Fully diluted porcine semen should have a final sperm concentration of 25×10^6 to 80×10^6 sperm cells/ml. Final sperm concentration is determined on the basis of the expected duration of storage of the product before use. As a general rule, if the ejaculate meets the minimum criteria for neat boar semen to be used for AI, then 1 billion spermatozoa per dose is included for every day of storage (e.g., if the extended sample will be stored for 2 days, 2 billion sperm/dose is used; if for 3 days, 3 billion sperm/dose; if for 4 days, 4 billion sperm/dose; and so on.). Depending on extender capacity, dilution rates of 1:4 to 1:25 (ratio of semen to extender) are used. If sperm concentration cannot be determined for the ejaculate, a conservative dilution of 1 part ejaculate to 4 to 7 parts diluent should be employed, with the extended product used within 24 hours of dilution. To maintain viability of a fresh ejaculate during processing, isothermal extender should be used during the dilution process.

After the ejaculate has been processed with appropriate extender, individual insemination doses are produced. Three different receptacles currently are used to store extended porcine semen doses: bottles, tubes, and bags/flatpacks (Fig. 97-2). These receptacles are made of nonleaching plastic materials and are nontoxic to spermatozoa. These receptacles are constructed to be flexible, rather than rigid, so that the receptacle collapses naturally with the female's uptake of the semen. Most currently marketed receptacles are designed to hold an insemination dose of up to 100 to 125 ml. Current dose

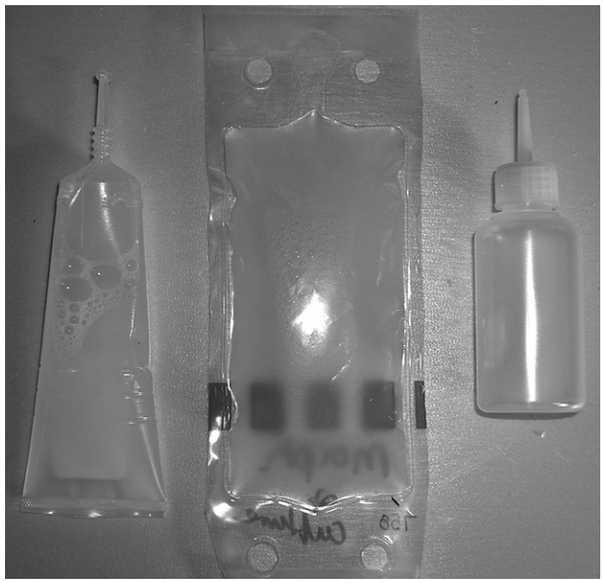

Fig. 97-2 Tube, flatpack, and bottle storage receptacles commonly used for holding extended porcine semen doses.

volumes used by the industry for cervical insemination are 70 to 85 ml. Final sperm concentrations, sperm/dose, and dose volumes may be reduced in the future if transcervical insemination is employed.

Mixing or pooling semen from different boars has become a common technique for processing boar semen for AI. Pooled semen has been found to yield good fertility results in swine.[12–21] The benefits of pooling semen are twofold. First, pooling semen tends to increase processing efficiency in the laboratory by allowing for a large number of boar ejaculates to be processed simultaneously. Second, pooling semen provides the producer with a means to reduce, or even eliminate, inherent differences in fertility found between sperm and between boars. Pooling semen is a simple process. Freshly collected ejaculates are examined for semen quality, as discussed previously, to eliminate any overtly poor-quality ejaculates. Processing of ejaculates for pooled semen can be performed in any of several ways. In one common method, good-quality ejaculates are diluted 1:1 with an extender and placed in a water bath (20° to 37°C, depending on laboratory processing protocols, type of extender, efficiency of laboratory, and so on) to maintain constant temperature while collecting/analyzing/diluting subsequent ejaculates that will be added to the semen pool. Another method of pooling involves adding ejaculates to a fixed amount of extender (e.g., 500 ml) until the target number of doses is reached. With either method, the number of boar ejaculates to be pooled together should not exceed the volume capacity that the operator can process at one time. A minimum of 3 ejaculates per pool is recommended. After the final ejaculate is added to the pool, the pooled sample is diluted to its final calculated volume with the remaining extender. The pooled sample is then further processed, handled, and stored using standard protocols. For large volumes, it may be necessary to provide constant mixing of the sample during packaging to prevent sperm settling, which can lead to variation in sperm concentration between doses.[22]

ADDITION OF COMPOUNDS TO SEMEN

A variety of hormonal compounds (e.g., estrogens, oxytocin, prostaglandins) have been added to semen before insemination in an attempt to increase overall fecundity. Compounds tested have been selected on the basis of their known actions in physiologic events that are important to successful reproduction. To date, their addition to semen has yielded equivocal results. The physiologic basis for the variation observed in response to these compounds is not known and requires further study.

SEMEN STORAGE

Storage temperatures range from 15° to 18°C for extended boar semen. Exposure of extended porcine semen to higher temperatures can increase utilization of the extender components, may induce terminal biochemical modifications to the sperm membrane, and, logically, may enhance bacterial growth of contaminated samples. Conversely, temperatures at or below 10°C may cause irreversible damage to both sperm motility and acrosome integrity.[23] Depending on extender type, stored semen should be gently agitated at least twice a day to resuspend sperm cells within the extender dose.

FROZEN SEMEN

A uniformly successful freezing and thawing protocol for porcine spermatozoa still eludes the industry. Certain boars and breeds appear to exhibit better sperm freezability than others, confounding results. Owing to the reduced longevity of frozen-thawed porcine semen in the female reproductive tract, insemination timing in relation to ovulation also is a contributor to its reproductive performance. Overall, reduced farrowing rates and litter sizes result from the use of frozen-thawed porcine semen in breeding programs. In light of this expected decrease in fecundity, frozen semen has established its value to the swine industry through its long-term preservation of valuable genetics, convenience for over broad distances and international lines, and availability for emergency use by farms when access to fresh extended semen is interrupted.

A variety of freezing methods have been used, including pellets, small straws (e.g., 0.5 ml), large straws (3.0, 5.0 ml), and flatpacks.[24] In swine, breeding doses frequently contain large sperm numbers (e.g., 6 to 8 billion), necessitating the handling of moderate-sized dose volumes. To handle this size breeding dose, freezing methods employing large straws and flatpacks are desirable. Current practices call for transferring frozen-thawed boar semen into a bottle containing diluent. This diluted, frozen-thawed dose is then inseminated by cervical deposition, as with fresh extended semen. Recently, the industry has been experimenting with use of a new type of transcervical disposable catheter (Fig. 97-3). If this method proves to be superior in ease of deposition of

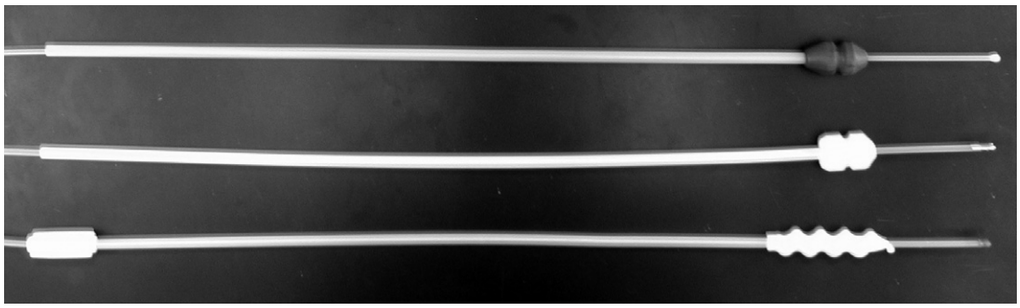

Fig. 97-3 Porcine transcervical artificial insemination catheter.

semen into the uterine body or horn, transcervical AI may facilitate use of frozen-thawed boar semen.

BOAR CULLING

Boars generally enter isolation and then the resident stud group between 6 and 8 months of age. In the United States, culling rates approach 15% during the isolation period alone.[25] Reasons for culling during quarantine, in order of frequency from most to least, were (1) poor conformation/lameness, (2) poor libido, (3) poor semen quality, (4) death, (5) serologic or clinical confirmation of presence of an unwanted disease, and (6) overly aggressive behavior toward handlers.

In resident stud groups, annual boar culling rates average 59.6%.[25] The average breeding life of a stud boar is 20 months. The most common reasons by frequency for boar culling are presented in Box 97-3. Culling of boars due to poor semen quality occurs at 58.2 days if by this time no improvement is seen in the spermiogram.

CHAPTER 98

Clinical Reproductive Physiology and Endocrinology of Sows: Mating Management

TIMOTHY J. SAFRANSKI and NANCY M. COX

GENETIC SYSTEM

The swine industry has embraced crossbreeding systems for several years. The two factors making crossbreeding systems superior are breed complementation and heterosis. **Breed complementation** is simply using breeds or lines in a manner to take maximum advantage of their genetic type. Each breed or line has evolved in response to selection for specific characteristics. Terminal breeds and lines have been selected primarily for growth and body composition (e.g., Duroc, Hampshire, Pietrain), whereas emphasis has been placed on reproductive performance in maternal breeds and lines (e.g., Yorkshire, Large White, Landrace). Crossbreeding systems are designed to maximize use of terminal lines as boars and of maternal lines as sows, as, for example, with a Duroc boar mated to a Yorkshire sow.

Heterosis, or hybrid vigor, is the other factor leading to adoption of crossbreeding systems. **Heterosis** is simply the tendency for crossbred progeny to perform differently from the average of their parents. In the Duroc × Yorkshire example, the average expected daily gain of Durocs is 0.88 kg and that of Yorkshires is 0.84 kg. The crossbred progeny would be expected to gain 0.86 kg daily without heterosis. Heterosis for daily gain typically is approximately 9%, so progeny would actually be expected to gain 9% better than the parental mean, or 0.94 kg daily.

Heterosis tends to be highest for traits with the lowest heritability, those most susceptible to environmental variation. Reproductive and fitness performance, therefore, benefits most from heterosis. This includes embryo survival, litter size born, neonatal survival, and so on. For traits such as neonatal survival, a crossbred pig benefits from individual heterosis, and if the dam is crossbred and produces more milk, the piglet also benefits from maternal heterosis. A summary of heterosis values for some economically important traits is presented in Table 98-1.

Heterosis may be thought of as recovery from mild inbreeding associated with development of breeds or lines. Accordingly, it is not surprising that heterosis is beneficial to the pig for all traits, and to the producer for most traits, backfat being the exception. In rare instances, heterosis may not justify crossbreeding. If only two lines of pigs were available for use in a maternal line, one with a litter size of 8 and the other with 10 pigs, an F_1 hybrid, with heterosis, would be expected to have (8 + 10) ÷ 2 + 10% heterosis = 9.9 pigs. Although this litter size is better

GENETIC SYSTEM

The swine industry has embraced crossbreeding systems for several years. The two factors making crossbreeding systems superior are breed complementation and heterosis. **Breed complementation** is simply using breeds or lines in a manner to take maximum advantage of their genetic type. Each breed or line has evolved in response to selection for specific characteristics. Terminal breeds and lines have been selected primarily for growth and body composition (e.g., Duroc, Hampshire, Pietrain), whereas emphasis has been placed on reproductive performance in maternal breeds and lines (e.g., Yorkshire, Large White, Landrace). Crossbreeding systems are designed to maximize use of terminal lines as boars and of maternal lines as sows, as, for example, with a Duroc boar mated to a Yorkshire sow.

Heterosis, or hybrid vigor, is the other factor leading to adoption of crossbreeding systems. **Heterosis** is simply the tendency for crossbred progeny to perform differently from the average of their parents. In the Duroc × Yorkshire example, the average expected daily gain of Durocs is 0.88 kg and that of Yorkshires is 0.84 kg. The crossbred progeny would be expected to gain 0.86 kg daily without heterosis. Heterosis for daily gain typically is approximately 9%, so progeny would actually be expected to gain 9% better than the parental mean, or 0.94 kg daily.

Heterosis tends to be highest for traits with the lowest heritability, those most susceptible to environmental variation. Reproductive and fitness performance, therefore, benefits most from heterosis. This includes embryo survival, litter size born, neonatal survival, and so on. For traits such as neonatal survival, a crossbred pig benefits from individual heterosis, and if the dam is crossbred and produces more milk, the piglet also benefits from maternal heterosis. A summary of heterosis values for some economically important traits is presented in Table 98-1.

Heterosis may be thought of as recovery from mild inbreeding associated with development of breeds or lines. Accordingly, it is not surprising that heterosis is beneficial to the pig for all traits, and to the producer for most traits, backfat being the exception. In rare instances, heterosis may not justify crossbreeding. If only two lines of pigs were available for use in a maternal line, one with a litter size of 8 and the other with 10 pigs, an F_1 hybrid, with heterosis, would be expected to have (8 + 10) ÷ 2 + 10% heterosis = 9.9 pigs. Although this litter size is better

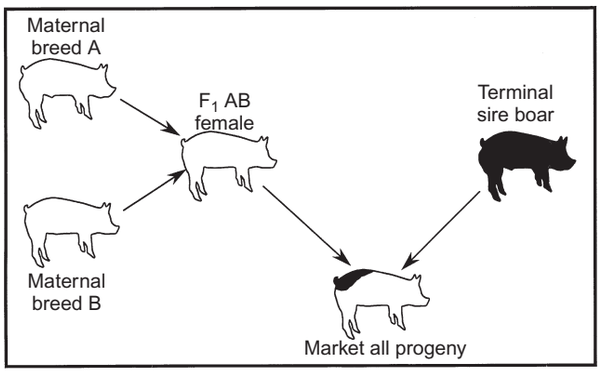

Fig. 98-1 An example of a terminal crossbreeding program.

than the parental mean, it is inferior to that of the better parent.

Figure 98-1 shows a crossbreeding system that maximizes heterosis and breed complementation. For this system to work, the F_1 AB female will need to be either produced on farm or purchased. Systems purchasing the F_1 AB maternal line female are referred to as parent systems. Those purchasing the pure breed A and breed B to produce F_1 AB females are referred to as grandparent systems. Great-grandparent systems are similar but use an F_1 female instead of the A or B breed. On-farm production of replacement females typically requires a commitment of 10% to 20% of the sows for replacement gilt production. Semen can be purchased and artificial insemination (AI) used to eliminate the need to maintain all of the boar lines.

The advantage of grandparent systems over parent systems is the reduced number of incoming animals. The disadvantage is that the progeny must be managed by the farm until ready for mating. This results in the need to raise maternal line pigs with market hogs. Fine-tuning management can be complicated in this scenario because the maternal line pigs typically grow differently and have different nutritional demands. Maternal line barrows may not fit marketing specification in some cases.

REPRODUCTIVE ANATOMY

Understanding the basic reproductive anatomy of the female pig is critical to trouble-shooting reproductive problems, at both the individual and the herd level. Reproductive organs, feet and leg soundness, and the suitability of other body systems to support long-term reproductive performance should be evaluated in potential replacement females.

Structural Soundness

Feet and legs of potential breeding animals should be free of injuries. Hoof cracks, sole bruises, foot rot, subsolar abscesses, and obvious injuries of the upper legs are reasons to cull a potential breeding animal. Uninjured and normal-appearing feet and legs should be examined for general structural soundness. Legs that are too straight or have too much slope to the pastern area may predispose the animal to leg injuries or leg weakness.

External Genitalia

Normal vulval size varies; however, once gilts begin cycling, the vulva should enlarge noticeably in comparison with that of the prepubertal animal. Infantilism, or extremely small size of the vulva, is a common abnormality of the reproductive tract and usually is associated with a small uterus and ovaries and failure to cycle.

A dorsally tipped vulva occasionally is observed. Although not known to be associated with problems with the internal genitalia, in a natural mating system the physical structure of the dorsally tipped vulva makes intromission difficult for some boars.

Male pseudohermaphroditism can occur in pigs. Animals with this condition usually have female external genitalia but also have testes, or they may have gonadal tissue of both sexes. The testes may be located subcutaneously within the scrotal area but often are located

within the abdomen. Male pseudohermaphrodites often have a "fishhook" or "sky-tipped" vulva.

Internal Genitalia

Although not available for examination except at slaughter or by real-time ultrasound evaluation, the internal genitalia of gilts may be affected with abnormalities that prevent normal reproductive performance. Hydrosalpinx and pyosalpinx are conditions that result from obstruction or distention of the oviducts, allowing them to fill with fluid, thereby blocking the passage of spermatozoa and ova. These conditions possibly are the result of abnormal embryonic development and may be hereditary. If both oviducts are affected, the gilt will be infertile but may have regular estrous cycles. Females affected in only one oviduct are prone to repeat breeding and reduced litter size.

Segmental aplasia in the body of one or both horns of the uterus may result in complete or partial infertility. Affected animals have normal reproductive cycles, with pregnancy possibly occurring in nonaffected segments of the uterus, but subsequent litter size is small.

A blind or missing cervix occasionally may be noted. Affected gilts usually cycle but do not become pregnant. Adhesions in the oviduct and around the ovaries are relatively common in sows and gilts. Normal cyclicity is possible, but litter size is usually reduced if pregnancy does occur.

Mammary System

The anatomy of the mammary system should be examined in all potential replacement animals. The underline should be well developed, with a minimum of six functional teats on each side, with three in front of the umbilicus. Nipple abnormalities such as blind teats (not fully developed), pin nipples, or inverted nipples are reasons for rejection of gilts as breeding animals. Sows should maintain a minimum of 10 functional teats throughout their productive lives. Abscesses and injuries may lead to nonfunctional teats, so regular examination is necessary.

ESTROUS CYCLES

Endocrinology

Changes in reproductive hormones during the estrous cycle have been well characterized[2–4] (Fig. 98-2). The length of the estrous cycle in swine is approximately 21 days. For the purposes of this discussion, the cycle is divided into the follicular phase (proestrus), the ovulatory phase (estrus), and the luteal phase (diestrus). Patterns of circulating hormones and intraovarian events are described.

The **follicular phase** is the period from luteal regression to ovulation. Luteal regression, as indicated by a decline in circulating progesterone concentrations, occurs between 13 and 15 days after the previous estrus. This decline in progesterone is caused by the uterine luteolysin, prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), in the utero-ovarian circulation. During this time, follicles destined to ovulate enter a period of accelerated growth resulting from increased frequency of episodic luteinizing hormone (LH) release after the progesterone decline. Increases in LH receptors on ovarian graafian follicles promote increased synthesis and secretion of follicular estradiol. Estradiol concentrations peak in serum between days 18 and 20 of the estrous cycle, due to increased follicular aromatase enzyme activity. Approximately 40% of follicles present on days 15 to 16 of the cycle undergo atresia or degeneration before the LH surge (day 20 or 21) (Fig. 98-3). Follicles that go on to ovulate reach diameters of 5 to 12 mm before ovulation.

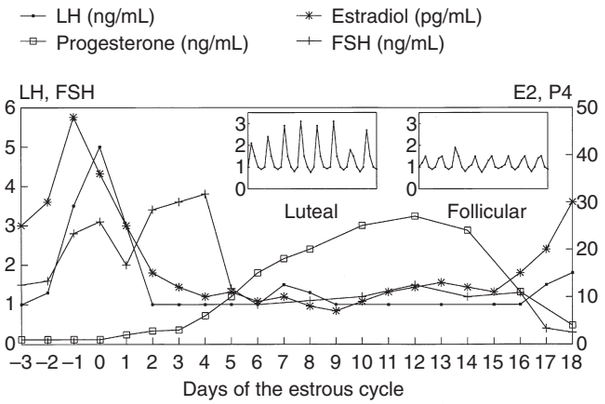

Fig. 98-2 Average concentrations of reproductive hormones during the estrous cycle in swine. *Insets* represent luteinizing hormone concentrations in samples collected every 10 minutes for 7 hours during the luteal and the follicular phases, respectively. (Data from references 1 to 3.)

The rise in estradiol during the follicular phase is responsible for triggering the preovulatory surge in LH and producing estrous behavior. Sexual receptivity lasts 1 to 4 days, with older animals in estrus longer. In most animals, ovulation occurs 36 to 44 hours after onset of estrus. Some of this variability in duration of the **ovulatory phase** can be explained by duration of estrus. Regardless of length of standing heat, sows ovulate two thirds to three fourths of the way through estrus. A sow in heat for 24 hours would be expected to ovulate 16 to 18 hours after onset of estrus. A sow that stands for 72 hours would be expected to ovulate 48 to 54 hours after onset of estrus. Natural ovulation in sows, determined using transrectal real-time ultrasound evaluation, lasts about 2 hours.[5] Other studies have determined the duration to be up to 9 hours. Duration may be affected by technique and by mating, which advances ovulation.[6]

The LH surge reduces estradiol production and shifts steroidogenesis to progesterone production. The oocyte resumes meiosis in response to the gonadotropin surge, and meiosis is completed after sperm penetration.

The role of follicle-stimulating hormone (FSH) during the ovulatory phase has been less well characterized than that of LH. A surge in FSH coincident with the LH surge has been reported, but the postovulatory surge in FSH is

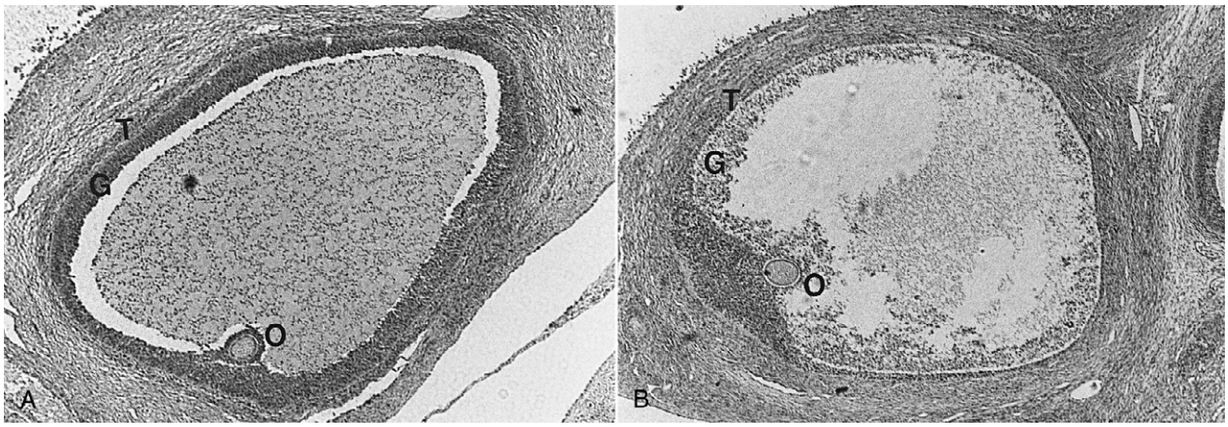

Fig. 98-3 Light micrographs of ovarian follicles (hematoxylin and eosin, original magnification 40×). In the nonatretic follicle **(A),** an intact granulosa layer (G) surrounding the ovum (O) and an intact theca layer (T) are visible. In the atretic follicle **(B),** the granulosa layer is fragmented owing to extensive degeneration of granulosa cells.

more distinct and appears to be responsible for activating small follicles for potential ovulatory growth during later cycles. Circulating FSH is inversely related to concentrations of inhibin, a follicular protein known to exert negative feedback on FSH. Inhibin is produced increasingly as follicles reach ovulatory size.

The **luteal phase** is the period of corpora lutea formation and progesterone production. Increasing progesterone is evident in serum between 2 and 4 days after estrus. Corpora lutea are formed from the cellular remnants of follicles after ovulation, which transitionally are called corpora hemorrhagica. As with other species, the corpora lutea of pigs contain identifiable cells of follicular granulosa (large luteal cells) and thecal (small luteal cells) origin.

Other hormones that have been characterized during the estrous cycle include prolactin, which increases at estrus and appears to have a luteotropic role during the estrous cycle and pregnancy. Cortisol also increases at the time of estrus and when prepubertal females are exposed to a boar as part of the puberty induction process.

Ovulation Rate

The number of ova released at estrus (ovulation rate) depends on the number of preovulatory follicles that develop and their rate of atresia. Ovulation rate is affected by age, breed, and nutrition. Ovulation rate increases by a factor of about 2 from pubertal to third estrus, although the way in which gilts are fed also influences ovulation rate. In full-fed gilts compared with gilts on restricted feed, ovulation rates are elevated. Flush feeding restricted-fed gilts eliminates the depression associated with limit feeding. **Flush feeding** refers to the practice of elevating feed intake for several days to 2 weeks before mating. The increase in ovulation rate is not always accompanied by increased litter size, presumably as a result of increased embryonic mortality. In instances in which increased litter size was observed, feeding excess energy was terminated at the time of estrus and did not continue through early pregnancy. Few studies, however, have systematically described specific uterine effects of elevated dietary energy.

Increasing ovulation rate has been reported with the use of immunization against inhibin and androstenedione, as well as with treatment with epostane, an inhibitor of progesterone synthesis, and gonadotropin-releasing hormone (GnRH). Metabolic manipulation with insulin and growth hormone also has been suggested to increase ovulation rate. Currently no therapies are approved for increasing ovulation rates in swine, so genetic selection, crossbreeding, and nutritional manipulation are the only avenues available.

PREGNANCY

Embryo Survival and Development

It generally is agreed that for sows when successful fertilization occurs, nearly 100% success in fertilization is achieved in swine. Between 20% and 30% of potential embryos (as reflected by number of corpora lutea) die during the first 30 days of gestation, and another 10% die before term. It appears that in most instances, embryo death occurs between days 13 and 20.[7] Some proportion of embryo deaths is due to chromosomal aberrations and congenital lethal defects that are unavoidable. Porcine embryos migrate into the uterine lumen from the oviduct at about day 4, and growth is supported by uterine histotrophs. Embryos begin to secrete estradiol at approximately days 10 and 11 of embryonic life, coincident with rapid development from the spherical to the filamentous stage (Fig. 98-4). A second increase in estradiol occurs after day 14. The estradiol secretion is associated with specific uterine protein secretion, uterine epithelial cell morphology and secretory patterns, maternal recognition of pregnancy, and embryonic migration.[7] Embryo size at this transitional stage of development can vary. Recent information indicates that strains of pigs with greater litter size, such as miniature swine selected

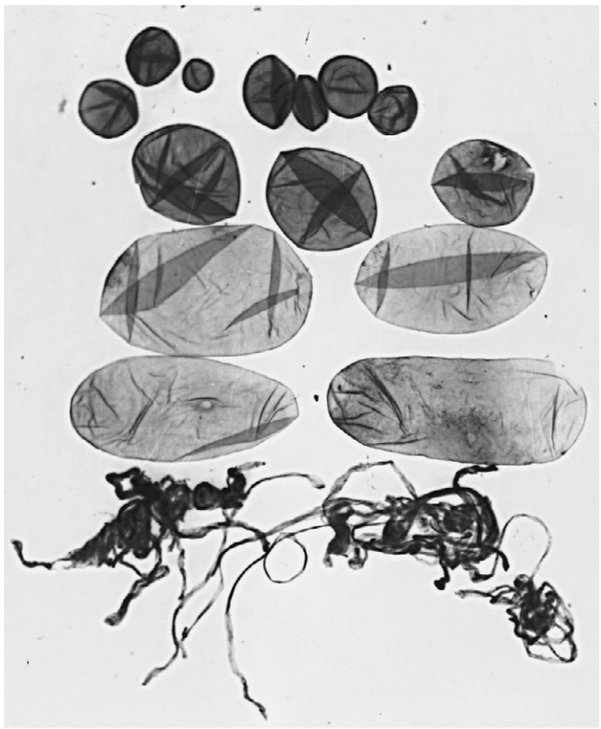

Fig. 98-4 Early porcine conceptuses collected between days 10 and 12 of gestation. Sizes range from 3-mm spherical blastocysts *(top row)* to tubular (15 mm length) to filamentous blastocysts. (Courtesy of Dr. Rodney D. Geisert, Oklahoma State University.)

for the D haplotype and Chinese Meishan swine, have blastocysts that grow more slowly and secrete estradiol more gradually than do domestic swine. As a result, intrauterine competition for space may be reduced during the critical period of distribution and elongation of embryos. Another hypothesis for variation in embryo development is that the later ovulations give rise to smaller embryos, and that initiation of estradiol production by older blastocysts inhibits this maturational process in the younger embryos. This hypothesis was not supported by research results showing that embryonic diversity at 98 hours was not related to duration of ovulation.[5]

Few therapies are available that reliably increase embryonic survival. Maintaining sows in a cool, calm environment for several hours after breeding seems to increase embryo survival. Limiting feed intake to a maintenance level for 2 to 5 days after breeding also has been suggested to be beneficial to embryo survival, presumably because of the relationship of intake with circulating progesterone levels.[8] This effect is seen more often in gilts than in sows. Parity 1 and sometimes parity 2 sows typically have a reduced subsequent litter size. A practice of mating these females at their second postweaning estrus rather than the first has been shown to increase litter size dramatically, and embryo survival has been proposed as the mechanism. A high level of hygiene and ensuring that matings occur only during sexual receptivity will enhance efficiency of reproduction and could be partly mediated through embryo survival.

Uterine Capacity

Although ovulation rate places an absolute limit on litter size, embryo and fetal survival depend on the complex uterine factors described. A practical term for these collective uterine influences is **uterine capacity.** Several investigations have proved the importance of uterine capacity when ovulation rate is not limiting. For example, the ovulation rate and number of fetuses are correlated linearly up to a certain point, but then the magnitude of this association levels off, being described by most researchers as a quadratic relationship. When ovulation rate is greater than uterine capacity, increased embryo or fetal death (calculated as a percentage of the ovulations) occurs. An increase of 3.7 eggs was realized from nine generations of selection for ovulation rate, but only 20% of the increase was reflected in an increase in litter size.[9] Direct selection for litter size for eight generations in the high ovulating line resulted in an increase of 1.06 in number of piglets, presumably as a result of enhanced uterine capacity. Uterine capacity may involve several mechanisms including physical size, degree of folding between uterine and placental tissues, and vascularity of the placenta.

POSTPARTUM PERIOD

Endocrinology

During lactation, the ovary is relatively inactive, with few follicles developing to larger than 5 mm in diameter. LH is suppressed during lactation, whereas FSH is not suppressed as severely, but ovarian factors (presumably inhibin) effect some suppression of FSH. On weaning of the litter, an increase in pulsatile secretion of LH occurs. The increased LH, together with the FSH present, stimulates follicular development, which culminates in a preovulatory LH surge and ovulation. In normal animals, this results in estrus about 3 to 7 days after weaning.

The mechanisms causing some sows to fail to come into estrus after weaning are not well understood. In many sows, an increase in estrogen occurs but induction of an LH surge does not. Later on, the hypothalamopituitary mechanisms appear to recover from the inability to produce a surge in LH, but this period is variable, and anestrus can persist for more than 1 to 2 months. Wean-to-estrus interval (WEI) is discussed later in the chapter.

Prolactin is elevated during lactation and returns to baseline after weaning. This hormone is not thought to be involved in delaying returns to estrus after weaning, because estrus can be reliably induced in the face of elevated prolactin levels. Oxytocin also is increased during suckling in lactating sows and is increased during feeding but does not appear directly involved in postweaning anestrus.

Metabolic factors are thought to affect return to estrus, but inconclusive results are obtained when feeding level between weaning and estrus, or body condition at

weaning, is examined. Static measures of metabolic status appear less sensitive than dynamic measures. It is known that sows will sustain milk production by catabolizing body fat and protein in the face of limited intake. The level of digestible lysine intake required to prevent protein catabolism resulting in reduced subsequent litter size was established as 45 to 48 g per day for first-parity sows.[10] In another study in which feed intake was experimentally limited, WEI was extended in limit-fed sows, but no additional benefit was achieved with hyperalimentation.[8] No differences were observed in ovulation rate or embryo survival, although numbers of sows per treatment were not large. Factors affecting metabolism in gestation clearly interact with metabolic factors during lactation and after weaning.

PREPUBERTAL PERIOD

Limited ovarian follicular growth occurs until the age of approximately 60 days in swine. Primordial and primary ovarian follicles are observed at approximately 68 and 75 days of gestational age in the fetus, respectively, and secondary follicles are observed at the time of birth. Tertiary follicles, recognized as gonadotropin-sensitive, appear between 60 and 90 days of postnatal life.[1] Concentrations of gonadotropins are elevated during the last few weeks of the fetal period and 3 to 4 weeks after birth; then LH is suppressed and FSH is fairly constant until puberty[11–14] (Fig. 98-5).

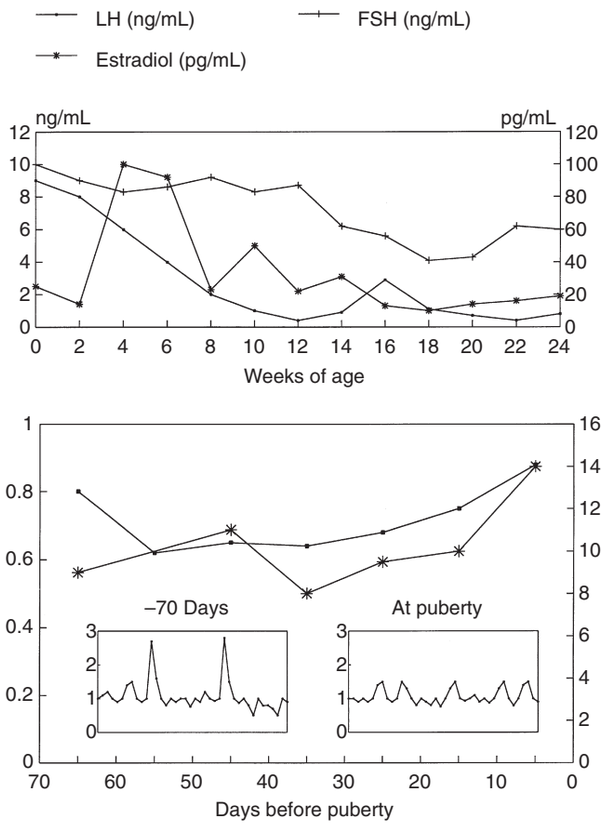

Fig. 98-5 Average concentrations of reproductive hormones of gilts according to age *(top panel)* and days from onset of puberty *(bottom panel)*. *Insets* in the bottom panel represent luteinizing hormone concentration in samples collected every 10 minutes for 7 hours at 70 days before puberty and at the time of puberty. (Data from references 11 to 13.)

PUBERTY

Endocrinology

Estrogen concentrations are elevated during the fetal period but decrease soon after birth. The first sustained rise occurs at the time of puberty, coincident with the first development of follicles to preovulatory size (5 to 12 mm).

The age of puberty ranges from 5 to 8 months, depending on genetic and environmental factors including season, social environment, and nutrition. For most common maternal lines under routine management, gilts are capable of expressing estrus around 165 days of age. Gilts not in estrus by a farm-specific maximum age should be culled, because they are likely to experience inferior reproduction throughout their lives. It is generally agreed that the final stage of preovulatory ovarian follicular development at puberty is due to an increase in LH secretion. Patterns of LH are lowered before puberty, presumably because of increased steroid negative feedback. The gradual increase in LH generally is taken to support the gonadostat theory, which describes the phenomenon of reduced hypothalamic responsiveness to negative feedback of ovarian steroids as puberty approaches. Several studies have demonstrated that LH pulse amplitude is reduced as gilts near puberty, but one study that measured LH in frequent samples up to the time of puberty found increased LH frequency immediately before puberty (see Fig. 98-5).

Responsiveness of the ovary to gonadotropins and the pituitary-ovarian axis to GnRH has been used to infer developmental aspects of puberty. The ovary responds to exogenous gonadotropins with follicular growth and ovulation as early as 100 days of age, although this response improves as gilts approach puberty.[14] Gilts 70 days of age responded to GnRH with no ovulation or a low ovulation rate. Administration of GnRH to gilts 100 days of age or older produced typical cyclic patterns of estradiol and LH and supported normal ovulation rates. It is clear that the ovary and the pituitary are competent in advance of puberty and await maturation of hypothalamic signals.

Gilt Development

Variation in productivity among sows can be attributed to several factors. Gilts will routinely have lower productivity than multiparous sows. The degree of this difference depends on gilt development and sow management programs. A discussion of events associated with puberty is appropriate at this point.

Once a gilt is identified as a potential replacement female, she should be managed as such, with provision of the best environment possible. If cross-fostering is

practiced, potential replacement gilts should be preferentially fostered to smaller litters. From weaning through early grow-finish, they can be managed with conventional production technologies. Historically a common practice was to pull gilts from the finishing phase immediately before mating. With changes in marketing age, space allowance, and feeding protocols, this practice cannot be endorsed.

Nutrition

Feeding replacement gilts conventional finishing diets *ad libitum* until market weight is an acceptable practice. Although the scientific literature concurs that full feeding results in the youngest age at puberty, with advanced growth rates observed in modern production, it is common to limit feed for replacement gilts for some period before mating. Limited research data support limit feeding of gilts to increase sow longevity. To achieve the benefits of limit feeding without subsequent negative production effects, it may be useful to flush-feed as previously described. Manipulation of diets is necessary depending on whether gilts are being fed *ad libitum* or with restricted diets, and use of a gestation diet is recommended when limit feeding is used. The National Research Council (NRC) provides several tables and a computer model to predict daily nutrient requirements for pigs of various stages.[15] For a gestating female expected to consume 1.96 kg of feed daily and gain 55 kg during gestation, a diet containing 3400 kcal/kg DE and 12.9% crude protein, 0.75% calcium, and 0.60% phosphorus is recommended. The female should then consume 11.4 g of total lysine daily.

Housing/Temperature/Photoperiod/Air Quality

Older literature suggested that growth performance would suffer from overcrowding before reproductive performance. Some systems today provide floor space known to limit growth of individual pigs because it results in greater gain for the total building. Accordingly, replacement gilts should be identified early and provided with a minimum of 0.74 square meter until 114 kg of liveweight is attained. As gilts enter the breeding herd, space allocation goes up dramatically. Recommendations are presented in Table 98-2.[16]

Gilts housed in very small groups (less than three) or very large groups (greater than 30) exhibit delayed puberty. Use of heat checks in groups larger than 12 typically is associated with reduced efficiency of estrus detection, so pens of 6 to 12 gilts should be considered ideal.

Other housing factors important for gilt development include temperature, photoperiod, and air quality. In practice, these factors often are confounded. Constant elevated ambient temperatures have been demonstrated to delay puberty. Poor air quality likewise delays puberty, independent of the effects on growth. From experimental data it is not possible to detect how much of this delay is due to a physiologic delay and how much could be due to interference with the ability to respond to olfactory cues associated with boar exposure. Data on photoperiod are more equivocal. Minimum or maximum photoperiods have been suggested, but results from controlled studies are not consistent. If a constant photoperiod is to be provided, a day length between 10 and 16 hours probably is the safest. Results of an experiment help to demonstrate part of the reason for disagreement among studies. The wild pig is known to be a seasonal breeder. The investigators found if day length was extended to 15 hours during periods of decreasing day length it helped to reduce the age at puberty. During periods of increasing day length, however, no benefit was observed.[17]

Comparison of housing systems is more difficult. Most scientific data suggest that outdoor production is superior to confinement with regard to gilt development. In these studies, however, differences in the various components previously discussed usually existed: space allocation, social environment, photoperiod, air quality, and so forth.

Boar Exposure

Many operations develop sophisticated gilt development programs but fail to effectively incorporate the most consistent and dramatic factor: boar exposure. The "boar effect" has been described and studied in detail.

It is commonly believed that boars reach sexual maturity at 7 to 9 months of age. If sexual maturity is defined as the ability to breed sows or gilts, this is largely accurate. Further maturation, however, occurs in the broader sexual system of the boar. Specifically, although sperm production and serum testosterone reach nearly mature levels by the age of 7 to 9 months, the submaxillary salivary gland does not mature until 10 to 11 months.

Table **98-2**

Recommended Minimum Space Allowances for Sows and Gilts

	GROUP PENS		INDIVIDUAL STALL	
Production Group	**Size (kg)**	**Solid Floor (m^2/head)**	**Slatted Floor (m^2/head)**	**Slatted Floor Dimensions (cm)**
Breeding gilts	114–136	3.72	2.23	61 × 213 × 102
Breeding sows	136–227	4.46	2.79	61 × 213 × 102
Gestating gilts	114–136	1.86	1.30	56 × 213 × 107
Gestating sows	136–227	2.23	1.49	61 × 213 × 107

Adapted from MWPS-43, *Swine breeding and gestation facilities handbook.*

It is in these glands that circulating testosterone is converted to pheromones, specifically, 5α-androstenone. The pheromones have two effects on females. In prepubertal gilts, the pheromones are the most significant component of boar effect that can stimulate puberty; this effect is referred to as a **primer effect.** Additionally, they can elicit lordosis or standing heat, an effect referred to as a **signaler effect.** It is critical that consideration be given to which effect is being sought in a particular situation.

To maximize the effect of the boar at stimulating puberty, a minimum of 10 minutes daily of full physical contact will yield the maximum effect comparable to that observed with 24-hour contact. Housing gilts with mature boars for prolonged periods increases their risk for injury, so 10 to 15 minutes is preferred. A compromise that requires less labor is to provide fenceline exposure continuously. This will capture 50% to 90% of the primer boar effect. If fenceline contact is used, the housing should provide as much nose-to-nose contact as possible, because olfactory cues are the most important of the various boar stimuli.

Miscellaneous

Besides the boar effect several factors are claimed to stimulate puberty in gilts. Among the most commonly mentioned are transportation, relocation, and mixing in a new social environment. Transportation alone has been shown to be ineffective. The relocation and mixing often associated with transportation, however, can help to induce puberty. Capitalizing on this phenomenon is not always a simple task. Historically, gilts could be moved to the breeding unit from finishing areas at appropriate ages—160 to 165 days for most lines. Although that still appears to be an appropriate age, the scientific literature lacks data regarding the optimal procedures given the additional moves associated with isolation and acclimation on many farms today.

Genetic variation exists among lines and breeds for several gilt development traits. An extreme example is the very early age at puberty for Chinese Meishan pigs of 90 to 120 days, versus 140 to 180 days for conventional breeds. Variation in other production traits, including longevity, lifetime productivity, WEI, gestation length, and milk production, also is likely. Unfortunately, limited data exist with current genetic lines/breeds. Fortunately, most reproductive traits are associated with a high level of heterosis. By using crossbred females, therefore, reproductive performance can be enhanced.

Manipulation of Estrous Cycles

Manipulation of estrous cycles is discussed in depth in Chapter 100. Induction of puberty through pharmacologic procedures may be a viable management tool. The role of FSH and LH in growth and ovulation of follicles has been described previously. For gilts physically capable of cycling but still prepubertal, the natural system can be mimicked with FSH and LH. As an alternative, pregnant mare's serum gonadotropin (PMSG) and human chorionic gonadotropin (hCG), compounds with FSH- and LH-like activities, can be used. A commercially available combination of PMSG and hCG, PG-600,* is approved for induction of puberty. Reported results have been good.[18] Producers often fail to achieve as good a response. Reasons are not known, but several factors can contribute to variation in response. Best results are obtained when this agent is used in conjunction with other stimuli (moving and mixing, boar exposure). It is critical that the label dose be administered intramuscularly. A common problem observed in the field is administration at an inappropriate age. Gilts that are too young are unable to respond or unable to maintain normal cycles, as previously described. This treatment also is ineffective in gilts that are already cycling. In practice, a proportion of gilts often are cycling before the initiation of estrus detection, and often at significantly younger ages than has been realized. If this problem is suspected, a slaughter check or real-time ultrasound evaluation of ovaries of presumed prepubertal gilts can be useful. Alternatively, blood samples can be collected for progesterone analysis. PG-600 often is used at or near weaning at times when poor return to estrus is expected (e.g., late summer).

In cycling females the only effective methods to synchronize estrus involve manipulation of the corpus luteum (CL). Pregnancy results in maintenance of the CL and cessation of cyclicity, and lactation results in suppression of cycles, as previously described. Unlike in cattle, swine CL are not responsive to $PGF_{2\alpha}$ until late in the estrous cycle (days 12 to 14). This makes administration of prostaglandin to cycling gilts an impractical method to control estrous cycles. Two alternatives exist. One is to prolong the life of the CL by mating the gilt. In gilts that conceive, the CL will persist, and remain responsive to prostaglandins for several weeks. Treatment with $PGF_{2\alpha}$ between days 14 and 35 of pregnancy typically induces regression of the CL, abortion, and a return to estrus in 4 to 5 days. Not all gilts respond, however, and provision must be made for those maintaining pregnancy. This procedure works only for those gilts conceiving, so a high conception rate is critical. Although demonstrated to be effective as a research tool, this protocol does not have label approval.

Another effective method involves use of a synthetic progestin, allyltrenbolone (Regumate*). Extensive research has been done with this product demonstrating that it can be fed at 15 to 18 mg/day to prevent estrus. Gilts and sows typically show normal estrus and ovulation 4 to 5 days after feeding of the product has ceased. Although used extensively in many parts of the world, this product is approved for use only in mares in the United States and is considered too costly to be used as a routine management tool in swine production. Another mechanism to deliver progesterone has been through the use of intravaginal devices for controlled internal drug release (CIDRs). Results are not consistent, with the development of follicular cysts occurring in some groups. CIDRs also are not currently available for use in swine.

Wean-to-Estrus Interval

Variability in WEI is attributable to many factors, some relatively responsive to management. First-parity sows will have a longer WEI than that observed in multiparous sows. This probably is unavoidable, and management systems should be designed to accommodate this fact, especially in start-up or expansion periods when the herd contains a disproportionate number of parity 1 females. WEI tends to be shortest with lactation lengths near 28 days. After parturition, several physiologic and physical changes must occur in the sow before successful subsequent reproduction, as previously described. The uterus must undergo some degree of involution, a process that is not complete for some 24 days in lactating sows. Sows not allowed to nurse at all have been found not to begin cycling for at least 8 to 10 days after parturition.

Seasonal delays in WEI are to be expected in late summer and early fall. This is part of what is commonly referred to as seasonal infertility, and the causes are not completely clear. Minimizing heat stress, ensuring fresh feed, and providing cool water can reduce this effect.

Litter size weaned has been repeatedly demonstrated to affect WEI. Nursing more and larger pigs places greater metabolic demand on the sows. Management to prevent these sows from reaching a catabolic state becomes increasingly important.

Field reports of delayed WEI in sows weaning very small litters also exist. Although this has not been investigated in controlled studies, the longer WEI in these sows is likely to be from a different reason. With very small litters, six or piglets or fewer, for example, suckling-induced inhibition is not adequate to prevent return to estrus during lactation. A proportion of these sows will return to estrus in the farrowing crate and not be observed. At weaning, therefore, rather than being acyclic, they are in the luteal phase of the cycle and will not exhibit estrus until regression of the CL.

Lactation feed intake is perhaps the single most important factor affecting WEI. During lactation a sow that does not consume enough nutrients will use body stores to support milk production. A reduction in body fat often is expected during lactation, but significant loin muscle loss also can occur and is associated with reduced subsequent reproduction.[10] Nutrient density should be adjusted for realized lactation feed intake. Conditions vary among farms, but to maximize feed intake some elements are constant. A comfortable environment for the sow should be provided for as much of the day as possible; lights should be on when temperatures are in the thermoneutral zone; presence of fresh feed should be ensured. Multiple daily feedings almost always increase feed intake. A regimen of at least twice-daily is suggested. Feeding more frequently may be beneficial if periods between feedings are of sufficient duration. Providing wet feed will enhance feed intake for some sows but has no effect on others. Regardless of whether feed is wet or dry, the feed in front of sows must be fresh. This will typically require discarding leftover feed once daily. Low lactation feed intake usually is indicative of an environmental factor that will respond to management.

The final element affecting WEI is exposure to a boar after weaning. Most farms begin boar exposure on the first day of estrus detection, typically day 3 or 4 after weaning. This practice evolved because detection of estrus is the primary objective. Limited data suggest that boar exposure at weaning can shorten the WEI. With this practice, consideration must be given to the difference between stimulation of estrus and detection of estrus.

Factors favoring shorter WEI also tend to favor other reproductive parameters. In retrospective analyses, sows with shorter WEI tend to have increased farrowing rates and subsequent increased litter size. This advantage is not related to length of WEI per se but derives from the fact that WEI is serving as an index for reproductive fitness. The implication is that systems must be designed to optimize reproductive performance, and WEI is a simple measure of this complex trait.

Mating Systems

An understanding of the physiology of the sow and gilt helps in the design and optimization of mating systems. Successful mating systems require that adequate supplies of viable semen be present in the oviduct at the appropriate time relative to ovulation. The use of real-time ultrasonography has allowed observation of ovaries of nonanesthetized sows at regular intervals and accurate description of time of ovulation relative to onset of estrus. In conjunction with timed inseminations, this knowledge has confirmed data regarding success of matings.

Insemination not more than 24 hours before or 4 hours after ovulation results in near maximum farrowing rate and subsequent litter size. Sperm cells must undergo capacitation in the female tract before fertilization, and this takes about 4 hours. After capacitation, a population of sperm cells exists in the oviduct that are slowly released from oviductal crypts over several hours. After 24 hours the number or quality of sperm cells released declines, with a consequent decline in fertility. Once ovulated, eggs remain viable for a relatively short time, 4 to 8 hours. A bioeconomic model was developed using these data to compare the performance of various mating schedules using once- or twice-daily detection of estrus.[19] The stochastic model demonstrated that the optimal timing of inseminations depends on frequency of estrus detection. Generally the model supports the practice of multiple inseminations, but a 12-hour interval rather than a 24-hour interval between inseminations is suggested. Conclusions might differ if intervals were not 12 hours, and further evaluation of the model under field conditions is needed.

The quality of the mating also is important. Although limited research has been conducted, field data suggest that having a boar present at insemination may increase farrowing rates by as much as 10%. Olfactory cues seem to be the most critical element, so fenceline exposure is adequate. Some farms find success by dangling rags soaked with boar saliva in front of sows during insemination. What role the boar's presence plays is not entirely clear. Certainly it will help to induce lordosis, which is associated with uterine contractions. Perhaps the greatest

effect is that it confirms that the sow is still in estrus. This helps the breeder to be calm. Historically, several investigators have demonstrated the improved fertility with multiple inseminations. A negative impact of a third insemination has been demonstrated when that insemination was given in late estrus or after estrus.[20]

The challenge to timing of inseminations is to predict time of ovulation. Ovulation seems to occur at two thirds to three fourths of the way through estrus, as previously discussed. This finding provides little value as a management tool because by the time prediction of ovulation becomes possible, it has already occurred. Understanding the relationship of WEI and duration of estrus, however, has led to the development of specific mating protocols based on WEI. Sows with short WEI tend to have longer estrus than sows with longer WEI. For example, sows returning to heat at 4 to 5 days after weaning might have first mating delayed for 24 hours, sows returning after 6 to 7 days might have a 12-hour delay, and sows returning after 7 days might be mated at first detection of estrus. Obviously this depends on the duration of estrus expected on a given farm.

Estrus Detection

Pen mating systems rely on the boar for detection of estrus. All other mating systems are predicated on the accurate detection of onset of estrus by breeding personnel. Lordosis, or standing heat, usually is identified by signs such as swelling and reddening of the vulva, vocalization, boar-seeking behavior, "ear popping," and standing for back pressure. Lordosis involves chronic flexing of the muscles by the gilt. This posture cannot be maintained indefinitely owing to muscle exhaustion. When a gilt or sow is in estrus but unable to display lordosis, she is said to be refractory. Because of this phenomenon, it is important that boar exposure be delayed until the time of estrus detection. Ideally, the boar is housed separately from the females. Gilts and boars can be moved to a neutral area for estrus detection, or the gilts should be moved to the boar area. All gilts exposed to the boar must be observed simultaneously, so groups of 6 to 12 gilts are ideal. If it is not possible to house boars and gilts separately, they should be housed as far apart as possible. General agreement is lacking on the separation distance required. Although a 76-cm aisle may represent an adequate distance in some cases, a greater distance often will be required. It also is important to address direction of air currents. In a tunnel-ventilated barn, for example, boars should be kept closer to the exhaust than gilts that will be observed for estrus. Because of the unpredictable nature of air currents in naturally ventilated facilities, a greater separation distance may be required.

In some production facilities, detection of estrus is practiced by parading the boar past gilt or sow pens. This practice provides very little stimulation to initiate cycling in prepubertal gilts. In any case, a boar used in this manner should be restrained to one group pen or be placed close to no more than 5 individual sow stalls simultaneously for 5 to 10 minutes. This allows the females to realize that the boar is present and for the technician to observe all females exposed to the olfactory cues of the boar. Travel route of the boar should consider air flow patterns in the barn. If observation of all females simultaneously is not possible, a minimum exposure time of 1 hour should be allowed before rechecking with boar exposure to avoid missed detection due to refractoriness.

Type of Mating

All mating systems should be designed around knowledge of physiologic factors previously discussed. Detection of estrus and appropriate timing of insemination are critical. Moving or mixing sows seems to be associated with elevated embryo mortality and should be avoided. Research data on embryo survival per se are lacking, so recommendations are based on the effects of fighting on various physiologic factors believed to affect embryo survival. Available data suggest that if mixing is necessary, the lowest impact on embryo survival will occur if mixing is within 2 days of mating or after 21 days. For practical purposes, delaying moves until after the 42-day heat check enhances efficiency on most farms.

Pen Mating

The use of **pen mating** has declined dramatically in the United States in recent years. The greatest benefit of pen mating is the reduced labor requirements. To maximize efficiency of pen mating requires more management than has been historically applied, with a consequent reduction in this labor advantage relative to that for other types of mating.

Pen mating systems rely on boars to accurately identify and breed sows in estrus. Movement of animals and boar-to-sow ratios can be adjusted to increase the likelihood that this goal will be achieved efficiently. A characteristic of successful pen mating systems is ample boar power, requiring an adequate number of boars, timeliness of use, and sexual rest. A boar-to-sow ratio of 1:8 is common.

Boars should not be expected to breed more than one sow daily. This is achieved by rotating sows into pens with the boar. For example, one or two sows can be added to a pen from each weaning group. Because of courtship behaviors of boars, pen mating can result in some sows not being mated, even though expressing estrus. Using groups of boars seems to reduce this. If new groups are formed after maturity, significant fighting will occur. Rotating boars also is useful. In addition, rotating boars can be coordinated with periods of sexual rest.

Because a majority of weaned sows return to estrus during a relatively short time after weaning, pen mating systems often involve adding sows to groups at weaning to avoid overusing the boar. The risk for reduced embryo survival expected with mixing pregnant sows may not be as dramatic in pen mating systems. Although scientific data are lacking, it appears that the presence of the boar provides an obvious dominant animal, and fighting among sows is dramatically reduced.

Hand Mating

Hand mating describes the practice of taking the female to a breeding pen and housing her with a boar for a

prescribed period of time. During this time the interaction of the animals is observed to allow removal of the female if needed to prevent injury, and to allow assistance with intromission if needed. In practice, very few services should require assistance.

Hand mating has several advantages over pen mating. Boar needs drop to approximately one fourth to one half of those needed for pen mating. Reducing the number of boars brought into the sow unit decreases overall boar cost and the risk of disease introduction. Additionally, greater genetic merit and uniformity of progeny can be expected. Breeding dates are accurately known. Boars that are infertile or subfertile can be detected and treated or eliminated. The disadvantage is that more daily labor is required.

Timing of mating is critical to the success of this program. Detection of estrus is critical to properly timing inseminations. Once- or twice-daily detection of estrus beginning 3 days after weaning is necessary for maximum productivity. Females should remain with the boar for at least 5 minutes. Some gilts and sows require more stimulation before they will exhibit lordosis. After successful mating, the boar should be removed. Ideally the female is allowed to remain in the breeding pen for at least 15 minutes. This is to minimize stress from heat or social interactions. If this is not possible, she should slowly be walked back to her housing area.

With hand mating systems, sows typically are mated once daily at 24-hour intervals for as long as they will stand. This protocol can be modified with *a priori* knowledge of timing of ovulation, as previously discussed. The duration of oviductal sperm viability after natural mating is believed to be longer than after AI, and some farms achieve very high farrowing rates with one natural mating.

Artificial Insemination

Chapter 97 is devoted to AI. Here it is discussed primarily to contrast it to other mating systems. Use of AI skyrocketed in the United States in the late 1990s, and today this method is used to mate a majority of U.S. sows. In comparison with pen mating, the same advantages that apply to hand mating apply to AI, but to a greater degree. The reduction in boar needs is more dramatic, with a 1:150 boar-to-sow ratio routinely achieved. AI also has specific advantages over hand mating. Semen quality can be assessed before use, and infertile or subfertile boars often can be identified before use. The same disadvantages exist. The only additional disadvantage is that a higher level of technical competence is needed to ensure success.

Typical AI programs will use timing and number of matings similar to those with hand mating. Exciting data are being reported using very-low-dose inseminations. These procedures utilize dramatically fewer sperm cells and place the semen into either the uterine body or deep into the uterine horn.[20] Preliminary results suggest 2- to 60-fold more efficient sperm use than with conventional AI, but a higher degree of hygiene and technical competence probably will be required as well.

Boars

The anatomy and physiology of the boar are covered in detail in another chapter of this text. Because the epididymis stores up to 5 days' sperm production, sperm numbers per ejaculate are maximal with 5-day intervals between ejaculation. For AI boars a 5-day interval is recommended for maximum efficiency of sperm collection. Total sperm output can be slightly increased with shorter intervals. For hand mating systems, boars can be used much more frequently. Although some boars will breed two to four times daily, fertility is expected to be lower when mature boars are used to breed more than once or twice daily. Younger boars (<12 months of age) should be used no more than three to five times weekly. After five matings, boars should be allowed a minimum of 24 hours' rest.

CHAPTER 99

Clinical Examination of Female Reproductive Organs

GLEN W. ALMOND

Detailed examination of records, with or without the assistance of computer programs, often identifies deficiencies in breeding herd performance. The computerized record systems and implementation of statistical process control (SPC) methodology are excellent tools to characterize, at least numerically, specific areas that require long-term or immediate attention. Despite the use of new technology and analytic procedures, swine practitioners often are required to provide accurate diagnoses of noninfectious reproductive failure or urogenital infections in female swine and to identify shortcomings in reproductive performance. Because sow and gilt reproductive organs are easily evaluated at slaughter, this diagnostic technique represents minimal cost to the producer yet provides accurate assessments of the precise causes of reproductive failure.

Complete histories, including age, parity, farrowing dates, weaning dates, and other pertinent information, should be obtained before examination of the reproductive organs. It is necessary to select animals that represent the condition or problem affecting reproductive performance and not animals culled for other reasons. Typically, it is easier to select a greater sample size of animals from sow farms with 1000 or more sows; however, with smaller farms, the entire procedure usually is repeated with two or more groups of animals that typify the farm problem. Reproductive slaughter checks are intended to verify an abnormality that is common to all of the affected animals.

POTENTIAL USES

Clinical examination of reproductive organs is useful to confirm infectious and noninfectious causes of reproductive failure (Box 99-1). Presence of physiologic or anatomic abnormalities associated with reproductive failure can be verified or refuted by examination of the female genital organs. Alternately, findings on these examinations may clearly illustrate shortcomings in breeding management.

Reproductive slaughter checks also can be used for collection of specimens for diagnostic procedures. Fetuses, uteri, oviducts, urinary bladders, and kidneys are readily obtained for histopathologic examination or the procurement of culture swabs. To adequately assess the significance of lesions or other abnormalities, it is imperative that veterinarians have sufficient understanding of normal ovarian and uterine structures.

SPECIMEN COLLECTION TECHNIQUES

Procedures at the Slaughterhouse

Reproductive and urinary tracts are examined at the slaughterhouse or removed to a clinic or laboratory with appropriate approval from regulatory officials. Individual identification of animals at slaughter is used to correlate gross and histologic findings with the reproductive history of the sow. Ear tags are convenient, but ear,

Box 99-1

Examination of the Reproductive Tract of Female Pigs: Clinical Applications

Noninfectious Causes of Reproductive Failure
Delayed puberty
Failure to return to estrus after weaning (anestrous sows)
"Silent" heats
Regular returns to estrus after mating
Irregular returns to estrus after mating
Pseudopregnancies and not-in-pig sows
Suspected cases of zearalenone toxicity

Infectious Causes of Reproductive Failure
Collection of fetuses and uteri from affected sows before parturition, e.g., PRRSV
Collection of fresh tissue, fetal blood, or thoracic fluid for submission to diagnostic laboratories
Evaluation of reproductive and urinary tracts for evaluation of urogenital infections

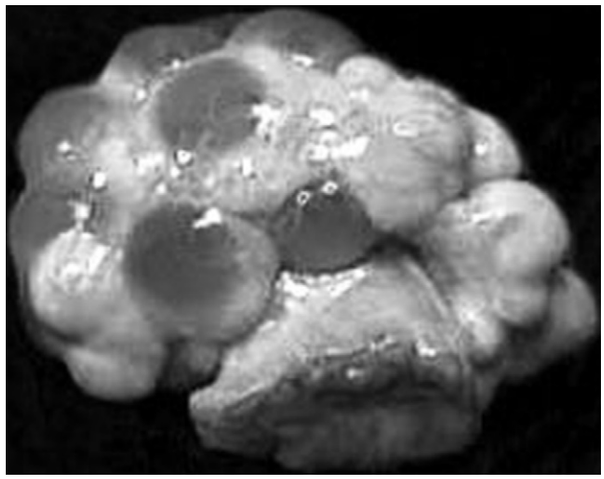

Fig. 99-1 Large, fluid-filled follicles are evident on the ovaries of a sow during proestrus. The corpora lutea are well regressed and white-yellow in color.

shoulder, or flank tattoos constitute a more reliable means of identification.

It is beneficial to examine other body systems while animals are being processed in the packing plant. Body condition and backfat thickness of animals are assessed after evisceration. Hence, additional information is gathered to assist in the interpretation of the cause(s) of reproductive failure. Abnormalities, such as acyclic ovaries, actually reflect suboptimal management of the breeding herd. For example, the absence of backfat on sows during the summer and early autumn months may reflect inadequate feed consumption or facility cooling systems. These shortcomings in management probably contribute to the pathologic conditions noted in the reproductive organs.

If specimens are to be transported to a laboratory, individual sow identification should be included with each specimen. Specimens are placed in sealed containers and packed in ice for transport. It is imperative to tie the cervix and the neck of the bladder closed with heavy string to prevent contamination or leakage.

Initial Procedures and Gross Examination

Gross lesions are noted on examination of the ovaries, oviduct, uterus, cervix, vagina, urinary bladder, and kidneys. If an infectious etiology is suspected, culture swabs are procured using aseptic technique from both horns of the uterus, urinary bladder, and kidneys. Failure to use aseptic technique usually results in gross contamination of the swabs and erroneous culture results. Urine is obtained by centesis with 20-gauge needles and stored on ice (5°C) for transport to the laboratory. Storage of urine for more than 12 hours limits the diagnostic value of the specimen.[1] Owing to the broad spectrum of bacterial agents involved in urogenital infections,[2] swabs are submitted for culture under aerobic and anaerobic conditions. Determination of bacterial sensitivities to antibiotics also should be requested for future reference.

After collection of swabs for bacterial cultures, the vagina, cervix, and each horn of the uterus are incised to allow adequate assessment of the mucosa and luminal contents. The urinary bladder and kidneys also are dissected to examine the bladder lumen and renal pelvis, respectively. To complete the evaluation, it is imperative to collect tissue samples from representative organs for subsequent histologic examination. These samples are fixed in either 10% buffered formalin or Bouin's solution and submitted for histologic preparation and evaluation. If the diagnostic tests may require special handling, storage, or shipping of tissue, it is beneficial to contact the diagnostic laboratory before collection of samples.

NORMAL MORPHOLOLGY

Normal Ovarian Structures

The possibility of errors in the recording of a sow's reproductive history make it necessary to determine the stage of the estrous cycle during gross examination of the ovaries. In addition, interpretation of uterine morphologic features is improved when the stage of the estrous cycle is known. The estrous cycle of the pig typically ranges from 17 to 25 days. Owing to this variation in the length of the estrous cycle, it is more convenient to classify the cycle into three distinct phases; proestrus (follicular phase), estrus (sexual receptivity), and diestrus (luteal phase).

Follicle Growth and Ovulation

Ovarian follicles destined for ovulation grow from approximately 4 to 5 mm in diameter on day 15 (day 0 = the first day of standing estrus) of the estrous cycle to an ovulatory diameter of 8 to 12 mm (Fig. 99-1). Preovula-

tory follicles have taut, almost transparent walls and contain straw-colored fluid. Estrogen (17β-estradiol), the predominant ovarian hormone produced at this time, contributes to estrous behavior and to morphologic changes in the reproductive tract and triggers the surge of luteinizing hormone (LH) from the anterior pituitary gland.

The LH surge is necessary to induce ovulation or rupture of the follicles with the subsequent release of ova. Onset of estrus usually coincides with the preovulatory LH surge; depending on age, females may be sexually receptive for 1 to 3 days. Ovulation occurs in most gilts during the latter part of the second day after the onset of estrus; however, the time between the onset of estrus and ovulation varies considerably among sows.

Luteal Structures

After ovulation, collapsed follicles are 4 to 5 mm in diameter. Blood rapidly fills the central cavity of the follicles. At this stage, these blood-filled structures are considered corpora hemorrhagica. Luteinization of the follicular remnants results in the formation of multiple corpora lutea. By day 5 to 6, each corpus luteum (CL) has reached its mature diameter of 9 to 11 mm, and the central cavities are completely replaced by luteal tissue (Fig. 99-2). The corpora lutea produce the steroid hormone progesterone. Serum progesterone concentrations, detectable within 1 to 3 days after estrus, increase until a maximum is achieved during mid- to late diestrus.

Degeneration of the corpora lutea commences at approximately day 13 to 15, coinciding with increased concentrations of the luteolysin prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$)[3] and decreasing concentrations of progesterone. It is assumed that $PGF_{2\alpha}$ contributes to regression of the corpora lutea; however, other factors evidently influence the structural regression of the corpora lutea. Obvious indications of CL regression are the change in color from reddish-pink to yellow and a gradual decrease in diameter. A new wave of follicular recruitment commences on days 13 to 15, with follicle enlargement and hyperemia obvious by day 17 (Fig. 99-3). Follicles continue to enlarge concomitant with regression of the corpora lutea.

