inhibit pituitary LH secretion sufficiently to prevent a preovulatory surge of LH and ovulation (see Fig. 35-5). Continuing patterns of follicular waves into pregnancy have been reported, however.[9]

Hormonal Patterns

The fetoplacental unit secretes estrone (E_1) (see Fig. 35-5), which becomes sulfated and increases throughout pregnancy in conjunction with fetoplacental growth and development. Estrone and estradiol produced by the fetoplacental unit are conjugated immediately by the placentomes to prevent excessive estrogenic effects on maternal tissues. The conjugated estrogens (estrone sulfate) are pooled in the fluids of the chorioallantois and amnion of the placenta and in maternal circulation. A gradual increase in conjugated and free estrogens (1% to 10% of conjugated forms) occurs during pregnancy, beginning by day 60 of gestation. In addition, during the last 2 months of pregnancy, the placenta may be capable of maintaining pregnancy by its de novo synthesis of progesterone and estrogen.[1] Concentrations of estrogen increase markedly during the last 1 to 4 weeks of gestation (see Fig. 35-5). Other steroids also appear to be synthesized in the placenta but are depleted immediately after birth of the calf and expulsion of the placenta.

During the latter few weeks of gestation, various changes in ovarian and placental secretions occur (see Fig. 35-5). In addition to the changes in ovarian and placental steroids discussed above, concentrations of relaxin are increased by secretions of either the corpus luteum or the placenta to prepare the cervix, uterus, and pelvic ligaments for fetal expulsion. Similar changes in maternal concentrations of PGFM and prolactin (PRL). The peak in PRL occurs just before parturition, to initiate lactogenesis. If this peak is blocked by various drugs, milk yield after calving is suppressed severely.

PARTURITION

Pregnancy is terminated by the fetus once it is capable of surviving outside the uterus. The specific mechanisms differ slightly between species, but in general, the hormonal changes associated with parturition are those involved with final maturation of the fetus, termination of pregnancy, expansion of the birth canal, initiation of uterine contraction, maternal behavior, synthesis of milk, and the ability to eject milk.

The signal to initiate parturition appears to reside in the hypothalamic-pituitary axis of the fetus (Fig. 35-6).[11] Thus, surgical removal of the fetal pituitary or adrenal glands prolongs gestation. Adrenocorticotropic hormone (ACTH) administration to fetuses causes premature birth, as does injection of cortisol or its synthetic analogues to the dam. Increased cortical growth in fetal adrenal glands during late pregnancy occurs in the absence of noticeable elevations in fetal ACTH. Recent work indicates that production of prostanoids within the fetal brain influences fetal ACTH secretion and that induction of prostanoid biosynthesis near the end of gestation may be important in the process of parturition.[11] Fetal ACTH becomes elevated 1 to 2 days before birth, coincident with increases in corticosteroids, however.[11]

The target for the fetal cortisol, which results from ACTH release or uteroplacental transfer of cortisol given to the dam, is the placenta. The rise in fetal corticosteroids during the last month of gestation is responsible for activation of enzymes in cotyledons that increase the conversion of progesterone to estrogens or their precursors.[11] Such an increase in placental steroidal activity is evidenced by the dramatic rise in prepartum concentra-

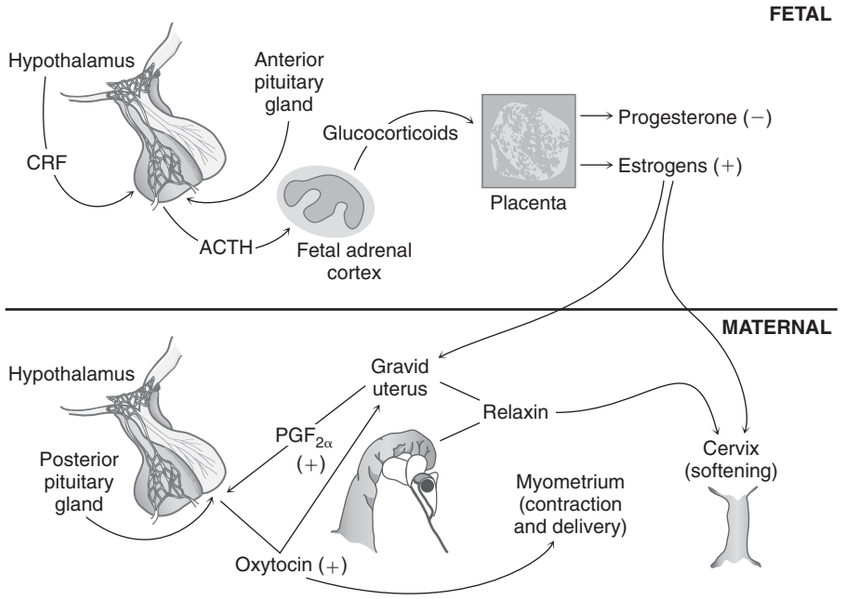

Fig. 35-6 A suggested sequence of fetal and maternal events leading to and associated with parturition in cattle. The time of parturition is controlled by maturation of the hypothalamic-pituitary-adrenal axis in the bovine fetus. Fetal corticotropin-releasing factor (CRF) is secreted from the hypothalamus and increases fetal adrenocorticotropic hormone (ACTH) from the anterior pituitary, which stimulates fetal glucocorticoid (cortisol) production by the adrenal cortex. In response to these events, (1) placenta production of progesterone declines (removal of progesterone block) and estrogen increases; (2) production of estrogen increases uterine secretion of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), myometrial receptors for oxytocin, and placental or ovarian secretion of relaxin, which softens the cervix and relaxes pelvic ligaments to accommodate fetal expulsion; and (3) increased $PGF_{2\alpha}$ production stimulates maternal release of oxytocin from the posterior pituitary, which further stimulates $PGF_{2\alpha}$ production by the uterus and contractions of the myometrium with eventual delivery. (From Geisert RD: *Learning reproduction in farm animals CD-ROM.* Oklahoma State University, Stillwater.)

tions of estrogens, estrone sulfate, and other estrogen precursors (see Fig. 35-5). Estrogen and androgens secreted by the placenta augment activity of the fetal hypothalamic-pituitary-adrenal axis by increasing fetal ACTH secretion and by decreasing negative feedback sensitivity to cortisol.[11] In sheep, cortisol can stimulate the rate-limiting enzyme 17α-hydroxylase, causing the placenta to secrete predominantly estrogen, rather than progesterone.[11]

Progesterone in maternal blood declines gradually during the last week, before falling rapidly to baseline concentrations at parturition (see Fig. 35-5). The gradual decline in progesterone may be due partly to increased placental metabolism of progesterone to estrogens or their precursors. Estrogen, in turn, stimulates release of maternal $PGF_{2\alpha}$ from the uterine endometrium (see Fig. 35-5), resulting in the regression of the corpus luteum of pregnancy. Estrogen also induces receptors for oxytocin, thus preparing the uterus for parturition by oxytocin-induced contractions. Prostaglandin $F_{2\alpha}$ induces release of oxytocin from the posterior pituitary, and both hormones act as smooth muscle simulators to elaborate contraction of the myometrium and expel the fetus.[1,11] Furthermore, $PGF_{2\alpha}$, estrogen, and relaxin cause softening of the cervix and relaxation of the pelvic ligaments to facilitate birth.

Although much of the foregoing discussion has been proved experimentally, some details remain elusive at present and need to be documented.

PUERPERIUM AND POSTPARTUM PERIOD

After parturition, the cow enters a variable period of sexual quiescence or lactational anestrus before cyclic ovarian activity resumes. Although numerous factors probably interact to affect the duration of the postpartum anestrus, including breed and age of cow, milk yield, nutritional status, body condition, season, and presence of bulls, the presence (in beef cows) or absence (in dairy cows) of suckling seems to be the key inhibitor of estrous cycles.

Puerperium

Involution of the previously gravid uterus is another critical event that must occur during the early postpartum period.[12] The rate of involution is somewhat remarkable, because by 20 days after calving, tissue sloughing and hemorrhage have ceased, and the size of the uterus has been reduced by more than 80%. By 40 days, the uterus has completely involuted except for isolated pockets of

leukocytes. Involution, first estrus, and first ovulation are delayed in cows with periparturient problems such as dystocia, twinning, uterine infections, ovarian cysts, injury, or metabolic diseases such as ketosis, displaced abomasum, and milk fever.[13] Furthermore, all measures of reproductive efficiency are reduced in cows with periparturient problems compared with normal cows. Infertility or reproductive failure often is difficult to resolve because of its multiple causes.

Postpartum Period

Anestrus

Initiating early reestablishment of normal estrous cycles after calving is essential to allow adequate time for cows to be inseminated and maintain a 12- to 13-month calving interval. Numerous studies in dairy cows, based on observed estrous activity, ovulations, and resulting estrous cycles documented by repeated samples of milk or blood progesterone, indicated that nearly 95% resume cyclic ovarian activity by approximately 4 weeks after calving.[13] Recent studies have indicated that in well-managed dairy herds, the proportion of cows not cycling by the end of the volunteer waiting period (i.e., 60 days post partum) is approximately 20% to 25%.

Milking

Approximately 50% of dairy cows in one study[14] expressed estrus before this first ovulation (according to daily video recordings during the first 80 days after calving), whereas the herdsman observed estrous behavior in only 20%. Second ovulations (at about day 44 post partum) were preceded by estrous behavior in 95% of the dairy cows, whereas the herdsman observed such behavior in only 44%. By the third ovulation (at about day 64 post partum), 100% of the dairy cows were detected in estrus by video recordings, whereas the herdsman detected only 64%.

Suckling

In the beef cow, suckling prolongs anestrus, but its duration is shortened if calves are weaned at birth or suckling is limited.[13] Suckled beef cows that calve in the spring may not begin estrous cycles for 40 to 60 days. Early weaning of calves, however, usually initiates estrous cycles in most situations, regardless of body condition or nutritional status. Suckling per se (suckling and concurrent milk removal) is not essential to prolong anestrus, because cows maintained with their calves that were fitted with nose plates or muzzles so that they could not suckle had periods of anestrus equal to cows maintained with their normally suckling calves. An intact udder is not essential, so long as the calf is maintained with its dam and attempts to "suckle" after bottle feeding.[13] Suckling-induced hormones, such as prolactin, cortisol, and oxytocin, are increased in mastectomized cows when their own calves attempted to "suckle," analogous to those of udder-intact cows at the time of suckling by their own calves. In either case, concentrations of LH are low and pulses of LH are inhibited by suckling or attempted "suckling" events, so that anestrus is maintained.[13]

Partitioning of Available Nutrients and Body Condition

Combined effects of various metabolic changes and nutrient repartitioning, essential for lactogenesis and galactopoiesis in cattle, compete for nutrients that are essential to reinitiate estrous cycles after parturition. Nutrient intake, adequate availability of nutrients, diet composition, acute changes in body weight or body condition before or after calving, variously related metabolites, metabolic hormones, and overall energy balance are factors that correlate with the reestablishment of estrous cycles and may be indicators of intervals to first postpartum ovulation.

Metabolic functions are regulated in mammals to achieve two major purposes: self-survival and perpetuation of their species. **Homeostatic** mechanisms achieve the first purpose because they regulate the internal biochemical environment. **Homeorhetic** regulations achieve the second purpose by altering metabolic support to sustain growth, pregnancy, or lactation. The concept of homeorhesis accounts for how various hormonal mechanisms orchestrate coordinated changes in metabolic pathways in specific body tissues necessary to support an existing physiologic function such as lactation or pregnancy at the expense of other, less vital bodily functions. For example, when lactation begins, various priorities for nutrient utilization to support lactation are established. These priorities involve redirecting homeorhetic mechanisms that may be mediated by prolactin, somatotropin, insulin, insulin-like growth factor I (IGF-I), estradiol-17β, glucocorticoids, and other hormones.

The approximate ranking priority for use of available energy in ruminants is as follows: (1) basal metabolism; (2) activity; (3) growth; (4) energy reserves; (5) pregnancy; (6) lactation; (7) additional energy reserves; (8) estrous cycles and initiation of pregnancy; and (9) excess reserves.[13] In accordance with this prioritized use of available dietary nutrients, reinitiation of the estrous cycle and all of its associated components (i.e., gonadotropin secretion, ovarian follicular development, and ovulation) occurs only after greater-priority needs are met (i.e., maintenance, growth, lactation, and minimal energy reserves). Nutrient repartitioning for milk production and reproduction is the result of complex interactions among diet quantity and quality, nutrient reserves (body condition), and the demand for growth and metabolism.

Differences in management of milked and suckled cattle of various genotypes account for some of the differences in postpartum reproductive recrudescence, but as previously discussed, their lactational management is the major determinant. In general, if adequately fed, cows nursing a calf rarely experience a significant negative energy balance or extensive loss in body weight that occurs in full-fed, milked cows producing up to five times more milk. The effect of nutrition in suckled cows depends somewhat on whether nutrition is adequate before or after parturition. In general, prepartum nutrient status, as estimated by body condition at parturition, is more important than that after calving. The relationship between body condition at calving and the interval to first postpartum estrus in suckled beef cows is nonlinear. That is, the effects of poor body condition are greatest at

very low body condition scores (<4 on a 10-point body condition scoring system) and become less significant as body condition increases to a value of 7 or greater. When nutrition is adequate in suckled cows, milk yield has little effect on postpartum anestrus, but when nutrition is limiting, particularly for cows having genotypes for high milk production, increased milk yield delays first ovulation and estrus. In milked cows, such a relationship of interval to first estrus and body condition has not been established. The magnitude of nutrient deficit (negative energy balance), however, seems to be an important factor that inhibits first ovulation and has some relationship to the number of days to first ovulation.

Postpartum changes in energy balance generally are predictive of when first ovulation will occur in milked cows. In milked cows, the nadir of energy balance occurs during the first or second week after calving and recovers at a variable rate, with first ovulation occurring approximately 10 to 15 days after the nadir. Days to first ovulation are correlated positively ($r = 0.76$) with days to nadir of energy balance. Furthermore, because milk fat percentage is high near the nadir of energy balance, it may be a good indicator of the severity of nutrient deficit. During the enormous metabolic demands of high milk production in early lactation, major amounts of nutrients are required for mammary synthesis of lactose, proteins, and triglycerides in the mammary gland that cannot be met by dietary intake. Nevertheless, milked cows with greater dry matter intake, despite having a negative energy balance, produce more milk, lose less body weight, and ovulate earlier post partum than those with lower intakes. Cows with greater intakes also reach the nadir of energy balance earlier and experience a more severe, but shorter, period of negative energy balance, suggesting that when cows are more efficient in partitioning dietary and stored nutrients toward milk synthesis, they also are better able to recover ovarian cyclicity.

Hormonal and Follicular Changes

Blood FSH concentrations increase from prepartum concentrations in suckled and milked cows within 5 days and peak before the appearance of each follicular wave after calving. The first or second dominant follicle generally ovulates in milk dairy cows after LH pulse frequency increases. Concentrations of LH in plasma or serum increase gradually from low, nearly nondetectable levels at calving until about day 10, when some dairy cows are observed to begin pulsatile secretion of LH.[1,13] The frequency of the LH pulses (determined by the pulse frequency of GnRH) increases over a period of days (to about one pulse per hour) until ovulation occurs. An hourly pulse frequency may be necessary for initiation of sufficient LH release, so that final follicular growth can occur before first ovulation. An increase in IGF-I is coincident with increases in LH pulse frequency and earlier first postpartum ovulation.

After ovulation, the frequency of GnRH and LH pulses decreases to one every 4 to 6 hours. Onset of these episodic patterns is delayed in suckled cows, particularly in those intensively suckled by several calves or suckled by one calf, but in poor body condition or in negative energy balance.[13] As a result, many follicular waves occur, each with its dominant follicle, but without ovulation until LH pulse frequency increases sufficiently. Studies have demonstrated that pulses of GnRH every 1 to 2 hours, and hence small pulses of resulting LH, will induce estrous cycles in suckled and milked cows.[13] Part of this mechanism whereby LH pulses induce ovulation is related to the ability of the hypothalamic-pituitary axis to respond to estradiol that is elaborated from developing antral follicles. In the early postpartum period, milked cows respond earlier than suckled cows to this positive feedback effect of estradiol on LH secretion.[1,13] Not only does a temporal delay occur in the LH response to exogenous estradiol, but the magnitude of LH release in response to the same dose of estradiol increases as the postpartum period progresses.

Most current evidence suggests that the temporary inhibition of estrous cycles during the postpartum period is due to a block at the hypothalamic-pituitary level. Factors that influence the release of GnRH seem to be mediated within the brain or central nervous system by other hormones or endogenous opioid peptides.[13] The latter belongs to a family of endogenous hormones that mimic actions of the opiates, such as morphine or opium. Infusions of either of the opioid receptor antagonists naloxone and naltrexone increase concentrations of LH in milked and suckled cows, suggesting that endogenous opioid peptides limit LH secretion during the early postpartum period, when endogenous pulse frequencies of GnRH and LH are infrequent.

The pulse frequency of LH increases gradually until a preovulatory LH surge occurs to ovulate a mature graafian follicle. The first preovulatory surge of gonadotropins is followed, as expected, by a rise in progesterone in 3 to 4 days. In approximately 20% to 50% of dairy cows, however, this luteal phase is of short duration (<10 days), whereas in suckled cows weaned at about 30 to 40 days post partum or after their first ovulation, 90% will display a shortened estrous cycle (<12 days). This short cycle appears to be due to a premature release of uterine $PGF_{2\alpha}$, increased sensitivity of the luteal tissue to early luteolysis, and a higher concentration of uterine oxytocin receptors.[1]

Other Factors

Exposing cows suckled post partum to bulls decreases the period of anestrus. Season influences the length of anestrus in suckled cows. Although season may be modified by other factors such as suckling, nutrition, and genotype, truly seasonal effects are related to day length. Some evidence indicates that fall-calving primiparous (not multiparous) cows may have delayed intervals to first ovulation and estrus, unless supplemental lighting is given to provide 16 to 18 hours of total light per day.[2] The relationship of day length and prolactin suggested that the high concentrations of prolactin associated with milking and suckling may inhibit the onset of ovarian cycles. Evidence against this mechanism, however, includes the following findings: (1) Treatment with pharmacologic agents to reduce prolactin concentrations does not hasten the onset of ovarian cycles; (2) infusion of prolactin into cows fails to alter prolactin concentrations; and (3) concentrations of prolactin have

not been shown to be higher in suckled than in milked cows.

CHAPTER 36

Estrus Detection

MICHAEL L. O'CONNOR

Faulty estrus detection is the most important problem in reproductive management confronting the herd manager and the veterinarian. For example, Barr[1] determined that the correlation between days lost because of missed heats and total days open was 0.92. Research using computerized simulation analysis clearly illustrated the economic advantage to improving the efficiency of estrus detection in dairy herds.[2] In this study, moderate improvement in the rate of estrus detection from 40% to 50%, coupled with a conception rate of 50%, increased income by $34 per cow per year. Further improvement to 60% estrus detection returned a total of $56 per cow per year. Although the costs to achieve such improvements were not considered in the analysis, the expenses associated with additional labor to more intense estrus detection, possible use of estrus detection aids, or an estrus synchronization program should result in a favorable net return per dollar invested. Earlier research reported a 4 to 1 return on investment to improve the rate of detection from 35% to 55%.[3] Failure to detect estrus or inaccurate heat detection results in an estimated annual loss of over $300 million to the dairy industry in the United States.[4] Poor estrus detection can be costly for a beef cattle cow-calf unit using artificial insemination for several reasons: (1) more conceptions occur late in the breeding season, reducing the potential value of calves because they are born late in the calving season; (2) cows bred late are likely to be bred late in subsequent years; and (3) more cows probably will be culled because they are not pregnant.

This chapter describes the characteristics of estrus, factors affecting estrous behavior, and methods to enhance estrus detection to include detection aids.

ESTROUS BEHAVIOR

Standing to be mounted is the most definitive sign of estrus in cows. During the period of **standing heat**, cows stand to be mounted by other cows. Cows that move away quickly when a mount is attempted are not in estrus. The average duration of a mount is approximately 2.5 seconds.[5] Considerable variation has been reported in

not been shown to be higher in suckled than in milked cows.

CHAPTER 36

Estrus Detection

MICHAEL L. O'CONNOR

Faulty estrus detection is the most important problem in reproductive management confronting the herd manager and the veterinarian. For example, Barr[1] determined that the correlation between days lost because of missed heats and total days open was 0.92. Research using computerized simulation analysis clearly illustrated the economic advantage to improving the efficiency of estrus detection in dairy herds.[2] In this study, moderate improvement in the rate of estrus detection from 40% to 50%, coupled with a conception rate of 50%, increased income by $34 per cow per year. Further improvement to 60% estrus detection returned a total of $56 per cow per year. Although the costs to achieve such improvements were not considered in the analysis, the expenses associated with additional labor to more intense estrus detection, possible use of estrus detection aids, or an estrus synchronization program should result in a favorable net return per dollar invested. Earlier research reported a 4 to 1 return on investment to improve the rate of detection from 35% to 55%.[3] Failure to detect estrus or inaccurate heat detection results in an estimated annual loss of over $300 million to the dairy industry in the United States.[4] Poor estrus detection can be costly for a beef cattle cow-calf unit using artificial insemination for several reasons: (1) more conceptions occur late in the breeding season, reducing the potential value of calves because they are born late in the calving season; (2) cows bred late are likely to be bred late in subsequent years; and (3) more cows probably will be culled because they are not pregnant.

This chapter describes the characteristics of estrus, factors affecting estrous behavior, and methods to enhance estrus detection to include detection aids.

ESTROUS BEHAVIOR

Standing to be mounted is the most definitive sign of estrus in cows. During the period of **standing heat**, cows stand to be mounted by other cows. Cows that move away quickly when a mount is attempted are not in estrus. The average duration of a mount is approximately 2.5 seconds.[5] Considerable variation has been reported in

the number of mounts received by an estrous cow. Using electronic pressure-sensitive mount detectors, Dransfield and co-workers determined the average (± SD) number of standing events for Holstein cows to be 8.5 ± 6.6 per cow.[6] The average duration of standing estrus, defined as the time from first mount to last standing event, ranged from 33 minutes to 35.8 hours, and the overall average for cows monitored in 17 commercial herds was 7.1 ± 5.4 hours. Standing behavior is critical because the onset of standing heat (estrus) is closely related to the time of ovulation. During the onset of estrus, estradiol (E_2) causes release of luteinizing hormone, initiating the process of ovulation. Using ultrasound examination to determine time of ovulation in relation to the onset of estrus based on electronic detection of estrus, the average interval from onset of estrus to ovulation was 27.6 ± 5.4 hours.[7]

Secondary signs of estrus include attempting to mount other cows, mucous discharge from the vulva, swelling and reddening of the vulva, bellowing, restlessness, trailing other cows, chin resting, sniffing the genitalia of the other cows, and lip curling. These signs may occur before, during, or after estrus and are not related to the time of ovulation. Such signs should be used as clues that cows are near estrus so that they can be watched more intensely for standing behavior. Figure 36-1 illustrates the relative changes in standing behavior and certain secondary signs before, during, and after estrus.

Estrus expression is maximized when the female has been previously exposed to progesterone (P_4), followed by a decrease in P_4 and an increase in E_2. The effect of E_2 for initiating behavioral signs of estrus appears to be "all-or-none." Once the threshold concentration of E_2 to induce estrus is achieved, additional E_2 does not further enhance the behavioral intensity of estrus. Furthermore, the inhibitory effect of high concentrations of P_4 on estrous behavior also is all-or-none.[8] Although E_2 and P_4 are considered the primary hormones involved in estrous behavior, the response of hypothalamic neurotransmitters to these steroids probably is the final signal controlling estrous behavior.

Estrus without subsequent ovulation and formation of a corpus luteum (CL) is estimated to occur in 60% of all peripubertal heifers. This is termed **nonpubertal estrus** and occurs early during the onset of puberty. By contrast, the condition of ovulation without estrus occurs toward the end of the postpartum anestrous period. This is termed **silent heat**, or silent ovulation, and generally occurs at the first postpartum ovulation in lactating cows. The incidence among dairy cows ranges from 50% to 94%.[8] The physiologic mechanisms responsible for this syndrome have not been resolved. One theory is that high concentration of estrogens present during late gestation and parturition induce a refractory state to the high concentrations of E_2 present at the first postpartum

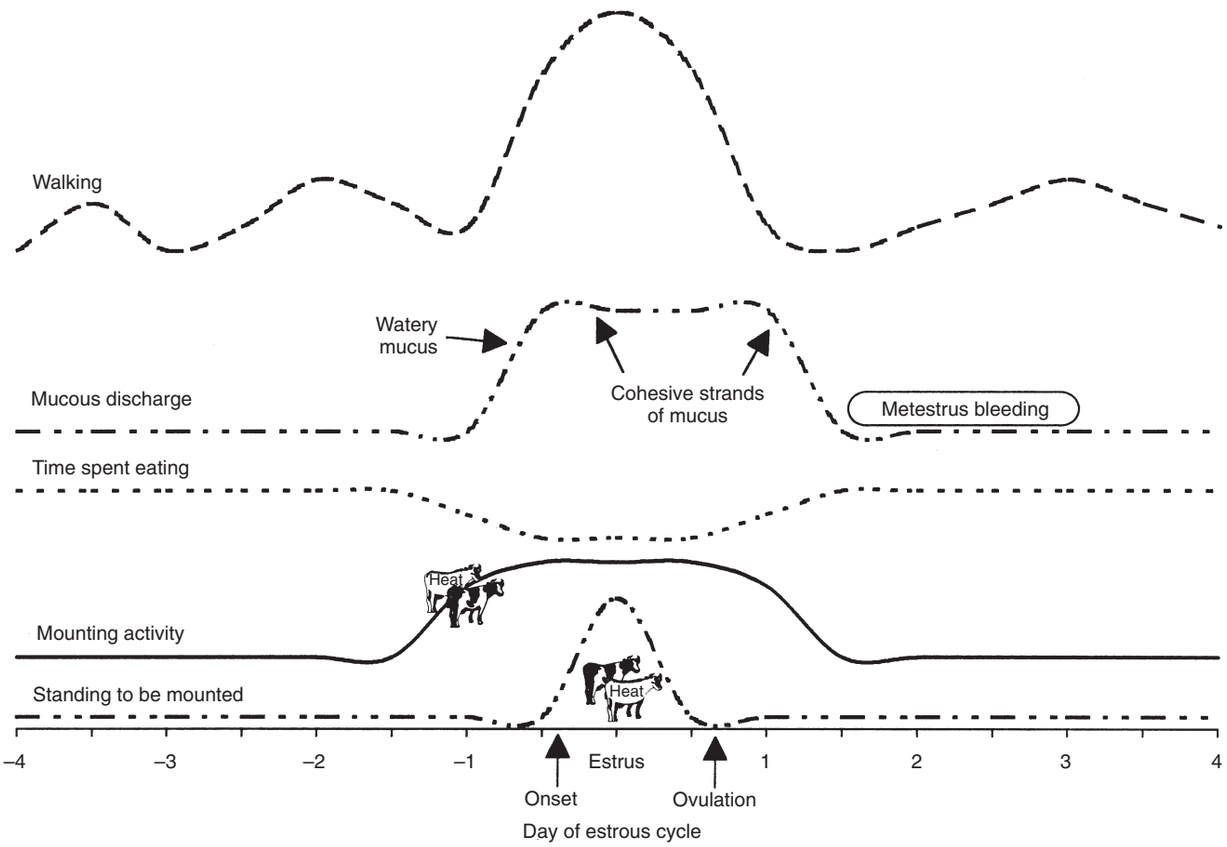

Fig. 36-1 Relative changes in standing behavior and secondary signs before, during, and after estrus.

ovulation. Consequently, estrus is not exhibited. P_4 released from the initial CL formed after the silent ovulation, however, overcomes the refractory state, allowing estrus to be expressed during the next ovulatory cycle.[8] A second possible explanation for the poor expression of estrus or silent ovulation is the low ratio of E_2 to P_4 concentrations. Vailes and co-workers showed that the estrogen-to-progesterone ratio caused a small but significant variation in mounting activity.[9] Behavioral traits that require active involvement of the cow (mounting and chin resting) do not appear to be suppressed by P_4 as much as receptive behaviors (mounts received, standing when mounted) are. Standing behavior, therefore, appears to be the behavior most sensitive to inhibition by P_4.[10]

Occasionally, pregnant cows exhibit signs of estrus. It is most frequently observed during middle to late gestation. Cows with ovarian follicular cysts have hormonal relationships similar to those in cows in estrus and may express estrus; however, most cows with ovarian cysts are anestrus. Some cows and most heifers have a bloody mucous discharge 1 to 3 days after estrus, but onset of such **metestrus bleeding** is quite variable. This discharge indicates that the cow was in estrus and does not mean that she failed to conceive.

EVALUATION OF ESTRUS DETECTION

It is important to periodically compare estrus detection efficiency with specific, realistic management goals. Complete and accurate records, including all dates of estrus, services, and pregnancy status information, are needed to calculate estrus detection efficiency. Most dairy record processing centers and herd management computer programs provide an estrus detection index. Other reproductive parameters, such as average days to first service and distribution of interestrual intervals, are useful in evaluating estrus detection. Most calculations of estrus detection efficiency or heat detection rate are based on the **voluntary waiting period** (VWP), which is the number of days after calving before which a dairy producer will not inseminate a cow, even if she is detected in heat.

Estrus detection efficiency is defined as the percentage of possible estrous periods that are observed during a specified period of time. Several methods have been developed to express the percentage of cows detected in estrus relative to the number of cows assumed or calculated to be in estrus. A review of this topic with equations and tables for determining the efficiency of estrus detection is available.[11] Computation of estrus detection efficiency and comparison among the various methods often are difficult because of differences in the time intervals used and in whether pregnant and open cows are included, and because of certain assumptions that may or may not be applicable. These assumptions include the following: (1) all cows are cycling by a certain day post partum; (2) reported estruses are in fact true estrous periods; (3) values used in the equations are accurate; and (4) the duration of all estrous cycles is 21 days, which is not the case with use of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$). The frequency of the use of $PGF_{2\alpha}$ and other synchronization programs to induce estrus and ovulation should be considered in evaluating any index of estrus detection efficiency.

Characteristics of Herds with Inefficient Estrus Detection

Using summary data from DHIA records or computer management programs or information from herd records such as days to first service and results from veterinary examinations, one can determine if the following characteristics of inefficient estrus detection exist.

- Very few estruses observed or recorded before first service
- Prolonged parturition to first service interval (which should be less than 21 days beyond the VWP)
- Excessive interval between services, especially when many intervals are multiples of a normal cycle (e.g., 42 days)
- Average interestrual interval greater than 35 days
- Greater than 25% of the cows routinely confirmed open at pregnancy examination 35 to 45 days after insemination
- Veterinary examinations confirming cows are cycling normally but estrous periods are not routinely detected
- Herd management computer programs or DHIA data routinely indicating heat detection rate less than 65%

Determining the Accuracy of Estrus Detection

Accuracy is defined as the percentage of estrous periods observed that are indeed true estrus. Frequently, management of herds with suboptimal reproductive performance is characterized by both inefficient and inaccurate estrus detection. Inaccuracies occur when cattle are inseminated at times other than true estrus. Examining the frequency distribution of interestrual intervals has been shown to be helpful in documenting estrus detection errors. Cows determined not to be in or near estrus at their first postpartum insemination on the basis of progesterone levels had abnormal intervals to the second service.[12] Twenty-nine percent and 20% of the intervals were between 11 and 14 days and 30 and 31 days after first service, respectively. Thus, cows incorrectly determined to be in estrus were in the midluteal phase when initially inseminated. Factors that contribute to errors in estrus detection include too much reliance on secondary signs instead of standing behavior to determine estrus status, unfamiliarity with correct signs of estrus by herd personnel, poor cow identification resulting in selection of cows to be inseminated that are not in estrus, and incorrect use or interpretation of estrus detection aids. The impact of all of these factors is magnified as herd size increases.

In addition to evaluating the distribution of interestrual intervals, milk progesterone testing can be a method of evaluating the accuracy of estrus detection. To document the variation in error rates of estrus detection

Table **36-1**

Error Rates for Estrus Detection in Cows Based on Milk Progesterone Concentration*

% of Cows within Herd with 1 ng/mL Progesterone Level at Insemination	No. of Herds within Each Category	Error Rate†
0	283	60.6%
<10	40	8.8%
10–19	102	21.8%
20	42	9.0%

*Data from Northeast dairy herds in which 5.1% of cows overall subsequently were found not to be in estrus.

among selected Northeast dairy herds, milk samples were collected on the day of insemination and analyzed for progesterone using radioimmunoassay. Cows with progesterone concentrations greater than 1 ng/mL at the time of insemination were considered not to be in or near estrus. The proportion of herds with various rates of estrus detection errors is presented in Table 36-1. Although overall only 5.1% of the cows were not in or near estrus when inseminated, the percentage of cows classified as not in estrus ranged from 0% to 60% among herds. Greater than 30% of the herds had error rates in excess of 10%.[12] Sturman and co-workers, using thrice-weekly milk progesterone analysis, determined that approximately 19% of inseminations were made when cows were in mid-cycle or in early pregnancy.[13]

FACTORS AFFECTING ESTROUS BEHAVIOR

Factors related to environment, nutrition, herdmates, and condition of feet and legs dramatically affect estrous behavior.

Type of Housing

Any housing arrangement that allows cattle to interact throughout the day provides more opportunity for expression of mounting and standing behavior. In fact, tie stalls and stanchion barn housing are not appropriate for optimizing estrus detection unless cows are released on a regular basis for observation of estrous behavior. If cattle are not allowed to interact, the herd manager must use secondary signs to guess which cows are in estrus.

Using milk progesterone analysis by radioimmunoassay to determine the percentage of cows that probably were not in estrus at the time of insemination, researchers found a slight but significant increase in detection errors in free-stall herds, compared with herds with conventional housing.[12] In addition, the proportion of cows determined to be in or near estrus when inseminated and conception rates were not related to herd size. Although opportunity to observe estrus is greater when cows interact frequently in free-stall barns or loose housing, taking time to observe estrous behavior is essential no matter what type of housing in used.

Footing Surface

The composition of the footing surface where cows interact significantly affects the intensity of estrous behavior. Research conducted in North Carolina compared estrous activity in high-producing Holstein cows that were observed for estrus during 30 minutes on dirt and 30 minutes on grooved concrete. A summary of mounting and standing behavior from this study is presented in Table 36-2. Behavioral expression of estrus lasted longer for cows observed on dirt. Mounting and standing behavior were nearly doubled when cows were observed for estrus on dirt compared with concrete.[14]

Icy or slick concrete is always a problem in free-stall herds and concrete exercise lots, alleyways, and entrances to conventional barns. Concrete should be grooved to provide better traction. Moving cattle to a dirt lot or from one area to another not only provides a better surface but also provides added stimulation of moving cattle. Moving cattle enhances behavioral symptoms of estrus.

Foot and Leg Problems

Cows with sore feet or legs or poor structural conformation are less likely to exhibit mounting activity, or they may stand to be mounted when not in estrus because it is too painful to avoid being mounted. This is confirmed by the results from a British study involving 770 cows with nearly 1500 lactations: Lameness caused by specific lesions on the hoof was associated with a 7-day increase in days to first service and 11 more days open compared with herdmates without lameness.[15] These differences were greater for cows with sole lesions that developed between 36 and 70 days post partum, the time when cows should first be detected in estrus. For those cows, the

interval to first service and days open increased by 17 days and 30 days, respectively. Data from a study involving 837 cows of which 30% were diagnosed as lame, most with claw lesions, showed that the number of services per conception was significantly higher in lame cows than in healthy (nonlame) cows. The median time to conception for lame cows with claw lesions was 140 days, compared with 100 days for healthy cows.[16]

In a subsequent study, the relationship between lameness and the onset of cycling during the first 60 days of lactation was evaluated.[17] Using the new modified six-point locomotion scoring system, cows in a large commercial dairy were examined weekly during the first 35 days of lactation for diagnosis of lameness. In addition, blood samples were obtained to determine the concentrations of progesterone, which indicate the onset of ovarian activity. Cows classified as lame (score 4) were 3.5 times more likely to have delayed ovarian activity than nonlame cows. Furthermore, ketosis was found to be a factor that delayed cyclicity. It was suggested that lameness and ketosis might interact to delay ovarian activity. Lameness depresses dry matter intake, causing negative energy balance and production of ketone bodies. If cows are in pain from lameness, they spend less time eating and ruminating and more time lying down. Consequently, dry matter intake will be reduced, which potentially may delay the onset of cycling during early lactation.[6]

Influence of Herdmates

Herd managers must rely on open cycling herdmates to detect cows in estrus. Cows in midcycle, however, do not participate in mounting activity as frequently as do cows in proestrus or estrus. In a controlled study, estrous cows encountered cycling herdmates one on one for 10 minutes.[18] Total number of mounts by each herdmate was determined on day 10, day 15, day of estrus, and day 5 of the next cycle. Herdmates in midcycle (days 10 and 15) and on day 5 had one mount or less during the 10-minute observation period. When the herdmate herself was in estrus, however, the number of mounts increased significantly. Thus, taken as a group, cows in the luteal phase are poor estrus detectors. Because this phase accounts for 50% to 60% of the estrous cycle, which reduces the number of effective estrus-detecting herdmates, managers must rely on cows in or near estrus to detect other estrous cows. Additional research revealed that approximately 86% of the mounting among dairy heifers was by heifers in proestrus and estrus.[19]

In small herds, most of the herd may be pregnant at certain times, and the stage of the cycle of the few nonpregnant cows may be such that they are not effective estrus detectors. As more animals become pregnant, the number of potential estrus-detecting animals is reduced. The situation is similar for herds that freshen on a seasonal basis. After an intensive breeding period, when a high percentage of the herd is pregnant, it becomes increasingly difficult to identify the few open cycling cows in estrus. There simply may not be enough herdmates in the proper stage of the cycle to interact with an estrous cow. A third situation may occur frequently in large herds in which cows are grouped according to production. Generally, the lower-production group contains a high percentage of pregnant cows, and some open cycling cows may be included in this group. It becomes very difficult to detect the open cows in estrus because their herdmates are pregnant.

Table **36-3**

Number of Cows in Simultaneous Estrus and Mounting Activity

No. of Cows in Estrus*	NO. OF MOUNTS PER COW	
	Mean	Range
1	11.2	1–30
2	36.6	1–179
3	52.6	1–173
4 or more	49.8	1–130

*Per herd.
Modified from Hurnick JF, King GJ, Robertson HA: Estrous and related behavior in postpartum Holstein cows. *Appl Anim Ethol* 1975;2:55.

Estrous activity also is influenced by the number of herdmates in proestrus and estrus simultaneously. Canadian scientists found that the number of mounts increased significantly when two or more cows were in estrus simultaneously[20] (Table 36-3).

Variation in Mounting during the Day

It would be useful to develop an estrus detection strategy based on time periods when cows are most likely to express estrus. Nebel reviewed research using radiotelemetric systems to document the onset of estrus and mounting activity throughout the day.[21] Data collected over five years from a Virginia Tech dairy herd showed no differences for the onset of estrus across hourly intervals for heifers or cows. Management practices, however, affected the onset of estrus. When heifers on pasture were assembled for concentrate feeding, a peak of mounting activity was observed. Distribution of the onset of estrus for cows increased when cattle were moved in groups for milking and when moved to dirt lots. Similarly, in New Zealand pastured herds in which radiotelemetric pressure-sensitive mount detectors were used to monitor estrus characteristics, no significant variation was found in the time to onset of estrus or total mounting activity when the data were grouped into 6-hour periods. A trend toward more mounting in the afternoon was observed.[5]

Environmental Temperature

In a study of effects of environmental temperature on estrous activity, as maximum daily temperatures increased from –15° C to approximately 25° C, mounting activity (mounts per hour) also increased. When temperatures peaked higher than 30° C, beyond the comfort range for cattle, mounting was less frequent.[22] During cold weather, cows exhibit more mounting activity than cows exposed to hot weather; however, during hot

weather, estrous cows tend to exhibit more secondary signs, such as rubbing, licking, and chin resting.[23] Thus, the estrus detection error rate may increase during hot weather. Reduced estrous behavior during heat stress may be due in part to the overall reduction in physical activity. It has been shown that heat stress reduced plasma concentrations of estradiol and delayed regression of the CL by 9 days in lactating cows.[24] It was suggested that heat stress prolonged luteal phases as a result of inadequate estradiol secretion. Such changes potentially may reduce expression of estrus. Heat abatement strategies should improve estrus detection rate and conception rate.

Nutrition and Level of Milk Production

Nutrition, specifically energy balance, has an impact on initiation of postpartum estrous cycles. The interval from parturition to ovulation is inversely related to average energy balance during the initial 20 days of lactation.[25] Mounting activity has been shown to be delayed in cows that lost more weight during the dry period or postpartum period than herdmates with minimal weight loss. For cows that have initiated estrous cycles, however, the evidence is less conclusive for an adverse effect of body condition loss on intensity and duration of estrous behavior. Few data are available concerning the effects of mineral and vitamin nutrition on estrous behavior.

Although reduced estrous expression was reported in higher-producing cows, the relationship between level of milk production and intensity of estrous behavior is unclear.[26] By contrast, estrus detection rates were highest for cows producing slightly above average and did not differ between cows in the highest and lowest milk production groups.[27]

METHODS TO ENHANCE EFFICIENCY OF ESTRUS DETECTION

Management Requirements

To achieve goals of accurate and efficient estrus detection, the management team should consider implementation of the following measures.

1. Improve cow identification. Studies have shown that as many as 25% of the cattle presented for insemination are not in estrus, and poor cow identification can be one cause of this problem in large herds. Legible neck chain numbers and large ear tags with bright contrasting colors can aid in accurate identification and reduce mistakes.

2. Promote and observe cow interaction. Isolate cows suspected to be in estrus with a sexually active cow or heat detector animal. Estrus may not be observed in a large group setting, but when isolated with an estrous female or detector animal, a cow possibly in estrus may be more likely to exhibit standing behavior. Introduction of a new or novel cow has been shown to increase estrus activity.[18] Watch for sexually active groups of cattle. Cows in proestrus or estrus tend to congregate together. Moving cattle to a separate area may stimulate estrous behavior.

3. Maximize nutrition and health. Adjust feeding programs so cows calve in proper body condition, weight loss is minimized during dry period and lactation, and dry matter intake is maximized. When cows have sore feet and legs, expression of estrous behavior is less likely, and feed intake is reduced, which may lead to severe negative energy balance with delayed onset of ovarian activity. Minimize these problems by trimming hoofs on a regular basis, and treat infected feet as soon as the problem is apparent. Proper use of a footbath is helpful.

4. Provide good footing surface. Slippery and muddy conditions severely inhibit mounting activity. Provide an area with a good footing surface where cattle are free to interact, with few obstacles to hinder movement.

5. Maintain and use accurate records. All estrous periods should be recorded, including those for animals that are not to be inseminated. Estrus detection will improve if future estrous periods are anticipated. Dairy management computer programs generate action lists indicating cows to watch closely for estrus or cows not observed in estrus since calving. Breeding wheels and estrous expectancy charts also are effective.

6. Establish employee responsibility. When several people are working with a herd, one person should be assigned the responsibility for estrus detection and allowed adequate time to do the job properly. All employees, however, should be trained to recognize signs of estrus, the importance of estrus detection, and to promptly report information relative to estrous behavior to the responsible person. Training sessions to review basics of estrus detection, identify problems, set goals, and assess progress in achieving goals should be conducted periodically with the entire management team in attendance.

7. Implement aggressive detection measures. Use time efficiently. Cattle should be observed at times and in an area where they are likely to mount. Even though loose housing systems provide more time for cow interaction, cattle must be observed frequently. Pastured cattle should be moved to an area where they can easily be observed. In stanchion and tie-stall housing systems, cattle should be released twice daily for 20 to 30 minutes for estrus detection. Turn cows out when time can be devoted to observing them. Avoid scheduling observation periods at feeding time or during the warmest hours during summer.

8. Develop estrous synchronization programs. Inducing estrus and ovulation using various synchronization programs increases the probability of identifying females in estrus because (1) the management team is more committed to detecting estrus; (2) estrus is anticipated on specific days and is more likely to be observed; and (3) as illustrated in Table 36-3, an increase in the number of animals in estrus simultaneously results in more mounts per estrous cow, thus increasing the likelihood of observing estrus.

Estrus Detection Aids

In addition to the use of accurate record systems and synchronization programs, as described previously, a variety of additional aids to estrus detection are available. Tradi-

tional aids include pressure-sensitive mount detectors, tailhead markings, and detector animals. Monitoring electrical resistance of reproductive tract tissue, pedometry, and electronic pressure-sensitive mount detectors are newer concepts.

Pressure-Sensitive Mount Detectors and Tailhead Markings

Mount detectors are applied with adhesive to the topline over the rump forward toward the hooks, according to the size of the animals. Sustained pressure for several seconds by the mounting animal will activate the device. Proper placement of the device is important. Marking the tailhead with livestock chalk, paint, or crayon and observing for evidence of rubbed-off or smeared markings constitute a less expensive approach than use of pressure-sensitive mount detectors that has gained popularity in larger herds. Research has confirmed that using these conventional systems without supporting visual observation for estrus results in lower pregnancy rates. Both methods can be useful for improving the efficiency of estrus detection during a synchronization program. This system works most effectively in loose-housing operations in which cattle can be restrained in self-locking headgates to be marked and observed for evidence of smeared or rubbed-off markings, which indicate that the animal was mounted. Research at Washington State University documented the effectiveness of an aggressive prostaglandin, tailhead marking, and timed-insemination program for dairy heifers.[28] Of the heifers inseminated as indicated by rubbed-off markings, only 2.5% had high P_4 levels. The conception rate was 62%. Thus, the error rate of this breeding program was low. Success depends on frequency of observation, proper placement of devices or markings, and the density and housing arrangement of the cattle.