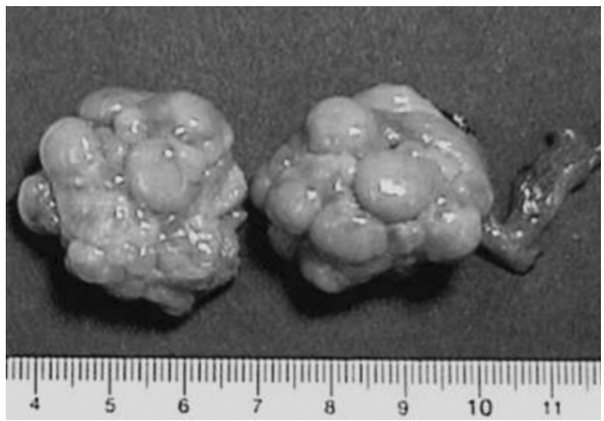

Fig. 99-3 Ovaries collected from a sow that was in late diestrus to early proestrus. The corpora lutea are beginning to regress. By contrast, growth of follicles has commenced, and follicles are approximately 5 mm in diameter.

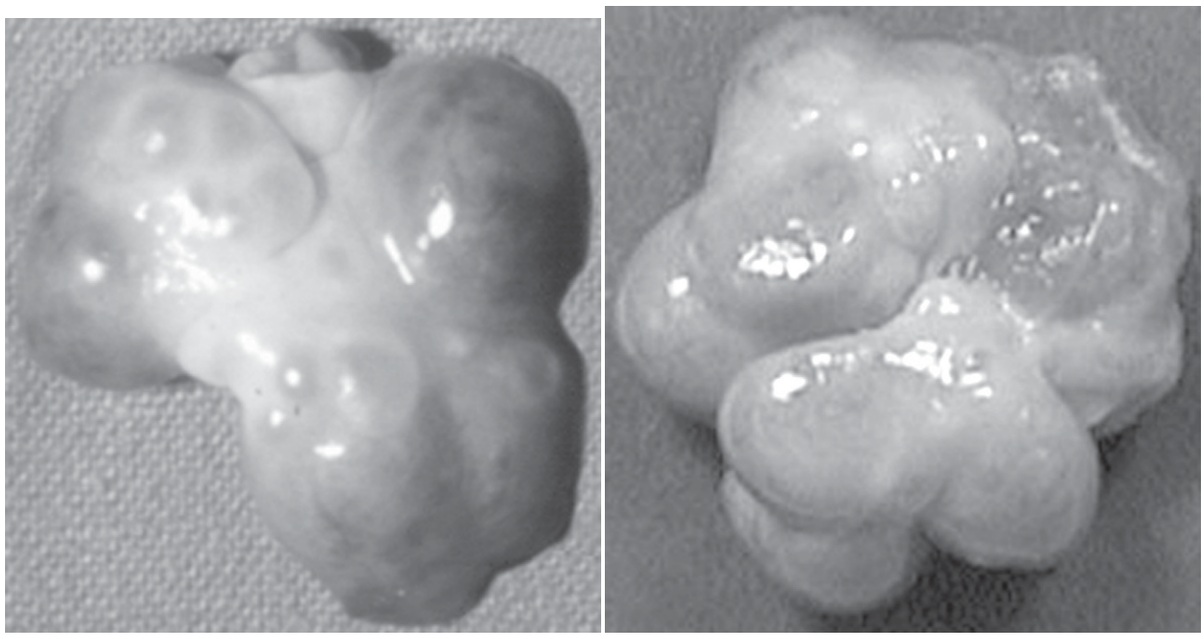

A **B**

Fig. 99-2 **A,** Ovaries collected from a sow at 1 to 2 days after ovulation. The blood-filled structures are corpora hemorrhagica. **B,** Mature corpora lutea are evident on the ovaries of a sow during diestrus.

Fig. 99-4 During pregnancy, the corpora lutea are similar to those in sows during diestrus. The corpora lutea of pregnancy are pale compared with those of diestrus.

With maternal recognition of pregnancy (occurring on days 10 to 14 after ovulation and successful mating),[4] CL lifespan is extended throughout pregnancy. The gross appearance of the corpora lutea of pregnancy (Fig. 99-4) is remarkably similar to that of the corpora lutea during diestrus. Dissection of the uterus will reveal fetuses if the animal's pregnancy had progressed to 20 days of gestation or later. Before 20 days of gestation, it is useful to flush both horns of the uterus to detect the presence of early embryos. Confirmation of pregnancy status is particularly applicable when the quality of matings or estrus detection requires scrutiny or when records of these events are not maintained in an orderly and detailed fashion. It is not uncommon to observe pregnancies in animals that were erroneously recorded as anestrous. These observations illustrate weaknesses either in the record system or in management practices.

After parturition, the corpora lutea regress to form corpora albicantia. These "white bodies" gradually decrease in size during lactation and are less than 2 mm in diameter at the time of weaning. Progesterone production is minimal by the corpora albicantia during lactation. Follicular development is inhibited during lactation, and few follicles are greater than 4 mm in diameter. Limited follicle growth occurs in late lactation (beyond 2 weeks after farrowing)[5]; however, the number of follicles greater than 5 mm in diameter increases within 2 to 3 days after weaning and with removal of the inhibitory effects of lactation. Follicles continue to increase in size as the animal approaches estrus after weaning.

Normal Morphology of the Tubular Organs

The tubular components of the genital organs include the vestibule and vagina, cervix, uterine horns, and oviducts. The gross appearance and histologic morphology of these organs change in a dynamic fashion during the estrous cycle. The primary determinant of these cyclic changes is ovarian production of estrogen and progesterone. Therefore, changes in ovarian structures and function exert corresponding changes in the tubular components of the tract.

Vagina and Vestibule

The vagina of the female pig is approximately 7 to 12 cm (3 to 5 inches) in length and is the part of the reproductive tract extending from the cervix to the urethral orifice. The vestibule is located caudal to the urethral orifice and occasionally is termed the caudal vagina. The vestibule is 7 to 9 cm (3 to 4 inches) in length and has numerous longitudinal folds, two rows of small round openings (minor vestibular glands), and solitary lymph nodules.

The predominant cell types in the epithelium of the vagina are either low cuboidal or stratified squamous cells. Changes in the vaginal epithelium tend to lag from 1 to several days behind ovarian changes, with considerable individual variation. Rapid growth of the vaginal epithelium occurs under the influence of estrogen. In addition, the vulva of the pig swells and has increased turgidity during periods of high serum estrogen concentration. The swelling subsides as estrogen concentrations decrease and the animal enters so-called standing estrus. Decreasing estrogen concentrations result in the degeneration and sloughing of the numerous epithelial cell layers from the vagina and the formation of vacuoles that contain dead cells and a few leukocytes.[6] By contrast, low cuboidal epithelium (4 to 6 layers) is present when progesterone concentrations are elevated—namely, during pregnancy, pseudopregnancy, and the luteal phase of the estrous cycle.

Cervix

The porcine cervix may be up to 20 cm (8 inches) in length and contains obvious transverse ridges. The lumen is lined with tall columnar epithelial cells and numerous goblet cells. The goblet cells have a large secretory surface and secrete mucus during the estrogenic phase of the cycle. Estrogen also stimulates contraction of the sphincter muscle and tightening of the lumen. During the luteal phase of the cycle, progesterone causes relaxation and closure of the cervix.

Uterus

The uterine wall consists of three layers: (1) the endometrium, consisting of the epithelial lining of the lumen, the glandular layer, and the connective tissue layer; (2) the myometrium or muscle layer, which is highly vascular; and (3) the serous membrane. The uterine glands are tubular invaginations of the epithelium and are either straight or convoluted. As a result of estrogen stimulation in the follicular phase, the glands are simple and straight, whereas the epithelium is lower and the endometrium thinner. By contrast, increased vascularization is present in the muscle layer, resulting in greater weight and tone of the uterine horns.

The endometrium increases in thickness under the influence of progesterone during the luteal phase. This increase reflects the branching and convolution of the

glands. Vascularity and uterine weight are reduced considerably during the luteal phase.

Oviducts

The basic functions of the oviducts are to "trap" the ova at ovulation, to transport the ova to the ampulla-isthmus junction (site of fertilization), and to provide a suitable environment for the ova, sperm, and early embryos. The lumen of the oviduct is lined with a folded mucous membrane with a ciliated, simple columnar epithelium. The isthmus has longitudinal folds that extend to the tip of the uterine horn. The folds are arranged as polyploid processes that are sensitive to ovarian steroids, particularly estrogen, which causes swelling of the processes during the preovulatory phase of estrus.[7] The uterotubal junction of estrous pigs is not patent to the passage of fluids from the uterus to the oviduct.

Because of the restricted luminal size of the oviduct, it is difficult and time-consuming to assess patency with routine dissection. To determine oviduct patency, a 20-gauge needle is inserted through the uterotubal junction, and 5 to 10 ml of saline is infused through the needle into the oviduct. The saline should pass through the oviduct and fill the infundibulum around the ovary. If subsequent histologic assessment of the oviducts is required, formalin is used for flushing. Use of this agent assists fixation and prevents sloughing of epithelial cells in the oviduct.

ABNORMALITIES OF THE REPRODUCTIVE TRACT

Ovarian Abnormalities

Cystic Ovaries

Multiple large, multiple small, and single cysts occur in the ovaries of sows[8]; however, the behavior and physiologic events differ between animals affected with each type of cyst. Most of the multiple large cysts (Fig. 99-5) have some luteinized tissue and produce sufficient progesterone to inhibit estrous cyclicity. Sows with such cysts usually fail to exhibit estrus and are culled from the herd. By contrast, multiple small cysts often are follicular cysts. Estrogen is the predominant steroid produced by follicular cysts, and affected animals may have irregular estrous cycles or exhibit "nymphomania." Because these animals fail to ovulate, it is unlikely that they will conceive. Single ovarian cysts rarely affect fertility or the estrous cycle of sows; their presence is noted in occasional sows at slaughter. Cystic corpora lutea evidently regress with the normal corpora lutea and supposedly do not interfere with fertility.

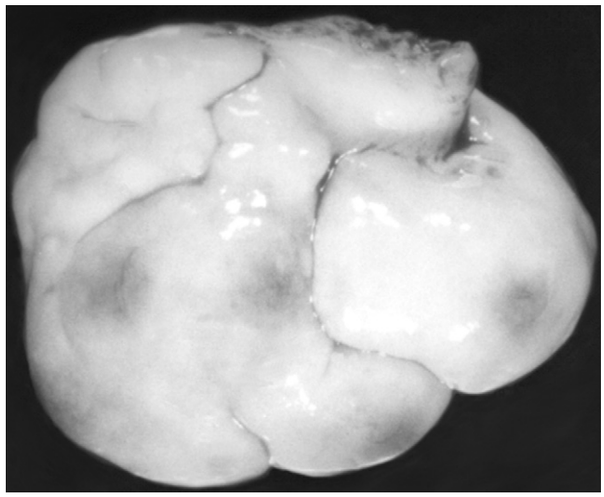

Fig. 99-5 This photograph illustrates multiple large cysts on the ovary of a sow. Note the thickened wall of the cyst. Typically, these cysts have luteinized tissue, which produces progesterone.

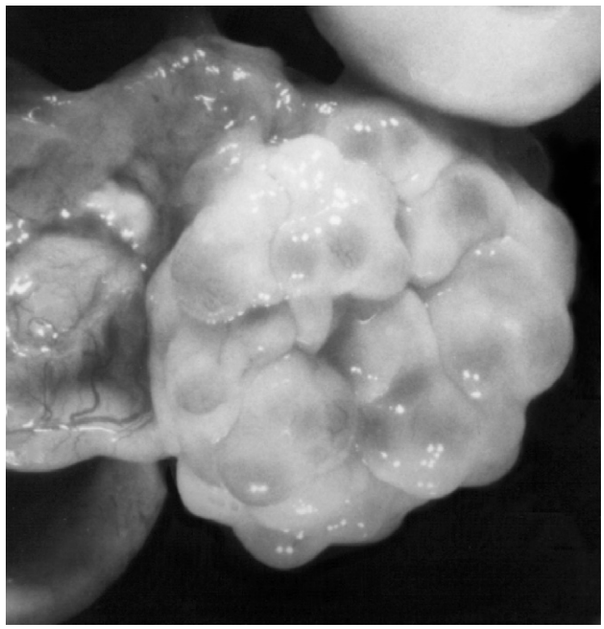

Fig. 99-6 Ovaries collected from an anestrous sow at 20 days after weaning. Note the absence of corpora lutea and presence of well-regressed corpora albicantia. Follicles are less than 5 mm in diameter.

Acyclic Ovaries

Anestrous sows are animals that fail to return to estrus following weaning. Ovaries from these sows have small follicles (less than 5 mm in diameter), well-regressed corpora albicantia, and no corpora lutea (Fig. 99-6). As previously mentioned, ovarian changes are minimal during lactation. Therefore, the gross appearance of ovaries from anestrous sows and that of ovaries from lactating sows essentially are identical despite differences in the endocrine mechanisms that inhibit follicle growth and maturation.

Ovaries from prepubertal gilts weigh approximately 0.3 g at 70 days of age. The weight of both ovaries will increase to 5.5 g at 112 days and stay at this weight until puberty.[9] Few follicles are greater than 3 mm in diameter at 140 days of age. In gilts with delayed puberty, findings typically include numerous small follicles (less than 4

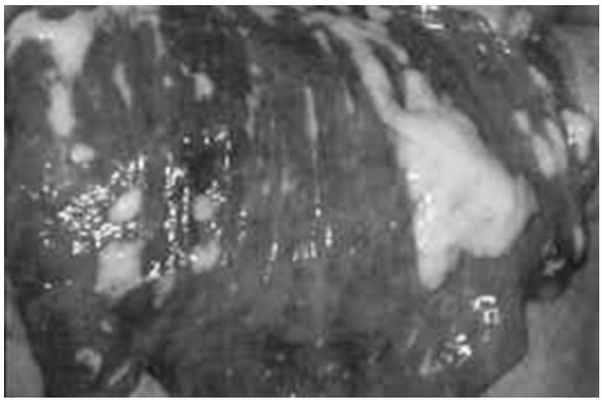

Fig. 99-7 The reproductive tract collected from a "discharging" sow. Note the large accumulations of purulent debris on the endometrium. Typically, purulent material is difficult to observe in sows with endometritis or metritis.

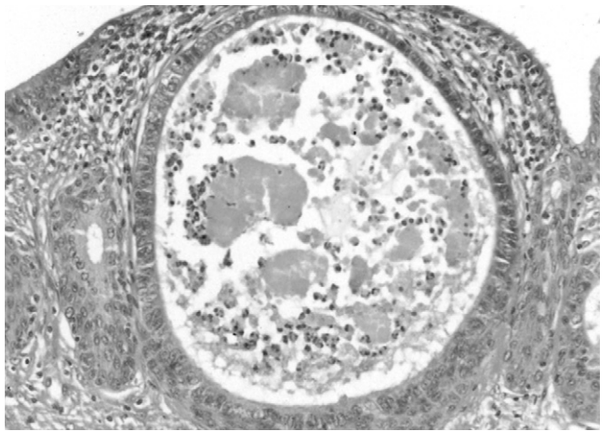

Fig. 99-8 This photomicrograph illustrates a microabscess in the vagina of a sow during estrus.

to 5 mm in diameter) without corpora lutea or corpora albicantia (see Fig. 99-6). Along with the failure of ovarian development, growth of the uterus and oviducts is retarded. The uterus typically weighs approximately 180 g and the oviducts are about 22 cm in length at puberty.[9] Obviously, a gilt with delayed puberty has acyclic ovaries and poorly developed uterus and oviducts.

Abnormalities of the Uterus, Oviducts, and Cervix

Metritis and Endometritis

Vulvar or vaginal purulent discharges commonly are observed in gilts and sows at 10 to 18 days after mating. It is assumed that these discharges originate from the uterus and are indicative of uterine infections.[10] **Metritis** is inflammation of multiple layers of the uterine wall, whereas **endometritis** refers to inflammation of the uterine lining or endometrium. It is unusual to observe metritis on histologic examination of the uterus from affected sows; a majority of animals have endometritis.

The contents of affected uteri vary widely, reflecting the pathogenic organism, chronicity of infection, and the stage of the estrous cycle.[10] Uteri may be distended with debris and exhibit thickening of the wall (Fig. 99-7), and uterine contents vary, ranging from vast quantities to focal accumulations of purulent exudate. By contrast, the uteri of many affected sows are devoid of debris after a standing estrus. Finally, in many instances, normal vulvar discharge associated with estrus is erroneously classified as indicative of metritis or endometritis. Gross and histologic examination of the reproductive organs will clearly illustrate the source of the discharge.

Salpingitis

The incidence of salpingitis, with or without endometritis, is essentially unknown in female pigs. Early reports indicated that salpingitis was associated with porcine reproductive inefficiency[11]; however, recent investigations did not examine the oviducts of sows affected with endometritis.[12] Histologic examination of serial sections of the oviduct would be useful to evaluate salpingitis. Oviduct patency is easily determined, as described previously. Adhesions of the infundibulum to the ovary occasionally are noted in sows without endometritis. Possibly, hemorrhage associated with ovulation or the rupture of ovarian cysts contributes to the infundibular adhesions.

Cervicitis

The significance and pathogenesis of cervicitis in female pigs have received little attention. One report indicated that a modest vulvar discharge (less than 20 ml in amount) occurs in animals with cervicitis and typically is concomitant with endometritis or vaginitis.[2] Gross examination of the cervix, with subsequent histologic assessment, should confirm the purulent nature of the exudate and presence of cervicitis.

Trauma to the cervix may result in the formation of fibrotic adhesions, which may occlude the lumen. Historically, sexually aggressive boars were considered the most likely cause of trauma to the cervix. The use of artificial insemination has gained popularity in the United States, however, and it is not uncommon to note hemorrhage and subsequent formation of cervical lesions after insemination by an inexperienced or impatient technician.

Vaginitis and Vestibulitis

Vaginal infections previously were reported to occur with or without chronic infections of the uterus or urinary tract.[2] Regardless of whether such infection is present, hyperemia and congestion, hemorrhage, and purulent exudate are typical of vaginitis. Microabscessation (Fig. 99-8) and erosions or ulcerations of the mucosa may be noted on histologic examination.[2] Similar lesions are evident in the vestibule.

Zearalenone Toxicity

Zearalenone, a toxin produced by *Fusarium roseum,* acts like estrogen in the sow. Consequently, affected sows

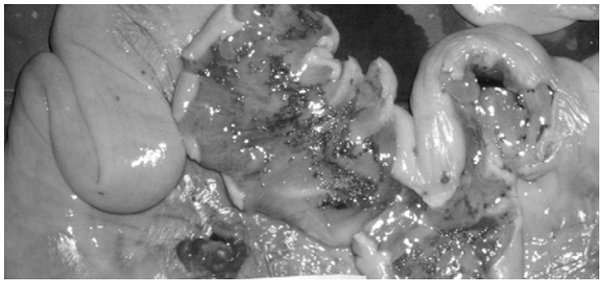

Fig. 99-9 With chronic exposure to estrogen or zearalenone, the endometrium becomes edematous and the uterine glands secrete uteroferrin. In this figure, the uteroferrin is evident as brown flecks and should not be mistaken for purulent debris.

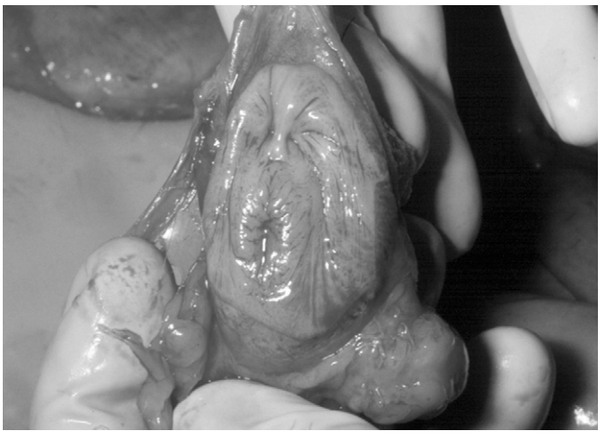

Fig. 99-10 Hymenal bands (dorsoventral septa) in the vagina are common in virgin gilts. In this example, the band is cranial to the urethral orifice and obstructs the cervical os. The width of the bands is quite variable.

have excessive uterine edema and numerous brown flecks (1 to 2 mm) of glandular secretions (uteroferrin) occasionally are noted on the endometrium (Fig. 99-9). These animals often exhibit estruslike signs, such as a red, swollen vulva; however, the ovaries do not contain mature, preovulatory follicles. Paradoxically, the ovaries often have corpora lutea because estrogen is luteotrophic in female pigs, and it is impossible for the animal to conceive.

Miscellaneous Abnormalities

Various other developmental abnormalities may be noted in the genital tract of gilts. Blind uterine horns, unilateral missing uterine horns, and blind, double, or missing cervix are relatively rare abnormalities (seen in less than 1% of gilts at slaughter).[13] Persistent vaginal hymen or presence of hymenal bands (dorsoventral septa) (Fig. 99-10) previously was observed in 4% of gilts; however, the clinical significance of these bands for gilt fertility remains unknown.

EMBRYONIC AND FETAL AGE

Recording of an erroneous breeding date and failure to record the breeding date are common on sow farms. Consequently, veterinarians must rely on other techniques to estimate the age of embryos or fetuses during examinations of the female reproductive organs.

The uterus is flushed with 100 to 200 ml of saline to collect blastocyst or morula stage embryos. Examination of flushings with a dissecting microscope facilitates detection of embryos less than 8 to 9 days of age. Older embryos typically are visible without the assistance of a microscope. Elongation of the threadlike blastocysts is evident by day 13 of pregnancy, and attachment of the trophoblast to the endometrium commences by day 13 and is well advanced by day 18.[14] Although embryo attachment is initiated at this early stage of pregnancy, routine flushing of the uterus should dislodge the embryos without excessive difficulty. The embryonic sacs range from 18 to 35 cm in length (in situ) during the period from days 13 to 18; however, it often is difficult to observe the embryos in situ.

Crown-rump length of fetuses provides a reasonable estimate of fetal age after day 20 of gestation. At days 25, 35, 45, 55, 65, 75, 85, and 95 of gestation, values for fetal crown-rump length are approximately 20, 35, 65, 110, 152, 166, 206, and 240 mm, respectively.[15] Number of fetuses, infectious microbes, parity, genetics, and other factors may influence relative size of some or all of the fetuses. This approximate determination of fetal age is useful to assess accuracy of breeding records, to estimate age of mummified or autolyzed fetuses, and to determine the time of fetal death in relation to stage of gestation.

The number of corpora lutea reflects the number of ovulated follicles, thereby providing an indication of the number of ova released at ovulation (i.e., ovulation rate). Quantitation of embryos at days 14 to 18 of pregnancy is useful to estimate early embryonic loss, whereas the number of fetuses in late gestation reveals both embryonic loss and early fetal loss before fetal calcification. It is not uncommon to note a 30% to 40% rate of early embryonic loss in most domestic sows.

CYSTITIS

Cystitis often is associated with reproductive tract infections, particularly in sows affected with purulent vulvar discharges. Collection and examination of urinary bladders are easily performed during evaluation of the genital organs. As previously mentioned, urine samples and mucosal swabs should be collected with aseptic techniques before dissection and examination of the mucosal surface of the bladder.

Mucosal hyperemia and congestion, mucosal ulceration, and accumulation of fibrinopurulent exudate over affected areas are indicative of cystitis.[2,16] The method of stunning in the slaughterhouse must be considered in interpreting the hyperemia and congestion in the

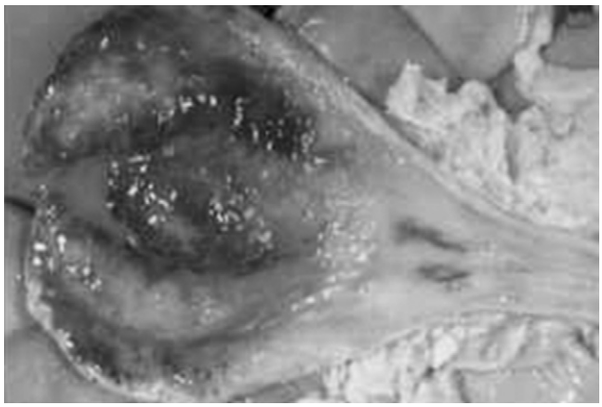

Fig. 99-11 This figure illustrates a urinary bladder with severe cystitis. The hemorrhagic areas and purulent urine are clearly evident. Hemorrhage and necrosis of the ureteric valves often are noted in severe cases of cystitis.

bladder. Prolonged electrocution may contribute to vascular changes in the bladder at the time of death. Thickening of the bladder wall and polyploid projections of the mucosa are apparent in chronic cystitis. The relationship between cystitis and pyelonephritis and respective lesions were reviewed elsewhere.[2]

Ureteric valves and intravesicular ureters deserve special attention because abnormalities of these structures are common in animals affected with pyelonephritis[17] (Fig. 99-11). Enlargement of the ureter and necrosis of the ureteric orifice were observed in animals with acute pyelonephritis, whereas the orifice was shrunken and swollen in animals affected with chronic pyelonephritis. Bacteria-produced factors evidently contribute to shortening of the intravesicular portion of the ureter in cases of acute and chronic pyelonephritis.[17]

SUMMARY

In contrast with the cow or mare, it is difficult or impossible for the veterinarian to examine the genital organs of a live sow or gilt. Therefore, detailed examination of the genital organs of female pigs at slaughter or necropsy is required to provide sufficient information to confirm or refute causes of reproductive failure. Consideration must be given to individual sow characteristics and herd history to improve the practitioner's interpretation of the lesions or abnormalities. The appropriate therapy or management changes can be suggested with a greater degree of confidence after evaluation of the reproductive organs of affected animals.

CHAPTER 100

Induction of Estrus and Control of the Estrous Cycle in Swine

ROBERT V. KNOX and WARREN D. WILSON

Despite many years of research investigating pharmacologic methods to control reproduction, swine producers and veterinarians are left with few options compared with those available for use in cattle. Nevertheless, the pharmacologic and managerial methods that have been developed have allowed for improved reproductive performance. Even so, estrous cycle control may not be practical or desired in all groups of swine, and pharmacologic methods must not be used to replace basic swine husbandry practices. Yet clear advantages are realized for swine producers who are able to control the timing of estrus and ovulation in large numbers of sows and gilts. Reproductive efficiency and improved economic return can be attained through maximizing the number of piglets weaned per sow per lifetime, reducing the number of nonproductive sow days, optimizing facility utilization for gilts, and reducing labor inputs. Although hormonal availability for control of pig reproduction varies throughout the world, most pharmacologic methods are similar and involve initiation of final follicular maturation, alteration of luteal lifespan, or synchronization of ovulation time. This chapter reviews the current knowledge of pharmacologic and management methodology for optimizing control of reproduction in the pig.

THE PREPUBERTAL GILT

Understanding the endocrine profile of the prepubertal gilt holds significance for influencing the timing of puberty and for developing technologies for inducing early reproductive function. Reproductive hormones originating from the hypothalamus, pituitary, and ovary regulate reproduction. Although hormones are synthesized and released by positive and negative feedback relationships in the mature female, in the prepubertal gilt the endocrine organs and their responsiveness to feedback are limited. Maturation is gradual and dependent on internal and external influences, some of which have yet to be identified. Endocrine control of ovarian activity occurs primarily through the pituitary hormones follicle-stimulating hormone (FSH) and luteinizing hormone (LH). These hormones control the processes of folliculogenesis and ovulation through their binding to receptors on the granulosa and theca cells of the ovarian follicle. Hormone binding stimulates a variety of activities including cell division, steroid synthesis, and follicle growth. Both hormones are controlled by hypothalamic gonadotropin-releasing hormone (GnRH) and by positive and negative feedback from ovarian steroids and the inhibin family molecules.

Immediately after birth, FSH, LH, and prolactin levels are elevated in circulation, but they gradually decline with age. This elevation is thought to occur because production mechanisms are functional, but feedback regulation has not yet developed. By contrast, circulating estrogen is low at birth but gradually increases with age in association with the increase in size and number of antral ovarian follicles.[1] The hormone profile before pubertal estrus and during the subsequent cycle is not different from that in later cycles; accordingly, endocrine indicators of why gilts become reproductively active have been elusive. Immediately before pubertal estrus, however, plasma cortisol and prolactin are elevated, but these increases do not appear related to age at puberty. In gilts expressing first estrus between 183 and 225 days, progesterone has not been observed to be consistently elevated within the 6 days before pubertal estrus. No increase in estradiol occurs in the weeks preceding pubertal estrus except for the expected increase in estrogen that occurs before estrus. Of interest, some gilts have significant estrogen increases that last for days after exposure to a boar, but most fail to show estrus and have no detectable LH surge. The external symptoms of estrus such as vulvar swelling and mucous secretion are inducible at 150 days of age with exogenous estradiol. Sensitivity to estrogen may be underdeveloped in immature gilts, however, because low doses that produce physiologic symptoms of estrus in adult females are only partially effective in prepubertal gilts, despite the fact that all gilts exhibit an LH surge. LH level remains basal until the ovulatory LH surge at estrus. Therefore, attempts to advance age at puberty in the gilt by exogenous administration or selection of the aforementioned hormones probably are of little benefit.

Factors Influencing Attainment of Puberty in the Gilt

Gilts that express early puberty and are mated earlier produce more pigs per lifetime than those mated at later ages. Unfortunately, age at puberty can vary by 60 to 80

days for gilts that express estrus before 300 days of age. The factors influencing age at attainment include genetic composition.[2] Differences within purebreds for age at puberty, however, can be as great as differences between breeds, owing to the different selection pressures from different genetic suppliers over time. It therefore becomes difficult to select purebred lines that have uniformly reduced age at puberty. Yet one of the most striking effects of breed on age at puberty is observed for the Meishan gilt, which reaches puberty at approximately 100 days of age, compared with 210 days for occidental breeds. Furthermore, offspring from matings of Meishan sires with crossbred occidental maternal line gilts show reduction in age at puberty and improved percentage of gilts expressing estrus, compared with females sired by occidental-breed boars.[3] Despite these important observations, a majority of commercial maternal line genetics used today are the result of occidental multiple-breed crosses, and age at puberty in these lines indicates no advantage for reduced age at puberty.[4] This finding is perhaps not surprising because most selection schemes for maternal lines do not include age at puberty.

Direct selection for reduced age at puberty has produced an estimated heritability between 0.11 for a single generation and 0.25 over multiple generations. Age at pubertal estrus can be reduced by –1.5 to –3 days in each generation with selection.[5] Selection for age at puberty is desirable and is not associated with any reduction in litter traits. Research also has shown expression of early puberty is not dependent on boar exposure because early puberty lines lacking boar exposure still express earlier puberty compared with nonselected lines.[6]

The available information is conflicting regarding the importance of gilt body composition and its relationship to puberty. Liveweight explains 77%, tenth-rib fat 40%, and average daily gain less than 10% of the variation in age at puberty.[7] It has been reported that gilts with more backfat thickness at 90 kg have more intense vulvar reddening and swelling at estrus, and gilts with strong vulvar symptoms are younger and lighter at estrus.[8] Similarly, in selection experiments, gilts selected for early puberty also tend to cycle earlier and have more backfat than those gilts selected for later puberty. Therefore, selection for age at puberty and related traits of economic importance must become a greater priority in reproductive selection processes.

It is difficult to separate out the effects of nutrition from growth rate and body composition. Nutritional influences, however, can greatly influence the genetic potential to express growth and body composition traits. Of the numerous reviews on the effects of diet for the developing gilt, most agree that severe energy or nutrient restriction can delay or even prevent puberty, whereas minor restrictions may have little detrimental effect on measured reproductive traits. Furthermore, excess energy intake also has not improved reproductive performance. Increased protein, and specifically, certain amino acids, has resulted in some cases of improved reproduction, however. This infrequent outcome may result from the complex issues of amino acid ratios, protein-to-energy ratios, and variation in reproductive responses measured. Nevertheless, at present most experts agree that when energy is not limiting and protein is available for maximal lean tissue accretion, diet should not be limiting to reproductive performance.

Physical and physiologic maturity are reported to be more important for attainment of puberty than age, weight, and even boar exposure.[9] Of all identifiable factors, physiologic age appears to hold the greatest relationship to the age at attainment of puberty. Physiologic age, more than chronologic age, is important because even though gilts can ovulate in response to exogenous gonadotropins and respond to exogenous estradiol with an LH surge after 100 days of age, strong evidence indicates that neither of these mechanisms is completely mature until after 160 days. This finding indicates that induction procedures should not be initiated too early.

The effect of season of birth on puberty is difficult to separate from the effects of temperature, light, and changing photoperiod during development. Some researchers, however, have shown that developing gilts during a shortening photoperiod (fall-winter) and maturing them under increasing light (spring-winter) induces a greater proportion of the animals into puberty than is observed with development of gilts during increasing photoperiod (spring-summer) and maturation under shortening photoperiod (fall-winter). Unfortunately, little evidence is available to suggest an overall advantage in earlier puberty by lighting regimen or type of light. Excessive darkness does delay estrus, however, and continuous light does not advance age at estrus when compared with shorter 8- to 16-hour intervals of light each day.

Although the issue is controversial, confinement has been shown in some cases to increase the proportion of anestrous gilts and to delay age at puberty by 3 weeks.[10] The general consensus is that that gilts raised in restricted space may be less likely to express estrus at an earlier age. Mature gilts raised in only 1 square meter of space expressed estrus at a lower rate than that observed for animals allowed 3 square meters of space (79% versus 100%).[11] The importance of small group size is unclear, but housing developing gilts in groups of less than 3 should be avoided, and little evidence is available to suggest an effect of housing 3 to 30 pigs per pen on age at puberty.

Boar exposure is an effective method for reducing age at puberty, inducing estrus, and improving estrus synchrony. The effect of boar exposure is presumed to be physiologic because it has been shown to transiently increase both LH and estradiol concentrations.[12] Exposing gilts to boars between days 150 and 170 appears to be most effective for advancing age at puberty and results in the highest degree of estrus synchrony. Earlier boar exposure beginning at 70 days of age, when compared with no boar contact or boar exposure at 160 days of age, had no effect on advancing age at puberty, however. Exposure duration of 5 to 30 minutes each day appears equally effective for advancing age at puberty.[13] Yet the proportion of females reaching puberty within 60 days from initiation of boar exposure at 160 days of age does improve as frequency increases between one and three times per day.[14] Continuous boar contact appears to have little detrimental effect on age at puberty, except that it can make detection of estrus in gilts more difficult.

Greater response to boar exposure can be obtained when combined with transportation stress at 160 days. This regimen shows major response effects for boar contact alone but not for transport alone. Typically, the boar effect is not observed in the first week but is evident by 30 days. Transportation for 1 km or more in conjunction with boar exposure has the greatest impact on the proportion of females induced into puberty.[15] To obtain optimal responses for estrus induction, physical contact with the boar is now recommended as superior to fenceline contact.[16] Age of the boar also is important, because exposure to boars 11 months of age and older is more effective than exposure to those 6.5 months of age or younger. It also is unclear whether exposure to a second boar or exposure of gilts to estrous sows will be effective for influencing the proportion of gilts expressing estrus, even though age at puberty may be reduced.[17]

It is not known whether ovarian status affects age at puberty. Ovary classification before puberty at 150 days of age and at 5-day intervals thereafter shows ovaries with only small and those containing larger follicles.[18] Of interest, the ovaries switched from one type to another over time, and no changes in circulating hormones were associated with any of these ovarian class changes. This evidence may suggest that follicle growth occurs in waves and that larger follicles in the prepubertal gilt undergo regression and do not undergo ovulation before puberty. The gilts with large follicles greater than 6 mm in diameter had a greater number of ovulations when compared with those with smaller follicles in response to human chorionic gonadotropin (hCG) given at 170 days of age.[19] Ovaries containing larger follicles versus those with only small follicles, however, do not always show an overall advantage in response to gonadotropins on estrus induction response, even though an early puberty line with only large follicles at time of injection did respond at a higher level than the nonselected line containing large follicles.[20] One explanation for this finding may be the observation that at 166 days in Large White gilts, only half of them have follicles (greater than 3.5 mm) that are responsive to hCG.[21] Thus, differences in physiologic maturity appear to be regulated at the origin of the ovary and may explain why only some animals respond to exogenous hormones.

Exogenous Hormone Control

In the pig, equine chorionic gonadotropin (eCG), also called pregnant mare's serum gonadotropin (PMSG), is the most commonly used and most effective product for induction of follicular growth, estrus, and ovulation in swine. In many European countries, eCG is commercially available for inducing estrus in sows and gilts. The hormone is administered in doses ranging from 250 to 2000 IU but often shows mixed results for estrus and ovulation, which may depend on the preparation purity, dosage used, and even physiologic status of the animal. Use of even moderate to high doses of eCG (greater than 750 IU) has not consistently resulted in improvements. Another gonadotropin, hCG, also will induce ovulation, but it is relatively ineffective in initiating estrus. When administered alone (in a dose of 200–750 IU), however, hCG has been reported to induce estrus and ovulation in prepubertal gilts, but as with eCG, this response also appears highly variable.

A combination of eCG and hCG has proved to be even more effective than either hormone given alone. In studies that have compared the use eCG and hCG alone with the administration of the hormones simultaneously or the use of 500 IU of hCG at 48 to 96 hours after an injection of eCG, estrus expression, ovulation, and ovulation rate all are improved. The most efficient and effective dose appears to be 400 IU of eCG and 200 IU of hCG, although variation of the amount of eCG (300–1000 IU) and hCG (200–750 IU) in a single injection or given separately 48 to 72 hours apart has been reported to be effective. Despite this, little or no advantage is gained with use of higher doses of either hormone. In most instances, the low doses of eCG (less than 750 IU) induce low to normal ovulation rates (6 to 16 ova), and superovulation (greater than 20 ova) usually is induced only after a dose of 1000 IU or more. The use of these agents combined in a single injection (400 IU eCG and 200 IU hCG) was made possible by the development of PG600.* This combination hormone is approved worldwide for induction of puberty in gilts that have attained a weight of 185 pounds and an age of $5^1/_2$ months. In most published reports, PG600 has been effective for inducing greater than 55% of gilts into estrus within 7 days of injection. The percentage of gilts ovulating is greater than 90%, and average ovulation rate, although variable, typically falls between 12 and 15 ovulations. When inducing puberty in gilts after 180 days of age and mating at the induced estrus or even at a fixed time after administration of PG600, 65% to 70% farrow, with no changes in litter size observed. When one cycle is skipped before breeding after PG600 estrus induction, however, both litter size and farrowing rate improve.[22]

Hormone products other than eCG (with or without hCG) are not as efficacious in inducing estrus and ovulation. Single injections of 250 μg of GnRH consistently fail to induce ovulation or estrus in gilts because the short release of FSH and LH apparently will not induce estrus or ovulation. Injections of GnRH in addition to eCG have not improved the response. Hourly administration of GnRH for several days is required to induce estrus and ovulation with this hormone alone. Combinations of porcine FSH and LH also have been reported to be effective for inducing estrus and ovulation, but their short half–lives (approximately 0.5 to 1 hour) relative to that of eCG (36 hours) dictates that they be administered in large doses and at multiple intervals. Induction of estrus in prepubertal gilts by estrogen administration (5–200 μg/kg) in single or even multiple injections over 2 to 3 days has resulted in both good and poor induction rates. In some instances, however, estrus without ovulation and low numbers of ovulations are observed. Exogenous estrogens such as estradiol benzoate (17β-estradiol-3-benzoate), and estradiol cypionate (estradiol-17β–cyclopentylpropionate) will consistently induce estrus and a preovulatory-like discharge of LH but will

*Intervet, Millsboro, Del.

induce ovulations in only a few instances. When females are treated with hCG plus estradiol, both estrus and ovulation occur, but litter size is reported to be reduced. As indicated by the relative ineffectiveness of these alternative hormones in comparison with eCG and hCG, and the difficulty in administration, these methods become less than practical in commercial situations.

CYCLIC GILTS AND SOWS

The control of reproduction in the mature cycling gilt and sow is limited to the techniques of superovulation through administration of hormones such as eCG, shortening or lengthening the estrous cycle with prostaglandin, use of supplemental progestogens or estrogens, and controlling the time of ovulation through the use of hCG, LH, or GnRH near the time of estrus. Cyclic gilts administered porcine FSH or PMSG at luteolysis express estrus sooner, but many fail to express estrus at all, owing to asynchronous follicle development and formation of cysts. In those that do express estrus, ovulation rate typically is much greater, however. Breeding after superovulation increases the number of embryos but generally does not improve litter size, owing to limitations in uterine capacity. Controlling the time of ovulation with hCG or GnRH administered at estrus, to improve time of mating, has not yet yielded any significant improvements in farrowing rates or litter sizes. For single inseminations, it is not known whether synchronizing ovulation with hCG or GnRH will be practical and improve conception, farrowing rate, and litter size. Results with studies involving GnRH or hCG at the time of breeding are promising, however.

In cyclic females, the timing of estrus and ovulation is dependent on reproductive hormones, and effective manipulation could aid in the precision of reproductive management. The estrous cycle of the mature female occurs at regular 21-day intervals but can vary between 18 and 22 days. Occasionally, the cycle can extend as long as 24 to 26 days, as a result of an extended luteal phase. The mature sow or gilt normally expresses estrus for a 2-day period and ovulates between 35 and 45 hours after onset of estrus.[23] The estrous cycle can be divided into the luteal and follicular phases. The luteal phase of the estrous cycle begins from day 2 after onset of estrus when progesterone increases and lasts until about day 15, when progesterone declines. The follicular phase begins 5 to 6 days before estrus and is characterized by low progesterone and increasing estrogen.

LH initiates the process of final follicle maturation and ovulation, but concentrations during the cycle typically are low except for the ovulatory LH surge that occurs 40 hours preceding ovulation. LH is released in a pulsatile manner from the pituitary and has a 30- to 60-minute half-life in circulation. FSH is elevated during much of the cycle but declines at the time of luteolysis. This hormone has a half-life estimated to be about 2 hours and binds to follicles with multiple layers of granulosa cells. FSH is responsible for recruiting follicles to grow, from which only some will be selected for eventual ovulation.

Controlling reproduction may involve synchronization of estrus. Prostaglandin administration can be useful for shortening the length of the luteal phase and can reduce the interval to estrus by 3 to 4 days if given on days 12 to 13 of the estrous cycle. This is because prostaglandin receptors are low before day 12 and increase to maximal levels on days 13 to 16.[24] Prostaglandin typically is low in circulation throughout the estrous cycle except at the time of luteolysis in nonpregnant pigs. It is well established that in females lacking embryos and their estrogenic signal, prostaglandin of uterine origin is released from the uterus to destroy the functional lifespan of the corpus luteum.

By contrast, administration of hCG has been used to prolong the luteal phase. A dose of 1000 IU of hCG (Chorulon*) given on day 12 of the estrous cycle induced 63% to show an average cycle length of 33 days. Furthermore, the number of corpora lutea tended to be higher in treated gilts (mean, 15.2) than in controls (mean, 13.6). Similarly, estrogen can be used to lengthen the luteal phase. Normally, estrogen induces an LH surge and most of the physiologic and behavioral signs of estrus, including the standing response. Growing ovarian follicles are the source of circulating estrogen, which is low during the greater part of the estrous cycle but increases after luteolysis on day 14 and peaks 5 days later. During pregnancy, however, conceptus estrogen extends the life of the corpus luteum. A prolonged luteal phase also can be established by serial administration of estradiol between days 11 and 14 of the estrous cycle. Furthermore, estrogen given on days 12 to 13 can induce short pseudopregnancy (23–35 days), whereas administration between days 12 and 19 can induce long pseudopregnancy (greater than 50 days).[25] These extended corpora lutea are susceptible to exogenous prostaglandins. A preliminary study demonstrated that randomly cycling gilts can be rendered pseudopregnant by administration of estradiol implants left in place for 21 days. When injected with $PGF_{2\alpha}$ on the day of implant removal, five of six gilts were in estrus 5 to 7 days later.[26] This procedure is labor intensive, however, and estradiol is not yet approved for pigs.

Progesterone also can be used to synchronize estrus. Progesterone regulates the pattern of LH release and inhibits expression of estrus, even in the presence of estrogen. In the cyclic female, progesterone increases from baseline on day 2 of the cycle and begins a rapid increase to reach maximal concentrations between days 10 and 14 before declining. The first attempts at pharmacologic manipulation of the estrous cycle in cycling swine involved prolonged administration of progestogen to inhibit the final stages of follicular development. On withdrawal of progestogen, follicles matured rapidly and underwent ovulation within a predictable time interval. When 100 mg of progesterone in oil was injected daily into cycling gilts on days 15 to 28 of an estrous cycle, estrus was suppressed for the duration of the treatment period, and estrus followed the last progesterone injection within 6 to 7 days.

*Intervet, Millsboro, Del.

In order to overcome the requirement for daily injections, several orally active progestational compounds have been studied for their utility in estrus control. One of the most successful compounds investigated for use in synchronizing estrus in cycling gilts was methallibure, which is a nonsteroidal compound that blocks gonadotropin release from the pituitary. When methallibure was fed for 19 days, fertile estrus was synchronously induced in a high proportion of animals within 5 to 8 days after the last feeding. Use of methallibure was halted and regulatory approvals were withdrawn in many countries, however, after reports of teratogenic effects. Alternatively, feeding 50 mg per day of 6-methyl-17α-hydroxyprogesterone acetate to gilts for 14 to 21 days resulted in induction of estrus in 50% of treated animals at 4 to 7 days after withdrawal, with 80% of treated animals ovulating. Estrus and follicular development were suppressed during treatment, and gilts were in fertile estrus an average of 4.4 days after drug removal.

Encouraging results eventually led to the development of the most successfully used orally active progestogen, allyltrenbolone (Regu-Mate*). When Regu-Mate was mixed with the daily ration or top-dressed onto the feed for 18 or 19 days at the rate of 10 to 15 mg/gilt/day, the average interval to estrus was 4.8 days, with normal ovulation and fertility at the time of synchronized estrus.[27] Although the 18-day treatment with Regu-Mate (15 mg/gilt/day) improved estrus synchronization when compared with 14-day treatment, no advantage of the 18-day treatment was found for subsequent farrowing responses.[28] The incidence of cystic follicles was low when compared with that observed with use of another orally active progestogen (6-chloro-Δ^6-17-acetoxyprogesterone) fed for 18 days. Regu-Mate also has been used to synchronize estrus for timed insemination without estrus detection. When gilts were artificially inseminated on days 5, 6, and 7 after Regu-Mate withdrawal, fertility and fecundity were equal to those in gilts that were tested for estrus and mated naturally 12 and 24 hours after the onset of estrus.[29] In practice, Regu-Mate, fed at the rate of 15 mg/gilt for 14 to 18 days, is an effective drug for synchronizing estrus in cycling swine. Treatment can be started on any day of the cycle. Underdosing Regu-Mate (less than 13 mg/day) may lead to increased incidence of cystic follicles, which could explain why some producers have reported variable responses in the field.[30] In the United States, Regu-Mate is approved for use only in horses, although it is used widely in swine throughout Europe.

A potentially useful approach to providing progestogen exposure for swine could be through a sustained-release implant. When randomly cycling gilts were administered an implant containing 6 mg of norgestomet, which was left in place for 18 days, five of six gilts were in estrus within 3 to 7 days after removal. Similarly, intravaginal placement of a progesterone-coated controlled internal drug release device for 14 days caused 17 of 24 (70.8%) gilts to come into estrus between 3 and 5 after removal.[31] At present, progesterone-releasing devices are not approved for use in swine in the United States.

*Intervet, Millsboro, Del.

WEANED SOWS

Most sows return to estrus after average lactational periods of 16 to 22 days within 3 to 8 days. In these sows, estrus usually lasts 56 hours.[32] Although the time of ovulation is influenced by wean-to-estrus interval, ovulation typically occurs 41 hours after onset of estrus. Return to estrus after weaning in this time interval is important for optimizing breeding conditions and maintaining the integrity of farrowing groups. Unfortunately, not all sows return to estrus in this window or at all, and delayed returns are well recognized in primiparous sows in certain seasons of the year. Longer wean-to-estrus intervals have been reported in the seasons of spring, summer, and fall, with the latter two seasons mentioned more frequently in reports of seasonal infertility. Attempts at alleviating seasonal effects by altering photoperiod or lighting have had little impact, and standard lighting regimens appear to be adequate.[33] The effect of housing system also has been implicated as a causative factor in delayed return to estrus that even exposure to boars cannot overcome.

Group weaning is the most successful method for estrus synchronization in adult sows for facilitating production scheduling. The occurrence of post-weaning estrus, however, is influenced by many factors, including lactation length, parity, and season. Shortening lactation length is used to increase the both the number of litters per year and to reduce vertical disease transmission. When the litter is weaned after a 21-day lactation, follicular development typically resumes and estrus occurs within 4 to 7 days. When parity 1 sows have lactation lengths less than 14 days, however, they take an average of 10 days or more to resume cycling.[34] In fact, for all sows lactating for less than 12 days, the interval to return is 1.8 days longer than for sows lactating for more than 18 days.[35] Furthermore, early-weaning sows have reduced first-service conception rates (68% versus 87%) and fewer live embryos (10.4 versus 13) when compared with conventionally weaned sows.

The length of lactation appears to be important in the damped LH response to exogenous GnRH or estradiol during the first few weeks of lactation. In fact, the magnitude of the response improves dramatically as lactation progresses up to 3 weeks. This lactation response, however, is independent of physical nursing, litter size nursed, and the presence of circulating prolactin. In most sows after weaning, LH and FSH increase in concentration, but this increase is not entirely related to aspects of post-weaning estrus. Most sows that exhibit an early or normal return have increased LH pulse concentration, however. In lactating sows that express estrus in response to litter removal and exposure to boars, levels of FSH decrease and LH, estradiol, progesterone, and cortisol levels increase. Those sows that do not respond with estrus to these stimuli differ the most in FSH and estradiol concentrations. In conventionally weaned sows that express estrus, the peak of estradiol is observed 3 hours

before onset of estrus and 11 hours before the LH peak, at 40 and 30 hours before ovulation, respectively.[36] Prolactin characteristically is elevated in the lactating sow. Immediately after weaning, however, prolactin levels decline. Although thought to inhibit follicular activity during lactation, this hormone does not appear to be related to altered gonadotropin levels. Progesterone concentrations are low in sows before weaning, and baseline levels are maintained until they begin to increase about 30 hours after the LH surge. This again indicates that ovulation does not typically occur in sows during lactation, regardless of wean-to-estrus interval.

Reducing suckling intensity has been used to minimize the time interval from weaning to estrus after longer lactation periods. Wean-to-estrus interval is reduced by split-weaning the larger piglets from the nursing litter, 2 to 5 days before weaning. Reducing the wean-to-estrus interval also can be accomplished through partial weaning of the entire litter for 6 to 12 hours each day beginning at the second to third week of lactation. This technique has been effective in some but not all instances. The benefit of boar exposure during lactation is unclear, but boar contact after weaning increases LH and estrogen levels and generally hastens both return to estrus and the occurrence of ovulation. Continuous boar contact after weaning, however, may cause problems with heat detection, leading to a lower percentage of multiple matings.[37]

The ovarian status of the sow at weaning may be the key for understanding the reproductive performance of the sow after weaning. Ovulation does not usually occur with lactations lasting up to 28 days. At weaning and during lactation, ovaries contain small to medium-sized follicle populations. After weaning, follicles begin to grow and increase in size. Follicular growth in lactating and post-weaning sows is dependent on increasing LH and FSH. These hormones can be increased by substantial reduction in the intensity of suckling during lactation or by administration of exogenous gonadotropins. GnRH given in hourly doses has been shown to stimulate estrogen production and follicular development, resulting in estrus and ovulation in lactating sows after 2 to 3 weeks of lactation.

The wean-to-estrus interval is linked to sow body condition at weaning, feed intake in gestation and lactation, diet density, and environmental temperature. Despite all of these influences, it is clear that sows that lose less weight during lactation are in better body condition at weaning and subsequently rebreed sooner after weaning. It also is clear that inadequate protein and energy intake during lactation leads to excessive weight and backfat loss. One explanation for the delayed return to estrus associated with low nutrient intake is reduced follicular development and altered LH.[38] Support for this mechanism is the observation that administration of exogenous hormones to nutrient-deficient gilts, and to post-weaning sows in general, induces estrus and ovulation.[39,40] Feeding level after weaning appears to have little effect on interval from weaning to estrus but has been reported to be more beneficial for primiparous sows in the summer, when feed intake may be reduced by environmental temperatures. Energy intake is at least partly involved, because administration of exogenous insulin to sows at weaning at 0.4 IU/day for 4 days was found to initiate follicle growth and to improve return to estrus and litter size.[41]

Exogenous gonadotropins have been used to synchronize and improve post-weaning return to estrus, ovulation rate, and fertility in herds failing to show optimal post-weaning reproductive performance. Equine chorionic gonadotropin in combination with hCG has been used prophylactically to control the wean-to-estrus interval in sows. When PG600 was administered to sows at weaning, the percentage of sows returning in 7 days increased from 78% to greater than 90%, and the interval from weaning to estrus was reduced by 1 day. The numbers of pigs per mated sow is higher even though no overall increase in farrowing rate and litter size is observed. The increased number of pigs per mated sow results from the increase in number of mated sows that farrow. The lack of overall improvement in farrowing rate and litter size presumably results because time of ovulation after estrus is altered through a shortened wean-to-estrus interval.[40] A few reports, however, have identified a trend for improvement in overall litter size, even though farrowing rate was not improved. Investigators giving eCG following weaning improved litter size in both parity 1 and parity 2 sows but not in parity 3 or greater sows,[42] whereas 1200 IU of eCG tended to improve litter size (11.3 versus 9.3).[43]

Estrus and ovulation induction protocols use 750 to 1500 IU of eCG at weaning, followed by 500 to 1000 IU of hCG 72 to 96 hours later. Females inseminated within 24 hours after administration of hCG have greater than 90% conception rates.[44] Another ovulation induction protocol has been developed to deal with the adverse effects of early weaning in sows. At the time of farrowing, sows are reported to have developed follicles on their ovaries, which regress within 48 hours. Treatment at the time of farrowing with 1000 IU of hCG can induce these follicles to undergo ovulation, and the resultant corpora lutea progress through a normal maturation cycle, preventing a return to estrus for +/– 20 days, despite early weaning of the litter. Unfortunately, the reported success rate for this treatment was only 48%, so it has been deemed impractical for commercial herd application.[45]

Predicting or inducing the time of ovulation is paramount for obtaining satisfactory reproductive performance from an artificial insemination (AI) program. Use of real-time ultrasound scanning to image ovarian structures and dynamics has opened a new window of understanding on the ovarian outcome with various management and therapeutic practices. Successful single-service AI is a major goal of breeding management for both labor and material costs. This has been achieved in some herds simply by designing an AI protocol around the two thirds rule for the timing of ovulation after onset of estrus. It has been shown that natural ovulation occurs consistently at two thirds (67% to 71%) of the way through the estrual period, regardless of the duration of estrus.[46] It was further demonstrated that sows returning to estrus early after weaning (3 to 4 days) have delayed estrus-to-ovulation intervals when compared with those in sows returning to estrus at later intervals (after 4 days), and those returning to estrus even later (after 6 days) may

ovulate even sooner. One ultrasound study showed that in sows with early return to estrus after PG600 treatment at the time of weaning, estrus-to-ovulation interval was prolonged, such that 25% of treated sows did not receive an insemination within 24 hours of ovulation.[40] Another ultrasound examination in sows that failed to return to estrus within 7 days after weaning, and then were subsequently treated with PG600, showed a shortened estrus-to-ovulation interval (15.8 hours) compared with that in untreated controls (30.0 hours).[47] Some of these animals actually ovulated before expressing estrus, possibly in part because of the presence of medium-sized to large developing follicles induced to ovulate by the hormonal blend of hCG and eCG. Premature ovulation induced by hCG results in immature ova release, delayed insemination timing, and even inadequate uterine lining development for embryonic implantation, all of which foster a subfertile outcome. Recent information indicates that a localized uterine mechanism originating from boar seminal fluids during natural mating also may accelerate ovulation timing. It was subsequently shown that placement of seminal fluids or natural prostaglandins into the uterus may reduce the estrus-to-ovulation interval.

SUMMARY AND CONCLUSIONS

The indications for and methods of estrus synchronization in swine are varied, but all methods are based on controlling events leading to follicular maturation and ovulation or altering the luteal phase. The swine veterinarian plays a crucial role for assisting producers in making informed decisions about what, where, and how these pharmacologic and management-related interventions should be made to improve the productivity and efficiency of the modern swine farm. The normal hormonal changes involving reproduction must be thoroughly understood before exogenous hormones can be used properly. Hormones are not a substitute for improper management or poor pig flow. Heat stress (season), nutritional intake, and parity are three of the most common factors that can adversely affect wean-to-estrus interval and cause an increase in nonproductive sow days, which limits number of pigs weaned per sow per year. Gonadotropins have been used to successfully stimulate estrus and ovulation, thereby increasing the likelihood that swine producers can meet their mating targets.

CHAPTER 101

Diagnosis of Pregnancy

GLEN W. ALMOND

Early and accurate identification of pregnant and nonpregnant sows and gilts has a strong potential to increase reproductive efficiency of commercial swine farms. Detection of returns to estrus after mating, ultrasound techniques, and several other methods have been used for pregnancy diagnosis[1]; however, for various reasons, only three or four techniques currently are used in commercial farms.

An ideal pregnancy detection technique is not available, and most producers use either a combination of techniques or one technique that apparently fulfills their requirements. Some methods are restricted to research applications, and it is unlikely that these methods will be adapted for on-farm use. This chapter reviews the techniques for pregnancy diagnosis in swine; the practical applications, or lack thereof, are emphasized for each technique (Table 101-1). For most procedures, **sensitivity** (ability to detect pregnant animals, representing the proportion of pregnant animals that test positively) and **specificity** (ability to detect nonpregnant animals, representing the proportion of nonpregnant animals that test negatively) are used to assess accuracy.

DETECTION OF ESTRUS

A common pregnancy detection technique is observation of the sow for failure to return to estrus after mating. This technique is based on the premise that nonpregnant sows will return to estrus within 17 to 24 days after breeding. Detection of estrus is improved if the sow's behavior is observed in the presence of a boar.[2] Thus, this technique requires gestation facilities that are designed to allow daily fenceline contact between boars and sows, or the placement of the boar and sow in the same pen each day. Injections of estradiol or estradiol plus testosterone will enhance estrous behavior in sows that are not pregnant[3]; however, these steroids are not approved for use in swine in the United States.

An early study reported an accuracy of 39% for the detection of return to estrus between 19 and 25 days after mating.[4] By contrast, daily estrus detection throughout gestation enabled a 98% accuracy in predicting farrowing rate.[5] Albeit rarely seen, a false negative result can be obtained if a pregnant sow shows spontaneous estrus.[5] False positive results occur in the following scenarios:

- Sows become persistently anestrous as a result of cystic ovarian degeneration or inactive, acyclic ovaries, or become pseudopregnant.
- Submissive sows are housed in groups with dominant sows.
- Group sizes are too large to permit individual assessments of estrus.
- Sows are housed in stalls that do not permit the sow to detect the presence of the boar.
- The design of gestation facilities does not allow daily boar exposure to the bred sow.
- Breeding herd personnel fail to dedicate sufficient time to estrus detection.
- Breeding herd personnel lack adequate training to identify sows in estrus.

HORMONE CONCENTRATIONS

Serum concentrations of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), progesterone, and estrone sulfate were used as indicators of pregnancy. These hormone concentrations are dynamic, and considerable knowledge regarding endocrine changes in pregnant and nonpregnant sows is required for correct use of these techniques for pregnancy diagnosis. Owing to technical requirements, these methods are not used in the swine industry.

Prostaglandin $F_{2\alpha}$

The endometrium of the nongravid uterus secretes $PGF_{2\alpha}$ into the uterine vein between days 12 and 15 of the cycle, thereby inducing regression of the corpora lutea.[6] When viable embryos are present, $PGF_{2\alpha}$ is not secreted into the uterine vein.[7] The prostaglandin pregnancy test is based on the principle that if serum concentrations of $PGF_{2\alpha}$ are low (less than 200 pg/ml) or undetectable between days 13 and 15 after mating, the sow can be assumed to be pregnant.[8] Routine blood sample collection, without the use of indomethacin or other cyclo-oxygenase inhibitors, causes release of $PGF_{2\alpha}$ from blood constituents. This $PGF_{2\alpha}$ release leads to obvious problems with interpretation of serum $PGF_{2\alpha}$ concentrations; however, prostaglandin metabolites are more stable, and serum metabolite concentrations are reasonable indicators of prostaglandin concentrations.

The prostaglandin pregnancy test has approximately 90% sensitivity and 70% specificity. Accuracy is lower when animals have delayed returns to estrus, or when fetal death occurs and sows manifest pseudopregnancy. This diagnostic method can be used during early pregnancy, but its unreliability in the detection of nonpregnant animals and the necessity of extensive laboratory procedures limit its practical application.

Table **101-1**

Applications of Techniques Available for Pregnancy Diagnosis in Swine

	APPLICATION			TIME OF TEST DURING PREGNANCY*		
Technique	**Commercial**	**Diagnostic**	**Research**	**Ultra-early**	**Early**	**Late**
Early pregnancy factor			X	X		
Estrus detection	X				X	
Estrogen injections		X			X	
Laparoscopy			X		X	
Prostaglandin $F_{2\alpha}$			X	X		
Progesterone	X	X	X		X	
Estrone sulfate		X	X		X	
Rectal palpation		X				X
Vaginal biopsy		X	X		X	
Doppler ultrasonography	X	X				X
Amplitude-depth ultrasonography	X	X				X
Real-time ultrasonography	X	X	X		X	X

**Ultra-early:* before 18 days after breeding; *early:* 18 to 24 days after breeding; *late:* beyond 24 days after breeding.

Progesterone

Maintenance of the corpus luteum (CL) is the result of a blastocyst "signal" that is produced at 10 to 12 days after mating.[9] The blastocyst-induced maintenance of corpora lutea causes serum progesterone concentrations to remain high (greater than 5 ng/ml) throughout pregnancy. Thus, serum concentrations of progesterone are high in pregnant sows and gilts during the expected time of return to estrus and low (less than 5 ng/ml) in bred sows and gilts that fail to conceive.[10]

The interestrus interval for sows of various parities ranges from 17 to 24 days, with a mean of 20 to 21 days and a mode of 20 days.[11] Therefore, the optimal time to obtain blood samples for progesterone determinations is from 17 to 20 days if nonconceiving sows and gilts are to be identified before the time they return to estrus. The serum concentration of progesterone that most accurately discriminates the nonpregnant from the pregnant sow or gilt has not been determined. Concentrations of 4, 5, 7, 7.5, and 9 ng of progesterone/ml of serum were used to discern pregnancy status[5,10]; a concentration of 5 ng/ml is most commonly used.

The progesterone pregnancy test has greater than 97% sensitivity at 17 to 24 days, but specificity ranges from 60% to 90%.[5,12] False positive results are common when nonconceiving sows and gilts have delayed or irregular returns to estrus, and when nonpregnant sows and gilts are anestrous as a result of cystic ovarian disease.[5] False negative results may be the result of laboratory error because it is assumed that greater than 4 ng of progesterone/ml of serum is required for pregnancy maintenance in swine.[13]

Commercial enzyme-linked immunosorbent assays (ELISAs) to measure blood concentrations of progesterone in swine can be used on farms or in veterinary clinics, thereby reducing the need for laboratory-based radioimmunoassays. The necessity of collecting blood is a significant limitation of this method; however, methods to quantitate fecal progestins were evaluated for monitoring reproductive function in swine,[14] dogs,[15] and ruminants.[16] It was evident that the extraction and assay procedures are feasible alternatives to blood progesterone assays. Despite the potential use of fecal progestin determinations, direct applications of this methodology for pregnancy diagnosis have not gained popularity, nor have they been evaluated on a large scale in commercial pig production.

Estrone Sulfate

A high proportion of fetal estrogens is secreted from the uterus into the maternal circulation as estrone sulfate.[17] Estrone sulfate initially appears in the maternal circulation at approximately 16 to 20 days and rises linearly to peak levels between 25 and 30 days before decreasing to a nadir at 35 to 45 days.[18] A second increase in estrone sulfate occurs concomitantly with increases in other estrogens, commencing at 70 to 80 days and continuing until farrowing.

Urinary and serum estrone sulfate concentrations have been investigated for applicability as pregnancy tests.[5,19,20] A 10-fold to 100-fold increase in maternal estrone sulfate concentrations typically occurs between 25 and 30 days after coitus in sows that conceive.[21] Because estrone sulfate increases during early and late pregnancy, determination of estrone sulfate levels has potential applications as an early pregnancy diagnosis test and as a confirmatory test later during pregnancy. Parity, season, and day of pregnancy when blood was collected have some effect on estrone sulfate concentrations.

Serum estrone sulfate concentrations greater than 0.5 ng/ml are indicative of pregnancy, whereas concentrations less than 0.5 ng/ml are suggestive of nonpregnant status.[5,19] The estrone sulfate pregnancy test has greater than 97% sensitivity and greater than 88% specificity when serum samples are collected between 25 and 30 days of pregnancy.[5] False positive results may be attributable to a transient increase of estrone sulfate concentrations in some sows and gilts during proestrus.[18] False negative results were obtained in sows or gilts with a premature or delayed rise in estrone sulfate concentrations[22] or in sows and gilts that had less than 4 pigs in a litter.[5] As with other early tests of pregnancy, animals may be correctly diagnosed as pregnant but subsequently will fail to farrow if the fetuses die after the test has been conducted.

Pseudopregnant sows frequently retain the endocrine function of the corpora lutea for prolonged periods and may appear to be pregnant even though they no longer have viable fetuses. Other sows experience loss of their pregnancies, followed by development of acyclic, anovulatory ovaries or cystic ovaries, and similarly fail to show estrus for various time periods. Serum concentrations of estrone sulfate in pseudopregnant animals were similar to those in females that had not been mated and distinctly less than those in pregnant sows.[23]

Urinary concentrations of estrone conjugates also have been used to predict pregnancy and to diagnose fertility problems.[20] for these investigations, urine samples were obtained through the use of vaginal sponges. It should be noted that the glucuronide conjugate of estrone, rather than the sulfate form, was measured; thus, different quantitative procedures were required.

Quantitative commercial assay kits for the determination of estrone sulfate concentrations in serum from swine are not available. The need to collect blood (or urine) samples limits the practical application of this technique for pregnancy diagnosis in swine.