Estrus-Detector Animals

Use of estrus-detector animals can improve estrus detection if this approach is conducted properly and is used to supplement visual observation. On an individual basis, however, vasectomized or surgically altered bulls and hormonally treated animals vary in their sexual aggressiveness. Such animals have the potential to increase the sexual activity in the herd. The more animals sexually active at one time, the more mounting will occur for each animal in estrus. Surgically altering the penis of a bull to prevent intromission may be more costly than vasectomy, but this method is preferred because vasectomized bulls can copulate and possibly spread disease. Such bulls can be used with beef cattle to stimulate early postpartum estrous activity, termed the **male effect**, and then remain with the herd for enhanced estrus detection during an artificial insemination program. Disadvantages include the hazards of keeping a bull, cost of vasectomy or surgical alteration, perception as an animal welfare issue, and general costs of maintaining a bull.

Testosterone causes increased sexual aggressiveness when injected or implanted into steers, cows, or heifers. Nonlactating cows or heifers, even freemartin heifers, are preferred candidates for this treatment and tend to be more docile than surgically altered or vasectomized bulls. Use of androgenized heifers, implanted with testosterone propionate and estradiol benzoate and equipped with chin-ball markers, for estrus detection during 30-minute periods increased the likelihood of detection of estrus.[29] By contrast, other investigators reported significant variability among androgenized heifers and relative ineffectiveness of this method for improving the efficiency of estrus detection.[30] Of note, however, none of the cows identified with use of androgenized heifers had high milk P_4 concentrations. The combined use of mount detection devices and androgenized heifers improved estrus detection over that achieved with each system used alone.

Electrical Resistance of Reproductive Tissue Fluids

Early research performed in Europe showed that electrical resistance (ER) of vaginal fluids decreased during proestrus and estrus. Other studies have validated this concept. Probes that measure ER of vaginal fluids are commercially available. The challenge is to adapt this technology to the herd management situation. ER measurements vary among cows; however, monitoring relative changes within cows during the estrous cycle can provide useful information. Once ER readings begin to decline, the cow should be probed frequently until the lowest reading is obtained. Theoretically, this lowest reading coincides with the time of estrus. In several studies summarized by Lehrer and co-workers, ER measurements have been useful to time insemination and improve conception rates, with detection efficiency ranging from 65% to 82% and accuracy between 57% and 82%.[31] This tool is expensive and labor intensive, because cattle must be probed frequently to detect significant changes in ER. The probe should be disinfected and dried each time it is used.

Miniature radiotelemetric sensors have been implanted experimentally within vulvar tissue to continuously monitor ER.[32] A strong relationship was found between concentrations of ovarian steroids and ER. These findings support this concept as a valid aid to estrus detection.

Pedometry

It has been well documented that cattle are more active during estrus and spend more time walking and standing than resting. Various pedometers have been developed. Earlier prototypes generally were unreliable because of a high rate of false positives and required frequent replacement. As pointed out by Lehrer and co-workers in a review of the technology, the efficiency of pedometry has been variable among studies and ranges from 60% to 100%, whereas the accuracy of detection of estrus ranged from 22% to 100%.[31]

Electronic pedometer systems have been installed in commercial herds. In a recent review, several concepts related to pedometry were noted.[33] Activity information usually is obtained by an interrogation unit in the milking parlor and transmitted to a herd management program for analysis. Devices are mounted on the neck or leg of the cow. Activity is measured by a mercury switch, which is activated by movement of the cow. The most common method for determination of the onset of estrus is attainment of a certain threshold of relative

activity compared with earlier measurements. Using a pedometer system that monitored steps per hour, Arney and co-workers showed a linear increase in activity during the 72 to 16 hours before estrus and a rapid increase between 16 hours and estrus. Following estrus, activity decreased exponentially.[34] Using pedometers attached to the inside of the cow's right hind leg, Maajtje and co-workers calculated the optimal time for insemination to be 11.8 hours after increased activity.[35] To be most effective in determining proper timing of insemination, pedometry systems should incorporate real-time data acquisition.[21]

Electronic Pressure-Sensitive Mount Detectors

A pressure-sensing radiotelemetric estrus detection system that monitors frequency and duration of mounting is commercially available to dairy and beef producers. This externally mounted device, which captures mounting information and transmits to a receiver interfaced with a computer, has been tested.[5,6,36,37] Results showed the accuracy of estrus detection for this system to be similar to that for visual observation for estrus, with rates of 96% and 94%, respectively. The efficiency of detection increased from 51% for visual observation to 91% with this system, however.[36] On the basis of timing of ovulation as determined by ultrasonography, the computer information should be accessed at least twice daily so inseminations can be properly timed. As noted in a review of this technology, duration of estrus varied among cows in the same herd and among studies using this technology.[21]

An alternative approach that has been tested but not commercially available involves a pressure-sensitive electronic device implanted subcutaneously in the cow's midsacral region that monitors duration and frequency of mounts received.[4] In addition to monitoring mounting, this device also has the capability to respond to skin movement across the midsacral region of the topline as the cow walks.[38] Combining the pedometry component with the mount monitor would make this device a very effective detection aid.

As shown in previous studies, the use of several detection aids or monitoring two or more aspects of estrous behavior is superior to a single method for improving the efficiency of estrus detection. The cost, durability, accuracy, functional life, maintenance requirements, access to and interpretation of data, length of time these devices remain attached to the animal, and labor commitment are factors that must be considered in evaluating any new estrus detection technology. As noted in a review of estrus detection technology,[4] unbiased field-based research data are necessary to document the effectiveness of such technology.

CHAPTER 37

Progestogen-Based Estrus Synchronization for Beef Replacement Heifers and Cows

DAVID J. PATTERSON and MICHAEL F. SMITH

The beef cattle industry has seen rapid gains in economically desirable traits, largely as a result of the selection and expanded use of genetically superior sires made available through artificial insemination (AI). Recent surveys indicate, however, that less than 5% of the beef cows in the United States are bred by AI, and only half of the cattle producers who practice AI use any form of estrus synchronization to facilitate their AI programs. The inability to predict time of estrus for individual cows or heifers in a group often makes it impractical to use AI because of the labor required for detection of estrus. Available procedures to control the estrous cycle of the cow can improve reproductive rates and facilitate genetic progress. These procedures include synchronization of estrus in cycling females and induction of estrus accompanied by ovulation in heifers that have not yet reached puberty or among cows that have not returned to estrus after calving.

The following protocols and terms are referred to throughout this chapter.

Protocols

$PGF_{2\alpha}$: Prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$): (Lutalyse, Estrumate, ProstaMate, InSynch).

MGA-$PGF_{2\alpha}$: Melengestrol acetate (MGA) (0.5 mg/day per animal) is fed for a period of 14 days, with

CHAPTER 37

Progestogen-Based Estrus Synchronization for Beef Replacement Heifers and Cows

DAVID J. PATTERSON and MICHAEL F. SMITH

The beef cattle industry has seen rapid gains in economically desirable traits, largely as a result of the selection and expanded use of genetically superior sires made available through artificial insemination (AI). Recent surveys indicate, however, that less than 5% of the beef cows in the United States are bred by AI, and only half of the cattle producers who practice AI use any form of estrus synchronization to facilitate their AI programs. The inability to predict time of estrus for individual cows or heifers in a group often makes it impractical to use AI because of the labor required for detection of estrus. Available procedures to control the estrous cycle of the cow can improve reproductive rates and facilitate genetic progress. These procedures include synchronization of estrus in cycling females and induction of estrus accompanied by ovulation in heifers that have not yet reached puberty or among cows that have not returned to estrus after calving.

The following protocols and terms are referred to throughout this chapter.

Protocols

$PGF_{2\alpha}$: Prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$): (Lutalyse, Estrumate, ProstaMate, InSynch).

MGA-$PGF_{2\alpha}$: Melengestrol acetate (MGA) (0.5 mg/day per animal) is fed for a period of 14 days, with

$PGF_{2\alpha}$ administered 17 to 19 days after MGA withdrawal.

GnRH-$PGF_{2\alpha}$ (Select Synch): Gonadotropin-releasing hormone (GnRH) injection (Cystorelin, Factrel, Fertagyl), followed in 7 days with an injection of $PGF_{2\alpha}$.

MGA-GnRH-$PGF_{2\alpha}$ (MGA Select): MGA is fed for 14 days, GnRH is administered 10 or 12 days after MGA withdrawal, and $PGF_{2\alpha}$ is administered 7 days after GnRH.

7-11 Synch: MGA is fed for 7 days, $PGF_{2\alpha}$ is administered on the last day MGA is fed, GnRH is administered 4 days after the cessation of MGA, and a second injection of $PGF_{2\alpha}$ is administered 11 days after MGA withdrawal.

Terms

Estrus response: The number of females that exhibit estrous behavior during a synchronized period.

Synchronized period: The period of time during which estrous behavior is expressed after treatment.

Synchronized conception rate: The proportion of females that become pregnant of those exhibiting estrus and inseminated during the synchronized period.

Synchronized pregnancy rate: The proportion of females that become pregnant from inseminations during the synchronization period of the total number treated.

A successful estrus synchronization program brings a number of well-recognized advantages to the beef cattle operation: (1) Cows or heifers are in estrus during a predictable interval, which allows for the use of AI, embryo transfer, or other planned reproductive techniques; (2) the time required to detect estrus is reduced, which in turn decreases labor expense associated with the breeding program; (3) cattle will conceive earlier during the breeding period; and (4) calves will be older and weigh more at weaning.

To maximize the benefits from estrus synchronization, females should be selected for a program when the following conditions are met[1]:

- Adequate time has elapsed between calving and the time synchronization treatments are implemented (a minimum of 40 days post partum at the beginning of treatment is suggested).
- Cows are in average or above-average body condition (scores of at least 5 on a scale of 1 to 9 on which 1 = emaciated and 9 = obese).
- Cows experience minimal calving problems.
- Replacement heifers are developed to prebreeding target weights of at least 65% of projected mature weight.
- Reproductive tract scores (RTSs) are assigned to heifers no more than 2 weeks before initiation of treatment (scores of 3 or higher on a scale of 1 to 5), and at least 50% of the heifers are assigned an RTS of 4 or 5.

DEVELOPMENT OF METHODS TO SYNCHRONIZE ESTRUS

The development of methods to control the estrous cycle of the cow has occurred in five distinct phases. The physiologic basis for estrus synchronization followed the discovery that progesterone inhibited preovulatory follicular maturation and ovulation. Regulation of estrous cycles was believed to be associated with control of the corpus luteum, whose lifespan and secretory activity are regulated by trophic and lytic mechanisms. **Phase I** included efforts to prolong the luteal phase of the estrous cycle or to establish an artificial luteal phase by administering exogenous progesterone. Later, progestational agents were combined with estrogens or gonadotropins in **phase II**, whereas **phase III** involved $PGF_{2\alpha}$ and its analogues as luteolytic agents. Treatments that combined progestational agents with $PGF_{2\alpha}$ characterized **phase IV.**

Precise monitoring of ovarian follicles and corpora lutea over time by transrectal ultrasonography expanded our understanding of the bovine estrous cycle and particularly the change that occurs during a follicular wave. Growth of follicles in cattle occurs in distinct wavelike patterns, with new follicular waves occurring approximately every 10 days (6- to 15-day range). We now know **(phase V)** that precise control of estrus and ovulation requires the manipulation of both follicular waves and luteal lifespan.

A single injection of GnRH to cows at random stages of their estrous cycles causes release of luteinizing hormone leading to synchronized ovulation or luteinization of most large dominant follicles. Consequently, a new follicular wave is initiated in all cows within 2 to 3 days after GnRH administration. Luteal tissue that forms after GnRH administration is capable of undergoing $PGF_{2\alpha}$-induced luteolysis 6 or 7 days later.[2] This method is referred to as the GnRH-$PGF_{2\alpha}$ protocol throughout this chapter. The GnRH-$PGF_{2\alpha}$ protocol increased estrus synchronization rate in both beef[3,4] and dairy[5] cattle. A drawback of this method is that approximately 5% to 15% of the cows are detected in estrus on or before the day of $PGF_{2\alpha}$ injection, so that a smaller proportion of females are detected in estrus and inseminated during the synchronized period.[6]

THE MELENGESTROL ACETATE PROGRAM

This section reviews recently developed methods using MGA to control estrous cycles of cows or heifers in breeding programs involving natural service or artificial insemination. Four methods are outlined for using MGA (MGA Premix, Pfizer Animal Health, New York, NY) to facilitate estrus synchronization in heifers or cows. The choice of which system to use depends largely on a producer's goals. MGA is the common denominator in each of the systems described. MGA is an orally active progestogen that will suppress estrus and prevent ovulation when consumed by cows or heifers on a daily basis.

MGA may be fed with a grain or a protein carrier and either top-dressed onto other feed or batch-mixed with larger quantities of feed. MGA is fed at a rate of 0.5 mg/animal/day in one feeding. The duration of

feeding may vary between protocols, but the level of feeding is consistent and critical to success. Animals that fail to consume the required amount of MGA on a daily basis may prematurely return to estrus during the feeding period. This can be expected to reduce the synchronization response. Therefore, adequate bunk space must be available so that all animals consume feed simultaneously.

Animals should be observed for behavioral signs of estrus each day of the feeding period. This may be done as animals approach the feeding area and before feed distribution. This practice will ensure that all females receive adequate intake. Cows and heifers will exhibit estrus beginning 48 hours after MGA withdrawal, and this behavior will continue for 6 to 7 days. It generally is recommended that females exhibiting estrus during this period not be inseminated or exposed to natural service because of the reduced fertility among such animals at the first heat after MGA withdrawal.

Method 1: MGA with Natural Service

The simplest MGA-based method of estrus synchronization involves using bulls to breed synchronized groups of females. This practice is especially useful in helping producers make a transition from natural service to AI. In this process, cows or heifers receive the normal 14-day feeding period of MGA and are then exposed to fertile bulls about 10 days after MGA withdrawal (Fig. 37-1).

This system works effectively; however, careful attention to bull-to-female ratios is indicated. A ratio of 15 to 20 synchronized females per bull is recommended. Age and breeding condition of the bull and results of breeding soundness examinations should be considered carefully.

Method 2: MGA plus Prostaglandin

A more precise means of estrous cycle control involves the combination of MGA with $PGF_{2\alpha}$. $PGF_{2\alpha}$ is a luteolytic compound normally secreted by the uterus of the cow. $PGF_{2\alpha}$ can induce luteal regression but cannot inhibit ovulation. When $PGF_{2\alpha}$ is administered in the presence of a functional corpus luteum (CL) during days 6 to 16 of the estrous cycle, premature regression of the CL begins and the cow returns to estrus.

In this program, $PGF_{2\alpha}$ should be administered 19 days after the last day of MGA feeding. This treatment places all animals in the late luteal stage of the estrous cycle at the time of injection, which shortens the synchronized period and maximizes conception rate (Fig. 37-2). Although a 19-day interval is optimal, 17- to 19-day intervals produce acceptable results and provide flexibility for extenuating circumstances.[7,8] Any of the four available $PGF_{2\alpha}$ products can be used for synchronization of estrus in cattle after the MGA treatment. Label-approved dosages differ with each of these products; the practitioner should carefully read and follow directions for proper administration before their use.

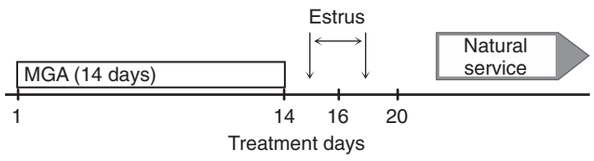

Fig. 37-1 Melengestrol acetate (MGA) and natural service. (Adapted from Patterson et al.[9])

Figure 37-3 illustrates the distribution of estrus comparing the MGA-$PGF_{2\alpha}$ system and an MGA-only system.[9] The combined MGA-$PGF_{2\alpha}$ system is best suited for use with AI programs because of the high degree of synchrony that can be achieved, which decreases the amount of time required for detection of estrus. Under natural mating conditions, distributing estrus over several additional days may be advantageous, to prevent overworking of bulls used in these programs.

Table 37-1 provides a summary of field trials involving heifers in which MGA was used in conjunction with natural service or MGA-$PGF_{2\alpha}$ was used before AI.[9] One of the major advantages in using MGA to control estrous cycles of cattle, as seen from the data presented in the table, is the flexibility in matching specific synchronization protocols with the particular management system involved.

Method 3: MGA Select

The MGA Select program[10] (Fig. 37-4) is useful in maximizing estrus response and reproductive performance in postpartum beef cows. The MGA Select protocol is a simple program that involves feeding MGA for 14 days, followed by an injection of GnRH on day 26 and an injection of $PGF_{2\alpha}$ on day 33. The addition of GnRH to the 14- to 19-day MGA-$PGF_{2\alpha}$ protocol improves synchrony of estrus while maintaining high fertility in postpartum beef cows.

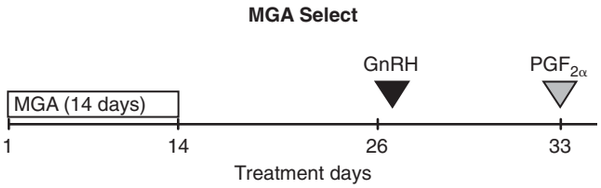

Fig. 37-4 The MGA Select protocol. Melengestrol acetate (MGA) is fed for a period of 14 days, followed in 12 days (day 26) by an injection of gonadotropin-releasing hormone (GnRH) and then prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) 19 days after MGA withdrawal (day 33).

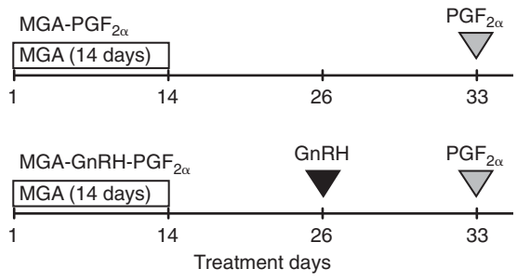

Fig. 37-5 Cows were fed melengestrol acetate (MGA) for 14 days; 19 days after MGA withdrawal, prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) was administered to all cows. Gonadotropin-releasing hormone (GnRH) was administered to one half of the cows 7 days before $PGF_{2\alpha}$. (Data from Patterson DJ et al.[11])

We conducted experiments during the spring 2000 and 2001 breeding seasons to compare the 14- to 19-day MGA-$PGF_{2\alpha}$ protocol with or without the addition of GnRH on day 12 after MGA withdrawal and 7 days before $PGF_{2\alpha}$ in postpartum-suckled beef cows[11] (Fig. 37-5). These experiments were conducted at the University of Missouri's Thompson Farm at Spickard, Missouri.

The results from the study conducted during the 2001 breeding season are summarized in several tables. Table 37-2 presents the number of cows within age group by treatment, the average number of days post partum and body condition score on the first day of MGA feeding, and the percentage of cows that were cycling before the treatment with MGA began. Cyclicity status was based on progesterone levels in two blood samples obtained 10 days before and on the first day of MGA feeding.

Table 37-3 provides a summary of estrus response, synchronized conception and pregnancy, and final pregnancy rates for cows assigned to the two treatments. Estrus response was significantly higher among MGA Select–treated cows than among the MGA-$PGF_{2\alpha}$–treated cows. Synchronized pregnancy rates were higher among cows 5 years of age and older assigned to MGA Select treatment.

Table **37-3**

MGA Protocols and Estrus, Conception, and Pregnancy Rates

Treatment	Age Group (yr)	Estrus Response Rate	Synchronized Conception Rate	Synchronized Pregnancy Rate	Final Pregnancy Rate

Control	23/45 (51%)	30/67 (45%)[b]	53/112 (47%)[b]
End of breeding season (final rates)			
MGA-treated	38/45 (84%)	64/70 (91%)	102/115 (89%)
Control	38/45 (84%)	59/67 (88%)	97/112 (87%)

[a,b]Percentages within column and category with unlike superscripts are different ($P < 0.05$).
Data from Perry GA, Bader JF, Smith MF, Patterson DJ: Evaluation of a fixed-time artificial insemination protocol for beef cows. *J Anim Sci* 2001;79:462 Suppl 1.

The objective of a second experiment during the spring 2000 breeding season was to determine if MGA pretreatment could improve conception rates with a GnRH-$PGF_{2\alpha}$-GnRH protocol.[12] Cows from two University of Missouri herds—Greenley Farm ($N = 90$) (herd 1) and South Farm ($N = 137$–) (herd 2) were assigned by age and days post partum to one of two treatments. Control and MGA-treated (Fig. 37-6) cows were fed a supplement carrier with or without MGA for 14 days. GnRH was administered to all cows 12 days after MGA or carrier withdrawal and 7 days before $PGF_{2\alpha}$. All animals were administered GnRH and artificially inseminated 72 hours after $PGF_{2\alpha}$.

Pregnancy rates to fixed-time AI were determined 50 days after insemination (Table 37-4). No difference was observed between treatments in herd 1 (MGA = 58% [26/45]; control = 51% [23/45]). A difference ($P < 0.03$) in pregnancy rate to fixed-time AI between treatments, however, was found for herd 2 (MGA = 63% [44/70]; control = 45% [30/67]). Furthermore, when the data from

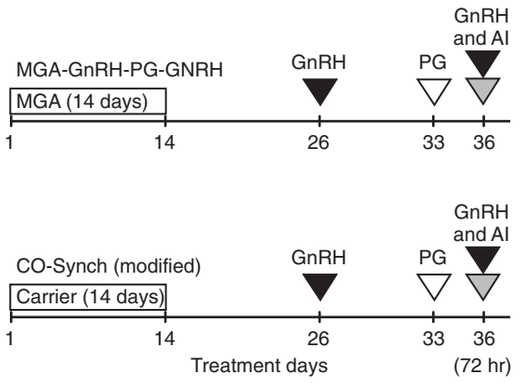

Fig. 37-6 Control and MGA-treated cows were fed a supplement carrier with or without MGA for 14 days. GnRH was administered to all cows 12 days after MGA or carrier withdrawal and 7 days before $PGF_{2\alpha}$.

both locations were combined, the overall difference remained significant (MGA = 70/115 [61%]; control = 53/112 [47%]; $P < 0.05$). These findings indicate that pregnancy rates resulting from fixed-time insemination are improved significantly when treatment with MGA precedes the GnRH-$PGF_{2\alpha}$-GnRH protocol.

Method 4: 7-11 Synch

Recently we developed an estrus synchronization protocol for beef cattle that was designed to (1) shorten the feeding period of MGA without compromising fertility and (2) improve synchrony of estrus by synchronizing development and ovulation of follicles from the first wave of development[6] (Fig. 37-7A). This new treatment, 7-11 Synch, was compared with the GnRH-$PGF_{2\alpha}$ protocol. Synchrony of estrus during the 24-hour peak response period (42 to 66 hours) was significantly higher among 7-11 Synch–treated cows. Furthermore, the distribution of estrus was reduced from 144 hours for GnRH-$PGF_{2\alpha}$–treated cows to 60 hours for cows assigned to the 7-11 Synch treatment[6] (Fig. 37-7B) The 7-11 Synch protocol resulted in a higher degree of estrus synchrony (91%) and greater AI pregnancy rate (68%) during a 24-hour peak response period compared with the GnRH-$PGF_{2\alpha}$ protocol (69% and 47%, respectively).

Additional Considerations

An additional consideration for methods 2, 3, and 4 pertains to cows or heifers that fail to exhibit estrus after the last $PGF_{2\alpha}$ injection. Such cows or heifers can be reinjected with $PGF_{2\alpha}$ 11 to 14 days after the last injection of $PGF_{2\alpha}$ was administered. These females then are observed for signs of behavioral estrus for an additional 6 to 7 days. This procedure maximizes the number of females inseminated within the first 2 weeks of the breeding period. Cows that were inseminated during the first synchronized period should not be reinjected with $PGF_{2\alpha}$. In addition, the decision to use method 3 or 4 in heifers should be based on careful consideration of the heifer's age, weight, and pubertal status.

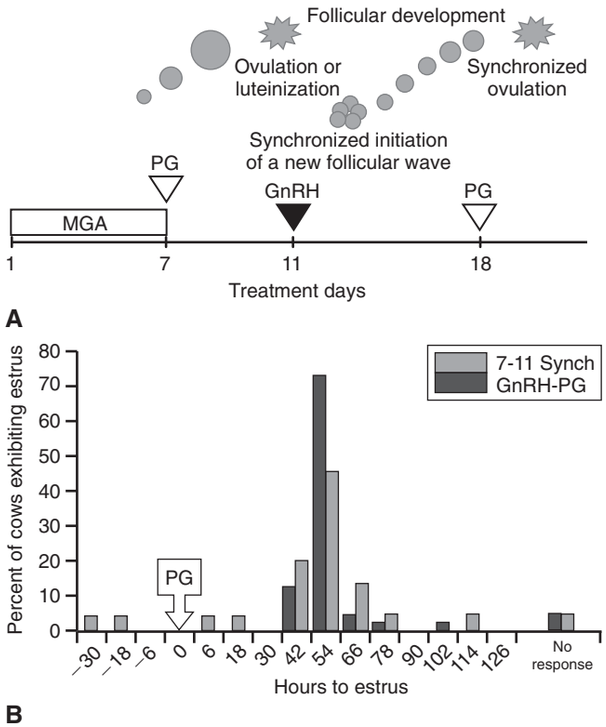

Fig. 37-7 **A,** Treatment schedule and events associated with the 7-11 Synch protocol. **B,** Estrus response of cows treated with the 7-11 Synch or GnRH-$PGF_{2\alpha}$ protocols. (Data from Kojima et al.[6])

INTRAVAGINAL PROGESTERONE-RELEASING INSERT

The presence of anestrous beef heifers and cows at the start of the breeding season is a major limitation to the success of a $PGF_{2\alpha}$-based estrus synchronization program. Administration of a progestogen improves estrus synchronization results through the induction of estrus and ovulation, as well as by providing time for corpora lutea to become responsive to the luteolytic action of $PGF_{2\alpha}$ (>5 days after estrus; day 0 = estrus). A controlled internal drug release device (CIDR) (EAZI-BREED, Pfizer Animal Health, New York, NY) has been developed for the intravaginal release of progesterone and has been proved to be effective for inducing and synchronizing estrus in heifers and cows.[13] CIDRs are marketed in more than 30 countries, including the United States.

Two types of CIDR inserts have been used worldwide: CIDR 1380, which contains 1.38 g of progesterone, and CIDR B, which contains 1.9 g of progesterone. In the absence of a corpus luteum, a CIDR functions as an artificial corpus luteum and suppresses estrus and ovulation for 7 days or longer. CIDR inserts consist of a T-shaped nylon backbone that is coated with a silicone layer containing 10% progesterone by weight. The CIDR inserts are placed into the vagina with a lubricated applicator, after disinfection of the vulva. The device has a flexible polyester tail that protrudes from the vulva and is easily removed by pulling the polyester tail. Although mild vaginitis is common with use of CIDR inserts, fertility is not compromised. The retention rate for CIDR inserts is approximately 95%. If the retention rate is considerably less than 95%, the devices may have been inserted incorrectly, or other animals may be pulling out the CIDR insert by biting on the polyester tails. In the latter case, the problem can be remedied by trimming the polyester tails. The CIDR treatment that has been approved in the United States includes insertion of a CIDR device on day 0, injection of $PGF_{2\alpha}$ on day 6, and CIDR insert removal on day 7 (Fig. 37-8, *A*). Cows and heifers typically are observed in estrus 24 to 72 hours after CIDR insert removal, and they commonly are inseminated after detection of estrus.

The efficacy of the CIDR treatment (CIDR plus $PGF_{2\alpha}$) in beef heifers and cows was evaluated in a multistate trial in Florida, Illinois, Missouri, Montana, and Nebraska).[13] This trial consisted of the following treatments: control (no treatment), $PGF_{2\alpha}$ (single injection), and CIDR plus $PGF_{2\alpha}$ (1.38 g CIDR for 7 days with $PGF_{2\alpha}$ on day 6). The proportion of heifers and cows that were detected in estrus and pregnant during the first three days of the

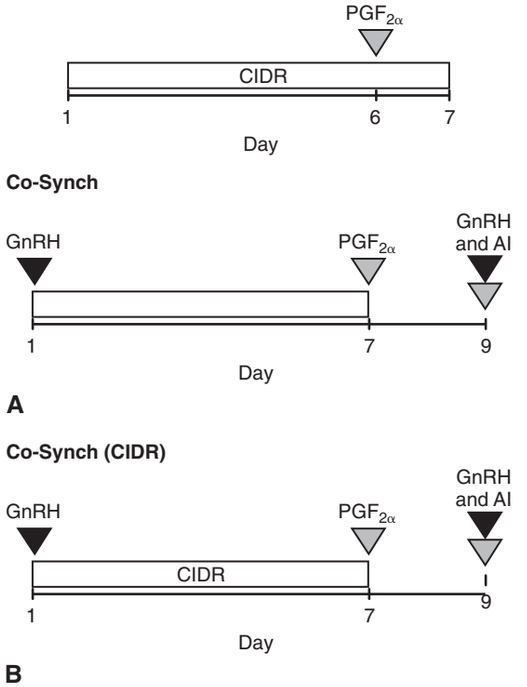

Fig. 37-8 Protocols for synchronization of estrus in beef heifers (**A**) and postpartum beef cows (**A** and **B**). "Day" refers to day of treatment. *Protocols:* CIDR = controlled internal drug release device (an intravaginal progesterone-releasing device); $PGF_{2\alpha}$ = a single injection of prostaglandin $F_{2\alpha}$ on day 6 or 7 to induce regression of luteal tissue; GnRH = a single injection of gonadotropin-releasing hormone to induce ovulation and formation of luteal tissue; AI = artificial insemination on day 9 of treatment for the CO-Synch protocol (**B**) or approximately 12 hours after detection of estrus in the other protocol (**A**).

breeding season was increased for the CIDR plus $PGF_{2\alpha}$ treatment, compared with the $PGF_{2\alpha}$ and control groups. The CIDR plus $PGF_{2\alpha}$ treatment was effective in both acyclic and cyclic cattle at multiple locations.

Expanded use of AI for beef heifers and cows probably will require the ability to inseminate cows at a fixed time, resulting in pregnancy rates that exceed 50%. Efforts to develop a more effective timed insemination protocol in beef cows have recently focused on synchronizing follicular waves by injecting GnRH, followed 7 days later with an injection of $PGF_{2\alpha}$ and then a second GnRH injection plus insemination 48 hours after the $PGF_{2\alpha}$ injection (CO-Synch protocol; see Fig. 37-8, *B*). This protocol permits the synchronization of ovulation in cows but at present has not proved to be as effective in heifers. In cows that have a dominant (≥10 mm) follicle at random stages of their estrous cycle, an injection of GnRH will induce ovulation and subsequent formation of luteal tissue. A new follicular wave is initiated in heifers or cows within 2 to 3 days of GnRH-induced ovulation of a dominant follicle, synchronizing the development of a new dominant follicle. Luteal tissue that forms after GnRH administration is capable of undergoing $PGF_{2\alpha}$-induced regression 6 or 7 days following the first GnRH injection. A limitation to GnRH-$PGF_{2\alpha}$ protocols (including CO-Synch) is that approximately 5% to 15% of the cows are detected in estrus on or before the day of $PGF_{2\alpha}$ injection, so a smaller proportion of females will conceive to the timed insemination 48 hours later. To address this problem, a multistate study was conducted in which a CIDR was inserted at the time of the first GnRH injection and removed at the time of $PGF_{2\alpha}$ injection[14] (see Fig. 37-8, *B*). The rationale for CIDR treatment was to prevent cows from showing estrus before the $PGF_{2\alpha}$ injection and to provide progesterone exposure to anestrous animals in which the first GnRH injection did not induce luteal tissue formation. The study consisted of 560 suckled beef cows, and the proportion of cycling cows before treatment ranged from 72% to 83%. The pregnancy rates after timed insemination with the CO-Synch protocol were greater for the CIDR-treated cows (58%) than for the control cows (48%).

SUMMARY AND CONCLUSIONS

Expanded use of AI and/or adoption of emerging reproductive technologies for beef cows and heifers requires precise methods of estrous cycle control. Effective control of the estrous cycle requires the synchronization of both luteal and follicular functions. Efforts to develop a more effective estrus synchronization protocol have focused recently on synchronizing follicular waves by injecting GnRH followed 7 days later by injection of $PGF_{2\alpha}$ (Ovsynch, CO-Synch, Select Synch). A factor contributing to reduced synchronized pregnancy rates in dairy and beef cows managed with the preceding protocols is that 5% to 15% of cycling cows show estrus on or before $PGF_{2\alpha}$ injection. We developed new protocols for inducing and synchronizing a fertile estrus in postpartum beef cows and beef heifers in which the GnRH-$PGF_{2\alpha}$ protocol is preceded by either short- or long-term progestogen treatment.

Although other types of progestogen treatments (CIDR, PRID, and norgestomet) can be substituted in these estrus synchronization protocols, we chose to use MGA for the following reasons:

- MGA is economical to use (approximately 2 cents per animal per day).
- MGA has been cleared for use in reproductive classes of beef and dairy cattle.[15]
- Methodology and understanding of the use of MGA are documented in the literature,[16–18] dating back as early as the 1960s.
- MGA is easily administered in feed and does not require that animals be handled or restrained during administration.

Perhaps more important, at the time these programs were developed, MGA was the only progestogen approved for use and available in the United States, making research of methods to improve and broaden the scope of its application all the more significant.

Table 37-5 provides a summary of results with various estrus synchronization protocols for use in postpartum beef cows. Included are data from our own published work, in addition to unpublished data from DeJarnette and Wallace. These results provide evidence to support

Table **37-5**

Estrus Response and Fertility in Postpartum Beef Cows with Various Estrus Synchronization Protocols

Protocol	Estrus Response Rate	Synchronized Pregnancy Rate
Two-shot $PGF_{2\alpha}$	241/422 (57%)	147/422 (35%)
Select Synch	353/528 (67%)	237/528 (45%)
MGA-$PGF_{2\alpha}$ for 14–17 d	305/408 (75%)	220/408 (54%)
MGA–two shot $PGF_{2\alpha}$	327/348 (93%)	243/348 (70%)
MGA-$PGF_{2\alpha}$ for 14–19 d	161/206 (83%)	130/206 (63%)
MGA Select	174/204 (85%)	134/204 (66%)
MGA Select + GnRH at AI 7-11 Synch	Fixed-time AI 40/44 (91%)	70/115 (61%) 30/44 (68%)

AI, artificial insemination; GnRH, gonadotropin-releasing hormone; MGA, melengestrol acetate; $PGF_{2\alpha}$, prostaglandin $F_{2\alpha}$.

our recommended sequential approach to estrus synchronization in postpartum beef cows.

Our preliminary studies identified significant improvements in specific reproductive endpoints among cows that received MGA before the administration of $PGF_{2\alpha}$, compared with cows that received $PGF_{2\alpha}$ only, including increased estrus response and improved synchronized conception and pregnancy rates. More recently we observed a significant improvement in synchrony of estrus without compromising fertility in postpartum beef cows and beef heifers that were pretreated, either short or long term, with MGA before GnRH and $PGF_{2\alpha}$ administration. We propose the general hypothesis that progestogen (MGA) treatment before the GnRH-$PGF_{2\alpha}$ estrus synchronization protocol will (1) successfully induce ovulation in anestrous postpartum beef cows and peripubertal beef heifers; (2) reduce the incidence of a short luteal phase among anestrous cows induced to ovulate; (3) increase estrus response, synchronized conception, and pregnancy rate; and (4) increase the likelihood of successful fixed-time insemination. The cumulative data suggest that new methods of inducing and synchronizing estrus for postpartum beef cows and replacement beef heifers in which a progestogen is included in the GnRH-$PGF_{2\alpha}$ protocol offer significantly greater potential to more effectively synchronize estrus, with resulting high fertility.

CHAPTER 38

Ovulation Synchronization Strategies in Dairy Cattle Using $PGF_{2\alpha}$ and GnRH

JAMES RICHARD PURSLEY and NORA M. BELLO

Synchronization of ovulation using timed injections of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) and gonadotropin-releasing hormone (GnRH)—the Ovsynch program of ovulation management—improves pregnancy rates and reduces days open in lactating dairy cows[1,2] (Fig. 38-1). Inadequate pregnancy rates are one of the primary obstacles to dairy farm profitability and sustainability.[3] During the past 50 years, pregnancy rates of lactating dairy cows progressively decreased, primarily because of low and steadily declining conception rates (CRs) and estrus detection rates (EDRs).[4,5] CR in cows decreased from approximately 70%[6,7] to 35%,[8,9] although CR in heifers remained steady at approximately 70%.[2,7] Current reports indicate that EDR is approximately 32% in lactating cows[4] and 70% in heifers. Poor EDR in cows may be attributed to changes in hormonal concentrations between the two groups,[10,11] as well as differences in environment—lactating dairy cows spend more time on surfaces with poor footing[12,13] and are more susceptible to heat stress.[14] Currently, the effectiveness of Ovsynch in lactating dairy cows is attributable primarily to an increase in EDR, or artificial insemination (AI) service rate, because all cows, regardless of cycling status or stage of estrous cycle, can be inseminated by appointment[1,2] without the need for detection of estrus. Thus, Ovsynch can be effectively used to control time to first and subsequent inseminations by AI, thereby maximizing service rate and improving overall EDR.[1]

Ovsynch is the basis for most timed-AI programs in dairy cows in the United States. Ovsynch was developed in the early 1990s at the University of Wisconsin–Madison by Pursley and Wiltbank.[15] The objectives of the original Ovsynch research were to (1) hormonally control the onset of a new follicular wave, (2) control the lifespan of the spontaneous and induced CL, and (3) control the time of ovulation of the dominant follicle (DF).

Three hormonal injections were needed to accomplish these three objectives (see Fig. 38-1). The first GnRH injection caused ovulation, or luteinization, if a functional DF was present in the ovary. Subsequently, if ovulation occurred, a new follicular wave emerged approximately 1.5 to 2 days later.[15] GnRH did not cause ovulation if the stage of follicle development was in the first 3 days of a spontaneous follicular wave. The newly induced wave, or a spontaneous wave if ovulation did not occur, was allowed to develop, with selection and dominance of a DF during the following 7 days. At that time, $PGF_{2\alpha}$ was administered to induce luteolysis, thus allowing for further growth and maturation of the DF. Then, 48 hours later, a second GnRH injection induced a preovulatory luteinizing hormone (LH) surge that triggered ovulation approximately 28 hours after treatment with GnRH. Cows treated with Ovsynch demonstrated overall CRs similar to those obtained in cows that had been bred to detected estrus (37% versus 39%, respectively; $P > 0.05$).[2]

This chapter discusses how Ovsynch works and how it may be altered in the future to improve the percentage of cows synchronized, and the possibility of improving

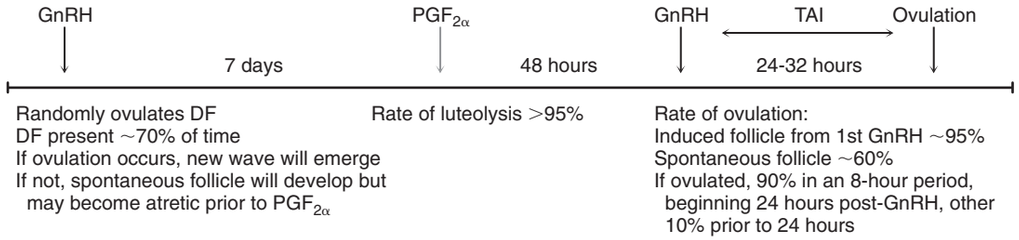

Fig. 38-1 Description of the original Ovsynch program, with outcomes from each hormonal injection.

CR by means of greater control over the ovulatory follicle.

SYNCHRONIZATION RATES WITH OVSYNCH

The main limitation of Ovsynch is the wide variability in **synchronization rate** (SR), defined in this protocol as regression of a CL and induction of ovulation in response to the final GnRH. Approximately 10% to 30% of cows may not synchronize.[9,16–18] It is likely that nonsynchronized cows could receive AI at an inappropriate time relative to ovulation, thereby decreasing their chances of becoming pregnant. Nevertheless, with SRs in this range, it is impressive that CR after Ovsynch is similar to that with AI at the time of detected estrus.

Vasconcelos and associates attributed most of the variation in SRs to the stage of the estrous cycle at which Ovsynch was initiated.[18] Cows started on Ovsynch at mid-cycle (days 5 to 9 of the cycle) had a greater probability of synchronizing and therefore had a greater chance of conception. The key reasons for increased SR in mid-cycle were the presence of a DF responsive to GnRH during the first follicular wave and a CL that remained functional during the 7-day period between GnRH and $PGF_{2\alpha}$. Early in the estrous cycle (days 1 to 4), synchronization was impaired by the presence of newly emerging follicles incapable of ovulating in response to the first GnRH dose. These growing follicles had an increased chance of reaching atresia before $PGF_{2\alpha}$ was given. Later in the estrous cycle (day 10 and beyond), the presence of a functional DF at the time of first GnRH dose varied depending on follicular wave pattern of the cow and on time of follicular emergence. Moreover, it was possible to encounter spontaneous luteolysis triggered by endometrial $PGF_{2\alpha}$ during this period. Characterization of the ovarian events that take place when Ovsynch is started at different stages of the estrous cycle indicates that the main causes of synchronization failure were (1) lack of ovulatory response to the first GnRH, (2) atresia of the DF before $PGF_{2\alpha}$ administration, and (3) spontaneous luteolysis between administration of the first dose of GnRH and of $PGF_{2\alpha}$.[18] As previously stated, early atresia of the DF before $PGF_{2\alpha}$ administration was primarily a function of lack of ovulatory response to the first GnRH dose. For example, a 3-day-old follicle at the time of first GnRH dose (which probably would be the oldest not capable of ovulating[19]) would be 10 days old at the time of $PGF_{2\alpha}$ administration and already undergoing atresia. Therefore, at the time of the second GnRH dose, another follicular wave could be emerging, and the follicle destined to be dominant would be too young to respond to the final GnRH dose with ovulation. Cows in the latter situation probably would be in standing estrus 3 to 5 days after the second GnRH dose. In addition, cows with spontaneous luteolysis during the time from the first GnRH dose to $PGF_{2\alpha}$ administration probably would be in late stages of the estrous cycle and undergoing natural luteolysis before $PGF_{2\alpha}$ was given. Such cows probably would be in estrus from 1 day before to 1 day after $PGF_{2\alpha}$ administration. In either case, cows would not have a synchronized ovulation in response to the second GnRH injection and probably would not conceive with the timed AI.

Because synchronization to Ovsynch depends primarily on the ovulatory response to the first GnRH, followed by emergence of a new follicular wave,[18] several studies tried to develop presynchronization strategies to ensure presence of a functional mature DF at the time of the first GnRH of Ovsynch.[20–24] The most popular strategies were based on the use of $PGF_{2\alpha}$ at specific times before Ovsynch was started. The absence of consistent synchronization results probably was due to the fact that $PGF_{2\alpha}$ controls only the lifespan of the CL, which has little effect on follicular development. Thus, stage of follicular development at the beginning of Ovsynch probably would have too much variation if it was presynchronized only with $PGF_{2\alpha}$-based programs.

For instance, Momont and Seguin demonstrated dramatic differences in time, and variation in time, to estrus with $PGF_{2\alpha}$ treatment of cows at day 7 versus day 10 or 11 of the estrous cycle. Treatment at day 7 of the estrous cycle resulted in fewer days to estrus and less variation in time to estrus compared with treatment at days 10 to 11. This is explained by the difference in stage of follicular development between the two groups—a greater percentage of cows have mature DFs at day 7 than at days 10 to 11. Thus, treating cows with $PGF_{2\alpha}$ at random stages of the estrous cycle will not ensure synchrony of follicular development. Moreover, none of the presynchronization studies provided data on follicular events throughout presynchronization and Ovsynch to assess synchronization of follicular development.

Heifers are poorly synchronized when treated with Ovsynch (50%–60% SR).[2] This is the key reason why heifers treated with Ovsynch have significantly lower CR compared with heifers bred to detected estrus (35% versus 74%, respectively; $P < 0.01$).[2] The physiologic events underlying such poor synchronization can be interpreted

as an exacerbation of what happens in some of the cows that do not synchronize. Therefore, the synchronization situation in heifers may be used as a model to illustrate the underlying ovarian physiology of some nonsynchronizing cows.

Newly emerging follicles grow more rapidly[15] and for a shorter period[10,11] in heifers than they do in lactating cows. Thus, a DF in heifers can be expected to reach atresia sooner. Ovsynch-treated heifers that respond to the first GnRH dose may undergo follicular turnover of the new ovulatory DF before $PGF_{2\alpha}$ administration. If a DF from a new wave becomes atretic before the $PGF_{2\alpha}$ is given, an emerging follicular wave, rather than a mature DF, probably would be present at the time of the final GnRH injection. Consequently, synchronized ovulation to the final GnRH dose of Ovsynch is unlikely—and so is conception.

PROTOCOL COMPONENTS AND STRATEGIES

Interval between First GnRH Dose and $PGF_{2\alpha}$ Administration

Effects of Increasing Time between First GnRH Dose and $PGF_{2\alpha}$ Administration

Two potential scenarios emerge when the time from first GnRH dose to $PGF_{2\alpha}$ administration is increased to greater than 7 days: The first is that extending this period may allow a greater number of DF to reach atresia. As previously explained, this may result in a new follicular wave and the absence of a DF at the final GnRH dose. Thus, no ovulation would occur. Cows would then have continued follicular growth and ultimately estrus and ovulation 2 to 4 days after the final GnRH dose. As a second possibility, extending the time may increase the age of the DF at the time of $PGF_{2\alpha}$ administration and final GnRH injection. This could result in a persistent-type DF.