Early Pregnancy Factor

Early pregnancy factor (EPF) activity is dependent on the presence of two components: EPF-A and EPF-B. Factor A is formed in the uterus during estrus and pregnancy, whereas EPF-B is produced in the ovary and is associated only with pregnancy. The production of EPF-B is a result of a combined action of endocrine signals from the pituitary and the zygote.[24] Serum concentrations of EPF peak 24 to 48 hours after fertilization and exhibit a polyphasic pattern throughout gestation.[25]

Detection of EPF, based on a rosette inhibition test, is time-consuming and cumbersome and possesses other limitations. Various applications of EPF detection have been proposed for embryo transfer programs and assessment of infertility and early embryonic survival.[26] Several investigations indicated that EPF detection was a useful technique to evaluate human infertility and embryonic loss; however, little evidence is available to substantiate the use of EPF detection in commercial swine production. One study indicated that the rosette inhibition test was not quantitative or suitable for pregnancy diagnosis in swine.[27]

PHYSICAL METHODS

Radiography

Radiography is a seldom-used method for pregnancy diagnosis in swine. In research studies, it was used after the sixth week of pregnancy,[28] when the fetal skeleton begins to calcify. Fetal age, viability, and abnormalities were determined with radiography.[29] Equipment costs, potential health hazards to users, and the impracticality of radiography in production facilities render this technique unsuitable for pregnancy diagnosis in commercial swine.

Rectal Palpation

Pregnancy diagnosis by rectal palpation of the sow has been demonstrated to be practical and highly accurate.[30] Sows in the relevant study were examined while standing in gestation crates or pens, or while tethered. The technique involves examination of the cervix and uterus, together with palpation of the middle uterine artery to assess its size, degree of tone, and type of pulse. Before 21 days of gestation, rectal palpation had a 30% sensitivity, but the sensitivity increased to 75%, 94%, and 100% in animals at 21 to 27, 28 to 30, and 60 days to term, respectively.[30]

The pelvic canal and rectum often were too small for the procedure to be used on low-parity sows. False positive results were obtained if the external iliac artery or one of its branches was mistakenly identified as the middle uterine artery. False negative results, presumably due to errors in palpation technique or performance of palpation too early, were more common than false positive diagnoses. Despite the potential application of this technique, it has not gained popularity in North America.

Laparoscopy

Initially, laparoscopy was adapted in swine for studies of ovarian activity,[31] and a research study revealed that pregnancy can be diagnosed with 100% accuracy using this technique.[32] Differences in color were noted between gravid and nongravid uteri, because of the greater blood flow to the gravid uterus and increased uterine tone in response to hormonal stimulation. Observation of the corpora lutea allowed an estimation of the number of ova shed, and follicular development in accompaniment with regressing corpora lutea was apparent in animals returning to estrus. When this test was conducted between 16 and 20 days after coitus, pregnancy could be diagnosed before return to estrus in nonconceiving animals. Obviously, laparoscopy is limited to research applications.

Vaginal Biopsy

Histologic changes in the vaginal mucosa characterize specific stages of the estrous cycle and pregnancy.[33,34] This relationship was the basis for a study in which vaginal biopsies were used to diagnose pregnancy in swine.

Specimens of vaginal epithelium, obtained with a biopsy instrument, were prepared for histologic examination. Histologic sections of epithelium were categorized according to the number, types, and arrangement of superficial epithelial cells.[35] This procedure can be conducted between 18 and 22 days after mating; however, the most reliable results are obtained when the specimen is collected after 25 days of gestation.[36] Erroneous test results were obtained for sows and gilts with irregular returns to estrus, sows and gilts affected with cystic ovarian degeneration, immature gilts, anestrous sows, and sows in which resorption of fetuses occurred after pregnancy testing. False negative results were noted when specimens were taken in late pregnancy.[36] The vaginal biopsy technique is impractical, and the potential delay in diagnosis with laboratory procedures reduces the usefulness of this technique for routine pregnancy detection.

ULTRASOUND TECHNIQUES

Mechanical ultrasound devices commonly are used because they are easy to operate and commercially available and are perceived as being accurate. Three types of ultrasound units are available for pregnancy diagnosis in swine. Each instrument functions on a different scientific principle.

Doppler Ultrasonography

Doppler instruments utilize the transmission to and reflection of ultrasound beams from moving objects such as the fetal heart and pulsating umbilical vessels or uterine arteries.[37] Blood flow to the uterine artery in the pregnant sow and gilt is detected as a regular 50 to 100 beats per minute, whereas blood flow in the umbilical arteries is detected at 150 to 250 beats per minute.[38]

Two types of transducer probes—namely, an abdominal and a rectal probe—currently are available for use with the Doppler instruments. The abdominal probe is positioned on the flank of the animal, lateral to the nipples, and aimed at the sow's pelvis area. The ultrasound waves are emitted and received by transducers and are converted to an audible signal. The rectal probe functions similarly, with the obvious exception of the positioning of the transducer. One study found no differences in sensitivity and specificity between the rectal and the abdominal probes.[5] Other reports showed that sensitivity was greater than 85% and specificity was greater than 95%.[39,40] Optimal results were obtained when pregnancy determinations were made later than 29 to 34 days; sensitivity decreased with scanning performed earlier in gestation.[40]

Doppler ultrasound techniques had greater sensitivity, specificity, and overall accuracy than amplitude-depth ultrasonography,[40] but substantial variation in the accuracy of different models of amplitude-depth devices may make the results of such comparisons misleading.[5,41] After 1 month of gestation, the Doppler devices apparently had greater specificity, whereas the amplitude-depth machines had greater sensitivity.[40]

The likelihood of false positive results was increased if examinations were done when sows and gilts were in proestrus or estrus, or if sows and gilts had active endometritis.[5] False negative results were obtained if examinations were conducted before 30 days, if examinations were conducted in a noisy environment, or if feces became packed around the rectal probe.[5,40] Another disadvantage associated with use of Doppler techniques is that training is required in the use of the instrument.

Amplitude-Depth (A-Mode or Pulse Echo) Ultrasonography

Amplitude-depth machines utilize ultrasound waves to detect the fluid-filled uterus.[42] A transducer is placed against the flank and oriented toward the uterus. Because the contents of the gravid uterus differ in acoustic impedance from that of adjacent tissues, some of the emitted energy is reflected to the transducer and is converted to an audible signal, a deflection on an oscilloscope screen, or illumination of a light (diode) or series of lights.[42]

In one study, pregnancies were not confirmed before 20 days, but progressive improvement in pregnancy detection was observed from day 20 until day 30.[41] From approximately 30 days until 75 days after breeding, the overall accuracy in the determination of pregnancy commonly was greater than 95%.[40,43] The percentage of false negative and uncertain determinations increased from 75 days until farrowing.[41] These changes in accuracy parallel alterations in volume of allantoic fluids and fetal growth.[44]

The amplitude-depth instruments had greater sensitivity but less specificity compared with Doppler instruments.[40] Some models of amplitude-depth instruments, however, were more severely affected by low sensitivity and specificity.[5] Errors in the placement of the transducer resulted in the detection of a fluid-filled urinary bladder, which yielded a falsely positive diagnosis of pregnancy.[40] False positive results were obtained when sows were affected with endometrial edema caused by zearalenone toxicosis or pyometra, or when the litter died and was neither aborted nor resorbed.[5] False negative results were noted when the test was performed before 28 days of gestation or after day 80.[41]

Real-Time Ultrasonography

Real-time ultrasound scanners have been used to evaluate the reproductive tracts of mares,[45] heifers,[46] and bitches[47] and for pregnancy diagnosis in sows and gilts.[48,49] Also, domestic animals such as sheep[50,51] and goats[52] have been scanned for pregnancy diagnosis and reproductive problems.

Real-time ultrasound techniques use beams of sound waves emitted from a multi-transducer. These beams travel in straight lines through different tissues until they encounter boundaries of differing acoustic density. Then they are reflected back to the same transducer and converted to electrical signals, ultimately being displayed on a monitor as a two-dimensional cross section of the interior of the animal.[48] The various tissues reflect the sound waves at differing amounts based on their acoustic

density. Accordingly, tissues such as bone reflect a large portion of the emitted waves and appear white on the screen, whereas other tissues are various shades of gray. Fluid-filled structures such as the urinary bladder or amniotic vesicles are nonechogenic and appear black because they do not reflect any sound waves.[50] The combination of these reflections generates the overall image viewed on the screen.

Previous work with real-time scanning utilized abdominal probes, with the transducer placed against the flank of the animal. This positioning is lateral to the nipples and posterior to the navel, similar to that for other pregnancy detection devices being used currently.[48] From this position the probe is directed toward the back of the animal, allowing the ultrasound waves to pass through the uterus before returning back to the transducer. Amniotic vesicles became visible on real-time scans around 18 or 19 days after breeding; embryos were observed by 21 days and easily detected by 25 to 32 days.[53] Fetal movement was observed after day 60.[48] Recently, 5.0- and 7.5-mHz probes were used transrectally to determine the pregnancy and estrus status of breeding females.[54] Use of the transrectal probes may be marginally more time-consuming than use of the abdominal probes; however, the increased structural detail of the ovaries and early pregnancy (days 16 to 20) improves the usefulness of transrectal ultrasonography for use in female pigs. General characteristics of real-time ultrasound probes and representative images are provided in Table 101-2 and Figure 101-1, respectively.

Table **101-2**

General Characteristics of Probes for Real-Time Ultrasonography

Probe	Depth of Field (cm)	Resolution	Timing*
3.5 mHz	10–12	Low	Days 25–26
5.0 mHz	7–10	Medium	Day 23
7.5 mHz	5–7	High	Day 21

*Day(s) of gestation on which pregnancy can be diagnosed with reasonable reliability.

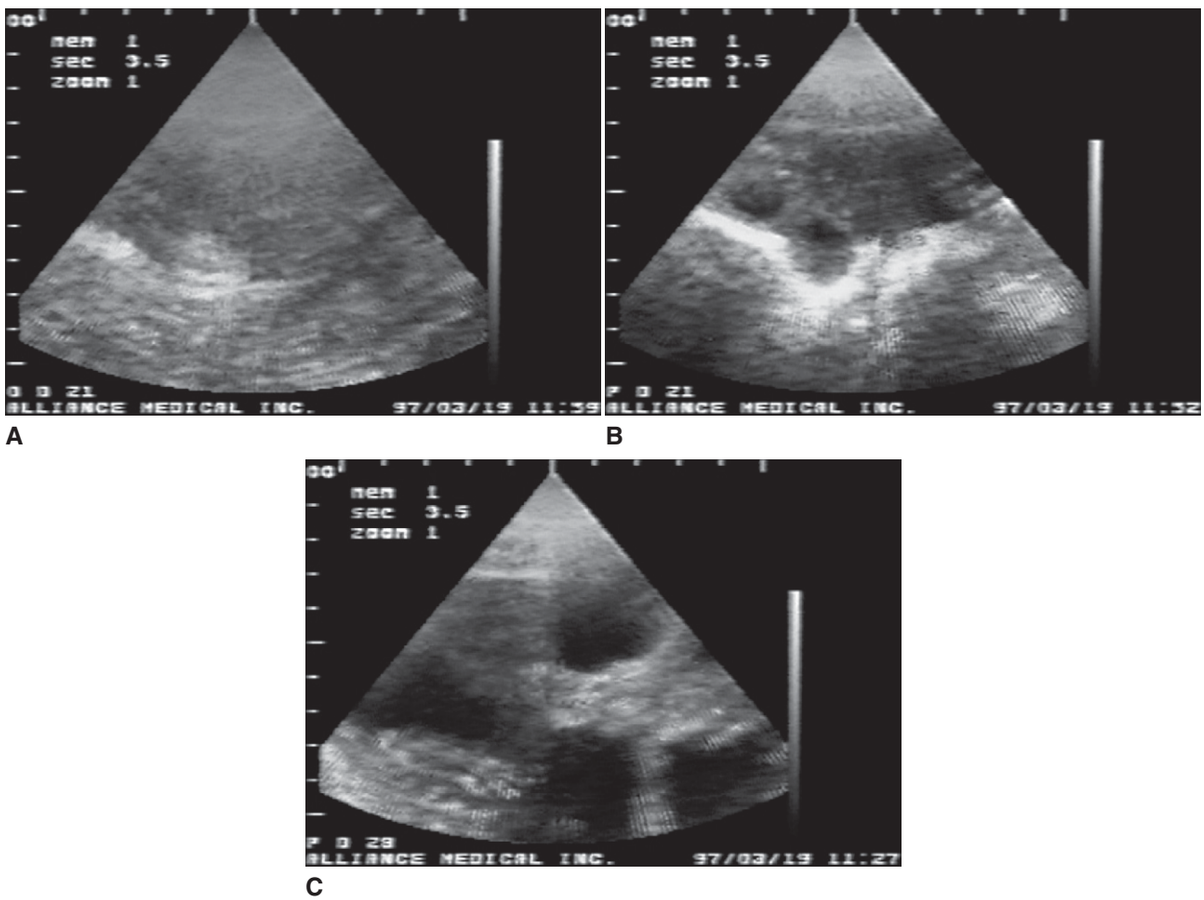

Fig. 101-1 Real-time ultrasonographic images of sow uteri observed with a 3.5-mHz sector probe. **A,** Image from an open sow at day 21 of the estrous cycle. **B,** A day 21 pregnancy. **C,** A day 28 pregnancy.

Early research indicated that real-time ultrasound scanning had greater than 95% sensitivity and specificity at 22 days of gestation or later.[48] False negative results were obtained if the scans were performed before day 22 of gestation, when the vesicles were too small to be detected regularly. False positive results were obtained in sows and gilts that had cystic ovarian degeneration or uterine infections resulting in accumulations of fluid.

Research with ewes showed that pregnancy status of the animal was a major determinant in the time needed to make a diagnosis using real-time ultrasound scanning. Pregnant ewes were diagnosed in about 10 seconds, whereas scanning of nonpregnant animals took much longer.[51] In general, similar time is required for real-time ultrasound scanning for pregnancy diagnosis in female pigs.

Our studies demonstrated several sources of variation affecting the success of real-time ultrasound evaluation for pregnancy diagnosis.[55] Sources of variation include type of probe, day of gestation when scanning is initiated, and technician skill (Tables 101-3 and 101-4). Parity is a potential source of variation that has not been thoroughly examined. With the exception of the field trials, most controlled studies were conducted with gilts. It is possible that scanning procedures need to be adjusted for the increased abdominal size and the changes in anatomic location and size of the reproductive tract in multiparous sows.

Because the initial purchase price ($7000 to $15000) of a real-time ultrasound instrument is considerably higher than that of other pregnancy detection devices, producers and veterinarians often are reluctant to purchase a real-time ultrasound unit. For farms with 100 or 200 sows, this reluctance may be justified. With larger herd sizes, however, the additional costs of a real-time ultrasound instrument quickly diminish on a per sow basis (Table 101-5).

Factors affecting the benefits of real-time ultrasonography are interrelated and can have compounding effects on the number of open sow days saved and the money saved per sow. The application of real-time ultrasound scanning as a pregnancy detection technique has greater impact when the farrowing rate is low. The percentage improvement, which is defined as percent of open sows detected by real-time ultrasound evaluation at 23 days that were missed by traditional detection methods (e.g., A-mode, Doppler) at 28 days or sooner, also has dramatic effects on the benefits of real-time ultrasonography. Addi-

*I.e., number of nonproductive sow days (NPSD)/year saved, as affected by number of sows and day of gestation on which scanning is initiated.
Assumptions: 1% improvement above results with A-mode ultrasonography and an 85% farrowing rate.
Data from Armstrong JD, Almond GW, White S, et al: Accuracy and economics of RTU pregnancy detection, and comparisons with A-mode. North Carolina State University. Available at: http://mark.asci.ncsu.edu/Reproduction/rtu/armstrong.htm (accessed 1997).

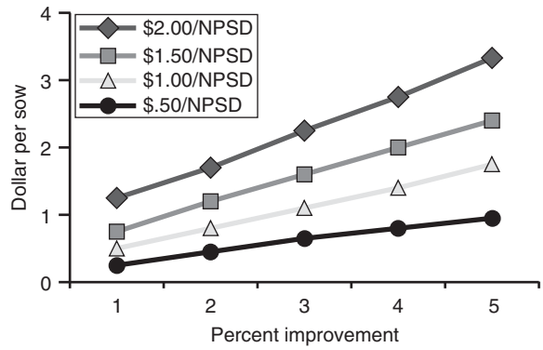

Fig. 101-2 Money saved per sow is influenced by both the percentage improvement and the cost of a nonproductive sow day (NPSD). The real-time ultrasound scanner was used at 23 days after mating, and the data are based on scanning 200 sows per week, with a 75% farrowing rate. The percentage improvement is based on a comparison of real-time ultrasound scanning at 23 days with amplitude-depth scanning at 28 and 35 days of gestation.

tional savings are gained when producers are willing to institute a 100% culling policy, rather than a standard culling policy (cull after the second return to estrus). Open sows are culled immediately after pregnancy detection with the 100% culling policy.

We have observed that many producers become very proficient with the use of real-time ultrasound techniques. These producers can diagnose pregnancy as early as day 23 (sometimes earlier). This proficiency is useful in assessing pregnancy status in breeding groups, when the test day includes animals at days 23 to 28 of gestation. It is not surprising that the greater benefits are gained with the use of real-time ultrasound scanning in large herds or as more sows are tested (Table 101-6). Again, the greatest benefits are gained when early testing is implemented in herds with low farrowing rates. The cost of an open day or nonproductive sow day (NPSD) varies from farm to farm. As the cost of an NPSD increases, the savings per sow with use of real-time ultrasonography also increase (Fig. 101-2). It also is evident that if real-time ultrasound scanning detects a greater percentage of open sows than is found with the traditional methods, then additional savings per sow will result.

Real-time ultrasound scanning appears to be more versatile than the other methods of pregnancy diagnosis currently available. Besides pregnancy detection, it has been used to assess reproductive disorders in goats[52] and to evaluate carcass characteristics in growing pigs.[56] These findings lend further support to the potential for other uses for this technique in swine production. For instance, pseudopregnant sows and gilts with uteri containing mummified fetuses have been differentiated from pregnant sows.[57] Recently, it was demonstrated that real-time ultrasound scanning is an effective technique to identify pseudopregnant sows between days 65 and 75 after mating.[58] Although the uterus of a pseudopregnant sow may contain fluid, the failure to observe fetal skeletons is indicative of pseudopregnancy. Furthermore, past research showed that this technique was useful to identify and distinguish sows and gilts with endometritis from females in later stages of pregnancy.[57]

SUMMARY AND CONCLUSIONS

The advantages of sensitive and specific methods for early pregnancy diagnosis in swine include early detection of conception failure, forecasting production levels, and early identification of nonpregnant animals, which facilitates decisions regarding culling, treatment, or rebreeding. At present, detection of nonconceiving sows that return to estrus and use of amplitude-depth ultrasonography are the most widely used methods of pregnancy diagnosis. Despite routine use of these traditional methods, a common finding is that many sows either fail to farrow after being considered pregnant or return to estrus at irregular times during a presumed pregnancy.

Perhaps the most promising technique for porcine pregnancy detection is real-time ultrasound scanning. This method is used routinely in a variety of species; however, applied research and improved technology have enhanced its applications in commercial sow farms. Perhaps the most intriguing aspect of real-time ultrasound scanning is that the user can visualize the uterus and its contents. Despite the obvious need for improved pregnancy diagnosis abilities for swine producers, little progress or changes were made until the development and application of real-time ultrasound techniques.

CHAPTER 102

Infertility Associated with Abnormalities of the Estrous Cycle and the Ovaries

GLEN W. ALMOND

Various reports have demonstrated the role of infectious agents in porcine reproductive failure. For most infectious agents, researchers and veterinary practitioners have elucidated the pathogenesis, modes of transmission, and reasonably effective control programs. By contrast, porcine reproductive and respiratory syndrome virus (PRRSV) disease continues to be difficult to control, and the swine industry recognizes the economic impact of the virus on all phases of production. PRRSV disease continues to be detrimental to reproductive performance in sow herds, with variable severity of clinical signs in affected animals. With these widespread problems associated with PRRSV, pig producers often attribute reproductive failure to the virus when in fact the underlying causes are noninfectious. Unfortunately, the precise pathogenic mechanisms of noninfectious causes of reproductive failure also are elusive, and the interactions between the various factors affecting reproduction create major challenges to any efforts to improve the performance of the breeding herd.

Various investigators have examined the physiologic control of estrus, ovulation, conception, and pregnancy; however, the endocrine changes associated with these processes are more complex than was previously believed. Season, nutrition, environment, and management are well recognized for their potential to alter reproductive processes. In addition, recent studies revealed that various components of the immune system also possess profound roles in porcine reproduction. This chapter provides information regarding the physiologic mechanisms and "management" factors involved with infertility due to abnormalities of the porcine estrous cycle.

CHAPTER 102

Infertility Associated with Abnormalities of the Estrous Cycle and the Ovaries

GLEN W. ALMOND

Various reports have demonstrated the role of infectious agents in porcine reproductive failure. For most infectious agents, researchers and veterinary practitioners have elucidated the pathogenesis, modes of transmission, and reasonably effective control programs. By contrast, porcine reproductive and respiratory syndrome virus (PRRSV) disease continues to be difficult to control, and the swine industry recognizes the economic impact of the virus on all phases of production. PRRSV disease continues to be detrimental to reproductive performance in sow herds, with variable severity of clinical signs in affected animals. With these widespread problems associated with PRRSV, pig producers often attribute reproductive failure to the virus when in fact the underlying causes are noninfectious. Unfortunately, the precise pathogenic mechanisms of noninfectious causes of reproductive failure also are elusive, and the interactions between the various factors affecting reproduction create major challenges to any efforts to improve the performance of the breeding herd.

Various investigators have examined the physiologic control of estrus, ovulation, conception, and pregnancy; however, the endocrine changes associated with these processes are more complex than was previously believed. Season, nutrition, environment, and management are well recognized for their potential to alter reproductive processes. In addition, recent studies revealed that various components of the immune system also possess profound roles in porcine reproduction. This chapter provides information regarding the physiologic mechanisms and "management" factors involved with infertility due to abnormalities of the porcine estrous cycle.

PROLONGED WEANING-TO-ESTRUS INTERVAL

Most pig producers attempt to have 95% (or more) of sows bred within 7 days after weaning (Fig. 102-1). Producers strive to achieve this goal to minimize the number of nonproductive sow days (NPSDs). An NPSD is a day on which a sow is not pregnant or lactating, and the number of NPSDs is recognized as an economic loss to the producer. The ability to have the vast majority of weaned sows bred within a week is helpful to maintain the integrity of breeding groups and provides a natural synchronization of estrus for breeding programs. In addition, the results of several studies indicate that the fertility, as measured by farrowing rate and litter size, is less in sows returning to estrus after 7 days than in sows that returned to estrus within 4 to 6 after weaning. It was suggested that animals returning to estrus 7 to 10 days after weaning are "subfertile."[1] Under certain circumstances, it may be warranted to postpone breeding these animals until the second postweaning estrus (i.e., skip a heat).

Culling surveys historically reported that 5% to 30% of sows are culled for failing to return to estrus after weaning. Many of these sows remained anestrous for prolonged periods (greater than 30 days), and their ovaries were acyclic. Such acyclic ovaries have small follicles (less than 5 mm in diameter) and well-regressed corpora lutea. At present, the incidence of these chronically anestrous sows appears to be less than that of sows with a relatively brief delay in return to estrus after weaning. For both types of anestrus, the condition is most prevalent in primiparous sows during the summer months.

Factors affecting the sow's ability to return to estrus after mating have been were reviewed.[2] The onset of estrus may be hastened or delayed, depending on the quality of management in both the breeding and the farrowing facilities. For example, sows consuming insufficient feed or feed with suboptimal energy or protein content during lactation in the summer months have longer WEI than sows with optimal feed and nutrient intake. Evidently, diminished feed intake during the first week of lactation, the last week of lactation, or throughout lactation contributes to postweaning reproductive failure.[3] It is apparent that the greatest challenge is to ensure sufficient feed intake by primiparous sows (Fig. 102-2). To overcome the problem of suboptimal energy intake, fat (5% of the diet) is added to feed to increase caloric intake. The protein and amino acid requirements of highly prolific sows also may require adjustments, particularly primiparous sows nursing large litters of piglets. In regard to daily feed intake, feeding schedules for lactating sows typically are adjusted to provide fresh feed at least three times a day. Furthermore, evaporative cooling is used in the farrowing rooms to improve feed intake during the summer months.

Various weaning strategies, based on the removal of suckling-induced inhibition of follicular growth, have been used to shorten the WEI. Weaning the heaviest half of a litter 2 days early shortened WEI, and when this split weaning was initiated early enough (at 5 days), the WEI was reduced to 1 to 2 days.[4] Potential benefits of this technique are to shorten WEI and to create a more synchronous return to estrus. The increased synchrony of estrus facilitates breeding and artificial insemination (AI) programs. Litter-sow separation (altered suckling) for 6 to 12 hours each day shortened the WEI if the previous WEI was longer than 6 days. This technique is labor intensive and provides limited advantages to pork producers.

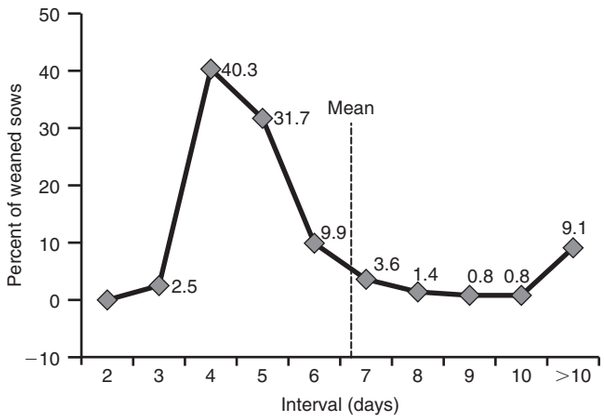

Fig. 102-1 Percent of sows (n = 2530 observations) returning to estrus from 2 to later than 10 days after weaning in a commercial farm. Although a majority of sows returned to estrus within 7 days after weaning, the mean weaning-to-estrus interval (WEI) was 6.77 ± 7.7 days. Obviously, a minority of the animals were not detected in estrus for extended periods of time after weaning. The median, which is a useful indicator of the population WEI, was 5 days. Collectively, the WEI accounted for 17,137 nonproductive sow days.

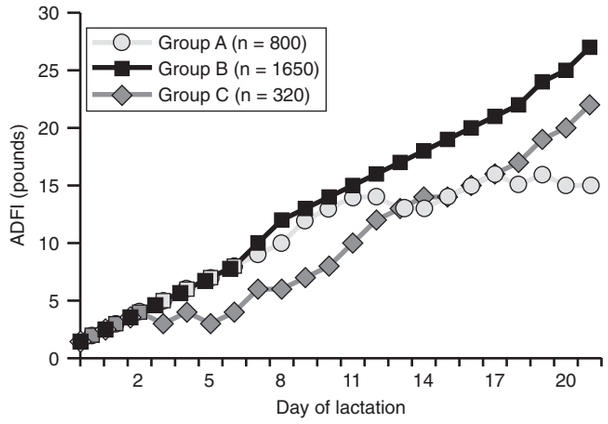

Fig. 102-2 Average daily feed intake (ADFI) in three groups of sows in a commercial farm. Feed intake increased steadily during lactation in multiparous sows (Group B) without postpartum health problems. Despite increasing feed allowance, feed intake reached a plateau of approximately 15 pounds per day in primiparous sows (Group A). Sows (Group C) with postpartum health problems and diminished ADFI in the first week of lactation failed to match the ADFI achieved in healthy animals. Groups A and C represent "high-risk" animals and are more likely to have prolonged weaning-to-estrus intervals.

A previous study indicated that the WEI is inversely related to lactation length.[5] This correlation generally is accepted; however, females of most genetic lines and parities can be weaned at 14 days or earlier and return to estrus within 7 days.[6] The most extreme example of short lactation length is the "zero-weaned" sow. Piglets are removed from these sows at birth. One investigation demonstrated that many of these animals will return to estrus at 14.8 ± 0.5 days after birth/weaning.[7] Although lactation length has the potential to lengthen WEI, most modern sow farms routinely wean piglets from sows at less than 21 days. The possible negative influence of short lactation length must be assessed for each farm (Fig. 102-3) and compared with the potential economic benefits of the early-weaning sow.

Numerous exogenous hormone preparations have been assessed for inducing estrus in the postweaning sow; however, an equine-human chorionic gonadotropin (eCG/hCG) combination, PG600, has received the greatest attention. It was suggested that the administration of PG600 to sows at weaning reduced the WEI and the incidence of anestrus in post-weaning sows, if a problem existed on the farm.[8] Subsequently, it was revealed that PG600 treatment of postweaning sows reduced the WEI from 7.8 ± 0.6 days to 6.0 days and from 6.4 ± 0.7 to 4.7 days in first- and second-parity sows, respectively, during the summer months.[9] These studies indicated that potential benefits could be obtained by using PG600 in postweaning sows, particularly in the summer. It is essential to conduct on-farm trials with any exogenous hormone combination to demonstrate its cost-effectiveness.

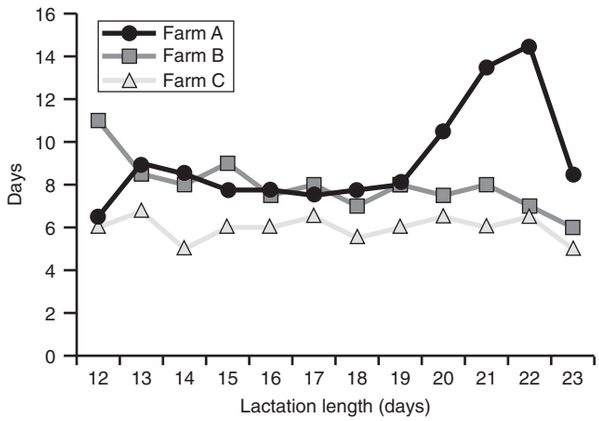

Fig. 102-3 The influence of lactation length on weaning-to-conception interval (WCI); days) for three 1200-sow farms (farm A, ●; farm B, □; farm C, ▲). The interval for each lactation day represents the mean of 100 to 400 observations. Most animals returned to estrus and were mated within 7 days of weaning. It was evident that lactation length had minimal effects on weaning-to-estrus interval (WEI) and WCI in farm C. By contrast, sows with a lactation length greater than 20 days had extended WEI and WCI in farm A. Sows with a lactation length less than 12 days tended to have a WEI greater than 7 days, with considerable sow-to-sow variation *(data not shown)* in the three farms.

The most common problem with the control of estrus and ovulation in the postweaning sow is the inability of personnel to detect the onset of estrus. Without appropriate boar exposure, it is extremely difficult or impossible to adequately assess estrus in the pig. Recently, it was demonstrated that 10 minutes of daily contact between postweaning sows and mature boars reduced the WEI. In fact, 10 minutes of daily contact between postweaning sows and estrogenized "estrous" females reduced the WEI in a fashion similar to that for sow-boar contact.[10] Obviously, estrus control requires certain behavioral and physical cues between animals.

FAILURE TO DETECT OVULATING FEMALES ("SILENT HEAT")

In approximately 20% (or more) of ovulating gilts and sows, signs of estrus are not detected by farm personnel observing the animals for estrus. Obviously, suboptimal estrus detection techniques contribute to the failure to observe estrus. The failure to use a mature boar for estrus detection is a common problem, particularly when a female exhibits subtle signs. With the increased use of artificial insemination (AI), some producers find effective estrus detection to be one of the main challenges associated with the transition from natural mating programs to AI programs.

It is easy to blame breeding herd personnel for deficiencies in estrus detection; however, it is not uncommon for females to have a propensity for reduced intensity of estrous signs. To distinguish problems with estrus detection from physiologic or pathologic causes of anestrus, examination of reproductive tracts at slaughter will reveal the presence of acyclic or functional ovaries. If a majority of animals have acyclic ovaries at slaughter, then the clinical assessment is directed at finding the causes of the acyclicity. Conversely, if most animals have active ovaries, as indicated by the presence of corpora lutea or regressing corpora lutea with developing follicles, it is apparent that estrus was not detected in the animals, and questionable estrus detection methods must be considered. Another technique to confirm acyclicity in female pigs is to collect two blood samples approximately 10 days apart. Failure of the serum progesterone concentration to reach 4 ng/ml or greater in either sample is indicative of ovarian acyclicity. At present, a rapid and inexpensive test (Target) is commercially available for on-farm assessment of serum progesterone concentrations.

It is evident that social environment contributes to the failure to detect estrus. Inadequate or inappropriate boar exposure and continuous boar exposure reduce the likelihood of detecting estrus by this means. Group size (8 animals or less is optimal) and space allowance (an area of 2 m^2/gilt is optimal) also influence estrus detection.

Veterinarians typically are asked the basic question "Can sows or gilts have a silent heat?" Previous research results indicated that silent heat or estrus is physiologically possible.[11] Sufficient estradiol was produced to induce an LH surge and subsequent ovulation, yet these animals failed to exhibit signs of estrus, including

reddening and swelling of the vulva. Evidently, the critical threshold of estradiol concentrations to induce ovulation differs from the threshold necessary for estrous behavior and vulvar changes. Despite this presumptive physiologic phenomenon, clinical experience typically confirms that "silent heat" often is an excuse for poor estrus detection.

CYSTIC OVARIAN DEGENERATION

Slaughterhouse surveys from the 1970s and 1980s reported that approximately 5% to 10% of sows culled for infertility are affected with cystic ovarian degeneration (COD). With the intensification of pig production, routine use of confinement facilities, and high replacement rates (greater than 50% per year), it would not be surprising to observe an increased incidence of COD in female pigs in the North American pig industry. Unfortunately, large-scale surveys of culled female pigs have not been conducted in recent years, so the precise incidence of COD is speculative.

Multiple large, multiple small, and single cysts occur in the ovaries of sows; however, the behavior and physiologic events differ between animals affected with each type of cyst. Most of the multiple large cysts have some luteinized tissue and produce sufficient progesterone to inhibit estrous cyclicity. Some sows fail to exhibit estrus and are culled from the herd. By contrast, other sows have irregular estrous cycles or exhibit "nymphomania." Typically, these sows have multiple small or follicular cysts on the ovaries. Because these animals fail to ovulate, it is unlikely that they conceive. Single ovarian cysts rarely affect fertility or the estrous cycle of sows; their presence is noted in occasional sows at slaughter. Because ovarian cysts do not regress with or without hormone intervention, it was postulated that the single ovarian cysts may represent the first step in a progressive process of degeneration affecting multiple follicles.

It is not unusual to observe corpora lutea with fluid-filled cavities. These particular corpora lutea commonly are referred to as cystic corpora lutea and presumably do not interfere with fertility of female pigs. The precise pathogenesis of the cystic corpora lutea is unknown; however, corpora lutea of normal size with fluid-filled cavities are relatively common in diestrous sows. One study demonstrated that luteal cells are physiologically similar in corpora lutea with cavities and in "solid" corpora lutea.[12]

Results of a recent study revealed that tonic and pulsatile patterns of luteinizing hormone (LH) release in sows with cystic ovaries are comparable with those in diestrous sows.[13] Evidently, the presence of ovarian cysts does not inhibit the hypothalamo-hypophyseal axis. Unfortunately, affected sows produce insufficient LH to complete luteinization of the cysts, or the luteolytic mechanisms are inadequate to promote regression.[14]

It is evident that the diagnosis of cystic ovaries poses a difficult challenge. Because serum concentrations of progesterone, estradiol, LH, and cortisol are similar in sows affected with COD and in diestrous sows,[13] the determination of serum hormone concentrations offers limited diagnostic value. It is not unusual to observe cystic ovaries during real-time ultrasound evaluation for pregnancy diagnosis or during scanning procedures to monitor follicle growth. Real-time ultrasonography offers a promising technique to assess COD in female pigs; however, the required time, training, and expense limit the practical application of this modality for evaluation for COD on commercial farms. Consequently, producers rely on estrus detection methods and culling policies to minimize the influence of sows with COD on nonproductive sow days and the reproductive performance of the breeding herd.

PSEUDOPREGNANCY AND NOT-IN-PIG SOWS

In general, two classifications of pseudopregnancy in sows are recognized. Not-in-pig (NIP) sows were bred, failed to exhibit an obvious return to estrus, were diagnosed pregnant, yet failed to farrow any pigs. This NIP status represents the extreme version of pseudopregnancy. The second classification of pseudopregnancy involves sows that were bred, failed to exhibit estrus at 21 days after mating, and finally show estrus at 30 to 35 days or >45 days after mating. Thus, pseudopregnancy can be classified as long term or short term.

European and Canadian culling surveys indicated that 3% to 20% of culled sows were classified as NIP at the expected time of farrowing.[15,16] An increased number of NIP sows is more commonly observed in the November-to-January period than at other times of the year—these sows were bred during the hot summer months. The overall incidence of NIP sows typically is 1% to 3% of all bred animals. If the incidence exceeds 3%, then interventions are necessary. Producers and veterinarians recognize the economic significance of NIP sows because these animals contribute to increased NPSDs, with unnecessary extra feed and housing costs for 115 or more days.

Numerous causes and conditions contribute to "false pregnancies"; however, pseudopregnancy is difficult to understand, diagnose, or prevent. In brief, pseudopregnancy can occur when all of the embryos are resorbed after the maternal recognition of pregnancy (days 10 to 14 after mating) and before fetal calcification (days 30 to 40 of gestation). Although the embryos are lost, the sow's ovaries continue to function as if the animal were pregnant. Consequently, the sow remains anestrous for a prolonged period. In the extreme version of pseudopregnancy, the NIP sows may exhibit variable degrees of udder development yet subsequently fail to give birth to any piglets, alive or dead. Unfortunately, producers often mistakenly diagnose these animals as pregnant when pregnancy status is assessed with ultrasound instruments or visual inspection.

It is important to consider the potential infectious agents or causes of embryonic loss between days 10 and 35 of pregnancy. Epidemics of porcine parvovirus, porcine pseudorabies virus, and potentially PRRSV infection can cause abrupt reductions in farrowing rates and increased frequency of irregular return to estrus (outside the typical 21-day interval) and pseudopregnancy. Moreover, infectious agent outbreaks typically induce any of

several other reproductive problems (e.g., abortions, stillbirths, mummification) that accompany the pseudopregnancy.

Increased conception failures and increased rate of embryonic death often result from elevated ambient temperatures. The highest embryonic mortality rate appears to be associated with heat stress in early pregnancy (before 16 days).[17,18] Because the maternal recognition of pregnancy has commenced around the time of embryonic loss, the sow will either return to estrus, experience a reduction in litter size, or demonstrate pseudopregnancy. In addition to heat stress, other stressors, such as regrouping sows at 2 weeks after breeding, may interfere with successful embryo implantation and maintenance of early pregnancy. Although scientific, controlled studies have not been conducted to demonstrate the association between regrouping or animal movement and embryo loss, many producers redesign animal flow to minimize animal handling for the first 21 days after mating.

Other potential causes of prolonged anestrus in sows include cystic ovaries, zearalenone (an estrogenic mycotoxin) toxicity, and endometritis or metritis. These conditions often interfere with the normal estrous cycle of a sow, resulting in erroneous classification of sows as pregnant. Our previous research indicated that less than 20% of NIP sows are affected with any of these conditions, and producers should not overrate their importance.[19]

Regardless of cause, NIP or pseudopregnant sows do not carry pigs to term. Pregnancy detection at approximately 35 days after mating should identify most of these open animals. Reevaluation at days 50 to 60 may reveal true pregnancy status; however, owing to the inherent error associated with pregnancy detection techniques, repeated attempts to identify these animals often are unsuccessful. The specific reasons for the repeated false positive results of pregnancy tests remain debatable.

Through several research projects designed to provide the best pregnancy diagnosis technique, it quickly was determined that no single method is 100% foolproof.[20] A combination of estrus detection at 21 days after mating and two or three ultrasound scans provides acceptable results. With improved technology and instrumentation, real-time ultrasound scanning has proved to be an effective method of visualizing the pregnant uterus. Although the initial cost of real-time ultrasound instruments appears excessive, these instruments commonly are used on large sow farms and integrated production systems.

The incidence of NIP sows varies from farm to farm and from season to season. Because these sows represent an economic loss on certain farms, practitioners need to determine the incidence and probable causes of the condition. Obviously, accurate records are essential to characterize the significance of NIP sows in commercial farms. Improved pregnancy detection methods will assist producer efforts to accurately identify open sows long before the expected farrowing dates.

SUMMARY AND CONCLUSIONS

Sound management of the breeding herd in all phases of production provides the most economical approach to control estrus, ovulation, and conception and farrowing rates. Boar exposure and a thorough understanding of the behavioral and physical changes associated with estrus are effective management tools. It is amazing to note that despite decades of research designed to improve sow reproductive performance, the optimal method to manipulate the porcine estrous cycle and ovulation is to provide male-to-female interactions. Furthermore, today's advanced knowledge of the reproductive physiology of the female pig has not proved to be as effective as competent breeding herd management by experienced personnel.

CHAPTER 103

Parturition and Dystocia in Swine

ROSS P. COWART

NORMAL PARTURITION

Normal parturition (or farrowing) in swine follows a gestational period of 111 to 117 days. Mean gestation length varies slightly among farms. Variation may be associated with breed or genetic differences and differences in way the beginning of pregnancy is recorded (e.g., first day of estrus, first mating, last mating). The mean gestation length of sows on most farms is 114 to 115 days with a standard deviation of 1.5 days.

Gestation and parturition in the sow are controlled by a complex interaction of physiologic and endocrine events. Although much is known about the hormonal changes that occur during gestation and parturition in the sow, the cause and effect relationship of these changes is either unknown or presumptive in most cases.

Maintenance of pregnancy in the sow appears to be dependent on secretion of progesterone (P_4) by corpora lutea on the ovary. Estrogen levels are also increased during pregnancy (especially the last trimester) and may act to support the function of the corpus luteum (CL). Maternal plasma P_4 levels are elevated throughout pregnancy and decline slowly during the last 10 to 14 days of pregnancy. The last 24 to 36 hours before parturition is marked by a more rapid decline in P_4 levels. The decline in P_4 concentrations coincides with the release of endogenous prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) from the uterus. Either endogenous or exogenous $PGF_{2\alpha}$ will result in the regression of a mature (greater than 12 days of age) CL. This appears to be an important endocrine signal for the initiation of parturition.[1,2]

Coincident with $PGF_{2\alpha}$ release from the uterus is a rise in the protein hormone relaxin. This hormone is synthesized and stored within the CL of pregnancy. Relaxin levels rise from day 110 of gestation and peak 15 hours before the birth of the first piglet. Relaxin acts to soften the cervix and to inhibit myometrial contractions. Relaxin levels decline during the final moments before parturition. This decline apparently frees the myometrium to begin the contractions of labor. More $PGF_{2\alpha}$ is released from the uterus during labor and apparently stimulates the release of oxytocin from the posterior pituitary of the sow. High levels of estrogen during the last month of gestation act to sensitize the myometrium to the contractile effects of oxytocin.[1]

Physical changes in the sow may signal impending parturition. Astute observers may notice abdominal distention as early as 80 to 90 days of gestation. Evidence of mammary development may be noted soon afterward. During the last week of gestation, the vulva may become swollen and reddened. The mammary glands become increasingly distended and may leak small amounts of colostrum during the day or two preceding farrowing. Large amounts of colostrum may be expressed from the udder within 6 to 12 hours of farrowing.[3]

During the 12 to 24 hours preceding farrowing, the sow becomes restless and may build a nest if bedding material is available. Alternatively, she may paw or root at the floor and bite at the bars of the farrowing crate. Other common behaviors during the last few hours before farrowing include frequent defecation and urination and an increase in respiratory rate. During the last 15 to 60 minutes before the first pig is born, physical activity will decrease and the sow will lie down in lateral recumbency. Abdominal straining may be evident and small amounts of fluid and meconium may flow from the

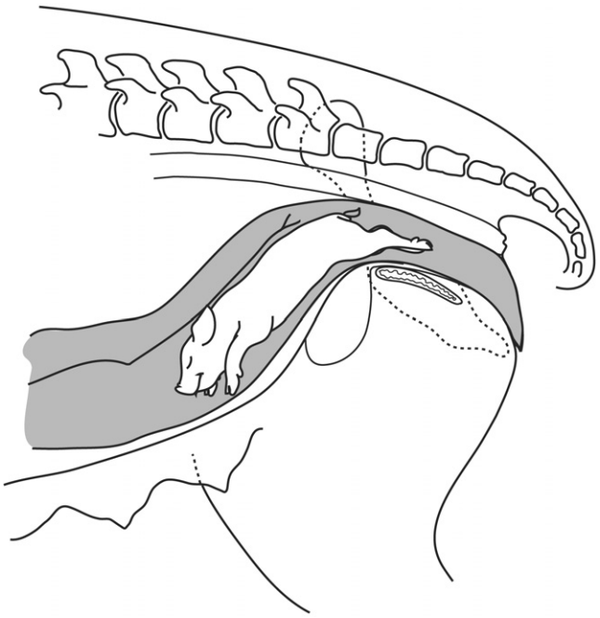

Fig. 103-2 Normal caudal presentation of piglet.

vulva. The first piglet usually is delivered within 15 to 20 minutes.[3]

The duration of farrowing is variable but usually is complete in 1 to 5 hours. The interval between expulsion of successive piglets varies from seconds to hours but typically is 15 minutes or less. An interval of greater than 15 minutes between piglets is associated with an increased probability that the next piglet will be stillborn. Placentas may be expelled between piglets but more commonly are expelled after the birth of the last piglet in the litter. Piglets may be delivered either in a cranial presentation—head first, with front legs folded back against the body (Fig. 103-1)—or a caudal presentation—rear legs first and extended caudally (Fig. 103-2). Although both presentations are considered normal, slightly more than half of all piglets are delivered in the cranial presentation.[4]

DYSTOCIA

Dystocia is relatively rare in sows. The dystocia rate is estimated to be 1% or less of all farrowings. Despite the low incidence, it is important that veterinarians and farrowing house personnel be familiar with the causes of dystocia and possess skills and strategies for dealing with it when it develops. Dystocia can adversely affect productivity by decreasing the number of liveborn piglets and by increasing sow mortality and culling rates. Dystocia compromises the welfare of affected sows, especially when it is not managed in an timely and expedient manner.

Dystocia usually is manifested by the failure to deliver piglets within an hour or 2 of the onset of labor or an interval longer than 1 hour between delivery of piglets within a litter. Other possible signs of dystocia may include prolonged gestation (beyond 116 days), illness of the sow (anorexia and depression), and discolored or fetid vulvar discharges.[3]

Dystocia is caused by conditions which obstruct or impede the passage of the fetus through the birth canal or by ineffective myometrial contractions (uterine inertia). Obstructive causes of dystocia may relate to the fetus, the maternal pelvis, or a combination of fetal and maternal factors. Primary uterine inertia (failure to begin the second stage of labor) is poorly defined but may be caused by hormonal or nutritional abnormalities of the sow. Uterine inertia more commonly is secondary to obstructive causes of dystocia. Abdominal pressing and myometrial contractions against an obstructed birth canal eventually result in fatigue and exhaustion both generally for the sow and specifically of the myometrium.

A mismatch between the size of the fetus and the maternal pelvis is a common cause of obstructive dystocia. In a normal presentation, the shoulders are the largest part of the fetus. If the fetus is especially large or if the maternal pelvis is especially small, the fetus may become lodged at the shoulders in an otherwise normal presentation. Fetuses tend to be larger when the number of piglets in the litter is few. Fetal anomalies, though rare, may result in abnormally large piglets. Maternal pelvic size is smaller in gilts than in mature sows. Some sows have a narrow, V-shaped pelvis (as felt by rectal or vaginal palpation) or lumps protruding into the birth canal from the pubic symphysis (W-shaped pelvis), both of which reduce the functional diameter of the birth canal. Old injuries, such as pelvic fractures, may have the same effect.

Other conditions unrelated to the bony structure of the maternal pelvis may reduce the functional diameter of the birth canal. Constipation or presence of excessive fecal material in the colon and rectum may result in partial occlusion of the birth canal. A full urinary bladder

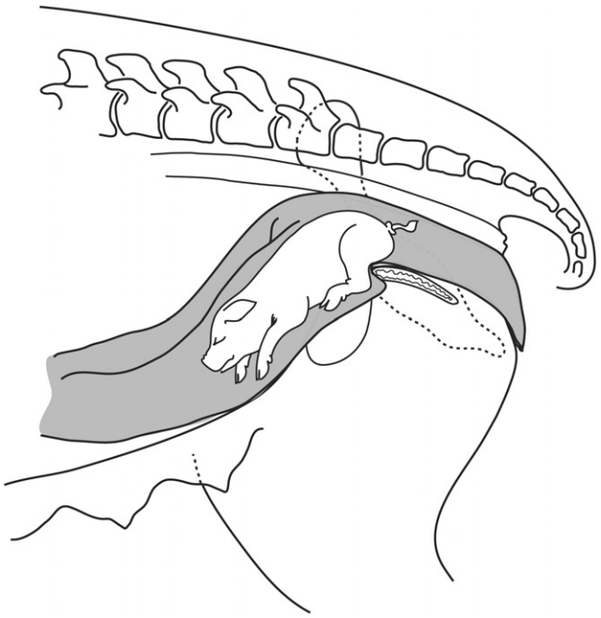

Fig. 103-3 Breech presentation of piglet.

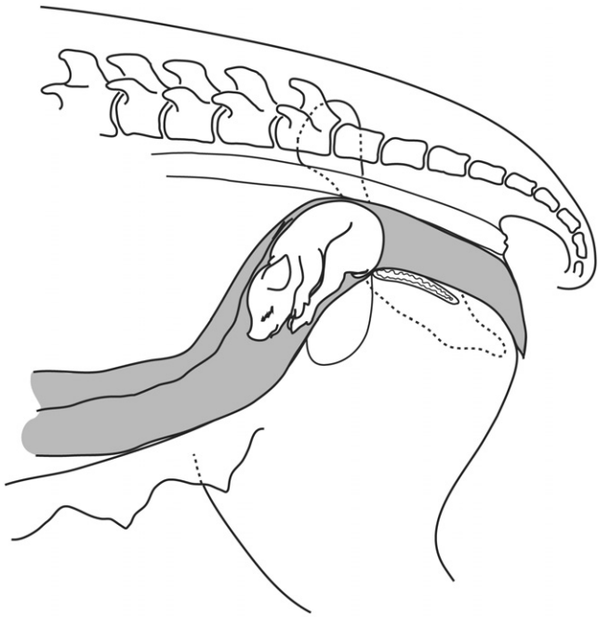

Fig. 103-4 Transverse (sideways) presentation of piglet.

may have a similar effect. Obese sows may have fat deposits in the birth canal that decrease its diameter. Excessive manipulation and examination of the genital tract during dystocia may result in trauma and swelling of the vaginal tissues, particularly if these procedures are performed with inadequate lubrication and gentleness. A persistent remnant of the hymen also may partially occlude the birth canal.

Abnormal posture or presentation of the fetus in the birth canal also may cause obstructive dystocia. In the breech presentation (Fig. 103-3), the fetus is proceeding backward or tail first through the birth canal. This differs from the normal caudal presentation in that the rear legs are flexed forward. In this position, the fetal hocks often catch on the brim of the maternal pelvis, impeding normal delivery. Occasionally, the fetus presents in a transverse or sideways position (Fig. 103-4). In this presentation the body of the fetus is flexed at the backbone or side and this part of the fetus becomes lodged in the birth canal. In the poll presentation (Fig. 103-5), the fetus comes head-first through the birth canal; however, the neck is flexed such that the top of the head (or poll) becomes lodged in the birth canal. In older sows with large litters, the uterus sometimes will be pulled down along the ventral abdominal wall and form an S-curve, with the lower part of the curve going underneath the brim of the pelvis (Fig. 103-6). A fetus may become lodged in this curve underneath the pelvis. On occasion, two fetuses may present in the birth canal at the same time (Fig. 103-7). The maternal pelvis usually is too small to allow the passage of more than one fetus at a time.[3]

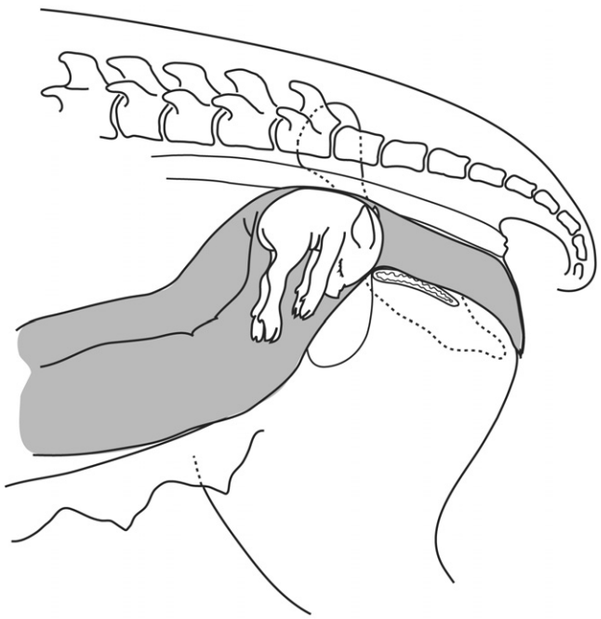

Fig. 103-5 Poll presentation of piglet.

Obstetric Intervention Strategies for Dystocia

Each farrowing enterprise should have a standard protocol in place for obstetric intervention. Although farrowing house personnel are expected to have primary responsibility for attending and assisting sows during parturition, the attending veterinarian should understand and have previously reviewed the protocol for that farm. This is especially important if the protocol includes the use of veterinary prescription drugs, such as oxytocin. Protocols may be individualized for each farrowing unit and should take into account the abilities and training of farrowing house personnel, the welfare of the sow, and the economic realities of intervention strategies.

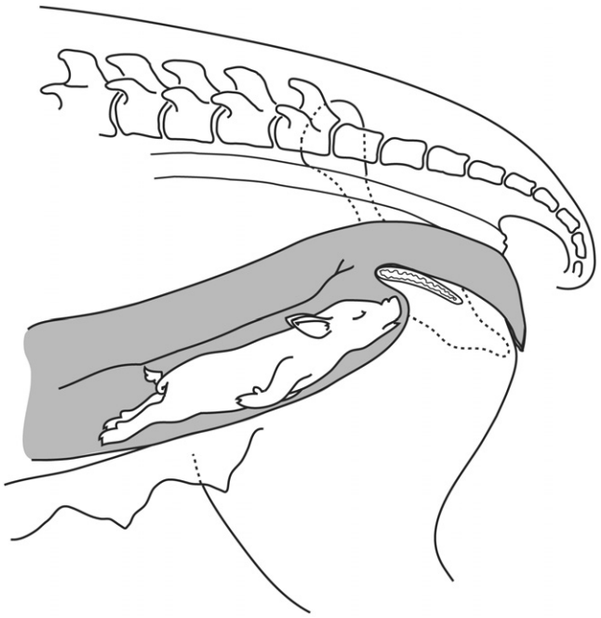

Fig. 103-6 S-curve in uterus of the sow.

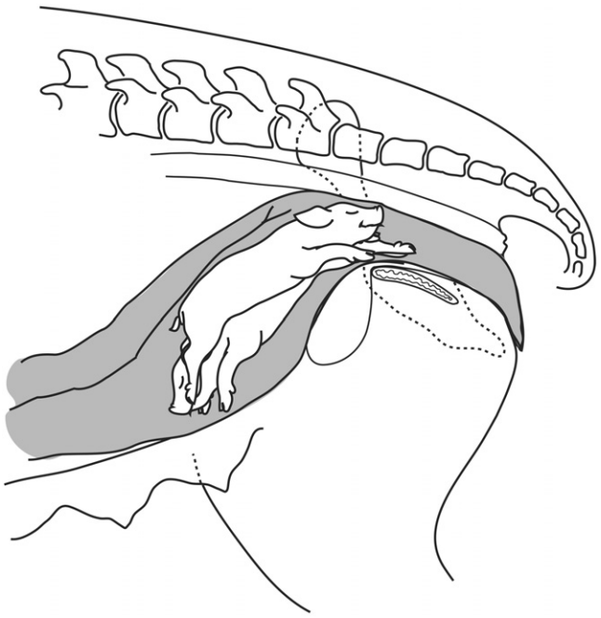

Fig. 103-7 Two fetuses presented at the same time at parturition in a sow.

The farrowing attendant should be observant and knowledgeable about the normal signs of impending parturition. Intervention should be considered if signs of parturition are evident (especially abdominal straining) and no piglet has been delivered for 45 minutes, or if the interval between the birth of piglets exceeds 45 minutes. Similarly, intervention should be considered if the gestation length exceeds 116 days, if the sow is near parturition and appears distressed, depressed, or anorexic, or if abnormal or malodorous vaginal discharges are noted.[3]

The first step of intervention should be a manual examination of the birth canal. The perineal area of the sow and the hands and arms of the attendant should be cleaned with water and antiseptic soap. The attendant should wear a disposable, shoulder-length plastic glove. The attendant's fingernails should be clipped short and the hands and arms should be free of watches or jewelry. A generous amount of obstetric lubricant should be applied to the gloved hand and arm of the attendant and to the vulva of the sow.

The two watchwords regarding obstetric intervention in sows are gentleness and lubrication. Violation of either of these principles can result in significant injury to the genital tract. Such injury may further decrease the probability of liveborn piglets and most certainly results in suffering for the sow. Farrowing attendants with small hands and arms have a distinct advantage when assisting sows with dystocia. Smaller hands can manipulate a fetus with greater dexterity in the limited space of a sow's genital tract and are likely to induce less traumatic injury to the sow.

The attendant should extend the fingers with the tips together so that the hand forms a cone and gently insert the hand into the vagina. The vagina normally courses dorsally from the vulva before passing through the pelvic inlet. Slow, deliberate, and gentle movements will minimize distress in the sow. An attendant with small or average-sized hands should be able reach through the birth canal and into the caudal parts of the uterus in a normal-sized sow. Factors associated with narrowing of the birth canal, such as constipation or a full urinary bladder, should be noted. Manual evacuation of the rectum or catheterization of the urinary bladder may be attempted if appropriate. Removal of the sow from the crate and mild exercise may encourage voluntary voiding of feces and urine.

If a fetus is encountered on manual examination of the birth canal, its position and posture should be determined. If the fetus is in a normal cranial or caudal presentation, the head or rear legs can be grasped by the attendant and gentle traction applied. This often will result in a successful delivery of the fetus. Deposition of obstetric lubricant in the birth canal with a flexible tube or bulb syringe often will make delivery easier and minimize trauma to the sow's genital tract. Abnormal presentations sometimes can be corrected by pushing the fetus farther into the uterus to create more room and then manipulating the fetus into a normal presentation. For example, the fetus in the breech position can be pushed forward and the rear legs grasped and extended into the birth canal, thereby converting the presentation into a normal caudal presentation. The fetus in the poll presentation can be pushed forward and the head and neck extended to result in a normal cranial presentation. Correction of fetal lie may be more difficult with the transverse presentation, but the principles are the same. The fetus is pushed forward and attempts are made to extend either the head or the rear legs into the birth canal.

Most dystocias can be relieved by manipulation and manual traction. In some instances, however, the fetus can be manipulated into a normal presentation, but room in the birth canal is still insufficient to allow passage of the fetus along with the attendant's hand grasping the fetus. In these cases, obstetric snares or forceps may be used. These instruments allow traction on the fetus without adding significantly to the mass or diameter of the fetus. The attendant should be trained in the use of these instruments, or call someone who is trained in their use, to avoid unnecessary injury to the sow or piglets. These instruments allow a great amount of extractive force to be applied and can severely damage the fetus and the sow's genital tract. Copious amounts of lubricant deposited directly into the birth canal and a gentle touch are essential in using these instruments.

An obstetric snare is a smooth wire cable with a loop on the end (Fig. 103-8). The loop can be worked around the head, snout, or hips of the fetus and tightened for a firm grip. A popular pig obstetric forceps consists of two hinged stainless steel rods formed into a handle at one end and a half-moon or semicircular clamp at the other end (Fig. 103-9). The clamping end can be opened on the hinges and worked around the head or hips of the fetus. Then, as the handles swing together, the half-moon clamp closes to firmly grip the fetus. Other clamps and forceps are available but tend to induce more trauma to the fetus than that associated with use of the snare or half-moon forceps.

If a fetus cannot be manipulated into a normal delivery position or extracted through the vagina, then the only remaining options are cesarean section and euthanasia of the sow. The decision between these options must take into account the welfare of the sow and the economic impact of each option. Delaying this decision probably will result in the death and putrefaction of the fetuses remaining in the uterus, with resulting exhaustion, toxemia, circulatory collapse, and death of the sow occurring during the next few hours to days. Therefore, delaying the decision is clearly not in the best interest of the welfare of the sow. Although a decision for euthanasia is onerous and the task unpleasant, it is much superior to no decision at all.

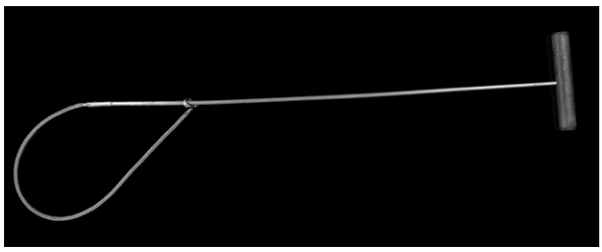

Fig. 103-8 Obstetric snare.

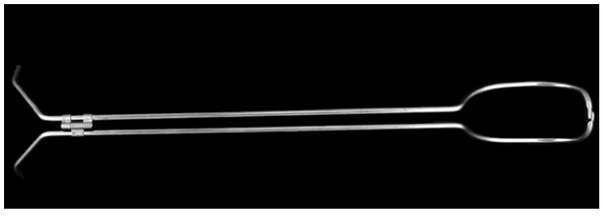

Fig. 103-9 Half-moon obstetric clamp

If a fetus is not encountered on manual examination, then the attendant must determine if (1) the sow is not actually ready to farrow, or (2) the sow is farrowing but the fetuses are farther down in the uterine horns and out of the reach of the attendant, or (3) the sow has completed the farrowing process. If the sow is not ready to farrow, the attendant will encounter a closed cervix approximately 12 to 18 inches inside the vagina. If the attendant's hand passes freely into the uterus, then either the sow has completed the farrowing process or more fetuses are out of the reach of the attendant.

Unfortunately, no practical and conclusive way exists to confirm that the farrowing process is complete. The horns of the uterus are too long to permit complete manual examination. Although radiography or abdominal ultrasound examination may reveal the presence or absence of more fetuses, these techniques are rarely practical on the farm. In most cases, the completion of farrowing is subjectively and fairly accurately assessed by considering the number of piglets born, the delivery of placentas, and the cessation of labor. A majority of sows will farrow at least 5 piglets and expel the placentas soon after the last piglet is born. Exceptions to both of these "rules" will be encountered, however.

Oxytocin is an endogenous pituitary hormone that stimulates myometrial contractions and milk letdown. Exogenous injections of oxytocin will have the same effect. The practitioner should never give injections of oxytocin without first performing a manual examination of the birth canal. Giving oxytocin to a sow with a closed cervix or an obstructive dystocia is ineffective and possibly dangerous. If the cervix is open, however, and no fetus is obstructing the birth canal, then an injection of oxytocin is indicated to stimulate uterine contractions and facilitate the movement of fetuses toward the birth canal. Dosages from 5 to 50 IU have been recommended, by either the intramuscular, subcutaneous, or intravenous route. The low to middle range of those dosages is effective and less likely to induce uterine tetany that is refractory to subsequent injections.[5]

Cesarean Section

Cesarean section offers a reasonable prognosis for survival of the sow and a potential for liveborn piglets if performed within a few hours of the onset of labor. Prognosis declines dramatically as time elapses and the sow shows signs of toxemia and shock. A decision for cesarean section should take into account the condition and prognosis of the sow, the availability of a capable veterinary surgeon within a reasonable time frame, the availability of a reasonably sanitary place to perform the surgery, the costs of surgery, the potential future or salvage value of the sow, and the value and probability of liveborn piglets.

Cesarean section must be performed with use of a local or a general anesthetic technique, or both in certain

instances. The administration of lidocaine into the lumbosacral epidural space will provide analgesia to structures caudal to the umbilicus. The recommended dosage is 1 ml of 2% lidocaine for each 9 kg of body weight, up to a maximum of 20 ml.[6] Alternatively, lidocaine may be infiltrated into the subcutaneous tissues along the incision site. Injectable sedatives or anesthetics usually are indicated to reduce apprehension and mobility of the sow. A number of injectable anesthetic protocols are described.[6] My preference is a combination of xylazine, ketamine, tiletamine, and zolazepam at a concentration of 50 mg/ml for each drug given, either by intramuscular or intravenous injection, to effect the desired level of sedation or anesthesia. This mixture is prepared by adding 2.5 ml each of 100 mg/ml ketamine and 100 mg/ml xylazine to a vial of dry, unreconstituted tiletamine-zolazepam preparation (Telazol*). A dosage rate of 1 ml/13.6 kg (30 lb) has been suggested[7]; however, lower doses may be effective if local anesthetics also are used. None of the suggested injectable anesthetics is currently approved by the United States Food and Drug Administration for administration to swine. Precautions appropriate for extralabel drug use, including extended preslaughter withdrawal times, should be observed. Intravenous administration of isotonic fluids such as saline or lactated Ringer's solution through a catheter in an ear vein may be beneficial, especially in those sows experiencing circulatory compromise due to toxemia.

The sow should be restrained in either right or left lateral recumbency. The uppermost rear leg should be pulled up (adducted) or caudally to expose the lower flank. The surgical site should be prepared in accordance with standard aseptic technique. A 20- to 25-cm incision is made slightly dorsal and parallel to the udder and underneath the fold of the flank. The incision is extended through the skin, subcutaneous tissues, abdominal musculature, and peritoneum. A gravid uterine horn is located and exteriorized and laid on a sterile drape or plastic sheet. A longitudinal incision is made in the uterine horn midway between the ovary and the bifurcation of the uterus. Ideally, all fetuses in one uterine horn can be delivered through a single incision; however, multiple incisions occasionally are necessary if the fetuses cannot be manipulated toward the incision site. The uterus should be carefully examined to ensure that no fetuses have been overlooked. Fetuses located near the bifurcation of the uterus are especially easy to overlook. When all of the fetuses have been removed from the horn, the serosal surface is rinsed with sterile isotonic saline and closed with a continuous inverting suture pattern using absorbable suture material. The procedure is repeated with the opposite uterine horn. The peritoneum and abdominal musculature are closed with absorbable suture material using a pattern of the surgeon's choice. The skin may be closed with a nonabsorbable suture material using an external pattern or with absorbable suture material using a subcuticular pattern. The latter choice obviates the need for suture removal 10 to 14 days later. Oxytocin may be administered postoperatively to enhance uterine contraction and evacuation. Systemic antibiotics may be administered if contamination from the environment or from putrefying fetuses is believed to be a problem.[6]

If a decision for cesarean section cannot justified on the basis of welfare or economics, then euthanasia should be promptly performed. Recommended procedures for on-farm euthanasia of swine have been published in a brochure available from the National Pork Board and the American Association of Swine Veterinarians.[8]

PHARMACOLOGIC INDUCTION OF FARROWING

Most sows normally will farrow within 2 days of a mean gestation period of 115 days (measured from the first day of estrus). A narrow time window of farrowing is helpful in scheduling the use of facilities and in ensuring that attendants are available to assist if necessary when the sow is farrowing. Although synchrony of breeding is the most important method in limiting the time window for farrowing, pharmacologic induction of farrowing can add further precision to the time of farrowing.