Treatments based on maintenance of subluteal levels of progesterone (P_4) (1–2 ng/ml) for an extended period are known to cause prolonged growth and dominance of the DF. This follicle is described as a persistent DF.[25–29] When the persistent DF is allowed to ovulate, fertility is decreased when compared with that of younger ovulatory follicles.[27,28,30–32] It was proposed that the negative effect of prolonged growth and dominance of the ovulatory follicle on fertility is associated with the hormonal environment in which the follicle is induced to persist. Subluteal levels of P_4 during a prolonged period cause increased frequency of LH pulsatility[33,34] and prevents a preovulatory LH surge from occurring.[28,32,35,36] As a result, the oocyte resumes meiosis while still contained in the follicle and starts undergoing premature nuclear maturation dissociated from follicular maturation and ovulation. Histologic characteristics of these persistent DFs indicate that the oocyte undergoes early germinal vesicle breakdown and continues a progression through the cell cycle toward metaphase I or II.[31,37] By the time of ovulation of the persistent follicle, the oocyte has already matured and aged, resulting in lower fertility, which may be explained by either low fertilization rates[38,39] or high early embryonic mortality,[40] or both. Also, persistent follicles are known to maintain a high and sustained production of estradiol, which may alter intrafollicular, oviductal, and uterine environments, thereby compromising sperm or oocyte transport and embryonic development.[26–28,31,32,37]

Follicular wave pattern and fertility. It is widely accepted that ovarian follicles develop primarily in two- or three-wave patterns throughout the estrous cycle of cattle[4,42,43] (Fig. 38-2). Lactating dairy cows generally have two waves of follicular growth per cycle.[10,11,44–46] In either wave pattern, the DF of the final wave is the one intended to ovulate. The mean interovulatory interval is shorter for two-wave versus three-wave cows (approximately 20 days versus 22–23 days, respectively), and the emergence of the ovulatory wave occurs earlier for two-wave than for three-wave cows (approximately day 11 versus day 16 of the cycle), leading to different lifespans of the ovulatory follicles for each wave pattern. At the time of ovulation, therefore, a difference in age can be observed between the preovulatory follicle coming from a two-wave (9 to 10 days) versus a three-wave (6 to 7 days) pattern of follicle development.[41,43] Thus, the two-wave pattern that pre-

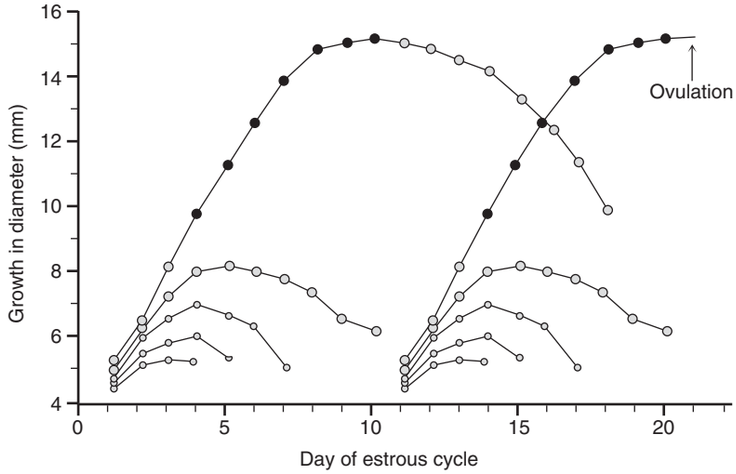

Fig. 38-2 Diagram of the growth in diameter (mm) of follicles during a 21-day bovine estrous cycle. The cow had two follicular waves during this estrous cycle. The black points indicate when a dominant follicle (DF) probably is responsive to GnRH.

dominates in lactating dairy cows generally is characterized by a larger and older DF reaching ovulation compared with that in three-wave patterns.[1,44] Moreover, second-wave preovulatory follicles were found to be approximately 3 days older than those of a third wave when the interval from emergence to estrus was measured.[44] This difference in lifespan between second-wave and third-wave ovulatory follicles was explained by a longer period of follicular dominance, rather than by the interval of follicle growth from emergence to dominance, which remained the same in both cases.[44]

As previously stated, the ovulatory follicle of a two-wave cycle is older than that of a three-wave cycle. By analogy with the effect of prolonged dominance of a persistent follicle, the older age of a second-wave ovulatory follicle could be expected to have a negative impact on fertility. If most dairy cows have two waves, then a high proportion of the population could be expected to be ovulating an older DF, thus providing a possible explanation of the low CR problem in lactating dairy cows. In applying this concept to Ovsynch, the established 7-day interval may be limiting the number of cows that ovulate an aged follicle. This may be the reason why fertility of cows that synchronized exceeds fertility of cows inseminated after a detected estrus. Decreasing the age of the follicle at the time of the final GnRH so that it is more like a three-wave follicle may offer greater improvements. Only a few studies compared fertility between three- and two-wave cows.[44,46,47] There may be significant trends toward greater CR in three- than in two-wave cows. Unfortunately, sufficient numbers of three-wave cows probably were difficult to procure for these studies, because most lactating dairy cows have two follicular waves during a normal estrous cycle.[48]

Effect of Duration of Dominance of Ovulatory Follicle on Fertility

An even stronger association is likely between fertility and the length of ovulatory follicle lifespan or duration of physiologic dominance, than between fertility and the number of follicular waves. In one study, the interval from emergence of the ovulatory follicle to estrus was approximately 1 day shorter in cows diagnosed as pregnant compared with cows diagnosed as not pregnant (7.8 ± 0.2 days versus 8.6 ± 0.2 days, respectively; $P < 0.01$), regardless of whether they had two or three follicular waves.[44] A key result from the same study was a significant inverse relationship between duration of dominance and CR. The longer the ovulatory follicle remained in the ovary waiting for the ovulation trigger, the lower the probability of establishing a pregnancy.

Furthermore, in a recent study that compared follicle development between lactating cows and nulliparous heifers,[11] heifers had a 1.2-day shorter duration of dominance of the ovulatory follicle when compared with cows. The relevance of this issue becomes clear when the CR difference between these two groups is considered. It may be possible to reduce the number of cows that would ovulate an old follicle. The only possible way to accomplish this, however, is to reduce the time from the first GnRH dose to $PGF_{2\alpha}$ administration.

Effects of Reducing the Time between First GnRH Dose and $PGF_{2\alpha}$ Administration

Altering the time from first GnRH dose to $PGF_{2\alpha}$ administration probably could affect the maturity level of the ovulatory follicle at the time of the final GnRH dose. Follicles that are induced to ovulate before reaching physiologic maturity may be less fertile. Several studies demonstrated the relationship between smaller follicular size at the time of induced ovulation with GnRH and lower CR.[9,49,50] In a recent study from our laboratory, cows treated with Ovsynch that ovulated to a GnRH-induced LH surge with ovulatory follicles less than 12 mm in diameter had lower CR compared with ovulatory follicles 12 mm or larger (27% versus 36%; $P < 0.01$) and comprised nearly 34% of the cows in the study ($N = 1424$).[9] It is likely that these follicles were not allowed to reach peak physiologic maturity.

Compromised oocyte quality and subsequent inadequate luteal function are possible reasons why reduced age, size, or physiologic status of follicles reduces CR. Lower circulating P_4 concentrations in the subsequent cycle[51] can impair embryo recognition, development, and implantation. Another possibility could be related to a nonsynchronized, and hence incorrect, timing of endocrine signals controlling final follicle and oocyte maturation, leading to ovulation of an immature oocyte.[52] Reduced estradiol concentrations due to a younger DF also can alter uterine and oviductal environment, affecting either gamete or embryo survivability.[16,29,43,52,53]

Physiology and Regression of an Early Corpus Luteum

The main requirement for an Ovsynch-type program that intends to increase SR and decrease lifespan and duration of dominance of its ovulatory follicle is regression of an early CL (5 days old or less; day 0 = estrus). To our knowledge, reducing the interval between the first GnRH dose and $PGF_{2\alpha}$ administration to less than 7 days has not been reported in lactating dairy cows. CL regression, however, was consistently attained after a 6-day interval between first GnRH and $PGF_{2\alpha}$ administration in dairy and beef heifers and beef cows.[55,56] Moreover, consistent regression of a 4- or 5-day-old CL is possible with repeated injections of $PGF_{2\alpha}$.[57–59]

Experiments carried out in the 1970s and 1980s provided evidence that a CL was refractory to exogenously induced luteolysis during the first few days after being formed. A single treatment with $PGF_{2\alpha}$ was unable to initiate CL regression within the first 4 days of the cycle,[57,60–62] and even though some sensitivity to a luteolytic dose of $PGF_{2\alpha}$ can be observed in 5-day-old CLs, this response was not consistent until the CL reached an age of approximately 7 days.[62–64] It is clear that this lack of early CL response cannot be attributed to lack of $PGF_{2\alpha}$ receptors, because a CL as young as 2 days already expresses $PGF_{2\alpha}$ receptors.[65–67] Despite several mediators proposed to explain this event,[68–73] the mechanisms underlying early luteolytic resistance of a CL are still not clear.

Nevertheless, some evidence supports a cumulative effect of frequently repeated injections of $PGF_{2\alpha}$ on early CL sensitivity to luteolysis. First, after twice-daily (12-hour interval) injections of $PGF_{2\alpha}$ on days 3 and 4 of the cycle (day 0 = estrus), the newly formed CL regressed, leading to shortening of the estrous cycle and manifestation of precocious estrus in Holstein heifers.[57] Second, in dairy heifers receiving a daily injection of $PGF_{2\alpha}$ from days 3 to 7 of the cycle, plasma P_4 levels remained low, and manifestations of estrus appeared.[59] Third, even less intensive treatments, consisting of a daily dose of $PGF_{2\alpha}$ on two consecutive days within days 0 to 5 of the estrous cycle, produced early luteal regression in a proportion of heifers.[58] Even in the heifers that did not show a complete luteolytic response, either a single injection of $PGF_{2\alpha}$ on day 4 or twice-daily injections on days 2 and 3 of cycle were enough to depress peripheral P_4 concentrations throughout the cycle.[57] Moreover, at the molecular level, repeatedly treated day 4 CLs showed up-regulation of $PGF_{2\alpha}$ synthase in luteal cells.[74] Therefore, it appears that a cumulative $PGF_{2\alpha}$ stimulus, together with a certain maturation level of the CL, may be associated with increased early CL sensitivity to an intensive luteolytic treatment in heifers. These results led us to postulate that early CL responsiveness to $PGF_{2\alpha}$ may be dependent on the magnitude or duration (or both) of the stimuli to which it is exposed, which can be tested through a dose-response study.

In this context, it is suitable to consider the type of luteolytic agent used to induce the demise of a CL at an earlier stage of the cycle (day 5 or 6). Two $PGF_{2\alpha}$ products currently are available for use in cattle: (1) dinoprost, a natural tromethamine salt of $PGF_{2\alpha}$, which is available as either Prostamate or Lutalyse; and (2) cloprostenol, a synthetic prostaglandin analogue, commercially available as Estrumate. These two products differ in their pharmacokinetic properties when administered to cows: Dinoprost has a short half-life ($t_{1/2}$) of 7 to 18 minutes,[75–77] whereas cloprostenol seems to be more resistant to endogenous metabolism, maintaining higher circulating concentrations for a longer period ($t_{1/2}$ = 3 hours).[57] Nevertheless, on the basis of findings in several trials performed to compare luteolytic efficacy of one dose of dinoprost or cloprostenol in cattle,[77,78,80–82] there seems to be no difference between them. All of these experiments, however, tested for differential luteolytic efficacy either at random stages of the estrous cycle or when a mature $PGF_{2\alpha}$-sensitive CL (8 days old or less) was present. None of these experiments tested the question of differential luteal regression using dinoprost versus cloprostenol at the critical period of early CL refractoriness. In considering the effect on early CL regression of both repeated $PGF_{2\alpha}$ treatments in a short time and a longer $t_{1/2}$ of cloprostenol in circulation, it seems reasonable to expect differential luteolytic efficacy of dinoprost and cloprostenol in this critical early period of the cycle.

Further physiologic reasons to support the relevance of a cumulative $PGF_{2\alpha}$ effect during luteolysis arise from a potential local autoamplification luteolytic pathway within the CL. There is evidence for hormonal interactions leading to luteal regression not only through an endocrine pathway but also by means of paracrine/autocrine mechanisms. At luteolysis, endometrial $PGF_{2\alpha}$ reaches the ovaries through a countercurrent mechanism and induces demise of the CL, both functionally, by cessation of P_4 production, and structurally, by involution of luteal tissue.[83–86] Additional evidence indicates that luteal secretion of $PGF_{2\alpha}$[74,86–88] may be a potential local amplification signal that would augment the luteolytic effect of uterine $PGF_{2\alpha}$. Although the physiologic significance of this local pathway is not clear, an intraluteal autoamplification pathway triggered by small amounts of uterine $PGF_{2\alpha}$ may be important to complete luteolysis.[89] The relevance of a local mechanism becomes apparent when one considers that more than 99% of uterine $PGF_{2\alpha}$ is metabolized and removed from circulation after a single passage through the liver and the pulmonary bed.[90] Thus, in the few seconds that it takes for portal blood to go through the lungs and be redistributed again in the systemic circulation, $PGF_{2\alpha}$ concentrations are reduced to less than 1%. The relevance of a potential local autoamplification pathway to our approach is related to the importance of a cumulative effect of the stimuli during luteolysis.

When developing Ovsynch, Pursley and collaborators[15] decided to establish a 7-day interval between the first GnRH of the program and $PGF_{2\alpha}$. A 7-day period was assumed to be an appropriate interval to allow for follicular development and CL maturity at the time of induction of luteolysis. It was never formally tested, however, whether the 7-day interval assumption was actually optimal for SR in Ovsynch-treated cows. Therefore, the question of whether SR can be improved by reducing the interval from first GnRH to $PGF_{2\alpha}$ remains unanswered. This reduced interval may allow greater control of the maturity level of the DF at the time of ovulation. We believe that an ovulatory follicle of reduced lifespan and duration of physiologic dominance may have a positive impact on fertility in dairy cows if this follicle is allowed to reach maturity. A synchronization program capable of consistently and accurately generating an ovulatory follicle of such characteristics will provide the opportunity to test this novel question. A significant by-product of the development of such a program could be a substantial improvement in SR, with indirectly improvements in CRs with Ovsynch.

Interval from $PGF_{2\alpha}$ Administration to Final GNRH Dose

A recent study from our laboratory suggests there is very little flexibility in time from administration of $PGF_{2\alpha}$ to the final treatment with GnRH in Ovsynch.[24] In order to control time of the LH surge so that time of ovulation can be controlled, the final GnRH administration of Ovsynch must be given before a spontaneous LH surge to control time of AI. Studies suggest that a spontaneous LH surge can occur as early as 36 hours after a $PGF_{2\alpha}$-induced CL regression, with the greatest percentage occurring after 48 hours. We tested the effect of inducing the LH surge with GnRH at 0, 12, 24, 36, and 48 hours after $PGF_{2\alpha}$ administration. Increasing the time between the decline of P_4 until the LH surge increased CR. This study yielded direct evidence of a positive association with length of time

from $PGF_{2\alpha}$ to GnRH and reduced short luteal phases in the subsequent estrous cycle. Other possible explanations for an increase in CR as time increased from luteal regression to the LH surge include improved oviduct contractility and oocyte transport and greater sperm survival and transport.

Lengthening the time from $PGF_{2\alpha}$ to the final GnRH is gaining attention in many herds, but no published data on this strategy are yet available. When GnRH is administered more than 48 hours after $PGF_{2\alpha}$, the chance of inducing an LH surge with the final GnRH diminishes with time, and so does the control over the time of ovulation. The reason for this is because cows begin having spontaneous LH surges at approximately 40 hours after $PGF_{2\alpha}$ administration. If all cows that had spontaneous LH surges were detected in estrus before the final GnRH, then timing of AI could be suited to the time of the onset of estrus. Thus, with use of this lengthened interval, it is critical to utilize and enhance estrus detection between $PGF_{2\alpha}$ and the final GnRH dose.

Timing of Artificial Insemination Relative to Final GnRH Dose in Lactating Holstein Cows

Data from Pursley and colleagues[91] suggest that AI at 16 hours after the final GnRH injection, when administered 48 hours after $PGF_{2\alpha}$ administration, results in the highest CR, compared with AI at 0, 8, 24, and 32 hours after the final GnRH dose. This study clearly indicated that AI after ovulation severely depressed CR and increased pregnancy losses between 28 and 56 days after AI. A study just completed in our laboratory indicates that AI at 8 hours before the final GnRH (equivalent to approximately 36 hours before ovulation) reduced CR nearly 30%, compared with AI at 16 hours after the final GnRH (32% versus 23%).[9] Of interest, both studies demonstrated a significant increase in female calves when AI was done at least 28 hours before ovulation.

FUTURE DIRECTIONS WITH OVSYNCH

Clearly, some aspects of the initial development of Ovsynch were novel, including the use of GnRH to initiate a new follicular wave and a second dose of GnRH to induce ovulation of the DF from that new wave. The development of Ovsynch, however, was not focused on improving the competency of the ovulatory follicle. Studies are needed to optimize the timing of all injections to ensure maximal development of a DF of reduced lifespan and duration of dominance. An increase in CR from improving SR alone could amount to 6% more pregnant cows every week on dairy farms. If it is possible to increase the fertility of the ovulatory follicle, then much greater increases in CR could be achieved. Because Ovsynch currently is in place in many dairy management systems across the United States and the world, key improvements could be implemented in a straightforward and trouble-free fashion. Increases in pregnancy rate due to improvements in each aspect of Ovsynch could be expected to have several benefits: (1) increased milk production per cow due to maintenance of a greater proportion of cows in early lactation, (2) decrease in involuntary culling due to either a lack of pregnancy or pregnancy too late in lactation, and (3) increase in the number of replacements born each year. These positive changes in herd management could increase dairy farm profit substantially.

CHAPTER 39
Pregnancy Diagnosis

ROBERT S. YOUNGQUIST

Since the beginning of civilization, animal owners have been interested in determining whether or not conception has taken place, and various clinical signs and superstitions have been used for millennia to diagnose pregnancy.[1] Over time, a number of more accurate methods for determination of pregnancy in cows and other female domestic animals have been developed, including observation, physical examination, chemical tests, and use of electronic instruments.

INDICATIONS

The purpose of examining cows for pregnancy is not to detect those that are pregnant, but to detect those that are not pregnant so that they can be inseminated again or culled from the herd. For profitable production, dairy cows should calve for the first time at approximately 24 months of age and should deliver subsequent calves at intervals of approximately 13 to 13.5 months. Thus, dairy cows should conceive within approximately 4 months or less of calving. Cows that are found to be not pregnant can be treated for any abnormalities of the reproductive tract discovered during the examination, observed closely for signs of spontaneous estrus, or treated with prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) to predictably shorten the time until return to estrus.

An ideal test would accurately detect pregnancy before the first expected estrus after insemination (about 21 days) so that the cow could be reinseminated without further loss of time. Unfortunately, no tests are currently available that are practical to use and allow detection of pregnancy in cows before the first expected estrus. Most methods for pregnancy diagnosis are capable of detecting pregnancy between 25 and 40 days after conception, and most authors have traditionally recommended that nonpregnant cows be identified before the second expected estrus after insemination.[2] In a recent prospective study, however, cows that were diagnosed as pregnant by palpation between 30 and 36 days after breeding were found to have a 2-week longer calving interval than that observed in cows examined for pregnancy later.[3]

The frequency of embryonic death in cattle is high during the first months of pregnancy, perhaps because of loss of abnormal embryos or failure of maternal recognition of pregnancy.[4] Thus, cows that are diagnosed as pregnant soon after insemination are more likely to suffer embryonic death and return to estrus, to be found not pregnant at a subsequent examination, or to fail to deliver a calf at the expected time than are cows in which pregnancy is diagnosed later. Owners frequently misinterpret this course of events and conclude that the test for pregnancy was inaccurate (i.e., the cow was not pregnant at the time of examination) or that the test affected the embryo and directly or indirectly resulted in termination of pregnancy. After approximately 60 days, fetal death rates are low, and in most, but not all, cows that are found to be pregnant after this time, the pregnancy proceeds to term with birth of a calf.

Beef cows usually are examined for pregnancy when their calves are weaned at 6 to 7 months of age, although in intensively managed herds, individual cows can be examined earlier. In most management systems, nonpregnant cows are culled from the herd to save the cost of maintaining nonproductive animals, but in herds that have spring and autumn calving seasons, cows sometimes are moved to the other group and given a second opportunity, although this decision may be difficult to justify economically. Although the cost of maintaining a nonproductive beef cow is variously estimated to be between $250 and $400 per year, a survey of herd owners in 18 states revealed that only 17.7% examine cows and that 15.9% examine heifers for pregnancy.[5]

MANAGEMENT METHODS FOR PREGNANCY DIAGNOSIS

As described later on, palpation of reproductive structures per rectum (probably to be replaced by ultrasound examination in the foreseeable future) has been the customary method of pregnancy diagnosis in cattle. Some cattle owners, however, may rely on the history, or on clinical signs that can be observed, for a presumptive diagnosis of pregnancy.

Exposure to a Bull or Artificial Insemination

A history of cohabitation with a bull, the observation of mating, or artificial insemination may be considered by some owners to be sufficient evidence that a cow has become pregnant. Although fertilization rates in cows typically are high, however, only approximately 50% of inseminations result in a detectable pregnancy. Conversely, unobserved, unplanned, or unrecorded matings are not uncommon, and cows frequently are presented with a complaint of infertility, only to be found pregnant when examined. Thus, history is not a reliable indicator of pregnancy status and sometimes may be deceptive.

Cessation of the Estrous Cycle

Bovine embryos signal their presence around 15 to 17 days after ovulation: The corpus luteum is maintained,

and the maternal estrous cycle is suspended. Thus, failure of a cow to return to estrus at approximately 18 to 24 days after mating suggests that conception has occurred. In fact, the most common cause of failure of cows to have normal estrous cycles is pregnancy.[6]

In beef herds in which natural service is used, perceptive managers may observe that a greater-than-expected number of cows return to estrus after mating. This situation suggests an infertile bull, the presence of a venereal infection, or some other cause of infertility, and an opportunity exists to take corrective action before the breeding season ends. Conversely, undernutrition is a common cause of anestrus in lactating beef cows, and the observation that few cows return to estrus after the first few weeks of the breeding season may mislead less astute managers to believe that cows have become pregnant when they are in fact not cycling.

Failure of a dairy cow to be detected in estrus at approximately 3 weeks after insemination is viewed as a favorable event by managers, and anestrous cows are assumed to be pregnant. Unfortunately, although the efficiency of estrus detection varies among observers and among dairy farms, it generally is lower than desirable, so this approach is not sufficiently accurate to be of use in diagnosis of pregnancy. Most dairy reproductive herd health programs are based on the practice of examining cows that have not been observed in estrus after insemination as indicated by some other method (most commonly rectal palpation) that more accurately differentiates between pregnant and nonpregnant cows.

A few pregnant cows show mild to conspicuous signs of estrus and may be mistakenly thought to be nonpregnant. Artificial insemination of pregnant cows may result in abortion if the insemination instrument is passed completely through the cervical canal and the fetal membranes are disrupted.[7]

Metestrus Bleeding

A sanguineous vaginal discharge is common in cows 24 to 48 hours after estrus and is the result of hemorrhage from the caruncular capillaries due to the rapid decline in estrogen concentration that follows ovulation. Some owners subscribe to the notion that metestrus bleeding is a sign of conception failure; however, metestrus bleeding is observed in nearly all cows and heifers and is not an indication of whether conception occurred. If metestrus bleeding is observed in a cow that was not seen in estrus a few days previously, it is implied that estrus was unobserved and that the animal is not pregnant.

PALPATION PER RECTUM

Palpation of the reproductive tract through the rectal wall (rectal palpation) has been used for diagnosis of pregnancy since the early 1900s and has been the customary method used in cattle for more than 50 years.[8–11] Depending on the skill of the examiner and the age and size of the dam, rectal palpation is useful to diagnose pregnancy as early as day 30 and thereafter until term. Although a number of changes occur in the size, texture, location, and content of the uterus during pregnancy, four *positive* signs of pregnancy that are detectable by rectal palpation are recognized:

- Palpation of the fetal membrane slip
- Palpation of the amniotic vesicle
- Palpation of placentomes
- Palpation of the fetus

The examiner must detect at least one of these four signs before declaring the cow pregnant.

Fetal Membrane Slip

The examiner can detect the chorioallantois within the lumen of the pregnant uterus by compressing the uterine horn between the thumb and forefingers, lifting the uterus, and then allowing the horn to slowly "slip" from the grasp. If the cow is pregnant, the chorioallantois can be felt to slip through the fingers just in front of the uterine wall. This membrane slip can be felt in the pregnant uterine horn as early as 30 days of pregnancy and can be reliably detected by day 35. The fetal membrane slip can be detected in the nongravid horn by approximately day 70 of pregnancy. During early pregnancy, the fetal membranes are thin, and a delicate touch and some experience are required to recognize this sign of pregnancy.

Amniotic Vesicle

The amnion contains the developing conceptus and the amniotic fluid and is palpable as early as 28 days after conception in heifers and by 32 to 35 days in pluriparous cows. The vesicle is recognized as a nearly spherical, turgid, fluid-filled structure that is approximately 1 cm in diameter at 28 days and increases in size as pregnancy advances. The amniotic vesicle is detected by encircling the uterine horn with the examiner's thumb on one side and the fingers on the other. The vesicle is free-floating within the uterus but most commonly is found at the cranial edge of the intercornual ligament. The amniotic vesicle becomes progressively less turgid and is difficult to recognize by about day 65 of gestation. At that time, the vesicle softens and the fetus becomes palpable. In a bovine conceptus, the heart is external until approximately day 42; therefore, caution must be exercised in attempting to detect early pregnancies, and undue pressure must not be applied to the amniotic vesicle because rupture of the embryonic heart or other fragile organs may result. Intentional rupture of the amniotic vesicle has been used as a method to provoke abortion in cattle.[12]

Placentomes

In ruminants, cotyledons of the fetal placenta produce villi that project into crypts of maternal caruncles to form placentomes. Seventy-five to 120 maternal caruncles arranged in two dorsal and two ventral rows are present in the uterus of cows. Placentomes begin to form early in gestation and are of sufficient size to be palpable by 75 to 80 days. The size of placentomes varies with the stage of gestation and their location in the uterus. Placentomes

are progressively larger near the middle of the gravid horn and are smaller at the cervical and ovarian poles. They are most consistent in size immediately cranial to the cervix and are palpated at that location to estimate the stage of pregnancy. Placentomes are identified by grasping a longitudinal fold of the uterine wall and rolling it between the thumb and fingers. In more advanced pregnancies, the examiner can palpate placentomes by passing a flattened hand over the uterine wall.

Placentomes remain palpable for a variable time after death of the conceptus, and detection of their presence may, in a few instances, result in a false positive diagnosis of pregnancy. A false positive diagnosis of pregnancy also can occur when an ovary is mistaken for a placentome consistent in size with a 120- to 180-day pregnancy. The examiner can easily avoid this mistake by identifying at least three placentomes before declaring the animal pregnant (there are only two ovaries).

A false negative diagnosis is possible during the fifth to eighth month of pregnancy, when the uterus is completely descended and may be out of reach, especially in large, deep-bodied cows, or to examiners with short arms. This mistake can be avoided if the examiner searches for other signs of pregnancy before declaring the cow pregnant, or positively identifies a normal, nongravid uterus before declaring the animal nonpregnant.

Fetus

The fetus becomes palpable at approximately 65 days, when the amniotic membrane loses its turgidity, and remains theoretically palpable for the balance of gestation. In the early stages of gestation, the fetus can be grasped directly. Later, the fetus is detected by ballottement: The examiner sets the fetal fluids in motion by rocking the hand against the uterine wall and recognizes the fetus as it rebounds against the hand. The fetus is easily palpable as a free-floating, firm object within the fluid-filled uterus during the first 4 months of gestation. As pregnancy advances, increased weight of the fetus and fluid pulls the uterus ventrally and cranially until the fetus comes to rest on the abdominal floor during the fifth and sixth months. Continued growth of the fetus positions it closer to the maternal pelvis during the last trimester (period of ascent), so that palpation of the fetus is facilitated. Roberts[11] has estimated that it is possible to palpate the fetus in greater than 95% of cows during the third and fourth months of gestation, in 40% to 70% of cows during the fifth and sixth months, in 80% at 7 months, and in greater than 95% during the eighth and ninth months.

False negative diagnoses are most likely if palpation of the fetus is relied on for diagnosis of pregnancy between the fifth and seventh months. Mistakes can be avoided if the cow is examined for other signs of pregnancy or if a nongravid uterus is identified before the animal is declared not pregnant.

False positive diagnosis is possible if another structure is mistaken for a fetus. Some of the normal maternal structures that may be incorrectly perceived as a fetus are the dorsal sac of the rumen and the left kidney. Among the abnormal structures that have been mistaken for a portion of the fetus are ovarian and uterine tumors, enlarged lymph nodes, adhesions and connective tissue secondary to previous surgical or obstetric trauma, and necrosis of abdominal fat. Mummified fetuses can be mistaken for a normal pregnancy if an examination is perfunctory. Although a mummified fetus can approximate the size of a viable fetus, mummies are recognized by a lack of uterine fluid and absence of fetal membranes and placentomes.

Supporting Signs of Pregnancy

Several palpable changes in the reproductive tract suggest pregnancy but can have other causes. Thus, these changes constitute supporting but not specific signs of pregnancy.

Asymmetry of the uterine horns. Examinations for pregnancy should always begin with palpation of both uterine horns to detect differences in their size. In very early pregnancies, the horns may be nearly identical in size, but as gestation advances, the pregnant horn enlarges. Asymmetry often is first detectable in the cranial portion of the gravid horn. If a difference in the diameter of the uterine horns is detected, the larger horn can be examined for presence of an amniotic vesicle or fetal membrane slip. Conditions other than pregnancy that potentially may cause enlargement of one uterine horn are pyometra, mucometra, and delayed postpartum uterine involution. In none of these conditions, however, is an amniotic vesicle or fetal membrane slip detectable.

Resilience and fluctuance of the uterine wall. As the gravid uterine horn fills with fluid, the wall thins and assumes a characteristic texture of resilience and fluctuance. With some experience, the texture of the uterine contents and the uterine wall typically associated with pregnancy will give the examiner an early indication that the cow is pregnant. This impression is confirmed by detection of at least one of the four positive signs of pregnancy.

Fixation of the cervix. The cervix can be lifted and the uterus retracted until approximately day 65 to 70. By about day 90, the weight of fluid within the uterus becomes sufficient to prevent the examiner from easily lifting the cervix, and the organ is said to be "fixed." Although fixation of the cervix commonly is associated with pregnancy, abnormal accumulations of fluid within the uterus such as those associated with pyometra and mucometra also can cause cervical fixation. Adhesions between the reproductive tract and other pelvic or abdominal organs such as those that follow cesarean section or obstetric trauma also can prevent retraction of the cervix. Uterine or ovarian tumors may be large enough to pull the reproductive tract into the abdominal cavity and also prevent retraction of the cervix.

Hypertrophy of the middle uterine artery. As gestation advances, blood supply to the uterus is increased to meet demands of the developing fetus. The middle uterine artery lies in the broad ligament, which allows it to be freely movable for a distance of 10 to 15 cm. An increase in size of the uterine artery supplying the gravid horn is detectable in heifers as early as day 60 to 75 and

in cows by day 90. Increased size and thinning of the wall of the artery lead to the unique palpable characteristic of fremitus. Fremitus is first palpable in the artery supplying the gravid horn and later the nongravid horn. The perception of fremitus may be enhanced by applying slight pressure to the artery, but it disappears if the artery is occluded. Although fremitus is a sign often associated with pregnancy, it persists for several days after abortion or parturition and also accompanies conditions other than pregnancy that increase blood flow to the uterus.

Ovarian changes. Every examination of the reproductive tract begins with a thorough examination of both uterine horns, and the ovaries usually are not examined until after the operator has determined that the cow is not pregnant; however, in some cases it may be useful to examine the ovaries if the operator is uncertain after palpating the uterus. Cows depend on progesterone secreted by the corpus luteum to maintain pregnancy throughout gestation. Transuterine migration of embryos is uncommon in cows; thus, a corpus luteum is almost always present in the ovary ipsilateral to the pregnant uterine horn. Consequently, the presence of a corpus luteum ipsilateral to an enlarged, fluid-filled uterine horn suggests pregnancy. Conditions such as pyometra and other abnormalities of the uterus, however, also cause persistence of corpora lutea and accumulation of fluid within the uterine horns. Furthermore, the ability of most clinicians to detect a functional corpus luteum by rectal palpation is inadequate; thus, failure to perceive a corpus luteum should not be the sole basis for declaring a cow not pregnant.[13] One of the positive signs of pregnancy must be identified before the cow is declared pregnant or their absence determined with certainty before the cow is declared not pregnant.

In some instances, it may be desirable to examine cows around the time of the first expected estrus (about 21 days) after insemination. If the cow is not pregnant, uterine and ovarian changes typical of approaching estrus such as increased uterine tone, a regressed corpus luteum and developing follicle or recent ovulation, and a clear mucous vulvar discharge are to be expected. If the cow is pregnant, no positive signs of pregnancy will be detectable, but a mature corpus luteum will be palpable in one of the ovaries.

Estimation of the Stage of Gestation

The stage of gestation can be estimated on the basis of palpable characteristics of the uterus and fetus. Estimation of the stage of gestation is most accurate during the first half of pregnancy. In early pregnancies, stage of gestation can be estimated on the basis of the size of the gravid horn and the diameter of the amniotic vesicle. In more advanced pregnancies, age of the fetus is estimated on the basis of determination of the size of placentomes at the base of the pregnant uterine horn, size of the fetus, fetal crown-to-nose length,[14] position of the uterus, and size of the middle uterine artery.[10,11] Characteristic sizes at different stages of gestation are summarized in Table 39-1.

Accuracy of Rectal Palpation

Traditionally, most theriogenologists have regarded rectal palpation to be the definitive method for diagnosis of pregnancy and have assumed that its accuracy approaches 100%. Until recently, few methods other than slaughter have been available to test the accuracy of rectal palpation. When performed diligently and thoroughly, rectal palpation probably is the most practical and accurate method of pregnancy diagnosis available for use in cows, but clinicians should not undertake examinations for pregnancy until animals have reached the stage of gestation when a diagnosis of pregnancy is possible. With a moderate amount of experience, a reliable diagnosis of pregnancy is possible after day 35 to 39. Clinicians with less experience may wish to delay examinations for pregnancy until 50 to 55 days after breeding, when positive signs of pregnancy are more easily detected.

Despite the confidence of practitioners, false positive and false negative diagnoses are possible. Veterinarians occasionally suffer the indignity of an owner's report that a cow declared not pregnant aborted after administration of prostaglandin $F_{2\alpha}$ to induce estrus or was found to be pregnant at slaughter. Conversely, some cows declared pregnant return to estrus or fail to calve. A proportion of such cases can be explained by diagnostic error, but a majority probably are due to embryonic or fetal death that occurs after examination. The incidence of pregnancy loss is high during early gestation, and owners should be informed of that possibility.[15] In a recent study it was found that of the cows diagnosed as pregnant by rectal palpation, 3.4% returned to estrus and subsequently were inseminated, and a further 1.5% were found not to be pregnant when examined at a later date. Approximately 5% of cows diagnosed as not pregnant calved at a time consistent with having been pregnant when the diagnosis was made.[3]

Prudent clinicians observe the rules for pregnancy examination set forth by Zemjanis[10]:

- Pregnancy examination should always represent the first step of genital examination.
- No animal should be treated unless the operator is positive that the animal is non-pregnant.
- No animal should be pronounced non-pregnant unless the uterus has been retracted and both horns of the uterus have been palpated carefully throughout their entire length.
- A diagnosis of pregnancy should never be made unless the positive signs of pregnancy have been detected and recognized beyond doubt.

Safety of Rectal Palpation

For decades, pregnancy diagnosis was assumed to be safe for the dam and the fetus. Several reports have appeared in the literature, however, that suggest that rectal palpation is not an innocuous procedure and carries with it inherent risks for both dam and fetus.

Fetal Death

The possibility that specific methods of pregnancy diagnosis by rectal palpation may contribute to embryonic

Table **39-1**

Characteristics of Pregnancy in Cows

Gestation Length, d	Amniotic Vesicle Size, cm	Pregnant Horn Diameter, cm	Placentome Diameter, cm	Middle Uterine Artery Size, cm	Crown-To-Nose Length, cm	Crown-Rump Length, cm	Uterine Position	Example of Fetal Size	Characteristics of Fetus	Positive Signs of Pregnancy
30	0.8–1 (size of a pea)	2–4	—	0.4–0.6	—	0.8–1	Pelvic	—	Head and limb buds; placenta is not attached	Amniotic vesicle
40	2–3 (size of a plum)	4–6	—	0.4–0.6	—	1.75–2.5	Pelvic	—	—	Amniotic vesicle; fetal membrane slip
50	3.5–5	5–7	—	0.4–0.6	—	3.5–5.5	Pelvic	—	—	Amniotic vesicle; fetal membrane slip
60	6–7.5	6–9	—	0.4–0.6	—	6–8	Pelvic	Mouse	Claw buds and scrotum visible; palate and sternum closed; placenta attached; small placentomes visible	Amniotic vesicle softens; fetus; fetal membrane slip
70	—	7–10	0.5–0.75	0.5–0.7	1.5 (one finger width)	7–10	Uterine descent begins	—	—	Fetus; fetal membrane slip; placentomes
80	—	9–12	0.5–1	0.5–0.7 (fremitus)	3.5 (two finger widths)	8–13	Uterus descending	—	—	Fetus; placentomes; fetal membrane slip
90	—	10–13	1–1.5 (size of a dime)	0.5–0.7 (fremitus)	5.5 (three finger widths)	13–17	Uterus descending	Rat	Hair on lips, chin and eyelids; scrotum present	Fetus; placentomes

120	—	12.5–18	1.5–2.5 (size of a quarter)	0.7–0.9 (fremitus)	10.5 (wide as hand and thumb)	22–32	Uterus descending	Small cat	Fine hair on eyebrows; claws developed; horn pits present; epithelial plaques on amnion	Fetus; placentomes
150	—	18–23	2.5–4 (size of a half dollar)	0.7–1.0 (fremitus)	—	30–45	Uterus on abdominal floor	Large cat	Hair on eyebrows and lips; testes in scrotum; teats developing	Fetus (palpation may be difficult); placentomes
180	—	—	4–5	0.9–1.25 (fremitus)	—	40–60	Uterus descended	Beagle dog	Hair on inside of ear and around the horn pits, tip of tail, and muzzle	Fetus (palpation may be difficult); placentomes
210	—	—	5–7.5	1.25–1.5 (fremitus)	—	55–75	Ascent of the uterus begins	—	Hair on metatarsal, metacarpal, and phalangeal region of extremities and beginning on the back, long hair on tip of tail	Fetus; placentomes
240	—	—	6–9	1.25–1.7 (fremitus)	—	60–85	Ascending	—	Fine short hair all over the body; incisor teeth are not erupted	Fetus; placentomes
270	—	—	8–12	1.5–1.9 (fremitus)	—	70–100	Ascended; fetus readily palpable	—	Hair coat complete and long; fetus large; incisor teeth erupted	Fetus; placentomes

and fetal death was raised by the report of a prospective study in which cows were examined for pregnancy by palpation of uterine fluctuation, palpation of the amniotic vesicle, and palpation of the fetal membrane slip.[16] In that study, it was found that palpation for uterine fluctuation alone in cows pregnant from 35 to 70 days was an accurate and safe method to detect pregnancy, but that detection of pregnancy by palpation of the fetal membrane slip and of the amniotic vesicle resulted in increased fetal death. Of interest, significant differences among palpation techniques of individual examiners were found in the detection of fetal loss after examination. Other authors also report that rectal palpation may be a significant iatrogenic cause of fetal death.[17] Still others, however, have been unable to confirm that fetal death after diagnosis of pregnancy is associated with rectal palpation.[18,19] Recently, fetal loss due to palpation of the fetal membrane slip was prospectively measured and compared with fetal loss in heifers diagnosed as pregnant by a noninvasive method.[20] Although substantial loss of embryos occurred between 30 and 60 days after breeding, it was not different between the palpated group and the control group, leading to the conclusion that embryo loss was not caused by rectal palpation.

It is difficult to separate fetal attrition potentially caused by rectal palpation from spontaneous fetal loss in nonpalpated animals. In light of the information currently available, a reasonable conclusion is that if rectal palpation is a cause of fetal death, the incidence probably is low and the value of the information gained is greater than the risk of iatrogenic fetal loss. Nevertheless, clinicians must be aware of the possibility of negative effects of rectal palpation on early pregnancies and conduct examinations meticulously, cautiously, and with dispatch.

Fetal Damage

Palpation of the amniotic vesicle for diagnosis of pregnancy before day 40 has been implicated as a cause of atresia coli in newborn calves.[21,22] Other investigators believe that atresia coli is a genetic defect, and although early-pregnancy palpation may contribute to the deformity, it is not an invariable etiologic factor in all cases of atresia coli.[23] The authors of a retrospective study of 26 cases of this condition found no association between atresia coli and a history of rectal palpation for diagnosis of pregnancy.[24]

Disease Transmission

Bovine leukemia virus (BLV) has been experimentally transmitted to seronegative cattle and sheep by rectal infusion of relatively large amounts of blood from viremic animals.[25] BLV also has been experimentally transmitted to calves by simulated palpation with obstetric sleeves contaminated with whole blood from a seropositive donor animal.[26] Other authors, however, have reported that BLV transmission by rectal palpation in the manner typically used for reproductive tract examination of cows either does not occur or is uncommon.[27] In herds in which other measures to control transmission of BLV are practiced, it may be prudent to use a separate clean obstetric sleeve for palpation of each cow. The role of rectal palpation performed by clinicians wearing common obstetric sleeves in transmission of other infectious diseases is unknown.

Maternal Bacteremia

Bacteria were isolated from blood samples collected from 4 of 35 otherwise healthy cows after rectal palpation of the reproductive organs was performed.[28] The authors of this report concluded that bacteremia following rectal examination of dairy cattle probably was not significant and that no changes in herd health protocols were warranted. However, they pointed out that clinicians should be aware that rectal palpation is not without consequences.

CHEMICAL TESTS FOR PREGNANCY

Progesterone

A number of investigators have attempted to diagnose pregnancy in cows and other domestic animals by measurement of progesterone concentrations in blood or milk samples taken after insemination at about the time of the first expected estrus.[29–31] Progesterone can be measured by laboratories using radioimmunoassays or by various assay kits that are available for on-farm use. This strategy is based on the requirement for luteal progesterone to maintain pregnancy in cows. If a cow is pregnant, she does not return to estrus, and progesterone concentrations in blood and milk are elevated at 20 to 24 days after insemination. Conversely, if a cow has failed to conceive, progesterone concentration is elevated until approximately day 17, when luteolysis is followed by a sharp decline in progesterone concentration by day 20 and return to estrus. Therefore, if progesterone concentrations are low in blood or milk samples taken at 20 to 24 days after insemination, the cow is assumed to be nonpregnant, whereas cows are assumed to be pregnant if progesterone concentrations are elevated.

Measurement of progesterone has been found to be from 75% to 85% accurate in correctly identifying pregnant cows and nearly 100% accurate in identifying nonpregnant cows. In a recently reported field trial, measurement of progesterone in a single milk sample taken on day 21 after insemination had the unacceptably low positive predictive value of 83.0%. If the combination of a low progesterone concentration on the day of insemination and a high progesterone concentration on day 21 after insemination was used, the positive predictive value of the test increased to 87.4%.[32]

False positive results may be due to errors in performing the assay or in sample identification, normal variations in the length of the estrous cycle (shorter than 18 days or longer than 24 days), ovarian abnormalities (luteal cysts), uterine abnormalities (pyometra), and errors in estrus detection that result in insemination during the luteal phase of the estrous cycle. Early embryonic death may lead to apparent false positive results by prolonging the lifespan of the corpus luteum if the embryo is lost after maternal recognition of pregnancy. Elevated milk progesterone concentrations on days 20 to 24 after insemination indicate only the presence of a

corpus luteum, which usually, but not invariably, is associated with a conceptus.

False negative results are unlikely unless due to laboratory error or misidentification of samples. Cows require progesterone to maintain pregnancy, and cows with low concentrations of progesterone are extremely unlikely to be pregnant.

Because progesterone assays are not accurate for identification of pregnant cows, the procedure has not become popular among veterinarians or cattle owners. Measurement of progesterone may be more useful in samples taken on the day of insemination to verify that progesterone concentrations are low and that the cow has not been erroneously identified as being in estrus and presented for insemination during the luteal phase of the estrous cycle.

Estrone Sulfate

Estrone sulfate is a product of the placenta and is present in the milk of pregnant cows in concentrations sufficient to differentiate between pregnant and nonpregnant cows after approximately day 100 of gestation.[32–34] In practice, however, assays for estrone sulfate are not useful for early detection of pregnancy and offer no substantial advantage over other methods for pregnancy diagnosis, except in the few cows in which rectal palpation cannot be performed.

Bovine Pregnancy-Specific Protein B

A pregnancy-specific protein secreted by trophoblastic cells in cows—bovine pregnancy-specific protein (bPSPB)—has been isolated and purified. Radioimmunoassays for measurement of bPSPB have been developed and used to differentiate pregnant from nonpregnant cows.[35–37] Concentrations of bPSPB are detectable in a few cows as early as 15 days after insemination and in nearly all pregnant cows by 24 days after insemination. The protein increases in concentration as gestation advances and is detectable until parturition. In a herd of beef cows, assay for bPSPB was found to detect pregnancy more accurately than rectal palpation. Concentrations of bPSPB are higher in twin pregnancies than in single pregnancies, but high individual variations did not permit accurate prediction of fetal numbers.[38] Assays for bPSPB have been found useful for detection of pregnancy in moose[39] but were not accurate when used in llamas.[40]

Immunosuppressive Early Pregnancy Factor

An assay has been developed for detection of a glycoprotein immunosuppressive early pregnancy factor in the serum of pregnant cows. Blood samples were collected from dairy cows within 24 hours of ovulation and assayed for presence of immunosuppressive early pregnancy factor. The assay was able to diagnose pregnancy in 87.5% of cows at less than 24 hours of gestation and was 12.5% inaccurate in the identification of nonpregnant cows.[41]

ULTRASONOGRAPHY

Real-time ultrasonography has been used for detection of pregnancy in cattle for more than a decade. The principles of ultrasonography and its use in animal reproduction have been described.[42] A number of transducers are available for use with ultrasonographic scanners designed or adapted for use in animals, but 5-MHz and 7.5-MHz transducers are most widely used for transrectal ultrasonography. Lower-frequency transducers are capable of penetrating greater depths of tissue but are not capable of resolving small structures. Higher-frequency transducers are capable of resolving smaller structures but do not penetrate deeply through tissues.

Pregnancy has been diagnosed with a 7.5-MHz transducer as early as 9 days after insemination in heifers.[43] The embryonic vesicle was detected in heifers with a 5-MHz transducer by day 13 or 14 and the embryo observed by days 26 to 29.[44] When a 5-MHz transducer was used to detect pregnancy, accuracy was no better than a guess until day 18 after insemination but then became nearly 100% on days 20 and 22 when examinations were conducted under optimal circumstances.[45] Most clinicians agree that under practical conditions, ultrasonography with a 5-MHz transducer is an accurate method for diagnosis of pregnancy after approximately day 24, when a heartbeat will be detectable in viable embryos. A 3.5-MHz transducer was found to be reliable for detection of pregnancy after day 30.[46]

The appearance of bovine conceptuses when examined with ultrasonography from days 20 through 60 of gestation has been described,[47] and ultrasonographic evaluation of the bovine conceptus has been reviewed.[48] The embryo proper was first detected within the amniotic vesicle on day 20.3, when it was found to be 3.5 mm in length. By day 60, the embryo had grown to 66.1 mm. Between days 28 and 31, forelimb buds became visible, and hindlimb buds were visible approximately 2 days later. Two claws became visible on the hooves between days 42 and 49, and movements of the fetal head and feet were first detected between days 42 and 50. Ribs could be visualized beginning on days 51 to 55. Placentomes were first visualized between days 33 and 38 in the area of the embryo and could be seen throughout the uterine horn by day 60.

The accuracy of ultrasonography for diagnosis of pregnancy may vary among animals. More incorrect diagnoses of nonpregnant were made using a 5-MHz transducer between 24 and 38 days after insemination in cows in which the uterus was located far cranial to the pelvic inlet than in cows in which the uterus was located within or close to the pelvic inlet when examined.[49]

An additional advantage of ultrasonography for diagnosis of pregnancy is the ability to determine fetal gender. Scrotal swellings and teats were detected between days 73 and 120, and gender of the fetus was determined with an accuracy of 94%.[50] Other investigators used ultrasonography to visualize the fetal genital tubercle.[51] On days 48 and 49, the tubercle was located between the hindlimbs, toward the umbilical cord in males and toward the tail in females. In male fetuses, the tubercle was immediately caudal to the umbilical cord by approximately day 56, and in females, the tubercle was under the tail by approximately day 54. Thus, an experienced ultrasonographer was able to accurately determine fetal gender between days 55 and 60.

Ultrasonography is likely to replace rectal palpation as the standard against which other techniques for pregnancy diagnosis are compared. At present, the cost of reliable ultrasonographic scanners precludes their routine use in food animal veterinary practices, but the technique is likely to become more popular as less expensive instruments become available and clients demand the service. Ultrasonographic scanners are reliable and rugged and can be used for examining large numbers of beef and dairy cows if precautions are taken to protect the console and transducer from moisture, dust, and impact. Properly grounded power connections are essential to protect the patient and the operator from electrical shock.

CHAPTER 40

Ultrasound Determination of Fetal Gender

RODNEY A. CHRISTMAS and JILL COLLOTON

Fetal gender determination by real-time ultrasound evaluation has become a common reproductive management tool employed by both dairy and beef cow-calf operations. Other benefits of ultrasonography include early pregnancy diagnosis, diagnosis of fetal viability, twins and uterine pathology, and increased accuracy of ovarian structure identification.[1–3] When fetal gender determination initially was utilized by beef cattle producers, the payback ratio was estimated to be at least 10:1 and sometimes as high as 100:1.[4] It was thought at that time that the high profit margin probably was a result of the newness of the technology and that the procedure would remain profitable even after widespread acceptance. Those predictions have turned out to be accurate, because pregnant beef cows that are marketed with known-gendered fetuses routinely sell for $25 to $50 more per head than contemporaries with unknown fetal gender. Benefits of fetal gender determination for the dairy cow include the increased sale value of pregnant animals carrying heifers, ability to plan embryo transfer programs to fill bull contracts, cull decision information for marginal cows, and ability to predict replacement needs.

To accurately determine fetal gender, it is important that the practitioner have good-quality ultrasound equipment, an excellent understanding of fetal anatomy, and thorough training in reproductive ultrasonography. It also is important for practitioners to recognize the limitations of their ability, and of the technology itself, to ensure producer adoption of fetal gender identification. The reported accuracy of fetal gender determination approaches 100%.[5] Under conditions of low light and calm cattle, this accuracy can be realized. Nevertheless, occasionally, despite the practitioner's best effort, the necessary view cannot be obtained and therefore an accurate diagnosis cannot be made. In such instances it is imperative that the practitioner refrain from guessing; the producer should be informed of the limitations, and the examination be should be repeated in a few days. With experience, nondiagnostic examinations will occur with decreasing frequency.

EQUIPMENT

A number of the ultrasound units available for purchase are more than adequate to identify fetal gender in cattle.

CHAPTER 40

Ultrasound Determination of Fetal Gender

RODNEY A. CHRISTMAS and JILL COLLOTON

Fetal gender determination by real-time ultrasound evaluation has become a common reproductive management tool employed by both dairy and beef cow-calf operations. Other benefits of ultrasonography include early pregnancy diagnosis, diagnosis of fetal viability, twins and uterine pathology, and increased accuracy of ovarian structure identification.[1–3] When fetal gender determination initially was utilized by beef cattle producers, the payback ratio was estimated to be at least 10:1 and sometimes as high as 100:1.[4] It was thought at that time that the high profit margin probably was a result of the newness of the technology and that the procedure would remain profitable even after widespread acceptance. Those predictions have turned out to be accurate, because pregnant beef cows that are marketed with known-gendered fetuses routinely sell for $25 to $50 more per head than contemporaries with unknown fetal gender. Benefits of fetal gender determination for the dairy cow include the increased sale value of pregnant animals carrying heifers, ability to plan embryo transfer programs to fill bull contracts, cull decision information for marginal cows, and ability to predict replacement needs.

To accurately determine fetal gender, it is important that the practitioner have good-quality ultrasound equipment, an excellent understanding of fetal anatomy, and thorough training in reproductive ultrasonography. It also is important for practitioners to recognize the limitations of their ability, and of the technology itself, to ensure producer adoption of fetal gender identification. The reported accuracy of fetal gender determination approaches 100%.[5] Under conditions of low light and calm cattle, this accuracy can be realized. Nevertheless, occasionally, despite the practitioner's best effort, the necessary view cannot be obtained and therefore an accurate diagnosis cannot be made. In such instances it is imperative that the practitioner refrain from guessing; the producer should be informed of the limitations, and the examination be should be repeated in a few days. With experience, nondiagnostic examinations will occur with decreasing frequency.

EQUIPMENT

A number of the ultrasound units available for purchase are more than adequate to identify fetal gender in cattle.

Key areas of consideration in purchasing a scanner are image quality, portability, service, and power source.

Image quality is determined by a complex set of factors. An ultrasound unit has two basic parts, both of which affect image quality: the transducer and the console.

Transducer

The number of elements of piezoelectric crystals in the transducer and the frequency of their vibration influence image quality. The number of crystals (or elements) in the transducer will be greater than 80 in most good machines. The frequency of vibration of the piezoelectric crystals is measured in megahertz (MHz). Transducers for bovine use commonly are available in frequencies of 3.5 MHz, 5 MHz, or 7.5 MHz. Lower-frequency transducers provide more depth of penetration but decreased resolution, so they are unsuitable for reproductive examinations. Higher-frequency transducers provide the best resolution but limit the depth of penetration, which may make scanning larger fetuses difficult. The standard transducer used in bovine reproductive ultrasonography has been the 5-MHz linear transducer, which we prefer in our practice. Some practitioners, however, prefer the increased resolution provided by the 7.5-MHz transducer.

Transducers are available in different shapes: linear, curvilinear, or sector. This designation refers to how the piezoelectric crystals are arranged in the transducer. As the name implies, the linear transducers have the crystals arranged in the head of the transducer in a linear fashion. The curvilinear transducer has a bend in the linear arrangement, and the sector scanner has a single crystal that oscillates, providing a wedge-shaped image. The sector and curvilinear scanners are awkward for routine rectal examinations. At this time, almost all transducers currently available for bovine ultrasonography are linear.

Console

The console should read at least 64 shades of gray. Most units have 256 shades of gray, but the human eye cannot detect anything greater than 64. The number of channels determines focusing ability. Twelve or more channels are adequate. Beyond 30 channels no visible difference will be noted.[6]

Other Components and Considerations

Portability and power source. Ultrasound units for use in the bovine vary in weight from 2 to 35 pounds. The larger units require an outside power source and are designed to be placed on a cart. They are most suitable for situations in which the patient comes to the machine. The smaller portable units are battery operated and are designed to be worn on the person. These are ideal when mobility is required.

Image display. Units may have a screen display, goggles, or both. Screen displays are useful when more than one person wishes to view the scan. Goggles are helpful when working outdoors or in bright light.

Additional options. Fetal aging software, image recording abilities, dual screen display, cine mode, M-mode, and color Doppler are just a few options available on some machines. None are critical for fetal gender diagnosis, but certain options may be desirable in some situations.

Warranty and service. One-year warranties are standard for most ultrasound units. Turnaround time on repairs should be short, perhaps as quick as 48 hours. Some companies will provide a loaner unit during repair.

Choosing an Ultrasound Unit

Image quality is the most critical criterion in selecting an ultrasound unit. A quick way to determine image quality is to scan an ovary with a corpus luteum. The ovarian stroma should be easily differentiated from the luteal tissue. Beyond good image quality, personal preference will determine a practitioner's choice of machine. The practitioner should try as many machine and transducer combinations as possible and then buy the one that feels the most comfortable and that has the best service contract.

ANATOMIC LANDMARKS

The genital tubercle is the prime structure that needs to be identified during an ultrasonographic examination for fetal gender. In the female, the genital tubercle will develop into the clitoris, so it is always located just below the tailhead. The male genital tubercle will develop into the penis, so it is always located immediately behind the umbilical cord. The male and female genital tubercles can be identified as early as day 55 using ultrasound examination.[5] The gestational period during which fetal sexing is most accurate is 60 to 80 days.[7] Before 60 days, the fetus may not be adequately developed; after 80 days, the ultrasound energy may not adequately penetrate maternal tissue to reach the fetus, especially in large dairy cows and overconditioned heifers. Figure 40-1 is a photograph of an 80-day-gestation bovine male fetus, with *arrows* demonstrating the important anatomic landmarks, foot, umbilicus, genital tubercle, and scrotum for fetal gender identification. Figure 40-2 presents a view of the

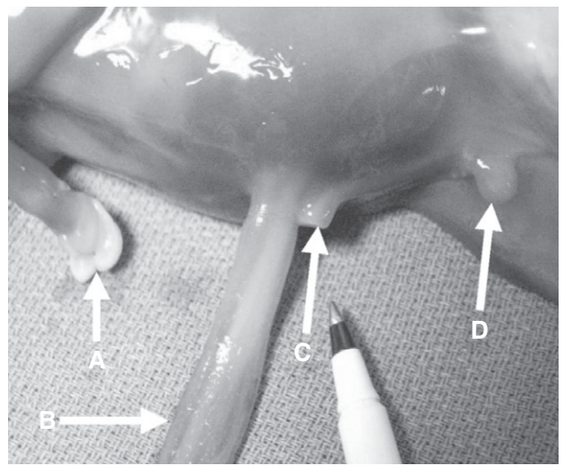

Fig. 40-1 Ultrasound view of the ventral surface of an 80-day bovine male fetus. *A,* Front foot; *B,* umbilicus; *C,* genital tubercle; *D,* scrotum.

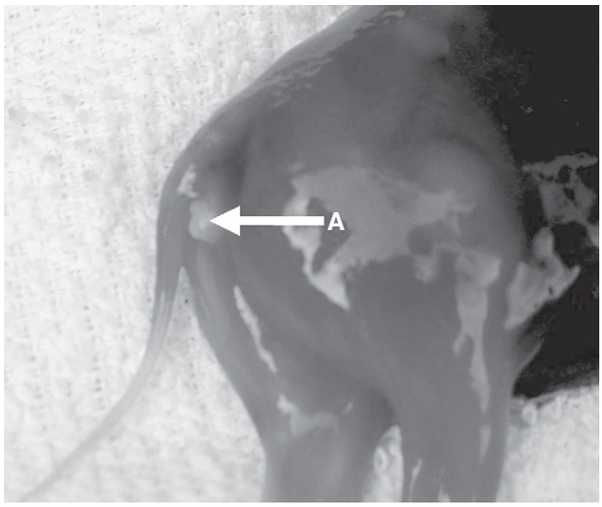

Fig. 40-2 Hindquarters of 75-day female fetus. A female genital tubercle is recognizable.

hindquarters of 75-day-gestation female fetus, with the female genital tubercle identified by the letter A.

Other key landmarks include the head, the caudal-to-cranial taper of the thoracic cavity, the fetal heart, and the fetal stomach and liver. These landmarks give the practitioner a cranial-to-caudal orientation to evaluate which direction the probe should be moved for imaging the genital tubercle. Teats or scrotum also may be seen, especially on fetuses more than 75 days in gestation, but diagnosis of fetal gender should not be based on identification of these structures alone. To have a reasonable chance at becoming proficient at ultrasonographic fetal gender determination, it is critical that the practitioner have an in-depth knowledge of fetal anatomy so that the images received from the ultrasound machine can be accurately interpreted.

GETTING THE IMAGE

After familiarization with fetal anatomy and the critical structures, it is time to make sense of the snowlike images on the screen. Often, the biggest struggle is breaking out of palpation mode, because most practitioners find ultrasound interrogation to be a very different skill from palpation. The transition from tactile to visual diagnosis can be difficult, especially for experienced palpators. In fact, good palpation skills are helpful, but not critical, to develop good ultrasonography skills. Ultrasound is a great teaching tool for novice palpators because they can "see" what they were just feeling. Faith and patience are the two keys in starting to image the reproductive tract of cattle, and in particular when the goal is to identify fetal gender. This section summarizes the basic examination points.

The goal of the examination to determine fetal gender is to identify a gender-specific structure: the genital tubercle. The genital tubercle is composed of highly echogenic (bright white on screen) tissue and usually appears bilobed. In the male, the genital tubercle will be located just caudal to the umbilicus, and in the female, just ventral to the tail. Refer back to Figures 40-1 and 40-2 for orientation. Individual clinicians will develop their own imaging technique as they gain experience. Some prefer to first palpate the uterus and retract it into the pelvic cavity; others, ourselves included, prefer not to palpate and instead immediately scan the uterus. The key is to develop a systematic and efficient approach. The first step is to obtain cranial-to-caudal orientation by visualizing the head, beating heart, and the umbilicus.

Unlike a radiograph, the ultrasound image represents only a thin cross-section of the tissues directly below the transducer. Accordingly, the transducer must be moved to find and identify the location of structures. To center the image on the screen, the transducer must be moved forward and backward. Once the fetus is centered, the transducer can be moved very slowly sideways in both directions to locate the genital tubercle.

Once the ultrasound operator is oriented, one of three basic views can be used to examine the fetus: a **lateral view,** a **frontal view,** and a **cross-sectional view.** Of these basic views, the cross-sectional view, is the most commonly used and easiest view to obtain. If a cross-sectional view is obtained, the transducer should be moved through the fetus to the umbilical attachment in the ventral abdomen and then moved slowly back and forth to diagnose the presence or absence of the male genital tubercle just caudal to the umbilicus. The genital tubercle will always be more echogenic than the umbilicus. If a male genital tubercle is noted, the examination is concluded. If the male genital tubercle is not conclusively identified the transducer should be advanced through the fetus to the perineal region. These simple manipulations sound easy in theory, but in practice the perineal area is relatively difficult to image because it often is obscured by the uterine wall or a placentome. It also is important to be able to distinguish the highly echogenic coccygeal vertebrae of the tail from the genital tubercle. In an oblique view, the pin bones also may be mistaken for the female genital tubercle. In general, the female genital tubercle will be bilobed or trilobed, and the tail or pin bones are monolobed. Another common reason for an incorrect identification of a female as a male is a fetal position in which the bright, echogenic tip of the tail is tucked between the hind legs.[8,9]

The frontal view is a little more difficult to obtain than the cross-sectional view but is the easiest to orient and in our experience provides the clearest view of the genital tubercle and other gender-specific anatomic structures. The ultrasound appearance of the female genital tubercle in the frontal view of the perineal region is demonstrated in Figure 40-3. A similar view of a male fetus is shown in Figure 40-4 demonstrating the scrotum. The lateral view is the least commonly used for fetal gender identification. The male genital tubercle may be obscured by the legs in this view. It also is more difficult to view the female genital tubercle. For these reasons, we rarely use this image.

Key points in the ultrasound examination are summarized in Box 40-1. Table 40-1 presents a sample worksheet for recording the ultrasound findings.

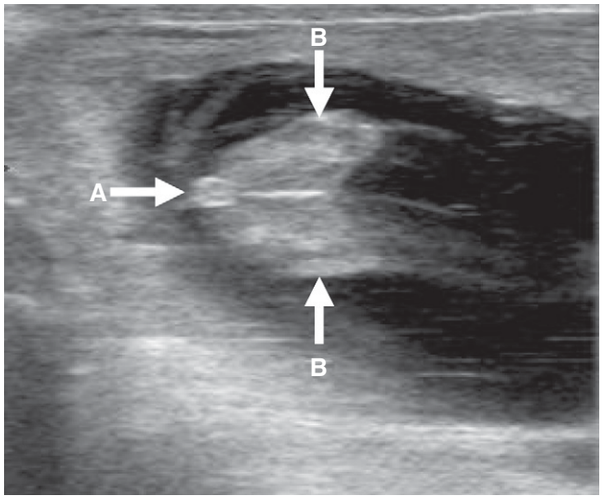

Fig. 40-3 Ultrasound view of the hindquarter of a 75-day female bovine fetus.

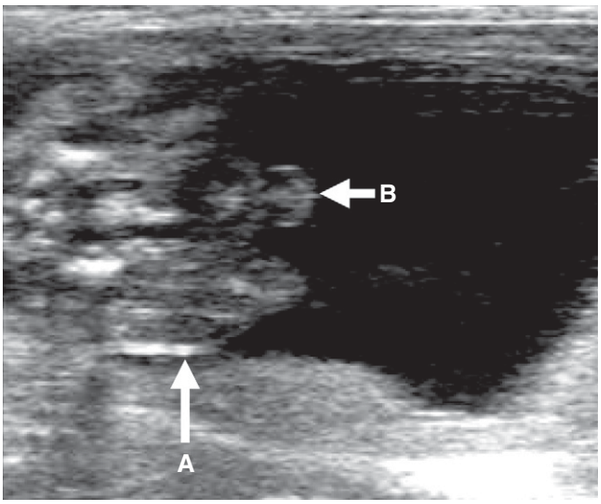

Fig. 40-4 Ultrasound view of the hindquarters of a 80-day male fetus. Image was obtained using a 5-MHz linear probe. The dorsal surface of the fetus is to the *left* in the figure. *A,* Right thigh; *B,* trilobed scrotum.

Fetal Age and Sexing Worksheet

Itsa Bullorheifer, DVM
Ultrasound Services, Inc./LLC
123-555-6789
Date: _____
Client: _____

ID	Date Bred or Fetal Age	Predicted Sex	Expected Calving Date	Comments

Research indicates that fetal sexing is 95–99% accurate.
Because of variability in fetal size and gestation length between animals, calving dates may deviate up to 1 month from fetal age measurements.
Although no research indicates that ultrasound is harmful to the fetus, no warranty is made for fetal viability beyond the date of examination.
No warranty is made on fetal sex determination or fetal aging.
Adapted from Colloton JD: American Association of Bovine Practitioners Seminar on Bovine Ultrasonography Notes. Vancouver, BC, Canada, September 2001.

SUMMARY

Achieving technical competence in ultrasonographic fetal gender determination will require (1) a high-quality ultrasound unit, (2) a detailed understanding and comprehension of ultrasonographic fetal anatomy, and (3) the skill to manipulate the ultrasound transducer to get a well-positioned, adequately focused image. The first two of these requirements are relatively easy to achieve; the third requires practice and patience. It is important to make the investment in training both through video tapes and in participation in "wet labs" and seminars. With commitment and the requisite investment, professional competence can be achieved.

Box 40-1

Fetal Sexing by Ultrasonographic Evaluation: Key Points

1. Fetal age: 60 to 80 days of gestation. The ultrasound examination can be performed as early as day 55 and as late as day 110.
2. Diagnosis is based only on the identification of the genital tubercle or gender-specific structure such as the penis.
3. Move the transducer in a slow, controlled fashion.
4. Keep your eye on the screen all the time, because sometimes structures move by quickly.
5. Locate the umbilicus and move caudally.
6. If possible, roll the transducer under the uterus to provide the best contact between the transducer and the fetus, for optimal focus and clarity.
7. Check for twins during the examination.
8. Keep careful records of the findings (see Table 40-1).
9. Stay relaxed, and focus on making smooth, controlled movements with the transducer.

CHAPTER 41

Induced Abortion

PHILIP G. A. THOMAS

Therapeutic abortion may be indicated during normal or abnormal pregnancy in the cow. Misidentification of a breeding female, accidental breeding of a very young heifer, and unwanted pregnancy in feedlot heifers are indications for abortion during normal gestation. Induced abortion can be included in treatment protocols for pathologic conditions of pregnancy, including fetal maceration, fetal mummification, hydramnios, and hydroallantois.

PHYSIOLOGY OF PREGNANCY MAINTENANCE

Gestation in the cow extends 270 to 292 days after breeding. Once conception has occurred, progesterone is essential for pregnancy maintenance. Both luteal and extraovarian sources of progesterone must be eliminated for successful induction of abortion. Although the maternal endocrine events of the first 15 days of cycle and of pregnancy are similar, the conceptus secretes a range of products, including steroids, prostaglandins, and proteins, beginning at 12 to 13 days of gestation. At least one of these products, interferon-γ, results in maternal recognition of pregnancy by inhibition of luteolysis and prolonged luteal lifespan.[1–3] These effects are mediated by attenuation of endogenous prostaglandin F_2 alpha ($PGF_{2\alpha}$) secretion.[4]

The functional life of the corpus luteum (CL) is controlled by a balance of luteotropic factors, including luteinizing hormone, and luteolytic factors, including $PGF_{2\alpha}$. $PGF_{2\alpha}$ is the naturally occurring luteolysin, acting both directly and indirectly on the CL. $PGF_{2\alpha}$ may cause local vasoconstriction of luteal blood flow; however, $PGF_{2\alpha}$ receptors are present on luteal cells, and $PGF_{2\alpha}$ has a direct effect on luteal progesterone secretion.[5] Endogenous luteolysis occurs in response to a cascade of hormonal events that result in pulsatile $PGF_{2\alpha}$ secretion. It has been proposed that as part of this cascade, estradiol

Gestation in the cow extends 270 to 292 days after breeding. Once conception has occurred, progesterone is essential for pregnancy maintenance. Both luteal and extraovarian sources of progesterone must be eliminated for successful induction of abortion. Although the maternal endocrine events of the first 15 days of cycle and of pregnancy are similar, the conceptus secretes a range of products, including steroids, prostaglandins, and proteins, beginning at 12 to 13 days of gestation. At least one of these products, interferon-γ, results in maternal recognition of pregnancy by inhibition of luteolysis and prolonged luteal lifespan.[1–3] These effects are mediated by attenuation of endogenous prostaglandin F_2 alpha ($PGF_{2\alpha}$) secretion.[4]

The functional life of the corpus luteum (CL) is controlled by a balance of luteotropic factors, including luteinizing hormone, and luteolytic factors, including $PGF_{2\alpha}$. $PGF_{2\alpha}$ is the naturally occurring luteolysin, acting both directly and indirectly on the CL. $PGF_{2\alpha}$ may cause local vasoconstriction of luteal blood flow; however, $PGF_{2\alpha}$ receptors are present on luteal cells, and $PGF_{2\alpha}$ has a direct effect on luteal progesterone secretion.[5] Endogenous luteolysis occurs in response to a cascade of hormonal events that result in pulsatile $PGF_{2\alpha}$ secretion. It has been proposed that as part of this cascade, estradiol

induces oxytocin receptors on endometrial cells.[6] Oxytocin activates those receptors, resulting in the synthesis and secretion of $PGF_{2\alpha}$.

Peripheral progesterone levels fluctuate between 6 and 15 ng/mL throughout gestation,[7] with a gradual decline in the 2 to 4 weeks preceding parturition.[8] Pregnant cows that undergo ovariectomy before the first 3 to 5 months of gestation will abort. In cows ovariectomized after 200 days of gestation, progesterone secretion is maintained, although at significantly lower levels than before ovariectomy.[9] These cows do not abort, but parturition is advanced by 2 weeks and may be accompanied by dystocia and retained fetal membranes. The adrenal gland may contribute 1 to 4 ng/mL of progesterone.[10]

In summary, progesterone is luteal in origin for the first 150 days of gestation. Between 150 and 250 days, the placenta acts as additional source of progesterone. In the final month of gestation, placental progesterone declines and pregnancy is again dependent on luteal progesterone. Successful treatment to induce abortion must lower circulating progesterone below 1 ng/mL, which is the threshold necessary to maintain pregnancy,[11] and must be directed specifically at the source of progesterone appropriate for the stage of gestation at the time of treatment.

MECHANISM OF ACTION OF THERAPEUTIC AGENTS

Prostaglandin F_2 Alpha

The CL is sensitive to $PGF_{2\alpha}$ beginning 5 to 7 days after ovulation. In both normal and abnormal pregnancy, administration of $PGF_{2\alpha}$ after that time results in luteolysis at any stage of pregnancy; however, $PGF_{2\alpha}$ treatment alone induces abortion only up to 5 months of gestation. Rarely, luteolysis is incomplete, in which case luteal progesterone remains above the threshold, and partial cervical dilation and abdominal straining may occur before the cow resumes normal gestation.[11]

Glucocorticoids

Glucocorticoid treatment appears to reduce placental progesterone secretion from 150 days of gestation. Luteal progesterone is unaffected, however, and abortion does not result from glucocorticoid treatment until the last month of gestation. During the final month of gestation, glucocorticoids act at the fetoplacental unit to increase the production of estradiol and $PGF_{2\alpha}$, resulting in induced parturition. A combination of $PGF_{2\alpha}$ and glucocorticoids will induce abortion from 150 days of gestation.

Estrogens

Treatment with estrogens during the first 2 to 3 days after ovulation alters oviductal transport of the bovine embryo and terminates pregnancy. After the development of the CL, estrogens cause luteolysis by inducing the endogenous $PGF_{2\alpha}$ luteolytic cascade from the endometrium, as described earlier. The endometrium must be intact for estrogens to induce abortion. Estrogen is an exogenous luteolysin with unknown effects on the fetoplacental unit; therefore, abortion can be induced reliably at up to 150 days of gestation. Treatment of cows between 200 and 220 days of gestation with 30 mg estradiol valerate, alone or in combination with dexamethasone, has not been shown to decrease serum progesterone or result in abortion, however.[11]

Treatment with estradiol or its synthetic derivatives results in prolonged estrous behavior, vulvar swelling, mucopurulent discharge, and relaxation of parts of the posterior reproductive tract. The function of the uterotubal junction as a sphincter may be impaired, possibly allowing ascending infection and salpingitis. Time to return to fertile estrus after estrogen treatment may be longer than after prostaglandin treatment.

Oxytocin

Treatment of cows with oxytocin from days 2 to 7 after estrus with 100 to 200 IU of oxytocin prevents pregnancy, probably by preventing normal luteal development.

TREATMENT STRATEGIES IN TERMINATING PREGNANCY

Normal Pregnancy up to 150 Days

In the first 5 months of pregnancy, the treatment of choice is $PGF_{2\alpha}$ or an analogue (Table 41-1). Cows do not respond until 5 to 7 days after ovulation. After that time, a majority of cows respond by returning to fertile estrus within 3 to 5 days of treatment.[12,13] Cows not in estrus within 5 days should be retreated. Treatment with oxytocin in the first few days after ovulation may prevent the establishment of pregnancy. Between days 5 and 10 after ovulation, intrauterine infusion of irritating solutions

Table **41-1**

Drugs and Doses Commonly Used for Induction of Abortion during Normal Pregnancy in the Cow

Drug(s)	Dose and Route	Days to Onset of Effect
Prostaglandin $F_{2\alpha}$	25 mg IM	5–150
Cloprostenol	500 µg IM	5–150
Fenprostalene	1 mg SC	5–150
Dexamethasone	25 mg IM	275–283
Dexamethasone plus prostaglandin $F_{2\alpha}$[†]	25 mg 25 mg IM	5–283
Diethylstilbestrol	40–80 mg IM	1–3
	150 mg IM	5–150
Estradiol esters[‡]	4–8 mg IM	1–3
	10–20 mg IM	5–150

*Days after ovulation.
[†]Other combinations include dexamethasone (25 mg) plus cloprostenol (500 µg) and dexamethasone (10 mg) plus cloprostenol (375 µg).
[‡]Esters of estradiol include estradiol valerate, estradiol benzoate, and estradiol cypionate.
IM, intramuscularly; SC, subcutaneously.

prevents the establishment of pregnancy and may cause luteolysis and early return to estrus. Infusion later than 11 days after ovulation occasionally lengthens the estrous cycle. Up to 90 days of gestation, the same strategy causes embryonic death necessitating manual evacuation of uterine contents. Suitable solutions include 0.5% percent aqueous iodine and 2 g tetracycline in saline.

Estrogens administered within 72 hours of ovulation impede oviductal transit of embryos. Up to 5 months of gestation, administration of an estradiol ester, such as estradiol valerate, results in abortion within 7 days (see Table 41-1). Occasional abortions occur up to 14 days after treatment. Estradiol should be administered every 4 days until abortion. Abortion was reported in 60% to 80% of heifers within 7 days of a single treatment.[11]

Manual techniques are of historical interest only. Manual enucleation of the CL by transrectal manipulation removes progesterone support for pregnancy and results in abortion at up to 150 days, but this technique may induce adhesions of the ovary and ovarian bursa and, occasionally, severe hemorrhage.[14] Manual rupture of the amniotic vesicle by transrectal manipulation is possible once the vesicle can be palpated at 30 to 35 days of gestation. After 60 days and up to 120 days of gestation, when the amniotic vesicle can no longer be isolated within the fluid-filled chorioallantois, it may be possible to terminate pregnancy by manual decapitation of the fetus. The mean time to abortion is 25 days, but abortion may occur up to 8 weeks after treatment.

Normal Pregnancy after 150 Days

Between 5 and 8 months of gestation, a combination of $PGF_{2\alpha}$ and dexamethasone is necessary to remove both luteal and extraovarian sources of progesterone. This combination is preferable to all other treatments. Abortion will occur reliably, with a mean time to abortion of 5 days.[11] Abortion may be preceded or accompanied by estrous behavior for a duration of 9 to 12 hours. This combination is approximately 95% effective, although repeat treatments occasionally are necessary.

Unwanted pregnancy in feedlot heifers results in costs associated with reduced feed conversion, lower carcass prices, and periparturient diseases including dystocia. Heifers should be examined on arrival at the feedlot to select appropriate candidates. All pregnant feedlot heifers are routinely treated with the combination of $PGF_{2\alpha}$ and dexamethasone, regardless of their stage of gestation. Progestin-containing growth promotants should not be used until after abortion has been induced, because these compounds may interfere with treatment. All heifers should be examined after treatment. Those still pregnant usually will respond to a second treatment.

In the final month of pregnancy, either dexamethasone or prostaglandin alone induces premature parturition within 2 to 3 days.

SEQUELS TO INDUCED ABORTION

Induced abortion after the fourth month of gestation results in an approximately 80% incidence of retained fetal membranes. In a majority of cases, fetal membranes are lost within 7 days without treatment. Fetal mummification develops in 2% to 4% of pregnant feedlot heifers treated with a combination of $PGF_{2\alpha}$ and dexamethasone. In occasional cows, metritis or pyometra will develop after induced abortion; however, acute toxic metritis is an unusual sequel.

Hydroallantois and Hydramnios

The pathophysiology and treatment of hydropic conditions of the uterus is addressed elsewhere in this book. Slaughter is recommended for most cows with hydroallantois. Pregnancy can be terminated within 48 hours in cows with hydramnios or hydroallantois with simultaneous administration of prostaglandin and dexamethasone, using doses recommended for normal pregnancy[11,13,14]; however, supportive treatment is necessary to compensate for lost fluid, and parturition usually is abnormal. Cesarean section may be an alternative to induced parturition.

Fetal Mummification and Maceration

Fetal death without luteolysis of the maternal CL results in fetal mummification or maceration. **Maceration** can occur at any stage of gestation, although usually it is noted only after fetal bone calcification has commenced. Maceration is accompanied by a partially dilated cervix and possibly a fetid discharge apparent in the vagina. **Mummification** becomes evident between 3 and 8 months of gestation and is characterized by autolysis and fluid reabsorption in a sterile environment.[14]

Prostaglandin $F_{2\alpha}$ or an analogue is the therapeutic agent of choice for fetal mummification, with excellent prognosis for return to fertility within 1 to 3 months. Expulsion of the fetus usually occurs within 24 to 72 hours. Retreatment of cows with mummified fetuses still present at reexamination occasionally is necessary. Luteolytic doses of estrogen (see Table 41-1) also results in expulsion of mummified fetuses. Repeated treatments may be necessary at 48-hour intervals.[10,13–15] After treatment, the mummified fetus may become lodged in the vagina, requiring lubrication and manual removal.

Fetal maceration usually results in chronic maternal endometrial damage; therefore, slaughter may be recommended. Response to treatment with $PGF_{2\alpha}$ or estrogen is unrewarding. Macerated bones may be removed at surgery or through a partially dilated cervix, before or after administration of $PGF_{2\alpha}$ or estradiol[14]; however, endometrial damage carries a poor prognosis for return to fertility. Glucocorticoids are ineffective in treating fetal maceration and mummification, because an intact fetoplacental unit is necessary for their mode of action.

CHAPTER 42

Parturition and Dystocia

SCOTT NORMAN and ROBERT S. YOUNGQUIST

Dystocia (difficult birth) occurs when the first or second stage of labor is prolonged and assistance is required for delivery. No clear boundaries exist between dystocia and eutocia (normal birth), but guidelines based on progress and duration of the delivery may aid the veterinarian and the producer in deciding when to interfere with the birth process. In the last century, a lot of improvement occurred in the techniques used to deliver and resuscitate calves. Only in the last three decades, however, has research been effectively directed toward the causes and management of dystocia. This may be associated with the more widespread implementation of herd health programs and the use of computers to facilitate data management. The incidence of dystocia varies but generally is more common among first-calf heifers, because they have not yet reached their mature size, and then decreases with age.[1] Death due to dystocia or as a result of injuries sustained during delivery is the most common cause of calf loss during the first 96 hours post partum, with most losses occurring during the first 24 hours after delivery.[2,3] The subsequent pregnancy rate among dams that suffer dystocia also is reduced.[4–6] Although it is not possible to eliminate dystocia, improvements in management of heifers during their development and observation of cows and heifers during the calving season are critical for reducing calf losses.

This chapter begins with a description of the process of normal parturition (eutocia). The diagnosis and treatment of dystocia are described next. Finally, owing to the importance of dystocia control and prevention, management techniques used to reduce the incidence of dystocia are discussed, with the main focus on specific control measures.

PARTURITION

During the last weeks of gestation, the dam prepares for delivery of the fetus and the initiation of lactation. Enlargement of the udder may begin in heifers at 5 to 6

bovine conceptus secretory proteins. *J Anim Sci* 1984;59:368 Suppl 1.

CHAPTER 42

Parturition and Dystocia

SCOTT NORMAN and ROBERT S. YOUNGQUIST

Dystocia (difficult birth) occurs when the first or second stage of labor is prolonged and assistance is required for delivery. No clear boundaries exist between dystocia and eutocia (normal birth), but guidelines based on progress and duration of the delivery may aid the veterinarian and the producer in deciding when to interfere with the birth process. In the last century, a lot of improvement occurred in the techniques used to deliver and resuscitate calves. Only in the last three decades, however, has research been effectively directed toward the causes and management of dystocia. This may be associated with the more widespread implementation of herd health programs and the use of computers to facilitate data management. The incidence of dystocia varies but generally is more common among first-calf heifers, because they have not yet reached their mature size, and then decreases with age.[1] Death due to dystocia or as a result of injuries sustained during delivery is the most common cause of calf loss during the first 96 hours post partum, with most losses occurring during the first 24 hours after delivery.[2,3] The subsequent pregnancy rate among dams that suffer dystocia also is reduced.[4–6] Although it is not possible to eliminate dystocia, improvements in management of heifers during their development and observation of cows and heifers during the calving season are critical for reducing calf losses.

This chapter begins with a description of the process of normal parturition (eutocia). The diagnosis and treatment of dystocia are described next. Finally, owing to the importance of dystocia control and prevention, management techniques used to reduce the incidence of dystocia are discussed, with the main focus on specific control measures.

PARTURITION

During the last weeks of gestation, the dam prepares for delivery of the fetus and the initiation of lactation. Enlargement of the udder may begin in heifers at 5 to 6

months of gestation but may not be obvious in pluriparous cows until the last weeks of pregnancy. The gland may become tightly swollen, and in severe cases, edema may be so extensive in dairy cows as to require induction of parturition or initiation of milking several days before calving. Initial secretions that can be expressed from the mammary gland are viscid and pale yellow to amber in color. As parturition approaches, colostrum is secreted and is white to yellow, turbid, and opaque. The pelvic ligaments relax under the influence of estrogens, relaxin, and the general hormonal milieu that initiates parturition; the gluteal muscles sink, the tailhead becomes more prominent, and the cranial border of the sacrosciatic ligament becomes less tense. A few hours before calving, the vulva becomes edematous, and the cleft elongates. Unfortunately, none of the signs of approaching parturition are specific enough to permit a precise prediction of the exact time of calving; thus, veterinarians have been admonished "to refrain from making too positive or definite a statement regarding the exact time of parturition, as subsequent events will more often than not prove him wrong."[7] Once initiated, delivery of a calf is a continuous process, but for the convenience of discussion, most authors divide labor into three stages or phases.

The **first stage of labor** signals the beginning of delivery and is characterized by progressive relaxation and dilation of the cervix.[8,9] Increased output of adrenocorticotropic hormone (ACTH) and associated cortisol from the fetal adrenals leads to an increase in the level of the enzyme 17α-hydroxylase in the fetal placenta.[10] This in turn reduces placental progesterone production by allowing pregnenolone to be metabolized through to dehydroepiandrosterone. Maternal plasma progesterone concentrations then decrease because pregnenolone is diverted through to estrogen production, and maternal plasma estrogen concentrations subsequently increase. In addition to converting progesterone to estradiol, fetal corticoids also cause the placenta to synthesize prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$). The synthesis of $PGF_{2\alpha}$ helps abolish the progesterone block to myometrial contractility. As both estradiol and prostaglandin become elevated, the myometrium becomes increasingly more motile and begins to display noticeable contractions. Also, $PGF_{2\alpha}$ causes the corpus luteum of pregnancy to regress, facilitating the decline in progesterone.

As the pressure inside the uterus continues to increase, the fetus rotates so that its presentation is with the front feet and head pointing toward the caudal aspect of the dam. This rotation is important to ensure an uninterrupted delivery. If the fetus fails to achieve the correct presentation, position, or posture, because of either disease or lack of space, dystocia may occur.

The external cervical os of cows may be sufficiently relaxed to admit two to four fingers as much as a week before calving, but the cervix of heifers usually remains tightly closed until the day before calving, when it begins to relax. Dilation of the cervix occurs in two phases. During the preliminary phase, the cervix dilates passively by a decrease in cervical tone. Dilation of the internal cervical os begins 2 to 4 hours after the external os reaches a diameter of 6 to 12 cm. The active phase of cervical dilatation begins approximately when the external os has dilated sufficiently to permit the introduction of a hand and is initiated by increased concentrations of estradiol, coupled with the elevation in levels of $PGF_{2\alpha}$. These hormones induce strong contractions of the myometrium that pull the cervix open and force the fetus and its membranes into the partially dilated cervical canal. Complete cervical effacement occurs when a portion of the fetus enters the cervix and applies mechanical pressure from within the canal.

Pressure on the cervix brought about by increased myometrial contractions and presence of the fetus activates pressure-sensitive neurons located in the cervix that synapse in the spinal cord and eventually synapse with oxytocin-producing neurons in the hypothalamus. Oxytocin released into the systemic circulation acts to facilitate the myometrial contractility initiated by estradiol and $PGF_{2\alpha}$. As pressure against a cervix continues to increase, so does the oxytocin secretion, and the force of contraction of the myometrial smooth muscle begins to peak. With application of this maximal force, the fetal head and forelegs completely enter the cervical canal, the chorioallantois usually ruptures, and the first stage of parturition is complete. At the end of the first stage of labor, the cervix and the vagina are a continuous canal.

It occasionally may be necessary to differentiate between dystocia caused by incomplete cervical dilatation and prolonged first-stage labor. A differential feature of the conditions is that progressive enlargement of the cervical canal can be discerned between two consecutive examinations in cases of prolonged first-stage labor, whereas the status of the cervix remains unchanged in cases of incomplete dilatation.

Clinical signs associated with the first stage of labor most often are observed in primiparous animals; the signs may be minimal or pass unnoticed in older dams. The signs of the first stage of labor generally are those associated with abdominal discomfort and include a variable degree of anorexia, restlessness, shifts of weight from one leg to another, and presence of an arched back with elevated tail. If given the opportunity, most dams will seek solitude away from the remainder of the herd. Some dams may demonstrate mild and intermittent abdominal straining during the late portions of the first stage; thus, the demarcation between the first and the second stage is not as clear in cows as it is in mares. Rupture of the chorioallantois and release of the allantoic fluid ("breaking water") may be a more accurate attribute by which to mark the end of the first stage of labor. The average duration of the first stage of labor is approximately 6 hours, but considerable variation among animals is observed, and the stage may last up to 24 hours in heifers.[11]

The fetus is delivered during the **second stage of labor**, which is characterized by the application of strong abdominal pressure by the dam. Myometrial contractions stimulated by oxytocin force the fetus into and stretch the cervical canal. In particular, the conical shape of the head as the nose enters the cervical canal is important because it progressively dilates the cervix with mechanical pressure. Stretching stimulates the release of more oxytocin from the maternal pituitary gland, which causes further uterine contractions. Oxytocin is thought also

to stimulate release of prostaglandins from the endometrium, which further stimulates myometrial contractions.[12] This positive feed-forward system makes it difficult to stop labor once it has begun. Forms of dystocia that delay or prevent entry of the head or limbs of the fetus into the cervix, to stimulate the pressure receptors, result in little if any abdominal straining by the cow. A typical example is cranial presentation with full flexion of the hips (true breech presentation).

The intact amnion should appear at the vulva as a fluid-filled sac shortly after rupture of the chorioallantois. After the amnion appears, the dam alternates frequently between standing and recumbency. The amnion usually ruptures while the dam is recumbent, and rupture is followed by regular bouts of abdominal straining. Early in the second stage of labor, each bout of abdominal straining consists of 5 to 7 abdominal contractions, which increases to 8 to 10 contractions as the process advances. The cow usually rests in sternal recumbency and may eat between bouts of abdominal straining. As delivery continues, the length of rest periods decreases and the force of abdominal contractions increases. As the contractions become more forceful, the dam rolls to lateral recumbency and lifts the head, hindquarters, and uppermost limbs and may vocalize with each effort. Maximal force is required to deliver the fetal head through the vulva, and in most instances of eutocia the remainder of the fetal body follows with little or no additional effort. In the case of large calves, additional abdominal pressure may be required to deliver the fetal shoulders or hindquarters. Most cows deliver their calves while in lateral recumbency, but a few may complete delivery while standing. Delivery while standing is more common in pluriparous dams than in heifers and may be the result of unintentional disturbance of the cow caused by handlers.

The average length of the second stage of labor in pluriparous cows is 2 to 4 hours, but this stage is longer in heifers because more effort is required to dilate the tissues of the birth canal. A healthy bovine fetus can survive for up to 8 hours after the beginning of the second stage of labor provided that the umbilicus remains intact; survival is longer when uterine contractions are weak or infrequent. Exhaustion and secondary uterine inertia result in cessation of uterine and abdominal contractions after 8 to 12 hours of labor.

The **third stage of labor** is characterized by detachment and expulsion of the cotyledonary placenta. Expulsion of the fetal membranes requires that the chorionic villi become dislodged from the crypts of the maternal side of the placenta. This release of the chorionic villi is believed to be brought about by powerful vasoconstriction of arteries in the villi associated with continued myometrial contractions. Uterine contractions continue after delivery of the fetus and sometimes are fortified by occasional bouts of abdominal straining. Myometrial contractions gradually subside in frequency and amplitude and are not detectable by 2 to 4 days after calving. The time required for expulsion of the placenta averages 8 hours but can range from a few minutes up to 12 hours without being considered abnormal. Most dams rise during the third stage of labor and begin to groom their calf, licking first its hindquarters and then the head and neck. Dams usually continue to face and lick their calves after they stand but soon allow the calf to move alongside, seek the udder, and nurse.

FACTORS CAUSING DYSTOCIA

Causes of dystocia related to management practices are discussed later in the chapter. From a clinical perspective, the etiology of dystocia is multifaceted and includes defects in the dam or the fetus and management factors, or a combination.[13] For purposes of formulating a clinical management plan for an individual animal, it is convenient to divide the causes of dystocia into those of maternal origin and those of fetal origin. It is important to remember, however, that clinical cases may result from multiple underlying disorders and also may require medical treatment to correct concurrent problems, in addition to the more traditional mechanical or surgical treatments.

Maternal Causes of Dystocia

Problems with the dam that impede or prevent delivery include a lack of expulsive force and abnormalities of the birth canal.