The administration of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) or an analogue will safely and effectively induce farrowing in sows after day 110 of gestation. Most sows will begin farrowing between 20 and 36 hours after $PGF_{2\alpha}$ administration. Therefore, if the objective is to have a majority of sows farrowing during a typical 8 AM to 5 PM workday, when attendants will be available, administration of $PGF_{2\alpha}$ should occur the previous morning. Few adverse effects are observed if sows are at least 111 days into gestation. If sows are at less than 110 days of gestation when treated, piglet viability will be compromised. Therefore, accurate breeding records are essential when pharmacologic induction of farrowing will be used.[5]

The only prostaglandin compound currently approved in the United States for the induction of parturition in swine is dinoprost tromethamine (Lutalyse*). A dose of 10 mg given by intramuscular injection to sows within 3 days of expected farrowing is indicated for induction of farrowing. This drug is available only by the prescription of a licensed veterinarian. Care should be exercised to avoid human exposure to this drug because injection or cutaneous exposure may result in bronchospasm or abortion. Although experimental data for prostaglandin analogues such as cloprostenol suggest safety and efficacy, these compounds are not approved for use in the United States.

Synchrony of farrowings is increased when oxytocin is given to sows 20 to 24 hours after administration of $PGF_{2\alpha}$. Injection of 5 to 30 international units (IU) of oxytocin 20 hours after $PGF_{2\alpha}$ injection will result in farrowing in a higher percentage of sows in the next 6 hours than if $PGF_{2\alpha}$ is given alone. Therefore, a reasonable protocol for induction of farrowing would include the injection of $PGF_{2\alpha}$ at noon the day before the targeted farrowing date and injection of oxytocin at 8:00 AM on the targeted farrowing date. Although oxytocin adminis-

tration at the higher end of the dosage range (20 to 30 IU) is more effective for synchronizing farrowings, these doses may induce uterine tetany and fatigue. The result would be a higher percentage of sows requiring obstetric intervention and a higher risk of stillbirths in the piglets and of genital injury and infection in the sow. Therefore, if oxytocin is included in the protocol for induction of farrowing, doses at the lower end of the range (5 to 10 IU) are recommended.[5]

CHAPTER 104

Postpartum Care of the Sow and Neonates

THOMAS J. FANGMAN and SANDRA F. AMASS

Swine production managers today find both personal and financial satisfaction in maintaining a comfortable and sanitary environment for the sows and pigs under their care. This requires the manager to be particularly attentive to the comfort of individual sows, which includes monitoring feed and water intake and environmental conditions. Profit and productivity depend on ensuring that piglets receive adequate colostrum and milk so that a large number of healthy pigs can be weaned from each sow that farrows.[1]

GESTATING FEMALE CARE

Ensuring that gestating gilts and sows are comfortable and adequately fed facilitates the farrowing event. The gestating sow should be fed to maintain good body condition without overconditioning (obesity). The gestation ration formulated for sows must be balanced to provide the daily nutrient requirement of sows as they progress through the stages of pregnancy. Gilt gestation rations should be optimized to provide adequate protein, energy, calcium, and phosphorus for growth of the gilt and her unborn litter.

Nutrient restriction is used to optimize weight gain in sows. Today's National Research Council (NRC) requirements for gestational sows utilize many factors to consider weight gain.[2] This weight gain is influenced by the gestating sow's requirement for energy, maintenance, protein accretion, fat accretion, products of conception, and thermoregulation.

Amino acid requirements of gestating sows are influenced by their maintenance requirements, protein deposition in proteinaceous tissues, and protein deposition in the products of conception. Folic acid and biotin can be used to supplement gestation rations for increasing the number of liveborn pigs.

Water should not be restricted for gestating females. Low water intakes can predispose female pigs to cystitis.

Use of gestation crates enhances body condition by allowing individual females to be fed according to their

CHAPTER 104

Postpartum Care of the Sow and Neonates

THOMAS J. FANGMAN and SANDRA F. AMASS

Swine production managers today find both personal and financial satisfaction in maintaining a comfortable and sanitary environment for the sows and pigs under their care. This requires the manager to be particularly attentive to the comfort of individual sows, which includes monitoring feed and water intake and environmental conditions. Profit and productivity depend on ensuring that piglets receive adequate colostrum and milk so that a large number of healthy pigs can be weaned from each sow that farrows.[1]

GESTATING FEMALE CARE

Ensuring that gestating gilts and sows are comfortable and adequately fed facilitates the farrowing event. The gestating sow should be fed to maintain good body condition without overconditioning (obesity). The gestation ration formulated for sows must be balanced to provide the daily nutrient requirement of sows as they progress through the stages of pregnancy. Gilt gestation rations should be optimized to provide adequate protein, energy, calcium, and phosphorus for growth of the gilt and her unborn litter.

Nutrient restriction is used to optimize weight gain in sows. Today's National Research Council (NRC) requirements for gestational sows utilize many factors to consider weight gain.[2] This weight gain is influenced by the gestating sow's requirement for energy, maintenance, protein accretion, fat accretion, products of conception, and thermoregulation.

Amino acid requirements of gestating sows are influenced by their maintenance requirements, protein deposition in proteinaceous tissues, and protein deposition in the products of conception. Folic acid and biotin can be used to supplement gestation rations for increasing the number of liveborn pigs.

Water should not be restricted for gestating females. Low water intakes can predispose female pigs to cystitis.

Use of gestation crates enhances body condition by allowing individual females to be fed according to their

needs. Pen gestation can result in variable body condition when smaller females cannot compete for feed. These pigs lose weight, whereas dominant females tend toward obesity.

In some production systems, protection of neonatal pigs from infectious diseases (e.g., infection due to *Clostridium* spp. or *Escherichia coli*) is required. To this end, generally the pregnant females are vaccinated once at 4 to 6 weeks and again at 2 weeks before farrowing for neonatal diseases endemic to the herd. Protection from pathogens can be partially controlled by ensuring that piglets receive high levels of protective immunoglobulins from the colostrum of their dam.

Controlling external and internal parasites commonly involves treatment of the sow approximately 2 weeks before farrowing to prevent pigs from being infected by their dams and to avoid contamination of the farrowing crate with expelled parasite eggs or larvae. Gestating females need to be identified, and individual sow records should be located in close proximity to the sow. Good records will ensure that sows are moved to the farrowing room 1 to 3 days before parturition. Extremely high piglet mortality is observed when litters are born in the gestation barn. The typical gestation length ranges from 113 to 117 days in most herds.

Pig flow can become uneven when management abandons an all-in–all-out strategy, resulting in insufficient time to sanitize the farrowing room. Farrowing in the gestation barn may occur with increased frequency, especially if the number of sows farrowing is large.

Gilts may require 3 to 4 days to adapt to the farrowing crate. This additional adaptation time may prevent agitation in gilts and reduce the incidence of piglet crushing and savaging.[3]

All sows entering the farrowing house should be examined, with particular emphasis placed on the underline of the sow. Damaged mammary glands or inverted nipples should be noted and recorded, because this information can be utilized in making cross-fostering and culling decisions.

It is tentatively assumed in the absence of convincing data that sows should be washed with soap or mild detergent and water to remove pathogen-containing manure before entry into the farrowing house. This assumption, however, requires further testing.

The farrowing facility generally is the most costly facility of the production system and requires the greatest labor specialization. Therefore, many production systems will have less than 48 hours to clean rooms in between groups, even though a longer time between groups may reduce contamination by bacterial pathogens in the barn. Sanitation of the farrowing facilities is crucial to preventing neonatal pig scours. To minimize neonatal disease, farrowing facilities should be managed on an all-in–all-out basis to allow thorough cleaning, disinfecting, and drying between groups.

Using flooring that provides a high proportion of open space to solid space that is easy to keep clean and dry can minimize pathogen exposure.[4] This flooring generally is made of cast iron or steel rods that may be coated. Plastic flooring also is used. Utilization of cast iron or steel flooring under the sow and plastic-coated wire or plastic flooring in the creep area can improve piglet comfort and decrease preweaning mortality by keeping the sow cool and piglets warm. Piglets will avoid being laid on by the sow by staying away from the "cool" sow flooring.

The number of sows that can be farrowed at any given time often limits the number of pigs produced. The number of pigs weaned per farrowing crate is a good measure of how a farrowing facility is being utilized. Farms weaning pigs before 21 days of age should have a goal of 140 pigs or more weaned per farrowing crate per year, or 9.5 weaned pigs per sow.[5]

CARE OF THE SOW AT FARROWING

Paying particular attention to the comfort of the sow at farrowing is paramount to the profitability of a production facility. Good animal husbandry skills are rewarded at this phase of production by increased sow survivability and employee satisfaction. Farrowing is a time of high risk for sows. It has been observed that 42% of sow deaths occur during the peripartum period, and an additional 16.5% of sow death loss occurs during lactation.[6] During the peripartum period, sows are prone to specific disease conditions, such as mastitis and metritis, that may lead to lactation insufficiency. Heat stress is common in sows during the hot months of summer, resulting in a seasonal increase in death loss. Uterine prolapse in the sow is rare but often is fatal; it accounts for less than 7% of all sow death losses.[6]

As the sow begins parturition, she will become partially or completely anorectic for several hours before and after parturition. Respiratory rate will increase 30 to 80 minutes before parturition to 95 to 105 breaths per minute (normal 13 to 18 per minute) and rectal temperature has been observed to increase from 38.7° to 40.0°C 24 hours before farrowing. Pigs are usually born at 15-minute intervals. Intervention is recommended if the farrowing interval is longer than 1 hour between pigs. The most common cause of dystocia is uterine inertia; however, sows should be manually examined using a hygienic technique before any treatments are administered. Oxytocin can be administered at a dose of 5 to 10IU every 2 to 4 hours to control uterine inertia after it is established that a piglet is not lodged in the birth canal. Larger doses of oxytocin can inhibit the desired effect.

Good animal husbandry practices include the following:

- Minimizing loud or sudden noises or disruptive activities around sows, especially piglet processing and castration in adjacent farrowing crates
- Ensuring the comfort of the sow, which may require drip cooling during the summer months
- Encouraging the sow to stand and drink water when it is apparent that farrowing is completed and the placentas have been passed
- Providing a farrowing crate design, particularly for the lower portion of the crate, that does not

interfere with the sow's ability to rise and lie down or obstruct the upper row of teats

POST-FARROWING CARE OF THE SOW

When the sow stops straining and begins to demonstrate an interest in her litter, the farrowing attendant can assume that farrowing is complete. Complete expulsion of the fetal membranes and placentas is the final phase of parturition, however. The time required for expulsion of the fetal membranes may range from 20 minutes to 12 hours after the last pig is born. Retained placenta occurs rarely in sows. Failure to find the placentas in the farrowing crate 4 to 12 hours post partum suggests the presence of another pig in the birth canal, and a vaginal examination is indicated. Sows that continue to strain, have a malodorous and discolored vulvar discharge, or show signs of depression or weakness also should be vaginally examined for retained pigs.

Many sows are anorectic during parturition and may refuse to eat for the next 48 hours. Feed should be withheld from sows (or only a very small amount provided) the day of farrowing. Then feed can be increased to 4 pounds daily, plus 1 pound per pig per day for the first week, with an average intake of 10 to 12 pounds of feed per day. Water intake is essential for optimizing feed intake and milk production during lactation. Lactating sows will drink 4 to 5 gallons of water per day, and the recommended flow rate for nipple waterers is 2 quarts per minute.

The sow is continually available for suckling by the newborn pigs for the first few hours after parturition. This constant mammary stimulation results in a high level of circulating oxytocin and facilitates the piglet's ability to readily obtain colostrum. The sow generally is exhausted from parturition and demonstrates little interest in the piglets. During this time, however, some sows are observed to savage their newborn pigs. This condition tends to occur more often in primiparous sows, and the aggressive behavior is often directed toward the first-born piglet. Separation of the piglets from the sow until farrowing is completed usually is all that is required to calm a sow that is savaging her piglets. On some occasions a sow may require sedation before accepting her piglets or fostered piglets. The sow's udder should be inspected for color, consistency, heat, and lesions likely to be associated with pain at this time to determine if the sow is suffering from mastitis or any other puerperal disease condition.

Approximately 24 hours after birth the sow will begin to actively encourage the pigs to nurse by grunting and positioning her mammary glands so that the nipples are available for suckling. Cyclic nursing begins at this time, and milk letdown occurs approximately every hour for a period of a few minutes.

POST-FARROWING CARE OF THE NEONATAL PIG

Newborn pigs require immediate energy intake and must be provided a microenvironment that is draft free and dry with a temperature of at least 30°C.[7] Heat loss can be reduced if piglets are dried at the time of birth or shortly after by temporary placement of an additional heat lamp at the rear of the crate. Piglets acquire immunoglobulins from colostrum. It is imperative that newborn pigs suckle within the first few hours after birth. Colostral immunoglobulin G (IgG) levels drop by 50% within 6 hours of the first nursing; late-born piglets may receive significantly lower levels of passive immunity than littermates born earlier in the farrowing order.[8] When the piglets are 24 hours old, the small intestine loses its ability to transport immunoglobulins (macromolecules) to the lymphatic system, and "gut closure" occurs. It is a good practice to collect excess colostrum from newly farrowed sows and store it in the freezer for the purpose of supplementing weak or orphaned piglets.

As piglets are born, an effort should be made to dry each animal and dip the umbilical cord into a mild disinfectant solution. Clipping of needle teeth usually is performed to reduce damage to the sow's underline and to minimize wounds sustained by piglets when fighting to establish dominance. Some producers in Europe and the United States do not clip needle teeth and observe no adverse effects. The decision to clip needle teeth will vary according to farm-specific conditions. Piglets should be allowed to suckle colostrum before their teeth are clipped. Further piglet processing usually occurs at 3 to 5 days of age. Processing tools should be sharp and should be disinfected in between litters. Sick litters should be processed last.

Pigs have a limited iron supply at birth, and sow's milk provides very little iron. Without iron supplementation, piglets will develop a microcytic anemia within 2 weeks of birth. To prevent microcytic anemia in piglets, it generally is recommended to administer an intramuscular injection of 200 mg of iron dextran in the neck of each piglet within the first 5 days after birth.

Taildocking often is performed at the same time the iron is administered so that any pigs that have not received an iron injection can be easily identified. Tails can be trimmed with side-cutting pliers to a length of about 2 cm from the body. Taildocking is performed to reduce the incidence of tail biting in the grow-finish stage of production. Ear notching or tattooing also can be performed before the pig reaches 5 days of age. Male pigs should be castrated between 5 and 14 days of age.[9]

Cross-fostering is the practice of moving pigs between litters to achieve uniform weight and to ensure that adequate functional teats are available to the number of pigs suckling. This practice is particularly important for sows with pendulous udders, which may not be able to expose the bottom row of teats to their piglets. Pigs should be moved from one litter to the next within the first 24 hours after birth so that the fostered pig can receive colostrum from its new dam. Care should be taken to avoid placing all small pigs on primiparous sows because the small pigs may not provide the young sow with aggressive-enough stimulation to ensure oxytocin release. Pigs can be bottle-fed, or mechanical feeding systems can be used. Feeding pigs milk replacers requires a great deal of additional labor to maintain a high level of sanitation of the equipment. Cost and labor considerations should be thoroughly evaluated before any decision regarding acquisition of a mechanical feeding system.

Providing additional attention to individual pigs can be rewarding. Warming individual pigs that become chilled or have limited mobility and providing nourishment by means of a stomach tube can give them a head start before they are placed with their littermates.

Splay-legged piglets can be assisted by providing support tape between their two rear legs. This tape should allow the animal to walk with short steps and can be removed in 2 days, allowing the pig to stand without assistance.

REDUCING PREWEANING MORTALITY

Significant improvements in management and housing have reduced baby pig mortality on many farms. From 15% to 25% of all piglets die during farrowing or within the first few weeks of life, however.[10] The death loss from birth to weaning is one of the major contributing factors limiting herd productivity and profitability.[10] Causes of neonatal mortality are tightly interlinked. Major death losses due to crushing and starvation probably reflect a variety of etiologic factors. Piglet losses tend to be the result of noninfectious causes and are strongly associated with management practices. Epidemics of certain neonatal diseases can occur and may result in extremely high mortality rates for limited periods of time. The most common causes of neonatal death include stillbirth, trauma, low viability, chilling, starvation, and diarrhea.

Most piglets that are born dead die of anoxia caused by premature rupture of the umbilical cord. Some decrease in blood flow to the fetus is common during normal uterine contractions at farrowing. More serious reductions can occur through damage or occlusion of the umbilicus, or with placental detachment. The resulting hypoxia can result in stillbirths and reduced postnatal viability. Hypoxia increases the amount of time between birth and first suckling and is associated with hypothermia, reduced postnatal growth, and higher neonatal mortality rates. Stillbirths are more common with older sows and among large litters and the last pigs born in a litter.[11] The number of stillborn pigs at each farrowing may vary, ranging from 5% to 10%, but can be higher on occasion. Manual intervention during prolonged farrowings is the most effective means to reduce the incidence of stillbirths. Such intervention should be conducted in a sanitary fashion and with a gentle touch, however, to avoid trauma to the sow. Females can be induced to farrow so that the number of observed farrowings is increased, and assistance provided when necessary.

Low birth weight is the greatest contributing factor to low viability of piglets. Approximately 30% to 40% of pigs that weigh less than 900 g at birth die during the first 3 weeks of life. In some production systems, a management decision is made to remove these very small piglets from the system. If it is determined to be feasible to raise these small pigs, then an intensive postnatal management plan will need to be instituted. This plan should include drying the piglets quickly after birth and moving them to a heat source to conserve their scarce energy reserves. Small, weak pigs may need assistance to nurse or may require colostrum and milk given by a stomach tube. A synchronized farrowing schedule combined with a proper cross-fostering program within the first 24 hours after birth will ensure litters of even weights and appropriate numbers for the nursing capacity of the sows. Placing all small pigs on a gilt or first-parity sow should be avoided because these piglets may not be strong enough to aggressively stimulate the dam's mammary gland, resulting in decreased milk letdown.

Chilling results when the environmental temperature drops below the pig's lower critical temperature and the animal must increase its metabolic rate. This critical temperature for baby pigs has been determined to be 34° C.[7] The pig's viability, activity, and vigor are greatly reduced when its core body temperature drops 2° C below this critical temperature. This chilling effect is observed more frequently in smaller pigs because they have a greater surface area–to–body weight ratio, resulting in greater heat loss. Air drafts of any kind must be minimized, because exposure to drafts will further reduce the effective temperature of the pig's environment. Cold pigs will not suckle and will subsequently die from hypoglycemia.

Neonatal pigs instinctively seek warmth at birth and often lie next to the sow's udder. A heat lamp placed behind the sow at farrowing is a good management practice to reduce chilling of wet newborn pigs. Placement of a heat lamp on either side of the farrowing crate encourages pigs to move away from the udder and reduces the number of pigs that may get laid on by the sow.[12]

Although slightly more males than females are born, females have a greater survival advantage than males.[13]

Sows lying on or crushing pigs is the most common cause of death in pigs in the first 3 days of life.[11] The incidence of crushing can be greatly reduced with the use of a well-designed farrowing crate. The crate design should encourage the sow to adopt a position of sternal recumbency before proceeding to lateral recumbency. Another important feature of crate design is nonslip flooring that will allow good mobility of the piglets and ensure that the sow can get up and down easily. Provide the sow with a comfortable resting environment and reduce sow irritation, anxiety and periods of restlessness by feeding at regular intervals (up to four times per day) and by avoiding loud or unfamiliar noises.

Infectious diseases of the alimentary tract are the most common type of disease in the suckling pig. Losses due to diarrhea can account for 5% to 15% of preweaning deaths.[14]

Enteropathogenic *E. coli* is the most important infectious cause of disease in neonatal pigs. These bacteria possess pili or fimbriae that enable the organism to adhere to the small intestines. Once *E. coli* has attached to the mucosa of the small intestine, it will induce hypersecretion of fluids and electrolytes by means of enterotoxins. Enteropathogenic *E. coli* infection can cause diarrhea in pigs by 12 hours of age. Control measures are directed at reducing piglet exposure to the organism through good hygiene and sanitation practices and by maximizing the passive immunity protection that piglets receive from sow's colostrum and milk. Effective commercial bacterins are available. Sows can be vaccinated before farrowing so that protective antibodies will be passed on to the piglets. Any disease in the sow that disrupts milk supply, such as mastitis (see Chapter 105), will

place the suckling litter at greater risk of infection by enterotoxigenic *E. coli*.

Coccidiosis in pigs is caused by *Isospora suis* and commonly is seen in pigs 7 to 14 days of age but can occur in pigs as young as 5 days of age. Mortality rate from coccidiosis usually is low, but diarrhea caused by this organism results in decreased growth rate and can affect a large number of the pigs exposed. Diagnosis can be made by identifying large numbers of *I. suis* merozoites in smears from intestinal mucosa. Control of disease due to this organism is best accomplished by strict sanitation measures including disinfection with 50% bleach and by using perforated flooring materials for raised farrowing crates. Currently, no coccidiostats are approved for use in swine in the United States.

Clostridium perfringens type C is regarded as an important swine pathogen in some production areas of the Midwestern United States. This organism classically will cause peracute enteritis in pigs that are 12 to 36 hours old; acute enteritis when pigs are approximately 3 days old; subacute enteritis when the pigs are 5 to 7 days old; and chronic enteritis when pigs are 1 to 3 weeks old. Lesions range in nature from severe hemorrhagic scours in peracute cases to thickened bowel with a diphtheritic membrane in chronic enteritis. Antibiotic therapy, antitoxin, and vaccination can be used in control programs combined with strict sanitation measures.

Viral diarrhea of piglets often is associated with a very sudden and dramatic increase in preweaning mortality rates and also can be a cause of endemic disease losses. Common viral etiologic agents include transmissible gastroenteritis (TGE) virus, porcine epidemic diarrhea virus, and rotavirus. Disease due to these viruses should be suspected whenever the small intestine of a suckling pig is thin and pale. An epidemic of TGE infection is characterized by vomiting and diarrhea affecting all pigs from 2 days of age to adult, with the greatest morbidity and mortality observed in the youngest animals exposed. Natural infection provides an extended high level of immunity in adult swine. Immune sows can protect their pigs with antibodies in colostrum and milk. In herds in which transmissible gastroenteritis is enzootic, vaccination of the sow before farrowing sometimes can help protect suckling pigs.

Systemic infections represent only a small proportion of death loss in neonatal pigs. Streptococci and *E. coli* are the main bacterial causes of septicemic disease during the neonatal period. Polyarthritis commonly leads to failure to thrive and may occasionally be a cause of death. Organisms commonly isolated from the joints of these pigs include groups C and L streptococci, *Actinomyces pyogenes, Staphylococcus* spp., and *E. coli*. Ensuring good colostrum intake by all pigs, ensuring ready access to milk throughout the nursing period, and hygienic processing procedures can prevent polyarthritis and systemic infections. Providing a clean and sanitary environment also will reduce the likelihood of systemic disease. Treatment with antibiotics can be successful if initiated very early in the course of the disease, but prevention through improved management is preferred.

Several important nonenteric viral diseases can affect suckling pigs. Porcine reproductive and respiratory syndrome virus (PRRSV) can cause death of affected piglets and is associated primarily with premature farrowings, weak-born pigs, and death loss due to respiratory disease (principally interstitial pneumonia) and secondary bacterial infections. Pseudorabies also can be an important cause of high piglet mortality during an acute outbreak but can be controlled by vaccination or natural immunity.

In addition to infectious agents, sudden increases in preweaning mortality rate can be caused by environment, husbandry, and nutritional factors. The most important factors to consider in dealing with an increase in preweaning mortality rate are the skill and attitude of the farrowing room stockperson. The best design features of a farrowing facility are those that make it easy for dedicated stock people to perform their duties to the best of their abilities.[15]

CHAPTER 105

Diseases of the Puerperal Period

THOMAS J. FANGMAN and MARCIA CARLSON SHANNON

Diseases of the puerperal period often have been referred to collectively as a syndrome consisting of **mastitis, metritis,** and **agalactia,** also known as the **MMA complex.** These three clinical entities can occur at the same time, but in many production systems it is common to see either mastitis or metritis followed by agalactia. Infections of the urinary tract also may lead to the production of endotoxins and serve as a source of bacteria that may lead to metritis and subsequent agalactia. Agalactia also has been be referred to as *lactation failure, postpartum dysgalactia,* and *preparturient hypogalactia syndrome.* The variety of names for this condition suggests a wide range of potential etiologic disorders, with variable levels of severity that may be unique to each production system.

A thoroughly cleaned and disinfected farrowing area that provides comfort to the sow or gilt is critical for preventing infections during the puerperal period, when these animals are tired and stressed from parturition. This period is characterized by an increased susceptibility to the development of cystitis, mastitis, metritis, and agalactia. Once the dam has become infected, the availability of milk to the litter will be reduced, with a consequent decrease in piglet survival.

This chapter reviews the potential causes of mastitis, metritis, cystitis, and lactational insufficiency syndrome, as well as the interactions among etiologic factors. Treatment and prevention protocols are described when appropriate.

COLIFORM MASTITIS

Mastitis describes any pain, swelling, or inflammation of the mammary gland. Coliform mastitis is an infectious condition caused by a variety of gram-negative organisms.[1] This condition is observed commonly in swine production systems. The increase in confinement housing during breeding, gestation, and farrowing has increased the comfort of the animal but also has increased the need for management practices emphasizing sanitation to reduce environmental bacterial exposure. Although *Escherichia coli* has been the most commonly encountered bacterial isolate in cases of coliform mastitis, other gram-negative bacteria such as *Klebsiella pneumoniae, Citrobacter freundii,* and *Enterobacter aerogenes* also have been suggested as possible pathogens.[1] Noncoliform organisms are occasionally isolated (*Staphylococcus epidermidis* or *Streptococcus* spp.). The small number of reported clinical cases involving gram-positive organisms, however, indicates that gram-negative bacteria are much more significant etiologic agents.[1] Systemic signs observed in mastitic sows are primarily the result of absorbed endotoxins and the formation of inflammatory endogenous mediators in the mammary gland.[2] Endotoxin has been observed to suppress the release of prolactin, resulting in a subsequent decrease in milk production.[3]

Epidemiology and Clinical Signs

Coliforms are part of the normal microflora of swine. These organisms have been isolated from udder, teat, urinary bladder, and uterine discharge.[4] Coliforms commonly are isolated from swine feces, suggesting that the source of infection may be from the sow or a contaminated, nonsanitized environment. Contamination of teats takes place within 2 hours after farrowing. Bacteria rapidly colonize the ductular or alveolar lumina of the mammary gland.

Clinical manifestations of coliform mastitis in sows include fever (40° to 42° C), anorexia, cachexia, malaise, and agalactia. The udder is erythematous and edematous. In severe cases of coliform mastitis, clinical signs may include induration and discoloration of the mammary glands, which may pit and blanch when digital pressure is applied. Sows may display behaviors indicative of high levels of pain when the gland is palpated. In some cases, constipation and mammary edema may be present. A purulent exudate often can be expressed from the nipples of affected glands, and single glands or gland complexes can be affected. Septicemia or toxemia may result in elevated respiratory and heart rates. Sows with coliform mastitis often lie in ventral recumbency and demonstrate a reluctance to allow piglets to nurse. This condition rapidly leads to lactation insufficiency, which is discussed in greater detail later in the chapter.

Diagnosis

Gross lesions of coliform mastitis are confined to the mammary gland and regional lymph nodes.[1] Postmortem findings include regional lymphadenopathy, and longitudinal sections of udders reveal scattered areas of firmness, which are gray to red in color.[1] Histologic lesions vary in severity within the same mammary gland, ranging from a small number of neutrophils in the alveolar lumina to severe purulent infiltration with necrosis. Inguinal and iliac lymph nodes may be affected with acute purulent lymphadenitis.[1] Laboratory tests used

for detection of mastitis in cows are not commonly employed in sows because of the naturally elevated cell count in sow's milk.[1] Culture of material from affected glands is difficult, and specimens are easily contaminated by bacteria on the skin of the sow or the practitioner. Contamination can be reduced by wearing sterile gloves or by surgical preparation of the udder with tamed iodine solutions. Samples should be inoculated onto sheep blood agar and MacConkey's agar and incubated for 24 hours at 37° C. Biochemical tests can be carried out to determine the identity of the organism isolated.

Treatment and Prevention

In acute cases of coliform mastitis, aggressive therapy is indicated. Antibiotic selection should be based on culture and sensitivity results. Response to antibiotics, however, is complicated by the heterogeneous pattern of antimicrobial susceptibility of individual isolates, not only within the herd, but also in the individual sow.[1] The pharmacokinetics of antimicrobials for mastitis therapy in swine has received only limited attention. Other compounds that may be administered in conjunction with antibiotics include prednisolone (50 to 100 mg), oxytocin (30 IU), and B vitamins to stimulate the appetite.[1] It also may be helpful to administer a prostaglandin synthetase inhibitor such as flunixin meglumine. Care of the piglets may require fostering or provision of a milk substitute (discussed later under Lactation Insufficiency Syndrome).

The best preventive measures include proper hygiene, especially removal of fecal material during and after parturition.[5] The farrowing room and sow area should be cleaned with hot water (temperature greater than 95° C), thoroughly disinfected, and allowed to dry before the sows are moved in. It is a good management practice to wash sows with a mild soap and water, with particular attention given to the mammary area, before entry into the farrowing room. If manual intervention is required during parturition, attendants should thoroughly wash their hands and arms, wear well-lubricated arm-length sleeves, and wash the perineal region of the sow before manually entry into the birth canal. All sows requiring manual assistance during parturition should be identified and treated with an effective antibiotic. Rectal temperatures should be taken two or three times a day after treatment. Those sows that demonstrate a rectal temperature higher than 40° C should be treated for 3 to 5 days.

Currently, no vaccines for prevention of mastitis are commercially available, and positive reports from the use of experimental products have been scarce. Accordingly, the most cost-effective measures for control appear to be the management factors described here.

METRITIS AND URINARY TRACT INFECTIONS

Metritis is characterized by inflammation of all layers of the uterus. Clinical signs of metritis are commonly seen 24 to 48 hours after parturition. The urinary tract may act as a source of endotoxins and bacteria that can infect the genital tract, leading to metritis.

Epidemiology and Clinical Signs

The same factors that predispose sows to the development of urinary tract infection also may increase their susceptibility to metritis. The numerous microbes that normally inhabit the porcine reproductive tract also can be found in swine manure and have the potential to be pathogens at parturition.[5] During gestation, the uterus is under the influence of high levels of progesterone secretions. This progesterone influence results in a closed cervix, generalized immune suppression, and an increased bacterial population.[6]

Contamination of the environment along with excessive microbial proliferation can result in infection of the uterus. Metritis also can be the result of overzealous infusion practices and excessive, unsanitary manual intervention during parturition.

Cases of metritis are characterized by a necrotic, malodorous discharge that frequently will contain remnants of fetal membranes. The sow often is anorectic, febrile, and septic. Septicemia in these cases often will result in death. Milk flow is minimal, and piglet mortality rate is increased.[5]

Diagnosis

Metritis can be readily diagnosed by the appearance of a vaginal discharge and the malodorous nature of this discharge. At postmortem examination, the uterine lumen may be filled with necrotic, yellow-brownish, purulent material.[5] Histologic evaluation generally will demonstrate edema and purulent exudate in several layers of the myometrium.[6] Colonies of bacteria may be evident microscopically as abscesses within the myometrium. Chronic cases are characterized by a diffuse infiltration of lymphocytes and denuded endometrial epithelium.[6] Culture of an affected uterus commonly results in isolation of *E. coli, Staphylococcus aureus,* or *Actinomyces pyogenes*.[5]

Material for uterine culture in a live animal is readily obtained if the cervix is patent. Culture specimens can be obtained using uterine swabs inserted through a vaginal speculum.[5] Reproductive slaughter checks also may serve as an opportunity to obtain tissue and bacterial isolates during an increased incidence of metritis. Vaginal cultures provide little information owing to the high level of contamination of this area with numerous species of nonpathogenic bacteria.[5]

Treatment and Prevention

Antibiotics for therapy of the infection should be selected on the basis of in vitro sensitivity and administered systemically. Intrauterine infusions of sodium penicillin or oxytetracycline produce satisfactory concentrations of these antibiotics in the uterine lumen. Intrauterine therapy is not widely accepted. Problems of uneven drug distribution exist. Some evidence also suggests that intrauterine infusion of antibiotics with a narrow spectrum of antibacterial activity has resulted in the elimination of an individual organism (such as *E. coli*), only to result in the abnormal proliferation of other bacteria,

which may prolong the required time for regeneration of the endometrial lining after parturition.[7]

The steps involved in the prevention of metritis are similar to those described for preventing coliform mastitis. Suspected cases of urinary tract infection or endometritis should be treated with an antibiotic selected on the basis of culture and sensitivity testing results, a history of effectiveness on the farm, or practice experience. The most important factor is proper hygiene before, during, and after parturition at a time when the cervix is open to pathogen invasion. It is critical to recognize that the fecal bacterial flora are the same etiologic agents of metritis.

LACTATION INSUFFICIENCY SYNDROME

Lactation insufficiency (LI) is a condition in which milk production and flow are inadequate to maintain the viability of the litter. This section focuses on the noninfectious causes of this syndrome and the effects of this syndrome on the pig. Rarely is there a total failure of lactation. Suboptimal milk production, however, is relatively common. Sows with generalized suboptimal milk production and individual gland mastitis will often raise normal litters, with one or two pigs that rapidly fall behind their littermates in development. Entire litters may linger without starving and dying but do not gain weight and grow as do other litters.

Epidemiology and Clinical Signs

Regardless of etiology, the primary clinical signs of lactation insufficiency are observed in the baby pigs, rather than the sow. Piglets become restless and hungry and rapidly lose body condition. Piglets will be vocal and nuzzle the udder aggressively. Eventually, they will become gaunt and dehydrated and die almost exclusively during the first 3 days of life.

The risk of diarrhea may be increased by 90% in litters for which milk production is suboptimal. In these cases, the causative organisms may be identified, but the underlying etiology is frequently not discovered.

Noninfectious causes of LI have traditionally been classified as heritable, nutritional, or endocrine imbalances and as those related to management or environment.[8] A genetic predisposition to LI is likely to exist but difficult to prove. Within breeds, certain lines or families of sows tend to demonstrate a higher incidence of LI. Those sows that are affected with LI once are more likely to have the same condition in subsequent lactations. Endocrine imbalances have been documented as contributing to LI. Such imbalances are more likely to occur as a result of endotoxemia, however, than as a primary cause of LI.

Ergot intoxication caused by *Claviceps purpurea* is rare but can result in LI in a group or herd of sows fed grains contaminated with this organism.

Other noninfectious causes of LI generally affecting individual animals include teat malformations (inverted nipples), psychogenic agalactia (pig savaging), and mammary gland edema.[8] The primary noninfectious categories of causes of LI are management/environment and nutrition/feeding.

More cases of LI are observed in sows that farrow and lactate on solid concrete floors. Sows that have difficulty farrowing, have large litters, or deliver mummified pigs are more likely to suffer from LI. Sows that are moved from a gestation pasture to a confinement farrowing facility immediately before farrowing, without an adjustment period, also are predisposed to the development of LI. Heat stress and other environmental stressors that decrease appetite also precipitate LI. A seasonal peak in the occurrence of LI also has been observed in the third quarter of the year in the United States.

Diagnosis

Clinical manifestation of disease in affected sows varies widely depending on the specific etiologic factors. Those cases that are caused by noninfectious agents are associated with few pathologic changes in the sow. In pigs the pathologic lesions will be characteristic of starvation. Lack of body fat, lack of digesta in the stomach and intestinal tract, and diarrhea often are features in pigs from affected litters.

Treatment and Prevention

Treatment of infectious cases of LI is directed toward the elimination of the cause, as well as alleviation of the clinical signs. Oxytocin (5 to 10 U) should be administered to stimulate milk letdown. This therapy can be repeated every hour for up to 6 hours, or at 2- to 4-hour intervals during the first day of treatment. Sows affected with LI thought to be of noninfectious origin should be treated with oxytocin initially. If mammary edema is present, a diuretic such as furosemide or a glucocorticoid may be indicated. Glucocorticoids should be avoided when coliform mastitis is suspected. Induction of parturition with prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) has been found to reduce the incidence of LI. It appears that $PGF_{2\alpha}$ induces an immediate increase in prolactin concentrations and may prevent premature mammary gland engorgement.

During the periods of agalactia, the piglets need particular attention. Energy-rich nutritional supplements and electrolytes should be administered, and if diarrhea is present, antibiotics should be administered. Piglets can be dosed with a stomach tube. Caution should be used to avoid causing aspiration pneumonia, however. Small amounts (2 to 5 ml) of supplement should be given every 1 to 2 hours until normal milk flow resumes.

FEEDING/NUTRITION

What happens in one phase of the sow's cycle influences her productivity in subsequent reproduction phases. For instance, a sow with low voluntary feed intake (less than 10 pounds/day) and nursing a large litter (more than 10 pigs) during lactation will lose body weight. This lactating sow will more than likely to wean a litter with a high weaning weight but more unlikely to rebreed promptly after weaning. Therefore, the sow's nutritional state in one phase of her cycle (lactation) influences the next phase of her reproductive cycle (rebreeding).

Gilt Development

A successful reproductive program begins early in the gilt's life to ensure complete preparation for a long productive life in the breeding herd. Feeding gilts for efficient, rapid lean gain allows accurate assessment of the female's growth potential and enables sufficient development of body tissues that will be needed later in her reproductive life. Beginning at 45 kg of body weight, dietary calcium and phosphorus should be increased by 0.1% above typical grow-finish diets to enhance skeletal development of gilts. The recommended dietary nutrient requirements for replacement gilts are a minimum of 0.8% calcium (18g/day) and 0.7% phosphorus (15 g/day).

Controlled growth is the target once females enter the gilt pool at about 150 days of age. Restricted feeding (2.3 to 2.8 kg) of a moderate-energy (3300 kcal ME/kg), high-protein (16%) diet will slow body growth and, more important, will reduce deposition of fat tissue while allowing continuous growth of lean body mass. In recent research, such a diet significantly increased the proportion of gilts that had a first litter and stayed in the breeding herd long enough to farrow a fourth litter.[9] Diets for females in the gilt pool contain the same vitamin and mineral fortification as in the diets for older sows in the breeding herd. Because feed intake is restricted in animals entering the gilt pool, gilts must receive a flushing level of feed intake 10 to 14 days before breeding to maximize ovulation rates. Feed intake needs to be reduced to pre-flushing levels immediately after breeding to avoid high embryo mortality rates common with high post-breeding feed intake.[9]

Feeding Strategies during Gestation

During gestation, the feeding and management practices focus on preparing the sow for parturition, fetal growth, and lactation performance. In the very early stages of gestation immediately after conception, the first objective is to provide conditions that will increase the likelihood of maximal survival of embryos and ensure a large litter size at the subsequent farrowing. Growth of the developing fetuses and increasing nutrient stores in the sow's body throughout growth toward mature body size, or replenishment of stores lost during the previous lactation, are the main objectives during mid-lactation (days 30 to 75). In late gestation, fetal growth continues at a very rapid rate, and mammary development occurs in preparation for the upcoming lactation. Growth of the products of conception is fairly resistant to nutritional manipulations at feed intakes typical of production settings during late gestation. Under conditions of adequate energy intakes (6 to 10 Mcal ME daily), changes in weight of fetuses at birth are relatively small and have little influence on body composition. Some research indicates that increasing energy feed intake of pregnant primiparous gilts increases total weight of fetuses at birth, but not in multiparous sows. The energy requirement for the products of conception has been set at 35.8 kcal ME daily for each fetus.[10] The desired outcome of a successful gestation feeding program is a large, vigorous litter of pigs and a healthy sow equipped with the adequate mammary development and body stores of nutrients to produce large quantities of the milk for the litter.

It has been well documented that excess energy intake during gestation decreases feed intake during lactation and causes a reduction in milk production and increased tissue catabolism. Several researchers have demonstrated the inverse relationship between feed intake during gestation and feed intake during lactation. As gestation feed intake increases, subsequent lactation feed intake decreases, and loss of body weight and backfat increases. The reduction in feed intake is thought to be due to reduced glucose tolerance and insulin resistance caused by excess feed intake during gestation. The decreased insulin resistance causes mobilization of stored nutrients and leads to high concentrations of circulating energy substrates in the plasma. Essentially, affected sows do not receive the metabolic signals that demand more nutrient intake. The reduction in feed intake is especially pronounced during the first week of lactation, a critical time for establishing milk production levels and subsequent reproductive function. Feed intake during gestation should be moderate (1.8 to 2.25 kg/day) to prevent depressed feed intake and excess tissue catabolism during lactation. Minimum daily allowances for amino acids, vitamins, and minerals must be maintained when energy intake is limited during gestation.

Calcium and phosphorus are very important to gestating sows for development of fetuses in utero and integrity of the sow's skeleton. A reduction in bone mineralization may compromise longevity of sows in the breeding herd owing to a higher incidence of crippling injuries and increased proportion of nonbreeders. Proper mineral nutrition during gestation can replenish bone mineral reserves that were depleted during lactation to satisfy the high mineral demands of milk production.[11] Daily intakes of 14 to 18 g of calcium and 12 to 16 g of total phosphorus during gestation seem to satisfy the reproducing sow's needs.

Mammary Development before Lactation

Body composition in late gestation may affect mammary development and ultimately milk production in the subsequent lactation. Very little mammary development occurs during gestation until day 75. After day 75, an exponential growth occurs in the concentration[12] and total quantity[13] of DNA and RNA in the mammary gland. DNA content is a measure of the total number of cells, whereas RNA content provides an indication of the protein synthetic capacity of a tissue. When dietary energy intake of gilts was increased from 5.75 to 10.5 Mcal ME daily after day 75 of gestation, a reduction in the weight and total DNA and RNA of parenchymal tissue in the mammary gland was observed, indicating that excess energy has the potential to reduce the capacity for milk synthesis.[13] Researchers reported that the percentage of protein, fat, ash, and DNA in each suckled mammary gland was affected only by total energy intake.[14] In contrast with the effects of elevated energy intake, altering protein intake of gilts during late gestation had no influence on mammary development.[13] Increasing lysine

intake from severely deficient (4 g/day) to liberal (16 g/day) concentrations[10] had no effect on number of milk-secreting cells in the mammary gland[15] but did increase milk production in the subsequent lactation.[16] As litter size increases, the total mammary gland weight and protein, fat, ash, and DNA contents increased, resulting in an additional required 0.96 g of lysine/day to account for the mammary gland growth for each pig added to a litter ranging in size from 6 to 12 pigs.[17] Therefore, providing adequate amounts of nutrients (energy and protein) to sows during lactation relative to litter size is important for achieving maximal growth of mammary gland and milk production. Ultimately, mammary gland growth is affected by nutrient intake during late gestation and early lactation.

Energy and Protein Needs during Lactation

Lactation is a particularly important stage of the reproductive cycle and ultimately places a tremendous nutrient demand on the sow. Lactating sows will produce milk quantities equal to 10% or more of their body weight daily. Therefore, the lactating sow produces as much dry matter output in 2 days as a pregnant sow produces in 114 days. Dietary nutrients need to meet the high milk production demand through either dietary intake or tissue catabolism. Proper nutrition is critical in order to avoid limiting milk production and to prevent excessive tissue catabolism, which can lead to poor reproductive performance after weaning. Long-term sow productivity depends on maintenance of body condition and ensuring optimal nutritional status relative to metabolic demand.

Energy intake during gestation is not a major cause of lactation failures, unless a severe energy deficiency occurs over an extended period of time. Inadequate energy intake during lactation, however, can reduce milk production and increase sow body weight loss. Increasing the energy density of the lactation diet (with supplemental fat) or increasing total feed intake can increase energy intake during lactation. The supplemental fat is used preferentially by the mammary gland to increase milk fat and increase litter weaning weight. Unfortunately, the added fat will not substantially reduce sow weight or backfat loss.

Lysine is the first limiting essential amino acid in most diets for lactating sows. The estimated total lysine requirements for the lactating sow range from 32 to 58 g/day. The amino acid requirements during lactation can be divided into the requirements for maintenance and the requirements for milk production. The maintenance requirement of the sow during lactation is relatively small. For example, an average lactating sow will require 2 to 3 g/day and 50 to 60 g/day of lysine for maintenance and milk production, respectively. The recommendations for amino acids are closely correlated with the level of sow productivity achieved, and lactating sows require 26 g/day of lysine for each kilogram of daily litter weight gain. These high amino acid requirements can be met only through nutrient intake and catabolism of body protein. Loss of body protein during lactation, however, may influence subsequent reproduction of sows.

Amino acid intake during lactation has a major impact on sow milk production and litter-weaning weight of primiparous sows.[18] It was not until recently that research indicated that increasing amino acid intake from 32.3 g/day to 73.3 g/day decreases voluntary feed intake during lactation and decreases subsequent litter size.[19] The lysine intake required to minimize protein loss (59 g/day) during the first lactation decreases subsequent total number of piglets born compared with the lysine intake required to maximize milk production (32 g/day). Thus, the goal during lactation is to feed adequate protein concentrations to maximize litter growth rate (44, 55, and 56 g/day lysine intake for sows of parity 1, 2, and 3, respectively) and only slightly reduce muscle catabolism. Overall, maximizing feed intake during lactation is critical to enhancing lactation performance and subsequent reproduction cycles.

Conclusions

An effective nutrition program for the sow herd must be based on sound nutritional principles. There are no "magic bullets" that allow producers to achieve high biologic performance while ignoring basic nutritional concepts. Every effort must be made to ensure that nutrient requirements are estimated accurately, feeding strategies are implemented properly, quality control programs are practiced, and results are monitored regularly. A sound feeding program begins early in the sow's life. Continual attention to specifics of the feeding program is necessary because nutrition in one phase of the reproductive cycle sets the stage for sow performance in the next phase of production. Many factors influence productivity of the swine breeding herd. Genetics, nutrition, health status, housing, and management all blend together to establish the level of productivity in a breeding herd. Just as factors interact to influence breeding herd productivity, phases of the sow's reproductive cycle interact. Any failures in the nutritional program of the breeding herd, however, could lead to increased incidence of diseases during the puerperal period.

CHAPTER 106

Bacterial, Rickettsial, Protozoal, and Fungal Causes of Infertility and Abortion in Swine

MONTSERRAT TORREMORRELL

Losses due to reproductive failure are high in today's swine industry. Many factors are involved in causing reproductive failure, including infectious agents, such as bacteria, viruses, protozoa, and fungi, and noninfectious factors, such as nutrition, genetics, environment, management practices, and husbandry procedures. This chapter reviews infectious causes of reproductive failure—primarily diseases caused by bacteria, protozoa, rickettsiae, and fungi. Such diseases have become less important in today's high-technology swine industry with the improvement of the sanitation procedures and the widespread use of artificial insemination. Some of the diseases discussed in this chapter are still considered important at the individual animal level and in specific herds, but for the most part such diseases are considered sporadic in the U.S. swine industry.

Bacteremias, septicemias, toxemias, and viremias exert their effects directly when microorganisms invade the bloodstream and pose a threat to the life of the conceptus or the dam, or indirectly through mechanisms to induce fever. The degree to which these diseases influence the conceptus depends on the stage of pregnancy and the virulence of the organisms. In order to understand the clinical signs associated with reproductive failure in swine, it is important to review some of the terminology used and understand the stages of embryo and fetus development. **Gestation**, which is the period between conception and parturition, lasts about 114 days in swine.

CHAPTER 106

Bacterial, Rickettsial, Protozoal, and Fungal Causes of Infertility and Abortion in Swine

MONTSERRAT TORREMORRELL

Losses due to reproductive failure are high in today's swine industry. Many factors are involved in causing reproductive failure, including infectious agents, such as bacteria, viruses, protozoa, and fungi, and noninfectious factors, such as nutrition, genetics, environment, management practices, and husbandry procedures. This chapter reviews infectious causes of reproductive failure—primarily diseases caused by bacteria, protozoa, rickettsiae, and fungi. Such diseases have become less important in today's high-technology swine industry with the improvement of the sanitation procedures and the widespread use of artificial insemination. Some of the diseases discussed in this chapter are still considered important at the individual animal level and in specific herds, but for the most part such diseases are considered sporadic in the U.S. swine industry.

Bacteremias, septicemias, toxemias, and viremias exert their effects directly when microorganisms invade the bloodstream and pose a threat to the life of the conceptus or the dam, or indirectly through mechanisms to induce fever. The degree to which these diseases influence the conceptus depends on the stage of pregnancy and the virulence of the organisms. In order to understand the clinical signs associated with reproductive failure in swine, it is important to review some of the terminology used and understand the stages of embryo and fetus development. **Gestation**, which is the period between conception and parturition, lasts about 114 days in swine.

In the first 2 weeks of life, the conceptuses lie free in the uterine lumen. Damage to them during this stage is almost always fatal.[1] **Implantation** begins around day 12 of gestation; death of the conceptus before then will result in resorption of the conceptus, and the sow will undergo a regular return to estrus at approximately 21 days. Death of the embryo before calcification, between approximately 14 and 35 days of gestation, will result in abortion or complete resorption of the embryo. A delayed return to estrus may be observed after 24 to 28 days, resulting in an irregular return to estrus.

Fetal death after day 35 typically is followed by mummification of the fetus, rather than pregnancy termination, because the mineral content of the fetus prevents complete absorption. Mummified fetuses are characterized by discoloration and resorption of fluids and soft tissues.[1]

Abortion refers to the delivery of an immature fetus, either live or dead, before the completion of the gestation period as a result of the failure of the mechanisms that control pregnancy. A **stillbirth** is a fetus that has matured fully in utero but is born dead. Stillborn piglets look normal, but their lungs do not float in water (respiration never occurred before death). Stillbirths may be caused by infectious agents; affected fetuses usually die before the end of gestation and around the **prepartal period.** Stillbirths also may be caused by noninfectious agents or conditions and are known as **intrapartum deaths.**[1] Most common noninfectious causes include hypoxia secondary to umbilical rupture or impairment of umbilical blood flow, high atmospheric carbon monoxide concentration, elevated temperatures (higher than 39° C) during farrowing, and prolonged parturition.[1] **Neonatal death** refers to that occurring primarily within the first 7 days of life. Death usually is due to events that take place during late gestation or shortly after parturition. In production records, neonatal death usually is captured within the preweaning mortality parameter.

Although a few bacteria such as *Leptospira* and *Brucella* are recognized to cause major reproductive economic losses, the reality is that in modern swine production systems these diseases are not significant, and they should be considered exceptional. On the other hand, sporadic losses due to infections caused by ubiquitous bacterial agents, often considered secondary to stresses and management practices, can result in significant economic losses because of the chronic nature and persistence of these diseases, which also typically are difficult to control and diagnose.

LEPTOSPIROSIS

Leptospirosis has been reported as a cause of reproductive loss in swine from all parts of the world.[2] Leptospirosis is caused by a variety of motile, aerobic spirochetes from the *Leptospira* genus. The leptospires that affect animal species (the parasitic strains) are grouped into about 23 serogroups containing approximately 212 serovars based on complicated agglutination reactions.[2] Reproductive signs in susceptible herds are characterized by abortion, birth of dead full-term piglets, weak-born piglets, and infertility.

Epidemiology and Clinical Signs

Leptospires persist in the kidneys and genital tracts of carrier swine. Shedding may occur intermittently for prolonged periods, for up to 2 years. Therefore, the primary mode of transmission of leptospirosis to pigs is through contact with voided urine from infected hosts. Contact of infected urine with the oral, nasal or ocular mucosa will result in a brief period of bacteremia of less than 10 days. During this time, bacteria can be isolated from most organs and fluids of the body, including the cerebrospinal fluid. Once the organism is cleared from the bloodstream, it will take up residence in the proximal tubules of the kidney.

Pigs act as maintenance hosts for serovars belonging to the pomona, australis, and tarassovi serogroups, whereas strains belonging to the canicola, icterohaemorrhagiae, and grippotyphosa serogroups are among the more commonly identified incidental infections in swine.[2]

Leptospira pomona has been the most common serotype isolated from pigs worldwide. Many strains of serovar pomona, especially those of type kennewicki, are adapted to pigs and have been found in the United States and Canada.[3] *L. pomona* is reported to be endemic in North and South America, Australia, New Zealand, and parts of Asia and Eastern and Central Europe, but not Western Europe. Many strains within the pomona serovar have rodent hosts. Transplacental infection occurring during the short period of maternal leptospiremia in the second half of gestation may result in abortion. Chronic leptospirosis also will result in stillbirths and weak-born piglets, with a majority of the fetuses in the litter being affected. *L. pomona* does not appear to cause infertility.

Leptospira bratislava serotype has emerged as a major swine-maintained leptospiral infection in the last few years. Serologic data have indicated widespread infection in Europe, United States, Australia, Brazil, and South Africa. The epidemiology is poorly understood, because evidently many strains are maintained in pigs, dogs, horses, and hedgehogs and other wildlife. Although the renal carrier state does become established, urinary excretion is poor compared with pomona excretion. By contrast, venereal infection is thought to play an important role in the spread of the disease because the bacteria are known to persist in the upper genital tracts of boars and the oviduct and uterus of sows.[2] Abortion caused by *L. bratislava* infection is the result of presence of the leptospires the genital tract. *L. bratislava* has been recognized as a cause of infertility.

The serotype icterohaemorrhagiae is carried by the brown rat *(Rattus norvegicus)*. Although serologic evidence of widespread infection has been reported in many countries, very few isolates are available from pigs.[4] Field investigations suggest that infection between swine is inefficient.[2] The duration of urinary excretion is short (less than 35 days) in naturally infected pigs. In acute episodes of infection, *L. icterohaemorrhagiae* will cause jaundice and hemoglobinuria in young piglets younger than 3 months of age. In chronic episodes, weak-born litters have been reported as a feature of *L. icterohaemorrhagiae* infection.[2]

The serotype grippotyphosa is maintained in wildlife, and swine are considered only an alternate host. Infection in pigs is considered incidental. Some serologic evidence of its presence has been reported in Eastern and Central Europe and the United States, but in general, this serotype is not considered a significant pathogen of swine.[2] Of interest, *L. grippotyphosa* was one of the most common serotypes recovered in a study involving Iowa herds.[3]

The serotype canicola has been recovered from swine in several countries. Little is known of its epidemiology in pigs, however. The dog is the recognized maintenance host for this serovar. *L. canicola* is excreted in pig urine for at least 90 days and has the ability to survive in undiluted urine for at least 6 days, suggesting that between-pig transmission could be possible, although no studies are available in this subject. This serotype can cause abortions, stillbirths, and periods of infertility.[2]

Published information is limited regarding the tarassovi, hardjo, and sejroe serotypes. The pig is considered to be the maintenance host for some of the tarassovi strains found in Eastern Europe and Australia. In the United States, *L. tarassovi* has not been recovered from swine, but serologic evidence of infection has been described in pigs of the southeastern states, where it has been isolated from wildlife (raccoons, skunks, and opossums).[2] *L. hardjo* is maintained worldwide in cattle.[2] The organism has been isolated in pigs in the United Kingdom and the United States. Between-pig transmission is considered to be irrelevant because persistence in renal tissue is very limited. Serovar sejroe has been isolated from swine in Europe and is mostly maintained by small rodents.[2]

Diagnosis

Lesions associated with leptospirosis infection are not serotype specific and are not considered pathognomonic.[2] The primary lesion is damage to the membranes of the endothelial cells of small blood vessels. Lesions are very limited in acute leptospirosis. Petechial and ecchymotic hemorrhages can be seen in the lungs of some pigs. Minor lesions can be seen in the renal tubules. Focal liver necrosis, lymphocytic infiltration of the adrenal glands, and meningoencephalitis with perivascular lymphocytic infiltrations also have been described. In chronic leptospirosis, lesions are confined to the kidneys and consist of scattered small gray foci, often surrounded by a ring of hyperemia. These lesions are characterized by focal interstitial nephritis, manifested as interstitial leukocytic infiltrations by lymphocytes, macrophages, and plasma cells. Focal damage also may involve glomeruli and renal tubules. Bowman's capsule may be thickened, containing eosinophilic granular material. Atrophy, hyperplasia, and presence of necrotic debris may be seen in the renal tubules. Chronic lesions may be noticeable as long as 14 months after infection. Leptospires can invade the pig's mammary gland and produce a mild, focal nonsuppurative mastitis. Lesions in aborted fetuses are nonspecific and may include edema of various tissues, fluid in body cavities, petechial hemorrhages in the renal cortex, and small foci of interstitial nephritis. The liver may exhibit focal necrosis manifested as small grayish-white spots. Placentas from aborted fetuses are grossly normal.

Laboratory procedures most commonly used for the diagnosis of leptospirosis include serologic testing, culture, and immunofluorescence. Serologic testing is the most widely used method, and the microscopic agglutination test (MAT) is the standard serologic test. MAT is considered a herd test. Rising antibodies in acute and convalescent animals constitute a sign of recent infection. Titers of 1:1000 or greater are strongly indicative of recent infection. Chronically infected animals may have titers below the accepted minimum significant value of 1:100, for which this test has very low sensitivity. Presence of antibodies in fetal sera or thoracic fluid is diagnostic of leptospiral abortion. Culture of leptospires from affected tissues is the definitive diagnostic tool. The organism is fastidious, however, so culture is time-consuming, with special requirements, and is not performed on a routine basis. Immunofluorescence testing is the method of choice for diagnosis of fetal leptospirosis in fetal body fluids or kidney smears. Darkfield microscopy of fetal fluids or urine also has been used; however, precautions have to be taken so that the organisms are not confused with tissue artifacts.

Treatment and Control

Prevention of transmission from an infected pig or other hosts, or from infected urine, to a pig is the critical factor in management. Control is achieved by a combination of vaccination, antibiotic treatment, and management factors. Commercially available vaccines are used routinely before breeding and contain five or six serotypes. Vaccines are available in most of the countries with intensive pig production. Vaccination will help reduce the prevalence in an infected herd but will not eliminate infection. Very few antibiotics are available to treat leptospirosis at this time. Feed-grade tetracyclines can be used, but high levels are required (800 g/ton). Streptomycin injections at 25 mg/kg of body weight also may be used. Main management factors for the control of leptospirosis are the prevention of direct or indirect contact with wildlife vectors and with other domestic animals such as pigs, cows, and dogs, or with their urine; maintenance of excellent hygiene; and provision of a dry environment for the herd. Effective rodent control programs should be instigated in and around all pig production complexes. The use of artificial insemination and the addition of antibiotics in the semen extender are important procedures in the control of *L. bratislava* infection. Leptospirosis is a zoonotic disease, and precautions need to be taken accordingly.

BRUCELLOSIS

Brucella suis is the ethologic agent of brucellosis in swine. Brucellosis occurs in most countries throughout the world. Prevalence is decreasing, however, because of improved sanitation, institution of husbandry standards, and national eradication programs. In the United States, brucellosis remains endemic in the South. *B. suis* not only

is a problem in swine in which it causes abortion, orchitis and infertility but also is an important zoonotic agent, with implications for public health.

Epidemiology and Clinical Signs

Pigs become infected through direct contact with aborted fetuses, fetal membranes, and body excretions.[5] Pigs of all ages may become infected. Brucellosis is a venereal disease. *Brucella* organisms can survive in organic material in the environment for prolonged periods at freezing or near-freezing temperatures. *B. suis* is readily killed by pasteurization, sunlight exposure, and most commercially available disinfectants. Feral swine constitute the most important reservoir in the United States and rabbits in Europe.[5]

On penetration of the mucosal epithelium, invading organisms are carried to the local lymph nodes, where they invade neutrophils and macrophages and become established intracellular microorganisms protected from the humoral immune response. A phase of bacteremia follows and may last from 1 to 7 weeks.[5]

The classic manifestations of pig brucellosis are abortion, infertility, orchitis, posterior paralysis, and lameness. Gilts or sows with infections acquired through the genital tract at the time of breeding will abort during the first third of gestation and will have irregular returns to estrus. Little or no vaginal discharge is observed. Abortions also may be seen during the middle and last thirds of gestation with infections acquired during pregnancy past 35 days of gestation. Testicular infection in the boars will result in infertility and lack of sex drive. If accessory genital glands are affected, *B. suis* organisms will be shed in large quantities. Clinical brucellosis in suckling and weaning pigs usually manifests with spondylitis associated with posterior paralysis.[5]

Diagnosis

Gross pathology is variable. Areas of abscessation may be seen in affected organs, which may progress to necrosis and desquamation of the mucous membrane. Focal microscopic granulomatous lesions also may be seen in livers in the acute phase of infection. Boars may experience unilateral testicular enlargement; the affected gland is hard to palpation.

Isolation of *B. suis* in the most sensitive and accurate method to diagnose swine brucellosis. Tissues from aborted fetuses contain large quantities of organisms. *B. suis* also can be cultured from semen, testicles, and accessory organs and from lymph nodes, fluid from swollen joints, and, in the early stages, blood.

A variety of serologic tests are available for blood samples. Agglutination and complement fixation tests, enzyme-linked immunosorbent assays (ELISAs), and card and plate tests are among the most commonly used serologic tests. The brucellosis card test, buffered plate antigen test, and the rose bengal test are the most practical methods at present to conduct large-scale surveillance monitoring. Both false positive and false negative results occur, and serologic testing must be used for herd testing, rather than for diagnosis in individual animals.

Treatment and Prevention

Treatment with antibiotics is not very effective and generally should not be attempted. Affected pigs should be destroyed. Safe and reliable vaccines against brucellosis in pigs are not available. There is a movement in a number of countries aimed at gradual elimination of the disease by compulsory slaughter of affected herds coordinated through national eradication campaigns. Overall, the degree of management of swine herds and the fact that breeding stock companies and artificial insemination centers have to be validated brucellosis free have played a major role in reducing the spread of *B. suis*.

ERYSIPELAS

Swine erysipelas is caused by the gram-positive bacterium *Erysipelothrix rhusiopathiae* and is characterized clinically by fever associated with characteristic diamond-shaped skin lesions, arthritis, vegetative endocarditis, and sudden death and by abortion in pregnant sows.[6]

Epidemiology and Clinical Signs

E. rhusiopathiae is regarded as a commensal organism of swine flora and is found in the upper respiratory tract and the intestinal tract of healthy pigs. Greater than 50% of pigs are considered to be carriers. *E. rhusiopathiae* survives in the soil for prolonged periods and may also be found in other mammalian species including sheep, fish, and birds. *E. rhusiopathiae* is considered to be a zoonotic agent.[7]

Infection is through oronasal exposure. Subsequently, invasion of the bloodstream results in septicemia. *E. rhusiopathiae* infection in swine is characterized by clinical illness with depression, high fevers (temperatures greater than 40°C), diamond-shaped skin lesions, lameness, and endocarditis. Abortions also may occur as a result of the high fevers and are seen in the acute form of the disease. If abortion does not take place, one or two piglets may die inside the womb and become mummified. Abortion may happen in any of the stages of gestation. Absorption of embryos and delayed returns also may be seen.

Diagnosis

The diagnosis is determined by the clinical picture and isolation of the organism, which is easy to grow in the laboratory. Erysipelas should be considered in depressed animals with high temperatures. The development of diamond-shaped skin lesions is considered pathognomonic.

Treatment

Penicillin is the therapeutic agent of choice. Affected animals and all animals in direct contact should receive injectable penicillin. Mass medication of entire

populations also is a very effective method of prevention and can be used in acute outbreaks.

Although vaccination is not entirely effective in preventing the disease, it provides a worthwhile means of control when used with other good management practices. Vaccination should be applied in young swine at about 6 to 8 weeks of age when there is no interference with maternal immunity and again before breeding. Boars also should be vaccinated. Commercially available vaccines include killed vaccines and oral live vaccines given at the end of the nursery stage. If disease breakdowns occur despite vaccination, it is likely that the level of contamination in the environment is high, and proper hygiene measures will have to be implemented accordingly.

EPERYTHROZOONOSIS

Eperythrozoonosis is caused by the rickettsial organism *Eperythrozoon suis*. *E. suis* attaches to the surface of red blood cells and destroys them, causing anemia and icterus.[8]

Epidemiology and Clinical Signs

Infection can be transmitted to pigs by bites from lice *(Haematopinus suis),* infected needles, and ingestion of blood and infected secretions. Infection in utero has been described but is not considered a venereal disease. The disease is very difficult to replicate in healthy pigs under experimental conditions. Stress and compromised immune status may predispose pigs to clinical illness.

Pigs of any age may be affected by *E. suis* infection. Abortion, stillbirths, weak-born piglets, and poor conception rates have been described as reproductive problems in the sow. High fever also can be seen. Young piglets are particularly predisposed to infection. Various degrees of unthriftiness, anemia, and jaundice can be present.[8]

Diagnosis

The most important clinical signs for diagnosis are apathy and fever with temperatures higher than 40° C. Anemia, watery blood, icterus of the carcasses, enlargement of liver and spleen, and presence of fluid in all cavities, with reddening of the bone marrow, are other relevant findings.

The diagnosis is confirmed by demonstrating the presence of organisms on erythrocytes in blood smears stained by Giemsa or acridine orange, particularly at onset of clinical signs.[9] Antibodies can be detected by indirect hemagglutination and indirect immunofluorescence testing; recently, ELISAs using whole organisms also have been described.

Treatment and Control

Administration of tetracyclines by injection in a dose of 20 to 30 mg/kg of body mass is the treatment of choice. Symptomatic treatment such as with iron (200 mg iron/dextran/piglet) also may be required.

Control programs should include ectoparasite management and insect reduction protocols. Management practices directed at preventing exposure to blood of infected animals (i.e., changing needles during vaccination) also will contribute to decreasing transmission. Vaccines against *E. suis* are not available.