Primary uterine inertia. Primary uterine inertia is characterized by failure of the myometrium to contract normally and bring the fetus into the cervical canal. The condition is encountered occasionally in cows, and causes that have been suggested include overstretching of the uterus by multiple or abnormal fetuses, a defect in the myometrium that renders it unable to contract normally, a defect in the hormonal milieu (see the description relating to ineffective labor and physiologic dystocia under "Management and Prevention of Dystocia" later on), and periparturient hypocalcemia. The dam may exhibit a few weak abdominal contractions but does not progress to the second stage of labor. On examination, the cervix is found to be dilated but the fetus has not yet entered the birth canal. The fetal membranes may be intact if labor has not been prolonged. Calves usually are delivered by gentle traction after correction of any defects in posture or position.

Secondary uterine inertia. Secondary uterine inertia is a result of exhaustion of the myometrium after prolonged unsuccessful attempts to deliver a fetus. Treatment is directed at removing the impediment and delivering the fetus by a method appropriate for the clinical circumstances. Sequelae of secondary uterine inertia include retained placenta, delayed uterine involution, and uterine prolapse.

Abnormalities of the birth canal. Delivery may be inhibited by inadequate size of the maternal pelvis, pelvic deformities or exostoses, incomplete dilatation of the cervix, vaginal cystocele, neoplasms of the vulva and vagina, remnants of the müllerian ducts persisting as bands of tissue from the dorsal to ventral walls of the vagina immediately caudal to the cervix, and uterine torsion. Stenosis of the vulva and vestibule may be the result of immaturity or may be a heritable defect in some breeds.

Fetal Causes of Dystocia

Broadly, the fetal origins of dystocia in cattle can be divided into those caused by abnormalities of the fetus (defects in fetal disposition and various forms of maldevelopment resulting in fetal monsters) and those caused by excessive fetal size relative to the maternal pelvis (fetopelvic disproportion).

Abnormal fetal presentation, position, and posture. See the later section "Mutation of Abnormal Presentation, Position, and Posture" for definitions of these and related terms. For normal delivery in cattle, the fetus is in cranial longitudinal presentation and in dorsosacral position, with the head, neck, and forelimbs extended. Caudal presentations are considered abnormal in cattle, but unassisted delivery can occur with the fetus presented caudally if the hindlimbs are extended. Spontaneous delivery with other fetal presentations, positions, or postures is unlikely unless the fetus is quite small or the dam's pelvis is unusually large.

Fetal monsters. A variety of malformations resulting in specific fetal phenotypes and conjoined twins have been described as sporadic causes of dystocia in cattle. Among the fetal monsters more likely to be encountered in cattle are schistosomia reflexus and perosomus elumbus. **Schistosomia reflexus**, shown in Figure 42-1, is characterized by extreme ventral curvature of the spine, so that the head is positioned near the sacrum. The abdominal and thoracic walls are not closed, and the viscera are exposed. Limbs of the affected fetus frequently are rigid because of ankylosis of the joints.

Fig. 42-1 Schistosomia reflexus. These fetuses often are presented in dorsal or ventral transverse presentation. Delivery can be by fetotomy or cesarean section.

Perosomus elumbus is characterized by a nearly normal fetal forepart but flexure and ankylosis of the hindlimbs. Vertebrae are absent caudal to the thorax, and the pelvis is deformed and flattened.

Fetal oversize. The most common cause of dystocia in cattle is fetopelvic disproportion. The situation is most common in heifers where the fetus is of normal size for its breed but the maternal pelvis is of insufficient size (relative oversize) or the fetus may be unusually large and cannot be delivered through a pelvic canal of normal size.

CASE MANAGEMENT OF DYSTOCIA

The spectrum of clinical presentations encountered by veterinary obstetricians is immense. The diagnosis of dystocia usually is made by the owner or manager of the animal, who may decide to seek professional assistance early in the course of delivery or not until labor has been unduly prolonged.

Review of History

The first step in clinical evaluation of bovine dystocia is to obtain as much pertinent history as possible. Although the usefulness and accuracy of the history will vary with the diligence of the manager, the clinician should attempt to obtain at least a minimal amount of information before initiating the examination.

Previous occurrences. If the clinician is not already familiar with the client's management style, it can be useful to gain a brief summary of previous dystocia cases and breeder management. Information on the bull used for the mating period also may be useful in determining the etiology of the current problem, in addition to providing insight for future recommendations. To save time, much of this information can be extracted during conversation as the clinical evaluation proceeds.

Gestation length. The breeding date, if known, should be ascertained. If delivery is premature and dystocia is associated with abortion, the clinician can take steps to reduce or eliminate exposure to infectious causes of bovine abortion that are zoonotic. Prolonged gestation is in most cases associated with excessive fetal size and poor viability.

Progress of the case. It is important to know how long the animal has been in labor. Cows and heifers should be allowed a reasonable amount of time to spontaneously deliver their calves. It is common for cows to vocalize during straining early in stage two of parturition. This is associated with stretching of the soft tissues of the birth canal.[14] Thus, although clinical judgment is necessary, the amount of vocalization during straining may be used as a rough guide to the duration of stage two if the history is not available. If an adequate time for the first or second stage of labor has been exceeded, examination is indicated. Heifers should be allowed a longer time for spontaneous delivery than is required in pluriparous cows. If intervals between observations are excessive (more than 3 hours), the manager will be unable to accurately determine the time of onset of labor, and immediate intervention may be justified. Early obstetric assistance has

been shown to improve the subsequent fertility of beef cows.[15]

The character of the expulsive efforts should be determined—whether they are weak and sporadic or substantial and frequent. In some individual animals, stage two labor may be manifested as only a few weak attempts to deliver the fetus before secondary uterine inertia supervenes. Vigorous and forceful attempts should result in steady progress; if they do not, the dam should be examined.

The clinician should determine if the fetal membranes have ruptured. Rupture of the chorioallantoic membrane and release of the watery allantoic fluid serve to indicate the onset of the second stage of labor. Rupture of the amnion is followed by release of the viscous amniotic fluid. Examination is indicated if delivery is not complete within 2 hours after the amnion appears outside the vulva.

It is important to determine if the patient has been examined, or if any attempts have been made to deliver the calf before attendants sought professional assistance. The ability of managers to determine the cause of dystocia varies, but the results of a proficient examination may be useful to the clinician. Information regarding futile attempts at delivery by attendants may be difficult to elicit, but damage to the birth canal or fetus caused by well-intentioned but inappropriate efforts should be discovered before intervention lest the veterinarian be held responsible.

Restraint

Accessible facilities and demeanor of the patient often dictate the restraint used for examination and relief of dystocia. Facilities and conditions often are less than optimal. Ideally, however, confinement of the parturient dam should be in a dry, well-bedded enclosure of generous size and with sufficient illumination. Difficult vaginal deliveries often are assisted if the dam can be placed in lateral recumbency; therefore, room to cast and restrain a recumbent animal is ideal. Access to a clean water supply also is desirable. A squeeze chute may be suitable for the initial examination, but the inclination of most cows to become recumbent during traction makes this choice undesirable in all but the simplest of deliveries. Although extraction of the fetus is better performed with the dam in lateral recumbency, the initial examination is more readily performed with the animal standing, because pressure within the abdomen is reduced in this posture. Thus, the patient is most conveniently restrained with a halter, but a stanchion or head bail may be used if caution is exercised to prevent asphyxiation or excessive pressure on the carotid arteries should the animal become recumbent during the examination. During delivery, sufficient space should be available behind the patient to allow manipulation of a fetal extractor or fetatome. A position of lateral recumbency can be achieved with a combination of ropes and sedation. Figure 42-2 shows ropes set on a heifer in preparation for casting in lateral recumbency once diagnostic traction has confirmed that vaginal delivery is possible.

Fig. 42-2 Rope placement for casting a heifer before vaginal delivery of the fetus. The side of the chute has been opened in preparation for releasing the head bail and allowing the heifer to exit through the side of the chute. Note that the halter rope is pulled back through the head bail and tied down low to the ground. Sedation may be administered immediately before opening the chute if necessary.

Administration of an epidural anesthetic is not routinely performed if vaginal delivery is to be used, because in most instances the expulsive efforts of the dam are beneficial in assisting delivery. Desensitization of the birth canal and the perineal area usually is reserved for cases that require moderate to extensive manipulation of the fetus before extraction, fetotomy, or surgical delivery is attempted.

Examination

Physical Examination

The clinician should note the general condition of the patient and identify abnormalities that may potentially influence the selection of a method to relieve the dystocia or have an impact on the prognosis. For example, overconditioned feedlot heifers have excessive deposits of fat in the pelvic canal, which reduces its caliber and increases the difficulty of delivery. Recumbent animals should be examined for the possibility of exhaustion, calving paralysis, or hypocalcemia. Pallor of the mucous membranes may suggest internal hemorrhage due to rupture of one of the large blood vessels that supply the uterus. The character of any discharge from the birth canal or any exposed portion of the fetus or membranes should be noted. Fetid or sanguineous discharges are more typical of protracted cases. Yellow-brown discoloration of the fetus or fluids by meconium is an indication of fetal hypoxia, and immediate intervention is indicated.

Rectal Examination

Examination of the reproductive organs by palpation per rectum is indicated in only a few cases of dystocia. The most common indication for rectal palpation is to confirm uterine torsion when stenosis of the cranial vagina is detected during a vaginal examination. Pelvic deformities and exostoses may be more readily detected by palpation per rectum than by vaginal examination.

Other indications for palpation per rectum include elicitation of spontaneous movements of the fetus when it is not possible by vaginal examination, confirmation of uterine rupture, and recognition of hemorrhage into the broad ligaments. Although unusual in cattle, firm feces should be removed from the rectum before the application of extractive force.

Vaginal Examination

Vaginal examination in dystocia almost always implies manual entry into the birth canal. In rare cases, however, speculum examination may be more suitable than manual techniques. Such cases include those in which straining is minimal and conception dates are only approximate.

Two essential requirements for effective obstetric intervention with minimal post-treatment complications are cleanliness and lubrication. Before invasion of the birth canal, the vulva and perineal area and any protruding fetal parts are washed with surgical soap and water. The hands and arms of the operator also are cleansed. Some clinicians prefer to wear shoulder-length plastic sleeves, whereas others find that wearing these sleeves reduces sensitivity and interferes with a thorough examination. Clinicians should be familiar with zoonotic diseases in their geographic area and take appropriate precautions. The hands and arms should be coated with a generous amount of a nonirritating obstetric lubricant before entry into the vaginal canal. It often is beneficial to pump 3 to 5 L of lubricant into the birth canal, in addition to applying lubrication to the operator's arms. Note that despite the long-standing doctrine of using warm soapy water during obstetric intervention, soaps are not the ideal product for the job. Although they may provide some short-term lubrication, they quickly increase the friction encountered owing to their propensity to cut fats and oils from the contact surfaces. In protracted cases with autolytic changes in the fetus, some clinicians elect to apply generous amounts of lanolin or barrier cream to the arms in order to reduce skin irritation and folliculitis, which may result from prolonged exposure to fetid tissues and fluids.

The birth canal and fetus are first examined for lesions or hemorrhage that may have been induced by previous attempts at delivery, and the caretaker is informed of their presence. The operator then determines as accurately as possible the presentation, position, and posture of the fetus and the presence, if any, of congenital abnormalities. In some cases, it is difficult to determine if the forelimbs or hindlimbs of the fetus are present in the birth canal; fetal elbow and fetal hock may have similar characteristics on palpation, which may confuse even the experienced operator. The limbs can be differentiated by starting at the hoof and counting the joints from distal to proximal up the limb. The forelimb has a carpal joint between the fetlock joint and the elbow, whereas on the hindlimb, the hock joint is palpable immediately proximal to the fetlock joint. The ears, eyes, and mandible can be used to identify the head, whereas the presence of the tail indicates a caudal presentation.

If the fetus is in dorsosacral position and the soles of the fetal hooves are directed ventrally, the limbs presented to the birth canal are the forelimbs, whereas if the soles are directed dorsally, the hindlimbs are presented first. The disposition of fetuses in transverse presentations sometimes is difficult to ascertain, and a careful examination is required. Fortunately, transverse presentation is rare in cattle, being commonly associated with fetal deformities or fetal monsters such as schistosoma reflexus.

Although cattle generally are considered to be uniparous, twins and greater multiples are not rare; thus, the number of fetuses must be determined and their appendages identified. The location of the internal septum between the two uterine horns is identified so it will not be inadvertently damaged by the wire saw should a fetotomy be selected as the method by which to relieve dystocia.

After determining the disposition of the fetus, the clinician then must determine if it is alive or dead before selecting the appropriate method to complete delivery.[24] In cranial presentation, the interdigital claw reflex can be elicited by pinching the web of tissue between the claws. A vigorous fetus responds by withdrawing the foot. A false positive result may occur if the operator mistakes movement caused by the maternal abdominal press for that of the fetus. False negative results can occur in live calves if the head and limbs are wedged in the birth canal. The swallowing reflex is elicited by applying pressure at the base of the tongue, to which a normal calf responds by swallowing or sucking. Slow or exaggerated reactions may be associated with hypoxia or may be agonal. Slight pressure on the eyeball elicits movement of the eyeball or eyelid. The eye reflex is preserved even in severely acidotic calves. The reflexes disappear in a peripheral to central progression as the condition of the fetus deteriorates. That is, the reflexes requiring the longest nerve pathways disappear before those with shorter nerve pathways as acidosis increases. Thus, the interdigital claw reflex disappears first, and the eye reflex is preserved longest. This differential loss of peripheral compared with central reflexes may aid assessment of the physiologic status of the calf.

In caudal presentation, the interdigital claw reflex of the hindlimb is similar to that in the forelimbs; however, it becomes negative earlier during the course of delivery than does the reflex in the forelimbs. Thus, the interdigital claw reflex may be negative in a viable calf, and elicitation of this reflex is a good prognostic sign. The anal reflex sometimes is used to assess the status of a fetus in caudal presentation. This reflex is elicited by pushing the examiner's finger against or into the anus. Evaluation of the response is subjective, however, and the reflex can be absent in a viable fetus.

If the fetal reflexes are ambiguous or absent, the obstetrician should examine the fetal heartbeat or umbilical cord pulse. The heartbeat can be palpated by passing the hand between the fetal forelimbs along the ventral aspect of the neck to the sternum. The fetal heartbeat is then palpable with the examiner's fingers placed on the left side of the fetal thorax. Palpation of the heartbeat in fetuses presented caudally is difficult. The normal intrauterine heart rate in calf fetuses of 70 to 120 beats per minute increases to 90 to 120 beats per minute during

delivery. The heart rate may fall to 40 to 60 beats per minute during uterine contractions. Hypoxia of the dam caused by excitement or exertion can lead to a more severe drop in fetal heart rate. Prolonged or excessive extractive force can cause the fetal heart rate to drop to near zero. As a calf becomes acidotic as a result of delayed delivery, the heart rate first increases to 140 beats per minute and then falls and becomes irregular as its condition deteriorates.

The umbilical cord of fetuses in cranial presentation is located by palpating it between the last rib and the abdomen. In caudal presentation, the umbilical cord is easily accessible. Pulsation of the umbilical vessels can be felt by applying slight pressure to the cord. The cord may be wrapped around the fetal abdomen or limb or may enter the birth canal alongside the fetus. Although not commonly required, the location of the cord can be ascertained and the cord repositioned if necessary. Pressure on the cord should be avoided during mutation of malpostures and during extraction.

Severe congestion of the head, tongue, and forelegs is the result of prolonged impaction of the fetus in the birth canal. The condition may occur in vigorous or moribund calves and does not suggest a prognosis. If delivered alive, affected calves have difficulty nursing and may require assistance plus the administration of anti-inflammatory agents.

Frequent or violent spontaneous fetal movements sometimes can be seen or felt. Exaggerated movements may be agonal, indicative of impending death due to hypoxia.

After the status of the fetus has been determined, the operator then must estimate the size of the fetus relative to the size of the maternal pelvic inlet and birth canal. Delivery by traction results in fetal respiratory acidosis, and the operator must determine if the risks of harming the dam and the fetus during extraction are justified.

For inexperienced obstetricians, effective guidelines have been formulated to assist in the decision-making process for determining if vaginal delivery is possible.[14] The basis for these guidelines sometimes is referred to as "diagnostic traction." When the fetus is in cranial presentation, dorsosacral position, and normal posture, if one person can pull the fetlocks 10 to 15 cm beyond the vulva (approximately one hand's breadth), the points of the shoulders will pass the maternal iliac shafts and the calf can be delivered vaginally if correct delivery techniques are used. When the fetus is in caudal presentation, dorsosacral position, and normal posture, if one person pulling on each leg can make the hocks appear at the vulva, the greater trochanters will pass the iliac shafts and the calf can be delivered vaginally. As experience is gained, other factors can be included in the decision-making process. For example, the chance for successful delivery by traction is increased in the following circumstances[14]:

- The head of a fetus in cranial presentation has spontaneously been brought into the pelvic inlet.
- The fetal hooves protrude from the vulva during an abdominal press and glide back into the birth canal when straining stops.
- A heifer vocalizes while applying an abdominal press—an indication that the birth canal is still being dilated.
- The fetal fetlock joints have been delivered beyond the vulva spontaneously.

By contrast, the chance for successful delivery by traction is reduced if the following conditions exist:

- The dam has not been able to spontaneously deliver the fetal head into the pelvis after a prolonged period of labor.
- The fetus is positioned in the birth canal with the forelimbs crossed—an indication that the width of the fetus at the points of the shoulders is excessive.
- The hooves are rotated with their volar surfaces directed medially—an indication that the elbows are forced together by a narrow ventral pelvic inlet.
- The fetus is so tightly lodged in the birth canal that it does not move when the abdominal press is applied—an indication that the birth canal is maximally dilated and that spontaneous delivery is not possible.

The vaginal examination is concluded by assessing the degree of dilatation of the vagina, vestibulovaginal sphincter, and vulva. Most ruptures of the vagina, vulva, and perineum occur during obstetric intervention and should be prevented by manual dilatation of the birth canal before application of traction. Manual dilatation of the caudal reproductive tract is an extremely important part of delivery technique, with many clinicians suggesting that the need for episiotomy can be dramatically reduced if time is taken to ensure that effective dilatation is achieved before application of traction. In addition, the stress and resultant acidosis in the calf are reduced, because resistance to delivery of the head and thorax is less. After application of an obstetric lubricant, the birth canal can be stretched by clasping the hands together and inserting both arms. Outward pressure with the forearms is placed in a diagonal direction with one forearm at the 2 o'clock position and the other forearm at the 8 o'clock position. Continual pressure is applied in the form of a wedge for as long as the operator can manage; then the arms are moved to the other diagonal of 4 o'clock and 11 o'clock, and the procedure is repeated. Tenacity is essential, because 10 to 20 minutes may be required to dilate the birth canal sufficiently to prevent soft tissue injury.

On completion of the examination and assessment of the condition of the fetus, the dam, and the birth canal, the clinician must then formulate a plan for resolution of the dystocia. The available options in cattle are mutation of abnormal presentation, position, or posture; forced extraction; fetotomy; pelvic symphysiotomy; and cesarean section.[16] Euthanasia may be indicated in situations in which the value of the animal is limited and the prognosis poor. When formulating a plan to deliver the fetus, the clinician must consider the value of the dam and the potential value of her offspring, the cost of the procedure and aftercare, and the prognosis for the life of

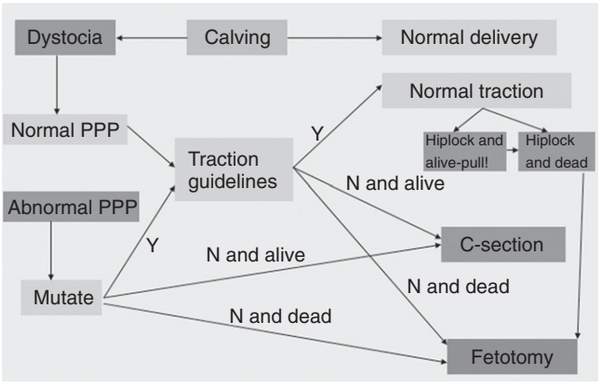

Fig. 42-3 Decision-making guidelines for dystocia case treatment (adapted from Schuijt, 1988). Y, yes; N, no. Note that a safe vaginal delivery is possible only if traction guidelines are met and correct delivery technique is used.

the dam and the fetus and for the dam's future reproductive performance. Often, the facilities and assistance available, as well as the personal preferences of the animal's owner and the clinician, will influence the decision. Figure 42-3 is a flow diagram of the decision-making process that can be used by the clinician in clinical management of dystocia.

MUTATION OF ABNORMAL PRESENTATION, POSITION, AND POSTURE

Definitions

In order to effectively communicate the details of a dystocia case, it is important to standardize terminology. In this book, the following definitions are used.

Presentation

Presentation is the relation of the spinal axis of the fetus to that of the dam. Presentation can be either longitudinal or transverse. The fetus' orientation is either **cranial** or **caudal** in the longitudinal presentation and **dorsal** or **ventral** in the transverse presentation. **Cranial longitudinal** is considered the normal presentation. Note the general trend away from the traditional use of the human descriptors of anterior and posterior in veterinary science.

Position

Position is the relation of the dorsum of the fetus to the quadrants of the maternal pelvis. These quadrants are the sacrum, right ilium, pubis, and left ilium. **Dorsosacral** is considered the normal position.

Posture

Posture is the relation of the fetal extremities (head, neck, or limbs) to its own body. Extremities may be flexed, extended, or retained (usually referring to the head). Retention can be to the right, to the left, or above or below the fetus.

Mutation

Mutation is defined as the process by which a fetus is restored to normal presentation, position, and posture by repulsion, rotation, version, or extension of extremities. Abnormalities of fetal posture generally are easier to correct when the dam is standing. In specific circumstances, however, placement of the dam in lateral recumbency can be advantageous, particularly if facilities such as a hydraulic tilt table or even a sloped loading ramp are accessible. For example, with retention of the fetal head, if the cow can be placed in lateral recumbency with the fetal head uppermost and the forequarters of the cow elevated slightly, mutation of the head to a normal posture can be facilitated. If mutation cannot be completed in 15 to 30 minutes, an alternate method for delivery should be selected.

Repulsion

Repulsion of the fetus out of the maternal pelvis into the uterine cavity where more space is available for correction is the first step in mutation. The fetus and birth canal must be well lubricated, and 3 to 5 L of a water-based lubricant can be gently introduced around the fetus through a stomach tube by means of a pump. It may be necessary to abolish abdominal straining with an epidural anesthetic, but the expulsive efforts of the dam will not subsequently be available for delivery of the fetus. In countries where it is registered for use, clenbuterol may be administered to assist in relaxation of the uterine musculature.

Care should be exercised in repelling a fetus, because uterine rupture may result from excessive pressure. Various instruments have been used for repulsion of a fetus, the most commonly used device being the Kuhn's crutch. In general, however, use of the operator's hands and arms is recommended to reduce the risk of uterine rupture below that associated with introduction of metal instruments into the uterus. In neglected cases, the uterus may be tightly contracted around the fetus, and repulsion should not be attempted.

Rotation

Rotation is defined as turning the fetus on its longitudinal axis to bring it from dorsoilial or dorsopubic position to dorsosacral position. Partial rotation also is an essential component of the routine vaginal delivery technique to ensure that the fetal hips enter the maternal pelvis on a diagonal.

In many cases, rotation can be accomplished by the hand and arm of the operator. By grasping the humerus of the ventral limb near the shoulder joint, the operator lifts the fetus upward and medially. If an assistant is available, traction on the dorsal fetal limb in a downward and medial direction can be applied to aid in rotating the fetus. Alternatively, the fetal limbs can be crossed and rotational force applied to bring the fetus to dorsosacral position. In difficult cases, use of a detorsion rod may be necessary, but excessive force that may result in injury to the dam and the fetus should be avoided.

Version

Version is defined as turning the fetus on its transverse axis into cranial or caudal presentation. Transverse pres-

entation fortunately is rare in cattle but must be converted to longitudinal presentation before delivery is attempted. Extractive force is applied to the portion of the fetus closest to the maternal pelvis while the opposite pole of the fetus is repelled. Version usually is limited to 90 degrees, and attempts to convert caudal presentation to cranial presentation are not likely to be successful and will commonly result in uterine tears.

Correction of Displacement of the Extremities

Mutation of malposture of the fetal extremities usually requires that the fetus be repelled out of the maternal pelvis before attempts at correction. In general, correction of flexion of an extremity is accomplished by repelling the proximal end, rotating the middle portion laterally, and applying traction to the distal end. Repelling and rotating forces can be applied with the operator's hand. Traction can be applied by the operator if sufficient space is available in the birth canal to permit the introduction of both arms, or by an assistant using an obstetric chain or snare.

Displacement of the Head

In cattle, the head most commonly is deviated to the left side of the fetus and lies against the thoracic wall. The malposture is corrected by grasping the orbital grooves with the thumb and middle finger (forceps grip) and drawing the head into the maternal pelvis. A rope snare placed behind the incisor teeth may be useful in difficult cases. Traction to redirect the head can be applied with the snare by the operator or by an assistant while with the other hand the operator guides the head and protects the uterine wall from the incisor teeth by covering the fetal mouth.

The head may be deviated ventrally between the forelimbs, with the mandible resting against the sternum. A hasty examination may fail to reveal the presence of the head, and the malposture may be mistaken for a case of caudal presentation. In some instances, the malposture can be corrected by repelling the fetal forehead with the thumbs while simultaneously lifting the jaw with the fingers. Correction in more severe cases requires that one or both forelimbs be repelled and flexed at the carpus, elbow, and shoulder joints. Space is then available to convert the ventral displacement of the head to lateral displacement, which is then corrected by drawing the head into the pelvis. The induced malposture of the forelimb is subsequently corrected after the head is in its proper position. Should attempts to reposition the head by these methods not be successful, the dam can be sedated, cast, and rolled to dorsal recumbency. The fetus then falls toward the maternal spine and away from the narrow ventral portion of the pelvis, allowing the head to be more easily guided into the pelvic canal.

Displacements of the Forelimbs

Unilateral or bilateral carpal flexion can be responsible for dystocia in cattle. If the flexed carpus along with the fetal head is within the maternal pelvis, the situation is described as engaged carpal flexion, whereas if the flexed carpus is cranial to the maternal pelvis it is described as disengaged carpal flexion. Correction requires that the fetus and the flexed limb be repelled cranially out of the pelvis to increase the space available for correction. The operator introduces the hand corresponding to the side of the displacement into the birth canal and grasps the metacarpus immediately proximal to the fetlock. Then the limb is lifted dorsally and the shoulder and elbow joints are flexed. When the fetlock is above the pubis, the hoof is cupped in the hand and pulled into the pelvis. If needed, traction can be applied with a snare placed proximal to the fetlock joint. While lifting and repelling the carpus with one hand, the operator applies gentle traction to draw the hoof into the pelvis with the other.

The shoulder joints also may be unilaterally or bilaterally flexed and the forelimb positioned alongside or under the fetal abdomen. Correction is accomplished by grasping the radius and pulling it toward the maternal pelvis. Shoulder flexion is thus converted to carpal flexion, which is then corrected by the methods previously described. If a traction snare can be placed distal to the carpal joint, it can be used to apply extractive force with one hand while the other repels the shoulder joint.

Shoulder-elbow flexion or elbow lock posture is most common in heifers and results in impaction of the elbow joints on the pelvic brim. The condition is recognized when the muzzle of the fetus lies directly above the hooves, rather than in its normal position approximately at the middle of the metacarpus. The malposture is corrected by first repelling the fetal body into the birth canal and then applying traction to the affected limbs, one at a time, until the elbow and shoulder joints are fully extended.

Foot-nape posture is not common in cattle but arises when one or both of the forelimbs is displaced upward to lie on top of the head and neck. The defective posture is corrected by grasping the fetlock of the affected limb and forcing it downward and laterally while simultaneously lifting and repelling the head with the other hand until the forelimbs are in their normal position. In protracted cases, continued attempts to deliver the fetus may force the hoof through the dorsal wall of the vestibule, resulting in the formation of a fistula or perineal laceration.

Displacements of the Hindlimbs

Displacement of the hindlimbs is rarely a problem unless the fetus is in caudal presentation. The incidence of caudal presentation in cattle can vary depending on management conditions and genetics, and such displacements frequently are complicated by dystocia. One or both hindlimbs may be retained and flexed at the hock or at the hip.

To correct hock flexion posture, the limb is grasped at the metatarsus and repelled cranially and laterally until sufficient space is available to draw the hoof in a caudal and medial direction into the pelvic canal. The operator should cover the hoof with one hand to protect the uterine wall as it is rotated medially. In some cases, application of a snare distal to the fetlock joint can facilitate

correction. The cord is placed between the digits of the affected hoof, and traction is applied. The operator then applies opposing forces by repelling the hock while simultaneously applying traction to the snare. This action results in flexion of the fetlock and pastern joints while the hoof is drawn toward the pelvic brim.

Bilateral hip flexion (colloquially referred to as "true breech" presentation) prevents entry of the fetus into the cervix; thus, the stimulus for the abdominal press is lacking, and signs of the second stage of labor may be minimal or absent. Hip flexion is corrected by grasping the lateral aspect of the tibia as closely as possible relative to the hock. The hock and stifle joints are flexed by drawing the hock toward the maternal pelvis. After the hock and stifle joints are fully flexed, the malposture becomes hock flexion, which subsequently is corrected as previously described.

Ventrovertical, or dog-sitting, position causes dystocia in fetuses presented cranially because of flexion of the hindlimbs at the hips. The hooves may be impacted against the maternal pelvis or lie in the vagina alongside the forelimbs. The cranial portion of the fetus is delivered normally, but the impediment is discovered when delivery cannot be completed. The condition is diagnosed by careful examination, which may be difficult if the cranial portions of the fetus occupy the pelvic canal. An attempt may be made to correct the malposture by repelling the hindlimbs as deeply as possible into the uterus. Correction is likely to be successful only when the fetus is small. Delivery by cesarean section or fetotomy may be preferable in many cases.

DELIVERY BY EXTRACTION

Early works on the topic of bovine obstetrics were written by physicians, with the first account published in 1793 and credited to Johann Günther Eberhard.[17,18] Since that time, various guidelines for delivery of bovine fetuses by extraction have been developed and modified. Advances in the science of veterinary surgery during the last half of the twentieth century have allowed veterinarians to routinely perform successful cesarean sections and have obviated the need for every case of dystocia. to be resolved by some form of vaginal delivery. The most recent obstetric guidelines are those developed and published by theriogenologists at the University of Utrecht, The Netherlands.[14]

Application of Extractive Force

During normal parturition, it has been estimated that an average force of approximately 70 kg (150 lb) is required to deliver a bovine fetus, and that 40% of this pressure is supplied by uterine contractions and 60% by the abdominal press.[19] The force required to fracture the leg of a calf varies with its weight. When traction is applied to the dorsal surface of a limb with an obstetric chain around the pastern, a mean force of 170 kg is required to fracture the leg.[20] The mean force that can be generated by veterinary students is 180 kg, with strong persons able to apply as much as 200 kg of force. A mechanical fetal extractor is capable of applying approximately 400 kg of force, and a tractor may apply greater than 5000 kg, far in excess of that considered safe. Extractive force should be applied only simultaneously with the dam's abdominal press, and tension is released when the dam ceases to strain. The abdominal press pulls the maternal pelvis into a position more nearly perpendicular to the spinal column and allows the pelvic inlet to more easily accommodate passage of the fetus. Maximum benefit from the movement of the pelvis via the sacroiliac joint is gained with the cow in lateral recumbency—one of the advantages of completing vaginal deliveries in the recumbent animal.

During a normal extraction, the force and duration of traction should not cause harm to either the dam or the fetus.[14] For this reason, the procedure should be described as "delivering" the calf, rather than "pulling" the calf. Delivering a calf implies that care has been taken to protect the health and welfare of the cow and the calf by selecting the most appropriate option for the clinical circumstances. By contrast, "pulling" a calf implies just one goal, to extract the calf, without necessarily considering the welfare of the cow and the calf. It is important from a philosophical viewpoint that veterinarians and attendants are clear on how the use of terminology can influence attitudes and behavior.

Ideally, the force applied for traction should be limited to less than the force that can be applied by one person (<160 kg). This commonly will be possible in cases in which presentation, position, and posture are normal; correct delivery techniques have been employed; and the guidelines for extraction outlined previously have been met. In a powerful extraction, the force applied is greater than for a normal extraction but is less than the pulling power of two persons (approximately 300 kg). The obstetrician needs to be aware that this amount of force has the potential to harm the dam or the fetus and that correct delivery technique such as rotation of the fetal hips before engaging in the maternal pelvis is essential. The only indication for applying the pulling power of more than two persons is in the case of hiplock of a valuable calf.

In addition to fractures of the legs,[21] improper or excessive obstetric traction has been reported to result in fractures of the ribs and vertebrae.[20,22] Calves delivered in cranial presentation also may suffer damage to the femoral nerve, with subsequent neurogenic atrophy of the muscles of the hindlimb, due to trauma associated with failure of the stifle joints to enter the pelvic canal.[23] The effect on the cow of excessive traction can include maternal obstetric paralysis, pelvic or hip fractures, and soft tissue tears of the reproductive tract. All of these potential complications negate any short-term benefit that may be gained from succumbing to the temptation to use excessive traction to effect a delivery.

Mechanical fetal extractors (Fig. 42-4) are useful devices when minimal human assistance is available. To avoid injury to the cow or the calf, however, it is essential that they be used in the manner for which they were intended. These devices are best used as a bent lever, with traction being applied to the fetus only when the cow strains. Before use, it is fundamental that the case be properly assessed and that a vaginal delivery has been

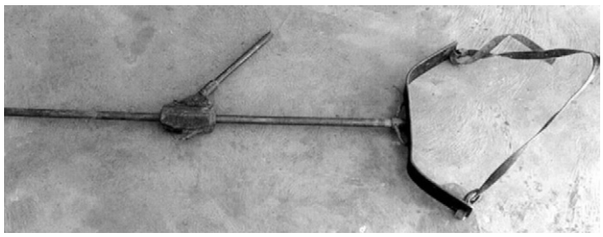

Fig. 42-4 Mechanical fetal extractors are useful for applying traction when minimal human assistance is available. To avoid applying excessive traction, such devices should be used only when diagnostic traction guidelines indicate that vaginal delivery is possible. In addition, they are designed to be used as a bent lever, with traction applied during maternal straining.

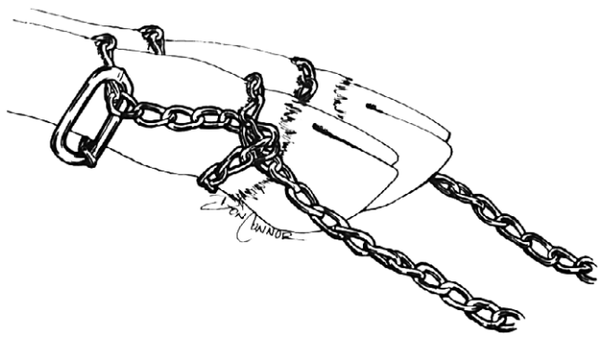

Fig. 42-5 In North America, the most common method of applying obstetric chains on a bovine fetus is to place the loop of the chain above the fetlock joint and a half-hitch around the pastern. Traction is applied to the dorsal aspect of the limb. (Original art by Mr. Don Conner, College of Veterinary Medicine, University of Missouri.)

determined to be the best option. The device is positioned on the cow and the chains from the calf's legs are attached to the hook on the ratchet. The ratchet is worked caudally along the shaft of the device until firm tension on the calf's legs is achieved. As the cow commences an abdominal strain, the shaft of the device is pushed firmly in a ventral direction to assist with the delivery. Once maternal straining ceases, the shaft is lifted dorsally and the ratchet worked to again take up the tension, in preparation for the next abdominal press.

Obstetric chains commonly are used to apply traction to the limbs of the fetus, but snares made from nylon or soft rope are equally serviceable. The main requirements with the material used to apply traction are that it can be easily cleaned, it can be easily released from the limb when traction is stopped, and it does not cause excessive trauma to the limb of the calf. The traditional method of applying obstetric chains used by many veterinarians in North America is to place a loop of the chain proximal to the fetlock joint of the fetus and place a half-hitch of the chain around the pastern (Fig. 42-5). It is thought that this practice spreads the extractive force over a larger area and may reduce the chances of injuring the fetus. Other veterinary obstetricians recommend, however, that only a single loop of chain be placed around the pastern, between the hoof and the fetlock joint.[24] In either mode of application, it is important that the large link be positioned to allow application of the force of traction along the dorsal aspect of the limb. This method of placement reduces limb fractures.

Although it is preferable for the dam to be standing during the initial examination, extraction is best attempted with the dam in right lateral recumbency. Delivering the calf with the cow in lateral recumbency is associated with a number of advantages. These include the previously mentioned movement of the pelvis at the sacroiliac joint; maximizing the potential movement of the cartilaginous pubic symphysis in heifers; and reduced gravitational effect negating the extractive force, because the operator is not required to lift the entire weight of a large fetus to bring it to the level of the pelvis. In addition, the dam can more effectively apply the abdominal press, and mechanical assistance can be applied more efficiently. An added advantage is that contamination of the area is reduced, because feces tend to fall away from the vulva and perineum when the dam is recumbent. Plastic trash bags are useful as ground sheets if the delivery is to be completed in a contaminated area.

Extraction of the Fetus in Cranial Presentation

The operator must determine if extraction is likely to be possible without endangering the dam or the fetus. The first step in delivering a fetus in cranial presentation is to position the head and extended forelimbs within the pelvic cavity. By applying traction simultaneously to both forelimbs, the strength of one person should be sufficient to pull the head into the pelvis while the dam applies an abdominal press. Traction is not placed on the head of the fetus, but the operator's hand is placed behind the head to guide it into the pelvis. The weight of an oversized calf may prevent the head from being pulled into the pelvis if the dam is standing, and it may be beneficial to cast the cow into right lateral recumbency before applying traction. If the head cannot be brought into the pelvis, a safe vaginal delivery is unlikely and an alternate method should be chosen.

After the head has been drawn into the pelvis or if delivery has progressed spontaneously to that point, the operator must determine whether continued traction is warranted by evaluating the space available between the fetal cranium and the maternal sacrum. To make this assessment, the extractive force of one person is applied simultaneously with the abdominal press, and the guidelines for extraction in cranial presentation described previously can be applied. An additional guide to the appropriateness of vaginal delivery is as follows: With the cow standing and one assistant applying traction, the operator should be able pass a hand between the cranium and the sacrum and palpate the points of both shoulder joints 10 cm or less cranial to the iliac shafts. The shoulder joints should be 5 cm or less cranial to the iliac shafts if the dam is recumbent. If the operator determines that an attempt at delivery by extraction is justified, the following procedures have been recommended.[14,25]

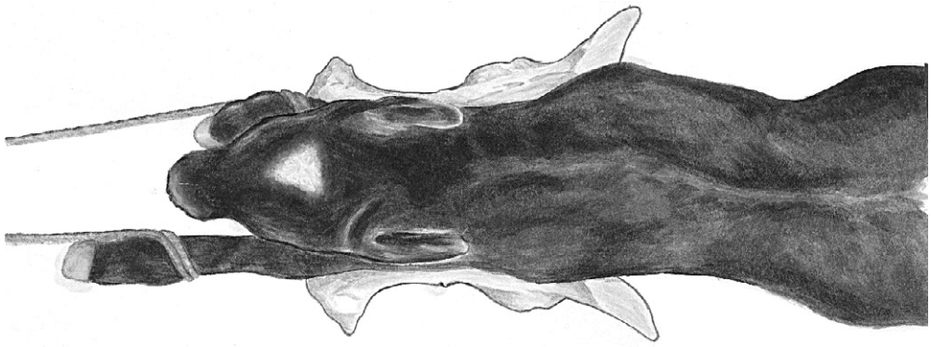

Fig. 42-6 Dorsal view of the proper application of traction for delivery of an oversized bovine fetus. Traction is applied to one limb, and that shoulder and elbow are extended. After the first limb has been extended, traction is applied to the remaining limb. Thus, the shoulders enter the maternal pelvis successively, not simultaneously. (Original art by Ms. Carmen Reed, *Dairy herd management.* Lenexa, KS: Vance Publishing, used with permission.)

The dam is cast in right lateral recumbency, and additional lubricant is pumped around the fetus if necessary. Unilateral traction is applied by one person to the left forelimb of the fetus until the shoulder is brought past the pelvic inlet (Fig. 42-6). In most instances, the shoulder can be felt to pass the ilium, but if this is not detected, it can be assumed that the shoulder has passed the ilium when the fetlock joint protrudes 10 to 15 cm (approximately one hand breadth) beyond the vulva. Then, extractive force is placed by a second person on the right forelimb until that shoulder is brought past the pelvic inlet. Delivery by traction is possible only if the second limb can be extended. If the second shoulder cannot be drawn past the ilium, the operator should elect delivery by cesarean section or fetotomy. A common error is to apply traction to both forelimbs before the shoulder joints have traversed the pelvic inlet. After both shoulder joints have passed the pelvic inlet, traction is applied simultaneously to both forelimbs in a caudal and slightly ventral direction until the head emerges from the birth canal.

The fetal hips and stifle joints constitute the next obstacle to delivery of a fetus in cranial presentation. Unfortunately, the pelvic canal of cows is oval in shape, with the greatest diameter between the sacrum and the pubis, whereas at the level of the stifle joints, the width of the fetus is greater than its height (Fig. 42-7). Thus, the fetus must be rotated from dorsosacral position to dorsoilial position to permit the widest portion of the fetal hindpart to pass through the largest diameter of the maternal pelvis. To achieve this goal, rotation of the fetus must begin as soon as the head emerges from the vulva and can be initiated by having the assistants exchange chains while they continue to apply traction. In most cases it is necessary to rotate the forepart of the fetus nearly 180 degrees to obtain the 60- to 90-degree rotation of the hindpart required for proper entry of the stifle joints into the pelvis. If sufficient rotation is not obtained by this maneuver, the operator can complete the process by wrapping the hands and arms around the fetal neck

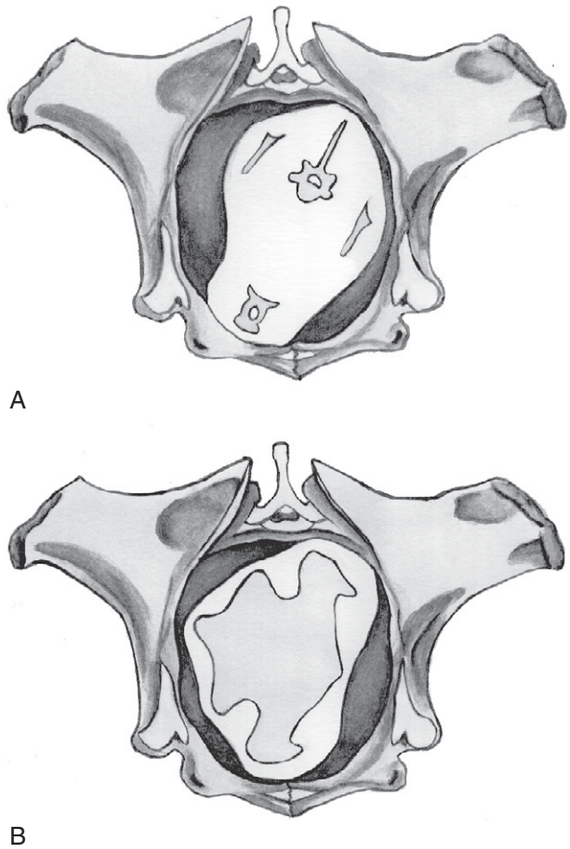

Fig. 42-7 **A,** Cross-sectional view of the fetal thorax as it passes through the maternal pelvis. The shape of the fetus conforms to the maternal pelvis, and the cranial portion of the fetus can be delivered in dorsosacral position. **B,** Cross-sectional view of the fetal hips and stifle joints as the caudal portion of the fetus is rotated into dorsoilial position to permit the largest part of the fetus to enter the maternal pelvis at its greatest diameter. Rotation of the fetus is begun as soon as its head emerges from the birth canal. (Original art by Ms. Carmen Reed, *Dairy herd management.* Lenexa, KS: Vance Publishing, used with permission.)

and applying rotational force. After the fetus has been sufficiently rotated, the operator stimulates it to breathe by clearing mucus from the nostrils and tickling the nostrils with a straw. After a normal breathing pattern has been established, traction is continued simultaneously on both limbs in a caudal and slightly dorsal direction and in concert with the dam's abdominal press.

Hiplock. Hiplock may occur despite use of proper technique, or cases may progress to that point spontaneously. In cases of hiplock, traction should be suspended and the fetus, if living, should be stimulated to breathe. An attempt should be made to palpate the fetal hindpart and determine the degree of rotation. If sufficient rotation has not been accomplished, the fetus should be repelled and rotated into position. In cases of hiplock of a living fetus, the extractive force of as many as three assistants may be applied in an attempt to deliver the fetus. Traction is applied in a caudal and slightly dorsal direction simultaneously with the dam's abdominal press. Continuous application of traction is contraindicated because the fetus has difficulty breathing while extractive force is employed and may die of hypoxia. If efforts to deliver the fetus are not successful, the fetus can be pulled sharply around toward the dam's flank. This tactic further rotates the fetal pelvis and causes one hip to enter the pelvis ahead of the other. Should these procedures fail to result in delivery, the final option is partial fetotomy or, in some instances, pubic symphysiotomy.

Extraction of the Fetus in Caudal Presentation

Delivery of a fetus in caudal presentation poses relatively more risk to the life of the fetus than does delivery in cranial presentation. With caudal presentation, the umbilical cord ruptures early, and the fetus is likely to become hypoxic and die before the head can be delivered. Therefore, delivery of fetuses in caudal presentation should be more rapid than that of fetuses in cranial presentation, and a decision should be made early on to resort to a cesarean section if the fetus is alive and delivery is impeded.

Before attempting delivery, the fetus is first rotated into dorsoilial position so that the widest portion of the fetal hindpart approaches the widest diameter of the pelvis. Rotation can be accomplished by crossing and twisting the hindlimbs. After the fetus has been rotated, two assistants apply traction simultaneously to both hindlimbs, in concert with the dam's abdominal press, in a caudal and slightly dorsal direction. Delivery is likely to be successful if the fetus can be extracted sufficiently to expose both hocks outside the vulva. If the hocks cannot be exposed, a safe delivery is unlikely and another form of delivery should be selected. After the hips have passed the pelvic inlet, the fetus is rotated back to its normal dorsosacral position by applying caudal and slightly ventral traction. When the hips have exited the vulva, the fetus is extracted as rapidly as possible, but traction is applied only while the dam strains. Excessive traction on fetuses in caudal presentation has been implicated as the cause of several injuries including fracture of vertebrae in the thoracolumbar region.