ENDOMETRITIS AND THE VAGINAL DISCHARGE COMPLEX

Diseases of the urogenital tract, often referred to collectively as the **vaginal discharge complex**, contribute to poor farrowing rates mainly through the associated increase in regular and irregular returns and decrease in productivity in general. These diseases often are undiagnosed, and up to 25% of herds may have an unrecognized problem with this disease.[10] Individual cases of vulvar discharge rarely represent a major concern. By contrast, if 5% to 10% or more of a breeding group show discharge, then the problem warrants attention.[11] Urogenital diseases are the result of a complex of social, environmental, hormonal, and stress factors that contribute to imbalance of the normal microflora of the urogenital tract, enabling commensal organisms to become pathogens.

Presence of a discharge after service does not necessarily mean failure of the pregnancy but may indicate presence of infection. Discharges may originate from the rectum, vulva, vagina, cervix, and uterus. Discharges also can arise from infection in the kidneys (pyelonephritis) or the bladder (cystitis). The main organisms associated with endometritis and vaginal discharges are opportunistic invaders. The most common organisms include *Escherichia coli, Chlamydia* spp., *Eubacterium suis, Streptococcus suis, Streptococcus equisimilis, Proteus* spp., *Staphylococcus aureus, Staphylococcus hyicus, Pasteurella multocida,* and *Pseudomonas* spp. Bacteriologic tests usually yield mixed cultures, and occasionally only one species may predominate.

Normal discharges are common within 3 to 4 days of farrowing. The sow appears healthy, the udder is normal, and no treatment is needed. Normal discharges also can be seen at mating and up to 5 days after service. A discharge should be considered abnormal if present after 5 days of lactation, between 14 and 21 days after service, and any time during pregnancy. Breeding herds in which vaginal discharges are recorded in greater than 2% are considered to be problem herds.[12]

Predisposing factors for endometritis and the vaginal discharge complex include a high number of older sows in the herd, short lactation lengths (less than 18 days), timing of mating toward the end of the estrus period, nonhygienic conditions during breeding, and housing of the gilts, sows, and boars (natural insemination) in wet, dirty crates and pens. Endometritis may take several forms. Sows usually are clinically normal. Visible changes can range from a pus-filled uterine horn to a slightly hyperemic uterine mucosal surface, or grossly visible changes in the uterus may not be apparent. Endometritis usually results in embryonic death and termination of pregnancy. The typical outcome in long-term cases of endometritis is chronic “recycling” secondary to impair-

ment of mechanisms for embryonic implantation.[10] Endometritis also can occur in nonpregnant animals exposed to environmental stresses.

Diagnosis is done by regular observation of the vulva, particularly 14 to 21 days after mating. Bacteriologic examinations also can be done; however, they are of little help because a wide range of organisms considered to be part of the normal flora may be isolated. Examination of the reproductive tract at slaughter may be beneficial in order to evaluate the entire urogenital tract, as well as to obtain samples for histopathologic study and culture. This procedure may not be practical, however.

Treatment of endometritis can be frustrating. Response to antibiotics may be very limited, and in most cases, animals will not fully recover their reproductive potential. Antibiotics commonly used are injectables or feed-grade antibiotics. Injectable antibiotics should be administered for 3 days (penicillin) or every 2 to 3 days (long-acting tetracycline). Feed-grade antibiotics usually consist of tetracyclines administered at 400 g/ton. Because of the overall poor response to systemic treatments, however, culling of the animals is the most cost-effective solution.

Hygiene in breeding and gestation barns is by far the most important means of controlling vaginal discharges.[12] Pens and crates should be designed to allow easy clean-up. Manure should be removed regularly, and crates should be kept clean and dry. Ventilation is important to enhance drying of the breeding and gestation facilities. At breeding, the perineal area should be cleansed to prevent infections. Special attention also seems warranted to maintaining a clean vulvar area from weaning to 14 days after service. Good hygiene during farrowing is important as well. For assisting at farrowings, technicians should wear clean plastic sleeves and should clean the perineal area before the birth canal is entered.

It is recommended to keep records of occurrence of discharges in sows and to correlate these data with estrus and parturition in order to identify whether a herd problem exists or whether the discharges are occasional.

MISCELLANEOUS INFECTIOUS CONDITIONS

Chlamydial Infection

Chlamydia spp. have been described in swine as agents responsible for causing arthritis, pneumonia, pleurisy, orchitis, uterine infections, and abortions.[13] At least three species are involved: *Chlamydia psittaci*, *Chlamydia trachomatis,* and *Chlamydia pecorum*. *C. psittaci* commonly is isolated from immunosuppressed animals infected with porcine reproductive and respiratory syndrome virus (PRRSV), and in general, it is considered an opportunistic invader. *C. psittaci* also has been identified in a wide range of domestic animals and birds. Outside the host, *Chlamydia* organisms are very resistant to drying and may survive months in that state.[14]

Many chlamydial infections are clinically inapparent, but respiratory and systemic infections may have specific manifestations. Many reports deal with genital tract infections and disturbances in reproduction. In the boar, infection is associated with orchitis, epididymitis, and urethritis, whereas infections in gilts and sows have resulted in late-term abortions and the birth of dead or weak piglets.[13] Infection occurs by inhalation and ingestion of contaminated feeds or through venereal contact. Lesions include enlarged bronchial lymph nodes and raised areas of gray or red consolidation in the lung. Laboratory diagnosis is done by demonstrating the agent in smears of affected tissue or by serologic testing (complement fixation test), immunofluorescence testing, electron microscopy, polymerase chain reaction (PCR) assay, and culture.

Tetracyclines are the drugs of choice, but the organism is not eliminated by the treatment. Vaccines for swine chlamydiosis are not available. Control should include the elimination of other immunosuppressive factors or diseases, proper hygiene, and prevention of exposure to other mammalian species, poultry or poultry droppings, or contaminated feed.

Actinobacillus Species

Various species of *Actinobacillus* have been isolated in cases of reproductive failure. *Actinobacillus ross, Actinobacillus equuli,* and *Actinobacillus suis* have been reported in cases of metritis, abortion, low number of viable pigs at birth, and decreased litter weights.[15,16] *A. ross* is considered part of the normal flora of the porcine vagina, and infection of the uterus may take place during breeding.[16] *A. suis* is considered part of the normal upper respiratory tract flora, and *A. equuli* infection has been associated with direct contact with horses.[15] *Actinobacillus* organisms frequently are isolated in reproductive disorders and fetal tissues. Affected fetuses also may be found to have microscopic lesions in the lungs characteristic of bacterial pneumonia.

Actinobacillus organisms can be readily isolated in the laboratory using standard procedures. Treatment is restricted to therapeutic protocols with variable results. Penicillin has been used for the treatment of *A. suis* infections. Autogenous bacterins also have been used, although their efficacy is doubtful.

Streptococcal Species

Various species of streptococci have been isolated in cases of reproductive failure; however, their significance remains unclear. The species more commonly recovered are *S. equisimilis* and *S. suis*. It is known that these organisms are part of the normal flora present in the vagina and semen. Therefore, their association with reproductive problems may be as secondary pathogens. Nevertheless, streptococci have been isolated in cases of abortion, vaginal discharge, stillbirth, and postparturient agalactia.[17]

Diagnosis is done by culture using standard laboratory procedures. Recommended treatment is administration of an effective antibiotic given intramuscularly. Bacterins are available; however, their efficacy to control reproductive disorders is doubtful. Because *Streptococcus* spp. are considered part of the normal vaginal flora, hygienic

procedures during breeding and parturition need to be practiced.

Toxoplasmosis

Toxoplasma gondii has been isolated in pigs in cases of abortion, stillbirths, premature farrowings, and low-viability piglets at birth.[18] *T. gondii* infection in swine is very uncommon, and for the most part infections are asymptomatic. Cats are the natural reservoir for this protozoan, and it is shed in feces. Transplacental infection can occur; *T. gondii* is a zoonotic agent and poses a risk to pregnant women.

Diagnosis should be directed at identification of cysts in affected tissues. Treatment for toxoplasmosis is not available, and control should be based on proper cat and rodent control programs and proper disposal of aborted tissues. *Toxoplasma* infection is mainly a concern for food safety programs.

Mycotoxicosis

Mycotoxins are secondary metabolites of mold growth in grains and forages. In swine, the most common sources for mycotoxins are corn, wheat, milo, cottonseed, and sorghum. Fungal and plant stressors such as drought, high ambient temperatures, insect damage, and mechanical harvest may predispose crop plants to infestation by toxigenic fungi, with subsequent mycotoxin production.[19] Conditions such as high relative humidity (greater than 70%) and high grain moisture content (23%) favor the growth of *Fusarium* spp.[19]

Two molds are associated with reproductive disorders in swine: *Fusarium graminearum (Fusarium roseum)* and *Claviceps purpurea* (ergot). *F. graminearum* produces zearalenone, which is an estrogenic mycotoxin. Because of its estrogenic activity it causes hypertrophy of the uterus and cornification of the vaginal epithelium.[19] Clinical signs will vary with dose of exposure and age of the affected animal. In prepubertal gilts, concentrations as low as 1 to 5 ppm in the ration will cause vulvovaginitis, edema of the vulva, and early mammary gland development. In mature cycling sows, dietary concentrations of 3 to 10 ppm can induce anestrus if zearalenone is consumed during the middle portion of the estrous cycle. Abortions are unlikely because of zearalenone's luteotropic activity. Anestrus may persist long after exposure to zearalenone has stopped. Reduction in litter size also may be seen. Female piglets may have enlarged, edematous vulvas and swollen teats. Young boars may exhibit decreased libido and reduced testicular size after consuming high levels (200 ppm) of contaminated feed; however, these changes are not observed in mature boars. Diagnosis of zearalenone intoxication usually is made by observing clinical signs of hyperestrogenism in immature females. Feed analysis is available, but it is time-consuming and commonly yields false negative results.

Ergot is a parasitic fungus that affects cereal grains, especially rye, oats, and wheat. The fungus produces alkaloids that cause gangrene and reproductive interference.[19] Ergot alkaloids affect reproduction indirectly by causing agalactia. Pregnant gilts that ingest feed contaminated with the fungus may subsequently give birth to piglets that exhibit low birth weight, low survival rate, and poor weight gains. Ergot in rations of pregnant sows is not generally a cause of abortion, and swine exposed to ergot during late gestation routinely suffer agalactia but rarely abortion. If the clinical signs suggest ergotism, grains should be examined for the presence of significant amounts of ergot sclerotia. Contaminated feed should be removed.

CHAPTER 107

Viral Causes of Infertility and Abortion in Swine

MONTSERRAT TORREMORRELL

Losses due to reproductive failure are high in today's swine industry. Many factors are involved in causing reproductive failure, including infectious agents, such as bacteria, viruses, protozoa, and fungi and noninfectious causes, such as nutrition, genetics, environment, management practices, and husbandry procedures. This chapter reviews infectious causes of reproductive failure attributable to viruses.

Several viruses have the potential to cause infertility and abortion of swine. The viruses described in this chapter are considered responsible for a majority of the infectious reproductive disorders seen in today's high-technology swine industry. The viruses commonly associated with episodes of infertility and abortion in swine are porcine reproductive and respiratory syndrome virus (PRRSV), porcine parvovirus (PPV), pseudorabies virus (PRV) (the agent of Aujeszky's disease), classical swine fever virus (CSFV) or hog cholera virus (HCV), porcine enterovirus (PEV), and encephalomyocarditis virus (EMC). Other viruses may be responsible for reproductive failure, but these pathogens are considered sporadic, with a more regional distribution. and typically causing isolated cases, such as porcine cytomegalovirus (PCMV) and blue eye disease virus (BEDV).

Viruses have the ability to cross the placenta and infect and kill the conceptus. Clinical signs will depend on the stage of gestation when the animals become infected, the pathogenetic mechanisms of infection for the virus, and the degree of virulence of the viral strains.

Gestation in pigs lasts about 114 days. In the first 2 weeks of life, the conceptuses lie free in the uterine lumen. Damage to them during this stage is almost always fatal.[1] Implantation begins around day 12 of gestation but is not completed until day 18 to 24 of gestation. Death of the conceptus before implantation will result in resorption of the conceptus, and the sow will undergo a regular return to estrus at approximately 21 days. Death of the embryo before calcification, between approximately 14 and 35 days of gestation, will result in an irregular return to estrus after 24 to 28 days. Complete resorption of the embryos or an abortion may occur. Sows usually return to estrus between 2 and 10 days after loss of pregnancy.

Fetal death after day 35 typically is followed by mummification of the fetus, rather than by pregnancy termination, because the mineral content of the fetus prevents complete absorption. Mummified fetuses are characterized by discoloration and resorption of fluids and soft tissues. If two or more fetuses survive, normal gestation and parturition can still take place.

At about day 70 of gestation, fetuses begin to develop immune competency. The epitheliomaternal placenta normally does not allow transfer of maternal antibodies to fetuses. Infection before 70 days by certain viruses may result in immunotolerance for the surviving fetuses. Immunotolerant-born piglets may be viremic at birth, and the virus is not recognized by the pig's immune system.

Infection after 70 days of gestation may result in a successful immune response by the fetus, with the production of antibodies. Although a fetus may successfully produce antibodies, it may still succumb to the virus and be stillborn.

Abortion refers to the delivery of an immature fetus, either live or dead, before the completion of the gestation period as a result of the failure of the mechanisms that control pregnancy. Abortions typically result from failure of some maternal system, rather than the effects of the

CHAPTER 107

Viral Causes of Infertility and Abortion in Swine

MONTSERRAT TORREMORRELL

Losses due to reproductive failure are high in today's swine industry. Many factors are involved in causing reproductive failure, including infectious agents, such as bacteria, viruses, protozoa, and fungi and noninfectious causes, such as nutrition, genetics, environment, management practices, and husbandry procedures. This chapter reviews infectious causes of reproductive failure attributable to viruses.

Several viruses have the potential to cause infertility and abortion of swine. The viruses described in this chapter are considered responsible for a majority of the infectious reproductive disorders seen in today's high-technology swine industry. The viruses commonly associated with episodes of infertility and abortion in swine are porcine reproductive and respiratory syndrome virus (PRRSV), porcine parvovirus (PPV), pseudorabies virus (PRV) (the agent of Aujeszky's disease), classical swine fever virus (CSFV) or hog cholera virus (HCV), porcine enterovirus (PEV), and encephalomyocarditis virus (EMC). Other viruses may be responsible for reproductive failure, but these pathogens are considered sporadic, with a more regional distribution. and typically causing isolated cases, such as porcine cytomegalovirus (PCMV) and blue eye disease virus (BEDV).

Viruses have the ability to cross the placenta and infect and kill the conceptus. Clinical signs will depend on the stage of gestation when the animals become infected, the pathogenetic mechanisms of infection for the virus, and the degree of virulence of the viral strains.

Gestation in pigs lasts about 114 days. In the first 2 weeks of life, the conceptuses lie free in the uterine lumen. Damage to them during this stage is almost always fatal.[1] Implantation begins around day 12 of gestation but is not completed until day 18 to 24 of gestation. Death of the conceptus before implantation will result in resorption of the conceptus, and the sow will undergo a regular return to estrus at approximately 21 days. Death of the embryo before calcification, between approximately 14 and 35 days of gestation, will result in an irregular return to estrus after 24 to 28 days. Complete resorption of the embryos or an abortion may occur. Sows usually return to estrus between 2 and 10 days after loss of pregnancy.

Fetal death after day 35 typically is followed by mummification of the fetus, rather than by pregnancy termination, because the mineral content of the fetus prevents complete absorption. Mummified fetuses are characterized by discoloration and resorption of fluids and soft tissues. If two or more fetuses survive, normal gestation and parturition can still take place.

At about day 70 of gestation, fetuses begin to develop immune competency. The epitheliomaternal placenta normally does not allow transfer of maternal antibodies to fetuses. Infection before 70 days by certain viruses may result in immunotolerance for the surviving fetuses. Immunotolerant-born piglets may be viremic at birth, and the virus is not recognized by the pig's immune system.

Infection after 70 days of gestation may result in a successful immune response by the fetus, with the production of antibodies. Although a fetus may successfully produce antibodies, it may still succumb to the virus and be stillborn.

Abortion refers to the delivery of an immature fetus, either live or dead, before the completion of the gestation period as a result of the failure of the mechanisms that control pregnancy. Abortions typically result from failure of some maternal system, rather than the effects of the

viruses on the fetuses. These system failures and the resultant abortions usually are sequelae of systemic effects of viruses on the dam, such as high fever or viremia.

A **stillbirth** is a fetus that has matured fully in utero but is born dead. Stillborn piglets look normal, but their lungs do not float in water (respiration never occurred before death). Certain viruses have tropism for fetuses at the end of the gestational stage. Stillbirths also may be caused by noninfectious agents or conditions and are known as **intrapartum deaths.**[1]

If less than the entire litter is infected transplacentally, the virus may spread within the uterus and infect littermates at different gestational ages, resulting in a variety of responses within the litter, including reduced litter size, mummification of fetuses, and stillbirths.

Viruses associated with reproductive failure also may cause increased neonatal mortality. **Neonatal death** refers to that occurring primarily within the first 7 days of life. Death usually is due to events that take place during late gestation, or shortly after parturition, or weak piglets infected late in gestation may die soon after birth. In production records, neonatal death usually is captured within the preweaning mortality parameter.

PORCINE REPRODUCTIVE AND RESPIRATORY SYNDROME VIRUS

Porcine reproductive and respiratory syndrome virus (PRRSV) is a fairly new virus first reported clinically in the late 1980s and isolated in Europe in 1991, and in the United States in 1992.[2] PRRSV has become the most important virus affecting the swine industry, with estimated annual costs of U.S. $570 million in the United States alone.[3]

Epidemiology and Clinical Signs

PRRSV characteristically causes both reproductive and respiratory clinical signs.[2] Reproductive clinical signs include late-term abortions, premature farrowings, weak-born piglets, and increased preweaning mortality rate. Respiratory clinical signs are due to the presence of interstitial pneumonia in nursery and finishing pigs, which can be complicated by secondary infections. Two main genotypes are recognized: European (or Lelystad virus) and North American. Within each genotype, significant strain variation exists. Differences in strain variation may influence virulence, pathogenesis, and clinical signs.

PRRSV is widely distributed throughout the world. Only few countries are considered free of the disease. Infected countries have widespread prevalence. PRRSV is readily transmitted by contact exposure of secretions of infected animals such as serum, saliva, milk, urine, and feces. PRRSV also is transmitted by semen, and this route of infection has gained greater importance since the increased use of artificial insemination and the establishment of central distribution boar studs. Infected animals can be viremic for prolonged periods of time. Duration of viremia will depend on the age of the animal, with longer periods of viremia in younger pigs than in older animals. After viremia has ceased, virus still persists in the tissues. Different studies show that such persistence may be detected in tissues for more than 100 days. Contact transmission has proved limited, however, in general lasting for up to 80 days after infection, although exceptions may exist.

PRRSV can be readily transmitted by contact with infected surfaces and through iatrogenic transmission by needles or materials that facilitate body fluid exchange.

Transport vehicles not properly cleaned and dried, contaminated fomites, exchange of material between infected and noninfected herds, and failure of farm personnel to follow biosecurity measures are considered important sources of infection between herds.[4–6] Insects and aerosol transmission also have been described as possible sources of infection, but their relevance is still unclear or limited to very specific regions. PRRSV is an RNA enveloped virus that survives well in cold and wet environments, and its infectivity decreases as infected surfaces become dry.

Diagnosis

Late-term abortions, premature farrowings and significant increase in preweaning mortality rate are very suggestive of PRRSV infection.[2] Acutely infected young piglets will be viremic for prolonged periods, up to 35 days. Blood samples and infected tissue specimens to detect presence of virus can be tested by virus isolation or polymerase chain reaction (PCR) assay. Several serologic tests that are based on enzyme-linked immunosorbent assay (ELISA) techniques are available commercially. Immunofluorescence assay (IFA) and IPMA tests also are available and are deemed more specific but less sensitive. Serologic tests measure exposure to the virus but not protection. When seronegative populations are monitored using these tests, serologic reactors may be found. In such instances, first performing a test with high sensitivity is recommended, followed by a more specific testing of the reacting samples. In the United States, the combination of ELISA followed by IFA has become the standard diagnostic laboratory procedure.

Infected piglets will be found to have microscopic lesions associated with PRRSV infection. In investigating a reproductive PRRSV infection, samples from weak-born piglets will constitute a good source of virus. Samples from mummified fetuses may yield false negative results because the virus may have become degraded.

Prevention, Control, and Eradication

Recent years have seen considerable advances in the area of prevention and control of PRRSV disease. Many new management techniques provide a means of control and even eradication of most PRRSV infections on swine farms. Control of PRRSV disease is directed at limiting damage from the viral infection; this strategy it is based on management of the replacement animals and prevention of reinfection by new viral strains.

A majority of new infections affecting commercial systems in the United States are considered to be a result of lateral transmission and not due to introduction of infected pigs or semen.[6] Area spread from neighboring units, transport of pigs in PRRSV-infected equipment, lack

of compliance with biosecurity protocols, and even potential introduction by means of insects[5–8] are considered risks for PRRSV introduction into herds. Biosecurity protocols need to be properly thought out and implemented. Special effort should be made in selecting isolated areas for establishing new units and in reviewing all of the procedures that involve movement of farm inputs and outputs——transport of pigs, supplies and materials, feed, water, and personnel; removal of manure; and reclaims. Because of the nature of the virus and its excellent survival in cold and wet conditions,[4] procedures must ensure the cleaning and drying of all equipment and material used at the farm. In particular, all equipment used for transport of pigs should be properly cleaned and completely dry.[5,9] All units also should have biosecurity measures in place to prevent infestation by pests such as rodents, insects, and birds.

Considerable advances in the control of PRRSV disease have been achieved during the last several years; however, control measures remain one of the most frustrating items for practitioners. The central component of PRRSV disease control is the reduction of the spread of the virus within the breeding herd, thereby preventing the infection of offspring before weaning.[10] The perpetuation of infection in chronically infected herds may potentially be due to the presence of subpopulations of animals of differing immune status and virus activity.[11] A step to prevent the development of such subpopulations has been the introduction of replacement animals that are previously exposed and immune to PRRSV infection before introduction in the PRRSV-positive herds.[12] The consistent acclimatization of incoming breeding stock to PRRSV results in the stabilization of clinical signs of disease, the improvement of production parameters, and the production of PRRSV-negative piglets at weaning; therefore, gilt introduction remains the key to PRRSV control.[13] Different methods for gilt acclimatization exist, and in general it is accepted that early exposure (at 2 to 4 months of age) will result in homologous protection of the exposed animals and introduction of the replacement animals at a time when shedding has stopped. A major challenge, however, remains the exposure method that will consistently induce PRRSV infection.

Control measures in the weaned pig population should be directed at minimizing the commingling of different pig sources at weaning, streamlining flows, strict implementation of all-in–all-out animal flow, implementation of nursery partial depopulations, and controlling other concurrent infections, mostly bacterial (e.g., *Haemophilus parasuis, Streptococcus suis, Mycoplasma hyopneumoniae*) and viral (i.e., swine influenza virus) aggravated by the PRRSV infection. Appropriate vaccination and medication protocols need to be determined for the individual infections. Finally, if the suckling piglet population is acutely infected, a series of management strategies directed at limiting the movement of piglets between litters in the initial 24 hours of life, humanely destroying chronically infected offspring before weaning, and maintaining strict all-in–all-out animal flow for the nursery should be helpful.[14]

Eradication of PRRSV is possible. Spontaneous elimination has been described in small-herd units.[15] Consistent PRRSV eradication was not possible until recently, however.[16,17] Total depopulation-repopulation, partial depopulation, segregated early weaning, testing and removal, and herd closure are among the most common strategies. The success of PRRSV elimination in the breeding herd resides in the introduction of seronegative nonexposed replacement animals into the breeding herd at a time when virus is no longer present.

Total herd depopulation-repopulation is a very successful technique, although it is costly and may be justifiable only if the elimination of other concurrent diseases is desired. Partial depopulation is indicated for the elimination of the virus from growing pigs when shedding from the breeding population has completely stopped. This technique alone has proved to be enough to eliminate the virus in small size farms.[18] PRRSV elimination through the herd closure technique has gained considerable popularity in the United States.[17] The principle of this technique is based in the fact that PRRSV infection tends to die out in an immune population over time. This strategy mimics the principles followed for eradication of transmissible gastroenteritis (TGE) in pigs, which ensure that all animals are exposed to the virus and that replacement animals that could perpetuate virus replication are not introduced during that time. In the case of PRRSV, longer periods of herd closure with no introduction of new replacement animals are required. Animals recovered from the infection will eliminate the virus from their tissues, although this will require prolonged periods (about 6 months). Introduction of seronegative replacement animals will be followed by attrition or scheduled culling of the previously infected animals. PRRSV elimination through the test and removal technique has also been used with successful results.[16] Elimination of PRRSV by testing and removal consists of blood testing the entire breeding herd, identifying PRRSV-infected animals using tests for both antibody and virus, and removing seropositive animals from the farm.

Several studies have established that vaccination against PRRSV can result in protective immunity.[3] Several commercial vaccine products are available today. Both attenuated and inactivated products are available on the various continents. In general, it is accepted that attenuated modified live virus vaccines induce a more efficacious immune response, although concerns regarding safety have been raised for some of the products. Inactivated vaccines also are available, but in general they are considered less efficacious when used in seronegative animals.

When used in the field, vaccines have met with various degrees of success in different countries. Differences may be due to differences in the commercial products available and how these products are utilized, and to differences related to presence of viral strains in different regions in which cross-protection is believed to be very limited. Also, induction of protective immunity among genetically different PRRSV strains, although it is possible, is very limited and difficult to assess. In addition, field reports that document the transmission of the vaccine virus and its reversion to the vaccine virus virulent form also can be found in the literature. Some vaccine virus strains may behave very similarly to field PRRSV strains

in relation to persistence, transmission to virus-naive pigs, crossing of the placenta to cause congenital infection, shedding in semen, and length of time required to induce protective immunity. Therefore, issues regarding the safety and efficacy of the live virus vaccine products remain unresolved. Research to provide safer and more efficacious products is in progress.

PORCINE PARVOVIRUS

Porcine parvovirus (PPV) causes reproductive disorders characterized by resorption of infected fetuses, increased number of fetal mummies, and reduced litter size, usually in the absence of obvious maternal clinical signs.[19] Traditionally, clinical signs of parvovirus infection are seen in gilts or sows of low parity. There is no evidence that infection of swine at times other than during gestation is of any clinical or economic significance.

Epidemiology and Clinical Signs

Porcine parvovirus is ubiquitous throughout the world. Infection is considered enzootic in most swine herds. Contaminated premises probably are major reservoirs for PPV. PPV is a nonenveloped virus resistant to most common disinfectants. In an established seropositive farm, gilts usually become infected after maternal antibodies have disappeared. In many instances, maternal antibodies may last up to 6 months. Gilts usually become infected by exposure to feces through the oral-fecal route as maternal antibodies wane. In order to prevent reproductive clinical signs, gilts must become immune before the first breeding, which usually occurs at about 6 to 7 months of age. In addition, acutely infected boars also may play a significant role in disseminating PPV. Semen also may become infected through external contamination with feces at collection for artificial insemination practices.

Dams may return to estrus, fail to farrow despite being anestrous, farrow few pigs per litter, or farrow a large proportion of mummified fetuses. All of these clinical scenarios can reflect occurrence of embryonic or fetal death, or both. PPV infection in early gestation will result in the resorption of fetuses and irregular return to estrus. Dams are susceptible to PPV infection during about the first half of gestation. Infection after 30 days of gestation will cause fetal death, resulting in mummification. PPV usually does not infect all fetuses at once. Usually fetuses will become infected sequentially, resulting in mummies of different sizes at birth. Fetuses infected after 70 days of gestation will be able to mount an immune response and usually will survive without obvious clinical effects in utero. Abortions are rare. Reduced litter size with multiple mummies and healthy piglets may be observed at birth. In the boar, evidence is lacking for an effect of PPV on fertility or libido.

Diagnosis

PPV infection should be considered in a differential diagnosis of reproductive failure of swine whenever there is evidence of embryonic or fetal death, or both. Litters with multiple-size mummies observed in first-parity gilts usually are characteristic of PPV infection. Abortions are rarely seen.

Fetal mummies infected before 70 days of gestation (size less than 16 cm) will carry the virus in multiple tissues. Mummy emacerate can be tested for the presence of virus using the hemagglutination (HA) test. Mummies infected after 70 days of gestation will have antibodies that can be assessed in thoracic fluid by the hemagglutination inhibition (IHA) test.

Serologic status of gilts and sows can be assessed using the IHA test. Because PPV is ubiquitous, the presence of antibody in a single sample is meaningless. Paired serum samples indicating a significant rise in antibody level is required to prove infection. In order to detect seroconversion on a population basis, a serum profile with the collection of 10 samples from multiple growing-age gilts and breeding-age gilts is recommended to determine time of seroconversion for the gilts. Titers induced by natural infection tend to be very high and confer lifelong protection.

Treatment and Control

Control of PPV infection is centered on ensuring immune status of the animals before breeding. Gilts should be either naturally infected with PPV or vaccinated for PPV before they are bred. Feedback exposure to feces from older animals or contact exposure between seropositive and seronegative animals as a measure to induce natural immunity in gilts is a common measure. A commercial killed vaccine also is available. Time of vaccination is critical, however, because maternal antibodies are long-lasting and may interfere with vaccine efficacy. Vaccination requires at least two injections 2 to 5 weeks apart before initiating breeding of the gilts. Subsequent vaccine administration in older-parity animals is recommended before each breeding. Vaccine administration also is recommended in boars.

PSEUDORABIES VIRUS

Pseudorabies virus (PRV), the agent of Aujeszky's disease, is a herpesvirus with the ability to establish latent infections. PRV causes reproductive failure characterized by abortion, embryonic death resulting in return to estrus, mummification, and stillbirths.[20] PRV also causes CNS signs in younger pigs and respiratory signs in growing and adult swine.

Epidemiology and Clinical Signs

The pig is the only natural host of PRV, which accounts for its ability to be subclinically and latently infected. Latently infected carrier animals can sporadically shed the virus throughout their lives. Infection in other farm animals such as cattle, sheep, goats, dogs, and cats is fatal, and herds located near pig farms often act as sentinels for the infection.

Transmission of the virus is by direct contact with infected animals, primarily other pigs. The virus is shed

in nasal and oral secretions and also can be transmitted transplacentally, by contact with the vaginal mucosa, and through semen and milk. Farm-to-farm movement of animals that are shedding the virus probably is the more common mode of spread of infections. Movement of contaminated feed, bedding, trucks and other vehicles, and people also plays an important role. Aerosol transmission also is believed to be possible under favorable environmental conditions of temperature and humidity. Exposure to infected feral pigs also can be an important source of infection. PRV has relatively low survivability in the environment and is susceptible to disinfectants and to drying, especially in the presence of direct sunlight.

Primary infection occurring as an outbreak of disease in a seronegative unprotected herd can be a devastating event. Infection will spread quickly throughout the entire herd. Clinical signs will vary depending on the virus virulence, the infectious dose, level of protection already existing in the herd (if already vaccinated or infected), and, more important, depending the age of the swine affected. Younger piglets are the most severely affected. Suckling piglets will exhibit CNS signs resulting in very high preweaning mortality. Weaning-age pigs also will exhibit nervous signs; usually these are less severe, but respiratory signs also may be present. Infected pigs typically develop high fevers. In grower-finisher pigs, respiratory signs have become the hallmark of PRV infection. Central nervous system signs may occur but only sporadically. Growth retardation also is seen. Adult swine may exhibit fever, anorexia, depression, and respiratory clinical signs, with the primary sign being reproductive failure if sows are pregnant. Infection in the first trimester of gestation may result in fetus resorption and return to estrus. Reproductive failure in the second and third trimesters usually is manifested as abortion or, if infection occurs close to term, as stillbirths or birth of weak piglets. PRV can cross the placenta and cause placentitis, resulting in abortion at any stage of gestation.

Diagnosis

Classic clinical signs often will lead to a presumptive diagnosis that often is supported by observation of gross lesions of focal hepatic, pulmonary, and splenic necrosis and necrotic tonsillitis in neonatal pigs. Additional microscopic lesions are seen primarily in the nervous system and include nonsuppurative meningoencephalitis, ganglioneuritis, and perivascular cuffing by mononuclear cells.

Several serologic tests are available. In most cases, positive test results indicate exposure to the virus and not necessarily causation. The most widely used tests are serum neutralization, latex agglutination, ELISA, and differential ELISAs that allow differentiation between antibodies induced by a gene-deleted vaccine and antibodies induced by natural infection. The infection also is confirmed by direct detection of the virus by immunofluorescent antibody test or isolation of the virus from fetal or neonatal tonsils, brain, spleen, or lung.

Treatment (Vaccination) and Control

Modified live virus, inactivated, and gene-deleted vaccines have been developed for the control of PRV disease and are available in most countries in which PRV disease is endemic. These vaccines have proved to be quite effective in reducing or preventing clinical signs and thus have reduced the economic impact of the disease. Vaccination will not prevent the infection, however.

Because of the advantages of using a differential ELISA diagnostic test, gene-deleted vaccines are preferred. Animals vaccinated with a gene-deleted vaccine will lack antibody against the specific glycoprotein encoded by the deleted gene, allowing a vaccinated pig to be differentiated from an infected one. In addition, these vaccines become extremely useful in the initial stages of a control and eradication program.

Most major swine-producing countries worldwide have undertaken area control and eradication programs. Recently, the United States has completed the eradication of the virus, and all states are considered Stage V, with surveillance at a maintenance level. Vaccination is then prohibited.

CLASSICAL SWINE FEVER

Classical swine fever is caused by the pestivirus classical swine fever virus (CSFV), also referred to as hog cholera virus (HCV). This disease still has a worldwide distribution, but gradually more countries are succeeding in the eradication of the virus. The United States became CSF free in the late 1970s. The virus is still an important pathogen in some parts of the world.

The pig is the natural host and is the significant source of spread of CSFV.[21] Direct contact between infected and susceptible pigs is the principal means of viral transmission. CSFV is excreted with oronasal and lacrimal secretions, urine, and feces. Chronically infected pigs shed the virus continuously or intermittently until death. Mechanical vectors contribute to the spread of CSFV between premises (equipment, trucks), but virus also may be mechanically transmitted by pets, birds, and arthropods. CSFV survives in frozen meat, and garbage feeding to pigs has resulted in clinical outbreaks of CSFV disease.

Gross lesions range from none in peracute infections to swelling, edema, and multiple hemorrhages in the lymph nodes and kidneys. Petechial and ecchymotic hemorrhages in the kidneys are common, and infarction of the spleen is considered very characteristic for CSFV infection. Infarction and hemorrhage also occur in the lungs. Encephalitis with perivascular cuffing may be seen microscopically.

Congenital CSFV infection can result in abortion, fetal mummification, stillbirth, malformations, and the birth of weak pigs with tremors, or of healthy-looking yet infected piglets. Among piglets infected in utero, skin hemorrhages are common, and the neonatal mortality rate is high. Piglets infected in utero may be persistently infected at birth and appear to be immunotolerant to the virus. Piglets can recover from an in utero–acquired CSFV infection, however.

CSFV infection may be confused on clinical and pathological grounds with several other viral or bacterial infections; therefore, it is recommended that clinical diagnosis be confirmed by the laboratory. It is virtually impossible to make a clinical diagnosis in cases of subacute, chronic, or late-onset classical swine fever because of the wide variability of clinical signs and pathologic lesions. Laboratory diagnosis is based on detection of viral antigen, isolation of virus, or demonstration of viral antibody. The direct fluorescent antibody test performed on frozen tissue sections is the method of choice for detecting viral antigen. Serologic tests also are available but cannot differentiate between vaccine- or infection-induced antibodies.

In countries in which CSFV is enzootic, vaccination is often practiced, and in some countries vaccination is supplementary to the killing of infected herds. Countries free of CSFV have stringent measures directed at preventing the introduction of the virus. Countries ban the import of live pigs, pork, and nontreated pork products from countries in which CSFV is present.

PORCINE ENTEROVIRUS

Porcine enteroviruses are ubiquitous and found in a majority of pig herds. They belong to the family Picornaviridae and are highly resistant to the rigors of the environment.

Although a majority of infections are asymptomatic, porcine enteroviruses have been associated with a variety of clinical presentations, including polioencephalomyelitis, female reproductive disorders, enteric disease, and pneumonia.[22]

The primary route of transmission is the fecal-oral route, and indirect transmission by fomites is very likely to occur because the viruses are relatively resistant.

Several serotypes of the virus exist. These differ in degree of virulence and clinical manifestations of infection.

Porcine enteroviruses can be associated with stillbirths, mummification of fetuses, embryonic death, and infertility. It is important to differentiate disease due to these organisms from parvovirus infection, because clinical signs are very similar. No remarkable lesions are seen in stillborn or neonatal piglets, although mild focal gliosis and perivascular cuffing in the brain stem have been found occasionally.

Commercial vaccines are not currently available. Controlled exposure, similar to that described for control of parvovirus, is the best method to prevent clinical signs. Diagnosis is confirmed by virus isolation, which is best performed using fetal lung tissue, or by detection of viral antigen by immunofluorescence.

ENCEPHALOMYOCARDITIS VIRUS

Encephalomyocarditis virus (EMCV) is a picornavirus regarded as a rodent virus, although the virus naturally infects a wide range of vertebrate species. Pigs are the domestic animals most susceptible to clinical disease by EMCV infection.[23]

Historically, the virus has been considered the cause of myocardial disease in neonatal pigs. It received considerable attention in the late 1980s and early 1990s as the potential cause of "mystery pig disease," which was later confirmed to be caused by porcine reproductive and respiratory syndrome virus (PRRSV).

The most important sources for swine infection appear to be feed and water contaminated with the virus by rats, other rodents, or infected carcasses. Therefore, it is important to control rodents on pig farms and minimize their contact with pigs either directly or indirectly through contamination of feed or water.

In breeding females, clinical presentation varies, ranging from no obvious illness to severe reproductive problems. Evidence of reproductive failure includes abortions and increased numbers of mummified and stillborn fetuses. Increased neonatal deaths and preweaning mortality also may be observed.

Diagnosis is confirmed by virus isolation from heart tissue of fetuses and young pigs. Alternatively, serum neutralization or IHA tests can be performed on serum or fluids from stillborn pigs or mummified fetuses for detection of antibodies to the virus.

CYTOMEGALOVIRUS

Porcine cytomegalovirus (PCMV) is a herpesvirus that usually induces a clinically silent infection in the adult; in the young pig it causes rhinitis characterized by inclusion bodies and may cause pneumonia.[24] The infection can be fatal in young piglets infected systemically. The virus has worldwide distribution. In susceptible pregnant sows the virus may infect the embryo shortly after implantation, which may lead to embryonic death. PCMV also may cause mummification of fetuses and stillbirths. Neonatal death also may occur; at necropsy, affected pigs exhibit retardation in growth with rhinitis or pneumonia.

Diagnosis requires laboratory support. Serologic testing and viral isolation are difficult to perform. Identification of the virus needs to be confirmed by immunostaining from nasal scrapings.

BLUE EYE DISEASE

Blue eye disease is caused by a paramyxovirus and is characterized clinically by central nervous system abnormalities, corneal opacities, and reproductive failure.[25] Blue eye disease has been reported clinically only in the central part of Mexico, although other members of the Paramyxovirus family have been isolated in swine in other countries. Reproductive failure is manifested as fetal death with return of the sows to estrus, stillbirths, and mummified fetuses. Abortion is not a feature but may be observed in the face of an acute outbreak. In boars the disease may manifest as orchitis and epididymitis.

CHAPTER 108

Noninfectious Causes of Infertility and Abortion

RODERICK C. TUBBS

ANATOMIC ABNORMALITIES

Anatomic abnormalities are present in about 2% of all newborn pigs. Nonlethal anatomic aberrancies may result in infertility and may account for 10% to 20% of cases of reproductive failure in nonbreeding gilts. Most anatomic abnormalities, except those of the external genitalia, are not apparent in live animals. Because of the frequency of occurrence of anatomic abnormalities, gilts that do not cycle within 30 to 60 days after selection or delivery, or those that do not conceive after the second or third mating, should be culled. Generally, diagnostic investigations of individual gilts are not justified; however, if more than 10% of a group of replacement gilts have infertility problems, a diagnostic investigation, including slaughter checks, is indicated.

CYSTIC OVARIAN DISEASE

Cystic ovarian disease is a common cause of reproductive failure in sows. Cystic ovaries may be present in 10% to 25% of infertile sows. Single cysts are an incidental finding at slaughter and do not affect cyclicity or fertility. Multiple cysts, small or large, may be associated with infertility. Multiple small cysts (10 to 15 mm in diameter) secrete estrogen and occasionally may be associated with anestrus. Multiple large cysts (15 mm to 10 cm) secrete progesterone and commonly are associated with anestrus.

PHYSICAL CONDITIONS THAT INTERFERE WITH REPRODUCTION

Physical problems that potentially interfere with reproduction include injuries of the vulva or vagina, or both; musculoskeletal problems; and diseases of the gastrointestinal and cardiovascular systems.

Trauma

Trauma to the genital tract may result from vulva-biting by aggressive sows in group housing systems, from farrowing injuries, or from breeding injuries. These types of injuries usually impair reproduction by causing adhesions that occlude the reproductive tract, thereby interfering with coitus or gamete transport. They also predispose the affected animal to the development of chronic vaginitis or endometritis. Animals with severe injuries to the lower genital tract or chronic endometritis as a result of those injuries should be culled.

Musculoskeletal System

Lameness due to foot pain, poor conformation, trauma, footrot, or nonseptic laminitis may predispose affected animals to reproductive problems. Gilts may be added to the breeding herd but never mated because they are too lame to mate or because they exhibit weak physical signs of estrus. Pregnant sows may be culled because of foot and leg problems. In some herds, musculoskeletal diseases represent the primary reproductive problems because of their impact on nonproductive sow days, farrowing rate, cull rate, death rate, and, subsequently, overall replacement rate.

Nonseptic laminitis occurs secondary to injury and is characterized by inflammation of the corium, foot pain, and a digital pulse. The front limbs are primarily affected. Damage to the hoof pad or hoof wall may allow penetration by bacteria into the corium, resulting in footrot, subsolar abscesses, or other hoof problems. Traumatic injury to the hooves is more common on the lateral toes, possibly because they bear more weight than the medial toes. Joint or bone infections may occur secondary to trauma as well.

Other musculoskeletal system problems that may interfere with reproduction, especially in gilts, are osteochondrosis and degenerative joint disease. These conditions result from developmental lesions that affect cartilaginous growth plates. Clinical signs range from subtle changes in gait to inability to stand. Such signs usually are noted in the first 4 to 8 months of life. Genetic background, conformation, and floor type are believed to contribute to the condition, although these conditions may develop in any fast-growing animal. Direct correlations between growth and nutrition and osteochondrosis and degenerative joint disease lesions are difficult to establish. The best methods to prevent joint lesions are to provide adequate nutrients, feed intake, and a proper environment and to select breeding stock with good physical conformation from genetic lines with no history of the condition.

Gastrointestinal System

Gastrointestinal problems may contribute to reproductive inefficiency either directly, by interfering with exhibition

of strong physical signs of estrus, or indirectly, by causing death or disorders leading to culling of pregnant sows. Common gastrointestinal problems include gastric ulcers and gastrointestinal accidents such as gastric dilatation, torsion, or volvulus. Clinical presentation with gastric ulcers is characterized by anemia, sudden death, gastrointestinal pain, vomiting, and bloody or dark feces. The definitive lesion seen at necropsy is ulceration of the pars esophagea. Maintenance of feed particle size at 700 to 800 μm or greater and added fiber in gestation diets may be helpful in preventing gastric ulcers.

Gastrointestinal accidents occur sporadically but may be common in some herds. Sows are predisposed to occurrence of gastrointestinal accidents by irregular feeding times, feeding of gruel or whey, and excessive excitement at feeding time. Establishment of a regular feeding time, addition of fiber to the diet, and use of a drop-feeding system that delivers feed to all sows simultaneously are the best methods for prevention.

Cardiovascular System

Cardiac failure is a commonly diagnosed cause of death in some sow herds. Obesity, parturition, heat stress, copulation, fights, and transport predispose affected animals to cardiac failure. A diagnosis of cardiac failure should be made only after other causes of death in adult sows have been ruled out.

TOXINS

Many compounds are potentially toxic to pigs, but few are specific to the reproductive tract and even fewer are likely to come into contact with sows in modern production systems. The discussion here is restricted to mycotoxins, primarily zearalenone, and carbon monoxide toxicity.

Mycotoxins

Mycotoxins are produced by molds that grow in grains such as corn, milo, and wheat under the proper conditions of moisture and oxygen content. Although commonly blamed for reproductive problems, **aflatoxins** have not been shown to have significant reproductive effects in swine.[1] **Ergot alkaloids**, produced by the fungus *Claviceps purpurea,* cause low birth weights, reduced survival, and diminished weight gains in piglets and agalactia in sows but only rarely cause abortion. **Fumonisin**, produced by *Fusarium moniliforme,* is associated primarily with a respiratory syndrome characterized by cyanosis, hydrothorax, and diffuse interstitial and interlobular pulmonary edema. Pregnant sows that recover from the respiratory disease may abort 2 to 3 days later.[1]

Zearalenone, also known as F-2 toxin, is produced by *Fusarium graminearum (Fusarium roseum).* Zearalenone is an estrogenic mycotoxin that is produced under conditions of high relative humidity (higher than 90%) and high moisture content (greater than 25%).[1] The severity of clinical signs caused by zearalenone varies with the level of exposure and age of the animal. Prepubertal gilts may develop vulvovaginitis, characterized by swelling and redness of the vulva, when exposed to as little as 1 to 2 ppm in the ration.[2] Vaginal and rectal prolapses are common sequelae. Removal of the contaminated grain from the diet for 40 days, even after 90 days of exposure to 1.5 to 2 ppm, results in normal sexual maturity and normal subsequent reproductive performance in gilts.[3]

In mature sows, zearalenone is luteotropic; ingestion of 3 to 10 ppm during midcycle maintains luteal function and progesterone secretion and leads to anestrus. Exposure to zearalenone during early pregnancy, particularly during the preimplantation stage (7 to 10 days after mating), may decrease litter size.[4]

The primary effect of zearalenone in boars is preputial enlargement, and no apparent reproductive problems have been recognized in mature boars exposed to levels of up to 200 ppm.[5] In young boars, testis size and libido may be reduced.[6]

Treatment for any of the conditions associated with mycotoxicosis is removal of contaminated grain. Definitive identification of mycotoxins in feed or grain samples may be difficult, because the molds tend to occur in "hot spots" and may have been consumed by the time the sample is taken. Although the clinical signs caused by most mycotoxins may be nebulous and may be difficult to document, vaginal swelling and precocious mammary development in prepubertal gilts can be considered pathognomonic for exposure to zearalenone.

Carbon Monoxide Intoxication

The primary reproductive manifestation of carbon monoxide intoxication is an increase in the number of stillborn pigs. Toxicity occurs when gas-burning space heaters or furnaces are operated improperly in tightly constructed, poorly ventilated farrowing houses. High concentrations of CO (greater than 250 ppm) can result in an increase in number of stillborn pigs, can cause sows to deliver dead pigs within a few hours after entering a farrowing house, or may be associated with the birth of entire litters of stillborn pigs to multiple sows.[7] Suspected CO-induced cases of stillbirths can be confirmed by (1) measuring the amount of CO in the air or (2) measuring the percentage of carboxyhemoglobin concentration in fetal thoracic fluid (concentrations greater than 2% are associated with CO intoxication).[7]

SEASONAL INFERTILITY

The primary noninfectious cause of infertility on most swine farms, other than management practices, is seasonal infertility.[8–11] The domestic pig is a year-round breeder, but its ancestor, the European wild pig, has a distinct seasonal breeding pattern, and domestic pigs have retained at least some of that characteristic as evidenced by the sharp decline in reproductive efficiency during late summer and early autumn on many farms. All measures of reproductive efficiency are affected, including decreased farrowing rates as a result of autumn matings (followed by reduced farrowing rates in December and January), increased wean-to-service interval (WSI), increased numbers of stillbirths and abortions, and fewer

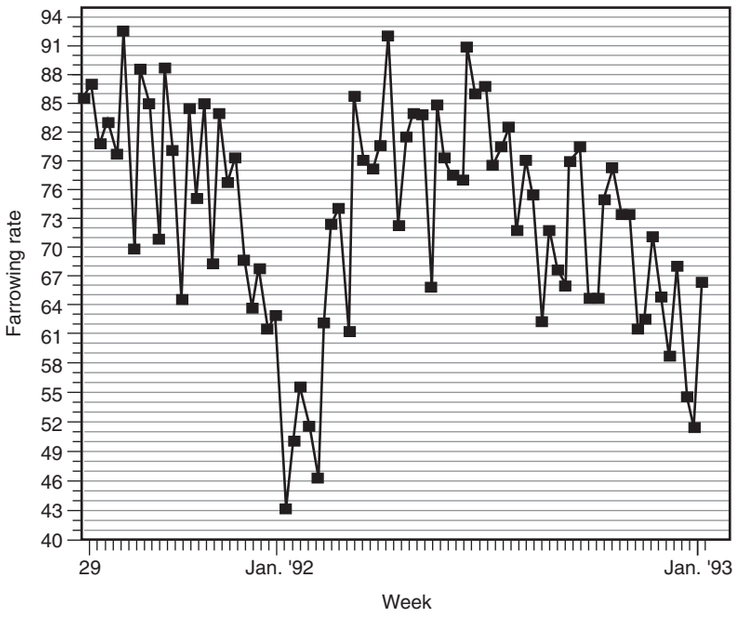

Fig. 108-1 Farrowing rate for a 1000-sow farm during 1992 and 1993. Note depression in farrowing rates during the winter months of each year (corresponding to late summer–early autumn matings). (From Tubbs RC, Zulovich JM: Facility design and housing for swine. *Vet Med* 1995;90:893.)

liveborn pigs. Progesterone concentrations are lower in sows during late summer and early autumn, and this decrease may indicate a propensity for pregnancy loss.[12]

Although high ambient temperatures frequently are blamed for seasonal infertility by producers and veterinarians, the problem probably is not related to heat, or to reduced semen production or libido in boars. The phenomenon of seasonal infertility is more likely to be related to the response of sows to changes in photoperiod. The exact mechanism has not been elucidated, and disagreement exists about whether sows respond to increasing photoperiod before the summer solstice (June 21) or to decreasing photoperiod after the summer solstice. Decreased photoperiod after the summer solstice may signal sows to become less reproductively efficient, possibly to avoid farrowing in the winter. The result is a decrease in farrowing rate due to reduced pregnancy maintenance. The number of sows that return to estrus after mating at regular intervals (18 to 25 days after mating) or irregular intervals (later than 25 days after mating) increases; a relatively greater increase is seen in the number of sows that return to estrus after a prolonged interval. Prolonged WSI in sows and anestrus, especially in gilts, occur as well. The peak time for abortions is around September 21, which falls between the summer solstice (June 21; longest daylight) and the winter solstice (December 21; shortest daylight).[13] Figure 108-1 shows the seasonal infertility pattern observed on a 1000-sow farm in the southeastern United States in 1992 and 1993.[14] Birth weights, weaning weights, and preweaning mortality rate also appear to have seasonal patterns on many farms, but these effects may be related primarily to temperature, rather than to photoperiod.

MANAGEMENT PRACTICES

Most reproductive problems on swine farms are related to the way in which animals are managed. The pivotal point

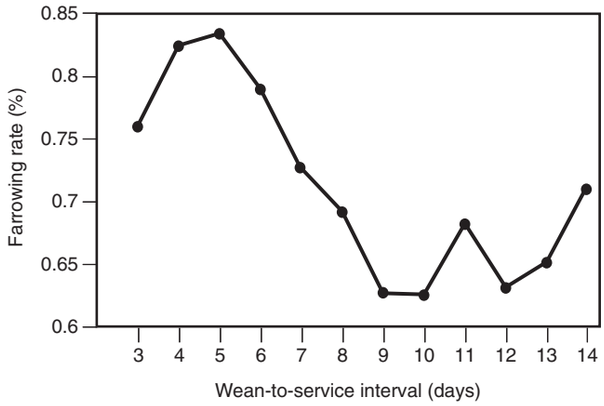

Fig. 108-2 Farrowing rate by wean-to-service interval. Based on records from approximately 51,000 hand matings. (From Tubbs RC: Evaluating management causes of swine reproductive failure. *Vet Med* 1995;90:195.)

of swine breeding programs occurs in the farrowing house, not in the breeding barn. Feed intake during lactation is the key to maintenance of reproductive performance from one litter to the next. Sows must have high levels of nutrient intake to rebreed quickly after weaning. A short WSI is important to achieve high subsequent farrowing rates and litter sizes (Figs. 108-2 and 108-3).[15] High feed intake during lactation, especially during the first 2 weeks of a 3-week lactation, is critical to stimulation of gonadotropin activity and reduction of the WSI.[16] To achieve a 3- to 6-day WSI, the following levels of nutrient intake are recommended during lactation: 16 Mcal of metabolizable energy, 800 to 1000 g of protein, 45 to 50 g of lysine, 40 to 50 g of calcium, and 35 to 40 g of phosphorus.[17]

CHAPTER 109

Influence of Environment and Housing on Swine Reproduction

JOSEPH M. ZULOVICH and RODERICK C. TUBBS

EFFECTS OF TEMPERATURE

The effects of temperature on reproductive performance have been examined by a number of researchers. Although the specifics may be debated, there is general agreement about the impact of temperature.[1] In general, increases in temperature above a critical level cause a decline in reproductive performance. In sows and gilts, the reduction in reproductive performance is expressed primarily as establishment of fewer pregnancies when heat stress is not severe. If heat stress is severe during breeding and early gestation, declines in reproductive performance also can be expressed as decreased embryo survival. Semen quality of boars is reduced by heat stress, but that effect may not become apparent for up to 40 days.[1] Boars exposed to a period of significant heat stress exhibit diminished semen quality for a limited period of time. The effects of heat stress on semen quality dissipate after a lag time of about 60 days after the heat stress ends.

Severe heat stress usually is characterized by sustained increases in rectal temperature. If rectal temperatures remain elevated, methods to reduce heat stress should be implemented. Such measures may include use of evaporative cooling pads, drippers and foggers, and circulating fans. To fully understand the effects of temperature, the concepts of **effective environmental temperature** (EET) and **lower critical temperature** (LCT) must be understood. EET is the temperature that a pig actually feels. EET includes the effects of air speed (drafts), floor type, building insulation, and supplemental cooling. The LCT is the EET at which pigs must increase metabolism to maintain body temperature and production.[2] If sufficient energy intake is not maintained, pigs use body reserves to increase metabolism. LCT also is defined as the EET at which cold stress begins to occur.[3] To prevent cold stress in sows, the EET should be above 15.5° C. EET can be used to evaluate the various methods for reducing heat stress.

Feed intake and subsequent metabolism in gestating sows or gilts provides energy for maintenance (i.e., basic life processes and body temperature control), pregnancy, and body condition or growth. Energy for metabolism must come from feed intake. Metabolic energy will be allocated to maintenance first, then to pregnancy maintenance and development, and last to body conditioning and growth. If sufficient energy intake is not provided, a sow or gilt will lose body condition. To stop loss of body condition, the EET must be raised or feed intake must be increased. If a number of animals are losing body condition, the EET should be raised if possible. If only a few animals are losing body condition, their energy intake should be increased. If the EET is increased for a few animals, the remaining animals in the same environment may become heat stressed. If an animal is heat stressed, it either will use additional energy to dissipate heat or will decrease energy intake. With constant energy intake, a heat-stressed sow could lose body condition because additional energy is used to dissipate body heat, through panting, for example.

EFFECTS OF HUMIDITY

Relative humidity (RH) should be maintained between 40% and 60% but must be maintained below 80%.[4] An environment that provides an RH between 40% and 60% is healthiest for sows. Most bacteria and other microorganisms thrive in an environment with high humidity. An RH between 40% and 60% minimizes the proliferation of bacteria while providing a level of humidity that is practical to obtain with typical ventilation and heating equipment. If the environment gets too dry, dust levels tend to increase. If the inside environment gets too wet (RH above 80%), moisture condensation problems typically occur when the outside weather is cold. During some periods during the year, it is nearly impossible or very impractical to maintain RH within the 40% to 60% range. During these periods, 70% RH should be the upper maximum, and good management practices, such as stringent sanitation, should be emphasized to help ensure a healthy environment for the sows.

Swine are less sensitive to humidity than to air temperature. A temperature-humidity index combines the effect of temperature, using the dry bulb temperature, and humidity, using the wet bulb temperature, into one numeric value. A temperature-humidity index for swine has been developed based on the physiologic responses of swine to various thermal environments.[5] The coefficients of the temperature-humidity index are 0.75 for dry bulb temperature and 0.25 for wet bulb temperature for adult swine. Because the coefficient for dry bulb temperature is considerably larger than the coefficient for wet

bulb temperature, adult swine are more sensitive to air temperature than to humidity. This fact is readily apparent in practice because evaporative cooling pads are extensively used in swine facilities to reduce heat stress. An evaporative cooling pad system converts energy in air based on dry bulb temperature to energy in air based on wet bulb temperature (humidity). By shifting the energy in air from a component to which large swine are highly sensitive to a component to which swine are less sensitive, the thermal environment the pig "feels" due to heat is minimized, and the environment is less stressful to the animal. If evaporative cooling pads are used, good management must be practiced so that adverse health effects due to high humidity are minimized.

EFFECTS OF LIGHT

Light frequency and intensity for swine housing typically are based on the needs of the workers and the activities they perform,[6] rather than on providing the best physiologic situation for the animals, largely because little research has been done on the influence of light, and the results of what has been done are conflicting.[7–12] The general level of illumination recommended for breeding and gestation facilities is 15 foot-candles. The level of illumination should be increased to 20 foot-candles for animal handling and inspection. For the breeding area, this would correspond to the times when hand mating activities are being conducted.

Despite conflicting research results, the effects of light on swine reproduction are beginning to be understood. Gilts attain puberty normally with a minimum of 9 hours of light per day. Boars exposed to 15 hours of light per day had better semen quality at 8 months of age than did boars exposed to natural short-day photoperiods.[2] Long photoperiods during lactation may or may not improve the wean-to-service interval (WSI) or postweaning reproductive performance. Long photoperiods during late gestation may predispose to longer WSIs.[13] A long photoperiod has been shown to increase the length of the estrous period in gilts by about 1/2 to 1 day.[14] One study has suggested that supplemental light during lactation (16 total hours of light versus normal daylength patterns in controls) synchronized the onset of postweaning estrus in sows, and a higher proportion of treated sows than control sows had WSIs of 5 days or less.[12] Other studies have shown no effect.[7–11]

EFFECTS OF AIR CONTAMINANTS

Air contaminants that typically are found in swine facilities include ammonia, dust, hydrogen sulfide, and carbon monoxide. High levels of these contaminants, such as ammonia levels above 100 parts per million (ppm), have been shown to decrease production levels and cause health problems.[1] The swine industry is rapidly moving to improve air quality in swine confinement facilities, however, to benefit the health of the animal caregivers.[15] The air quality in swine breeding and gestation facilities should be maintained within the standards for gases defined by the National Institute for Occupational Safety and Health (NIOSH). No worker health standards are currently in effect for agricultural workers. The current NIOSH standards for industrial workers are used only as a guide for agricultural workers. If gas contaminant levels are kept within these standards, air quality should not have any adverse effects on worker health. Air quality in modern breeding and gestation facilities should not adversely affect sow reproductive performance if the air quality is adequate for the workers inside the facility.

The manure management system has a major impact on the air quality inside a swine facility. Manure management systems affect the levels of ammonia, hydrogen sulfide, and methane. Ammonia levels in buildings with scraper systems can average about 25 ppm[16] or higher, and buildings with scraper systems have a difficult time maintaining air quality that is acceptable for worker health as just described. Therefore, scraper systems probably should not be considered as an acceptable method of manure removal. Deep pit buildings can have average ammonia levels that are acceptable,[17] but when pits are emptied, ammonia levels, along with hydrogen sulfide and methane levels, usually are not acceptable and can reach dangerous levels for both workers and pigs. Acceptable ammonia levels can be achieved with the use of flush systems and pit recharge systems. These systems either quickly remove manure from the building or immediately submerge manure in water. Another acceptable manure handling system is a gravity-drain, liquid manure system (hairpin gutters). This system submerges manure in liquid and then periodically removes manure from the building. When manure is either quickly removed from the building or submerged in water along with periodic removal of the liquid, air quality inside a facility usually is acceptable.

INFLUENCE OF TYPE OF HOUSING ON SOW REPRODUCTIVE PERFORMANCE

Although most data now indicate a clear advantage in reproductive performance for sows housed individually in stalls,[18,19] opinions about the best way to house sows continue to be divided. This division occurs because of disagreements about the type of system that provides the best animal welfare and because of the perceived desires of the public for some input into the management practices that produce the meat they consume.[20] It is beyond the scope of this chapter to discuss all of the social implications of sow housing. We concentrate on practices that obtain high reproductive performance while simultaneously providing for sow health and longevity.

Inside versus outside sow housing. McGlone[21] has summarized data comparing inside-housed and outside-housed sow herds in three countries (Table 109-1). These data indicate that inside sow housing has a definite advantage in reproductive performance. One problem with interpreting the data is that outside sow herds in Europe tend to be more intensively managed than those in the United States. There is general agreement, however, that reproductive performance is higher in sow herds housed inside.

Inside sow housing: individual versus group. With inside sow housing, several options are available. Sows may be housed individually, in large groups, in small

groups, or in groups in which feed is delivered by computer-controlled feeders (electronic sow feeders [ESFs]) that require electronic sow identification. These systems have been compared[21,22] (Tables 109-2 to 109-4). From the data, it is apparent that in the United States and the Netherlands, individual sow housing is the superior system for high reproductive performance. In the United Kingdom, ESF systems are equal to individual housing, at least when the results from stalls and tethers are combined. These results must be interpreted with some caution, because stalls and tethers are different systems and usually are associated with different levels of reproductive performance[21] (see Table 109-3).

Data from the Netherlands, collected from 1987 to 1990, support the use of individual stalls for higher reproductive performance. In this study, individual stalls, girth tethers, and group housing with electronic identification and computer-controlled feeding were compared

(see Table 109-4). Although all of the systems gave acceptable reproductive performance, individual stalls had a numerical advantage in almost all of the categories reported.

Influence of housing on the wean-to-service interval. Studies of the influence of various types of housing systems on the WSI are divided. Some studies show no influence of type of housing.[23] Others show a definite advantage for individually housed sows.[24–27] Our observations are that sows housed individually either show stronger physical signs of estrus or are more readily detected in estrus by most breeding managers.

SUMMARY

Regardless of specific housing situations, the sow's needs and her care and comfort are of primary importance. Sows usually are under some degree of stress after weaning, because of the demands of lactation and the abruptness of weaning. The endocrine system undergoes profound changes, and physical changes occur as well. In most management situations, individually housed sows require but also receive more individualized attention. Feed intake can be measured and controlled more accurately. Observation for signs of estrus and responsiveness to the presence of a boar may be facilitated by individualized housing. Like individual housing, group housing has its own unique set of potentially stressful situations. Injuries due to fighting, inadequate feed intake by some sows and excessive feed intake by others, and poor exhibition of the physical signs of estrus by sows that are low in the social order within a group all are potential problems with group housing.

Caution must be used in interpreting most of the available data on sow housing, for several reasons. First, the data in most instances is from records of field observations, not controlled studies. A controlled study would require a single farm to provide the various housing options in the same or identical buildings operated by the same or identical management. Second, statistical significance is not reported for most of the studies, only numerical differences. Third, all outdoor systems are not equal; likewise, all indoor systems are not equal, and group size is not defined in many of the reports. Finally, animal handling and human-animal interactions have a profound influence on sow reproductive performance.[28] Sows respond to their treatment. Data from farm records cannot account for differences in husbandry skills from farm to farm.

CHAPTER 110

Reproductive Health Programs for Swine Herds

JAMES G. FLOYD, Jr and RODERICK C. TUBBS

Veterinarians often have concentrated on infectious diseases when addressing reproductive problems in swine herds. The enhanced ability to critically analyze farm records with computer databases, however, has led to the conclusion that greater than 90% of suboptimal reproductive performance is due to factors other than infectious disease, such as seasonal effects[1] or shortcomings in management.[2] Nevertheless, infectious disease cannot be ignored when it comes to optimizing reproduction. Establishing a comprehensive reproductive health program minimizes the adverse effects of disease and enhances reproductive management. Many measures to control infectious disease involve scheduled production flow, which necessarily involves optimal breeding management to provide sufficient numbers of pigs to enter that flow as a group.

Biosecurity is the term used to describe those efforts taken to protect swine herds from infectious agents—viral, bacterial, fungal, or parasitic.[3] A comprehensive biosecurity program should systematically (1) prevent disease entry, (2) maintain disease resistance, (3) monitor disease status, and (4) control disease outbreaks.

PREVENTING DISEASE ENTRY

Specific measures should be taken to prevent pathogen entry from other farms and nonpig vectors. In addition, contact between the established herd and new additions to the breeding herd must be regulated to protect both.

Location of the herd is a major determinant of the ability to deny pathogen entry.[4] Airborne spread is a major route of pathogen movement[5] (Table 110-1). Spread of pseudorabies virus has been documented in consistent directions along prevailing seasonal winds.[6] Porcine reproductive and respiratory syndrome virus (PRRSV) also may be spread by aerosols, although the data are inconclusive. Ideally, a facility should be located as far as possible from other facilities or farms, although in pig-dense areas the choices may be limited.

Nonpig vectors such as rodents, birds, insects, pet or stray dogs and cats, and humans can mechanically introduce pathogens from contact with pigs and their wastes on other farms. Constructing a barrier perimeter fence 12 to 15 m from buildings to restrict animals, vehicles, and people to one portal of entry is now standard for new construction in the swine industry.[7] Prominent signs warning visitors to stay out without prior approval and to check in before making deliveries will reinforce the importance of biosecurity to herd employees and visitors.

Establishing an apron of gravel or limestone 0.6 to 0.9 m wide and 15.2 cm deep and eliminating weeds around hog buildings, along with strategic placement of traps and baits, help to rodent-proof a building.[8] "Hardening" a building by tight construction and closing potential openings help to control rodents, flies, and birds.