DELIVERY BY PELVIC SYMPHYSIOTOMY

In some geographic regions, the technique of pelvic symphysiotomy or pelvis splitting has been used to deliver oversized fetuses from underdeveloped beef heifers less than 26 months of age.[26] It is not indicated in older animals or in dairy heifers. Although the technique is effective, it lacks aesthetic appeal and may not be acceptable to some clients. The objective of the procedure is to split the pelvic symphysis and allow the pelvic canal to expand while traction is exerted on the fetus.

The patient is restrained with a halter and the perineal area desensitized with an epidural anesthetic. The skin ventral to the vulva is shaved and the perineal area prepared for aseptic surgery. An incision is made on the midline ventral to the vulva and deepened by blunt dissection until the caudal border of the ischium is reached. The operator places one hand in the vagina as a guide and with the other holds the blade of a heavy chisel against the symphysis. The chisel is driven cranially through the symphysis to a point 1 cm from the cranial border and the remainder of the symphysis is split by lateral pressure on the shaft of the chisel. As the fetus is extracted, the halves of the pelvis are separated and the pelvic canal is allowed to expand.

The skin incision is not closed but allowed to heal by second intention. The patient is confined to a box stall for 10 days after surgery. Antibiotics and other supportive treatments are administered as indicated.

DELIVERY BY FETOTOMY

If delivery by traction is not possible without danger to the dam or the fetus, the veterinary obstetrician must consider the option of cesarean section or fetotomy. Two basic types of fetotomy have been described in the veterinary literature. Subcutaneous fetotomy is performed with chisels and hooks, and fetal parts are removed while leaving the fetal skin to protect the genital tract and serve as points of traction. Percutaneous fetotomy is performed with a fetatome and wire saw, with sections of the fetus progressively removed.[27]

Equipment Required for Fetotomy

There are few procedures in veterinary obstetrics in which the need for experience and for proper equipment are as essential as in fetotomy. The basic equipment required is shown in Figure 42-8 and described next.

Fetatome. A two-barrel fetatome with a smooth head made from hardened steel is used. A hardened head is required to prevent the saw wire from cutting into the head during cuts parallel to or at right angles to the head. The fetatome also has a notched plate near the handle that allows fixation of an obstetrical chain under tension to maintain proper position of the instrument relative to the fetus. The ability to attach the chain to the fetatome is considered essential for efficient completion of the fetotomy procedure.

Threader and brush. A flexible shaft with an eye on one end is used to thread the saw wire through the barrels of the fetatome. Many threaders have a brush on the

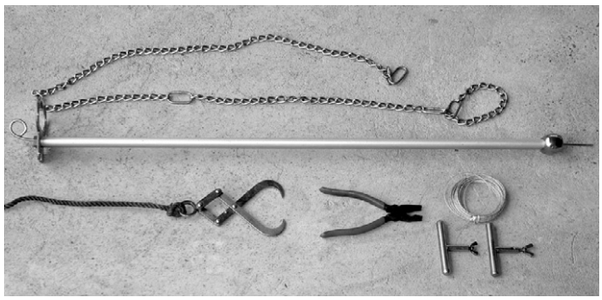

Fig. 42-8 Basic equipment required to complete a fetotomy. From *bottom left* in clockwise direction are shown the Krey hook with attached rope, Utrecht fetatome with wire threader inserted through one barrel, calving chains, a roll of fetotomy wire, fetotomy handles, and pliers. A wire introducer also can be included in the kit; however, a calving chain can be used for this purpose in most cases.

opposite end, which is necessary to clear the barrels of lubricant and debris.

Wire saw handles. Several types of wire saw handles are available, and the choice depends on the preference of the operator. Those that incorporate a spool for saw wire are convenient, but the type selected should provide a positive grip on the saw wire, be easy to attach, and be comfortable for the assistant while sawing.

Krey hook. A Krey hook with an obstetric chain or rope attached is necessary to anchor the fetatome to the fetus while making several cuts and to extract fetal parts after they have been separated.

Saw wire introducer. A curved wire introducer facilitates passage of the saw wire around fetal parts. If a wire introducer is not available, the fetotomy wire can be attached to an obstetric chain to assist in passing the wire around the fetal hindquarters.

Saw wire. A good grade of saw wire should be selected. Poorly manufactured or improperly maintained (rusted) saw wire breaks easily. Approximately 5 m of wire is required to thread the fetatome. The Utrecht fetatome is approximately 1 m long and serves as a good field guide to drawing out a suitable amount of wire. To reduce the chance of breaking the wire while sawing, it is good practice to rotate the wire through the fetatome as each cut is made and to replace the wire after several cuts.

Restraint and Anesthesia for Fetotomy

Clinicians develop personal preference for performing fetotomy with the dam either standing or in laterally recumbency. Both positions have advantages and disadvantages, and sometimes the choice is dictated by available facilities or the condition of the cow. Initially, many operators find that fetotomy is most easily performed with the patient standing in an area that allows adequate space behind the cow for manipulation of the instrument and saw wire. If the dam is recumbent and cannot be induced to rise, elevation of the hindquarters is helpful initially.

Epidural anesthesia is indicated in nearly all instances to relieve pain as well as straining. Where available, clenbuterol also should be administered to reduce the risk of uterine rupture. Tranquilization may be indicated in some instances, but general anesthesia is only rarely necessary. The administration of antibiotics before the commencement of the procedure should be considered.

Lubrication

A generous amount of lubricant is required during a fetotomy to protect the genital tract of the dam, as well as the hands and arms of the operator. Petroleum-based lubricants are preferred to water-soluble types because of their proclivity to cling to tissues and resist dilution by fetal fluids.

Assistance

At least one and preferably two assistants are required to perform a fetotomy. If one assistant is available, the clinician covers the head of the fetatome with one hand and maintains the position of the fetatome with the other hand while the assistant saws. If two assistants are available, the clinician covers the fetatome head while one assistant maintains position of the instrument and the other saws. Sawing should begin with slow, short strokes, with only light pressure on the wire. After the wire is seated beneath the fetal skin, strokes of the wire can be lengthened and heavier pressure applied. Tension on the saw wire should not be relaxed during the cutting procedure, because the saw wire may tangle and break.

Indications for Fetotomy

Percutaneous fetotomy is not a substitute for cesarean section but is indicated in certain cases of dystocia. The decision guidelines shown in Figure 42-3 are a useful aid to determining when fetotomy is indicated. Of importance, fetotomy should not be used as a last resort after the application of excessive traction when the dam and the operator are exhausted and the birth canal has been traumatized. A decision to perform a fetotomy should be made promptly after it becomes obvious that further attempts at delivery by traction are not justified. In general, fetotomy is useful to relieve dystocia caused by fetopelvic disproportion, pathologic enlargement of the fetus (fetal gigantism), incomplete cervical dilatation, fetal malposture and malpresentation, and fetal malformations including those resulting in fetal monsters. Fetotomy is not useful when the birth canal is obstructed or reduced in size, as in uterine torsion, or in instances of transverse dorsal presentation.

Percutaneous fetotomy is given primary consideration to relieve dystocia when the fetus is dead, and cesarean section is given primary consideration when the fetus is living. Exceptions may be indicated when the value of the dam and of her future reproductive ability and milk production is greater than the value of the fetus.

Either partial or complete fetotomy may be required to relieve dystocia. A complete fetotomy usually is required to deliver oversized fetuses. A complete fetotomy

following the Utrecht guidelines requires a maximum of seven cuts in cranial presentation and six or seven cuts in caudal presentation. The amputated fetal parts should be no larger than can be extracted by the obstetrician using only light traction.

Partial fetotomy is indicated in cases of fetal malposture. The offending appendage can be quickly amputated, after which the fetus can be delivered by traction. The clinician should be aware that in protracted cases, the uterus can be tightly contracted around the fetus, so that the repulsion necessary to allow mutation may result in uterine rupture. Partial fetotomy also is useful in cases of a dead fetus in hiplock that cannot be relieved without excessive traction.

Fetotomy in Cranial Presentation

Amputation of the Head

Removal of the head allows easier access to the forelimbs for amputation or mutation. A loop of saw wire is passed over the head until it rests immediately caudal to the ears. The head of the fetatome is introduced alongside the head and positioned between the mandibles and caudal to their posterior borders. If this area is not accessible, the fetatome can be positioned on the lateral surface of the face with the fetatome head caudal to the ramus of the mandible (Fig. 42-9). After the head has been amputated, it is extracted. The Krey hook can then be fixed to the exposed cervical vertebrae when needed for subsequent cuts.

Amputation of the Forelimbs

Before being amputated, the forelimbs must be extended and the distal portion of the limb protruded from the vulva. An obstetric chain is first fixed to the limb, and the chain is passed through the loop of the wire saw from above to below (Fig. 42-10).

The saw wire loop is then placed between the claws of the forefoot to temporarily anchor it. The fetatome is passed alongside the lateral surface of the limb until the head rests near the middle of the scapula. After moderate traction to extend the leg, the obstetric chain is anchored to the fetatome. The saw wire loop is removed from the interdigital space, and while the assistant applies slight tension on the wire handles, the loop of saw wire is moved up the medial surface of the limb until it lies medial to the scapula in the axillary space. The chain is then detached from the fetatome and the instrument advanced more deeply into the uterus until the head lies dorsal and caudal to the scapula. Traction is applied to the obstetric chain to fully extend the joints of the limb, and the chain is again anchored to the fetatome. The final placement is shown in Figure 42-11.

The obstetrician covers the head of the fetatome with a hand and the limb is amputated. When the fetatome has been positioned correctly, the forelimb along with the entire scapula is amputated so that the diameter of the fetus is reduced. Common errors include cutting through the shaft of the humerus or through the shoulder joint, which results in formation of sharp bone fragments and eliminates the leg as a point of traction without reducing the diameter of the fetus. The second forelimb is amputated similarly, but in most instances the procedure will be completed more easily because of the space made available by removal of the first leg.

Fig. 42-9 One method of placing the fetatome and wire in preparation for removal of the head. In some cases, this single cut will create enough room to allow mutation and completion of a vaginal delivery.

Fig. 42-10 Before placing the fetotomy wire for removal of the forelimb, the obstetric chain attached to the limb is passed through the wire loop from above.

Fig. 42-11 Placement of the saw wire and head of the fetatome for an acute-angled cut to remove the forelimb.

Transverse Division of the Trunk

Two transverse cuts are made to section the fetal trunk. The first includes the neck and the cranial portion of the chest; the second cut is made caudal to the last rib. In some cases, the fetus can be partially delivered after the forelimbs have been amputated, and the first transverse cut is not necessary. In preparation for amputation of the cranial portion of the chest, the Krey hook is fixed to the exposed cervical vertebrae. The chain attached to the hook is passed from above to below through the loop of saw wire, as previously described for the forelimb. While the loop of saw wire is held externally, the fetatome is passed along the dorsolateral surface of the fetal chest until the head is near the area where the scapulas were attached. The chain from the Krey hook is then anchored to the fetatome, and while moderate tension is applied to the saw wire, the loop is positioned around the fetal thorax. The final position of the saw wire is approximately at the middle of the sternum, and the loop is at a right angle to the fetatome. Before sawing, the obstetrician should check the position of the saw wire to ensure that the fetatome was not rotated while being positioned and that the saw wires were not crossed. The fetatome tends to move up and down when sawing begins, but this motion can be minimized by pushing the fetatome against the fetus and by using short strokes with the saw wire when beginning the cut. After it has been amputated, this portion of the chest is narrow and in most instances extracted easily by traction on the Krey hook.

Amputation of the remaining portion of the chest is conducted similarly. With the Krey hook anchored to the thoracic vertebrae, the head of the fetatome is positioned on the dorsolateral surface of the fetus immediately caudal to the last rib so that the saw wire loop is at right angles to the fetatome. In the case of a large fetus, this portion of the chest may be too large to permit safe extraction. The diameter can be quickly reduced by separating the ribs from their attachment to the vertebrae. The saw wire is removed from one of the tubes and attached to an introducer. In attaching the wire to an introducer, care is required to ensure that the loose end of the knot is long enough to prevent it from acting as a cutting device, which could occur if it were left too short. After puncturing the diaphragm with a finger, the obstetrician passes the introducer and saw wire through the lumen of the thorax. The hand is withdrawn from the thoracic cavity ans reintroduced down the lateral aspect of the thorax, the introducer and wire are retrieved, and the fetatome is rethreaded. The head of the fetatome is placed near the vertebral body, and the saw wire is positioned to sever the ribs near their vertebral attachment. After the ribs have been separated, the thorax can be collapsed and easily withdrawn.

A final longitudinal division of the fetus separates the hindquarters and reduces them in size for delivery. Using an introducer, the saw wire is passed over the dorsal aspect of the pelvis and the introducer retrieved between the hindlimbs. The fetal hindpart can be divided into equal parts by placing the head of the fetatome against the lumbar vertebra or into unequal parts by placing the head of the fetatome on the lateral surface of the fetus cranial to the hip joint.

Hiplock

A partial fetotomy can be used to expeditiously relieve dystocia caused by hiplock, whether the condition arises spontaneously or is the result of inadequate rotation during delivery by traction. The forepart of the fetus is first removed by a transverse cut between the last rib and the pelvis. The hindpart of the fetus is then divided and delivered as described previously.

Fetotomy in Caudal Presentation

Amputation of the Hindlimb

An obstetric chain is attached to the limb to be amputated and passed from above to below through the loop of saw wire at the head of the fetatome. In a manner similar to that described for amputation of a forelimb, the wire loop is temporarily anchored between the claws, and the fetatome is introduced along the lateral surface of the limb and advanced until the head rests in the area of the greater trochanter of the femur. After the obstetric chain is anchored to the fetatome, the saw wire is removed from the interdigital space and advanced up the medial surface of the limb until it lies medial and cranial to the stifle joint. Traction is then placed on the obstetric chain to extend all the joints, and the head of the fetatome is further advanced until it rests dorsal to the greater trochanter of the femur. The chain is anchored to the fetatome and the limb amputated. If the fetus is very large, the second limb can be amputated similarly, or the trunk can be divided transversely with the second limb still attached if it appears that delivery of the severed portion will be possible.

Transverse Division of the Trunk

The first transverse division of the trunk is made between the pelvis and the last rib. If one hindlimb has been removed, the cut is begun by positioning the fetatome in the manner described for amputation of a hindlimb. The fetatome is positioned farther forward on the fetus, however, and the saw wire loop is positioned caudal to the last rib. This cut results in delivery of the remaining hindlimb, along with the fetal pelvis. If both hindlimbs have been removed, the pelvis is secured with a Krey hook, the saw wire loop is positioned transversely around the fetus, and the pelvis is removed.

The second transverse division of the trunk is made by positioning the head of the fetatome on the dorsolateral surface of the fetus immediately caudal to the scapulae. The saw wire loop is then positioned at a right angle to the fetatome so as to divide the fetus at approximately the middle of the sternum. If the rib cage cannot be safely extracted, it can be divided and collapsed as described for fetotomy in cranial presentation.

Division of the Forepart

The remaining fetal forepart can be reduced in size by amputation of each forelimb separately or by diagonal division of the forepart. Forelimbs are amputated by passing an introducer and saw wire dorsally between the neck and the limb and retrieving them ventrally, positioning the wire between the elbow joint and the chest. After the fetatome has been rethreaded, its head is posi-

tioned in a space that has been bluntly dissected between the scapula and the thorax. If diagonal division of the forepart is selected, the saw wire is positioned similarly, but the head of the fetatome is placed on the lateral surface of the opposite scapula. The larger portion, consisting of the cranial thorax and one limb, is delivered first, followed by delivery of the remaining forelimb and head.

Fetotomy in Abnormal Posture

Displacement of the Head

Access to the flexed neck can be facilitated by amputation of the forelimb on the side opposite that toward which the head is displaced. The saw wire attached to an introducer is then positioned between the neck and the body of the fetus. After the fetatome is rethreaded, the fetatome head is positioned as close to the thorax as possible and the neck is severed.

Carpal Flexion

If dystocia due to carpal flexion cannot be corrected by repulsion and mutation, the dystocia can be easily relieved by partial fetotomy. If the head prevents easy access to the flexed carpus, it is amputated first. Then, with the use of an introducer, the saw wire is placed around the flexed carpus and the fetatome is threaded. The head of the fetatome is positioned against the distal portion of the carpal joint. The limb is amputated and the distal portion removed. An obstetric chain can then be anchored proximal to the carpal joint for delivery by traction.

Hock Flexion

Amputation of the limb immediately distal to the hock reduces the danger of uterine rupture that may accompany attempts to repel the fetus and mutate the malposture in protracted cases. The saw wire is threaded around the limb and positioned distal to the hock joint. An obstetric chain can be anchored to the limb proximal to the hock for delivery by traction.

Hip Flexion

Using an introducer, the saw wire is passed over the dorsum of the fetus and directed between the limb and body. The introducer is retrieved ventrally and the fetatome threaded. Before the limb is amputated, the head of the fetatome is placed against the fetal ischium. In bilateral cases, it may be necessary to amputate the second limb if the malposture cannot be safely mutated.

Fetotomy for Delivery of Abnormal Fetuses

Fetal monsters are occasionally encountered as causes of dystocia in cattle. The variety of configurations will challenge the resourcefulness of the obstetrician, but fetotomy often is preferable to cesarean section.

Schistosomia Reflexus

In schistosomia reflexus, if the fetus is presented with its viscera exposed, the fetal organs can be removed after a thorough examination to ensure that rupture of the uterus has not resulted in prolapse of maternal organs. An attempt is made to encircle the fetus with the saw wire and divide the trunk near the point of deviation. Frequently the portions can then be delivered. If not, they can be reduced in size by further divisions. Sharp bone fragments frequently result, and the dam's birth canal should be protected when the fetal segments are delivered. Some abnormal fetuses are presented with three or more limbs and the head in the maternal pelvis. In these cases, an attempt is made to amputate the most accessible limb in the most expeditious manner, followed by further section of the fetus at the discretion of the clinician.

Perosomus Elumbus

In perosomus elumbus, the fetus usually is not oversized, and the fetal forepart is delivered spontaneously. Difficulty is encountered when the operator attempts to complete the delivery because the hindlimbs often are ankylosed and distorted. Attempts to withdraw the fetus by traction may result in perforation of the uterus. Delivery can be accomplished by a partial fetotomy similar to that described for resolving cases of hiplock.

Modified Fetotomy

A modification of the Utrecht method for complete fetotomy has been described that reduces the number of cuts required and is applicable in cases in which the fetus is not excessively oversized.[28]

Cranial Presentation

The head is first amputated by encircling the neck with the saw wire. The head of the fetatome is then positioned dorsal to the fetal scapula in a manner similar to that described for amputation of a forelimb, except that the saw wire is positioned between the stump of the neck and the opposite forelimb. This diagonal cut results in amputation of one forelimb, the neck, and a portion of the thorax. The resulting opening in the thorax permits evisceration of the thoracic and abdominal cavities, which further reduces the size of the fetus. In addition, the size of emphysematous fetuses is reduced by the escape of gas after breach of the body cavities. Traction on the remaining forelimb is then continued until delivery is complete or until the size of the fetal hindpart obstructs progress. If necessary, the fetal pelvis is sectioned in the manner described for resolution of hiplock.

Caudal Presentation

The first hindlimb is amputated in the manner described by the Utrecht guidelines. The fetus is then reduced in size by evisceration. If size of the fetus is not reduced sufficiently to permit delivery, a transverse cut is made through the thorax caudal to the scapula. The ribs can be severed from their attachment to the vertebrae and the thorax collapsed if necessary. A final cut is made obliquely through the remaining forepart of the fetus. One section is composed of a forelimb and most of the thorax and the other is composed of the head, neck, and remaining forelimb.

Aftercare with Fetotomy

In most cases, the dam requires less care after fetotomy than after cesarean section. On completion of a fetotomy, the uterus is routinely lavaged with warm (42° to 45°C) water to which is added a small amount of a nonirritating disinfectant or salt. Approximately 4L is pumped into the uterine cavity through a stomach tube and then siphoned out. The procedure is repeated until fetal tissue and lubricant have been removed and the efflux is clear. Dystocia is a common antecedent to secondary uterine inertia, and treatment with an ecbolic agent such as oxytocin often is indicated. Systemic antibiotics frequently are indicated, especially in cases with protracted labor. Other supportive therapy such as administration of intravenous fluids or calcium is given as required. Anecdote suggests that the uterus will contract and involute more effectively if the cow is allowed to exercise, rather than being confined in a stall. Fertility and milk production typically are higher after fetotomy than after cesarean section.

LAPAROHYSTEROTOMY (CESAREAN SECTION)

Cesarean section is an option for treating dystocia that is commonly employed when the guidelines for extraction indicate that vaginal delivery would be unsafe for the dam or fetus, and fetotomy is not a viable alternative because the fetus is alive or there is inadequate room to place the fetatome.

Cesarean section may be performed through the paralumbar fossa (most commonly on the left side), a low flank or ventrolateral incision (again, most commonly on the left), a lateral oblique incision, a paramedian incision (commonly on the right, but also can be done on the left), Marcenac's approach, or ventral midline laparotomy. The paralumbar fossa and the lateral oblique laparohysterotomy procedures usually are performed with the cow standing; all other techniques are performed with the cow recumbent. The left paralumbar fossa approach is arguably the most commonly used approach, particularly when the fetus is alive (Fig. 42-12). With this approach, no or only mild sedation is required; many owners have facilities to safely restrain a standing animal; most surgeons are more comfortable in the standing position in contrast to kneeling; and the risks associated with wound dehiscence are minimal compared with those with the more ventral approaches. Probably the greatest disadvantage with this approach is the reduced exposure of the uterus compared with the more ventral approaches. This increases the risk of abdominal contamination from leakage of uterine contents, which is a major consideration if the fetus has been dead for more than 12 hours. The paralumbar approach is not recommended for the removal of emphysematous fetuses.

The choice of sedation or anesthesia will depend on the surgical approach. Other presurgical treatments that should be routinely considered include the administration of an epidural anesthetic, clenbuterol where available, and preoperative antibiotics. In all cases, the uterus (or part of it) should be exteriorized from the abdomen

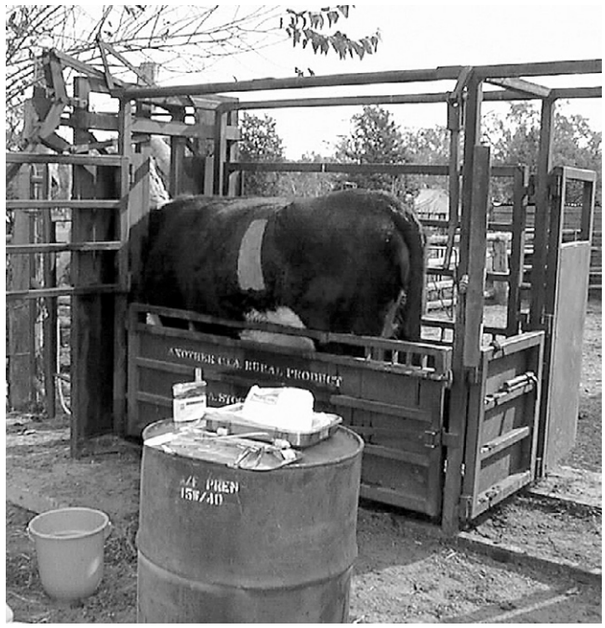

Fig. 42-12 A heifer is prepared for delivery of a calf by a left paralumbar laparohysterotomy. An inverted lumbar block and epidural anesthesia have been administered, in addition to clenbuterol and preoperative antibiotics. The left paralumbar fossa has been shaved in preparation for cleansing. No sedation was necessary in this case.

if possible. This is particularly important if extensive attempts at manual correction of dystocia have been tried or if the fetus is emphysematous. Some contamination of the abdomen is tolerated if the fetus is alive at the time of surgery. When the fetus has been dead for more than approximately 12 hours, however, the fluids within the uterus become very toxic if they leak into the abdomen.

Once the fetus is removed, the healthy uterus is closed with metric 7 chromic catgut in a double layer using the Utrecht suture pattern, which is a Cushing pattern modified so that the suture is turned to a 30- to 45-degree angle away from the incision. A double-layer closure is made so that the suture line is less likely to leak uterine fluids during postdelivery contraction of the uterus. When the health of the uterus is in question, such as with vascular damage from uterine torsion, bruising due to excessive handling, or an emphysematous calf, closure with a monofilament absorbable suture material (e.g., polydioxanone suture [PDS]) may be more suitable. These suture materials will maintain tension strength despite regional inflammation. The uterine serosa should be thoroughly lavaged clean of all blood clots before being replaced into the abdomen.

For paralumbar fossa and lateral oblique incisions, the peritoneum and transverse abdominis muscle are closed in one layer and the internal and external abdominal oblique muscles closed in the second layer using metric 7 chromic catgut suture. For ventral midline and paramedian incisions, the abdominal wall should be closed with metric 6 PDS or Vicryl suture. The far-near-near-far

suture pattern is particularly suited to closure of the bovine ventral abdomen. The skin is closed using metric 7 (special) vetafil (Braunamid) in a forward (Mayo) interlocking suture pattern.

Some surgeons lavage the abdomen (the uterus and ovary regions) with fluids containing various additives such as antibiotics, nonsteroidal anti-inflammatory drugs, and heparin before closure in an attempt to limit postoperative infection and adhesions, particularly if abdominal contamination was substantial. This precaution usually is not necessary if the surgery was routine, and there is little evidence to suggest that the inclusion of additives has any advantage over saline alone.

Oxytocin should be administered at the completion of surgery to assist with contraction of the surgical site. Antibiotics are continued for 3 days after surgery and should be directed against the most common bacteria resident in the normal postpartum uterus for the geographic region. The administration of nonsteroidal anti-inflammatory drugs for 48 hours after surgery, to control pain and limit adhesion formation, should be considered.

MANAGEMENT AND PREVENTION OF DYSTOCIA

In beef cattle production, dystocia most commonly occurs in heifers. Although results from the literature vary, it appears that common estimates of dystocia in British breed beef heifers fall in the range of 10% to 40%, with an average of approximately 20%.[29,30] In addition, dystocia is reported to be the primary cause of calf loss in 2-year-old beef heifers.[31] By contrast, among older breeders, occurrence of dystocia generally is insignificant, with estimates ranging from 0.8% to 3%.[32] Accordingly, the focus of this section of the chapter is on reducing dystocia in heifers, with some reference to older cows where relevant.

Despite the enormity and long recognition of the problem, a large deficit remains in current understanding of the causes of dystocia. For example, one prediction equation found that only 63% of the variation in calving difficulty could be accounted for when all known variables were included.[33]

Causes of Dystocia

Not a great deal has changed in the last 30 years or so regarding our understanding and classification of the general causes of dystocia in cattle. In beef cattle, these causes generally are limited owing to the relatively low metabolic pressure placed on these animals compared with dairy cattle. For example, clinical or subclinical hypocalcemia as a contributory factor to ineffective labor, or perhaps uterine torsion, is expected to be more common in dairy cattle than in beef cattle.

In decreasing order of occurrence, the three most important general causes of dystocia in beef cattle are (1) fetopelvic disproportion, (2) cranial presentation of the fetus, and (3) ineffective labor. These three causes of dystocia are reported to account for 30% to 70%, 20% to 45%, and 10% to 20% of dystocias in beef heifers, respectively.[34]

Although it is convenient and traditional to classify the causes of dystocia in this way, these broad classifications do not lend themselves to implementation of specific control measures. For example, fetopelvic disproportion simply suggests an incompatibility between the size of the fetus and the size of the maternal pelvis. The reason for the incompatibility could be one or a combination of many factors. Specific control measures can be implemented only if specific causes have been identified. In beef heifers, these specific causes usually are associated with physical traits of the heifer or calf, endocrinology of the heifer, or metabolism of the heifer.

In Australia, a recent study identified seven physical traits that influence dystocia incidence in beef heifers[35]:

- Higher mean calf birth weights
- Male calf gender
- Lower mean body weight of heifers at 12 months of age
- Lower mean pelvic area of heifers at 12 months of age
- Lower ratio of pelvic area of heifers at 12 months of age to calf birth weight
- Higher mean body condition score at calving
- Heavier placental weights at calving

In the same study, two environmental factors were identified as influencing dystocia incidence: lower mean rainfall during the second trimester of gestation for heifers bred to calve as 2-year-olds and a later mean calving date for heifers calving as 2-year-olds.

Another study focused on specific causes of dystocia associated with ineffective labor.[36] The authors described the calving difficulty experienced by heifers, which was not attributable to high calf birth weight, as "physiological dystocia." They found this type of dystocia to be associated with a deficit in precalving estradiol-17β production with consequent poor expulsive efforts. Also present may be the confounding effect of a periparturient increase in serum progesterone levels. Placental preparations from cows experiencing weak labor and requiring obstetric assistance have produced lower rates of in vitro conversion of androstenedione and pregnenolone to estrogen than those found in such preparations from cows that calved unassisted.[37] In addition, dystocia due to ineffective labor has been reported to result from deficiencies of calcium, phosphorus, copper, cobalt, selenium, iodine, sodium, zinc, magnesium, and manganese.[38]

To pinpoint endocrine imbalance as the underlying disorder, dystocia due to a large calf must be differentiated from dystocia due to ineffective labor. Estradiol-17β concentrations in plasma are positively correlated with calf birth weight.[36] It has been suggested this factor is responsible for the often increased concentrations of plasma estradiol-17β in heifers suffering dystocia due to a large calf.[39] This is in contrast with physiologic dystocia, which appears to be due to an endocrine imbalance involving low plasma estradiol concentrations, possibly in combination with high serum progesterone levels. This may stem from inadequate placental function, resulting in lower conversion rates of androstenedione and pregnenolone to estrogen in late gestation. Zinc deficiency

can reduce protein synthesis and impair estrogen-mediated responses.[40] So it also is possible that low serum zinc concentrations may be involved at this level.

Some of the aforementioned specific causes, such as high birth weight of calves, have been recognized for many years. Still others, although intuitive, have only recently been identified and may require further trials to become unequivocal.

To further complicate effective dystocia management, many underlying factors can influence how specific causes of dystocia manifest themselves. These factors can be classified in a number of ways; however, one classification method divides the factors into the following categories[7]: hereditary, nutritional, managerial, infectious, traumatic, miscellaneous, and combined. An environmental category also could be added to this list, because environmental characteristics such as temperature and humidity cannot be readily included in nutritional or managerial categories.

Identifying the Problem

Dystocia management is easier if the specific physical traits or managerial situations that influence its incidence are identified. Steps that can be taken to achieve a specific diagnosis include weighing replacement heifers at intervals from weaning to calving as 2-year-olds, measuring yearling heifer pelvic areas, weighing calves at birth, recording calf birth dates, monitoring and recording pasture quality and quantity, monitoring and recording daily rainfall figures, collecting suitable samples to assess trace element status, and recording comments for all assisted calvings. With this information, prospective and retrospective assessments can be made.

Investigations of mineral deficiency in herds experiencing dystocia associated with ineffective labor should start by analyzing 10 blood samples from heifers in late pregnancy.[38] Ideally, the blood should be collected within 2 weeks before parturition or, in the case of dystocia, at parturition. The use of postpartum blood samples may overestimate prepartum mineral levels. Whole-blood copper and glutathione peroxidase are used to assess copper and selenium status, respectively. Sample collection to determine selenium status may be an exception to the prepartum collection rule because the half-life of red blood cells affects the assessment of selenium levels. This means that blood glutathione peroxidase levels reflect not current selenium status but the animal's selenium status approximately 2 months before sampling.[40] Plasma inorganic iodine is used to assess iodine status. Plasma calcium and magnesium concentrations are used to indicate the respective levels of these minerals.[38] Serum copper and zinc concentrations also are determined.

Specific Management Practices

Several studies into the cause and management of dystocia in beef herds have been carried out.[29,30,35,41] Many general suggestions for reducing the impact of dystocia have arisen from these and other studies.[6,42,43] Ideas include changing to a breed with lower dystocia incidence, increasing surveillance of heifers during calving, delaying calving until the heifer is older than 2 years of age, manipulating nutrition at different stages of heifer development, and manipulating calf birth weight by careful bull selection. Most of these suggestions were derived from studies performed 30 years ago, and debate and confusion remain about the effects of nutrition, season, age of heifer at breeding, and pelvic area on the incidence of dystocia. Of all parameters studied and reported, high calf birth weight and male calf gender are the only ones that appear to be unequivocally linked with increased dystocia incidence.

Many specific techniques have been used in an attempt to decrease the incidence or impact of dystocia in beef herds. These are summarized next.

Objective Bull Selection

Lowering calf birth weight is one means of reducing the incidence of dystocia that remains unchallenged. With regard to selecting bulls that are to be bred to heifers, the aim is to minimize calf birth weight without dramatically reducing postpartum growth. This is easier said than done, but the use of expected progeny difference (EPD) figures can help. Even if some postpartum growth is sacrificed, the production of a live calf from a live heifer with minimal surveillance input is a beneficial outcome. In the future, the use of gene markers most likely will help to dissociate desirable traits such as low calf birth weight from undesirable traits such as low postpartum growth rates.

Limited work has been done to determine the influence of measuring pelvic area in bulls on the incidence of dystocia in heifers. Although more research is necessary, selecting bulls to produce heifers with larger pelvises appears to be a potentially useful strategy.[44] If bull pelvic areas are measured, the aim is to breed bulls with larger pelvic areas to the main cow herd so that heifer progeny have an increased pelvic area.[33]

The Use of Half-Sibling or "Littermate" Sires

In commercial herds, use of half-sibling or littermate sires appears to have given consistent reductions in the incidence of dystocia in heifers.[45] Heifers are joined to bulls that were born in the same calf crop, that is, their half-brothers. In this sort of program it is essential that the bulls be from an unassisted birth and of mean birth weight for the crop. Producers must resist the urge to select the biggest bull calf. This method of control is considered a "quick fix" only for commercial herds.

Use of Jersey Bulls

The use of Jersey bulls over heifers results in very few dystocias,[45] but also is a "quick fix" for a problem commercial herd and is not recommended as a long-term answer.

Visual Appraisal

Producers commonly use visual selection of bulls based on shoulder and pelvis conformation. It has been suggested that scapulas that slope medially from a ventrodorsal aspect are a desirable trait in bulls to be bred to heifers.[45]

Comments from field days and producer meetings indicate that many producers practice the use of visual

selection of heifers to identify those with a large frame or pelvic structure. No scientific evidence supports the effectiveness of this procedure in reducing calving difficulty. To the contrary, it has been shown that external measures of the pelvis do not necessarily reflect internal measurements of pelvic area.[33]

Use of Crossbred Heifers

A great deal of research has been carried out to compare the incidence of dystocia between purebred cattle breeds and crossbred animals.[46–51] Some of these studies refer to "specific combining abilities," which describe the likelihood of dystocia from specific crosses—for example, a Brahman dam crossed with a Hereford sire. By contrast, "general combining ability" describes the overall performance of, for example, Hereford dams crossed with any other sire type.

This research has yielded several important points:

- Calf birth weight can be significantly controlled by the dam. In this regard, dystocia incidence generally is low in Brahman cows even when bred to bulls of different breeds.[49,51] This indicates that they have a general combining ability that results in reduced dystocia.
- In Australia, purebred Poll Hereford and Hereford cattle appear to be more prone to dystocia than other breeds.[29]
- Heterosis affects heifer pelvic area, with Brahman crossbred heifers having increased pelvic areas compared with those in purebred contemporaries.[52] This may reduce dystocia incidence in crossbred heifers.
- Heterosis affects calf birth weight. Brahman-sired crossbred calves can have large birth weights as a result of the hybrid vigor associated with *Bos indicus–Bos taurus* crosses and the relative inability of *B. taurus* dams to control calf growth compared with *B. indicus* dams, as noted.

The important aspect of the last two points is that the heifer should be the crossbred animal and hence benefit from any heterosis. By contrast, if the calf is the crossbreed, heterosis may lead to higher birth weights.

Heifer Management from Weaning to Breeding

It could be argued that management of the heifer during the weaning-to-breeding period is one of the most important factors influencing subsequent calving ability as a 2-year-old. Evidence that calving difficulty in beef heifers can be influenced by energy intake and growth rates of the heifers between weaning and breeding has been available for at least 20 years.[34,53–55] One study reported a 24% increase in the proportion of heifers on a low-energy diet between weaning and breeding requirement for calving assistance compared with those on a high-energy diet.[54] Despite this knowledge, little information is available on practical methods of incorporating it into management procedures for reducing heifer dystocia. Data from a recent unpublished study suggest that British breed beef heifers should reach approximately 280 kg as yearlings in order to have greater than an 80% chance of an unassisted calving as a 2-year-old. Heifers that weigh 280 kg or more at 12 months of age will weigh approximately 320 kg three months later at joining if a growth rate of 0.5 kg/day is maintained. This mating weight is approximately 40 kg or 14% heavier than the current critical mating weight recommended for British breed beef heifers.[56] With this in mind, it is worth restating some of the relevant aspects of heifer nutrition from weaning to breeding, even though most of the research has focused on cyclicity and conception, rather than calving ability.

Heifers must reach puberty at 15 months of age if they are to conceive in time to calve as 2-year-olds. As many as 35% of all beef heifers fail to reach puberty by this time.[57] Puberty in heifers is related to height and weight; however, a minimum age requirement also must be met. The age at which heifers begin regular estrous cycles is correlated with gains in body weight from birth to puberty. It also is controlled by an array of genetic and environmental variables. The standard deviation for age and weight at puberty is considerable.[57] It is clear from the literature that variability is greatest in undernourished animals.[58] Low planes of nutrition during the prepubertal period delay puberty by inhibiting the development of a mature reproductive endocrine system.[59] An array of physiologic factors are involved; however, weight appears to be the major factor affecting age at puberty. Subsequent weight gains are needed to ensure that regular estrous cycles continue.[60] Although age at puberty is influenced by nutrition, body weight at puberty is unaffected by nutrition.[57] In addition, correlations between gains in body weight and age at puberty indicate that increased growth rate in heifers results in reduced age at puberty.[61] When winter feed levels were increased for replacement heifers,[62] it was observed that heifers on the higher plane of nutrition reached puberty earlier, had a higher rate of conception, conceived earlier in the breeding season, and experienced decreased pregnancy loss, in comparison with their lower-nutrition-plane contemporaries. These findings suggest that body weight is a useful monitor for predicting when heifers will reach puberty, so the concept of a target weight at first mating is important.[63]

Target Weights (Critical Mating Weights)

The use of target weights, or critical mating weights, for heifer selection before breeding has been recommended for approximately 30 years.[57,64] These weights give an indication of heifer maturity. They indicate when heifers are cycling and when they are mature enough to breed and will achieve acceptable conception rates in a restricted breeding period. With respect to dystocia, some evidence suggests that current recommendations may be on the "light" side.

Pelvic Area Measurements

The use of pelvimetry in both heifers and bulls is a controversial basis for programs of dystocia control.[33,65] A study in southeastern Queensland,[35] however, confirmed previous reports[33] that heifers requiring assistance at

calving as 2-year-olds had significantly smaller pelvic areas as yearlings. It also confirmed that heifers requiring assistance had smaller pelvic area–to–calf birth weight ratios. Both of these findings confirm the value of increasing the pelvic area of yearling heifers in the management of dystocia. One concern identified in the Queensland study, however, was that precise progressive measurements may be difficult to achieve using the Rice pelvimeter. This apparent imprecision suggests that the technique currently is more suited to group selection methods than to attempts to identify individual heifers that may require assistance at calving. The technique may be more useful if a more precise measuring technique is developed.

Use of a Restricted Breeding Season

The benefits of a restricted breeding season are well documented. This approach results in a defined calving period, in contrast with enterprises in which bulls are left in the herd all year. With respect to dystocia, this strategy allows more efficient surveillance of heifers at calving and provides a calf crop of similar age, to make quantitative selection of future heifers more equitable.[49] Management of nutrition for the replacement heifers is also more efficient.

Nutrition during Gestation

Studies on the effects of nutrition during gestation usually have focused on manipulating feed intake during the last trimester of pregnancy. During the last trimester of gestation, the bovine fetus gains approximately 80% of its final weight. Increased energy levels at this stage can increase calf birth weight, but the higher birth weight generally is not associated with an increase in dystocia incidence or neonatal mortality rate.[53,66–70] Restricted precalving nutrition limits calf birth weight; however, heifers on a low plane of nutrition may put less effort into the parturition process. In some trials, the feed restrictions have been severe enough to cause maternal weight loss.[68] It seems that except for extremes, attempts to reduce dystocia by manipulating nutrition during late pregnancy, in isolation from the rest of gestation, almost always fail.

A more recent study looked at the effect of rainfall throughout gestation on subsequent calving ability of extensively grazed heifers.[71] The assumption was that any effect of rainfall on heifer dystocia or calf birth weight would be through its influence on available nutrition. The findings indicated that rainfall in the first and third trimesters may have the most influence on the eventual birth weight of the calf, whereas second-trimester rainfall may be pivotal to the eventual delivery type. To summarize the findings for the whole gestation period, heifers exposed to above average rainfall in the first two trimesters followed by below-average rainfall in the third trimester had low calf birth weights and required moderate calving assistance. By contrast, heifers exposed to below-average rainfall in the second trimester followed by above-average rainfall in the third trimester had mean calf birth weights and required high levels of calving assistance. Heifers exposed to low second-trimester rainfall experienced high levels of calving difficulty.

It seems that the ideal situation is steady growth throughout gestation in the vicinity of 0.5 to 0.75 kg/day. Net growth of the heifer should be considered in the last trimester, taking into account that the conceptus is putting on 0.2 to 0.3 kg/day at this stage.

Use of Mineral or Trace Element Supplements

There is a lack of information in the literature on the effect of dietary mineral and trace element concentrations on the occurrence of dystocia in beef heifers. Dystocia due to ineffective labor has been reported to be increasing in incidence in the Irish Republic.[38] Deficiencies of calcium, phosphorus, copper, cobalt, selenium, iodine, sodium, zinc, magnesium, and manganese were identified as possibly causing increases in the duration of parturition. The correction of these multiple mineral deficiencies has been attempted using a precalving mineral supplement containing 15% magnesium, 4500 parts per million (ppm) of copper, 600 ppm of iodine, 100 ppm of cobalt, and 50 ppm of selenium, with the addition of unspecified amounts of sodium, phosphorus, zinc, manganese, and vitamins A, D_3, and E. Clinically, the use of this mix solved the problem in some cases, but a substantial number failed to be corrected, and controlled studies were not performed.[38]

In all ages of cattle, low levels of available calcium result in poor uterine muscle tone by disturbing the membrane potential across muscle cell walls. The resultant uterine inertia means that the cow has an impaired ability to expel the fetus.[38,72] Such impairment occurs when serum calcium concentrations drop below 2.2 mmol/L but is not associated with clinical hypocalcemia. Dietary control of hypocalcemia in dairy cattle is achieved by manipulating the anion/cation balance of the diet.[73] This involves reducing the precalving intake of dietary cations Na, K, and Ca and encouraging the intake of Cl and S. On an extensive production basis, the goal of reducing Na, K, and Ca intake can be achieved by prohibiting substantial grazing of extremely lush, highly fertilized grass pastures or of excessive amounts of legume; feeding only those supplements that do not contain added calcium or salt; and avoiding water that is high in Ca or Na.[40]

The role of serum zinc concentrations in the etiology of bovine dystocia has been incompletely investigated. Zinc influences hormonal synthesis, secretion, and activity.[40] Specifically, zinc can alter essential fatty acid levels and thereby affect prostaglandin synthesis. Thus, high levels of zinc may reduce $PGF_{2\alpha}$ production, which plays an important role in the initiation of parturition. Zinc deficiency can reduce protein synthesis and impair estrogen-mediated responses.[40] Initial research found a difference in the pattern of change of serum zinc concentrations in cows experiencing normal or difficult parturition.[74] A more recent trial found that mean serum zinc concentrations were significantly lower at calving in heifers requiring assistance (483 ± 28 µg/L) than in heifers not requiring assistance (655 ± 49 µg/L), despite no significant differences between the two groups during gestation.[35] Although these findings suggest that serum zinc concentrations could not be used in a predictive manner, supplementation may be considered in following years if the problem is suspected from assessing serum zinc concentrations in previous years.

The type of relationship that may exist between selenium intake and dystocia incidence is still unconfirmed. Anecdotal evidence has incriminated low selenium levels as a contributory cause of dystocia[38]; however, controlled studies have failed to confirm this assumption.[40] Recently, a small study found that heifers requiring assistance had significantly higher glutathione peroxidase activity throughout gestation than that found in contemporaries not requiring assistance.[35] The close association of iodine with selenium activity via the iodothyronine deiodinases and thyroid activity may provide a mechanism by which iodine and selenium could be associated with dystocia.

Body Condition at Calving

Some evidence in the literature suggests that dystocia resulting from "ineffective labor" may be due to overfat condition of beef heifers at the time of calving.[34,35,75] Suggestions regarding the cause of this condition have included an inability to rapidly mobilize calcium and other minerals when required[35,38]; the accumulation of fat around the vagina, decreasing its ability to dilate[34]; and an increase in fat marbling within the myometrium, possibly reducing its tone and contractility.

Recognition of this problem as a cause of dystocia correlates with the common management plan of not having heifers too fat at calving and supports the idea of including mechanisms for increasing heifer exercise in the dystocia control program.

Increasing heifer exercise. Providing exercise to heifers by forcing them to walk to water has been recommended.[76] Anecdotal evidence suggests this strategy may be useful in preventing heifers from becoming too fat during late gestation. The proposed method of action is that in addition to reducing the possibility of heifers becoming overfat, the effort also may improve uterine and abdominal muscle tone. The technique has been widely advocated throughout the industry and intuitively has merit, but currently only indirect scientific evidence is available to support its use.[75]

Time of Calving

Research on the effects of ambient temperature during late gestation on calf birth weight has produced conclusive results. Holstein calves born during the hot summer months in Florida have lower birth weights than those of calves born in the cool winter months.[77] The investigators suggested that decreased uterine blood flow during hot weather may lead to lower placental weights and less nutrient support for the fetus. Heifers calving during winter in North America are reported to experience increased dystocia compared with heifers calving during the warmer months.[7,55] More recent research involving British breed beef heifers in Nebraska supports the suggestion that cooler temperatures during the last trimester of gestation result in higher calf birth weights.[78] The authors reported mean calf birth weights 4.6 kg lighter with a 6.1°C increase in mean air temperature during the last trimester of gestation, compared with heifers calving after a cooler last trimester.