Although pigs remain the primary source of introduction of new diseases, humans can be a significant mode of pathogen entry. Establishing shower-in–shower-out entry, with protective clothing provided by the farm, and disinfectant foot baths will control most of the potential for pathogen introduction by humans. Because of concerns that the human body may temporarily harbor certain swine pathogens that may not be eliminated by

CHAPTER 110

Reproductive Health Programs for Swine Herds

JAMES G. FLOYD, Jr and RODERICK C. TUBBS

Veterinarians often have concentrated on infectious diseases when addressing reproductive problems in swine herds. The enhanced ability to critically analyze farm records with computer databases, however, has led to the conclusion that greater than 90% of suboptimal reproductive performance is due to factors other than infectious disease, such as seasonal effects[1] or shortcomings in management.[2] Nevertheless, infectious disease cannot be ignored when it comes to optimizing reproduction. Establishing a comprehensive reproductive health program minimizes the adverse effects of disease and enhances reproductive management. Many measures to control infectious disease involve scheduled production flow, which necessarily involves optimal breeding management to provide sufficient numbers of pigs to enter that flow as a group.

Biosecurity is the term used to describe those efforts taken to protect swine herds from infectious agents—viral, bacterial, fungal, or parasitic.[3] A comprehensive biosecurity program should systematically (1) prevent disease entry, (2) maintain disease resistance, (3) monitor disease status, and (4) control disease outbreaks.

PREVENTING DISEASE ENTRY

Specific measures should be taken to prevent pathogen entry from other farms and nonpig vectors. In addition, contact between the established herd and new additions to the breeding herd must be regulated to protect both.

Location of the herd is a major determinant of the ability to deny pathogen entry.[4] Airborne spread is a major route of pathogen movement[5] (Table 110-1). Spread of pseudorabies virus has been documented in consistent directions along prevailing seasonal winds.[6] Porcine reproductive and respiratory syndrome virus (PRRSV) also may be spread by aerosols, although the data are inconclusive. Ideally, a facility should be located as far as possible from other facilities or farms, although in pig-dense areas the choices may be limited.

Nonpig vectors such as rodents, birds, insects, pet or stray dogs and cats, and humans can mechanically introduce pathogens from contact with pigs and their wastes on other farms. Constructing a barrier perimeter fence 12 to 15 m from buildings to restrict animals, vehicles, and people to one portal of entry is now standard for new construction in the swine industry.[7] Prominent signs warning visitors to stay out without prior approval and to check in before making deliveries will reinforce the importance of biosecurity to herd employees and visitors.

Establishing an apron of gravel or limestone 0.6 to 0.9 m wide and 15.2 cm deep and eliminating weeds around hog buildings, along with strategic placement of traps and baits, help to rodent-proof a building.[8] "Hardening" a building by tight construction and closing potential openings help to control rodents, flies, and birds.

Although pigs remain the primary source of introduction of new diseases, humans can be a significant mode of pathogen entry. Establishing shower-in–shower-out entry, with protective clothing provided by the farm, and disinfectant foot baths will control most of the potential for pathogen introduction by humans. Because of concerns that the human body may temporarily harbor certain swine pathogens that may not be eliminated by

baths or disinfection, some farms have required that visitors must not have been on another hog farm at any time during the preceding 72 hours. Although such steps may decrease potential for disease entry, information regarding delay periods that are adequate or even reasonable is scarce. In addition, this requirement can significantly restrict the activities of veterinary consultants.[9]

Swine transport vehicles should be sanitized between loads. Movement of hogs should be one-way, with no reentry after the vehicle has passed the "point of no return." Disease outbreaks have been traced back to hogs that went onto a truck, only to scurry back into the finishing floor.

Incoming breeding stock are potential sources of disease entry. Although breeding stock sources recognize that a "clean" reputation is vital to continued success, a wide spectrum of health programs exist on those farms. **Minimum-disease status**, sometimes referred to as **high health**, implies a low level of pathogens without specifying those not present. Some breeding stock companies utilize these terms for the herds in their distribution pyramid.[5] Herds with **specific pathogen–free** designation are certified free of certain enumerated pathogens by virtue of cesarean derivation and immediate isolation of pigs. Those pigs are used to populate primary specific pathogen–free herds or to farrow pigs naturally, which are then used to populate secondary specific pathogen–free herds. Breeding stock from minimum-disease herds, some now preferentially located in areas not traditionally swine-dense, may be more at risk from diseases present in the herd of entry than the recipient herd is from the new animals. Quarantine and isolation of these pigs are essential, in conjunction with planned exposure to the organisms resident on the farm. Examples of recommended introduction protocols from two seedstock companies are shown in Table 110-2. In general, a 60-day quarantine period is recommended to reduce the possibility of PRRSV transmission. After 14 to 21 days, animals are serologically tested for any diseases of regulatory concern. Appropriate vaccines and exposure protocols are applied following the retesting procedure.

Artificial insemination (AI) and embryo transfer technology may offer opportunities for reducing the need to introduce new animals into a breeding herd. At present, AI is a more practical technology than embryo transfer for routine use. In most situations, use of AI can improve health status.

Buying and introducing fewer boars because AI is being used constitute one reason AI can decrease disease risk. A 600-sow farm with 30 boars probably will buy 10 new boars per year. A 600-sow farm using AI and maintaining 6 boars is likely to purchase only 2 new boars per year. Fewer introductions of new animals reduce the risk of introducing disease with the new animals.

An off-site boar stud facility may offer an opportunity for improved biosecurity in some systems of production. An off-site facility requires at least the same level of biosecurity as that practiced in the breeding herd. To gain the full benefit of improved biosecurity with a boar stud, separation between collection technicians and processing technicians should be maintained in the AI laboratory. A pass-through window or a processing area separated from the collection area is needed. Collection technicians should never enter the laboratory area.

Buying semen rather than boars may further reduce the risk of introducing disease; however, the source herd

Table **110-1**

Airborne Pathogen Spread

Pathogen/Disease	Maximum Distance, (km)
Transmissible gastroenteritis virus	0.8
Atrophic rhinitis	0.8
Pleuropneumonia	0.8
Mycoplasma hyopneumoniae	3.2
Porcine reproductive and respiratory syndrome virus	3.2
Swine influenza virus	4.8–6.4
Pseudorabies virus	40.2
Foot-and-mouth disease virus	40.2

Data from Moore C: Biosecurity and minimal disease herds. *Vet Clin North Am Food Anim Pract* 1992;8:461.

Table **110-2**

Breeding Stock Company Protocols for Introducing Animals

Program Feature	Company 1	Company 2
Duration of isolation	30–42 days	28 days, 28 days acclimatization
Distance of isolation facility from herd	Minimum 91 m; 0.8–1.6 km desirable	1.6 km minimum; 3.2 km desirable
Commingling	Adjacent pen contact with animals from herd (including culled sows OK) after 1 week	Nose-to-nose contact with culled boars and sows
Feedback	Fresh manure from breeding herd three times a week for 2 weeks	Manure, placentas, and dead fetuses continuously for 3–4 weeks (in consultation with herd veterinarian's DVM)
Vaccination	Same vaccines used in existing breeding herd	Leptospirosis, parvovirus, erysipelas (others in consultation with herd veterinarian's DVM)

should be checked in the same way as that used for screening live animals for purchase. Several species of bacteria are commonly found in boar semen. Many of them are commensal inhabitants of the preputial area and are not specific pathogens for the reproductive system but nevertheless may disrupt individual pregnancies. A major problem with many of the contaminating bacteria is that they reduce the shelf-life of semen. Some bacteria may have a spermicidal effect as well. Because the temperature at which swine semen is stored (15–20° C) does not inhibit bacterial growth, antibiotics are routinely added to semen extenders.

Many viruses have been shown to be present in boar semen. Only three, African swine fever virus, porcine parvovirus, and PRRSV, have been proved to be transmitted to sows through semen. The same precautions must be taken with the source of semen as are taken with live animals, to minimize the risk of bringing these viruses into the herd with semen. Because viruses and their by-products usually are not spermicidal, and antiviral agents are much more expensive than antibiotics, antiviral agents are not commonly added to semen extenders.

In addition to the potential for reducing the risk of disease from incoming animals, AI can reduce the spread of disease organisms within a breeding herd. For example, on a 600-sow farm, 30 boars are more likely to transmit disease organisms within a breeding herd than are 6 boars that never actually come into physical contact with the sows. At least some anecdotal evidence suggests that correct use of AI can limit vaginal discharge problems within a sow herd.

MAINTAINING DISEASE RESISTANCE

However free a herd may initially be from infectious pathogens, this status tends to erode over time. The speed and degree of erosion depend on the biosecurity measures employed to protect the herd from entry of outside pathogens, and on measures taken to decrease pathogen transmission and multiplication within the herd.

Within a herd, infectious agents such as coccidia, ascarids, and clostridia can be present in the environment long after pigs have been removed.[5] The pig itself, however, is the source of most pathogens, with disease transmission within a herd occurring by direct pig-to-pig contact.[5] The cycle of transmission for both environmental and pig-to-pig sources can be broken through production flow technologies that minimize contact of susceptible pigs with pathogens present in other pigs or the environment.

Production flow should be managed so that groups of pigs start out life in a closely matched age group and stay together in that group until finished or introduced into the breeding herd as replacements. **All-in–all-out** production systems move pigs through facilities as a group so that the facilities can be totally emptied on a schedule, allowing adequate time for clean-up between groups. This reduces the chance of infection of the next group of pigs from an unsanitary environment. Perhaps even more important, all-in–all-out production keeps pigs of similar age and immune status together, without exposing them to older pigs that may be shedding organisms to which younger pigs may not have developed immunity.

Table **110-3**

Maximum Weaning Age to Eliminate Pathogens

Organism	Maximum Weaning Age, (d)
Mycoplasma hyopneumoniae	<10
Pasteurella multocida	<10
Salmonella choleraesuis	<12
Haemophilus parasuis	<14
Actinobacillus pleuropneumoniae	<21
Pseudorabies virus	<21
Transmissible gastroenteritis virus	<21

Segregated early weaning is another production flow technology that refines the all-in–all-out system. Because the breeding herd serves as the resident source of most infectious pathogens on a farm, separating pigs from the breeding herd as soon as possible before pathogen transmission takes place is a logical step (Table 110-3). Weaning before 21 days of age accomplishes this goal at a time when the pig's colostrum-derived immunity is still sufficiently high to provide some protection. Traditional weaning at 3 to 4 weeks of age coincides with the time at which colostral immunity has waned, when the pig's immune system is just beginning to respond to the organisms it encounters.

Coupling segregated early weaning with **two- or three-site isolated production** adds a further biosecurity element to the all-in–all-out system. Two-site production includes weaning pigs at 10 to 21 days old and moving them to a nursery on the same site as the finishing unit, usually located at least 1.7 km away from the farrowing site. With three-site production, the early-weaned pigs are moved to an isolated nursery and then at approximately 18 to 27 kg are moved to a finishing facility at a third site.

Enhanced production flow technologies allow the manager to optimize each unit's environment for the age of the pig it contains. Temperature and ventilation requirements can be maintained in a more cost-effective manner if the pigs are within a narrow range of ages, while an environment is created that is more conducive to pig comfort and reduced pathogen transmission. Accurate production scheduling allows for accurate scheduling of farrowing, which facilitates induced and attended farrowings to lower intrapartum and peripartum piglet mortality.

Although vaccine efficacy data may not accurately reflect the degree of protection against reproductive or other diseases in field settings,[10] routine vaccination of breeding swine for common diseases is still recommended. Prebreeding vaccination of sows and gilts and twice-yearly vaccination of boars against leptospirosis, porcine parvovirus infection, and erysipelas are routinely recommended by most veterinarians. Prefarrowing vaccinations against *Escherichia coli* and atrophic rhinitis also

are widely used. In some segregated early weaning protocols, especially in the initial **medicated early weaning** and **modified medicated early weaning** programs, extensive prefarrowing immunization protocols have been recommended to maximize colostral antibodies for pigs to undergo early weaning. Actual vaccination protocols should be based on disease monitoring programs established by a herd veterinarian who is intimately associated with the production flow and management of the herd. The specific protocols should be reviewed by the veterinarian and the on-farm manager at least semiannually.

MONITORING DISEASE STATUS

Programmed herd visits in conjunction with careful monitoring of production data through computer databases are the basis of veterinary consultation in modern swine herds. The expanded use of databases has allowed for better definition of "normal" production figures and for establishment of intervention levels when those figures lie outside the normal range[2] (Table 110-4).

Serologic monitoring may be a useful adjunct to regular veterinary consultation; however, immunodiagnostic profiles must be interpreted carefully because the degree of antibody response may vary tremendously depending on the laboratory, the sensitivity and specificity of the particular test, the sample size, and the time of collection with respect to incidence of clinical or subclinical disease.[5,11,12] It is important to recognize that a rising antibody titer indicates exposure to a particular organism. Exposure, however, does not necessarily equal causation.

Serum banked from blood collections for regulatory purposes may be useful for retrospective diagnosis of disease emergence. With specific reference to reproductive problems, however, relying on serologic testing alone may lead to the conclusion that infectious disease is at fault, when other factors are more likely.

Table **110-4**

Target and Intervention Levels for Commonly Used Reproductive Parameters

Parameter	Target	Intervention Level
Farrowing rate, %	87	80
Liveborn, *n*	10.5	10
Stillborn, %	5	8
Mummies, %	1	3
Birth weight, kg	1.6	1.4
Weaned, *n*	9.3	8.5
Preweaning mortality, %	10	15
21-day adjusted wean weight (litter), kg	59.1	50
Litters/sow/year, *n*	2.5	2.2
Pigs/sow/year, *n*	23	20
Pigs/crate/year, *n*	130	110
Cull rate, %	35–40	<30; >50
Nonproductive sow days	40	60

Necropsy of pigs that die is desirable if it can be practically accomplished. It may not be feasible for every dead pig to be examined; however, if mortality exceeds the established intervention level, it should become a priority. Necropsy can be facilitated on some farms by training competent employees to collect applicable tissues and forward them to the prearranged diagnostic laboratory. Similarly, some consultants have instructed workers to freeze dead neonatal pigs for gross necropsy during the regular visit. In this fashion, stillborn pigs can be distinguished from those with inflated lungs, and gastrointestinal disease sometimes can be detected as a cause of death.

Slaughter checks are useful for veterinary consultants to track diseases of the respiratory and gastrointestinal systems, if sample size is sufficient for the size of the herd and disease prevalence.[13] It must be kept in mind that gross evaluation of slaughterhouse specimens of finished hogs provides information on disease that has occurred during the last 2 months of production. Indeed, some recent studies have failed to demonstrate a significant relationship between snout and lung lesions at slaughter and measures of growth performance.[14,15]

Examination of reproductive tracts of breeding age animals at slaughter may aid in the diagnosis of noninfectious causes of reproductive failure and infectious conditions of the urogenital tract. Coupled with knowledge of normal ovarian, uterine, and fetal morphology and physiology, examination findings may help the consultant to formulate appropriate intervention strategies.[16]

CONTROLLING DISEASE OUTBREAKS

Effective treatment begins with accurate diagnosis. Acute "storms" of infectious disease may dramatically affect reproductive parameters, such as occurred with the previously unrecognized PRRSV in the late 1980s. Reproductive signs of acute PRRS include premature farrowings, increased stillbirths, mummification of fetuses, and birth of weak piglets.[17] Reproductive problems, however, usually do not occur as storms but more often are manifested as decreasing production levels.

When seeking the cause of reproductive performance shortfalls, swine veterinarians must evaluate (1) people, (2) environment, (3) nutrition, (4) genetics, and (5) health.[2] A correct and timely diagnosis is more likely with systematic investigation of these potential factors.[18]

Critical analysis of farm records in light of management changes over time may be the most effective diagnostic tool available. For example, making personnel changes in the breeding gestation unit may be reflected by a decreased weaning-to-first-service interval, although this may not be seen for some time after the new person takes over.[2]

Although resort to medications often is the first response when reproductive problems are recognized, such agents have seldom been demonstrated to be efficacious. This probably is reflected in the scarcity of label approval of drugs for swine reproductive diseases. Oxytetracycline and chlortetracycline as feed additives have label uses for reducing the abortion rate in the presence

of leptospirosis, and injectable erythromycin and oxytetracycline are labeled for swine leptospirosis.[19]

Vaccinations at critical periods may increase resistance to disease and reduce its effects. Such periods can be identified serologically in some instances. Vaccination is more often utilized with diseases caused by agents such as *Actinobacillus pleuropneumoniae* than with reproductive disease.

Depopulation-repopulation may be indicated when disease has become endemic in a herd. The cost-benefit ratio of such a strategy should first be carefully studied because of the concurrent disruption in cash flow and significant expenses incurred. In addition, this extreme strategy may not solve "people" problems if the same personnel are present after depopulation. Furthermore, certain reproductive problems such as vaginitis and cervicitis, viral embryonic loss (e.g., from parvovirus or enterovirus infections), effects of parity distribution, and leptospirosis may occur despite depopulation-repopulation.[20]

Creative strategies such as **partial depopulation** of the nursery facility for a limited period have been successfully used to eliminate nursery deaths associated with chronic PRRS.[21] This strategy was based on the recognition that pigs did not seroconvert until 8 weeks of age, and these pigs were infecting younger pigs when they were introduced to the nursery. Such partial depopulation allowed the preservation of valuable breeding stock and minimized the loss of cash flow.

CHAPTER 111

Using Statistical Process Control to Investigate Reproductive Failure in Swine

ROBERT B. MORRISON, GARY D. DIAL, PETER B. BAHNSON, WILL E. MARSH, JAMES E. COLLINS, and DALE D. POLSON

You are called by a producer who is alarmed that the farrowing crates are half empty this month. What should he do? Another producer calls to report yet another abortion. Should he vaccinate? A third producer calls: She has noticed an increase in the number of returns to service. What should she do?

The diagnostician investigating a case of reproductive failure usually is presented with a primary clinical sign. There are relatively few manifestations of reproductive failure but many potential causes of each. Reproductive failure may be clinically manifested by one or more of the following signs:

- Failure to show estrus
- Return to estrus after being bred
- Abortion or premature parturition
- Failure to farrow despite having conceived
- Abnormal litter characteristics at birth as evidenced by low number of liveborn piglets or an elevated number of stillborn piglets, mummified piglets, or weakborn piglets

For example, one might be presented with a low farrowing rate; that is, a lower than expected percentage of sows that were apparently bred are farrowing. To investigate this case, the diagnostician must first know what the expected farrowing rate is for this herd. Assuming a "real" decrease has occurred, the diagnostician then must determine if the sows were actually bred and whether they conceived, and, assuming they conceived, why they did not farrow (Fig. 111-1). A relatively simple-appearing clinical situation quickly becomes complex. The case is further complicated if the producer lacks detailed reproductive records (arguably, without good records, the case is simple—it is unsolvable).

In investigating a case of reproductive failure, it may help to remember that the breeding herd exists to produce weaned pigs. The number of weaned pigs per unit of time is referred to as the herd's **output** and is determined using the following formula:

number of females bred × farrowing rate × average liveborn × survival rate = output

For example:

30 bred per week × 80% farrowing rate × 10 liveborn × 90% survival = 216 pigs weaned

The gilt pool and breeding, gestation, and farrowing facilities will have a certain capacity in terms of pigs weaned per unit of time, and the actual number achieved divided by the potential is referred to as the **average utilization rate.** This commonly is expressed as a percentage. As might be expected, unused capacity costs money (i.e., the opportunity cost attributed to pigs that could have been produced but were not), and the usual intention is therefore to maximize the utilization rate. The first step in maximizing utilization is to breed the appropriate number of females per unit of time. This having been accomplished, any real decrease in utilization rate may be caused by reproductive failure. The diagnostician's job is to identify the source of the problem and implement solutions.

Returning to the farrowing rate example, suppose a herd's farrowing rate has decreased from 85% to 70%. The diagnostician must now determine (1) whether the clinical manifestation represents a "real" change or random variation and (2) if the problem is "real," what the cause of that problem is. The purpose of this chapter is to guide the diagnostician through these decisions.

APPROPRIATE DECISION MAKING: WHEN IS A SYSTEM OUT OF CONTROL?

Reproductive failure may present itself as an epidemic within a herd (sudden onset—an "outbreak") or as a chronic, lower-than-expected level of performance. Diagnostically, the method of investigation and the likelihood of identifying the cause differ markedly between these two presentations.

Epidemic Reproductive Failure

In our experience, epidemics of reproductive failure are more likely to be caused by a single infectious agent such

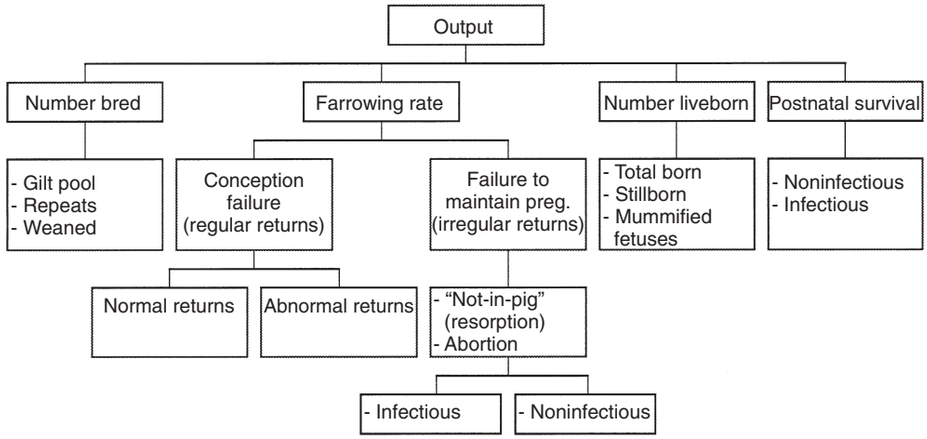

Fig. 111-1 Summary flow chart for investigating reproductive failure.

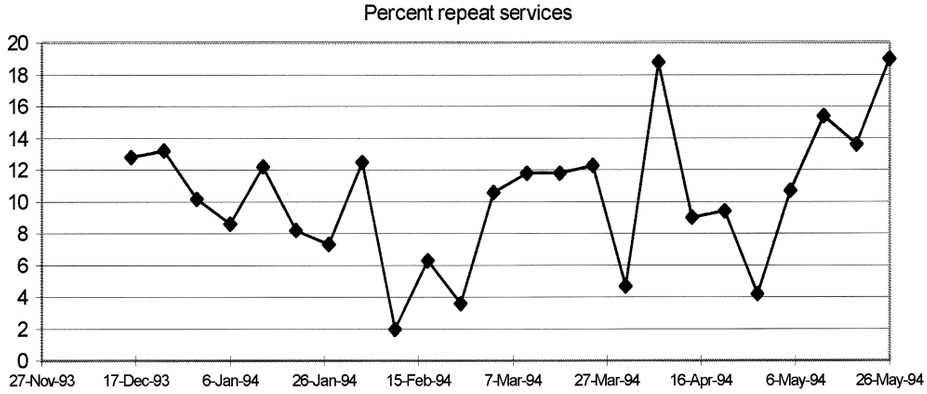

Fig. 111-2 Run chart of percent of sows returning to service in a 1400-sow herd.

as PRRSV or porcine parvovirus. A sudden, but less dramatic, decline in reproductive performance may be associated with epidemics of infection due to pseudorabies virus, transmissible gastroenteritis virus, or swine influenza virus. These latter cases of mild but significant reproductive failure also may be caused by a variety of bacteria, including *Leptospira* spp. Diagnostically, submission of appropriate samples from a herd epidemic is likely to be very revealing if an infectious agent is involved.

Noninfectious causes of reproductive failure also can present as epidemics. This might include such factors as the use of infertile boars, a change in breeding techniques, poor feed quality, seasonal infertility, and others.

How does the diagnostician know when a herd is experiencing an epidemic of reproductive failure? An **epidemic** may be defined as the number of failures being "one more than expected." Unfortunately, managers and consultants usually are not sure of what is expected. Although an intuitive impression may be correct, veterinarians need to be cautious as they evaluate herd performance and make recommendations. Effective decision making entails (1) knowing when a real change has taken place and not random variation, (2) evaluating the cost-benefit ratio of options, and (3) deciding when the problem should be reevaluated.

Two types of errors are possible in making such decisions. A problem might be diagnosed and a treatment or prevention instigated when the apparent problem was really random variation (type I error). It is this type of error that is responsible for many needless vaccination or medication programs. Our bias is to err on the conservative side and intervene when an intervention is not called for. A second type of error (type II) occurs when a situation is examined and intervention is not elected when, in reality, corrective measures were indicated. That is, the situation was "out of control" and action really *was* necessary. The first step is to chart the data. Columns of data are extremely unrevealing, and graphing techniques have been developed that help present and interpret the trends.

A **run chart** is a type of line graph on which time is on the *x*-axis and the variable of interest is on the *y*-axis (Fig. 111-2). Run charts are very easy to compose and allow quick interpretation of trends. However, it is difficult to differentiate between random fluctuations and early, mild trends in the data. Therefore, another type of chart called a control chart was developed.

The **control chart**, like the run chart, plots the actual values over time but also considers the recent variation while estimating control limits (Fig. 111-3). Control limits are calculated by adding and subtracting three standard deviations to the average value. A critical step in using control charts is to start with a process that is "in control" to determine the expected standard deviation.

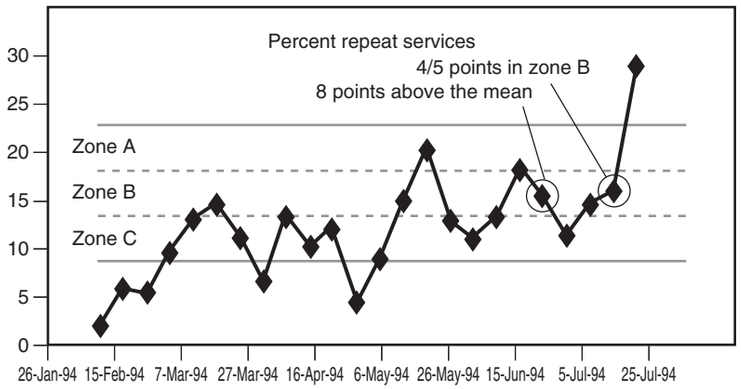

Fig. 111-3 Control chart of percent of sows returning to service in a 1400-sow herd.

Using these expected standard deviations, if the number of returns to service per unit of time is beyond the upper or lower control limit, one can be extremely confident that the process is "out of control." At this point, the consultant must intervene and initiate a diagnostic investigation.

Control charts can be further modified to create an "early warning system." That is, the area between the average and the control limit can be subdivided into three zones based on standard deviations (see Fig. 111-3). Zones C, B, and A correspond to the average ±1, ±2, and ±3 standard deviations, respectively. If the measurement of interest is normally distributed around the average, then data points should appear approximately normally distributed within the limits. Also, there should be no evidence of trends or recurring cycles. Approximately 66% of the measurements should be in zone C. Approximately 95% of the measurements should be in zone B or C, and 99% of them should be in zone A, B, or C. Therefore, only 1 out of 100 times will a measurement be expected to be outside the control limits by chance alone. In other words, if a measurement occurs outside the control limits, one can be very confident that something has disrupted the process. The zones also can be used in conjunction with statistical probability to establish some guidelines that will detect a process out of control sooner than waiting for the control limit to be surpassed.[1] The detection criteria are as follows:

- Presence of 2 out of the last 3 points in zone A
- Presence of 4 out of the last 5 points in zone B
- Presence of 8 successive points outside zone C
- Linear trend: 6 successive points with continuous increase or decrease
- Oscillation: 14 successive points oscillating up and down
- Presence of at least 8 successive points above or below the centerline, indicating that the mean has changed
- Presence of 15 successive points in C zone, indicating that the process variability has decreased

With the multitude of measurements being taken within farms that veterinarians are serving, it is impossible to monitor them all manually. Relatively simple computer programs, however, can scan all measurements for all farms on a routine basis to quickly detect any process that is getting out of control.

Endemic Reproductive Failure

In our experience, chronic suboptimal reproductive performance is considerably more difficult to investigate than epidemic reproductive failure. A myriad of possible factors can affect performance, including genetics, management, environment, nutrition, feed quality, infectious agents, and season. The goal is to optimize output from the reproductive herd. Accomplishing this entails three steps:

- Determine the reproductive capacity of the herd.
- Determine what components of reproductive performance are suboptimal.
- Identify what might be done to improve them.

As an example, a herd has a nursery/grow-finish capacity for 250 pigs weaned per week and has averaged 200 per week over the last year. The standard deviation for pigs weaned per week at this herd is 80. Is this herd achieving its potential? If it is not, where does the diagnostician start? Recall that pigs weaned per week is a reflection of number of sows bred, farrowing rate, number of liveborn pigs, and survival rate of pigs (see Fig. 111-1). In this case, the diagnostician must set a realistic goal or target for each of these components. Second, and equally important, an attempt should be made to reduce variation in each component between time periods. Two herds might both average 20 pigs per sow per year, but one might wean 250 per week ± 20 and the other might wean 250 ± 80. The former herd has considerably less disruption in planning pig flow, labor requirements, feed requirements, and cash flow.

Achieving targets and reducing variation require the diagnostician to be comfortable with data analysis and interpretation. In swine herds, production information can be collected with well-designed systems such as PigCHAMP.* Unfortunately, most record systems either bedazzle or intimidate most managers. Those who are

*Developed by the University of Minnesota, St. Paul, MN.

afraid shun them, whereas others often become prisoners of their fascination. The goal of herd advisors is to first understand how managers make decisions. In other industries, most managers do not rely on computer-based information to make decisions.[2] These managers get two thirds of their information from face-to-face or telephone conversations and acquire the remaining third from documents, most of which are from outside the organization. Davenport has summarized the facts of life regarding information:

- Most of the information people really care about is not on computers.
- Managers prefer to get information from people, rather than from computers; people add value to raw information by interpreting it and adding context.
- The more complex and detailed an information management system is, the less likely it is to change anyone's behavior.
- An element of flexibility and disorder in the manner of presentation is desirable.
- If information is power and money, people will not share it easily.
- The willingness of people to use a specified informational format is directly proportional to how much they have participated in defining it or trust others who did.
- To make the most of electronic communications, one must first learn to communicate face-to-face.
- Raw data are not information; and accumulating data is not the same as interpreting and putting these in a usable form.
- There is no such thing as information overload; if information is really useful, our appetite for it is insatiable.

Returning to the example herd, suppose it has a nursery capacity for 250 weaned pigs per week. This can be achieved if (1) 30 females are bred, (2) an 85% farrowing rate is achieved, (3) an average of 10.5 pigs are born alive, and (4) 93% survive to weaning. Furthermore, it is desirable to achieve this level of output as consistently as possible (with minimal variation). The major source of variation in pigs weaned per week is the number of sows served per week. Breeding the desired number of females is a managerial decision that requires ensuring that there is an adequate number of sows to be weaned and of gilts in the pool to supplement the expected number of returns to service.

Achieving an average farrowing rate of 85% is dependent on the conception rate and the pregnancy retention rate. Each of these needs to be approximately 92% to achieve a farrowing rate of at least 85% ($92\% \times 92\% = 85\%$). A more achievable goal is to strive for at least a 90% conception rate and at least a 95% pregnancy retention rate. The most practical method to measure conception rate is to monitor the number or percent of females that return to service.

A number of factors influence litter size.[3] Average total-born litter size is influenced in large part by maternal genetics and parity distribution of the herd. During gestation, certain feed-borne mycotoxins and several infectious agents such as porcine parvovirus, pseudorabies virus, porcine reproductive and respiratory syndrome virus, and *Leptospira* spp. can decrease the average number of liveborn pigs. The parturition process plays an important role in decreasing the number of stillborn pigs, thereby increasing the proportion born live. Finally, the farrowing environment can influence the survivability of liveborn pigs.

After capacity of the herd and the facilities have been assessed and targets have been set for the number of services per time unit, the diagnostician must determine if the herd is experiencing endemic reproductive failure, and if so, at what point in the management process? As discussed earlier, control charts can be used to identify as early as possible when a process is out of control. The other application for control charts is to help gradually improve a process over time. This is done by reducing the variation in the system. By reducing variation over time, the control limits are narrowed and the process is continually improved.

To understand how the variation is reduced, the investigator must (1) identify reasons why the process is either above or below the target, (2) calculate the frequency of reasons, and (3) focus the investigation on the most frequent reasons for failure. This investigative process is referred to as **Pareto analysis.** The Pareto principle, also commonly called the **80/20 rule**, is that most of the instances of a process not being on target can be attributed to relatively few causes: the "vital few." That is, investigation and resolution of a vital few causes are needed to address the greater part of the problem. This strategy is in contrast with the dilution of impact that occurs in attempting to solve the "trivial many." In addressing the vital few, management concentrates on preventing these causes from recurring. For example, in some herds, at least 80% of the stillborn piglets are delivered by less than 20% of the sows. Identifying these "vital few" sows that cause a majority of the stillbirths will allow appropriate action to be taken.

Finally, once the herd is performing as desired, the investigator must ask whether the herd is as "in control" as it can be or whether there is still room for improvement. One of the caveats of control charts is that a system may appear to be in control when in fact there is much room for improvement. Benchmarking provides this answer by determining what reproductive performance is being achieved in other herds both for absolute values and for variation (Tables 111-1 to 111-3).

EXAMPLE HERD

In early August, the owner of a 1400-sow herd becomes suspicious that a reproductive problem may exist. He is particularly concerned with an apparent increase in sows returning to service. Returns to service can be identified as "normal" or "abnormal," the distinction being whether sows return to estrus at normal intervals (18–23 or 36–46 days after initial service). Normal returns to service are thought to reflect failure to conceive, whereas returns to estrus at abnormal intervals are more likely to reflect a problem independent of the breeding process, possibly an infectious disease. In view of the apparent

increase in returns to estrus in this herd, should a diagnostic investigation be initiated?

Using a control chart, it can be seen that on July 25 the herd was "out of control" for repeat services (see Fig. 111-3). Intervention is indicated; by failure to initiate intervention, a type II error is committed.

Aborted fetuses from two sows and stillborn piglets and large mummified fetuses from two other sows were submitted for complete diagnostic examination. No causative agent was identified. Convalescent sera were collected from 15 representative gilts and sows that had returned to estrus or aborted. All samples were seropositive for porcine parvovirus and seronegative for pseudorabies virus and *Leptospira* spp., and 9 of 15 were negative for PRRSV. Further serologic tests from acute and convalescent sows would lend evidence for any etiologic role of PRRSV.

The proportion of normal to abnormal returns to estrus was analyzed for significant change. When the herd was "in control" (April–May), the ratio of regular to irregular returns to estrus was 6.0. During the epidemic (July–August), the ratio was not markedly different at 5.7 (Fig. 111-4).

The herd owner reported that on June 1 a new employee started work in the breeding area. In this herd, AI was used almost exclusively, and the new employee, who claimed to be very competent in this technique, was put in charge of breeding. Simultaneous with this change, the source of replacement gilts was changed. The new source was thought to be of considerably higher health status than the usual source.

This diagnostic investigation indicated that the repeat breeding pattern reflects primarily failure to conceive and probably is of noninfectious origin. In all likelihood, this failure was due to incorrect semen handling, heat detection, or insemination technique, alone or in combination.

The control charts were extremely useful for easily detecting the point in time when the percent of repeat breeding went "out of control." On examining the control chart, it can be seen that on July 1, the last eight points were above the centerline, indicating that the historical average percent repeat services had increased. This is the first significant warning that the breeding process has gone awry. Two weeks later, four of the last five points

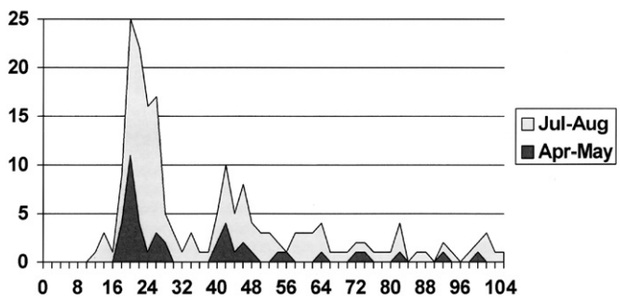

Fig. 111-4 Frequency of sows returning to service at various days after initial service from April to May versus July to August in a 1400-sow herd.

are seen to be in zone B or beyond, another significant warning. A diagnostic investigation should have been initiated 3 to 4 weeks before the producer became aware of the increase.

Control charts identify a process when it becomes "out of control" and are helpful to veterinary diagnosticians in deciding when to intervene. Even more important, however, control charts are powerful tools for reducing variation that is endemic in a process. In the example herd, it was assumed that the repeat service data were "in control" during March and April. It may be possible to reduce variation in repeat services over time from the current standard deviation of ±4.9. In so doing, a process improvement has been made that will reduce variation in output per unit time and also improve the early warning system for when the herd parameters are "out of control." By monitoring variation, consultants and managers can gradually become aware of its impact on the system and begin to realize the financial benefits of reducing it.

CHAPTER 112

Assisted Reproductive Technologies in Swine

†ANTONIO GARCIA

Manipulation of animal reproduction probably is as old as domestication itself. Since humans started to keep animals in captivity, they have exerted a profound influence on the natural behavior of domesticated species, including reproduction. Assisted reproductive technologies will allow continued genetic advancement in farm livestock. Artificial insemination (AI), used by the Arabs in ancient times for the dissemination of male gametes and first described for publication by Lazzaro Spallanzani in 1784, probably was the first technique of modern "assisted reproduction." The first embryo transfer work, in rabbits, by Walter Heape in 1891 and the subsequent successful embryo transfers in many other species over the next century turned out to be the first step in increasing the female role in reproduction. Other assisted reproductive technologies have been developed and applied to swine under research settings. The in vitro fertilization (IVF) of oocytes and micromanipulation of domestic animal embryos, first started in the early 1980s, nowadays are accepted as commonplace and as vital components of several procedures that are rapidly transforming the embryo transfer industry. In addition to these technologies, embryo cryopreservation, intracytoplasmatic sperm injection (ICSI), oocyte transfer, and nuclear transfer are dramatically altering the very manner in which we view our own reproductive capacity. It is important to recognize, however, that assisted reproductive technologies in general do not directly apply from one species to another, as has been well illustrated by the work with pigs.

The first successful pig embryo transfer was reported in 1951 (Table 112-1), the same year as for cattle. Of all of the large domestic animal species, however, the pig is the animal for which implementation of these reproductive technologies on a production basis has been the slowest. Several unique features of the physiology of reproduction in swine, as well as technical limitations, have slowed the widespread use of embryo transfer in pigs relative to its application in the cattle industry. Part of this hesitancy can be attributed to the greater delicacy and sensitivity of swine gametes and embryos to manipulation and in part to the perception that little is to be gained owing to the high reproductive efficiency that this species naturally possesses. An additional impediment to

the greater use of reproductive technologies in swine is the highly variable response to synchronization and superovulation of donor animals; furthermore, collection and transfer of porcine embryo thus far have been accomplished only by surgery. The size of the donor and unique anatomic characteristics of the reproductive tract appear to make nonsurgical recovery an unlikely prospect. Although surgical embryo transfer has been successfully used, methods for the nonsurgical transfer of embryos into recipients are still being developed. The swine embryo transfer activity has just started to grow around the world, with an estimated 7000 embryos transferred either experimentally or commercially in 2000.[1] Until now, however, the swine industry has never successfully implemented a commercial viable embryo transfer process as an alternative method of improving hog genetics. Despite the limitations, embryo transfer and related reproductive technologies hold promise as a means to accelerate genetic improvement and to take advantage of superior breeding sows, to break the link between health status of customer and source herds, to eradicate disease from a swine herd, and to facilitate inexpensive transport of genetic material around the world. This chapter presents an overview of recent work in this field, to collate existing knowledge and to establish guidelines for future work.

ARTIFICIAL INSEMINATION STRATEGIES

Reduction in Sperm Number per Dose and Intrauterine Insemination

A conventional insemination technique in swine requires 2×10^9 to 3×10^9 sperm cells per dose and a volume of insemination per dose between 80 and 100 ml. Currently, however, interest has increased in the novel possibility of introducing a lower number of sperm cells per dose or lower volumes of insemination per dose directly into the uterus. In contrast with the traditional intracervical insemination method, instruments and techniques are currently being developed to allow the semen to be deposited beyond the sow's cervix and into the uterine horns. This deep uterine insemination technology will have obvious economic repercussions in the overall productivity of boar stud facilities, and the cost per dose of semen may be reduced accordingly. Concepts for this technology began evolving in the early 1990s in an effort to help reduce the effects of summer infertility in hot climates by improving conception rates with use of poorer-quality semen. More recently, the main thrust for further refinement of this technique has been to advance the application of sperm sorted for sex and to develop a method for performing nonsurgical embryo transfer. Several manufacturers, in connection with research institutions, have created a growing array of catheter devices that are can be passed through the cervix of the sow to inseminate beyond the cervix. To date, however, research data are not sufficient to confidently establish the necessary cell numbers, semen volume, and semen placement location. Research reports demonstrate that the number of semen per dose could be reduced significantly without a corresponding decrease in either fertility or litter size. Recent results using a fiberoptic endoscope technique for deep uterine horn insemination in sows demonstrated that using only 50 to 200 million sperm cells per dose was now possible.[18] This number represents only a fraction of the 2 to 3 billion sperm commonly used in conventional AI. By this calculation, 400 to 500 doses could be potentially prepared from each ejaculate. With this technique it was possible to insert the insemination catheter past the cervix to deposit semen in the anterior region of one uterine horn in about 90% of the sows, with subsequent

farrowing rates and litter size of 85% and 9.5 piglets, respectively. Although endoscopic deep uterine insemination is an alternative technique for insemination of a small number of spermatozoa in sows, the flexible fiberoptic endoscope is an expensive and fragile instrument to be used under field conditions.[18] For this reason, a new catheter for insemination with flexibility and propulsion force similar to those of the fiberoptic endoscope was used in a subsequent trial.[19] Sows were inseminated within the anterior region of one uterine horn 36 hours after administration of human chorionic gonadotropin (hCG) with 150, 50, 25, or 10 million sperm cells in a total volume of 10 ml of Beltsville thawing solution (BTS) diluent. Investigators were able to inseminate and impregnate almost 90% of the sows, and no difference in litter size was observed. Only use of large doses of 50 million and 150 million sperm cells for deep insemination, however, resulted in pregnancy rates comparable with those achieved with insemination using a conventional dose of 3 billion sperm (74.4%, 80.9%, and 79.8% respectively). Apparently, by ligating the noninseminated horn, investigators were able to demonstrate that after deep insemination, sperm cells travel transperitoneally through the opposite infundibulum to fertilize oocytes ovulated from the contralateral ovary.

Several research institutions have experiments under way to validate low-dose, deep-uterine insemination techniques using different catheters for deposition of fresh, frozen-thawed semen with spermatozoa sorted for sex. In a recent commercially based field trial, a 200-mm catheter that extends over the insemination rod (Deepgoldenpig*) was used for deep insemination of sows with reduced sperm numbers.[20] During this trial, doses of 1, 2, or 3 billion total spermatozoa diluted in X-cell extender* () to a standard volume of 80 ml in a flatpack bag were used to evaluate the insemination device in more than 3000 sows. At the two higher sperm doses, no difference in farrowing rates was found between the experimental insemination device and a control catheter, and both gave rates exceeding 90%, with a mean litter size of 12.4. At the 1 billion sperm dose with the conventional catheter, however, the farrowing rate dropped to 66% with a litter size of 10.3, but with the Deepgoldenpig, the farrowing rate remained not significantly different from that in the other groups at 87% with a litter size of 12.1. Currently, use of this insemination technique device provides a method to reduce the insemination dose for sows without serious loss in production. Because of difficulties with catheter insertion and increased risk of reproductive trauma and hemorrhage, intrauterine insemination is not recommended for gilts. At present, several practical issues prevent its routine commercial acceptance for farm use. This technique requires trained inseminating staff and good estrus detection to avoid late (postovulatory) inseminations.

Low-dose insemination in combination with a single (fixed-time) insemination has the potential to give an even higher economic advantage in genetic dissemination, with doubling of current boar productivity. Owing to the nature of the estrous cycle in pigs, however, it will be very difficult to predict the right time to perform a single-dose insemination per cycle to achieve a farrowing rate and litter size comparable with those obtained with multiple inseminations. Traditionally, multiple (two or three) inseminations are performed throughout estrus to increase the chances that one insemination will be performed at an optimal time relative to ovulation. In recent years, the use of real-time ultrasonography (transabdominal or transrectal) has helped redefine insemination strategies by characterizing ovulation patterns in the sow retrospectively. As a consequence, optimal time for insemination has been found to be in the interval from 28 hours before to 4 hours after ovulation.[21] Ovulation in the pig normally occurs approximately 38 hours after the onset of estrus, but this timing can vary considerably between females (16 to 52 hours) and with genetic makeup and environment.[22] In addressing the topic of potentially reducing the number of inseminations and therewith allowing the possible use of fixed-time AI, it is essential to recognize that accurate heat detection and familiarity with general estrous behavior in gilts or sows are essential components to improve the prediction of timing of ovulation and for the implementation of an AI schedule. Although up-to-date ultrasonography does not appear to be effective in predicting time of ovulation,[23] defined relationships between the time of ovulation relative to estrous behavior have led to methods that allow producers to more accurately pinpoint the best time for insemination.[24]

SPERM SEXING TECHNOLIGY

Being able to preselect the sex of offspring at the time of conception ranks among the most sought-after reproductive technologies of all time. Sexing mammalian sperm has several important applications in the swine industry; however, sperm sexing will have a huge impact on the efficiency of existing multiplication systems. We are seeing dramatic changes in swine production with consolidation and vertical integration that affects how swine are produced and marketed. The use of sex preselection has great potential for increasing efficiency. In the future, those not taking advantage of efficiencies such as sex control may be buying animal products from those who do.[25]

For several years, investigators have attempted more than a dozen approaches to separate the X chromosome– and Y chromosome–bearing sperm based on perceived and assumed differences in physical characteristics or immunologic factors, with little success. Recently however, a new approach based on the well-established differences in DNA content between the two sex chromosomes has been the only consistently successful method of sorting sperm from a variety of species, including swine.[26] This DNA fluorescence–activated cell sorting technique involves treating sperm with a fluorescent dye, Hoechst 33342, which binds to their DNA, and then sorting them into separate X- and Y-bearing sperm populations using a flow cytometer–cell sorter modified

*IMV International, L'Aigle Cedex, France.

specifically for sperm to measure the relative fluorescent intensity reflective of DNA content of each sperm as it traverses a laser beam. Flow-cytometric separation of viable X chromosome– from Y-chromosome–bearing sperm is now a well-established technique and has proved to be repeatable at numerous locations and with many species at greater than 90% purity.[27] On average, the X-bearing sperm of common mammals contain 3% to 7% (3.6% in swine) more DNA than the Y-bearing sperm.[28] The wider the difference, the easier it is to sort with great accuracy.

Offspring of the predetermined sex in swine and other domestic animal species have been born after insemination using this technology since its introduction in 1989.[12] The current technology, however, has certain obstacles that prevent a broader application. First, the number of spermatozoa that can be separated per hour is low (about 16 million X-bearing sperm at 73% to 80% purity); second, labeling with the fluorochrome decreases sperm viability, leading to a higher embryonic mortality; and third, the expenses associated with use of an appropriate flow cytometer are enormously high. Nevertheless, new technological advances in high-speed cell sorting technology are being made to make the process produce more viable X and Y sperm per unit time at the highest purity.[27] Although the limited numbers of sperm available with flow-cytometric sperm sorting can be circumvented by using IVF or ICSI and subsequent embryo transfer, these are likely to be minor avenues for sex regulation relative to AI because semen can be delivered through different routes and techniques such as surgical (intrauterine or intratubal), deep uterine, cervical, and laparoscopic. In pigs, these sperm numbers are still insufficient for conventional insemination techniques; however, it recently has been shown that a numerical reduction in the number of sperm per insemination and the use of sorted sperm do not necessarily affect the pregnancy rates if semen is deposited surgically closer to the uterotubal junction a few hours before ovulation. It was demonstrated that the number of sperm inseminated can be reduced by several orders of magnitude in a low insemination volume down to 5×10^6 in 0.5 ml of Androhep extender per uterine horn in hormonally stimulated prepubertal gilts[29] or in sows[30] without significant reduction in rates of pregnancy or farrowing or in litter size.

Currently, sexing sperm is a tool that has matured sufficiently to be valuable for experimental purposes and for certain niche applications related to production animal agriculture. For wide agriculture applications, cost must be low and efficiency and convenience, high. Skewed sex ratios of 85% to 100% of one sex or the other have been repeatedly achieved in most species. In a preliminary experiment, pigs of the desired and predicted sex were born after surgical insemination at rates of 74% females and 68% males.[12] Offspring all were morphologically normal and were reproductively capable in adulthood, showing no negative effects of the sorting process. With improved techniques for pig IVF, sexed sperm were used to fertilize in vivo–matured oocytes, and the resulting embryos were used to produce two litters of pigs, all of the desired sex.[14] This was the first successful use of sexed sperm to produce offspring of preferred sex after transfer of sexed embryos derived by in vitro embryo production (IVP).

Improvements in IVF protocols led to more investigations in this field but now using ova matured in vitro. In one study, ova inseminations were done within 1 hour of completing the sorting process, and embryos were transferred at the four-cell stage.[31] Thirty-four piglets were born from 6 embryo recipient sows; 33 were females and 1 was a male (97% success rate). In another study, in vitro matured pig oocytes were fertilized with either X- or Y-sorted sperm at 20 hours after sorting.[32] Three litters were born from embryos produced from Y-sorted sperm, resulting in 9 male piglets (100%), and 5 litters were born from transferred embryos produced from X-sorted sperm, resulting in 23 females and 1 male (97%). Collectively, the results from these experiments demonstrated the effectiveness of using sexed sperm to produce sexed offspring in the pig by first producing sexed embryos. Currently, new flow cytometer machines are being perfected for commercial use through collaborations between the Beltsville Germplasm and Gamete Physiology laboratory and several scientists around the world.

Another approach for sperm sexing, currently under development, is based on the hypothesis that sex-specific proteins present on the surface of the sperm cells of a desired sex can be removed by polyclonal antibodies that, when added to the sperm, will result in agglutination of the cells. The free-swimming sperm cells can be then filtered off and used for fertilization of oocytes in vitro.[33] The preliminary results of trials conducted in bovines suggested that this viable immunologic sperm sexing procedure has potential for application in other species, including the pig.

EMBRYO TECHNOLOGY

Embryo Transfer Procedure

Strictly speaking, the term *embryo transfer technique* refers only to the process that begins with embryo collection and continues through embryo transfer. The basic technique of **embryo transfer** consists of removal of an embryo from a genetically superior animal and introduction of that embryo into a host surrogate. The resulting offspring will have qualities that duplicate those of the embryo supplier while not retaining any characteristics of the surrogate. Although embryo transfer in pig was first reported more than 50 years ago (see Table 112-1), it has limited applications in commercial swine production. In the swine industries, the primary reasons for recovering and transferring embryos are to minimize the risk of disease transmission, to propagate genetically superior animals, and, in some cases, to simplify shipment of genetic material. In addition, the application of embryo transfer technologies to breeding strategies also will generate significant advancements in selection, by allowing for the constant introduction of new genetic material into nucleus breeding herds. Embryo transfer provides a complete genetic package to the purchaser, resulting in rapid genetic upgrading at the lowest possible cost and lowest risk of disease transmission. Embryo transfer has been well established as an important tool in research,

and a great deal of current knowledge regarding reproductive physiology in swine has been a result of research studies using this technique. In practical application, embryo transfer comprises a complex series of measures including selection and stimulation of donor sows, recovery of embryos, embryo handling, and transfer of recovered embryos to recipients.

Superovulation and Donor Selection

The rationale for use of technologies increasing the number of embryos during collection is obvious for several domestic species. Gilts and sows, however, normally ovulate between 10 and 25 eggs, so superovulation has not been essential; accordingly, very few research groups have been interested in this development. Nevertheless, it is estimated that a total of 20 to 25 embryos per donor sow can be potentially collected, and use of superovulatory protocols apparently will increase the number of embryos collected per donor, thereby justifying the cost and time of the procedure. In the United States, no commercial product is currently available for induction of multiple ovulation in pigs, and porcine or ovine follicle-stimulating hormone (FSH) preparations are relatively ineffective in inducing superovulation in swine.

Several available gonadotropin preparations have been used in swine to increase the number of ovulated oocytes. Traditional methods of synchronization accompanied by superovulation include the use of 1000 to 1500 IU of equine chorionic gonadotropin (eCG) (e.g., Folligon* or Novormon†) either 24 hours after weaning in sows or 24 hours after a luteolytic dose of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) (e.g., Lutalyse‡) administered on days 12 to 15 of the estrous cycle in mature gilts, or administered any time to prepubertal gilts. In cycling gilts, eCG also can be administered after an altrenogest (Regu-Mate*) feeding regimen providing 15 mg/day of altrenogest for 15 to 18 days for estrus synchronization. To induce ovulation, 500 to 750 IU of hCG (e.g., Chorulon*) also is administered 72 to 80 hours after eCG, and the animals are inseminated 36 hours after that. The response after such treatments can be highly variable, however, even in animals of the same weight and age. Factors such as product impurity due to luteinizing hormone (LH) content and lot-to-lot variation in bioactivity also may contribute to the variable response.

Using this hCG-eCG protocol, our laboratory has been able to obtain a mean of 23 ± 5.0 total ova or embryos per donor, compared with approximately 15.2 ± 3.8 from non-superovulated gilts. In a recent review of 12 studies using gilts as donors, however, investigators report superovulatory responses as high as 32 embryos collected, but in some cases no improvement in superovulatory response was observed.[34] In addition, with repeated embryo collections, more than one batch of embryos per donor also could be obtained. The methods of embryo collection will determine how often collection from one donor is possible. The stage at which collection takes place (days after mating) has an impact on the type of technology to use. For non-superovulated animals, pubertal gilts and sows can be used successfully as donors. In my experience, a higher embryo yield has been obtained in mature gilts (those undergoing more than three estrous cycles) and sows. More recently, investigators reported that very young prepubertal gilts (approximately 100 days of age) were poor candidates for embryo donors or embryo recipients. Lower pregnancy rates were achieved when these animals were used as embryo donors and lower pregnancy rates and retardation of fetal growth when they were used as embryo recipients.[35] It also has been reported that embryos from prepubertal gilts do not have the same in vitro developmental capacity as those from cyclic gilts when surgically collected at early stages of development and culture in vitro to the blastocyst stage.[36]

Embryo Collection Techniques

Embryo recovery in swine usually is accomplished surgically with the animal under general anesthesia, with the reproductive tract presented through a midventral incision in the caudal abdominal region involving retrograde flushing of the oviducts or uterine horns, or both. Surgery in swine is simple, inexpensive, and reliable once the necessary skills are developed. This surgical technique for embryo collection has been described previously and remains relatively unchanged.[37,38]

Other, less invasive alternative techniques for embryo collection also have been investigated. These techniques include nonsurgical embryo collection after surgical resection of the uterine horns[39,40]; endoscopic techniques[41,42]; and flushing of the reproductive tract after slaughter of the donor animal. Collectively, these techniques have some limitations, and results obtained with these procedures need to be improved. The number of ovulations, the age of the animal, the day of collection, the quality of the semen, and the fertility of the donor sow or gilt all influence the success of embryo collection. Results with traditional surgical embryo collection suggest that a success rate of about 90% recovery can be expected when an average group of donor gilts or sows is used.

Embryo Manipulation and Embryo Yield

After collection, the fluids are left to settle, to allow the embryos to sink in the bottom of the tube. Embryos are morphologically examined in vitro under a stereomicroscope and transferred into a holding or culture medium. Embryos also are evaluated according to their morphologic characteristics at the expected stage of development, and then viable (transferable) embryos are selected. Swine embryos usually are recovered over the first 5 to 6 days after the onset of estrus (about 120 hours after ovulation) to ensure that collection is performed while the embryos are still contained within the zona pellucida. At this stage, morula and early to expanded blastocysts generally are recovered. They also can be recovered at different stages of development, however. Embryos at the one-cell to the early four-cell stage are col-

lected from the oviduct on days 1 to 3 after ovulation, whereas embryos from the four-cell stage up to the hatched blastocyst are flushed from the proximal uterine horn on days 4 to 7. Embryos with a difference of one cell cycle can be accepted as transferable, whereas embryos less developed could be left in culture for an additional 24 hours before transfer. Embryo evaluation 24 hours after culture gives a good indication of their developmental capacity, and embryos that do not develop after culture can be discarded.

In a study performing embryo collection in 229 non-superovulated donor gilts, our laboratory obtained a mean number of corpora lutea of 15.2 ± 3.8, a mean total number of ova or embryos of 13.4 ± 4.2, and a mean number of viable (transferable) embryos of 11.8 ± 4.8. These results translated to an 88.1% recovery rate and a proportion of transferable embryos of 86.0%. When gilts were grouped by the number of estruses detected (one to three or more) before embryo collection, however, a significant increase was demonstrated in the number of corpora lutea, total ova or embryos, and total number of transferable embryos as the number of estruses increased before collection.[43] By contrast, when embryos were collected from non-superovulated sows (greater than fourth parity), a higher number of transferable embryos (up to 20) was obtained.

Embryo Transfer

Selection of recipient gilts has a major impact on embryo transfer results. Although prepubertal gilts can be used as recipients, cycling gilts and sows are preferred because of their stable endocrine and uterine development. As in embryo transfer programs in cattle, management of the recipient probably is an important factor affecting pregnancy rate. Recipient animals, in which the embryos are to be implanted, are not inseminated. For embryo transplantation to be successful, however, it is necessary for the recipient animal to be in the same stage of the estrous cycle as the donor. The degree of synchrony between donor and recipient needed during a surgical embryo transfer is not as precise as in cattle. Traditionally, during a surgical embryo transfer, investigators prefer to transfer embryos into recipients at either the same stage of estrous cycle (day 0) as in the donor or into asynchronous recipients (–24 hours) with a less advanced uterine development. It has been previously demonstrated, however, that during a nonsurgical embryo transfer procedure, recipients that ovulated between 24 hours before and 12 hours after the donor achieved a higher pregnancy rate. This finding suggests that transfer to recipients ovulating later than 12 hours after the donor is associated with very low pregnancy rates.[44]

Although several groups of investigators are making progress in the area of nonsurgical embryo transfer to recipients, traditional surgical transfer is still the method of choice for most embryo transfer programs.[45] Surgical embryo transfer is carried out using a ventral midline laparotomy approach, after general anesthesia has been obtained. One of the ovaries and the adjacent proximal portion of the uterine horn are exteriorized from the surgical incision. After examination of the ovary for identification of a sufficient number of corpora lutea, the embryos are transferred, depending on their stage of development, either to the oviduct (one-cell to early four-cell embryos) or into the tip of the uterine horn (four-cell embryo to hatched blastocyst). Embryos are transferred in a small amount of medium by means of transfer pipettes or catheters.

Other procedures have been evolving for transferring embryos including transcervical (nonsurgical) techniques. For a long time, nonsurgical embryo transfer in pigs has been considered a technique that was almost impossible to perform. The reason was the complex nature of the genital tract with its constricted cervical canal and long, coiled uterine horns, as well as the location of the embryos in the proximal area of the horns during early pregnancy. These challenges have discouraged attempts at nonsurgical transcervical introduction of a catheter into the uterine horn. During the last decade, several experiments regarding nonsurgical procedures were reported in detail by five independent research groups, all using different approaches.[13,44,46–49] The three main differences among various procedures are the use of sedation, the type of instrument used (AI spirette or special design), and the volume of fluid used for transfer. Collectively, results from these studies have demonstrated that nonsurgical transfer of embryos in swine is feasible and has resulted in pregnancy rates ranging from 9% to as high as 64% and average litter sizes ranging from 3.1 to 10.9 piglets. Although all groups used different approaches for their transfers, the best pregnancy rates were achieved without recipient sedation.[44,49] On the other hand, specially designed instruments, which enable deposition of embryos into the uterus with a small volume of fluid, resulted in higher litter sizes (approximately 6 to 11 piglets).[44,47,48] More recently, the nonsurgical embryo transfer technique in sows developed by Hazeleger and Kemp has been applied under commercial farm conditions.[50] Nonsurgical transfers were performed in 45 synchronized recipient sows, each receiving 25 to 30 blastocyst-stage embryos. The farrowing rate (44%) and litter size (7.4 ± 3.2) obtained were lower than those achieved with the experimental conditions previously reported (59% and 10.9 ± 3.4, respectively).[44] In a subsequent small trial, a modified flexible catheter, similar to the ones used with a fiberoptic endoscope, was successfully deployed to penetrate the anterior third of one uterine horn during early diestrus.[51] With this procedure, a pregnancy rate and litter size of 72.7% (8/11) and 6.0 were obtained after transfer of 24 to 30 morula-to-blastocyst stage embryos, placed at a depth of 30 to 70 cm into the uterine horn in a small volume of medium (0.8 ml).

Endoscopic procedures for embryo transfer also have been recently developed.[42,52,53] This minimally invasive technique has some advantages, including repeatability compared with surgical procedures, but requires expensive endoscopic equipment and very experienced handling and usually takes longer than laparotomy procedures do. The equipment consists of a small cold-light fountain, a light cable, a metal catheter for an oblique optic telescope, a metal catheter for an atraumatic forceps, and a metal catheter for the venous catheter. Five cm caudal to the umbilicus the catheter for the optic is

introduced into the abdomen, and 10 cm lateral of the optic the catheter for the optic also is inserted. After observation of the ovary for the presence of corpora lutea, the forceps is used to stabilize the infundibulum and embryos are deposited by advancing the venous catheter. Using this technique, pregnancy rates greater than 40% and litter size ranging between 2 and 10 piglets have been reported.[54]

Regardless of the reproductive technologies used to propagate genetically superior animals, it must be recognized that the development of a nonsurgical embryo transfer method that is simple, rapid, and cost-effective will eventually lead to adoption of the technology. Although the results achieved to date are still lower than with the traditional surgical procedures, a commercially viable nonsurgical embryo transfer (NSET) technique will revolutionize the hog industry and ultimately alter the method of genetic dissemination in swine.

Pregnancy Rate after Embryo Transfer

Under optimal conditions, high-quality embryos with intact zona pellucida can be efficiently collected and transferred by established surgical procedures. The average pregnancy rate on transfer of embryos without an extended intermediate in vitro phase after collection reaches 80% to 85%, and approximately 35% to 50% of the transferred embryos survive to term, which is similar to the rate after AI insemination or mating.

Traditionally during surgical transfer, embryos are deposited in the tip of the horn distal to the uterotubal junction. Embryo deposition at this uterine site has achieved good pregnancy rates. By contrast, it was previously reported that when embryos were transferred to different sites along the uterine horn, embryo survival and pregnancy rate dropped dramatically (3% and 12%, respectively).[55] These results suggested that the uterine body seems to be an unsuitable site for embryo transfer in pigs and explained the unsatisfactory results that some investigators have achieved with nonsurgical embryo transfer. Unlike with surgical embryo transfer, during the nonsurgical embryo transfer procedure other factors, apart from uterine site deposition, also may be critical for a successful embryo survival. These factors, as previously mentioned, include the recipient's age and superovulatory program, size and stage of development of the embryo at the time of transfer, donor-recipient synchrony, number of embryos transferred, and volume of fluid during embryo transfer deposition.

Interest in porcine embryo transfer research is strong in several institutions. Published reports, however, demonstrated that when embryos are transferred surgically, pregnancy rate and litter sizes were significantly higher than those achieved with nonsurgical embryo transfer techniques. These results clearly demonstrate that several modifications are needed in order to improve results with nonsurgical embryo transfer.

The transfer of 16 to 22 embryos seems to be optimal to achieve high pregnancy rates, and the nonsurgical transfer of up to 30 and 40 embryos has been reported. Some investigators have been surgically transferring an average of 21.4 embryos, resulting in a 35% embryonic survival rate. When fewer embryos (about 16) are transferred, however, the embryonic survival rate increases to as high as 50%. Apparently, a strong positive correlation has not been found between the number of embryos transferred and the number of piglets obtained after parturition.[43]

Factors such as the superovulatory regimen, technique of collection and transfer, age of the donor and the recipient, embryo quality and stage of development, embryo culture, synchrony of the donor and the recipient, and management of the recipient affect the pregnancy rate after embryo transfer.

Embryo Storage

Porcine embryos typically are transferred within an hour of recovery or placed in culture at 39° C for up to 4 hours before being transferred. Embryo storage in culture medium for an extended period of time (up to 48 hours), during which the embryos continue to develop or are arrested at a certain stage of development, is an important consideration, however. The ability to support in vitro development of embryos is essential to biotechnological applications such as cloning and production of transgenic animals. Washed and certified embryos can then be transported to any destination across the globe in highly protected and reliable small shipping incubators.

The development and implementation of an extended embryo culture are obviously another important point to consider in an embryo transfer program, to enable transfer of embryos to recipient host sows anywhere in the world. Another advantage is greatly reduced shipping costs and potential losses in comparison with those for live animal transport. These combined economic and health advantages make embryo transfer a logical choice for the safe international exchange of swine genetic material.

It recently has been reported that in vitro culture up to the blastocyst stage of development of in vivo–fertilized embryos collected at early stages of development is very effective when North Carolina State Medium-23 (NCSU-23) or Beltsville Embryo Culture Medium-3 (BECM-3) is used.[36] Embryos also can be cultured for 24 hours in a simple TL Hepes medium, in which they can successfully grow to a more advanced stage of development.[56]

Until recently, only fresh porcine embryos could be transferred. Long-term preservation by freezing, however, is by far the most important technological development to ensure the application of embryo transfer in the swine industry. Since the mid-1980s, the animal industry has routinely used embryo freezing for extended preservation and storage of embryos of several livestock species, especially cattle. Unfortunately, because of physiologic and cellular differences in pig embryos, successful cryopreservation techniques have only been newly developed. Pig embryos can be severely damaged after exposure to hypothermic conditions (below 15° C). Because boar semen also is extremely sensitive to cooling and cryopreservation, however, this chilling sensitivity may be species specific. Although birth of live piglets after

cryopreservation has been reported, porcine embryos are limited in their ability to withstand freezing and cryosurvival.[10,11,57] This vulnerability is believed to be due, at least in part, to the high concentration of lipid material that pig embryos naturally possess. Presence of these lipid droplets may lead to uneven intracellular ice formation and is considered the major cause of embryo degeneration after freezing and thawing.[58] Subsequent experiments revealed that the freezability of pig blastocysts is greatest immediately after hatching at a size of 150 to 300 μm and then decreases rapidly when the blastocysts increase in size.[59] This finding suggests that older embryo stages contain less lipid material and subsequently have a greater tolerance to freezing. With regard to disease, however, protocols based on cryopreserved hatched blastocysts are not ideal, because the intact zona pellucida is an efficient barrier to various types of pathogens.