Other factors that may influence the calving time include expected rainfall and pasture conditions. This was discussed previously under "Nutrition during Gestation."

The fact that higher incidences of dystocia have been noted in heifers calving later in the calving period[35,79] may be related to natural variations in gestation length. Such variation would be expected regardless of when the calving season was scheduled. In the stud situation, accurate records of gestation length, associated with active selection, may help to reduce the occurrence of extended gestation lengths.

Parturition Induction

Parturition induction programs using corticosteroids and prostaglandins have yielded mixed results.[80] The aim is to induce calving early in order to deprive the calf of extra time to grow in utero. With the fetus growing at approximately 100 g/day during late gestation,[81] parturition would have to be induced approximately 10 days early to reduce calf birth weight by 1 kg. Unfortunately, calves born more than 2 weeks before their estimated calving date have a poor prognosis for survival in extensive management situations. The small duration between useful birth weight reduction and a nonviability of the calf means that calf losses are easily incurred using this technique. In one study in dairy cattle, 55% of induced calves either were stillborn or died before sale.[82] Problems with retained fetal membranes and the uncertainty of breeding dates in extensive situations make this an awkward method of dystocia control. Induction may potentially result in increased dystocia if used incorrectly in situations in which ineffective labor is a major problem.

Gestation Length

Gestation length is known to have an influence on dystocia incidence, but the mechanisms leading to dystocia are different for gestation periods longer or shorter than those considered normal. Gestation periods longer than 280 days may result in progressively increased calving difficulty, primarily as a result of increased calf birth weight. Gestation periods shorter than 267 days also have been found to be associated with increased calving difficulty, perhaps as a result of an hormonal environment that is not optimal for reproductive tract preparation before parturition. The prepartum hormonal environment depends heavily on the normal development of the fetoplacental unit. The length of gestation has been found to be heritable and so could be changed by selection.[66]

Increased Surveillance of Heifers at Calving

Although increased surveillance of heifers does not reduce the incidence of dystocia, this strategy can reduce the impact of the problem by controlling losses. Despite some reports suggesting that increased surveillance leads to increased dystocia,[83] the general conclusion is that potential losses probably are reduced as a result of closer supervision.[29]

THE FUTURE

Already, gene technology is allowing the identification of quantitative trait loci (QTL) that have the potential to significantly increase the rate of genetic improvement through the use of marker-assisted selection.[84] This

technology also allows antagonistic genetic correlations among traits to be broken. For example, estimates of the genetic correlations between direct effects on birth weight and yearling weight are approximately 0.5 across all breeds.[85] As a result, producers may base selection on phenotype or EPD' values, because greater yearling weight also may significantly increase birth weight, potentially increasing dystocia incidence. The converse also is true: selection for lower birth weight probably will reduce yearling weight.[84] The identification of genes or genomic regions affecting birth weight but not yearling weight will provide powerful tools to manipulate pre- and postnatal growth rates to fit individual production requirements.

The practical application of marker-assisted selection probably will mean that in the near future, a sample of blood or tail hair will allow the accurate identification of individual animals with the required traits.

The Economics of Dystocia Management

Independent estimates of the loss dystocia causes to the Australian national herd have ranged from $30 million to $48 million up to $200 million annually.[76,86,87] Even the smallest of these amounts is substantial.

Dystocia has been shown to cause significant economic loss to beef cattle properties in southeast Queensland. Although the definition of what constitutes a significant economic loss may be considered to be subjective, it could be argued that if long-term preventive measures can be instituted for less than the cost of 1 year's financial loss due to dystocia, then the economic impact of dystocia is significant.

A study based on cattle prices in 1995 found that in southern Queensland, for each percentage decrease in the dystocia incidence, the increase in gross margin was $0.13 per hectare. For the average-size beef cattle property in the study (2090 hectares), this represented an increase in the annual total gross margin of approximately $272 for each percent decrease in the heifer dystocia rate. These figures may assist decisions on how much should be spent on dystocia control methods. For example, reducing the dystocia incidence by 10% on an average-size property described above would provide approximately $2,720 extra annual income. This amount of money could help cover the cost of a set of weighing scales, or be added to the annual bull-buying budget to allow the purchase of a bull with more objective calf birth weight data.

Conclusions

Hundreds, if not thousands, of genes are estimated to be involved in the precise events leading to normal growth and development of the fetus.[88] In addition, review of the literature indicates that the causes of dystocia in beef cattle are complex and interactive. Thus, it would seem unreasonable to expect simple control methods to completely eliminate such a problem. What can be expected is to derive a set of guidelines that may be followed to alleviate the problem in the short term. This approach should be coupled with support for ongoing genetic and managerial developments to promote long-term reduction of dystocia incidence in beef heifers. The fact some breeds and individual herds are virtually free of dystocia[76] is testimony to the theory that a sustainable solution is attainable.

SUMMARY

Dystocia is a major cause of calf loss in cattle herds. Although difficult birth cannot be accurately predicted or eliminated, the effects can be reduced by improved management and skilled intervention when necessary. Replacement heifers should be well developed and fed adequately to reach 65% of their mature weight at breeding. Their nutritional needs for growth and maintenance should be met during gestation, and they should calve in good body condition. Reduced energy intake during the last trimester of pregnancy reduces calf size but does not reduce the incidence of dystocia. Dystocia may potentially be reduced by selecting service sires that have a negative EPD for birth weight; calves from sires selected for calving ease, however, suffered comparable death loss and were significantly lighter at weaning than calves sired by other bulls.[39]

Parturient cows should be observed no less frequently than every 3 hours, and delivery should be assisted if the first or second stage of labor is prolonged. Options for assisted delivery include mutation of abnormal postures, extraction, fetotomy, pelvic symphysiotomy, and cesarean section. The method selected should be effected expeditiously and proficiently and should result in damage to neither the dam nor the fetus.

CHAPTER 43

Principles of Colostrum Feeding

MAISIE ERNESTINE DAWES and JEFF W. TYLER

The prenatal transfer of immunoglobulins to the bovine fetus is limited by the syndesmochorial placental structure. Consequently, calves are essentially agammaglobulinemic at birth.[1] This makes the ruminant neonate totally dependent on colostrum as an immunoglobulin source. Immunoglobulin G_1 (IgG_1) is the predominant isotype in bovine colostrum, but IgA and IgM isotypes also are present.[2]

Colostrogenesis is a distinct phase of mammary gland development that clearly is regulated in part by the lactogenic hormones estrogen and progesterone. In ruminants, this phase occurs during the last month of gestation and ceases abruptly just before parturition.[3] During this period, circulating maternal IgG_1 molecules diffuse across the vascular endothelium within the mammary gland and bind to specific IgG_1 F_c receptors on the basolateral membrane of the mammary secretory epithelium. The molecules then enter the lacteal secretion by micropinocytic endocytosis.[2] Premature induction of parturition has significant implications. Prostaglandins reduce IgG concentrations, whereas corticosteroids reduce the volume of colostrum produced.[4,5] Mammalian lacteal secretions also contain nonimmunologic factors such as maternal leukocytes, lactoperoxidase, and the iron-binding apoprotein lactoferrin. Lactoferrin binds the lipid A portion of endotoxin and also sequesters iron. It is both bactericidal and bacteriostatic and may be important in neonatal immunity in the face of gram-negative infections.[6]

Neonatal survival is dependent on an interaction among the host, its environment, and management influences. Calves with failure of passive transfer (FPT) have an increased risk of death; however, many calves with FPT will survive.[7] Adequate passive transfer reduces the risk of morbidity and mortality during the first months of life. Improved productivity in feedlot animals and in dairy heifers during their first lactation also has been attributed to adequate passive immunity.[1]

FACTORS INFLUENCING PASSIVE TRANSFER

Adequacy of passive immunity in the neonate is determined by several factors. These include the age of the dam or number of previous lactations, the quality of the colostrum ingested, the volume of colostrum ingested, the timing of ingestion, and the method of colostrum administration.

Age of the Dam

It often is advocated that the colostrum from first-calf heifers has a lower IgG concentration than that of older cows and should therefore be discarded and substituted with colostrum from older cows. Several recent studies, however, failed to demonstrate any differences between colostral IgG concentration from cows in their first and those in their second or later lactations. Third-lactation cows did produce colostrum with a higher IgG concentration.[8,9] A reasonable conclusion is that calves should be fed only colostrum obtained from third-lactation cows. Third-lactation cows generally constitute only about 30% of a dairy herd, however. Consequently, in order to provide colostrum for the total calf population, each third-lactation cow would have to produce sufficient colostrum for 3.33 calves. This is an unreasonable expectation. Additionally, the magnitude of the change in colostral IgG concentrations between the first and later lactations is relatively small.[1,8]

Quality of the Colostrum

Differentiating high-immunoglobulin-concentration colostrum from low-immunoglobulin-concentration colostrum is problematic.[1] Furthermore, colostrum immunoglobulin content is highly variable across cattle breeds. Some generalizations hold true, however. Beef breed cows, such as Angus and Hereford, generally have higher colostral immunoglobulin concentrations than those in dairy cows.[2] Among the dairy breeds, Jersey and Guernsey cattle have higher colostral IgG concentrations than those in Holsteins[2,4,8] (Fig. 43-1). Pritchett and colleagues evaluated the weight of colostrum at first milking as a measure of colostrum quality. This variable correlated most highly with colostral IgG_1 concentration ($r = -0.29$). They observed that colostrum weighing less than 8.5 kg had a significantly higher IgG_1 concentration ($P = 0.0001$). Although this trend was observed in cows of all ages, it was more pronounced in the second-lactation cows.[9] In 1979, Fleenor and Stott proposed the use of hydrometry. This approach involved using the colostrometer to assess IgG_1 concentration based on the relative density of the colostrum sample.[10] Recently, however, Morin and co-workers observed that colostral specific gravity correlated more closely with colostral protein concentration ($r^2 = 0.76$) than with colostral IgG_1 concentration ($r^2 = 0.53$).[11]

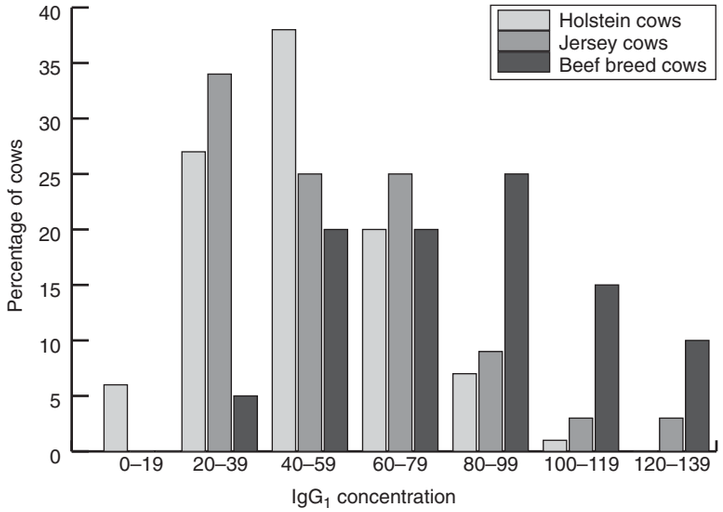

Fig. 43-1 Colostrum immunoglobulin concentrations (mg/ml) in Holstein, Jersey, and mixed-breed beef cows. (Adapted from Besser TE, Gay CC: The importance of colostrum to the health of the neonatal calf. *Vet Clin North Am Food Animl Pract* 1994;10:107–117.)

Stott and associates observed a rapid decline in all three immunoglobulin isotype concentrations (IgG_1, IgA, IgM) 12 hours after the first complete milking. In some instances, the quality of the colostrum deteriorated after the first milking, but such changes usually were seen after the second milking. Consequently, to ensure effective passive transfer, it is advocated that only the first-milking colostrum be fed to neonates.[12]

Colostral pooling, the practice of combining colostrum samples from multiple dams, is more common in dairies in which the storage of colostrum is necessary. Additionally, pooling often is encouraged in order to eliminate the deficiencies of low-quality colostrum. Of interest, colostrum produced in large volumes tends to have lower immunoglobulin concentrations, and unfortunately, it is the low-immunoglobulin, high-volume colostrum samples that will be overrepresented. In effect, they lower the pool IgG_1 concentration and hence colostrum quality. Consequently, the practice of colostral pooling is now strongly discouraged.[1,9]

Volume of Colostrum Ingested

The primary determinants for attaining adequate passive immunity are the quality and the volume of colostrum ingested. Because colostrum quality varies greatly between cattle breeds, the volume required to attain adequate passive immunity in calves also is variable. Adequate passive transfer is defined as a serum IgG_1 concentration of 1000 mg/dl in the colostrum-replete calf. To achieve this, approximately 100 g of immunoglobulin must be available in the initial colostrum meal.[2] Of interest, serum concentrations greater than 1000 mg/dl will not further decrease the mortality rate.[1]

It is currently recommended that 3 to 4 L of colostrum be delivered in one feeding to Holstein calves to ensure adequate passive immunity. The volume needed to meet IgG_1 intake goals in Guernsey and Jersey calves probably is lower.[7] The required volume greatly exceeds the voluntary intake of bottle-fed or suckling dairy calves. Besser and associates observed high rates of FPT in Holstein calves that naturally suckled their dam.[13] Consequently, force-feeding using an esophageal feeder is routinely recommended in dairy calves. By contrast, unassisted intake is an efficient method of attaining passive immunity in beef calves. Occasionally, with a less than optimal maternal-neonatal bond, human intervention becomes necessary. Adequate passive transfer generally is ensured if 2 L of colostrum is fed to neonates of the beef breeds. Force-feeding, rather than bottle-feeding, is recommended because the former is less likely to interfere with the later development of a bond between the dam and calf.

Timing of Colostrum Ingestion

Wide variations exist among calves regarding serum IgG concentrations. Time of ingestion and the amount of IgG ingested per unit body weight are the primary determinants of this variation. Colostral macromolecules are nonspecifically absorbed at the level of the ileum and jejunum of the neonatal intestinal tract. The mucosal epithelial cells that line these portions are immature and highly vacuolated and possess an apical tubular system that facilitates macromolecular absorption by a pinocytotic mechanism. The molecules then enter the systemic circulation through the venous capillaries and central lacteals of the villi. Termination of intestinal permeability or gut closure generally is age-dependent and rapidly progresses after 12 hours post partum.[5] Although immunoglobulin transfer across the gut epithelium is optimal during the first 4 hours post partum, mean gut closure time is approximately 24 hours in calves. The effect of dystocia and hypoxemia on immunoglobulin absorption has been studied. Although the absorptive capacity between normoxic and hypoxic calves was not statistically significant, gut closure was significantly delayed under hypoxic conditions (40.5 versus 20.5 hours).[14]

ASSESSING PASSIVE TRANSFER

Passive immunity is ideally assessed between 24 hours and 2 weeks of age, because endogenous immunoglobulin production and the normal decay of colostral IgG will cloud test interpretation in older calves. Several methods are available to veterinary practitioners as well as clients.[1] These vary in terms of technicality, accuracy, cost, and speed.

The gold standard for IgG_1 determination is radial immunodiffusion. Its disadvantages include the 72-hour delay for results, technical difficulty, and cost. Tests that yield results in a more timely fashion include the Quick Test Calf IgG Kit, a whole-blood immunoassay, the sodium sulfite turbidity assay, and determination of total solids by refractometry. The former test requires no prior laboratory processing, is adaptable to field use, and yields results in 20 minutes. Blood samples to be tested by the two latter methods require prior centrifugation. Such tests are easily undertaken in veterinary practices with minimal laboratory facilities, however, and yield results in a very short time. Other tests including glutaraldehyde coagulation, serum gamma-glutamyl transferase (GGT) activity, and the zinc sulfate turbidity test are not recommended because of inherent inaccuracies in test results.

CONCLUSIONS

In summary, adequate passive immunity is defined as a serum IgG_1 concentration of 1000 mg/dl. This goal is easily attainable if calves ingest adequate amounts of colostrum containing 100 g or more of IgG_1. Beef calves often will voluntarily attain adequate passive immunity. Because the quality of colostrum obtained from dairy cows is comparatively inferior, however, force-feeding is recommended in dairy calves. A volume of 4 L of colostrum is routinely administered in one feeding. In beef cattle neonates, 2 L usually is adequate.

ACKNOWLEDGMENT

The authors wish to thank Drs. Jeff Lakritz and Phillip Johnson for their contribution.

CHAPTER 44

Postpartum Uterine Infections

CARLOS A. RISCO, ROBERT S. YOUNGQUIST, and M. DAWN SHORE

Uterine infections are common disorders affecting dairy cows during the postpartum period. The literature is replete with case reports and retrospective and prospective studies suggesting that uterine infections decrease milk yield and subsequent reproductive performance. In these reports, however, no differentiation was made among the types of infection, and uterine infection was classified as a disease complex with clinical manifestations ranging from minimal or none to life-threatening sepsis. Consequently, a divergence of opinion continues to exist among veterinarians regarding diagnosis and treatment of uterine infections.[1]

ETIOLOGY AND DEFINITION

The uterus normally is protected from bacterial contamination by the vulva, vestibular sphincter, and cervix. During and immediately after parturition, these mechanical barriers are breached and the uterus normally is contaminated by a variety of pathogenic and nonpathogenic microorganisms. Most of these bacteria are merely transient residents and are promptly eliminated by the uterine defense mechanism during the puerperium. In some cases, however, pathogens persist in the uterus and cause disease. The organism most commonly associated with uterine disease in cattle is *Actinomyces pyogenes*.[2,3] In addition, the gram-negative anaerobes *Fusobacterium necrophorum* and *Bacteroides melaninogenicus* frequently are associated with *A. pyogenes*. *Bacteroides* decreases chemotaxis and inhibits phagocytosis by neutrophils, allowing *A. pyogenes* to persist.[4] A variety of other microorganisms occasionally are associated with uterine disease in cows and include coliforms, *Pseudomonas aeruginosa,* staphylococci, hemolytic streptococci, and others. *Clostridium* spp. occasionally infect the uterus and cause severe gangrenous metritis or tetanus. Some of the organisms that transiently contaminate the uterus during the postpartum period produce penicillinase; this should be a consideration in the selection of drugs and routes of administration used in treating the disease. In cows with a normal puerperium, the uterus is nearly free of bacterial contamination by 4 weeks after calving.[5]

Uterine infections are associated with retained fetal membranes (RFM), dystocia, delivery of twins, overconditioning, underconditioning, long-term feeding of urea to dry cows, and large herd size.[6–11] In one study, severe uterine infections frequently followed manual removal of retained membranes.[12] Unsanitary calving conditions and traumatic obstetric procedures predispose cows to uterine infections. Because of differences in their calving environment, postpartum uterine infections more commonly affect dairy cows than beef cows.

Definition of uterine infections has considered character of uterine discharge, days postpartum, clinical findings, and endocrine status.[1,13] Unfortunately, clinicians and researchers have vaguely applied terms such as metritis and endometritis when describing uterine infections, which has contributed to confusion among veterinarians in the definition and economic impact of uterine infections. Therefore, as suggested in the review by Bondurant,[13] definitions used by theriogenologists and pathologists should be applied in describing uterine infections, in order to avoid confusion. Specific definitions of related entities are presented next.

Metritis or perimetritis. Metritis is a result of a severe inflammation involving all layers of the uterus (endometrial mucosa and submucosa, muscularis, and serosa).[13] It generally develops during the first week after calving and is associated with dystocia, RFM, and calving trauma. Affected cows may be septic and present with fever, depression, anorexia, and reduced milk yield (Olsen). In addition, a copious fetid vaginal discharge may be present. Other terms used to describe metritis have included "acute puerperal metritis" and "toxic metritis."

Endometritis. Endometritis is characterized by inflammation of the endometrium extending no deeper than the stratum spongiosum.[13] This condition may follow parturition, copulation, artificial insemination, or infusion of irritants into the endometrial cavity. Usually, presence of a purulent exudate is noticed on visual inspection of the vulva. The affected animal is rarely systemically ill, and the uterus is found to be normal on palpation. Acute endometritis typically is a temporary condition, and after several estrous cycles, the offending bacteria usually are eliminated. In chronic cases of endometritis, a purulent vaginal discharge may persist. Affected cows may have a lower first-service pregnancy rate than their herdmates and require more time to conceive.[14]

Pyometra. Pyometra is characterized by a collection of purulent exudate of variable amount within the endometrial cavity, persistence of a corpus luteum, and suspension of the estrous cycle.[15] This condition is most likely to develop in cows that have their first postpartum ovulation before bacterial contamination of the uterus has been eliminated. The ensuing corpus luteum persists beyond its normal lifespan because intrauterine fluid prevents luteolysis. Progesterone continues to dominate the uterus and suppresses the uterine defense mechanism.[16] Pyometra also is an occasional clinical sign of trichomoniasis, and *Tritrichomonas fetus* should be suspected as a cause of pyometra that develops during the breeding season.

The lactation incidence of postpartum uterine infection varies among reports and with criteria used for

diagnosis. In a large retrospective study, metritis complicated 13.8% of lactations,[17] whereas the authors of a review of published literature found a mean incidence of 17.4% and a range of 8.5% to 24.2%.[18] Published reports are very difficult to interpret, however, because of the inordinate variety of criteria used to define uterine infections. Furthermore, it is likely that misinterpretation of the normal postpartum discharge from reproductive tracts of cows leads to inflated estimates of incidence of the disease.[19]

DIAGNOSIS

Clinical Signs

Clinical signs of uterine infection vary with the virulence of the causative organism and the presence of factors that predispose to the disease. Lochia normally is expelled from the reproductive tract during the first few weeks after calving, and the discharge may persist for up to 30 days if uterine involution is delayed. Normal discharges range in color from dark brown to red to white; discharge usually should not be considered abnormal unless the fluid is fetid or clinical signs of sepsis are present.

Palpation per Rectum

Examination of the uterus by palpation through the rectal wall commonly is used to evaluate the degree of involution before breeding. Palpation may not be useful to diagnose abnormalities of uterine involution during the first 2 weeks post partum, however. When involution is delayed, the uterine wall may be atonic and lack the longitudinal rugae (involution lines) typical of a normal uterus. In cases of metritis, the uterus is swollen and friable, and occasionally fibrin deposits and adhesions between the uterus and other organs or the body wall may be palpable. If involution is normal, fluid should not be palpable within the uterine lumen by 14 to 18 days after calving. In one series, cows in which a uterine lumen was palpable at the postpartum examination were likely to have pathologic changes that suggested delayed uterine involution or permanent uterine damage.[20]

A common method used for diagnosis of endometritis combines palpation of the uterus and visual inspection of the vulva for a purulent exudate. The size and consistency of the uterus and cervix, along with evaluation for the presence of fluid within the lumen of the uterus, are criteria used to diagnose endometritis. Visual inspection may reveal crust of a purulent nature formed in the perineal region. In addition, a purulent exudate may be present at the ventral commissure of the vulva.

Palpation per rectum is, however, neither a sensitive nor a specific method for accurate diagnosis of endometritis. In one trial, 157 cases of endometritis were diagnosed by palpation, but bacteria were isolated from uterine fluid in only 22% of the samples taken.[21] By contrast, evaluation of cervical size and the presence of a purulent discharge may be of diagnostic value. In a study that involved lactating dairy cows, diagnosis of endometritis was based on the presence of a purulent uterine discharge or cervical diameter greater than 7.5 cm after 20 days post partum or a mucopurulent discharge after 26 days post partum.[22] This definition was based on the negative effect that these criteria have on subsequent fertility.

Vaginoscopy

Observation of purulent exudate with the aid of a vaginal speculum has been reported to be a useful tool for diagnosis of subacute and chronic endometritis and for evaluation of response to treatment.[3,22] A prevalence of 16.9% of endometritis was found in one study, and vaginoscopy was required to identify a purulent discharge in 44% of the cases.[22] These findings suggest that visual inspection of the vulva or palpation of the uterus may not be sufficient to identify a purulent content for a confident diagnosis of endometritis. Unfortunately, the requirements for sterile and disposable specula and for aseptic preparation of the perineum and external genitals make this procedure cumbersome when cows are examined in free-stalls or lock-up stanchions.

Ultrasonography

Real-time ultrasonography has been used to demonstrate uterine changes associated with postpartum infections.[23,24] The intrauterine fluid associated with uterine infections contained echogenic particles and was easily distinguished from clear nonechogenic fluid associated with estrus and pregnancy. In addition, the uterine wall of cows affected with uterine infections was variably thickened.

Hematology

In cows with septic metritis, a degenerative left shift and marked neutropenia may occur. Hypocalcemia, which can occur early post partum, may accompany metritis. An association between ketosis and metritis has been reported in dairy cows.[25,26] Furthermore, high blood concentrations of nonesterified fatty acids (NEFAs) in cows have been demonstrated to impair lymphocyte function in vitro.[27] Thus, fat mobilization with increased blood concentrations of NEFAs may explain the higher incidence of infections observed in cows that experience an energy deficit early post partum.

Bacterial Culture

Guarded culture instruments can be passed through the cervix and samples of intrauterine fluid obtained for bacterial culture. Samples should be cultured in both aerobic and anaerobic environments. Under most circumstances, however, samples from individual animals are rarely submitted for bacterial culture because a decision to treat usually is made before results of culture are available. The cost of the procedure can only rarely be justified. *A. pyogenes* and gram-negative anaerobes usually are assumed to be the most likely causative organisms. Bacterial culture and antibiotic sensitivity tests may be indicated on farms that have an unusually high incidence of uterine infection, or if cows fail to respond to treatment.[28]

Endometrial Biopsy

Evaluation of endometrial biopsy specimens has not become as common in cows as in mares.[29] An association between isolation of *A. pyogenes* and endometrial lesions has been demonstrated.[30] Uterine biopsies at days 26 and 40, however, are reported to have a detrimental effect on future fertility.[31]

Endometrial Cytologic Studies

Neutrophils are the primary response against pathogenic bacteria of the postpartum uterus, resulting in an increase in polymorphonuclear (PMN) cells within the uterine lumen. Evaluation of the PMN count through endometrial cytology has been successful in identifying dairy cows with endometritis.[32] In clinically normal cows (without evidence of an abnormal discharge), subclinical endometritis was defined as greater than 18% PMN leukocytes during days 20 to 33 post partum and as greater than 10% during days 34 to 47 post partum. Cows with subclinical endometritis were less likely to become pregnant than cows without subclinical endometritis.

TREATMENT AND PROGNOSIS

Few topics are more controversial among clinicians than appropriate treatment for bovine uterine infections, perhaps because of the lack of precise diagnostic criteria and lack of controlled trials in which various therapeutic options have been rigorously compared. In a retrospective study, the authors concluded that the type of treatment had little effect on the outcome of the disease and suggested that only supportive therapy was needed while the patient recovered spontaneously.[33] Therapy for uterine infection has fallen into the broad categories of intrauterine therapy (antibiotics and antiseptic chemicals), systemic antibiotics and supportive therapy, and hormone therapy.[34]

Intrauterine Therapy

A variety of antibiotics and antiseptic chemicals have been infused into the uterus of cows in attempts to treat postpartum infections. Some authors have found intrauterine treatment to be beneficial, whereas others have found it to have no effect. Still others have recommended that it not be used. The bovine uterus is an anaerobic environment; thus, antibiotics chosen for intrauterine use must be active in the absence of oxygen.[35] In addition, most antibiotics and chemicals depress activity of uterine neutrophils and interfere with the uterine defense mechanism; therefore, the potential benefit of their use must be carefully weighed against their deleterious effects.[36]

Organisms that cause postpartum uterine infections usually are sensitive to penicillin, but bacterial contaminants during the first several weeks after calving produce penicillinase, which renders the drug ineffective if applied locally. By 30 days post partum these organisms usually are eliminated, and intrauterine treatment with penicillin is more likely to be effective after that time. The daily intrauterine dose recommended to reach the minimal inhibitory concentration (MIC) for *A. pyogenes* is 1×10^6 U.[37]

Oxytetracycline commonly is recommended for intrauterine therapy for postpartum infections. In a recent study, however, most isolates of *A. pyogenes* recovered from the uterus of cows were resistant to oxytetracycline, and intrauterine treatment with large doses did not affect the frequency of *A. pyogenes* isolation.[38] Furthermore, many preparations of oxytetracycline are irritating and cause chemical endometritis. If oxytetracycline is selected for intrauterine therapy, doses of 4 to 6 g/day have been recommended.

No antibiotics are approved in the United States for intrauterine administration to lactating dairy cows. Intrauterine administration of antibiotics results in contamination of milk,[39] and appropriate withdrawal times have not been determined. Assays for detection of antibiotics in milk that are available for on-farm use may be inaccurate; therefore, it is extremely difficult to ascertain whether milk from individually treated cows does or does not contain antibiotic residues.[40–43]

The use of iodine solutions for intrauterine therapy has been advocated by some veterinarians; however, there is no evidence of a therapeutic value. The incidence of RFM and endometritis was reduced in cows infused with 500 mL of 2% Lugol's iodine immediately after calving and again 6 hours later. Subsequent reproductive performance of treated cows was not reported, however.[44] Conversely, routine infusion of 50 to 100 ml of 2% polyvinylpyrrolidone-iodine solution 1 month after calving did not improve reproductive performance of normal cows and was detrimental to the fertility of cows affected by endometritis.[45] Hence, intrauterine therapy with iodine solutions for the treatment of uterine infections is not recommended.

Systemic Antibiotics and Supportive Therapy

A variety of broad-spectrum antibiotics have been recommended for parenteral administration to cows with uterine infections.[46] Penicillin or one of its synthetic analogues most commonly is recommended (20,000 to 30,000 U/kg bid). Oxytetracycline probably is not a good choice for systemic administration because of the difficulty in reaching the MIC required for *A. pyogenes* in the lumen of the uterus.

Ceftiofur is a third-generation cephalosporin that has broad-spectrum activity against gram-positive and gram-negative bacteria implicated in causation of metritis.[47] Moreover, ceftiofur has been reported to reach all layers of the uterus without violative residues in milk. Subcutaneous administration of ceftiofur at a dose of 1 mg/kg in dairy cows after parturition resulted in a concentration of ceftiofur and its active metabolites in plasma, uterine tissues, and lochial fluid that exceeded reported MIC values for common pathogens involved in metritis.[48] Smith and associates[49] demonstrated that in postpartum dairy cows affected with metritis (rectal temperature

>102.6°F, flaccid uterus and a fetid vaginal discharge), ceftiofur administered at a dosage of 2.2 mg/kg daily for 5 days, is as effective as procaine penicillin G or procaine penicillin G plus intrauterine infusion of oxytetracycline for treatment of the infection. In a multilocation study that involved 406 cows in the first 14 days post partum, ceftiofur administered at a dosage of 2.2 mg/kg daily for 5 days was efficacious in the treatment of metritis (rectal temperature >103.1°F with a fetid vaginal discharge).[47] Ceftiofur is approved in the United States for systemic administration to lactating dairy cows affected with metritis.

If dehydration complicates metritis, appropriate fluid therapy should be instituted and may be life-saving. Depending on the degree of dehydration, oral or intravenous administration of a polyionic nonalkalizing solution is indicated. Nonsteroidal anti-inflammatory drugs such as flunixin meglumine are used to combat toxemia and improve appetite. Furthermore, cows with metritis may experience depressed appetite, affecting calcium and energy status. Consequently, therapy with calcium and energy supplements may be warranted.

Hormone Therapy

A variety of hormones have been administered to cows in attempts to prevent or treat postpartum uterine infections. Estrogen has been administered to initiate or strengthen myometrial contractions, but its use is controversial. Contractions induced by estrogen have been blamed for forcing the septic contents of the uterus not only through the cervix but also into the uterine tubes, to result in severe bilateral salpingitis.

Oxytocin causes contraction of the myometrium if the organ is dominated by estrogen. Thus, oxytocin is expected to be effective in aiding uterine evacuation if administered within 48 to 72 hours after calving. Doses of 20 to 40 U repeated every 3 to 6 hours are commonly used.

Prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) and its synthetic analogues have been widely used to treat a variety of abnormalities of the reproductive tract, including postpartum uterine infections.[50] During the immediate postpartum period, serum concentrations of $PGF_{2\alpha}$ and its metabolites are elevated; these increases are thought to be related to the process of uterine involution.[51] Administration of exogenous prostaglandin during the postpartum period does not alter the rate of uterine involution, however, nor is involution retarded when prostaglandin synthesis is inhibited. $PGF_{2\alpha}$ is a potent luteolysin perceived by some investigators to have an additional beneficial effect on the pituitary, affecting resumption of postpartum cyclicity. Prostaglandin treatment did not have any effect on the time required for cows to resume ovarian activity after calving, however, and had no consistent effect on plasma luteinizing hormone concentrations.[52] Several clinical trials have shown that administration of prostaglandin during the postpartum period may enhance the reproductive performance of dairy cows that are otherwise unaffected by periparturient diseases.[53,54] Likewise, cows affected with dystocia, RFM, or both and treated with $PGF_{2\alpha}$ early post partum, followed by a second treatment of $PGF_{2\alpha}$ 14 days later, experienced a higher conception rate to first service than did untreated cows experiencing a normal or abnormal parturition.[55]

Prostaglandin is the agent of choice for therapy of pyometra. Treatment is followed in 3 to 9 days by evacuation of the uterus in 85% to 90% of treated cows. After endometrial lesions are allowed 30 days to heal, fertility is restored in most patients.[56]

Pituitary responsiveness to gonadotropin-releasing hormone (GnRH) is low at parturition but increases until sufficient luteinizing hormone to induce ovulation is released by administration of GnRH at approximately 2 weeks post partum in milked cows.[57] GnRH treatment at 2 weeks post partum has been shown in some clinical trials to improve reproductive performance of cows affected by puerperal abnormalities such as dystocia, retained placenta, uterine infections, hypocalcemia, and ketosis.[58] The mechanism by which reproductive performance might be improved by treatment with GnRH is unclear, because treatment with GnRH at 15 days after calving neither hastened uterine involution nor reduced bacterial infections of the uterus.[59] Induction of ovulation during the early postpartum period with GnRH may have some negative effects on reproductive performance. Longer intervals to first estrus and pregnancy followed treatment with GnRH in a herd affected by an above-average number of postpartum uterine infections because of increased pyometra and prebreeding anestrus.[60] Furthermore, treatment with GnRH early post partum, alone or in combination with $PGF_{2\alpha}$ 14 days later, which potentially may have induced cyclicity, did not improve reproductive performance in dairy cows affected with dystocia, RFM, or both.[55]

The prognosis for recovery from postpartum uterine infections varies with severity of the condition. Most cows with uncomplicated endometritis can be expected to recover. Metritis complicated by septicemia may result in permanent impairment of fertility, decreased milk yield, laminitis, or, in extreme cases, demise of the patient despite aggressive treatment. Pyometra is rarely accompanied by abnormal clinical signs other than anestrus in cows and rarely endangers the health or life of the animal. Most cows recover promptly from pyometra if the condition is diagnosed and treated early in its course.

The cost of a case of metritis has been estimated to be $106,[61] and most clinicians assume that metritis has a negative influence on subsequent reproductive performance of affected cows.[18] In only one of four herds studied, however, did cows with metritis treated systemically with oxytetracycline have reproductive performance inferior to that of their unaffected herdmates.[62] In another large retrospective study, metritis was found to affect neither milk yield nor subsequent fertility of cows in their first lactation.[63] Likewise, a study that evaluated data from 37,776 Finnish Ayrshire dairy cows determined that metritis had no effect on milk yield when considered as a one-disease complex.[64] When early and late metritis events were analyzed separately, however, the time of disease occurrence affected milk

yield. Late metritis was not associated with milk loss. By contrast, early metritis (within 28 days post partum) significantly reduced milk yield, as indicated by monthly-test-day milk yields.[64]

PREVENTION AND CONTROL

Cows affected by periparturient abnormalities such as hypocalcemia, dystocia, and RFM are more likely to contract uterine infections than are cows that calve normally. Thus, management of sanitation, nutrition, population density, and stress to prevent or reduce the incidence of these predisposing factors should be impeccable. The most sanitary environment possible should be provided for calving, and strict attention paid to asepsis when relief of dystocia is necessary. Routine treatment of cows with antibiotics after calving has been shown to reduce fertility.[65] Excessive contamination of the environment with pathogenic microorganisms has resulted in infection of the reproductive tracts of cows during the second and third months post partum. Usual sanitary procedures did not appear sufficient to prevent spread of infections, and isolation of cows with purulent discharges was recommended.[66]

Management of RFM commonly involves an intrauterine antibiotic regimen to prevent the development of metritis.[19] Alternatively, the prophylactic use of systemic antibiotics in cows affected with RFM to prevent metritis may be considered. Systemic administration of ceftiofur in dairy cows affected with dystocia, RFM, or both reduced the incidence of metritis by 70% compared with cows not treated with antibiotics or those treated with estradiol cypionate (ECP).[67]

CHAPTER 45

Retained Placenta

HUGO EILER and KELLIE A. FECTEAU

DEFINITION

Primary retention of the fetal membranes results from a lack of detachment from the maternal caruncles, whereas secondary retention is related to a mechanical difficulty in expelling already detached fetal membranes (e.g., uterine atony). Primary and secondary retention mechanisms can coexist.

Physiologic versus Pathologic Retention

Theoretically, all cows that calve have retained fetal membranes (RFM). Greater than three fourths of cows, however, expel their placenta by 6 hours, and very few cows after 12 hours post partum (Table 45-1). Detrimental effects on reproductive performance, milk production, postpartum disease, and culling rate were detected when duration of retention exceeded 12 hours (Table 45-2). For fourth parity and higher, the cows' overall performance was best with expulsion of the placenta within 6 hours post partum. For this reason, it has been proposed that, in older cows, retained placenta is a failure to expel placenta within 6 hours after parturition. Heifers that expelled their placentas within 6 hours after calving had the lowest incidence of mastitis occurring within 1 week after calving. Because the incidence rates of RFM and postpartum disease vary with parity, the definition of retained placenta also may be age-dependent or parity-dependent. Periods from 8 to 48 hours have been proposed by various authors, but 12 hours is a widely used lapse to define RFM.

Duration of Pathologic Retention

In one series, spontaneous expulsion of retained membranes occurred between 5 and 7 days post partum in greater than one half (59%) of cows with RFM (Table 45-3). In a different experiment, however, when detachment was tested by manual traction on the membranes, they were found to be loose and "floating" in the uterus between 2 and 4 days post partum in 50% of cows with RFM. It seems that in some cows, a delay of 1 or 2 days may occur between detachment and expulsion of retained membranes. Delayed expulsion was more frequently observed in cows induced to deliver with dexamethasone (70%) than in cows with naturally occurring RFM (40%). Only 6% of the cows retained fetal membranes for 2 weeks or more. A mean retention duration of 6.8 days (range, 2–11 days) was reported. Distribution of the values for duration of retained placenta was reported to be bimodal, with a first peak at day 3 post partum and a second peak by day 7. One explanation for the bimodal distribution in expulsion of RFM is that cotyledon proteolysis was the detachment mechanism by day 3, and caruncle necrosis by day 7 post partum.

EPIDEMIOLOGY

Incidence, morbidity, and mortality rates are shown in Table 45-2. An average incidence frequently reported for a relatively large number of calvings has been shown to range from 4% to 11%. A comprehensive study of about 369,000 calvings showed the incidence of RFM to be 6.6% after all births and 4.1% after normal deliveries only. Risk factors that are known to affect incidence rates are listed in Table 45-4. Notice the high risk factor values in conditions in which both physical damage to the uterus was inflicted and hormone imbalances were induced. Also of interest is that eradication of brucellosis did not statistically decrease RFM incidence.

ECONOMICS

In a study conducted in The Netherlands with 160,000 calvings, the relative economic impact expressed in percentage was identified in four main areas: decreased milk production (40%), increased veterinary services (32%), increased culling rate (19%), and increased calving interval (9%). In other studies in Holsteins in the Northeast United States and in Ayrshires from Finland, however, retained placenta had a significant effect on milk yield. For example, it was calculated that second-parity cows decreased milk production by 1.4 kg/day as a result of retained placenta. In these same studies, it also was estimated that retained placenta lowered conception rate by 14%, compared with that in cows free of this disorder.[1]

Information concerning the cost of RFM in the United States is not readily available. For cows treated by a veterinarian, a cost of $244 per affected cow, or about $154 million per year, was estimated. Perception of economic losses per affected cow varied between veterinarians ($100 to $200) and producers ($150 to $300) in East Tennessee. It is possible that our calculations (1995) represent an overestimate, because the cost for a lactation with metritis was estimated at $106 in a 1986 study conducted in Michigan, and total health-related costs for 1990 in Ohio were $188 per cow. Herds with RFM incidence of 30% but not with 10% are considered problem herds.

Table **45-1**

Timing of Placental Expulsion after Parturition*

Hours Postpartum	% of Cumulative Expulsions
3	16.0
6	77.3
9	88.7
12	94.6
15	96.2
18	97.8
21	98.5
24	100.0

*During 3-hour time intervals. *N* = 871. Only cows expelling placentas by 24 hours or less were included. Values are approximate.
Data from van Werven T, et al: *Theriogenology* 1992;37:1991.

Table **45-2**

Biomedical Effects of Pathologic Retention of Fetal Membranes in Cows

Factor	Change*
Physiologic	
Appetite	Decreased in 60% of cows
Uterine involution	Delayed 11 days
Uterine chemotaxis	Decreased
Uterine immunity	Decreased
Milk volume secreted	(0) % to (–) 2%
Milk chemistry	Fat, protein unchanged
Uterine bacteria	Increased
Reproductive Management	
Return to heat	Delayed 17 d, 19 d
Number of inseminations	(+) 15%
Conception rate	(–) 11%, (–) 19%
Calving interval	(+) 10 d, (+) 19 d, (+) 20 d
Culling rate	(+) 5.2%, (+) 7.9%, (+) 10.5%
Milk production	(–) 207 kg, (–) 200 kg, (–) 168 kg
Days open	(+) 26 d, (+) 31 d
Overall performance	Best when retention is less than 6–12 h
Health-related	
Metritis	(+) 18%, (+) 23%, (+) 28%, (+) 53%
Lochiometra	(+) 20%
Mastitis	(0) %, (+) 5.8%, (+) 10%, (+) 15%
Previous retention	(+) correlation
Cystic ovary	(+) 0%, (+) 15%, (+) 50%
Ketosis	(0), (+) correlation
Epidemiologic	
Incidence	Average 7.5% (2–55%)
Effect of season	(+) 2%, (+) 5%, (+) 12% summer
Effect of year (1976–1983)	1.6% curvilinear increase in 7-year period
Morbidity	1.96–55%
Mortality	1–4%
Effect of age/parity	Positive correlation

(0) (+) (–), unchanged, increased, or decreased compared with cows without retained fetal membranes.
*Range or values reported by different researchers. Because of inconsistent experimental designs, data cannot be extrapolated between studies.

ETIOLOGY

Detachment of the fetal membranes indicates that uterine involution is progressing normally. Involution of the uterus is accompanied by a massive breakdown of collagen and other proteins. Lack of cotyledon proteolysis (collagenolysis) appears to be the underlying cause of RFM. If placenta-anchoring systems are not enzymatically degraded, fetal membranes are retained. Analysis of risk factors (see Table 45-4) may help to identify causes.

Anchoring Systems

The fetal cotyledon engulfs the maternal caruncle to form the primary anchoring system of the placenta, which keeps maternal and fetal tissues in apposition. Cotyledons form a cul-de-sac (pouch) that fits perfectly around the caruncle, and the open end simulates a purse-string closure (Fig. 45-1). Secondary anchoring mechanisms involve the rootlike penetration of caruncle crypts by cotyledon villi and the adhesive fluid present in the fetal-maternal interface (Fig. 45-2). The main function of the secondary anchoring mechanism is to hold together maternal and fetal epithelia within the placentome for physiologic exchange. By itself, the secondary anchoring mechanism seems to be capable of maintaining the fetal-maternal attachment throughout pregnancy, as observed in placentomes that are flat, without engulfment of the caruncle by the cotyledon (see Fig. 45-1).

The Cotyledon-Caruncle Detachment Process

Morphologic Events

Detachment of placenta in the cow involves separation of the finger-like cotyledon villi from the caruncle crypts without significant tearing of either fetal or maternal epithelia. By contrast, in the ewe, a breakdown of the cotyledon epithelia ensues when the placenta separates and, in invasive types of placentation, detachment occurs at the uterine matrix. These findings suggest that collagenolysis and proteolysis during placental detachment break apart link number 1 in the ewe and link number 2 in the cow (see Fig. 45-2).

For the cotyledon villi to separate from the caruncle crypt, it is critical that the mouth of the cotyledon "pouch" be opened first by proteolytic enzymes. This is achieved either by following three or four natural lines starting from the "mouth" of the cotyledon toward the apex (dehiscence) or by following a concentric band pattern in which the edge of the cotyledon "pouch" is digested first (Fig. 45-3).