A new cryopreservation technique called **vitrification** is under development, with promising results. With this technique, embryos are equilibrated in a highly concentrated cryoprotectant solution for a few seconds and then frozen in liquid nitrogen. Rapid cooling prevents ice crystals from forming in and around the embryo, retaining many of the physical characteristics and ensuring a much more friendly environment for the embryo. Vitrification has been used in porcine embryos; however, only a few pregnancies have been achieved after this procedure. Early attempts to successfully cryopreserve pig embryos included micromanipulation to physically remove the intracellular lipids and resulted in the first litter born using this procedure.[15] Without such micromanipulation, pig embryos up to the morula stage do not survive cryopreservation.[60] Although piglets were produced, results with this technique for embryonic removal of cytoplasmic lipids before freezing were far from practical. Recently, investigators have been working on vitrification techniques that eliminate the need to remove the lipid material with some success.[61] Even more recently, however, using a modified vitrification technique, pig embryos were successfully cryopreserved without the need of micromanipulation.[62] For this procedure, intact morula or early blastocyst stage pig embryos were centrifuged and then vitrified. After thawing, the embryos were surgically transferred to asynchronous (–24) recipient females. This novel methodology resulted in a farrowing rate (82%) and litter size (7.0 piglets) comparable with those achieved with traditional surgical transfer of fresh porcine embryos. Results from this study clearly indicate that this method is both simple and inexpensive and has the potential for immediate commercial application. Although some fine-tuning of the procedure and demonstration of repeatability are required, this recent advance in methodology for freezing pig embryos will have major ramifications for the long-term preservation and movement of genetic material in the swine industry.

Elimination of Disease by Embryo Transfer Technologies

Because disease transmission is an important consideration in the swine industry, the possibility of transmitting infectious organisms through embryo transfer has been the subject of extensive investigation. Embryos are considered to be the safest agent for domestic or international exchange of livestock genetics, however. The disease status of the donor sow has no impact on the disease status of piglets derived from embryo transfer if proper embryo washing procedures are adhered to during the transfer process. This lack of health status relationship between donor sows and their offspring derived from embryo transfer arises from the protective barrier formed by the zona pellucida (eggshell). The zona pellucida completely encases the developing embryo over the first 6 to 7 days of life, creating an impermeable physical barrier to all disease-causing viruses and bacteria. Because bacteria and viruses cannot pass through this natural barrier to infect at the stage of transfer, the risk of disease transmission is reduced to its lowest possible level. Because of the impermeable nature of the zona pellucida, only those pathogens that can adhere to the outside surface of the zona pellucida could be transmitted with the embryo during the transfer process. Accordingly, washing the embryos after they have been flushed from the donor uterus is a very effective means of the elimination of those pathogens. In fact, provided that the zona pellucida is intact, the embryo washing procedures established by the International Embryo Transfer Society virtually eliminate any chance of pathogen transfer during embryo transplantation. With more than 20 years of use of this technique in the dairy industry, not a single case of disease transmission has been linked to the commercial transfer of embryos.

Because swine embryos can be certified pathogen-free after washing, breeders will be free to import new genetic stock without risk to the resident herd. This will allow internationally based breeding companies to rapidly, economically, and safely disseminate new genetic lines of breeding stock throughout their entire international network in a single step. In addition, embryo transfer can be used to "clean" valuable genetic lines of swine that have become infected with disease-causing pathogens. Embryos recovered from infected donors can be washed and transferred to clean recipients, thereby breaking the disease cycle and producing pathogen-free offspring that nevertheless retain the full genetic composition of the donor line. With all of this knowledge, however, only a few reports have described any extensive use of embryo transfer in minimizing the risk of disease transmission. James and associates[5] used embryo transfer to successfully conserve valuable genetic material from pseudorabies-infected swineherds in the United States. In another trial, investigators used embryo transfer to introduce newly imported genetic material into five specific pathogen–free (SPF) herds in Australia.[63]

More recently, confirming results of previous trials, researchers used embryo transfer to successfully conserve valuable genetics from porcine reproductive and respiratory syndrome virus (PRRSV)-infected herds.[43] Experimentally, several investigators had reported the use of specific embryo washing procedures to eliminate pathogens from embryos collected from donors infected with PRRSV,[64–66] hog cholera virus,[67] and many other viruses.[68] Collectively, results from these studies have

demonstrated that embryo transfer will result in the birth of virus-free piglets provided that the embryos are washed (or unwashed, as in one report of PRRSV elimination) and pathogens were not detected or were not present during the early stages of development. These findings indicate that this technique is a highly effective clinical tool for the elimination of pathogens from an infected breeding stock.

IN VITRO EMBRYO PRODUCTION

For many years, scientific interest has existed in the capture of genetic material present in the ovaries of superior sows, in a manner similar to the use of AI for the boar. **In vitro embryo production** (IVP) is a collective term used to describe the three steps in the in vitro process in which recovered immature oocytes are matured (in vitro maturation [IVM]) and fertilized (IVF) in the laboratory, with the resulting embryos subsequently cultured in vitro (in vitro culture [IVC]) to a transferable stage of development. IVP of swine embryos has been one of the more rapid technological advances of this decade. The difference that gives IVP an advantage over embryo transfer from a genetic or breeding standpoint is the potential for acquiring a large number of oocytes from a given animal. The number of oocytes acquired could be considerably greater than the maximum number of in vivo embryos that can be obtained. It was estimated that a female pig may have approximately 500,000 or more primordial follicles containing oocytes stored in her ovaries at the time of birth. These stored oocytes will be all she will ever produce in her lifetime and will develop or regress during the course of her productive life. Success in IVP has stimulated increased research in other areas that can be enhanced by the availability of embryos without requirement of surgical collection from gilts or sows. One example is the combined use of IVF, sperm that have been sorted for sex, and embryo transfer to produce offspring of a predicted sex.

In vitro embryo production is a multi-step process that requires a well-equipped laboratory and a skilled technician. The IVP process involves harvesting immature oocytes from the ovaries and maturing them for about 44 hours in either tissue culture medium (TCM) 199 or in NCSU-23. To induce oocyte maturation, the culture medium is supplemented with hormones, macromolecules (follicular fluid, fetal calf serum [FCS], bovine serum albumin [BSA], or polyvinyl alcohol [PVA]), and growth factors. Matured oocytes are then fertilized in vitro, and the resulting embryos are held in culture medium inside an incubator (at 39°C and 5% CO_2 in humidified air) for 6 additional days and then transferred to an unmated recipient female at the same stage of the estrous cycle as for the donor female. The pregnancy success rate for good-quality IVP-derived porcine embryos is expected to range from 50% to 75%.

Early studies on IVM clarified the importance of both nuclear and cytoplasmic maturation on the developmental competence. In a preliminary report, when porcine follicular fluid (pFF) and FSH were added to the maturation medium, nuclear maturation to metaphase II was enhanced and blastocyst formation (29.2%) was superior compared with maturation rates without pFF (11.5%) or FSH (8.7%) after IVF.[69] The results of this study clearly indicate the beneficial effects of pFF and FSH on the maturation process and overall embryo yield in vitro. Although some investigators have reported pregnancies and live piglets after transfer of IVP porcine embryos, the developmental potential of in vitro–produced embryos is still lower than that of their in vivo counterparts.[70–72] Cheng and associates reported production of the first piglets through IVF in 1986.[8] In vitro embryo production techniques, however, have not been developed for swine to a commercially usable state, compared with this technology for other domestic species. Numerous reports now testify to the fact that little or no difference exists between in vivo–and in vitro–derived cattle embryos subjected to transfer in terms of ability of the mature animal to produce calves. By contrast, very few reports exist demonstrating that normal offspring can be produced from the transfer of in vitro–derived swine embryos. One of these reports described a recent study aimed at improving the developmental competence of pig oocytes.[72] The investigators reported no differences in blastocyst development between oocytes matured in a protein-free medium supplemented with epidermal growth factor (37%) and those matured in a control medium (NCSU-23 plus 10% pFF) (also 37%), and a farrowing rate of 72% was obtained after embryo transfer to unmated recipient animals.

Analysis of published reports suggests that several obstacles in IVP of porcine embryos need to be overcome before such techniques become commercially available. One of the limitations to practical application of IVP technology in swine is the high incidence of multiple sperm penetration occurring during the IVF process. **Polyspermy** is the term used to describe the occurrence of oocyte penetration by more than one or two sperm cells. Polyspermy in swine oocytes ranges in frequency between 13% and 90% and is associated with formation of an irregular male pronucleus and perturbation in early embryonic development. Under in vivo conditions, fertilization occurs in a few hours after ovulation, and the female reproductive tract evidently plays an important role in regulating the initial number of spermatozoa that reach the site of fertilization to obtain, in most instances, monospermic penetration.[73]

In order to improve monospermic penetration and cleavage rates during the IVF process, investigators have to either modify the fertilization media components or reduce the number of sperm cells per oocyte without affecting the penetration rate. One possible strategy for reducing the occurrence of polyspermic penetration is to fertilize oocytes in an oviductal epithelial cell monolayer[74] or in the presence of oviductal fluid collected from gilts during estrus.[75] A low rate of polyspermy, however, also is accompanied by reduced sperm penetration.[76] In an experiment in which the concentrations of Ca^{2+}, lactate, and PO_4^- were different in the fertilization medium, no differences were observed in monospermic penetration.[71] Many research laboratories produce in vitro pig embryos developed from oocytes aspirated from prepubertal gilts after slaughter. More recently, however,

investigators were able to demonstrate that when compared with those from adult animals, oocytes aspirated from ovaries of prepubertal gilts have an increased incidence of polyspermic fertilization.[77] This finding suggests that adult ovaries contain oocytes with a higher developmental competence that that of prepubertal ones. Clear developmental difference also has been observed after IVF of pig oocytes, and investigators have demonstrated that oocytes matured in vivo displayed higher penetration and cleavage rates, a synchronous pronucleus development, and also a lower polyspermic rate compared with oocytes matured in vitro.[78]

Another obstacle limiting the potential practical application of IVP technology in swine is that currently this technology depends on a supply of developmentally competent oocytes from large antral or preovulatory follicles, which are present in the ovary of prepubertal gilts in only relatively small numbers (two to six) at the time of slaughter and aspiration. These ovaries, however, contain a number of primordial and preantral follicles that potentially can be harvested and cultured in vitro to a mature stage of development. Studies involving isolation of immature ovarian follicles and analysis of the requirements, metabolism, and differentiation processes of IVM of ovarian follicles already have been undertaken by researchers using ovaries from prepubertal gilts or any of several other animal species. Unfortunately, after several years of investigation, results with the culture–to–metaphase stage of development have been very disappointing. More recently, however, a study was conducted to identify an in vitro culture system that would support intact porcine follicle growth from preantral to antral stages all the way to oocyte maturation, fertilization, and embryonic development.[79] After 4 days in culture, 51% of these preantral follicles completed meiotic maturation to the metaphase II stage, and after fertilization, 13% of the cleaved zygotes developed to the blastocyst stage.

Oocyte Collection

Oocytes can readily be aspirated either from ovaries collected at slaughter or after a valuable female dies or undergoes ovariectomy. To preserve the genetic material and obtain a higher number of oocytes from a desired superior animal, however, noninvasive techniques need to be developed in swine. Early attempts at retrieving oocytes from potential donors included surgical and less invasive laparoscopic procedures, but the number of procedures that can be performed safely without causing injury to the donor animal is limited.

In the mid 1980s, a method was developed in humans for retrieving oocytes using ultrasonography to visualize the ovary while a needle was guided transvaginally into the follicle.[80] These efforts paved the way for the new reproductive technology developed to harvest oocytes from live cattle.[81–83] Ultrasound-guided **transvaginal follicular aspiration**, also known as ovum pick-up (OPU) in human medicine, recently has come under evaluation in pigs and other domestic and exotic species. Ultrasound-guided transvaginal follicular aspiration combined with embryo IVP is emerging as a successful method for obtaining preimplantation stage embryos. This nonsurgical method has become a common procedure for repeated retrieval of immature oocytes from ovarian follicles in live animals and has the potential for replacing previous procedures of conventional superovulation and traditional embryo transfer technologies. The prime advantage of this procedure resides in the fact that immature oocytes potentially can be aspirated in a continuous basis from follicles of mature sows, and possibly in prepubertal gilts as well. Oocytes also can be collected mature from live donors, thereby eliminating the need for IVM, or can be potentially collected from pregnant donors or a few days after weaning. In addition, this approach provides a highly efficient source of oocytes for the production of embryos for research purposes or for certain commercial applications that require zygote or embryo manipulation. Transvaginal follicular aspiration has the additional advantages of being noninvasive, with few risks to the animal, and being readily adaptable to on-farm application. Results from a preliminary study reported that the transvaginal ultrasonography–guided oocyte aspiration technique was successfully used to harvest oocytes from mature adult sows.[84] Using this aspiration procedure, 15 of 25 sows (60%) yielded an average of 4.5 oocytes/donor and had a mean of 6 follicles punctured/ovary. These findings indicate that this procedure has the potential for practical use in the future for IVP and nuclear transfer technologies. More research is needed to improve the efficiency of this approach, however. The oocytes were recovered from the ovaries of properly restrained donor sows by inserting a probe-guided stainless steel 55-cm, 17-gauge aspiration needle through the anterior vaginal wall near the cervix to aspirate the oocytes from the follicles detected by ultrasonography. A regulated vacuum pump produced negative pressure that caused the collapse of the follicle and allowed retrieval of the follicular fluid. The oocytes were harvested in phosphate-buffered saline (PBS) supplemented with 1% calf serum, 2 U of heparin, and 100 µg streptomycin/ml of medium. The follicles punctured were 4 to 6 mm in diameter, with more oocytes being produced from eCG-stimulated sows. All oocytes were morphologically evaluated, and 53% were classified as of good quality.

Intracytoplasmic Sperm Injection Procedure

Advanced techniques developed in conjunction with IVP include complex micromanipulation procedures such as injecting sperm into a matured oocyte (i.e., ICSI). Recent advances in ICSI have provided exciting opportunities not only for the treatment of male infertility but also for the study of gamete physiology during fertilization and early development. More recently, such a procedure has been studied for the production of transgenic animals using spermatozoa as a vector for introducing recombinant DNA into the oocyte. Although normal fertilization can be achieved by the injection of spermatozoa, sperm heads, or round spermatids into matured oocytes, the fertilization process after injection remained largely unknown. Despite the fact that human IVF using ICSI is relatively common and efficient, only a few offspring have been produced in laboratory animals and some domestic species including cats, cattle, and sheep.

Likewise, ICSI of porcine oocytes has been developing slowly, and it was not until recently that the birth of a single piglet was reported.[16] During this trial, in vitro–matured oocytes were injected with in vitro–capacitated spermatozoa; after 40 hours of culture, two- to four-cell-stage embryos were transferred to the oviduct of induced-estrus gilts 24 hours after the expected ovulation time. Pregnancy of the surrogate mothers was maintained using 5 mg of estradiol benzoate from days 10 to 16 after transfer to induce maintenance of the corpora lutea. Only one of four recipients carried the pregnancy to term; she gave birth to a single male piglet after receiving 32 embryos. Before this success, ICSI was performed in several studies using porcine in vivo–matured oocytes that were fertilized using either fresh ejaculated[85] or cytometrically sorted sperm[86] with good cleavage rate. All attempts to transfer cleavage embryos failed to deliver pregnancies.

Recently, experiments have been conducted to determinate fertilization rates and developmental ability of porcine oocytes after ICSI. In vitro–matured oocytes were injected with either spermatozoa, isolated sperm heads, round spermatids, or spermatid nuclei.[87] At 6 days after injection, the percentage of embryos developed in vitro to the blastocyst stage were 38% and 22% after ICSI and isolated sperm head injection, respectively. Unlike spermatozoa, spermatids are unable to activate oocytes, mainly because of the lack of activation factors. When electrical stimulation was used 2 hours before spermatid injection to induce activation, however, rates of formation of two pronuclei and blastocysts were not different in oocytes after intracytoplasmic spermatid and spermatid nucleus injection (25% and 27%, respectively). Results from these studies clearly suggest that although the embryos produced were not transferred, pregnancies and piglets could be produced after intracytoplasmic sperm or spermatid injection into matured oocytes.

GAMETE INTRAFALLOPIAN TRANSFER PROCEDURE

In an effort to circumvent some of the problems encountered with classic IVF techniques, swine reproductive researchers have recently turned to the technique of **gamete intrafallopian tube transfer** (GIFT), or oocyte transfer. This assisted reproductive technique is an alternative tool to produce pregnancies from genetically superior individual animals. The GIFT procedure is currently being used by several commercial embryo transfer centers in some domestic species, and pregnancy results are likely to improve. For this procedure, in vivo– or in vitro–matured oocytes collected from a live donor animal or at slaughter are transferred into the oviducts of a number of synchronized preovulatory recipients. At the time of donor oocyte transfer, all of the recipient's preovulatory follicles are aspirated to remove the "native" oocytes, and sperm are placed within the recipient's uterine or oviduct lumen, along with the donor oocytes. Removal of "native" oocytes from the recipient's preovulatory follicles will lead to luteinization and the development of functional corpora lutea. In swine, oocyte transfer would function in an equivalent fashion to that of embryo transfer as used currently, with the principal difference residing in the fact that the oocyte replaces the embryo as the primary unit of exchange. It is this difference that gives gamete transfer its primary advantage over embryo transfer from a genetic or breeding standpoint, in that the ability of today's veterinary scientists to reliably acquire large numbers of oocytes from every gilt being slaughtered is considerably greater than their ability to recover an equivalent number of embryos. Preliminary results indicated that the GIFT procedure can be used successfully in pigs and can be a valuable tool for the study of gamete interaction, as well as for the continued development of biotechnological procedures such as sex preselection.[88]

An alternative to this technique is the so-called **zygote intrafallopian tube transfer** (ZIFT) procedure whereby cleaved in vitro– or in vivo–matured and fertilized embryos are transferred to the oviduct of nonbreed recipients. Laparotomy traditionally has been performed for the oocyte or zygote transfer during these procedures in pigs. Of course, laparoscopy also could be an alternative to performing these procedures; however, reports have yet to be published regarding use of this technique in the pig.

PRODUCTION OF IDENTICAL MULTIPLETS

Many examples of cloning are found in nature. For instance, in human and animal reproduction, clones, or genetically identical animals, are produced when early embryos split into halves, creating identical twins. Each half contains the same genetic code. In the laboratory, artificial embryo manipulation attempts to achieve the same results through a variety of techniques including embryo bisection, dissociation of blastomeres, and cloning by nuclear transfer. A **clone** is a genetic copy of another living organism. Cloned organisms are produced asexually; sperm does not fertilize the oocyte. Hence, the genetic material of cloned offspring is drawn from a single source, rather than being a combination of sperm and oocyte genes.

Embryo Bisection

Creation of identical twins has been simulated in the laboratory by cutting embryos in half using different microtools. Embryo bisection, to propagate specific animals at a more rapid and efficient rate, is making dramatic progress in the field of embryo transfer technology. Monozygotic twin piglets also can serve as excellent models in various areas of biologic research. Bisection of bovine embryos has been applied widely under experimental and commercial conditions, and pregnancy rates after nonsurgical transfer of demi-embryos are only about 5% to 10% lower than those with nonbisected embryos.[89] In pigs, however, splitting of preimplantation stage embryos is associated with a significant decrease in viability in vivo, and very few sets of identical twin piglets have been obtained after transfer.[90–92] Several factors with profound effects on the viability of pig demi-embryos have been identified, such as the presence or absence of the zona pellucida, embryonic stage,[90,92] competition

between demi-embryos and intact embryos,[91] and temperature during the bisection procedure,[93] as well as experimental day, donor animal, boar, embryo quality, duration of the in vitro culture before bisection, and size of the halves after bisection.[94] Demi-embryos derived after splitting fair-quality blastocysts have a higher percentage of development in vitro (32%) than was observed for their morula stage (22.2%) or early blastocyst stage (16.7%) counterparts after bisection.[95] Results from a previous investigation demonstrated that pig demi-embryos possess a great developmental potential in vitro (66% were considered transferable after 24 hours in culture), and with transfer of a sufficient number of demi-embryos (about 28) per recipient, high pregnancy rates can be obtained (approximately 80%).[92] Although farrowing rate also was similar to that after transfer of intact embryos or after mating, litter size and postnatal survival were considerably reduced (6.0 piglets and 73%, respectively). These results suggest that in contrast with in vitro development, when demi-embryos are transferred to female recipients a significant reduction in developmental potential is observed. Nevertheless, higher success rates can be expected when embryos at the blastocyst stage with excellent morphologic quality are split into two even halves immediately after recovery.

Proliferation of Isolated Blastomeres

Use of isolated blastomeres derived from mammalian embryos has gained particular significance for purposes such as multiplication of genotypes from superior animals[96] or screening for sex determination, or for the transmission of genetic disorders.[97] In a preliminary report, approximately one third of blastomeres derived from four- to six-cell pig embryos developed to blastocysts after transfer to recipient gilts.[98] Several other recent experiments, however, demonstrated an improvement in developmental rate of isolated blastomeres after culture. Approximately 40% to 70% of single blastomeres derived from four- and eight-cell embryos could develop to normal morula and blastocysts after either a reaggregation of isolated blastomeres (transferred to a surrogate zona pellucida),[99] by being subjected to an electrical pulse to stimulate their development[100] or by modifications in the in vitro culture conditions.[101] Collectively, these results suggest that it is feasible to use dissociated blastomeres from embryos, at least up to the eight-cell stage, to produce a group of identical piglets after transfer.

Cloning by Nuclear Transfer and Gene Transfer in Pigs

Researchers have long been interested in nuclear transplantation both as a tool to study developmental biology and as a means for producing identical animals. **Nuclear transfer** is a term used to describe the basic technique that involves the transfer of a nucleus from one cell to another cell from which the nucleus has been removed. For cloning animals, this entails transferring the nucleus of a cell obtained from the individual to be cloned into a recipient oocyte that has had its own nucleus removed.[102] After transfer, the plasma membranes of the oocyte and donor cell are closely aligned so that they can be fused with an electric current to create a single cell. If the fusion process is successful, this newly created, single-cell embryo will begin to divide, becoming an embryo genetically identical to that of the donor from which the cell was obtained. This embryo can then be transferred into a surrogate mother for gestation.

Although the history of animal cloning dates back to the early 1900s, the most acclaimed example of animal cloning is, of course, the report by Wilmut and colleagues in 1997—the first to demonstrate that cloning of adult animals was possible.[103] Nuclei of cultured mammary epithelial cells derived from an adult ewe were transferred into enucleated sheep ova, ultimately resulting in the birth of a cloned lamb, Dolly. The first cloned sheep actually were described more than 10 years earlier by Willadsen, who used embryonic blastomeres as nuclei donors.[104] This was the precursor for subsequent work involving nuclear transplantation in domestic species and sparked considerable interest in the development and improvement of techniques for cloning livestock species. The impact of this work now seems minor compared with the explosion in research efforts targeted at cloning mammals that has occurred since Dolly's birth.

Without a doubt, one of the major factors influencing the probability of cloning a specific animal is species. Although the basic approach involving nuclear transfer may be similar, the specific material and methods utilized for cloning one species of animal do not automatically apply across different species. Cloning animals by nuclear transplantation involves several key steps, including (1) acquisition of mature ova, (2) removing the chromosomes contained within the ova (enucleation), (3) transfer of cell nuclei obtained from the animal to be cloned into the enucleated ova, (4) activation of the newly formed embryo to initiate embryonic development, (5) embryo culture in vitro, and (6) transfer of the cloned embryo into a surrogate recipient.

Progress in animal cloning technology is being fueled by the many potential benefits for humankind. Currently, efforts are focused on the production of transgenic animals by utilizing genotypes defined by a particular genetic modification to produce bioengineered pharmaceuticals, such as the production of proteins for the treatment of human diseases[105]; to increase disease resistance, growth, and reproductive performance in swine[106]; and to produce pig organs for transplantation.[107]A considerable demand also exists, however, for cloning animals with inherent genetic value. The production of recombinant pharmaceutical proteins is targeted to those expressed almost exclusively in the mammary gland or blood of transgenic pigs. In the past, genetic modifications (transgenics) of livestock could be achieved only by microinjection of several hundred copies of a specific gene construct into the pronuclei of a newly fertilized oocyte.[94] Currently, however, the use of cultured specific cells (with the desired genetic change) for genetic modification by nuclear transfer has several advantages in comparison with the method of direct injection. Although many transgenic pigs already have been produced using different DNA constructs by pronuclear microinjection, several

investigators are now, for practical reasons, applying nuclear transfer techniques for genetic modifications.[94]

The production of transgenic pigs by nuclear transfer for xenografts offers the best approach to creating organs for human transplants because of the similarities in size and biology. **Xenotransplantation** refers to the transplantation of organs or tissues from an animal of one species into another species (e.g., pig-to-human). The major limiting factor in organ transplantation today is the increasing shortage of suitable donor organs. It has been estimated that in the United States alone, approximately 60,000 people are listed for solid organ transplantation, yet only approximately one third of needed donor organs are obtained.[108] The discrepancy between the number of potential recipients and donor organs is increasing by approximately 10% to 15% annually; pigs, however, will hold promise for supplying an unlimited number of organs to replace ailing hearts, livers, and kidneys in humans. Pig organs, when transplanted to humans or nonhuman primates, are rejected hyperacutely within minutes, however, by antibody-mediated complement activation.[109] Methods have been successfully developed to prevent this hyperacute rejection, including depletion or inhibition of recipient antibodies or complement and the development of transgenic pigs that express a human complement-regulatory protein. Although experimental pig-to-primate organ xenotransplantation now results in transplant function for days and weeks, rather than minutes, the presence or return of anti-pig antibodies, however, even after the use of organs with the human protein, inevitably leads to what has been variously termed *acute vascular rejection* and *delayed xenograft rejection,* which is again believed to be antibody-dependent. The next step in pig cloning will be to modify the cells from which the pigs are cloned to prevent the human immune system from launching an acute rejection. Considerable progress has been made in recent years, but experimental results do not yet warrant the initiation of a clinical trial of organ xenotransplantation. It may take several generations of clones and many years to weed out the genes that cause rejection. Nevertheless, trials of pig cell transplants are already under way in patients with diabetes and neurodegenerative conditions, such as Parkinson's disease. Some researchers are concerned that using pig organs or tissue for transplantation could cause humans to contract some unusual swine viruses. These viruses have been infecting pigs for thousands of generations and now are part of the swine genes, passed along from parents to offspring.[110]

Animal cloning by nuclear transplantation is extremely inefficient, and in pigs only approximately 1% of the embryos transferred survive to term—even discounting the numerous trials that have resulted in no offspring. As mentioned before, pigs are a particularly illustrative example of a species in which techniques for nuclear transfer cannot be directly applied to other species. As with the sheep, the birth of cloned pigs also was reported first by investigators using embryonic blastomeres[9] and, a little more than 10 years later, by workers starting with somatic cells from an adult pig[17] using a modified double nuclear transfer technique, and then with fetal fibroblasts as nuclear donors.[111]

The first piglet to be born in these studies started as 1 of 88 reconstituted embryos that had been transferred, together with control embryos to increase the likelihood of maintenance of pregnancy. During the double nuclear transfer procedure, in vitro–matured oocytes were collected, enucleated, and fused with adult granulosa cells. The following day, a second round of nuclear transfer was performed by replacing the two pronuclei of in vivo–derived pig zygotes with the pseudo-pronuclei obtained from the nuclear transfer embryos. Embryos were then transferred into the oviduct of recipient females within 2 hours of the second nuclear transfer procedure. In total, 401 double nuclear transfer embryos were transferred into seven recipients, and 185 single nuclear transfer embryos were transferred into three recipients. Only one recipient receiving double nuclear transfer embryos became pregnant, and this animal gave birth to five piglets, whose birth was reported in *Nature*. In a second report, Japanese and British scientists each have claimed success in cloning pigs.[111] The Japanese piglet has been called Xena because of the belief by her creators at the National Institute of Animal Industry that she will contribute to the use of pigs as sources of organs for human transplantation. Fetal fibroblast nuclei were microinjected into in vivo–matured oocytes from which the nucleus had been removed. An electrical pulse stimulated the oocytes to grow into an embryo, and the resulting embryos were transferred into the oviduct of recipient females after a short-term culture. The transfer of 110 cloned embryos into four recipients resulted in the birth of one female piglet, whose birth is reported in *Science*.

The goal of current research is to grow thousands of cells in the laboratory, each of which will have a chance of developing into an entire animal once transferred into an oocyte. By applying transgenic techniques to thousands of cells in culture, those cells with appropriately altered DNA can be selected for nuclear transfer; then, if this procedure is successful, transgenic animals can be produced effectively. These made-to-order animals that possess new genes of special interest are the main focus of current research in cloning technology.

CONCLUSIONS

Reproductive technologies, such as embryo transfer, that allow for the simultaneous control and manipulation of both the genetic composition and the health status of selected animals will become an indispensable tool for internationally based swine-breeding companies. This methodology, combined with sperm sexing and deep uterine, single-low-dose insemination, may further reduce the overhead for producing replacement females. Nonsurgical methods must continue to be explored for embryo transfer before it will be widely applied in the industry. Potentially, embryo transfer could become a technique nearly as routine as AI. The use of these reproductive technologies will lead ultimately to the rapid development of genetic lines of swine specifically selected to meet the requirements of the markets in animal agriculture. In the past decade, amazing progress has been made with in vitro embryo production, nuclear transfer,

and related technologies. As they are refined, these technologies will no doubt be used increasingly, and entirely new areas for commercial applications will be discovered. Overall, the importance of animal health to the efficiency and profitability of the global swine industry may lead to the integrated use of reproductive technologies in a manner and level unmatched for any other livestock species.

CHAPTER 113

Demographics and Herd Management Practices in South America

JULIO SUMAR

EARLY HISTORY

Current archeological evidence indicates that llamas and alpacas were domesticated in the Andean *puna* at elevations of 4000 to 4900 m above sea level.[1] Identification of the ancestral forms from which they were domesticated, however, remains a matter of debate. Once these animals were domesticated, llama and alpaca herding economies spread beyond the puna limits and became important for Andean peoples living in all geographic regions, from sea level to high mountain elevations.[2]

Everywhere in the Andean mountains, as well in lower-elevation sites and caves, rupestrian paintings more than 9000 years old have been found depicting camelids being herded or hunted. When the Spanish conquistadors arrived in the Andes in the early 16th century, they found millions of alpacas and llamas, together with a similar number of the wild species vicuñas and guanacos. They were distributed throughout the 380,000 square miles of the Inca Empire, from the coastal deserts to the snow line at 4500 meters above sea level. The culturally advanced Inca Empire relied extensively on the alpaca for fiber production and on the llama as a beast of burden and meat production, and used the wild species in a sound and rational manner. They also used these animal species as sacrificial animals and regarded them as tokens of wealth.

THE PLACE OF ALPACAS AND LLAMAS IN THE ANDEAN ECOSYSTEM AND IN THE ANDEAN CULTURE

Since their domestication alpacas and llamas have played a critical role in the Andean agroecosystem. In the cold Andean highlands, as well as along parts of the Pacific Coast, the **alpaca** is the most important source of wool. The **llama,** also a secondary provider of wool, became a most efficient pack animal, enabling the transportation of goods over long distances. As remains true today in traditional villages, both species were a very important source of manure for agriculture, which also served as fuel in the high treeless *puna* environment. Although meat has always been considered of secondary importance in the Andean diet, salted and freeze-dried camelid meat is a potentially important source of high-quality protein.[3]

Camelid bones provide the raw material for work utensils and beautifully crafted items, whereas sinews are turned into thongs. Camelid lard, in addition to acknowledged health properties in the rich Andean medical lore, still plays an important role in religious rituals. Camelid fetuses resulting from natural abortion are still sold in rural markets and are widely used in fertility rites. Similarly, stone formation in the digestive system of alpacas and llamas—**bezoars**—are considered to be charms possessing medical and magical properties.[3]

Finally, and not least important, alpacas and llamas have always been an abundant source of images and concepts in the rich and metaphorical Andean ancestral mythology. Herders state that "we take care of our animals and they take care of us,"[4] showing the strong interdependence of animals and humans. Peasants believe that *pachamama* (mother earth) gave alpacas and llamas to men as a loan, and that the future of humanity depends on the proper conservation of herds. They believe camelids originated in the underworld and came out from water springs. At the end of the world they will all return to those sacred springs. A sign that the end of the world is approaching, they say, will be depletion of the alpacas and llamas.[3]

Myth and rite also play an important role in enhancing animal fertility through propitiatory ceremonies that are part of the activities associated with mating, and with controlling herd size through animal sacrifice during the dry season.

Habitat

The continent of South America comprises 13 separate countries or territories and is the third largest land mass in the world. It contains the widest extremes of topography and climate and features the traditional and modern life and customs of many different sectors of human culture.

Along the western border of South America runs the high mountain range known as the **Andes,** or *Cordillera de los Andes*. These mountains are relatively young and are still in the process of being formed from the interaction of the South American and Pacific tectonic plates. Massive uplift has led to high, undulating land surfaces that contrast with the more continuous sharp relief of many other mountain systems.[5]

Faulting, folding, and volcanic activity have produced a rugged and mountainous surface topography, and glaciation and erosion have generated many deep valleys. The complex geologic history of the Andes has produced a landscape of rolling, relatively flat plateaus, with occasional mountain chains rising above them (approximately 6000 m above sea level) and deeply incised gorges cutting into them.[5] The term *puna* is used to refer to this intermediate zone, ranging in altitude from 3700 to 4800 m above sea level.[6] It has a relatively even terrain and its vegetation is characterized by bunch grasses and very sparse shrubs. It is this zone that constitutes the present-day habitat of the South American alpacas and llamas.

Two general climatologic seasons occur in this part of the Andean region: a mildly warm, rainy growing period from December to April and a cold, dry period from May to November. About 80% of the rainfall comes during the wet season, and the remaining 20% during the dry season in form of hail and snow (total rainfall of 300–900 mm). Weather data collected in the Department of Puno, where the La Raya High-Altitude Research Station is located, from 1931 to 1963 show the mean daily minimum temperature to be –3°C and the mean daily maximum temperature 17.3°C.[7] As in other high-altitude regions, the diurnal variation in temperature is great, at times exceeding 30°C.[8] This high-altitude environment is characterized by low atmospheric pressure, very dry climate, low oxygen availability, and intense solar radiation. In thin air, bodies absorb heat rapidly from the sun, and they lose it quickly when the rays of the sun are blocked by clouds. Moreover, wind, dry air, and low atmospheric pressure all are factors that increase the rate of evaporation.[7]

Because of the rugged climatic and geographic conditions, little or no agriculture is possible in this zone. Consequently, grazing of camelids and, to a lesser extent, sheep is the only means of subsistence for inhabitants of the highlands. With traditional herding practices, low-quality natural pastures can be converted into useful animal products.

History of International Exportations

The first contact of Europeans with South American camelids probably was that of Captain Francisco Pizarro's crew when he first arrived at the port of Tumbes in northern Perú, some time in 1528. Pizarro took some llamas back to Spain and displayed them at the Spaniard court. In those days, llamas were known by the Spaniards as *carneros de la tierra* ("rams of the land") and later as *carneros de cuello largo* ("long-necked rams").[3] Since that time, many attempts were made to introduce members of the South American camelid family to Spain, England, France, Germany, and Holland during the 16th, 17th, and early 18th centuries. Some accounts of these introductions are available at the literature.[9–11] By 1770 the government of Holland auctioned a herd of 32 alpacas and llamas belonging to King Wilfred II. It is said that this herd was purchased by the Frenchman Buffon, known in modern times as the "father of veterinary science," and sent to the Veterinary School of Alfort, where the present-day museum's exhibits include a beautiful dissection of a llama done by the anatomist Fragonard and hundreds of anatomic parts dissected by the best 18th century anatomists.

The greatest number of South American camelids ever carried to Europe at one time was a herd that arrived in Cadiz in 1808. It consisted of 36 animals, including llamas, alpacas, and vicuñas. They were brought from the highland of Peru to Buenos Aires, on the Atlantic Coast, by slowly travelling 2 to 3 leagues a day, and then shipped to Cadiz. Only 11 animals arrived at Cadiz alive, 2 of which died there. These animals were carried to Europe as a present from the Prince of Peace, Godoy, to Empress Josephine. In one report, six alpacas were imported to New Hampshire in the United States in 1849.[3]

One of the most interesting accounts of the introduction of alpacas and llamas to other countries is that of Charles Ledger, who wrote about his attempts to introduce them into Australia. He was particularly impressed by camelid adaptability: "No animal in the criation [sic], it is my firm conviction, is less affected by the changes of climate and food." In 1858, he landed 274 animals in Sydney after 4 months at sea. In 1864, however, the Australian government decided to abandon the alpaca business entirely, under the duress of the merino sheep breeders, who saw in the alpaca a fine wool producer and a future competitor.[12]

In the late 1800s, the llama was introduced into United States as a zoo exhibit; the number of imports was small and generally included guanacos or guanaco hybrids. One of the more significant importations was made in the early 1900s into the California coastal area by W. R. Hearst. In 1930, U.S. importation of camelids was cut off by a "foot and mouth disease" embargo on all South American hoofed stock. Finally, in the early 1980s, some American llama breeders started to import llamas and alpacas from Chile, and now the llama and the alpaca have developed from a zoo curiosity to the focus of a multimillion dollar industry growing at an exceptional rate. In the last 15 years, a total of 30,000 llamas and alpacas have been exported from Chile, Bolivia, and Peru to the United States, Canada, Spain, Israel, Ecuador, Libya, United Arab Emirates, Australia, New Zealand, Italy, Germany, and elsewhere.

Genetic Diversity, Distribution, and Number

Available census data for current populations of llamas and alpacas in the Andean Region are presented in Table 113-1.[13–17] The area of greatest concentration is located between 11 degrees south and 21 degrees south. Eighty-eight percent of the South American alpaca population are found in Peru. Likewise, the greatest population of llamas is found in Bolivia (62.5%). The rest of the alpaca and llama populations inhabit Chile and Argentina, and a very few are raised in Ecuador.

South American domestic camelids bred in different geographic zones of the Andean Mountains have sometimes been given local names, but it would be misleading to call them breeds. A survey carried out in 1991[13] studied the genetics of alpacas and llamas from Bolivia, Chile, and Peru, with the following findings:

Table **113-1**

Estimated Population and Distribution of Alpacas and Llamas in the Andean Region

Country	Alpacas	Llamas	Total	% Regional
Argentina	Few	75,000 (2%)	75,000	1
Bolivia	324,326 (11%)	2,022,126 (63%)	2,346,452	37
Chile	30,657 (1%)	66,383 (2%)	97,040	2
Peru	2,687,363	1,070,541	3,757,904	60
Total	3,042,346	3,234,050	6,276,394	100
Percent*	49	51	100	

*Percent of the total domestic camelid population.
Data from references 13 to 17.

Table **113-2**

Regional Names for Different Breeds of Alpaca and Llama

Country	Alpaca Breeds	Llama Breeds
Bolivia	Huacaya/Suri	Tampully/Kcara
Chile	Huacaya	Tajulli/Lutica
Peru	Huacaya/Suri	Chaku/Kara

Data from Sumar J: Data on alpacas and llamas: population and genetic diversity. EAAP/FAO information on livestock population. Data bank on animal genetic resources, Institute for Animal Breeding and Genetics, Hannover School of Veterinary Medicine, Hannover, Germany; and from Sumar J: Características de las poblaciones de llamas y alpacas en la sierra sur del Perú. In *Informe de la mesa redonda sobre camelidos Sudamericanos.* FAO/INIA, Lima, Peru, 1991, vol VI, pp 71–78.

Table **113-3**

Prevalence of Alpaca and Llama Breeds in the Andean Region

	ALPACA BREEDS		LLAMA BREEDS*	
Country	% Huacaya	% Suri	% Kara	% Chaku
Bolivia	100	—†	80	20
Chile	100	—†	60	40
Peru	99	1	80	20

*10% of the llamas are considered to be of an "intermediate type," the result of crosses between both breeds of llamas.
†There is a small number of specimens of the Suri breed.

1. Peru has two breeds of alpaca: the *Huacaya* (99% of the total alpaca population) and *Suri* (1% of the total alpaca population). Two breeds of llama are recognized: the *Kara* or nonwoolly species (accounting for 80% of the total llama population) and the *Chaku* or woolly species (which makes up 20% of the of the total llama population).
2. Bolivia and Chile have only one breed of alpaca, the *Huacaya,* representing 100% of the total alpaca population in those countries, although a few alpacas of the Suri breed live in the northern part of Bolivia, close to the Peruvian border. Of note in this context, since 1992, a number of the Peruvian breed *Suri* have been transferred to Chile for breeding. Likewise, Chile has two breeds of llama: the *Lutica* (60% of the total llama population), called *Kara or Kcara* in Peru and Bolivia, and the *Tampulli or Tajulli* (40% of the total llama population), called *Tampully* in Bolivia and *Chaku* in Peru (Tables 113-2 and 113-3).
3. It has been observed that approximately 20% of llamas in the three countries are of the "intermediate type"—that is, the result of crosses between animals of both breeds; also, crosses between alpacas and llamas also have been observed. In Peru, it is not uncommon to find intermediate phenotypes of alpaca (resulting from crosses between alpacas of the Huacaya and Suri breeds).
4. Tables 113-4 to 113-5 summarize data on coat color in alpacas and llamas of different breeds in Bolivia, Chile, and Peru.

CAMELID FARM CHARACTERISTICS

At present, 95% of all llamas and 75% of all alpacas in the Andean Region are under the control of traditional pastoralism. These alpacas and llamas have survived within the framework of a traditional, non-European, socioeconomic organization because they constitute an essential element of the Andean culture.[3] Typically, small herd holders maintain flocks of 30 to 300 head on communal grazing lands.[18] Most herders, however, include multiple species of domestic animals in their flocks, with alpacas and llamas being the dominant species. In the *puna,* mixed herds of alpacas, llamas, and sheep are quite common. Sometimes cattle graze along with the rest of the animals.

Table **113-4**

Coat Color Frequency in Alpacas

	% HUACAYA			% SURI		
Coat Color	**Bolivia**	**Chile**	**Peru**	**Bolivia**	**Chile**	**Peru**

In *Informe de la mesa redonda sobre camelidos Sudamericanos.* FAO/INIA, Lima, Peru, 1991, vol VI, pp 71–78.

Intensity of herd management varies greatly between producers, but in general, herders employ only traditional management. Herding practices typically are governed by availability of grass and community custom.[20] Little attention is given to protecting vegetation from overgrazing or to separating herds by specific species and classes. No attempt is made to provide supplementary feed for alpacas and llamas, resulting in low reproductive efficiency, high offspring mortality, parasitism, and consequently low animal productivity.

Regarding health, infectious diseases are important in this species. Neonatal enterotoxemia may kill as many as 70% of the crias.[21] Parasitic diseases are no less important as causes of reproductive inefficiency, particularly mange and parasitic gastroenteritis, which retard growth and decrease fiber yields and meat production.

Most alpaca and llama herds are maintained without any definite breed improvement criteria. Possible high levels of inbreeding due to small flock sizes also may potentially contribute to the low reproductive rate. Shearing is not done at regular intervals, typically being performed as a means to get money for a specific purpose.[3]

By contrast, better herd management practices are used on larger cooperative farms. In most of these large, mainly alpaca farms, animals are classified according to breed (Huacaya or Suri), coat color, age, and sex and maintained in groups of 200 to 800. The proportion of females of breeding age, however, usually varies, ranging from 34% to 57%,[18] whereas the proportion of castrated males kept as fiber producers may be 31% of the total farm total population. Shearing is mainly annual and in some cases biannual. From a practical standpoint, annual shearing is recommended because the fleece will be less damaged by the environment (e.g., solar radiation, rain, dust, dryness), allowing better external parasite control, and annual weighing of the live animal and its fleece allows for better control of production and genetic selection.

At present, culling of animals is based mainly on age: Mostly females older than 10 years of age and surplus males are sent to the slaughterhouse.

Reproduction and Survival of Offspring

Research done in the last 20 years has shown that biologic principles governing reproduction in Camelids are peculiar to the species and must be taken into account in applying techniques to improve birth rate and survival. For optimal breeding efficiency, females should not be bred until 10 to 15 days post partum, because earlier

matings can lead to uterine infections and would entail unnecessary use of stud animals.[23]

Neonatal mortality rates can be very high. In one investigation, the neonatal mortality rate for small herds was reported to be between 18% and 50%, and the rate for cooperative farms was higher, reaching 70% in some instances (Centro de Investigación IVITA, 1981). *Clostridium perfringens* type A enterotoxemia, which commonly occurs during the birthing season (very rainy season).[21]

Mating Systems

Alpacas and llamas are considered to be seasonal breeders. The breeding season occurs from the end of December to March (summer rainy months in the South Hemisphere). In small herds, in which males and females run together year-round, parturition also is restricted to the rainy months, as the gestation length is around 345 days.[24]

In better-managed herds, however, in which males and females are kept in separate herds, the females are bred using a specific male-to-female ratio; the males are introduced into the female herds at a rate of 6% for the entire breeding period of approximately 60 days.[25]

Half of the males are used for 1 week; then the other half are used also for 1 week, in an alternate system, to avoid the continuous association of males and females, which seems to inhibit libido in males. Use of this alternate or rotary breeding system on large alpaca farms in Peru resulted in an increase in birth rate from 57% to 81%.[25] This method of mating works well for mass selection, crossing the "best with the best," when it is not necessary to know the sire.

In those herds for which knowledge of sire identity is necessary (as required by the Peruvian Alpaca Registry), the system used is to join 20 females and 1 male in a fenced paddock for 60 days. A pregnancy rate of 70% is obtained with this method. The disadvantage of this method is the high cost of fencing large areas of pasture to keep the mating groups separate while providing the animals with enough food and water. Nevertheless, one of the advantages is that it allows testing of reproductive performance of the stud animal, with a required yearly minimum of 7 crias (offspring) from each male.

High rates of pregnancy have been obtained using **hand mating**, in which the females are checked daily for sexual receptivity and mated when appropriate with a proven fertile male.[26]

Peruvian Alpaca Registry

The Peruvian Alpaca Registry was established in 1995. The initial objectives of the registry were (1) to identify alpacas with certain fleece and conformation characteristics, allowing breeders or owners to make use of their best animals to improve offspring productivity, generation after generation; (2) to establish accurate records for pedigrees and other genetic studies; and (3) to avoid the exportation of the best alpacas—typically, those that win top prizes in the National Alpaca Show—in order to avoid what is called *genetic erosion*.

All alpacas graded higher than 75 points (100 points is the score for the ideal alpaca or the prototype) are recorded in the so-called **open book**, the first stage in the process of registry entry. In the second stage, only the offspring of those males and females recorded in the open book are registered. This is the initial step in establishing the pedigree. For the screening process, conducted under the auspices of the Consejo Nacional de Camelidos Sudamericanos (CONACS) (i.e., the National Council of South American Camelids), each alpaca presented to the examiner must score more than 75 points on the Alpaca Characteristics Evaluation Form. The Peruvian Registry assigns 30 points to body conformation and 70 points to fleece characteristics, and 40 points is given to fineness of the fleece. Alpacas must have a permanent double identification consisting of metal or plastic ear tags.

A **pedigree** is simply a record of ancestry, and most problems in practice arise over the value of such records.[27] The pedigreed animal has only an officially registered name and number assigned by the Livestock Association, which are of very limited value. For the pedigree to become a useful tool in alpaca production and improvement, official records for individual animals must include performance data. Originally, when pedigrees were written down by the first breeders, an animal's name was all that was necessary, because it was believed that everyone knew how it performed. This may still be the situation in the alpaca and llama industry in some countries, where the names of certain alpacas are internationally famous because they came from a certain alpaca farm, or because they have won many blue ribbons.

Before the establishment of the Alpaca Registry in Peru, a few breeders actually kept records of some kind that permitted assessment of the quality of the animal examined. In this manner, some breeders successfully improved their herds. The scientific basis for such records is very similar to what in modern genetics management is called a *performance test;* however, the accuracy of the data may not be highly reliable.

Because the fleece constitutes the main source of income for the Peruvian alpaca breeder, data on amount and quality of the fleece produced for some lines of alpacas are of considerable value. Reflecting the genetic diversity among Peruvian alpacas, fleece weights may range from 3 to 12 pounds in adult alpacas sheared annually. The management goal is intensive breeding of those alpacas with the highest fleece quality and weight.

Disease, Vaccination, and Deworming Practices

Infectious and parasitic diseases that affect alpacas and llamas play a prominent role in the economics of animal production owing to associated high mortality rates and decrease in productivity.

Both species are susceptible to most of the infectious diseases affecting other domestic animals. In mixed herds in the highlands of the Andean Region, cross-infections occur between the different animal species.[3] Camelids

are particularly sensitive, however, to some infections and relatively resistant to others. The introduction of camelids to other continents have resulted in the presentation of many new diseases not reported in South America. Whether or not alpacas and llamas are susceptible to a number of important viral diseases of cattle, sheep and horses is still unknown. Perhaps these animals have not been exposed to these viruses, or clinicians and researchers may not have conducted adequate virologic testing to discover them.[28]

Enterotoxemia is the most important infectious disease of neonatal domestic camelids. This disease is characterized by sudden death, with neonatal mortality rates as high as 70% during the first month of life. *Clostridium perfringens* types A and C are involved.[21] In adult alpacas, so-called alpaca fever, a bacterial septicemia caused by *Streptococcus zooepidemicus,* is associated with high morbidity and low mortality; this disease can be prevented by minimizing stressful situations. Other diseases in alpacas and llamas that have been diagnosed are osteomyelitis of the mandible, brucellosis, necrotic stomatitis, otitis, tetanus, tuberculosis, and keratoconjunctivitis. The prevalence of viral diseases—contagious ecthyma, rabies, herpes virus, adenovirus, bovine viral diarrhea, and foot-and-mouth disease (FMD)—is unknown. Infectivity and severity of FMD in alpacas and llamas, however, appear to be very much lower than in either cattle or sheep.[28] Herd health programs for domestic camelids in the Andean Region, do not include any kind of vaccination. Several vaccines have been advocated for use in alpacas and llamas, especially against enterotoxemia, although the efficacy of such vaccines and the optimal vaccination schedule remain unknown.

Both endoparasites and ectoparasites[29] cause considerable losses among camelids. Gastrointestinal parasites are reported to cause significant disease problems in the llama and the alpaca. Fecal examinations have recovered species-specific parasites including *Graphinema, Spiculoteragia, Camelostrongylus, Nematodirus lamae,* and *Lamanema*. In addition, *Ostertagia, Trichostrongylus, Cooperia, Nematodirus, Bunostomum, Oesophagostomum, Trichuris, Capillaria,* and *Haemonchus* are well recognized to occur. Many anthelmintics, although not specifically labeled for treatment of gastrointestinal parasitism in camelids, can be used safely. Fenbendazole and ivermectin provide the most effective and safest treatment, eradicating mature gastrointestinal parasites and effective against the dormant stages of these parasites. Liver fluke, *Distoma hepatica,* also occurs in domestic camelids, even at high altitude, although such environmental conditions are hostile to the intermediate host, snails. Coccidiosis due to species of the protozoan *Eimeria* also may affect young animals after weaning, causing diarrhea. Clinical coccidiosis is treated with sulfonamides and can be prevented by good management practices. Finally, sarcocystosis, caused by the coccidial protozoan *Sarcocystis,* can be prevented by deworming dogs, cats, and humans; prevention is important because there is no treatment for this disease. Alpacas and llamas are considered equally susceptible to these diseases.

Of the external parasites, the most common are the *Sarcoptes* and *Psoroptes* agents of mange; the scabies mite burrowing within the epidermis causes a papular dermatitis. The affected regions become alopecic, crusted, thickened, and hyperpigmented. Many therapies have been used for mange in camelids. Recently a popular agent for mange treatment has been ivermectin formulated for bovine use.

CHAPTER 114

Reproductive Management of Llamas and Alpacas

DAVID GARTRELL PUGH and MARY BETH STANTON

Llamas and alpacas have grown in popularity in the United States. These large domestic farm animals are commonly encountered by today's veterinary practitioners.

In 2002 the Alpaca Registry reported 42,000 alpacas owned by greater than 4000 owners in North America.[1] That report shows that concentrations of alpacas are greatest on the west coast, in the western Midwest, and on the northeast coast of the United States, with fewer alpacas in southern states. In Canada, the provinces of Alberta and British Columbia have the most registered alpacas. These numbers reflect only registered animals. The International Llama Registry (ILR)[2] reports greater than 5500 llamas in Canada and greater than 144,000 in the United States. The distribution of areas with the highest numbers of llamas is similar to that for alpacas in both countries. The ILR reported greater than 11,000 owners and greater than 350 owners of registered llamas in the United States and Canada, respectively. We believe that the reported number of registered animals is closer to the total number of animals, both registered and unregistered, for alpacas than for llamas. There are probably many more unregistered llamas than unregistered alpacas. Both alpaca and llama ranches appear to occur

CHAPTER 114

Reproductive Management of Llamas and Alpacas

DAVID GARTRELL PUGH and MARY BETH STANTON

Llamas and alpacas have grown in popularity in the United States. These large domestic farm animals are commonly encountered by today's veterinary practitioners.

In 2002 the Alpaca Registry reported 42,000 alpacas owned by greater than 4000 owners in North America.[1] That report shows that concentrations of alpacas are greatest on the west coast, in the western Midwest, and on the northeast coast of the United States, with fewer alpacas in southern states. In Canada, the provinces of Alberta and British Columbia have the most registered alpacas. These numbers reflect only registered animals. The International Llama Registry (ILR)[2] reports greater than 5500 llamas in Canada and greater than 144,000 in the United States. The distribution of areas with the highest numbers of llamas is similar to that for alpacas in both countries. The ILR reported greater than 11,000 owners and greater than 350 owners of registered llamas in the United States and Canada, respectively. We believe that the reported number of registered animals is closer to the total number of animals, both registered and unregistered, for alpacas than for llamas. There are probably many more unregistered llamas than unregistered alpacas. Both alpaca and llama ranches appear to occur

in all sizes, ranging from very large (with greater than 1000 breeding females) to very small (with only 1 or 2 animals). In the authors' experience, alpacas tend to be handled, bred, fed, and managed in a more intensive manner than that used with llamas.

Llama and alpaca owners vary greatly in animal husbandry experience and in knowledge of these species. The clinician may be called on to be very involved with all aspects of farm management. The ownership of these species is expanding, and many new owners have little in the way of livestock experience. With some experience and acquaintance with the subtle differences between llama and alpaca breeding, feeding, and health maintenance, a practical understanding of small ruminant medicine will enable veterinary practitioners to easily include llamas and alpacas as a profitable and interesting part of their practice.

NUTRITIONAL MANAGEMENT

Llamas and alpacas have three compartments in the forestomach that are referred to simply as compartments C1, C2, and C3. C1 and C2 contain 85% to 90% of the total stomach volume and function as fermentation vats, similar to the rumen and reticulum of cattle, sheep, and goats.[3,4] The first compartment contains numerous saccules lined with glandular epithelium that aid in the absorption of water and solutes[3] and will retain fibrous feedstuffs longer (up to 60 hours) than in sheep (up to 40 hours).[5] The cranial portion of C3 also functions as a fermentation vat, whereas the caudal portion of the compartment is "abomasum-like."[4] Llamas and alpacas appear to have greater salivary production relative to foregut volume, and a faster liquid flow rate from the forestomachs, than are reported for sheep.[5] This faster liquid passage may result in quicker forestomach removal of soluble minerals, vitamins, and microbial protein.[5] Llamas and alpacas are capable of thriving on a diet that contains less dry matter on a body weight basis (1.2% to 1.8%) than has been recognized for many other herbaceous animals (greater than 2.5%). Llamas and alpacas may have a 10% to 25% greater efficiency in digestion and assimilation of nutrients than that in true ruminants, but when they are fed nutritionally good- to excellent-quality feedstuffs, this advantage appears to be lost.[3–6] Llama and alpaca nutrition has been discussed elsewhere, and interested readers should refer to those publications for further information.[3–6]

The llama is a browser by nature but will graze, whereas the alpaca is a grazer that shows a preference for succulent forages. Both species appear to be very adaptable to many types of feeding systems.[3,4] Cereal grains or pelleted supplements are rarely indicated except in older, chronically thin or ill animals, during prolonged periods of cold stress, or to ensure adequate intake of specific nutrients (e.g., selenium, zinc, protein).[4] The assessment of body condition helps in determining long-term nutritional intake, particularly with respect to energy. A 10-point scoring system is most commonly used in which 1 is very thin, 10 is extremely obese, and 5 is ideal.[3]

Body condition in llamas and alpacas is best assessed by palpating the transverse processes of the lumbar vertebrae, around the shoulders, and over the ribs. A convex or concave plane from the dorsal spine to the tip of the transverse processes would be considered to indicate condition scores greater than 5 and less than 5, respectively. If the ribs are easily palpated, the condition score is less than 5, but if the ribs are difficult to feel and if fat cover over the lumbar vertebrae is bulging and slightly soft, body condition for that animal is scored at 6 or greater.[4] The lateral aspects of the transverse processes of the lumbar vertebrae should not be sharp but should be easily palpable. The shoulder structures also should be palpable, with the bones and joint edges not sharp but appearing to have a slight smoothness. With weight gain, subcutaneous fat accumulates over the brisket, between the rear legs, and around the perineum. If the brisket is flat or soft between the front legs, then the body condition is 8. If the sternum is sharp and easily palpated, the condition score would be closer to 3. The pelvic bones can be easily palpated in all but obese llamas and alpacas.[4] When possible, body weights should be evaluated on a continuous basis, and steps should be taken to minimize body weight changes. Llamas and alpacas naturally gain weight in spring and early summer and tend to lose weight in late summer, fall, and winter. If they are weighed at 60-day intervals, adults that do not show this seasonal pattern, but continue to gain (or lose) weight, should be examined, and appropriate dietary changes made.[4]

Llamas and alpacas that are healthy, parasite-free, nonpregnant or nonlactating, and mature may have their nutritional requirements met by being fed 1.2% to 1.8% of their body weight daily of a diet that has an average of 55% total digestible nutrients, 8% to 10% crude protein, 25% crude fiber, 0.6% to 0.8% calcium, and 0.3% to 0.5% phosphorus.[4,5] These maintenance requirements usually are met by good-quality grass or grass-legume pastures or hay. All llamas and alpacas should have free access to fresh, clean water. Modification in energy intake may be needed during extremes in weather. In most instances, the mineral needs are met by offering a well-formulated trace mineral supplement as the only source of salt in a granulated form. Salt blocks do not permit adequate intake of trace minerals and are not recommended. In areas in which forages are badly deficient in phosphorus, selenium, zinc, or other minerals, diets may be designed to supplement such deficiencies. The clinician can aid in dietary management of the herd by nutritional analysis of pasture, hay, grain, and, when indicated, water. In cases of suspected mineral deficiency, adequacy can be assessed by tissue analysis (e.g., whole blood for selenium level, serum or plasma for copper and zinc levels).[4]

The requirements of adult males can be met by the recommendations previously discussed, with the exception that energy content be increased or decreased, depending on body condition. Male fertility can be depressed during periods of extreme high temperature and humidity.[4] To help minimize the incidence of heat stress, males should be shorn, fed highly digestible feeds (to avoid the increased heat of digestion associated with high-fiber feeds), fed to meet but not grossly exceed protein requirements, fed in the late afternoon or early morning, offered free-choice clean water, and maintained at a body condi-

tion score of 5 to 6. The hemostatic mechanisms used to dissipate heat (panting, sweating, and increased heart rate) may result in greater energy, mineral, and water requirements, and animals should be fed appropriately. Very aggressive males may lose excessive amounts of body weight and condition during a heavy breeding season.[7]

During the first two trimesters of gestation, dietary requirements will be met by feeding for maintenance. In the final trimester of gestation, mature females should be fed 1.5% to 1.8% of body weight of a good-quality forage, with a crude protein content of 10%. Energy requirements may increase to 1.5 times maintenance during the final trimester.[5] These requirements can be met by feeding a good-quality legume-grass pasture or hay with supplemental grain.[5] Overfeeding and obesity are common problems in llamas and alpacas in North America. Obesity should be avoided in breeding females because it may be associated with a higher incidence of heat stress, poor milk production, and dystocia.

During lactation, nutrient needs may increase by as much as 2 to 2.5 times maintenance requirements, particularly in heavy-milking females.[5] To meet these demands, total digestible nutrients and crude protein content of the ration should be increased to 60% to 65% and 12% to 15%, respectively,[4,5] Intake of some excellent milk-producing alpacas may approach as much as 2.2% to 2.5% of their body weight. These requirements can be met by good-quality legume-grass hay, fed on a free-choice basis, with some supplemental grain. The dam's diet can be reduced at the time her young are weaned (usually 3 to 5 months) to avoid obesity. Moderate energy restriction can be used for weight reduction in middle to late lactation for obese females; however, diets severely restricted in energy and protein should be avoided in late gestation because they may result in the formation of poor-quality or decreased quantities of colostrum, or in fatty liver syndrome.[4]

IMMUNIZATION AND PARASITE CONTROL

Vaccination guidelines for llamas and alpacas have been suggested, but the efficacy of these vaccine protocols has not been studied extensively in llamas and alpacas. Hence, vaccine use in camelids has been extrapolated from work performed in other species and from empirical use in field reports.[8–10] Bred females should be maintained on a program of yearly to biyearly immunization against *Clostridium perfringens* types C and D, *Clostridium tetani,* and perhaps other clostridial species *(Clostridium chauvoei, Clostridium novyii)* if disease due to these organisms is known to be endemic. In areas in which snakebite may be a problem, immunization for *Clostridium septicum* should be considered. Pregnant females can be vaccinated at 1 month before parturition to enhance colostral antibody content and to ensure adequate maternal immunity at time of parturition, particularly on ranches with a history of clostridial diseases of crias or where management is intense and crias are creep-fed.[4] Although many clinicians use seven-way or eight-way clostridial bacterins, these products are reported to be associated with abortions[8] and premature births.[4] We use three-way *Clostridium* bacterins unless specific diseases exist on a particular farm or ranch. If neonatal diarrhea is diagnosed, pregnant females may be immunized in late gestation with a commercially available vaccine for use in cattle. The use of these vaccines is off-label and not without risk, but this approach may be useful on some farms.

Although commercially prepared *Leptospira* vaccines are commonly used, the immunologic response to such vaccines in llamas and alpacas has been questioned.[11,12] If leptospirosis is endemic, strategic vaccinations every 3 to 4 months with multivalent vaccines should be strongly considered.[4] The clinician should resist a false sense of security when vaccinating against leptospirosis and should attempt to institute management practices that are effective in decreasing exposure. In areas in which llamas and alpacas have exposure to exotic equids (e.g., zebras), the use of a killed form of equine herpesvirus type 1 (EHV1) has been advocated.[9] These vaccines also may be useful in preventing bovine herpes in camelids. Two initial immunizations should be given, followed by boosters every 2 years. In areas endemic for rabies, the use of a killed product approved for use in ruminant species may provide protection. We recommend an initial vaccination at 4 to 6 months of age with a second immunization 2 weeks to a month later, followed by a yearly booster.[13] Bovine viral diarrhea (BVD) has been documented in both llamas and alpacas, but the prevalence is low.[14] Serologic testing of llamas and alpacas showed that exposure was less than 0.9% in the southeastern United States.[14] In areas or on farms where BVD has been documented as a problem, killed vaccine may provide a titer response and may be useful in BVD prophylaxis.[15]

Methods of parasite control are varied and, like vaccination programs, should be designed to logically fit the specific farm or ranch. Little in the way of basic research dealing with anthelmintic use in llamas or alpacas has been published to date, and dosages must be extrapolated from use in other species. The basic principles of parasite control are proper pasture management and rotation, adequate nutritional intake, and appropriate use of anthelmintics. When anthelmintics are decided on, dosage based on accurate body weight and proper administration route are imperative. As a general rule, only oral or injectable anthelmintics should be employed in llamas or alpacas. We authors can find no documented evidence that supports the idea that poor reproductive performance (e.g., abortion, infertility) or birth defects are linked to the use of any anthelmintic in llamas and alpacas. Anthelmintics that are associated with abortion or anomalous fetal development in other species (e.g., albendazole given during early gestation) should be avoided, or the prescribed precautions should be followed when such agents are used in llamas or alpacas.

BREEDING MANAGEMENT

In our experience, the most common cause of subfertility in llamas and alpacas is poor management. Breeding programs being used in North America are varied, and the clinician should be able to help design and implement a reproductive management system best suited for the

particular farm. The physical facilities, available labor, husbandry experience, and the number and type of animals are some of the parameters that aid in the decision regarding what type of breeding program to utilize. All breeding programs require complete, easily understood records. Accurate identification of animals is paramount in all breeding systems; therefore, each animal should be labeled, tagged, tattooed, or implanted with a unique, easily read identification number.[4]

A thorough understanding of the reproductive pattern of llamas and alpacas and the use of transrectal ultrasonography will enhance the clinician's ability to assist in reproductive management. The breeding and birthing seasons should be planned to minimize birth of crias during periods of extreme heat, humidity, or cold.[4] Females should be bred after 12 months of age and not before they attain 65% of projected mature adult weight. If animals have a body condition score greater than 6, then the female should have attained greater than 65% of the projected adult weight before breeding. Before the breeding season, all animals should be condition-scored, vaccinated, and dewormed and undergo all other health care practices (e.g., toenail trimming).[4]

Pasture breeding (in which one or more males are placed with a group of females) is commonplace in South America and in many large operations in North America. In some Peruvian pasture breeding programs, males are maintained at only 3% of the herd (3 males per 100 females). Up to 18 copulations per day are possible by males, particularly on the first day of presentation to females.[4,7,16] Close observation for breeding, accurate record keeping, and periodic (biweekly or monthly) reproductive examinations of females will help maximize effectiveness of pasture breeding.

In a modified form of pasture breeding, the males are removed after 7 to 14 days and reintroduced 14 to 21 days later. Females that refuse mating after reintroduction are examined for pregnancy (e.g., by transrectal ultrasonography). Such modified pasture breeding programs allow more accurate record keeping and more rapid identification of problem animals.[4]

Hand mating requires the most intense management and, if carried out properly, yields very high reproductive performance. As intensity of intervention in breeding increases, management of animals also must be dramatically improved. Inaccurate record keeping and poor or "sloppy" management practices will result in poor performance. An advantage of hand breeding is early identification of females with reproductive problems.