After placental detachment is accomplished, uterine involution is completed in an average of 39 days in normal cows and 50 days in cows with RFM. By day 6

Table **45-3**

Duration of Retention*

Retention (d)	% Expelled (Cumulative %)	% Retraction (Cumulative %)
2–4	32 (32)	50 (50)
5–7	27 (59)	38 (88)
8–10	28 (87)	8 (96)

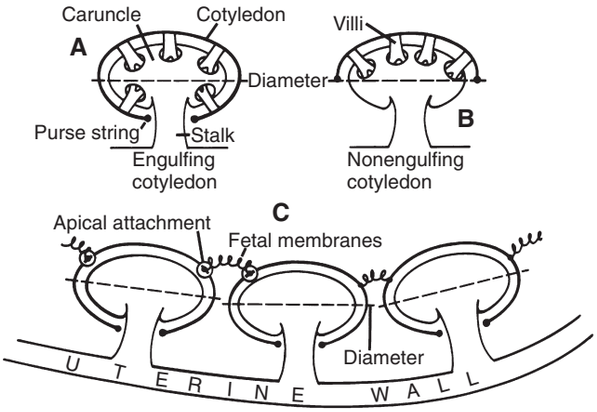

Fig. 45-1 Anatomy of the anchoring mechanism hypothesis. **A,** Cotyledon exceeds the diameter of the mushroom-like caruncle dome and engulfs the caruncle. This feature has the effect of a purse string, securing the cotyledon around the caruncle stalk. **B,** Conversely, the cotyledon ends at the maximal diameter of the caruncle dome, without engulfing the caruncle. **C,** Fetal membranes have apical attachments to the cotyledon, distal to the maximal diameter of the caruncle dome, preventing exertion of excessive pulling force on the easy-to-tear edge of cotyledons. When membranes are under tension, the oval shape of the placentome favors the formation of divergent folds. This anatomic arrangement decreases the risk of cotyledon detachment during pregnancy and makes manual removal of retained fetal membranes more difficult. (From Eiler H, Hopkins FM: *J Med Vet Assoc* 1993;203:436–443.)

Table **45-4**

Association of Obstetric, Physiologic, Hormonal, Nutritional, and Infectious Factors with Retained Placenta in the Bovine

Factor	% Retained Placenta	Relative Risk*
Obstetric		
Abortion	62	10.3
Multiple birth	37	8.3
Two previous retentions	25	6.0
Cesarean delivery in hospital	62	6.0
Stillbirth	19	4.4
Fetotomy	26	4.1
Advanced age of cow	10	3.3
Cesarean delivery	26	3.2
One previous retention	12	3.0
Difficult calving	13	2.1
Physiologic		
Short gestation plus low calf weight	12	3.0
Summer calvings	11	1.6
Sex of calf (male)		1.05
Hormone Imbalance		
Prepartum ovariectomy	100	15.1
Prepartum corpus luteum ablation	100	15.1
Abnormal (high/low) prepartum		
Progesterone	90	13.6
Estrogens	34	5.1
Induced delivery		
Prostaglandin $F_{2\alpha}$	80	12.1
Dexamethasone + prostaglandin $F_{2\alpha}$	79	12.0
Dexamethasone	67	10.1
Dexamethasone + estrogens	67	10.1
Dexamethasone + relaxin	15	2.2
Nutritional		
Selenium/vitamin E deficiency	23	2.4
Feeding hay crop/corn silage	28	1.8
Excess iron	16	1.5
Infectious		
Brucellosis-positive status of cows	28	3.0

*Calculated by dividing the proportion of cows with the factor of interest (column 1) that caused retained placenta by the proportion of cows without the factor. An error in the estimates is possible owing to variation in experimental designs.

post partum, caruncle septa are disorganized; by day 15, caruncles are completely sloughed as a result of necrosis. Consequently, RFM are detached by caruncle necrosis within 6 to 10 days and not later than 17 days post partum (see Table 45-3). The surface of the endometrium is covered by new epithelium by day 26 to 30 post partum.

Biochemical Events

Postpartum uterine biochemistry is dominated by increased collagenase and other protease activities that correlate with different stages of parturition, resulting in a massive breakdown of collagen and other proteins during uterine involution. As a result, the weight of the cow's uterus decreases from 9.0 kg at parturition to 1.0 kg at 30 days post partum.

Physiologic Events

Physiologic release of placenta is accomplished in most cows between 3 and 6 hours post partum. Cotyledon proteolysis (dehiscence) and decreasing adhesiveness (viscosity) of the cotyledon-caruncle interface fluids seem to

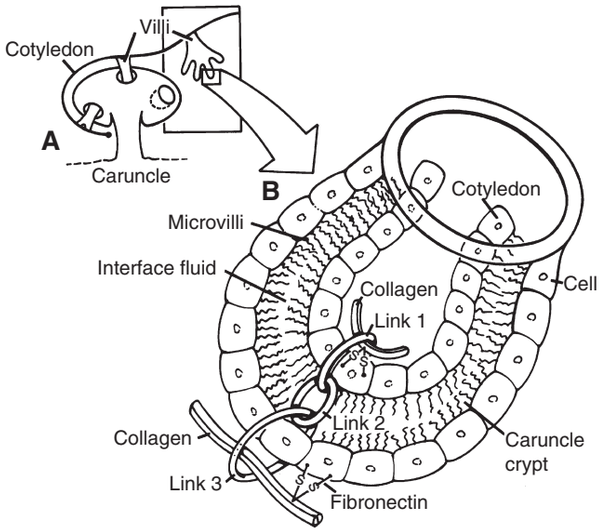

Fig. 45-2 Cotyledon-caruncle interlocking mechanism hypothesis. **A,** Root-like cotyledon villi are housed in caruncle crypts. Villi can be easily detached from the caruncle crypt by pulling from the edge of the cotyledon. **B,** Components of the fetal-maternal interface are the fetal (cotyledon) and maternal (caruncle) epithelia, epithelial attachment fibrils (perhaps fibronectin) to their own collagenous matrices, and the adhesive interface fluids between microvilli of both epithelia. The fetal-maternal interface is held together as if by three links of a chain. Link 1 is the binding of the cotyledonary epithelium to its matrix collagen. Link 2 is the gluing action of the proteinaceous interface fluids that join the fetal and maternal epithelia. Link 3 is the binding of caruncle epithelium to its matrix collagen. Hypothetically, disruption of any of the three links would cause release of fetal membranes. Conversely, persistence of the three links would cause retention of fetal membranes. (From Eiler H, Hopkins FM: *J Med Vet Assoc* 1993;203:436–443.)

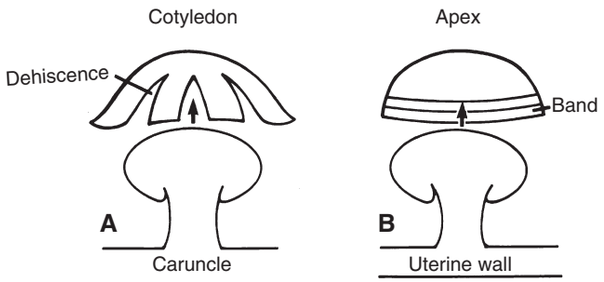

Fig. 45-3 Cotyledon proteolysis hypothesis. **A,** Proteolytic enzymes, most likely collagenase, may cause dehiscence of engulfing cotyledons by hydrolysis of cotyledon tissues towards the apex from the periphery, following three or four natural lines. **B,** In nonengulfing cotyledons, proteolysis progresses in concentric bands from the periphery to the center of the placentome, with or without dehiscence. Proteolysis opens the cotyledon, causing release of the caruncle. Lack of cotyledon proteolysis would result in retention of fetal membranes. Ultimately, retained membranes would be released by caruncle necrosis. (From Eiler H, Hopkins FM: *J Med Vet Assoc* 1993;203:436–443.)

be key factors in the release of placenta. Collagenases are capable of reducing the specific viscosity of collagen. Collagenase activity of cotyledon villi during delivery is increased in healthy cows and decreased in cows with RFM. The cellular sources of collagenase and proteolytic enzymes for placental release in the cow are unknown. In laboratory animals and humans, myometrial cells, fibroblasts, and leukocytes have been identified as sources of collagenase in the uterus. Lack of uterine motility is not considered as a reason for primary retention, because uterine motility is normal or above normal in cows with primary RFM.

Trigger of Uterine Involution Proteolysis

Serotonin, abundant in fetal blood but not in neonatal calf blood, causes release of collagenase by uterine cells. Serotonin has been proposed as a signal to begin the massive collagen degradation that occurs in the postpartum uterus. It has been suggested that the roles of serotonin during delivery are to stop blood circulation between the placenta and the fetus and to trigger uterine proteolysis.

Furthermore, uterine distention by the fetus has been proposed as an inhibitory factor to prevent uterine involution. In rats, regression of a pregnant uterine horn can be triggered by removal of the fetuses, while the contralateral horn with fetuses remains large. Consistent with this observation, the empty horn in the pregnant cow remains small, regardless of the presence of developed placentomes with blood circulation from the pregnant horn.

The following observations suggest that activation of biochemical mechanisms for uterine involution may occur before delivery: (1) placentomes collected from the uterus at term (≥270 days) are relatively smaller than those collected at day 240; (2) dexamethasone administered before delivery, instead of immediately after delivery, can induce RFM; (3) injection of relaxin (collagenase inducer) after delivery cancels the RFM-inducing property of dexamethasone injection; (4) softening (collagen breakdown) of the cervix occurs before delivery; and (5) plasma collagenase activity increases at term, but before labor. It is suspected that collagenase is activated before delivery about 9 hours before the release of placenta in the cow.

Failure of Cotyledon-Caruncle Detaching Mechanisms

It is proposed that the biochemical disturbance leading to RFM may be triggered either before or during delivery. The collagenolytic activity of cotyledon villi is decreased in cows with RFM, and persistence of type III collagen is observed in cows with RFM. Activity of matrix metalloproteinase-9 (MMP-9) in cows with retained placenta is lower than in cows without retained placenta, and specific active forms of MMP-2 are absent in retained placenta. The differences in enzyme activity between cows with and those without retained placenta may affect the hydrolysis of collagen and subsequent release of the

fetal membranes.[2] These observations suggest that a deficiency of collagenase may be involved in the hydrolysis of type III collagen. It is possible that RFM also may be due, in some cases, to the presence of an anticollagenase system in the placenta, because intraplacentome injections of collagenase are unable to hydrolyze collagen in 15% of cows with RFM. Collagenases are calcium-dependent enzymes; however, the decreased level of serum calcium found in cows with RFM does not preclude collagenase activity. Several factors have been related to failure of cotyledon-caruncle detachment.

Hormone Imbalances

Hormone imbalances existing before delivery are effective in inducing RFM (high-risk factor; see Table 45-4). Progesterone, more than estrogen, inhibits uterine collagenases and slows uterine involution. Dexamethasone increases synthesis and utilization of progesterone by cotyledon tissues in the cow. These changes may contribute to blocking postpartum expression of cotyledon collagenases. Moreover, it has been found that glucocorticoids down-regulate collagenases. Because of inconsistent reports, the mechanism for dexamethasone and prostaglandin F_2 alpha ($PGF_{2\alpha}$) to induce delivery with a high incidence of RFM remains unclear. It has been proposed that increases in prepartal $PGF_{2\alpha}$ metabolites and cortisol may constitute an indicator of RFM in cows. In one study, bovine production of $PGF_{2\alpha}$ by cotyledons predominated when membranes were released, whereas prostaglandin E_2 (PGE_2) production predominated if fetal membranes were retained. In the rabbit, however, PGE_2 and $PGF_{2\alpha}$ increased collagenase activity. The fact that previous retention is a significant risk factor (see Table 45-4) suggests that RFM may be due in part to a random expression of a malfunctioning gene that regulates uterine involution, including cotyledon proteolysis. Gene expression of proteolytic enzymes can be modulated by steroidal hormones; however, the prepartal hormonal signal to block cotyledon proteolysis and cause RFM has not been identified. Some critical hormone imbalances leading to RFM are presented in Table 45-4.

Leukocytes and Chemotaxis

The role of leukocytes and chemotaxis in the etiology of RFM has been widely discussed. Deficient neutrophil phagocytic activity, decreased migration, and decreased superoxide anion production have been proposed as factors in the pathogenesis of RFM in cattle. In fact, circulating neutrophils from cows with RFM produced less superoxide anion than did neutrophils from control cows. Positive chemotaxis resulted in an RFM incidence of 2.6%, and negative chemotaxis, 35.6%. Moreover, leukocytes are a mobile source of collagenases and may be involved in uterine regression and release of placenta.

Major Histocompatibility Complex

It has been proposed that major histocompatibility complex (MHC) provides an initial trigger for expulsion of the placenta and that consequently, maternal tolerance of fetal MHC products will lead to RFM, this mediated by temporary immunodeficiency.

Integrative Mechanism of Placenta Attachment/Detachment

Serotonin is suspected to be involved in placenta attachment/detachment and in various aspects of pregnancy and parturition in cows. Blood concentrations of serotonin are extremely high (54 μM) in the fetal calf during pregnancy and dramatically decrease (13 μM) at parturition to near adult cow concentrations. Coincident with decreased blood serotonin concentrations is decreased serotonin concentration in fetal membranes (cotyledon) during placenta detachment.[3] Thus, a physiologic pattern of serotonin concentrations related to placenta detachment during parturition exists in blood and placental tissues. Several important effects of serotonin have been recognized: (1) it has a proliferative effect on numerous cell types, including cultured bovine placentome cells, which may favor placenta attachment; (2) it inhibits secretion of proteolytic enzymes in bovine placentome cells, which may prevent placenta detachment during pregnancy; (3) it affects cortisol secretion, which may trigger parturition; (4) it is a powerful narcotic in newborn calves and probably in fetal calves, which may keep the fetus asleep during pregnancy. These four effects of serotonin can support a pivotal role for serotonin in placenta detachment, activation of the fetal-adrenal axis, and fetal awakening after prolonged gestational narcosis. The integrative hypothesis developed in our laboratory is presented in Figure 45-4.

Retained Fetal Membranes as a "Living" Organ

The lack of blood circulation to retained membranes and their release of offending odors suggest that these membranes are dead or nearly dead tissues. When membranes are kept in controlled laboratory conditions, however, they are capable of active utilization of oxygen and glucose, and more than 30% of the cells can exclude vital dye for 3 or more days. When membranes are kept at 1° to 2°C, they stay metabolically active for 8 weeks or longer. Fetal membranes have an outstanding potential to "survive" without a live fetus. These properties suggest that RFM may respond to ischemia, anoxia, and bacteria by releasing biochemicals that cause inflammation, thus predisposing the cow to metritis. It is suspected that chemical irritation of RFM by the intrauterine infusion of chemicals such as tetracycline may cause an inflammatory reaction that may cancel the beneficial effects of therapy.

Pathophysiology of Retained Fetal Membranes

A proposed flow chart for the pathophysiology of RFM is shown in Figure 45-5. Biochemical disturbances that inhibit cotyledon proteolysis may occur before parturition in the absence of uterine trauma and during parturition when uterine trauma is incurred. Prepartum inhibition of the cotyledon proteolysis mechanism is expressed after delivery by a lack of both cotyledon dehiscence and liquefaction of cotyledon-caruncle

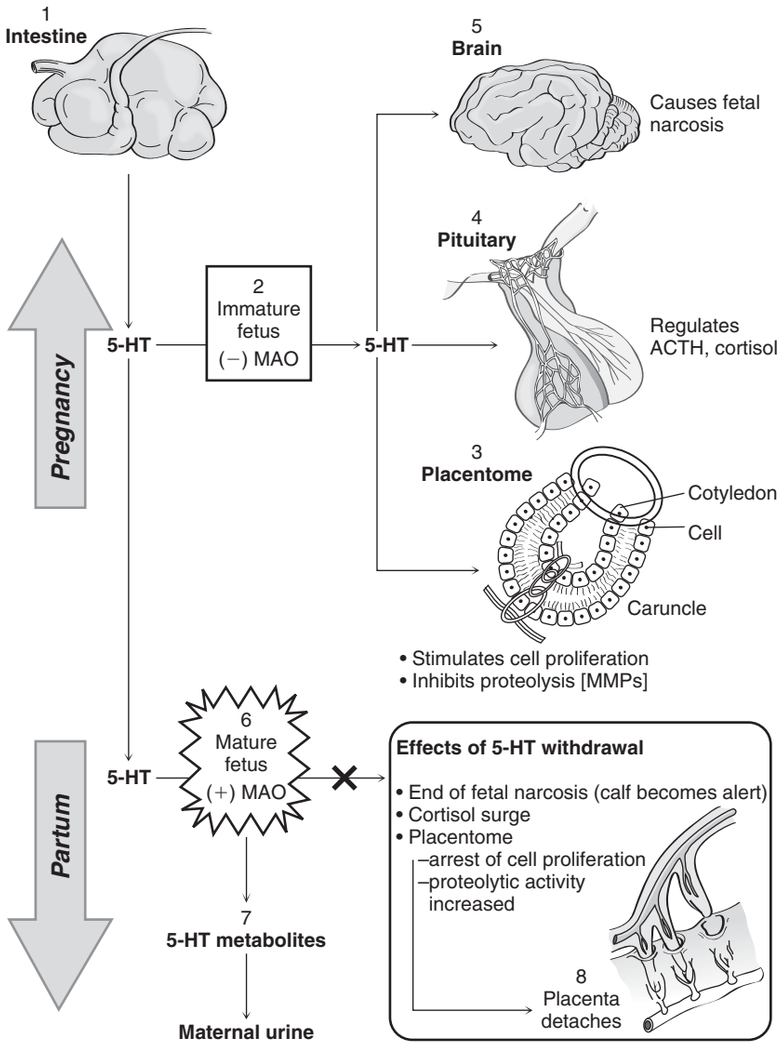

Fig. 45-4 Pivotal role of 5-hydroxytryptamine (5-HT, serotonin) in pregnancy, placenta detachment, and fetal narcosis. Integrative hypothesis. The main source (95%) of 5-HT is the intestinal wall *(1)*.[8] During fetal life *(2),* 5-HT may freely circulate through an immature fetal lung, liver, and placenta without significant inactivation, reaching high concentrations in the blood of fetal calves (6 times neonatal concentration),[3] humans, and goats. [9,10,11] In the placentome *(3),* 5-HT is a "growth factor" to stimulate placental cell proliferation[3] and inhibit placental matrix metalloproteinase activity,[12] which protect the "links" that favor placenta attachment.[13] Five-HT is a potent stimulator of pituitary ACTH secretion *(4)* in calves[14] and other species.[15,16] However, chronically high concentration of circulating 5-HT in fetal blood is hypothesized to suppress ACTH and cortisol secretions by down-regulation; this is to be investigated further. Moreover, excess of circulating 5-HT in the fetus may affect the brain *(5)* and cause fetal narcosis.[14,17] Fetal narcosis is a protective mechanism for the mother as well the fetus and may aid in keeping the placenta attached during pregnancy. Three days prior to partum, lung, liver, and placenta monoamine oxidase (MAO) enzyme systems (responsible for 5-HT inactivation) mature in rats, *(6)*[18] along with a transitory decrease of 5-HT content in the wall of the fetal intestine in calves.[19] Moreover, at the end of gestation there is an increased 5-HT uptake by the lungs in sheep.[20] The increase in MAO activity and 5-HT uptake may cause, in part, a drop in circulating 5-HT in the fetus. Increased MAO activity in the fetus may be the cause for more 5-HT metabolite to be excreted in maternal urine at the end of pregnancy in women.[10] A drop in circulating fetal 5-HT is proposed to reverse the physiological effects *(3–5)* of 5-HT during pregnancy, promoting cortisol surge in the fetus, placenta detachment, and alertness and walking behavior in the neonate *(8).* Experimental evidence using different animal species is available for most aspects of this hypothesis, however further research is needed to validate the above model for placenta detachment in bovines.

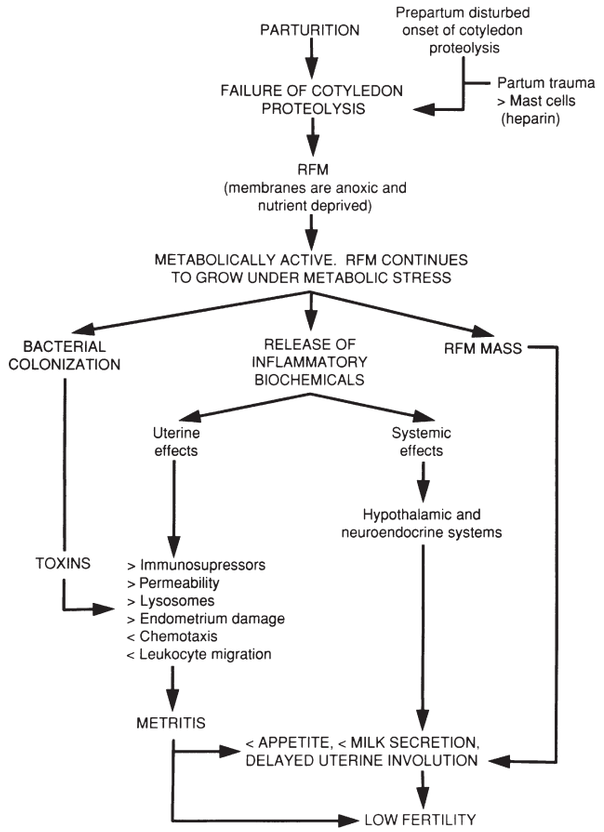

Fig. 45-5 Pathophysiology of retained fetal membranes. See text for explanation. (Copyright 2002 The University of Tennessee, College of Veterinary Medicine.)

interface–adhesive fluids. The retained membranes are ischemic, anoxic, and nutrient-deprived; nevertheless, they continue to grow and are metabolically active for several days. Under metabolic stress, retained membranes release inflammatory biochemicals that, in the uterus, cause immunosuppression (PGE_2), increased vascular permeability (histamine, prostaglandins), increased lysosome activity (proteolysis), endometrial damage (including release of heparin by mast cells), and decreased chemotaxis and leukocyte migration that lead to metritis and decreased fertility. Inflammatory biochemicals from RFM may cause systemic effects that are mediated by hypothalamic centers, including control of hormones, causing decreased appetite and milk secretion and possibly delayed uterine involution. Bacterial colonization is increased, favoring the release of both bacterial endotoxins and inflammatory biochemicals by RFM. Physical mass of the retained membranes (approximately 3–4 kg) within the uterus may contribute to delayed uterine involution, leading to the clinical complications and reduced reproductive performance associated with RFM.

Uterine trauma during calving has high risk factor values for RFM (see Table 45-4). One possible explanation for this association may be the release of heparin by an increased number of mast cells at the site of injury, causing the inhibition of both collagenases and collagen breakdown and delayed uterine involution. Inhibition of collagenase in placentome tissues may contribute to the occurrence of RFM.

RETAINED FETAL MEMBRANES AND METRITIS

RFM and metritis are positively correlated (see Table 45-2). In one study, 44% of lactations that began with RFM were eventually complicated by metritis. By contrast, only 16% of the lactations without RFM were complicated by metritis. The relative risk in that study for development of metritis in cows with RFM is therefore 2.8, and the attributable risk is 28%. A survey found that cows with RFM had a significantly higher incidence of metritis (53%) than cows without RFM (30%); also, a significant difference was found between conception rates in cows with RFM and metritis (66%) and in those with only metritis (77%). In an earlier study, metritis, not RFM, impaired reproductive performance; cows experiencing both RFM and metritis were more severely affected than cows that had only RFM or metritis.

Uterine involution, even in the absence of clinical complications, is a septic process; moreover, bacterial colonization increases during metritis. It has been proposed that the metritis that accompanies RFM results from the presence of decomposing placental tissues, which provide a favorable environment for bacterial colonization. Coliform bacteria and high concentrations of endotoxins present in lochia of cows with RFM are potent inducers of prostaglandins and cytokines, favoring development of uterine infections.[4] Bacteria found in the early postpartum uterus or their endotoxins may interact with retained membranes to secrete PGE_2, which may further predispose the uterus to infection (see Fig. 45-5).

RETAINED FETAL MEMBRANES AND MASTITIS

Although the main economic impact of RFM seems to be decreased milk production (more days open, decreased milk volume, milk from treated cows withheld), the correlation between RFM and mastitis is controversial (see Table 45-2). In a hospital-based study, cows with RFM (25.8%) were three times more likely to develop mastitis during hospitalization than cows without RFM (8.2%). In a different study, the relative risk factor for cows with less than 5 days' retention was 1.5, and 5.4 if retention lasted more than 6 days. More milk and more fat were recorded in cows with RFM than in cows without RFM in one trial, whereas in another, no correlation between RFM and mastitis was found.

TREATMENT

Objectives

The treatment objectives for RFM are to cause early detachment of the membranes in order to reduce the occurrence of metritis, decrease milk losses, reduce reproductive inefficiency, and decrease veterinary expenses.

Treatment versus No Treatment

Untreated cows more often are affected by endometritis and require repeat breeding than are treated cows. In a trial, uncomplicated retention did not affect the fertility of cows mated beyond 60 days of the last calving. In other studies, however, retention for more than 12 hours has been found to be detrimental to reproductive performance and milk production. Many clinicians believe that dairy cows with RFM should be treated, but the evidence regarding the advantage of treating RFM in beef cows is not conclusive.

Historical Overview

Many approaches have been used to detach retained membranes. These include manual removal, attachment of a weight to the membranes to speed expulsion, electrical stimulation of the membranes with a pulse generator to initiate uterine motility, acupuncture to dilate the cervix, and administration of uterokinetic drugs, sulfonamides, prostaglandins, antibiotics, antiseptics, and hormones. None of these methods is effective in the treatment of RFM.

Manual Removal

Manual removal of retained membranes is contraindicated because uterine infections are more frequent and more severe after this form of intervention than they are in untreated cows. Manual removal has been found to prolong the interval from calving to first functional corpus luteum by 20 days. When the placenta is not removed completely, a prolonged vaginal discharge follows. It is not easy to properly remove a retained placenta; 62% can be removed completely, 27% partially, and 11% are nonremovable. Often, attempts at removal during the first 48 hours after calving are unsuccessful because the placenta is too firmly attached and the apical part of the gravid horn is beyond the reach of the veterinarian.

Hormones

Hormones are not effective in either detaching the placenta in primary RFM or preventing early postpartum metritis in cows with RFM. Injections of relaxin have been shown to prevent the occurrence of RFM when dexamethasone is used to induce parturition. Clinical use of relaxin for either treatment or prevention of RFM has not been reported, however.

Prostaglandin

Use of $PGF_{2\alpha}$ in the treatment of RFM is of limited value. $PGF_{2\alpha}$ does not cause detachment of retained membranes, significant uterokinesis in the early postpartum cow, or improvement of reproductive performance.

Oxytocin

Oxytocin is the uterokinetic hormone of choice in the early postpartum cow. In one study, 200 U given intramuscularly (IM) caused an almost immediate uterokinetic effect that lasted over 2 hours, with no spastic contractions. In another study, however, large doses of oxytocin were shown to create uterine spasm. Therefore, doses of 20 U three to four times daily have been used. The value of oxytocin in the membrane detachment in primary RFM is questionable, because uterine motility is normal or increased in cows with primary RFM.

Antibiotics

Intrauterine and systemic antibiotics do not hasten detachment of retained membranes. On the contrary, inactivation of collagenase by tetracycline in some tissues has been reported. Bacterial collagenase and oxytetracycline, injected into the umbilical arteries, are compatible substances when combined as a treatment for RFM, however. One opinion is that antibiotics should not be used to treat RFM because they may delay the release of retained membranes by inhibiting the putrefaction process. Regardless of the undisputed benefit of antibiotics in the management of most kinds of bacterial infections, the value of antibiotics in the prevention and treatment of RFM metritis remains controversial. Single intrauterine applications of antibiotics often fail to prevent clinical metritis or to improve fertility in treated cows compared with untreated cows.

In one study, despite intrauterine treatment with 5 g of tetracycline powder on day 1 and 10.5 million U of procaine penicillin G IM on days 1, 2, and 3, 76% of the cows developed metritis. The reason for the lack of effectiveness of antibiotics has been attributed to the use of inadequate dosages, because it is difficult to attain adequate tissue concentrations of antibiotics in the uterus by using uterine infusions. Moreover, intrauterine tetracycline has been reported to have a negative effect on subsequent fertility. A possible explanation for this effect is that tetracycline may cause irritation of the endometrium and perhaps also of the metabolically active retained membranes. Chemical inflammation may override the beneficial effects of the antibiotic. Another complicating factor with infusion of antibiotics into the uterus is the extreme pH of the antibiotic solutions used, which may contribute to damage of the uterus. For example, tetracycline solutions can be strongly acidic (with a pH of 1.8–3.0) or alkaline (for oxytetracycline for IV injections, pH is 8.0–8.5). Nevertheless, there is consistent support for the use of antibiotics, especially in severe cases of metritis, provided that adequate dosage and route of administration are used. Umbilical arteries are a potential route to be explored in the treatment of RFM not only for antibiotics but for other drugs. The small mass of the retained membranes (3.0 kg for the purpose of dose calculation) and the lack of blood circulation favor a long-lasting effect of a single and relatively small dose of antibiotic. Under these conditions, the passage of antibiotic into blood and milk is unlikely. More research is needed in this area, however.

Antiseptics

A variety of antiseptics, including chlorhexidine and dilute iodine, have been used in the treatment and

prevention of RFM. In most cases, their efficacy remains to be demonstrated. These compounds should be used with caution, especially iodine preparations, some of which can be extremely irritating.

Collagenase

A new approach for the treatment of RFM is the injection of collagenase into the umbilical arteries retrieved from RFM. This approach may be superior to traditional treatments because it is specifically directed at correction of the lack of cotyledon proteolysis. Bacterial collagenase from *Clostridium histolyticum* is used because it can degrade several types of collagen, it is commercially available, it is affordable, and it does not cause residual blood clotting in placenta.

The technique. In this procedure, the umbilical cord is located and is recognized by two firm arteries and two veins (pencil diameter) that slip off the fingers when palpated. Once the cord is located, a second hand is introduced into the vagina and the cord is retracted by alternating hands in the vagina. Once the umbilical cord is in the vulva, the arteries are clamped with Kelly forceps. Collagenase solution* (200,000 U, plus 40 mg calcium chloride and 40 mg sodium bicarbonate dissolved in 1 L saline) is injected rapidly. Injection of collagenase solution can be accomplished easily by using a hand-pressurized 1000-ml saline bag attached to an intravenous administration set. The needle tip of the set is directly inserted into the artery (and ligated) without using a catheter. To ensure perfusion of the entire placenta, a volume of 1 L is injected. Oxytetracycline (100 mg total dose, which is approximately 30 mg/kg fetal membranes) for intravenous injection can be added to 1 L of collagenase solution if an antibiotic is desired; however, final pH of the solution should be adjusted to approximately 7.5. Five hundred ml of collagenase solution is injected into each artery, or 1000 ml into one artery if only one is available. Because of arterial anastomosis, it is unnecessary to inject the two arteries in single births or the two umbilical cords in twin births. Thirty-six hours later, the retained membranes are easily extracted by gentle traction if they have not been expelled spontaneously.

Comments. Collagenase treatment is effective in 85% of affected cows within 36 hours. In the 15% of cows that fail to respond, however, repeat treatment is not recommended because it rarely is effective. The treatment is safe and has no side effects. This therapy can be applied between 12 hours (best) and 96 hours after calving. After 48 hours of retention, there is a tendency for the residual blood in the placenta to clot and for anastomoses to close, which limits the perfusion of retained membranes with collagenase solution. The technique is simple, and the procedure can be completed in 25 minutes by a skilled veterinarian without an assistant. In approximately 6% of cows, sufficient retraction of the umbilical cord is not possible. The most time-consuming steps are retracting the umbilical cord and injecting 1 L of solution into the umbilical arteries. Another advantage of the treatment is that collagenase causes liquefaction of fetal membranes, and siphoning of uterine fluid is facilitated in cows treated with collagenase.

Hypothetically, oxytetracycline plus collagenase constitutes a useful, therapeutic combination, owing to the advantage of loosening retained membranes while preventing infection. Antibiotic-collagenase combinations should be used with caution, however, to avoid inactivation of collagenase by the antibiotic. Furthermore, infusions of collagenase into the lumen of the uterus are not effective.

Collagenase is not currently approved for use in food-producing animals in the United States. This procedure is highly effective in mares with retained placenta,[5] in which location of the large umbilical vessels for collagenase injection is easier than in cows. Moreover, placental collagen is more sensitive to collagenase hydrolysis in the mare than in the cow (and women).[6]

Collagenase and Cesarean Section

Cesarean section is followed by an increased incidence of RFM in cows (see Table 45-4). Injection of collagenase into the umbilical arteries during cesarean section is potentially effective in preventing RFM. A small number of cows undergoing cesarean section in our hospital have been treated in this manner, with excellent results.

Treatment with Hyperosmotic Solutions

Delivered placentas contain osmoactive substances that cause considerable retention of water and increased tissue volume (by 50%) when immersed in saline. Injections of osmoactive solutions or expandable solutes into the placentome via the umbilical circulation may cause mechanical detachment of cotyledons from caruncles by increasing cotyledon volume. This finding provided the rationale for the treatment with hyperosmotic solutions. This approach, however, has been tested without satisfactory results in our laboratory.

Future Treatment

We believer that future treatment for RFM may be based on the development of an inexpensive injectable substance capable of triggering the activation of cotyledon proteases (collagenases). Serotonin injections were thought to be a potential treatment for detachment of RFM in the bovine because addition of serotonin to cell culture medium stimulated secretion of the proteolytic enzyme collagenase by cultured rat and human myometrial cells. Moreover, in one study in which a preparation containing serotonin and ergometrine (uterotonic substance) was injected in cows after calving, the incidence of RFM was 10%, compared with 38% observed in control cows injected with saline.[7] We have not been able to confirm the researchers' result, however. Experiments in our laboratory in which serotonin was injected repeatedly into cows either suffering from RFM or at high risk for RFM failed to detach fetal membranes or to prevent occurrence of RFM. Furthermore, serotonin failed to induce collagenase activity in isolated placentomes and

*Type XI, Sigma Chemical Co., St. Louis, MO.

inhibited collagenase secretion by cultured placentome cells, which suggests that serotonin injections may not be an effective treatment for RFM. On the contrary, serotonin is suspected to favor placenta attachment in the bovine (Fig. 45-4).

CHAPTER 46

Metabolic and Nutritional Diseases of the Puerperal Period

ROBERT J. VAN SAUN

Metabolic adaptations associated with the transition from pregnancy to lactation take place in all cows, including those that are well fed. These metabolic changes may become exaggerated, however, when maternal supplies of glucose, protein, or calcium (Ca), or any combination thereof, are inadequate, thus leading to metabolic disease problems. A poor transition is evidenced by slow or cyclic feed intake, excessive body condition loss, and high prevalence of metabolic and infectious diseases during the puerperium, followed by poor lactational performance.[1] Milk production in dairy cattle with periparturient disease is differentiated from that in nonaffected cows by low first-test and peak milk production and altered composition, typically a high (>1.5) fat-to-protein ratio.[2] As previously characterized, perturbed transition also accounts for poor reproductive performance[3] and increased involuntary cull rate.[4,5]

This chapter describes commonly encountered metabolic and nutritional diseases associated with improper transition from pregnancy to lactation.

DISEASES OF ENERGY BALANCE

All dairy cows, and to a lesser extent beef cows, experience a period of negative energy balance immediately before and through 4 to 6 weeks after calving. A variety of metabolic, hormonal, homeorhetic, and environmental factors influence individual cow response to negative energy balance and associated health, productive, and reproductive consequences. Metabolic alterations associated with the transition from pregnancy to lactation and their impact on substrate metabolism are described in Chapter 57. A cow's inability to maintain homeostasis of key metabolites during the transition period is prerequisite to a variety of periparturient diseases. Severe or prolonged negative energy balance resulting in rapid and excessive lipid mobilization, coupled with perturbed nonesterified fatty acid (NEFA) metabolism, a consequence of an inability to maintain glucose homeostasis, manifests in a number of clinical and subclinical syndromes of ketosis and fatty liver infiltration. To some degree, hepatic lipidosis usually precedes and is concurrent with development of deranged fatty acid metabolism, but fatty infiltration can become excessive and become a clinical entity itself. Several excellent detailed reviews of negative energy balance and its relationship to the pathogenesis of ketosis and hepatic lipidosis are available.[6–10]

Elevated blood NEFA concentration is requisite to excessive hepatic NEFA uptake as absorption is directly proportional to concentration.[11] Metabolic fate of absorbed NEFAs in the liver is limited primarily to partial oxidation (ketogenesis) or esterification to triglycerides (lipogenesis). Complete oxidation in peroxisomes and triglyceride export as very-low-density lipoproteins (VLDLs) are other disposal pathways for NEFA but are limited options in ruminant animals. Availability of glucose coupled with current metabolic milieu determines the fate (lipogenesis or oxidation) of absorbed NEFAs in the liver.[12] **Ketosis** is characterized by an excessive accumulation of ketone bodies when glucose availability is limited.

Kronfeld[13] suggested differentiating ketosis syndromes on the basis of underlying pathogenesis. Spontaneous or **primary clinical ketosis** was defined as a disease syndrome independent of an initiating disease process. This is in contrast with **secondary ketosis**, in which the ketotic state is induced by a primary disease process further exacerbating negative energy balance. **Alimentary** (or dietary) **ketosis** is defined as a ketotic state resultant from consumption of excessive ketone bodies or their precursors within the diet. Ensiled feeds exhibiting a clostridial fermentation will contain an increased amount (>1%) of butyric acid as a proportion of total volatile fatty acids (VFAs). Butyric acid is converted to β-hydroxybutyrate (BHB) by the rumen epithelium, which can contribute significantly to ketone body production. **Subclinical ketosis** is defined as elevation of blood ketone concentration (>14 mg/dl) in the absence of clinical signs of ketosis.[14]

Glucose supply is determined by fractional rate of hepatic gluconeogenesis and glucogenic substrate availability, given that minimal dietary glucose is directly available as a result of ruminal fermentation. Holtenius and Holtenius[15] suggested further characterizing spontaneous clinical ketosis into types I and II, based on differences in metabolic derangements of glucose homeostasis. Cows unable to meet glucose demands of milk production exhibit the metabolic underpinnings of type I ketosis: gluconeogenesis is maximized but sufficient glucogenic substrate is lacking.[15] These cows are severely

hypoglycemic and have low insulin-to-glucagon ratios, thereby facilitating a catabolic state utilizing amino acids for gluconeogenesis. Absorbed NEFAs are metabolized almost exclusively to ketone bodies to provide alternative energy substrate for tissues in an effort to increase glucose availability and to minimize detrimental effects of excessive body protein catabolism. This metabolic description is consistent with classic spontaneous ketosis associated with high milk production in early lactation; accordingly, the term **peak lactation ketosis**[7,12] is used for this entity in this chapter.

Another ketotic syndrome, type II ketosis, occurs more immediately around parturition and is characterized by moderate hyperketonemia, greater hepatic fat infiltration, and moderate hypo- to normoglycemia.[7] Metabolically, neither gluconeogenesis or ketogenesis is maximally stimulated, and more NEFAs are directed to esterification in these cows. As fatty infiltration increases, gluconeogenic capacity is compromised, ultimately leading to reduced glucose availability and increased ketogenesis.[12] Holtenius and Holtenius[15] attributed type II ketosis to insulin resistance and impaired glucose utilization as a result of dry period overfeeding and hence equated the syndrome to type 2 diabetes mellitus. **Periparturient ketosis** is a descriptive term suggested for this type II ketosis syndrome,[12] to be differentiated from peak lactation ketosis.

Clinical Signs

Cows affected with primary ketosis will not present different from any other early-postpartum cow experiencing one or more typical periparturient diseases. Careful physical examination should be completed to determine presence of current disease. Progressive loss of appetite and milk production over a period of a few days is a typical presentation for peak lactation ketosis.[12,16] Milk production losses vary depending on when energy equilibrium relative to dietary intake is established but may become severe, exceeding a 50% reduction in previous production. Ironically, cows will select against grain consumption, further exacerbating their energy deficit and, in conjunction with reduced dry matter (DM) intake, will rapidly lose body weight and condition. Affected cows often have a rough appearance, look gaunt and "tucked up" in the abdomen, show moderate depression, and have a sweet acetone smell to their breath. Vital signs typically are normal, with decreased rumen motility and firm, dry feces of reduced volume. A small proportion of ketotic cows (10%) will present with neurologic signs including abnormal licking, head pressing, circling, and walking blind.[16,17] Nervous ketotic cows may periodically show hyperesthesia, ataxia, tremors, or tetany, which may be confused with other neurologic diseases. The mechanism responsible for neurologic signs is unknown, and an individual cow's clinical presentation is not associated with blood ketone concentration. Most commonly, cows present with peak lactation ketosis between 3 and 6 weeks post partum, a period characterized by rapidly increasing milk production and lagging DM intake.

Cows experiencing periparturient ketosis will present with clinical signs similar to those in cows with peak lactation ketosis, with the following differences. Time of presentation occurs earlier, typically 7 to 10 days relative to calving, and cows have higher (>3.75/5.0) body condition score (BCSs). By definition, cows with subclinical ketosis show no diagnostic clinical signs, but herds experiencing problems with energy balance and high prevalence of subclinical ketosis may show lower milk production, reproductive inefficiency, and higher than expected prevalence of left displaced abomasum. Subclinical ketosis occurs during the same time frame as for clinical ketosis and most often is seen at approximately 4 weeks post partum.[14]

Clinical signs in cows with fatty liver are similar to those in cows with periparturient ketosis, and fatty liver may represent a more severe form of this disease. Affected cows typically present with clinical manifestations around the time of calving and have excessive body condition at the time of dry-off.[18] At presentation their BCS may be slightly reduced. Clinical fatty liver disease is more common in older cows but can be seen in primiparous cows.[18,19] Severity of hepatic fatty infiltration will determine additional accompanying clinical signs and secondary metabolic and infectious disease processes.[10] Morbidity and mortality rates in cows experiencing concurrent periparturient diseases and reproductive inefficiency increase with degree of fatty infiltration. Cows with severe fatty infiltration (>10% wet weight) will be extremely anorectic and depressed and may show neurologic signs.[19] These cows also show very poor response to therapies targeted at concurrent diseases, possibly a result of impaired immune function[10,20] and hepatic gluconeogenesis[21] and ureogenesis.[22] Even with aggressive therapy, death and culling rates are greatly increased among clinically affected cows.[18,19]

Diagnosis (Individual and Herd)

Ketosis

Definitive diagnosis of ketosis in an individual cow is established by measuring excessive concentration of ketone bodies in blood, milk, or urine. Signalment, clinical signs, and a thorough physical examination will suggest the form of ketosis present. Acetoacetate, acetone, and BHB comprise the ketone bodies generated from partial fatty acid oxidation. Acetoacetate and acetone account for only 10% to 20% of total ketone bodies, but this proportion increases during ketosis as acetoacetate production is greatly increased. As a result of acetoacetate instability in harvested blood specimens, however, measurement of more stable BHB concentrations typically is used in diagnosing ketosis with blood samples. Total blood ketone or BHB concentration in excess of 30 or 25 mg/dl, respectively, generally is considered a threshold for clinical ketosis.[12] Ketone bodies are concentrated in urine at 2 to 4 times blood levels; thus, total urinary ketones often exceed 80 mg/dl.[12,17] By contrast, milk ketone concentration is 40% to 50% of blood concentration; therefore, milk total ketone concentrations of 10 mg/dl or greater are found in clinical ketosis cases. Cows with peak lactation ketosis generally have more profound ketonemia (blood ketone level >40 mg/dl) compared with those with periparturient ketosis.[12] Based on greater risk

association with clinical ketosis and displaced abomasum and reduced milk production, subclinical ketosis in cows was defined as blood BHB concentrations greater than 14 mg/dl (1400 µmol/L).[14] Milk acetoacetate or BHB concentrations greater than 1 mg/dl (100 µmol/L) are considered indicative of subclinical ketosis.[14]

To facilitate cow-side diagnosis, a number of semiquantitative commercial tests are available for estimation of ketone body concentration in milk or urine. Powder or test strips based on the nitroprusside reaction measure acetoacetate concentration, whereas a newer test kit (Ketolac-BHB or Keto-Test) measures milk BHB concentration. As a result of its concentrating property, evaluation of urine ketone concentration results in an overestimation of ketosis prevalence, whereas milk ketone concentration underestimates ketosis prevalence. Studies evaluating cow-side test sensitivity and specificity relative to blood BHB concentration suggest using a threshold value of 1 mg/dl (100 µmol/L) of either milk acetoacetate or BHB as a good indicator of subclinical ketosis.[14,23,24] More recent work suggests that using a time-restricted (5 sec) interpretation of urine ketones (Ketostix) can be as accurate as milk ketone evaluation.[25]

Fatty Liver

Definitive diagnosis of hepatic fatty infiltration is determined by direct measurement of triglyceride content from a liver biopsy sample. Hepatic triglyceride content can be determined quantitatively by chemical methods or semiquantitatively by histologic volume or flotation methods[18,19,26] (Table 46-1). Ultrasound examination holds some promise as a noninvasive method to categorize liver fat content.[27]

Table **46-1**

Methods for Determining Hepatic Triglyceride Content

	DEGREE OF HEPATIC TRIGLYCERIDE INFILTRATION			
Methodology	***None***	***Mild***	***Moderate***	***Severe***
Histologic, % volume	0–5	5–20	20–40	>40
Chemical, % wet weight	<1	1–5	5–10	>10
Chemical, % dry matter	<3	3–15	15–33	>33
	HEPATIC TRIGLYCERIDE CONTENT (% DM)			
Buoyancy in solution (specific gravity)	***<13***	***13–25***	***25–35***	***>35***
1.000 (distilled water)	Sink	Sink	Sink	Float
1.025 (3.18% $CuSO_4$)	Sink	Sink	Float	Float
1.055 (8.11% $CuSO_4$)	Sink	Float	Float	Float

In Howard JL, Smith RA (eds): *Current veterinary therapy 4: Food animal practice.* Philadelphia: WB Saunders, 1999, pp 230–233.

Various liver function tests have been used to evaluate degree of fatty infiltration relative to clinical severity of ketosis and hepatic lipidosis. A wide variety of serum biochemical tests were evaluated for their ability to predict severity of hepatic lipidosis and hepatic function. Nearly all tests were of questionable value diagnostically and prognostically, as a result of their nonspecificity for liver function and minimal association with degree of liver fat content.[18,19,28] Biochemical measures of aspartate aminotransferase (AST), sorbitol dehydrogenase (SDH), and total bilirubin were significantly increased with severe hepatic lipidosis; however, most such measures were of low specificity.[28] Cows with severe hepatic lipidosis also tend to have much lower serum total cholesterol concentrations (<70 mg/dl), reflecting a reduction in total circulating lipoproteins.[19] Although not specific for liver function, elevation of AST (>100 U/L) has been suggested as the best supportive evidence of hepatic fatty infiltration.[18,19,28]