Males may be presented in hand or set free in a paddock with an individual female. Females with a mature ovarian follicle (greater than 7 mm in diameter) usually will assume sternal recumbency quickly when presented with the male. Considerable individual variation is possible, however, because some females are very protective of their cria or are very aggressive and may not show receptivity as readily. This procedure may be repeated, at frequencies ranging from daily to weekly, until the female refuses the male's advances. Successful hand breeding requires the ability to identify females at the most receptive stage of their cycle.[4] Good teasing protocols and records aid in identifying the best time to breed. Ultrasonographic examination of the reproductive tract enhances success of a hand breeding program, particularly if the findings are correlated with teasing.[4] Teasing should commence 10 to 14 days after breeding and continue on alternate days for 9 to 10 days. Females that continue to breed over three breeding cycles should be examined for abnormalities.

CHAPTER 115

Reproductive Anatomy and Life Cycle of the Male and Female Llama and Alpaca

JULIO SUMAR and GREGG P. ADAMS

Present-day alpacas and llamas developed from a common feral ancestry in South America during the last millennium. Many aspects of their reproductive pattern are similar but extrapolation from one species to another must be done with caution. Although differences in the reproductive biology have not been documented, few critical studies have been conducted to compare the various species of camelids. Breeding experiences and research with llamas and alpacas under different latitudes and lower altitudes such as those being carried out in Australia, Canada, and the United States may soon contribute to a better understanding of the biology of reproduction in llamas and alpacas.

GROSS AND ULTRASONOGRAPHIC ANATOMY OF THE FEMALE

The gross appearance of the female reproductive organs in the alpaca is illustrated in Figures 115-1 and 115-2. The dimensions of alpaca and llama reproductive tracts are compared in Table 115-1.[1–3] The ultrasound appearance of the ovary is illustrated in Figure 115-3.[4] The ovum itself is too small to be detected by present-day ultrasound instruments, but antral follicles as small as 1 to 2 mm in diameter can be detected. Several fluid-filled follicles (e.g., from four to eight), with or without a corpus luteum, may be detected in the ovaries at any given time. On ultrasound examination, the appearance of the llama or alpaca ovary is more similar to that of the cow than of the mare. The ovary and ovarian structures are, however, smaller than in cows (e.g., ovulatory-sized follicle, 10 mm versus 16 mm in diameter, respectively; mature corpus luteum, 13 mm versus 28 mm, respectively). As in the cow but not the mare, ovarian follicles are arranged in a peripheral cortex, and ovulation can take place at any spot on the surface of the ovary. The corpus luteum and large follicles protrude distinctly from the surface of the ovary in llamas and are readily palpable. On ultrasonography, corpora lutea are seen to have a very characteristic spherical shape and are hypoechogenic (dark gray) relative to the surrounding tissues. A horizontal echogenic (light gray) area traversing the center of the corpus luteum also is a distinctive ultrasonographic feature. The capability to ultrasonographically recognize and monitor the development of the corpus luteum is fortuitous because it allows confirmation of ovulation and is a rapid method of "progesterone testing."

The oviducts are long and tortuous and end in an open bursa that normally covers the ovary. The tip of the uterine horns in both domestic species is blunt and

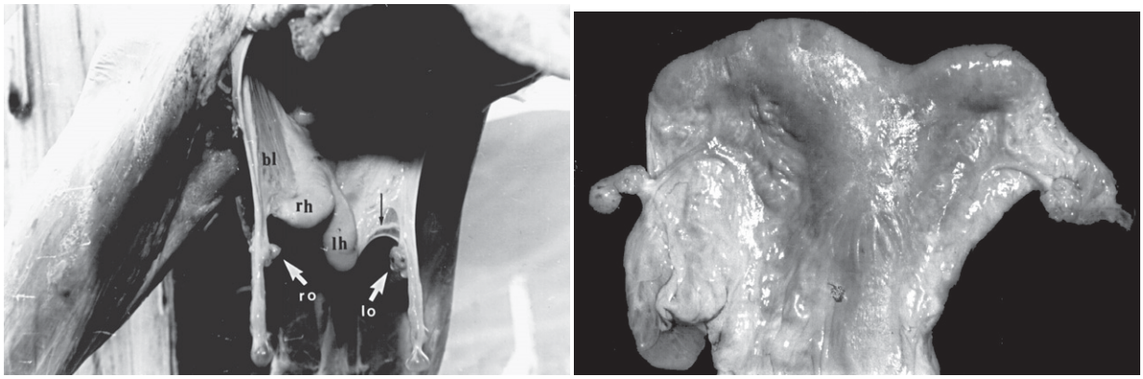

Fig. 115-2 Reproductive organs of the alpaca and llama. **A,** Craniolateral view of the suspended reproductive tract of an alpaca at slaughter showing the left and right uterine horns (lh, rh) suspended by the broad ligament (bl), the left and right ovaries (lo, ro), and the left oviduct *(black arrow).* **B,** Dorsal view of the excised tract of a llama. The uterine horns are relatively short, not tapered, and come to a blunt uterotubal junction, unlike in cows or ewes, in which the uterine horns are long and taper toward the uterotubal junction.

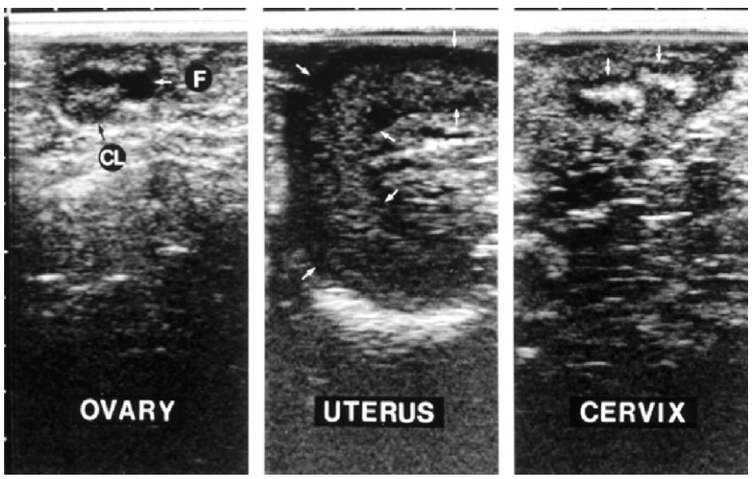

Fig. 115-3 Ultrasound images of the llama ovary, uterus, and cervix. Morphologic features are characteristic of the luteal phase:, a follicle and a corpus luteum in the ovary, curled uterine horn, and distinct cervical folds. The scale at the *top* is in 1-cm increments, and the images are in a sagittal plane with the cranial direction to the left.[4]

rounded, unlike in other ruminants, in which it tapers slowly toward the uterotubal junction. Accordingly, the oviduct of alpacas and llamas opens into the uterine horns through a small, raised papilla, which acts as a well-defined sphincter. Even under great pressure it is not possible to flush liquids from the uterus into the oviduct, but flushing in the opposite direction is possible. As in other domestic species, the uterus of the alpaca and llama is bicornuate, but the left uterine horn is slightly longer than the right (7.9 ± 1.3 cm versus 7.4 ± 0.9 cm), even in the nullipara.

In situ, the uterine horns curl ventrally and caudally, and the degree of curl is maximal during the luteal phase (progesterone dominance) and minimal during the follicular phase (estrogen dominance)[4] (Fig. 115-4). The degree of uterine horn curl is much less than in other ruminants (e.g., sheep, goats, cattle), and in the excised tract, the uterine horns shrink and may not appear curled at all, but rather appear Y-shaped. The echotexture (grain of the ultrasound image) of the uterus changes from homogeneous light gray (smooth and uniform) during the luteal phase and early pregnancy to heterogeneous and increasingly dark during the follicular phase (see Fig. 115-4). Estrogen causes the reproductive tissues to imbibe water and, since fluid is nonechogenic, the uterus becomes relatively hypoechogenic during the follicular phase. A similar pattern has been reported in cows.[5] In nonpregnant llamas, the body of the uterus is short (2 to 3 cm) and not clearly differentiated from the base of either horn on ultrasonography. Uterine tone, based on digital palpation, is maximal during the follicular phase and minimal during the luteal phase and early pregnancy, as in cattle. The uterus is remarkably turgid during the follicular phase, and longitudinal grooves can be palpated along its upper surface. Thus, both the homogeneous dark echotexture and extreme turgidity of the uterus indicate a profound accumulation of interstitial fluid during follicular dominance. The tubular genitalia are suspended

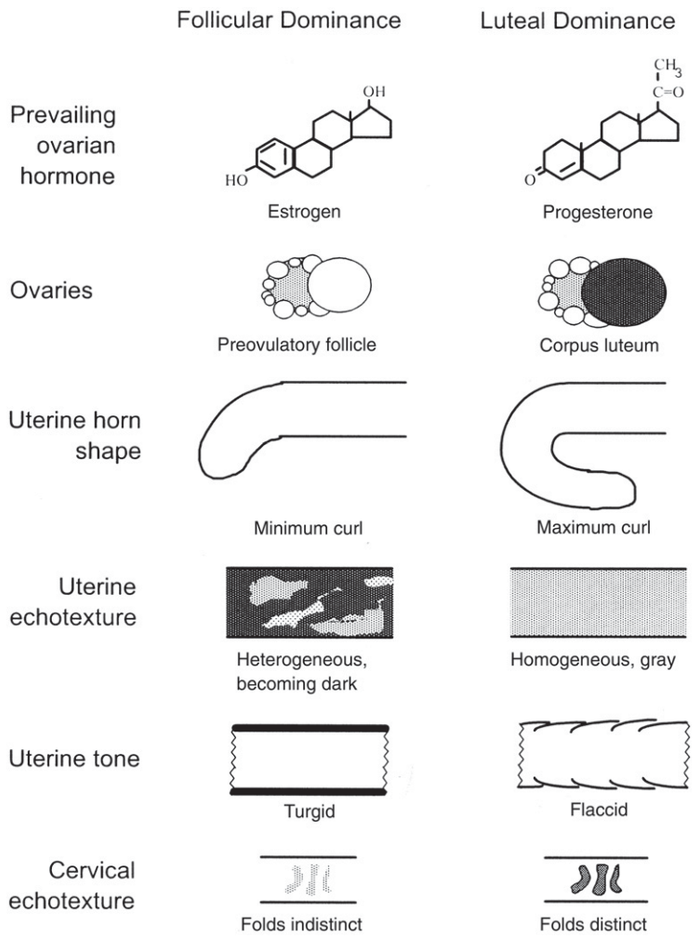

Fig. 115-4 Characteristic differences in the reproductive organs of alpacas and llamas during the follicular phase (receptive) versus the luteal phase (nonreceptive).[4]

from the lateral pelvic and abdominal walls by the broad ligament; the ligament attaches along the ventral aspect of the uterus such that the uterine body and horns are readily palpable per rectum.

The cervix has two or three irregular annular or spiral folds. On ultrasonography, the cervical folds appear as transverse echogenic bands and are especially prominent during the luteal phase and pregnancy (see Fig. 115-4). Presumably, edema of the cervical folds during the follicular phase is responsible for the dark echotexture and indistinct appearance on the sonogram characteristic of this phase. The vagina is surprisingly long and commonly exceeds 20 cm.

ANATOMY OF THE MALE

In the adult alpaca, the testes are found in a nonpendulous scrotum in the perineal region 5 to 9 cm ventral to the anus.[1,6] The testes are small and elliptical and positioned so that the long axis is oriented vertically or in an oblique dorsocaudal orientation. Normally, both testes are of the same size and of a firm consistency, with free movement inside the scrotum. The head, body, and tail of the epididymis are small and firmly connected to the testes. The average weight of one fully developed alpaca testis is approximately 17 g (range, 13 to 28 g), measuring between 4 and 5 cm in length and 2.5 to 3.0 cm in depth.[7] Considerable variation, however, has been found in testicle size and liveweight in alpacas. In one study, male llamas that reached the age of 2 years (83 kg of body weight) had testes weighing about 12 g, with dimensions of 3.5 × 2.2 cm and a volume of 13 cc. At the age of 5 years, llama testes weighed about 24 g, with dimensions of 5.0 cm × 2.7 cm and a volume of 22 cc.[9] In another study,[10] body weight and testicular index increased linearly from birth to 24 months of age, with a subsequent slower increase to adulthood. A positive relationship was found between age and testicular index ($R^2 = 0.88$).

The deferent duct (ductus deferens) is very thin (2 mm) at its beginning and thickens (3 mm) when it reaches the abdominal cavity and ends near the bladder, forming what in other species is the ampullae.[14] The prostate consists of a clearly defined body at the neck of the bladder, and a disseminate part along the pelvic urethra. The prostate body measures approximately 3 cm × 2 cm and is easily palpable per rectum in the adult. The bulbourethral glands are oval and are located on either side of the urethra at the pelvic outlet. Camelids have no vesicular glands.

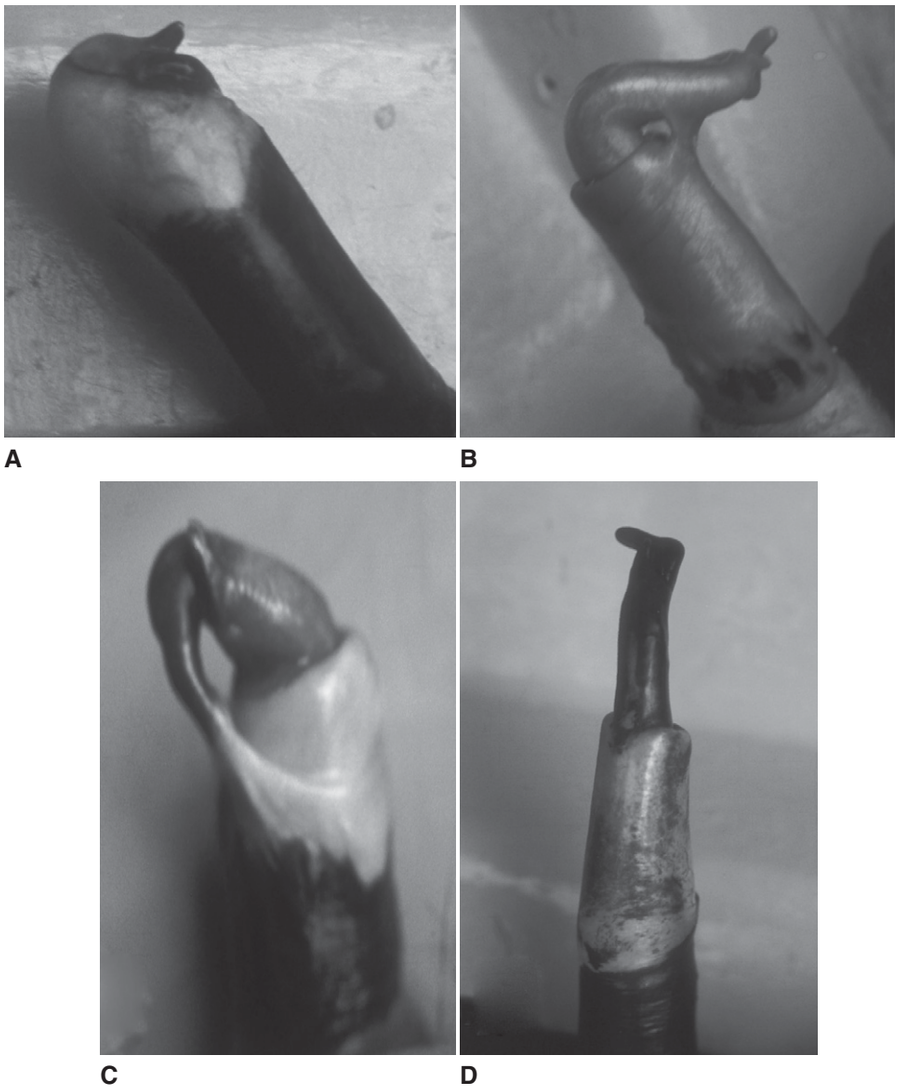

Fig. 115-5 Penis of alpacas showing progressive stages of separation of the free end of the penis from its preputial adhesions. **A,** Complete adhesion with only the tip of the cartilaginous process showing; **B,** the beginning of separation; **C,** persistent adhesion of the tip of the penis, and **D,** a penis completely free of its preputial adhesions.

The penis is fibroelastic, with a small (approximately 1 cm across) cartilaginous process that has a hooklike curve at its tip (Fig. 115-5). The length of the nonerect penis in the alpaca is 26 cm, and the sigmoid flexure is prescrotal.[6] The prepuce is small, located approximately 15 cm caudal to the umbilicus, and has a triangular opening that is oriented caudally.[1] During urination, camelids direct the stream of urine backward between the hind legs. The protractor preputial muscle pulls the prepuce forward before mating, changing the direction of the preputial opening and thus allowing for the penis to be directed forward.

PUBERTY

Young female alpacas of 12 to 13 months of age display behavioral estrus similar to that in adult alpacas.[11] A majority of females display sexual receptivity at 12 months of age even though ovarian activity begins at 10 months of age, with the presence of follicles of 5 mm or more in diameter. In a study carried out in southern Peru using 280 yearling alpaca females,[12] a highly significant relationship ($P < 0.001$) was found between body weight at mating and subsequent birth rates. For each kilogram increase in body weight up to 33 kg, a 5% increase in natality was observed; for increases in excess of 33 kg, the percentage of nonpregnant females was relatively independent of body weight. In traditional Peruvian production systems, only about 50% of yearling alpacas reach a body weight of 33 kg at mating time (January through March). Therefore, breeding age is postponed to 2 years of age and often to 3 years of age in llamas. It also has been shown that with better nutrition after weaning (7 to 8 months of age), nearly 100% of yearling alpacas can reach 33 kg body weight.[13]

In males, the penis is completely adherent to the prepuce at birth. Under the influence of testosterone, the adhesions disappear gradually as the male matures.[6,7]

At 1 year of age the males show sexual interest in the females, but only about 8% of alpaca males have complete liberation of penis-prepuce adhesions and are capable of copulating. At 2 years of age, approximately 70% of the males are free of adhesions, and 100% are free at 3 years of age (see Fig. 115-5). Puberty, based on penis-prepuce detachment, is attained at an average of 21 months of age (range, 9 to 31 months) in llamas, at a body weight of 70 kg (range, 48 to 92 kg).[10] Also, testosterone concentration starts to increase exponentially at 21 months of age (to 300 pg/mL), reaching a plateau at 30 months of age (650 pg/ml).[9,10] From 2 to 11 months, the testes grow slowly (infantile stage), with a sequential increase of noncanalized sex cords and undifferentiated Leydig cells.[14] At an age of about 12 months, the sex cords start to develop a distinct lumen containing Sertoli cells and spermatogonia. The first spermatozoa appear at about 18 months of age, with half of the animals having spermatozoa in the caput epididymidis. From 18 months, the number of Leydig cells increases considerably, and by 20 to 24 months, the diameter of the tubules is greatly increased, with presence of considerable numbers of spermatozoa in the caput epididymidis. Beginning at 3 years of age, normal alpacas have spermatozoa in the epididymis. Spermatogenesis is initiated in some alpacas as early as 16 months and in others as late as 26 months.[59] The general practice in Peru is to start using the males for breeding at 3 years of age.

SEASONALITY

Studies with alpacas and llamas in their natural habitat in the highlands of Peru showed that sexual activity is seasonal and lasts from December to March (summer months). These are the warmest months of the year, with sufficient rain and abundant green forage.[15] In farms on which males and females are together all year, the birthing and breeding times lie within this time range. This marked seasonality of reproduction also is characteristic of the wild species—the vicuña and guanaco.[16] Observations in different zoological parks of the world, however, indicate that llamas are year-round breeders.[17] In North America, where llamas are kept under good nutritional conditions year-round and copulation is allowed only on an individual basis, they are considered nonseasonal breeders. An analysis of llama birthing records from the Rocky Mountains area of the United States revealed that births occurred during all months of the year, but with a preponderance (73%) between June and December.[18] In another study, ovulation, fertilization, and embryo survival rates were not affected by the season of the year.[19]

Males show much less seasonal variation in libido and testicular function. The male alpaca is capable of producing fertile ejaculates year-round, but as in other domestic species, semen quality and libido are affected by season and availability of feed. Under North American conditions of management, no seasonal effect on testosterone values of adult male llamas has been found.[10] In a study of male alpacas and llamas in Peru, plasma testosterone concentrations were markedly elevated during spring and summer (the breeding season), whereas lower levels occurred in autumn and winter[20] (Table 115-2).

Table **115-2**

Seasonal Variation in Peripheral Testosterone Level in Male Alpacas and Llamas

	TESTOSTERONE CONCENTRATION (pg/ml): MEAN ± SEM	
Season: Month	**Alpacas**	**Llamas**
Spring: March	1142 ± 108	208 ± 52
Summer: June	992 ± 388	37 ± 14.9
Autumn: September	877 ± 91	291 ± 74
Winter: December	2445 ± 694	362 ± 73

PATTERN OF OVARIAN EVENTS

Because copulation is a necessary prelude to ovulation, alpacas and llamas have been classified as **reflex ovulators** or **induced ovulators**, as opposed to spontaneous ovulators.[21,22] Female alpacas and llamas do not have estrous cycles like those in other species of large domestic animal; estrus and ovulation are not manifested in a repetitive cycle. Highlights of ovarian function are presented here, but a more detailed account is found in Chapter 118.

Based on laparoscopic examination of the ovaries of alpacas ($n = 20$)[23] and llamas ($n = 12$),[24] it was found that growth, maintenance, and regression of a follicle each required an average of 4 days (total, 12 days; range, 9 to 17 days). In a study of 74 llamas kept in their natural habitat in South America and examined daily by transrectal ultrasonography,[25] successive dominant follicles emerged at intervals of 19.8 ± 0.7 days in unmated and vasectomy-mated llamas and 14.8 ± 0.6 days in pregnant llamas.

The minimum time to ovulation was estimated to be 26 hours after natural mating and 24 hours after treatment with intramuscular human chorionic gonadotropin (hCG) at a dose of 500 to 700 IU.[21] Using an ultrasonographic technique in llamas, ovulation was detected, on average, 2 days (range, 1 to 3 days) after a single mating.[4,25] Single service by an intact or vasectomized male resulted in an ovulation rate of 77% to 82%, and an increase in the number of services by intact males to three within a period of 24 hours did not significantly affect ovulation rate.[15] In females allowed a single mating, 50% ovulated between 26 and 30 hours, 24% ovulated between 30 and 72 hours, and 26% failed to ovulate after mating.[26] Forty percent of the animals that failed to ovulate were yearlings, and 15% were adults.

Some evidence indicates that females can ovulate without coital stimulation or exogenous hormones, especially when initially isolated from and then reintroduced

to a male. The rate of spontaneous ovulation has been reported to be approximately 5% in alpacas.[6,15] Spontaneous ovulation was detected in 3 of 20 (15%) llamas by palpation in one study,[27] and in 3 of 34 (9%) llamas by ultrasonography in two other studies.[4,25]

Laterality of ovulation (from either the left or the right ovary), as indicated by the presence of a corpus luteum of pregnancy, has been reported in several studies.[6,24,26,28,29] On examinations of the genital organs of 928 pregnant alpacas, no differences were found in the ovulatory rate between ovaries. A corpus luteum was detected in the right ovary in 51% of the alpacas, in the left in 47%, and in both ovaries in 2%.[28] In the llama (n = 110), a corpus luteum was detected in the right ovary in 54% of females, in the left ovary in 44%, and in both ovaries in 1%.[29]

Luteal function after sterile and fertile matings has been studied in llamas by several investigators.[6,25,27,28,30] In nonpregnant alpacas, the corpus luteum underwent rapid development after ovulation, reached maximum size and secretory activity at 8 to 9 days after mating, and declined sharply in both size and secretory activity by 12 days after mating.[31] Similar characteristics were observed in nonpregnant llamas (i.e., mated to vasectomized males) evaluated by ultrasonography.[32] Although prolonged luteal phases have been anecdotally reported in association with embryonic loss, spontaneous pseudopregnancy (prolonged luteal phase unassociated with embryonic loss) has been wrongly inferred in llamas.[21] A prolonged luteal phase was not observed in any sterile-mated (nonpregnant) alpacas or llamas.[25,27,31,32] In pregnant animals, the corpus luteum reaches maximal diameter at 22 days after mating and is maintained throughout gestation.[32,33]

SEXUAL RECEPTIVITY AND MATING BEHAVIOR

In the absence of copulatory stimulation, female alpacas display periods of sexual receptivity of up to 36 days, with short periods of nonreceptivity that may last 48 hours.[21] Considerable variability in display of overt receptivity is apparent between individual animals, regardless of parity. The variability in sexual receptivity may be attributable primarily to the degree of follicle maturity at any given stage of the follicular phase; however, no documentation is available in this regard.

The receptive female will assume the prone position (ventral recumbency) after a short period of pursuit by the male, or she may approach a male that is copulating with another female and adopt the prone position[21] (Fig. 115-6). Some receptive females may occasionally display mounting behavior with other females of the herd, although such behavior is much less common than in cattle. If the female is nonreceptive, rejection is shown by running away and spitting at the male. Males will attempt to mount receptive or nonreceptive females; their initial approach is indiscriminate. In a study of sexual behavior in llamas, the male attempted to mount eight of nine females a total of 60 times during a 12-hour period.[20] Each of the eight females was mounted an average of four times, for an average of 5 minutes per mount; mounting was attempted irrespective of the receptivity of the female. Normally, only receptive females will adopt the prone position, but in some instances, aggressive males can force nonreceptive females to adopt the prone position. During the very short courting phase and during mating, the male makes blowing, grunting, nasal sounds. Copulation takes place in a recumbent position, with the male mounted above and just behind the female. The female assumes a very passive attitude during copulation and, in some instances when copulation is prolonged, will appear to tire and may assume lateral recumbency. Compared with other domestic species, coitus is remarkably prolonged in alpacas and llamas (10 to 50 minutes).[6] After a certain amount of time has elapsed, the continuous association of males and females somehow inhibits the sexual activity of the males, a situation that may prevent mating of females returning to estrus after a sterile mating or early embryonic death.

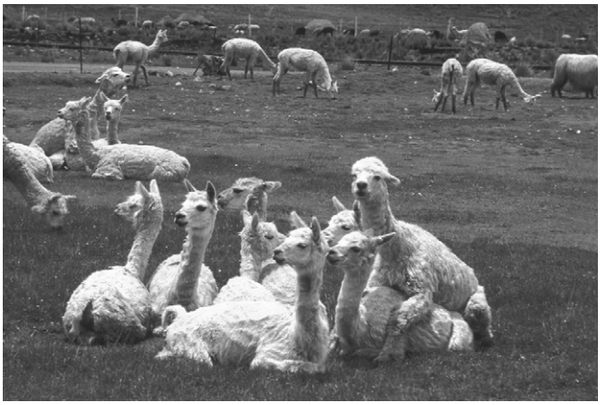

Fig. 115-6 A pair of copulating alpacas in a prone position, surrounded by six females also in the prone position, typical of a display of sexual receptivity.

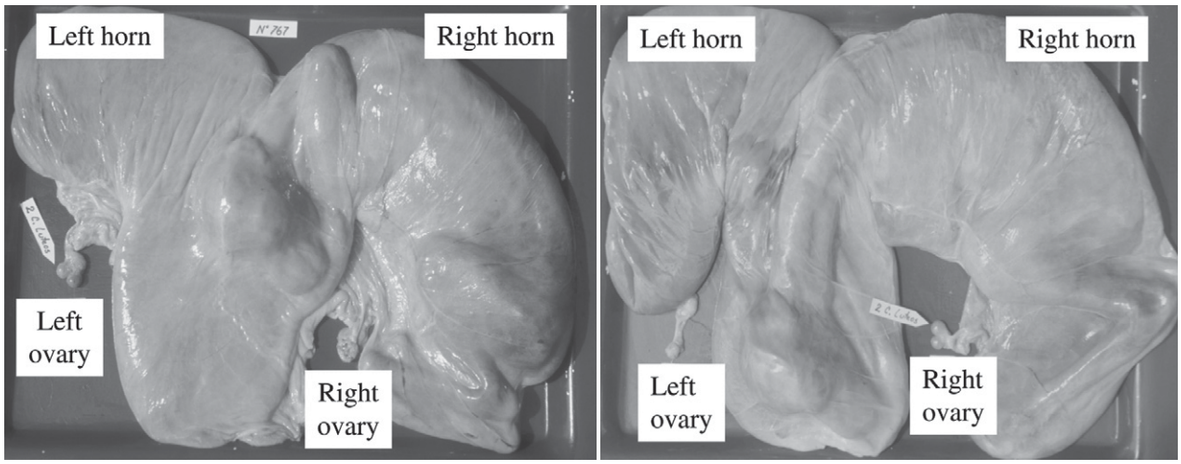
MATING SYSTEMS

Observation of the sexual activity in the open field, when males and females are joined, at the beginning of the sexual season, showed that mating activity was particularly intense during the first week of the breeding season.[34] Greater than 70% of 262 females were recorded as having been mated at least once during this short period. But sexual activity decreased thereafter, reaching a frequency of zero in some instances. After different males were introduced and the original males were removed, however, sexual activity was reactivated and reached a level comparable to that of the first week.[35]

Based on these observations, a breeding system named the **alternating** or **rotary system** was developed.[36] This system works well in the large herds commonly found in southern Peru. Males are used at a stocking rate of 6% for the entire breeding period of 60 days. Half of the males are used for 1 week and are then rotated the following week with the other half. By alternating the males in this manner, libido and mating activity remain high, and the opportunity for the females to be mated once or more may be maximized. Use of the rotary system in a large alpaca cooperative in Peru (adults and yearlings, n = 1399) resulted in a birth rate increase from 57% to 81%.[36]



A B

Fig. 115-7 Unusual right-sided pregnancy in alpacas (approximately 8 to 9 months) with the corpus luteum *(arrow)* in the left *(left image)* or right *(right image)* ovary.

PREGNANCY

The duration of gestation in the alpacas of the Huacaya and Suri breeds has been reported as 341 and 345 days, respectively.[21] For llamas in the United States, a mean of 344 days (range, 331 to 347) was reported.[18] In one study of 79 nulliparous and 61 multiparous llamas in southern Peru in which only two matings were allowed (at an interval of 6 to 8 hours apart), the length of the gestational period (mean ± SD) was 346 ± 8 days (range, 327–357).[37] Neither parity of the dam nor sex of the cria was found to influence gestation length.

Despite the fact that ovulation occurs from both ovaries with equal frequency, nearly all alpaca and llama fetuses occupy the left uterine horn (as indicated by position of the conceptus and site of umbilical attachment), with rare exceptions (Fig. 115-7). This finding indicates that embryos originating from the right side migrate to the left horn for attachment. The reason for the right-to-left migration, which apparently is unique to Camelidae, is not known. One explanation for this phenomenon implicated a differential luteolytic effect of the left versus the right uterine horn.[38] It was concluded that the right horn effects luteolysis through both systemic and local pathways. An interesting difference was found between the uterine vascular system in the llama and the alpaca and that of animals of other farm species.[40] This was the presence of a major branch of the right uterine artery that crossed the cranial intercornual area to supply much of the left uterine horn. Thus, the vascular anatomy indicated that much venous blood from the left horn drained to the right side; this finding is compatible with the hypothesis that the left horn can exert luteolytic control over the corpus luteum in the right ovary through a local venoarterial pathway. Whatever the cause of migration of the embryo to the left uterine horn, this may be a unique mechanism by which camelids reduce twins to a single fetus.

Multiple ovulations occur in 3% to 10% of alpacas after natural mating and in 9% to 20% after treatment with gonadotropins, but twins born alive are very rare.[41,42] Twin pregnancies are not uncommon in the early stages of gestation but are very seldom observed at late stages or at parturition. Very few cases have been recorded in Peru in alpacas or llamas; a higher rate reported in the United States[42] may be a reflection of better nutrition.

The role of the corpus luteum during pregnancy in the alpaca and llama has been studied,[46] and results indicated that the corpus luteum is necessary for the maintenance of pregnancy throughout gestation in both llamas and alpacas. On the basis of the source of progesterone required to maintain pregnancy, these species may be classified as corpus luteum–dependent, similar to the cow, goat, and sow.

The placenta in the alpaca, as in other camelids, is diffuse and epitheliochorial in type. The chorionic epithelium is thrown into unbranched villi or folds, which are closely apposed to corresponding undulations in the endometrial epithelium. Hence, the fetal-maternal interface consists of an intricate interdigitation of microvilli. In late gestation, both chorionic and uterine epithelia are deeply indented by placental capillaries, so that the intercapillary distance may be as little as 2 µm. The distance appears to be less that that found in the epitheliochorial placenta of any other species of domestic ungulates in late gestation and may be one of the several adaptations to pregnancy at high altitudes.[43] A unique extrafetal membrane has been described in newborn alpacas, llamas, vicuñas, and guanacos.[44,45] The extra membrane encases the entire fetal body and is attached at the mucocutaneous junctions and coronary bands; it appears to be a product of the basal layer of the epidermis.

EMBRYONIC AND FETAL MORTALITY

Diverse studies have established that prenatal loss attains considerable levels in all farm animal species and that the bulk of this loss occurs during the early embryonic stages.

In an early study[31] more than 80% of the ova recovered 3 days after mating were in the process of dividing, and only 50% of the fertilized ova survived for more than 30 days of gestation. In a later study,[47] however, reproductive wastage in a group of alpacas of differing ages and parity was 83% (ova, embryo, and fetus loss). Very few fetal losses were found from 90 days after mating to parturition, and most were late-term abortions.

Factors responsible for this high attrition rate are unknown, but nutritional constraints, hormonal imbalance, improper day of mating and mating system, and chromosomal aberrations may be principal causes. These studies were conducted in alpacas living in their natural habitat, affected by a harsh natural environment, deteriorating feed supply caused by overgrazing, and the presence of infectious and parasitic diseases. Specific infections of the reproductive organs, however, have not been identified as a cause of embryonic losses in llamas.[7] The overall rate and causes of embryo and fetus loss await more critical evaluation.

PARTURITION AND ITS CONTROL

Among 130 alpacas observed giving birth at La Raya Research Station in Cusco, Peru, unassisted labor lasted a mean of 203 ± 129 minutes for primiparous females (n = 34) and 193 ± 122 minutes for multiparous females (n = 96).[39] The time course for the three different stages of labor is indicated in Table 115-3. In llamas (n = 95), a mean of 176 minutes has been reported for the three different stages of labor.[49] Birth in alpacas and llamas appears to be achieved more easily than in the cow or mare. Camelids in general do not lick their offspring at birth, nor do they engage in placentophagia.

More than 90% of births in alpacas and llamas occur between 7 AM and 1 PM. This adaptation gives the cria the best chance to get warm and dry before nightfall, because even in the summer freezing temperatures are common at altitudes higher than 4000 m.[6] In studies done in Australia,[50] the time of parturition in alpacas has been shown to be under photoperiodic control. Also, alpacas appear to be able to delay birthing for hours or even a day to avoid giving birth during the night or during inclement weather.[51] It has been postulated that the fetus may determine the day of birth and the mother determines the hour.[52]

Induction of parturition may be used in farm species to concentrate the birthing season to a confined period. The birthing season in the highlands of Peru lasts about 3.5 months as a result of a prolonged period of mating. In a group of females exposed to males for 60 days, the birthing period lasted 75 days (Sumar, unpublished data). In an early study done in Peru,[53] pregnant alpacas within 45 days of parturition were treated with prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) 0.12 mg, $PGF_{2\alpha}$ 0.25 mg, dexamethasone 10 mg, dexamethasone 10 mg plus estradiol 10 mg, or saline (in control animals). Results showed that both doses of $PGF_{2\alpha}$ significantly shortened the interval to parturition. No undesirable effects were observed during parturition or lactation; however, some excess risk for mortality was found for crias born with a body weight less than 5 kg (normal = 7 kg). The results clearly show the effectiveness of $PGF_{2\alpha}$ for elective induction of parturition. In a more recent study, a prostaglandin analogue, fluprostenol, effectively induced parturition, whereas dexamethasone was associated with fetal death and oxytocin had no effect.[54] In another report,[55] another prostaglandin analogue, cloprostenol, effectively aborted llamas at up to 7 months of gestation without adverse effects on subsequent fertility (250 µg given intramuscularly, to time at 24 hours interval). Of interest, the interval from treatment to parturition or abortion was 21 hours 29 minutes (range, 19 to 29 hours) in alpacas given fluprostenol, whereas in llamas given cloprostenol the interval was 3 days. It is unknown whether differences are due to species, prostaglandin analogue or dose, or the stage of gestation at the time of treatment.

Table **115-3**

Duration of Labor Stages in Primiparous versus Multiparous Alpacas

	DURATION (MEAN ± SD MINUTES)		
Parity	**First Stage**	**Second Stage**	**Third Stage**
Multiparous (n = 96)	87.5 ± 67.2	24.7 ± 16.0	80.7 ± 39.0
Primiparous (n = 34)	101.5 ± 77.6	24.5 ± 12.8	77.0 ± 38.6

Data from Condorena N, Sumar J, Alarcón V: Per yodo de gestacion en llamas *(Lama pacos). Turrialba* XXXX;42:112–113.

POSTPARTUM PERIOD

Up to the fourth day after parturition, the female alpaca is submissive and will allow herself to be mounted by the male.[47] Luteal regression, follicular growth, and uterine involution are not complete, however, and the female will not ovulate; moreover, she is at risk of uterine infection from such early matings. By 10 days post partum, the diameter of the largest follicle is about 8 to 10 mm, the corpus luteum has regressed considerably, and the uterus has involuted substantially (weighing only one fifth of its weight 24 hours after birth). Mating of females within 15 to 20 days after birthing has been recommended to obtain good pregnancy rates, with one offspring per female per year.[56] In a study of llamas, pregnancy rates from breeding at 20 or 30 days were threefold higher (61%) than at 10 days post partum (21%).[10]

CHAPTER 116

Breeding Soundness Examination of the Male Llama and Alpaca

P. WALTER BRAVO

Breeding soundness examination (BSE) is common in several livestock species and is an excellent tool that can be used to discard males that do not fit selection criteria. In llamas and alpacas, this procedure is still under development; nonetheless, there is tangible evidence that semen evaluation may be done without much elaboration or the use of sophisticated instrumentation. This section does not deal with different traits that are used to select a sire, commonly known among llama and alpaca breeders as a "padre." Other phenotypic criteria are beyond the scope of this section and the reader is counseled to look for further literature. Rather, this section is devoted completely to the examination of the external genitalia and their physiology, including semen evaluation and assessing circulating concentrations of testosterone. Some general criteria for identification are also considered because most BSEs will be used for future sires.

IDENTIFICATION

Most males considered for BSE should have an accurate and lasting identification. Ear tags, collars, and recently, microchips are used to identify animals. Different brands of microchips, ear tags, and collars are available on the

the newborn guanaco *(Lama guanicoe)*. *Theriogenology* 1988;30:437–439.

CHAPTER 116

Breeding Soundness Examination of the Male Llama and Alpaca

P. WALTER BRAVO

Breeding soundness examination (BSE) is common in several livestock species and is an excellent tool that can be used to discard males that do not fit selection criteria. In llamas and alpacas, this procedure is still under development; nonetheless, there is tangible evidence that semen evaluation may be done without much elaboration or the use of sophisticated instrumentation. This section does not deal with different traits that are used to select a sire, commonly known among llama and alpaca breeders as a "padre." Other phenotypic criteria are beyond the scope of this section and the reader is counseled to look for further literature. Rather, this section is devoted completely to the examination of the external genitalia and their physiology, including semen evaluation and assessing circulating concentrations of testosterone. Some general criteria for identification are also considered because most BSEs will be used for future sires.

IDENTIFICATION

Most males considered for BSE should have an accurate and lasting identification. Ear tags, collars, and recently, microchips are used to identify animals. Different brands of microchips, ear tags, and collars are available on the

market. Microchips, once properly inserted, last for as long as the animal lives. They are easily inserted beneath the skin in various parts of the body. Most common places are at the base of the ear's pinna. Sometimes, though, the microchip may be inserted at the base of the tail. Owners in the United States use specific names for their animals and usually the name refers to or is correlated to the animal's lineage.

EXAMINATION OF THE EXTERNAL GENITALIA[1–3]

Testicles are a set of paired organs within the scrotum located in the perineal area of the animal. They should be ovoid in shape and resilient to digital palpation. The scrotum is relatively small, nonpendulous, and protrudes from the body outline in a position rather similar to that seen in boars and dogs. The testicles should move freely within the scrotum. Any attachment to the scrotum may signify a previous or ongoing insult to them. The longitudinal and transverse axes of the testicles may be measured using calipers. The testicles increase in size with age (Table 116-1), represent 0.02% of the animal's body, and mature relatively slowly. Ultrasonography of the testicles may be done with the animal in a standing position or in lateral recumbency. The echo texture of the testicle is hypoechogenic with a clear echogenic line in the middle indicating the presence of the mediastinum.

The epididymis may also be palpated, and head, body, and tail portions can easily be distinguished. In llamas and alpacas, the head of the epididymis is bigger than the tail, in contrast to rams and bulls in which the tail is markedly bigger than the head.

The penis has a sigmoid flexure just cranial to the scrotum, and the tip of the prepuce is directed caudally in the nonaroused state. Thus, the stream of urine is directed backward. However, during copulation and with the aroused penis, the prepuce is directed cranially. The penis may also be inspected when the animal is sedated and in lateral recumbency. For this purpose, the sigmoid flexure may be straightened by manual manipulation and the penis may be pushed toward the preputial orifice while the other hand retracts the prepuce. A second person is needed to grasp the penis with a gauze sponge and exteriorize it to check for anatomic abnormalities. In young animals, the prepuce is attached to the penis and this natural attachment disappears with time, driven by the rise in circulating testosterone at 21 to 24 months of age. The glans penis is totally free from any attachment by 3 years of age. The process of detachment begins with the distal tip of the glans.

EXAMINATION OF THE INTERNAL GENITALIA[1–4]

The internal organs that may be evaluated are the prostate and the bulbourethral glands. The prostate has been examined by ultrasonography and has been described as a hypoechogenic mass of tissue located cranial to the bladder. The bulbourethral glands may be also evaluated digitally and by ultrasonography. Digitally, a gloved and lubricated finger is inserted into the rectum and is directed laterally where two well-defined and hard rounded structures are palpated. By ultrasonography, the bulbourethral glands appear as discrete, round structures with a hypoechogenic texture.

TESTOSTERONE CONCENTRATIONS[2]

Testosterone is the main male reproductive hormone. Its presence drives sexual libido and imposes some secondary sexual characteristics. Testosterone is present in basal concentrations from birth through 18 months of age (see Table 116-1). Thereafter, there is a dramatic increase (especially in alpacas), which coincides with appearance of sexual libido as well as disappearance of prepuce-penis attachment. Some males, though, are precocious; they have an accelerated burst of testosterone and consequently an increased sexual drive. On the other hand, some other males have a slow change in testosterone concentrations, which naturally will make an impact on sexual drive. In clinical circumstances when a male is presented for BSE, it is useful to collect a blood sample for testosterone determination to correlate with age, testicular size, and sexual drive.

Table **116-1**

Mean Testicular Size and Testosterone Concentrations by Age in Llamas and Alpacas

	LLAMAS		ALPACAS	
Age (Months)	Testicle Size*	Testosterone†	Testicle Size*	Testosterone†
6	2.4 × 1.4	120	1.0 × 0.4	67
12	3.4 × 2.3	150	2.3 × 1.5	213
18	3.5 × 2.6	140	2.8 × 1.9	1156
24	3.9 × 2.3	500	3.3 × 2.2	2163
30	4.4 × 2.5	600	3.6 × 2.4	2835
36	4.5 × 2.7	800	3.6 × 2.4	5385
Sires	5.4 × 3.3	1000	3.7 × 2.5	5247

*Measured in cm (length × width).
†Measured in pg/ml.

SEMEN COLLECTION[5–10]

Many methods can be used to collect semen and evaluate it. Llamas and alpacas copulate for periods in excess of 20 minutes, and semen deposition is at the level of the uterine horns. In addition, ejaculation is constant and the penis interchanges uterine horns during copulation, which leaves some semen at the level of the external cervical os. Hence, the most practical method to collect semen under clinical circumstances and for BSE is aspiration from the external cervical os after the male has finished copulating. The other reliable method of semen collection is by using an artificial vagina fitted in an alpaca dummy in copulatory position. This method has been widely used in South America and has been instrumental in the definition of some semen characteristics and the initiation of making semen available for artificial insemination. However, it requires training of the male to the dummy. In the case of BSE a male is not trained to an artificial vagina, which leaves the alternative of using the aspiration from the external cervical os. Briefly, a male is presented to a receptive female (a second female should be available in the event that the first is nonreceptive to the male). The male is allowed to copulate for the time he wants and then when he withdraws, the female is restrained. The female's perineal zone is cleansed and a warm lubricated vaginal speculum is inserted into the vagina. The speculum is inserted gently, first upward to pass the vestibule, and then horizontally into the vagina. Once the cervix is reached, a scooping motion of the speculum is made to retrieve as much semen as possible. The vaginal speculum is withdrawn and its contents, a reddish gelatinous material, is transferred into a warmed vial, or alternatively the fluid material is siphoned into a warmed insemination pipette. A drop of the material collected is deposited onto a warmed glass slide, a coverslip is applied, and motility is assessed immediately using a light microscope. The rest of the semen sample may be set aside and kept warm for later evaluation.

SEMEN EVALUATION[6–10]

The appearance of the ejaculate is reddish because of presence of red blood cells as a result of irritation of the endometrium by the copulatory process. Most of the time, the semen collected is gelatinous.

Motility is assessed in terms of the percentage of motile spermatozoa in a microscopic field. Spermatozoa appear to move in a slow manner due to the presence of the gel material in the seminal fluid. In the author's experience, this is perfectly normal for a camelid semen; there is no progressive motility. There are many red blood cells in the sample and spermatozoa may be clumped in certain spots or spread evenly on the slide (Table 116-2). In general, motility may be as high as 70% to 80%, but usually decreases to 0% to 55% during the summer months in the Northern Hemisphere (Fig. 116-1).

Vital staining may also be done using Hancock's stain provided by the Society for Theriogenology. The proportion of live/dead spermatozoa is also affected by season. During the spring, fall, and winter, the percentage of live spermatozoa varies between 70% and 85%, but during the summer it decreases to 0% to 40% (Fig. 116-2). Generally, there are no significant differences in motility and percentage of live sperm between llamas and alpacas (Table 116-2). Sperm morphology may be evaluated by using an assortment of stains. The author has used Giemsa staining as well as spermatic stain (Table 116-2).

Sperm concentration is difficult to evaluate when semen is aspirated from the cervix after copulation. The limiting factor is the unknown volume of semen ejaculated. The sample is set aside for at least 3 hours and then is diluted 1:50 or 1:100 depending upon initial motility

Table **116-2**

Motility and Live Sperm in Different Ages of Male Alpacas

Age	Motility (%)	Live Sperm (%)
Young males (20–26 months)	74	73.3
Three years old	72.2	80
Adult sires	68.5	73.5
Old sires (>11 years)	70	70

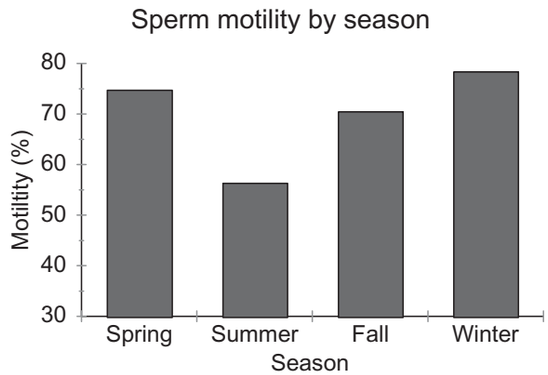

Fig. 116-1 Sperm motility by seasons in the United States.

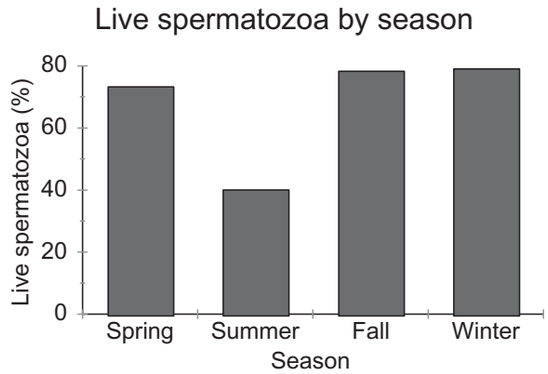

Fig. 116-2 Live spermatozoa by seasons in the United States.

Table **116-3**

Fertility of Young and Adult Male Alpacas

Age	Females Bred	Females Ovulated	Females Pregnant
Young males	45	47%	48%
Adult males	248	70%	69%

assessment. Using the hemacytometer method the author has determined that concentration is the semen characteristic that varies most. On seven different adult males, spermatic concentration varied from 3.5 to 65 million/ml (Bravo, PW, unpublished data).

The age of the male also affects semen characteristics. This is particularly important in North America where some alpaca and llama owners desire to use their males at an earlier age (e.g., 18 to 20 months of age). This is in contrast to South America where males are not used as sires until they are 3 years of age or older. Table 116-3 illustrates the fertility of young and adult sires in the United States. Most important, young males do not impregnate as many females as adult males.

In conclusion, breeding soundness examination in male llamas and alpacas is a tool that may represent a small investment considering the value of the animals and attempts to predict the functionality of the testicles. Anatomy of the different reproductive organs is easily done. Digital palpation and ultrasonography may be used. The most important advance in assessing semen without elaborate and sophisticated instrumentation is semen retrieval from the vicinity of the cervical os. This implies that the male copulates for as long as he wants, there is no interruption, and a sample of semen is available for examination. Motility, numbers of live/dead spermatozoa, and spermatic concentration may be measured, giving the seller, buyer, and clinician a precise and objective indication of semen characteristics.

CHAPTER 117

Semen Collection and Artificial Insemination in Llamas and Alpacas

WILFREDO HUANCA and GREGG P. ADAMS

Artificial insemination (AI) with frozen semen is one of the most important reproductive technologies in farm animal production and is used worldwide in several species of domestic ruminants including cattle, sheep, and goats. The economic benefit of AI has been well documented as a means of enhancing the genetic potential within a herd. The use of AI in South American camelids would provide important opportunities for (1) genetic improvement of the domestic species (llama and alpaca), (2) preservation of threatened wild species (vicuna and guanaco), and (3) international movement of genetic material. However, difficulties with semen collection, dilution, and cryopreservation have limited the development and use of AI in camelid species.

METHODS OF SEMEN COLLECTION

Several methods have been used to collect semen from camelids, with variable results. It is difficult to collect and handle semen from llamas and alpacas because of the mating posture, duration of copulation (varying from 12 to 50 minutes[1]), intrauterine deposition of semen, and the viscous nature of the ejaculate. Attempts at semen collection in camelids have included the use of condoms or intravaginal sacs, vaginal sponges, electroejaculation, postcoital vaginal aspiration, and fistulation of the penile urethra. The use of intravaginal sacs was first described by Mogrovego,[2] but the procedure was cumbersome, it hindered normal copulation, and it was associated with vaginal injury ostensibly when intrauterine intromission was attempted. An alternative approach was to insert sterile sponges into the cranial vagina, but again, semen collection was poor and the semen that was collected was of low quality and highly contaminated.[3]

In early reports[4,5] electroejaculation was attempted in alpacas and involved the insertion of an electroejaculator probe into the rectum and applying gradually increasing electrical stimulation in a periodic fashion (i.e., 4 to 6 seconds of stimulation followed by 4 to 6 seconds of rest). From 1.1 to 1.8 ml of semen was collected but sperm concentration (range: 1000 to 255,000 spermatozoa/mm^3) and quality were extremely variable, and contamination with urine was common.

The development of an artificial vagina (AV), similar to that used in sheep, was first reported by Sumar and Leyva.[6] The AV included a coil spring to simulate the cervix and was mounted inside a dummy that the males were trained to mount. However, the lack of adequate heating equipment required repeated refilling of the hot water chamber to maintain a stable AV temperature during prolonged copulation. The technique was improved with the use of an electric heating pad wrapped around the AV.[7] Collection of semen by an AV mounted inside a dummy is more reliable than other methods and provides a more physiologic sample of semen[6] (Fig. 117-1). An alternative to a dummy mount is the use of a receptive female; the penis of the male can be directed into an AV during the mount.[7,8] The disadvantage of semen collection with an AV is that the males must be trained to serve the AV; perhaps because ejaculation occurs over such a long time, male llamas and alpacas do not serve an AV as readily as bulls and rams. However, consistent results can be obtained once the males become accustomed to the AV with a dummy or live mount.

The results of semen collection by electroejaculation or with the use of an artificial vagina are summarized in Table 117-1. Note the extreme variability in semen volume and concentration. Results of llama studies appear less variable; the average volume of semen per collection was about 2 to 3 ml and the concentration of spermatozoa was about 1×10^6 to 80×10^6 sperm/ml.[8–10]

SEMEN HANDLING—FRESH AND FROZEN

Effective use of AI requires the dilution and storage of semen, but difficulties in semen collection and handling in llamas and alpacas have been an impediment. The semen of alpacas and llamas is highly viscous[13,18] and makes assessment of sperm concentration, morphology, and motility difficult. Ejaculates vary in color from nearly clear to milky white, depending on the concentration of spermatozoa,[19,20] and a comparatively high proportion of morphologic abnormalities (i.e., 40%) is common.[13] Unlike the progressive motility of sperm seen in other domestic ruminants, only oscillatory movement is seen in the ejaculate of llamas and alpacas.[12,21]

The role of high viscosity of camelid semen is not known, but it may create a type of sperm reservoir[22] or may be important for maintaining sperm viability within

Fig. 117-1 Semen collection in llamas and alpacas using an artificial vagina wrapped in an electric blanket to maintain the temperature at 35° to 40° C and placed within a dummy mount.

the uterus.[23] To facilitate handling and processing semen, attempts have been made to liquefy the ejaculate. In a study designed to test the effectiveness of enzymes for liquefying semen (i.e., collagenase, fibrinolysin, hyaluronidase, or trypsin),[24] collagenase was effective in eliminating semen viscosity within 5 minutes with little or no influence on sperm characteristics. A mechanical technique of liquefying the ejaculate[25,26] involved alternately aspirating and expelling the ejaculate through a needle; the technique effectively liquefied the ejaculate and had little influence on other characteristics of semen.

Little information is available on the use of semen extenders. Motility of llama semen was conserved for 24 hours after collection when diluted with a solution of 30% BSA and 60% glucose and placed in a refrigerator.[8] Dilution with a TRIS–glucose–egg yolk semen extender without elimination of viscosity resulted in poor motility (5%) after 3 hours,[15] but recent results with prior mechanical liquefaction and preservation at 5°C improved motility. Pacheco[27] reported the use of semen diluted with 10% egg yolk and 3% citrate and although no information was given about semen quality after dilution, a pregnancy rate of 60% after AI was reported. In another study,[28] semen collected by AV and diluted with TRIS and EDTA extenders with or without surfactant (Equex STM) was prewarmed to 38° to 40° C and maintained at that temperature until insemination.

ARTIFICIAL INSEMINATION TECHNIQUE: INDUCTION OF OVULATION AND PREGNANCY RATES

The first attempt at AI in llamas and alpacas[1] involved 42 female alpacas inseminated with fresh undiluted semen obtained from two vicunas and four paco-vicunas (cross between male alpaca and female vicuna). Semen was obtained by electroejaculation. Immediately before insemination, the females were mated with vasectomized males to induce ovulation. Semen was deposited in the area of the uterine bifurcation by means of a 35 cm-long plastic catheter guided transcervically by rectal manipulation. Only 1 of 42 artificially inseminated females gave birth.

In a study designed to determine the optimal time for AI after an ovulation-inducing stimulus (i.e., hormone

treatment or copulation with a vasectomized male), 96 female alpacas were artificially inseminated 7 to 45 hours after stimulus. Fresh, undiluted semen collected by electroejaculation was infused transcervically by rectal manipulation or through a vaginal speculum.[5] The alpacas were slaughtered 72 hours after AI and the fertilization rate was 12%, 53%, 43%, 75%, and 58% at 7 to 18 hours, 19 to 26 hours, 27 to 34 hours, 35 to 45 hours, and 52 hours after AI, respectively. No differences were observed between groups stimulated to ovulate by hormone treatment or through the use of a vasectomized male.

Leyva and associates[29] reported a study of 83 alpacas and 11 llamas inseminated with fresh undiluted semen collected by electroejaculation from one vicuna and four paco-vicunas. Semen was deposited into the uterine horns, and ovulation was induced by administration of human chorionic gonadotropin (hCG) or mating with a vasectomized male. The pregnancy rate was 48% in females treated with hCG and 11% in females mated to vasectomized males. More recently[13] the pregnancy rate of female alpacas inseminated with fresh semen obtained by AV and deposited into the uterine horns transcervically or by laparoscopy (20 per group) was 73% and 67%, respectively. Similar results were reported by Pacheco[27] using semen diluted with egg yolk (10%) and citrate (3%) using transcervical deposition and induction of ovulation with gonadotropin-releasing hormone (GnRH) 24 hours before AI (Table 117-2). In another recent study,[26] 51% of 207 alpacas were diagnosed pregnant after transcervical insemination using semen collected by AV and mixed 1:1 with BSA (30%) and glucose (60%); ovulation was induced with a GnRH analogue (Busereline; Intervet) 24 to 26 hours before AI.

Reports on the use of frozen semen are limited. Llama semen collected by electroejaculation and diluted with TRIS–egg yolk–glycerol had only 10% motility after freezing and thawing.[30] Ejaculates collected from two llamas and three alpacas by AV were liquefied with collagenase (1 mg/ml) and diluted first with a mixture of sodium citrate (2.9%) and egg yolk (10%) and then with 7% glycerol added at 15-minute intervals in three equal parts before freezing.[31] Sperm motility was estimated at 80%, 60%, and 30% to 40% before freezing, after final dilution and cooling (before freezing), and after thawing, respectively. Most recently,[32] ethylene glycol was used as cryopreservation agent for alpaca semen collected by AV, liquefied by mechanical action, and diluted with skim milk and fructose. Postthaw motility was 30% and highly correlated with estimates of live sperm and the acrosome reaction.

CONCLUSION

Consistent results for semen collection can be obtained with the use of an AV placed within a dummy mount or held adjacent to a receptive female. The semen of alpacas and llamas is highly viscous and difficult to handle, and although it is possible to liquefy the ejaculate with the use of enzymes such as collagenase, fibrinolysin, hyaluronidase, or trypsin, more research is necessary to determine the effects of such treatment on sperm quality. Development of an efficient method of mechanical liquefaction of semen may be a superior alternative. The potential for use of frozen semen for AI in llamas and alpacas is high, but studies are needed to develop effective protocols for freezing semen that preserve post-thaw viability and satisfactory pregnancy rates.

CHAPTER 118

Ovarian Function in Llamas and Alpacas

GREGG P. ADAMS

South American camelids possess some unique reproductive characteristics generally unfamiliar to veterinarians practicing outside the indigenous zone for camelids, the Andes mountains. Camelids are the only large domestic species that are induced ovulators; females are in virtually constant estrus until successful mating induces ovulation. The term *estrous cycle* must be qualified when used in reference to induced ovulators because a regular cyclic pattern of behavior does not occur as it does in spontaneous ovulators. The terms *receptive* versus *nonreceptive,* and *follicular phase* versus *luteal phase* are more appropriate for communicating "cyclic" changes in camelids. Sexual behavior and copulation time is strikingly different from any other domestic species, gestation is unusually long, and uterine anatomy, placentation, and birthing all have distinctly different characteristics in camelids than any other species. Although the reproductive characteristics of llamas and alpacas appear to be virtually identical, extremely little work has been done directly comparing the two species. As veterinarians, we have been frustrated at the lack of information about the normal reproductive function of camelids. Our inability to distinguish normal from abnormal has made it difficult to diagnose or prognose clinical conditions, or make any meaningful recommendations regarding breeding management. This chapter is intended to focus on the basic aspects of reproductive physiology of llamas and alpacas. Emphasis is placed on ovarian function including follicle and luteal dynamics, and the implications of endogenous patterns on clinical diagnosis, treatment, and reproductive management.

FOLLICULAR DYNAMICS

As induced ovulators, three naturally occurring reproductive statuses exist in llamas and alpacas: (1) nonovulatory, (2) ovulatory but not pregnant, and (3) pregnant. In a study involving ultrasonographic examination of llamas (n = 41; Fig. 118-1) daily for a period of 60 days or longer,[1] ovarian follicle development was found to follow a wave-like pattern regardless of reproductive status (nonovulatory, ovulatory nonpregnant, or pregnant) or lactational status (lactating, nonlactating). That is, a group of follicles begins to grow synchronously, one of which continues to grow and become dominant while the others (subordinates) grow for a short period and then regress. If ovulation is not induced, the dominant follicle eventually regresses as well, and a new wave emerges so that the ovarian "cycle" repeats itself (see Fig. 118-1). The interval between emergence of successive waves of follicles was longer in nonpregnant animals (20 days) than in pregnant animals (15 days), and lactation was associated with a 2.5-day abbreviation in the interwave interval. Maximum diameter of nonovulatory dominant follicles ranged from 9 to 16 mm and was greater, on average, in nonpregnant animals (12 mm) than in pregnant animals (10 mm). Dominant follicles of successive waves are equally as likely to develop in the ipsilateral as contralateral ovary; they do not regularly alternate between ovaries.[1,2]

In a recent ultrasonographic study, the wave pattern of follicle development was also documented in alpacas.[2] The mean (±SEM) interwave interval was 15.4 ± 0.5 days

This chapter is intended to focus on the basic aspects of reproductive physiology of llamas and alpacas. Emphasis is placed on ovarian function including follicle and luteal dynamics, and the implications of endogenous patterns on clinical diagnosis, treatment, and reproductive management.

FOLLICULAR DYNAMICS

As induced ovulators, three naturally occurring reproductive statuses exist in llamas and alpacas: (1) nonovulatory, (2) ovulatory but not pregnant, and (3) pregnant. In a study involving ultrasonographic examination of llamas (n = 41; Fig. 118-1) daily for a period of 60 days or longer,[1] ovarian follicle development was found to follow a wave-like pattern regardless of reproductive status (nonovulatory, ovulatory nonpregnant, or pregnant) or lactational status (lactating, nonlactating). That is, a group of follicles begins to grow synchronously, one of which continues to grow and become dominant while the others (subordinates) grow for a short period and then regress. If ovulation is not induced, the dominant follicle eventually regresses as well, and a new wave emerges so that the ovarian "cycle" repeats itself (see Fig. 118-1). The interval between emergence of successive waves of follicles was longer in nonpregnant animals (20 days) than in pregnant animals (15 days), and lactation was associated with a 2.5-day abbreviation in the interwave interval. Maximum diameter of nonovulatory dominant follicles ranged from 9 to 16 mm and was greater, on average, in nonpregnant animals (12 mm) than in pregnant animals (10 mm). Dominant follicles of successive waves are equally as likely to develop in the ipsilateral as contralateral ovary; they do not regularly alternate between ovaries.[1,2]

In a recent ultrasonographic study, the wave pattern of follicle development was also documented in alpacas.[2] The mean (±SEM) interwave interval was 15.4 ± 0.5 days

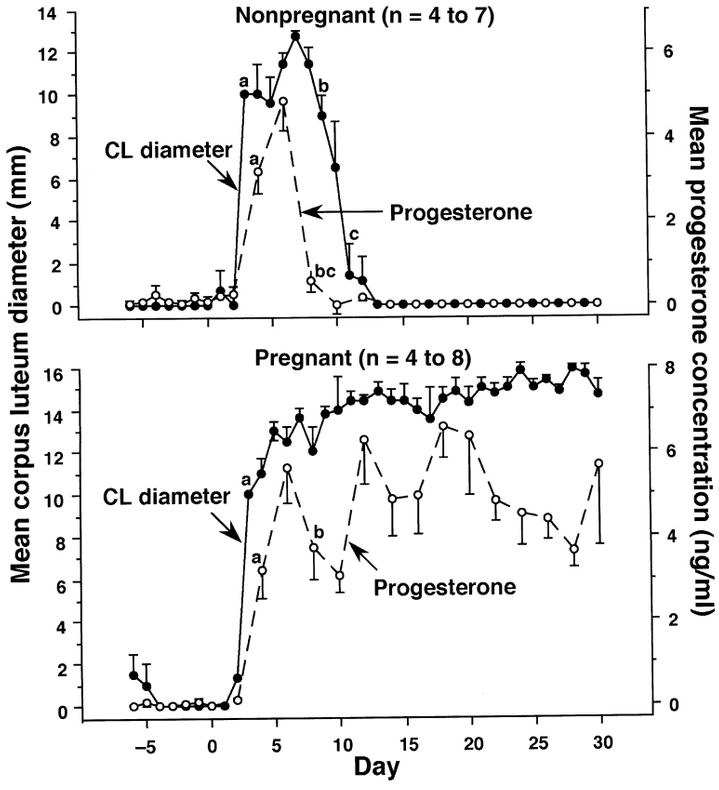

Fig. 118-1 Mean (±SEM) diameter of the dominant follicle of successive waves in llamas of different reproductive status (nonovulatory, ovulatory nonpregnant, and ovulatory pregnant). The arrow indicates the day of mating and the shaded bar indicates the life span of the corpus luteum for the ovulatory groups. (From Adams GP, Sumar J, Ginther OJ: Effects of lactational and reproductive status on ovarian follicular waves in llamas *(Lama glama). J Reprod Fertil* 1990;90:535–545.)

and ranged from 12 to 22 days. Individual alpacas exhibited relatively short as well as longer interwave intervals, and body weight did not appear to be related to the length of the interval. However, the growth rate of dominant follicles was consistent over the first 10 days after emergence and the dominant follicle reached a diameter capable of ovulation by this time, regardless of subsequent interwave interval. The authors concluded that the optimal time of mating might be predicted in alpacas, provided that the emergence of ovarian follicular waves was controlled.

OVULATION

Female llamas and alpacas ovulate only after copulation, or after the administration of hormones with LH (luteinizing hormone)-like activity.[3,4] In an early study designed to determine factors associated with eliciting ovulation,[4] it was concluded that mounting with penile intromission is necessary to induce ovulation, regardless of whether the male is intact or vasectomized. Neural stimuli from penile intromission, treading and clasping of the male's legs on the back and sides of the female, and gutteral humming sounds emitted by the male are thought to influence ovulation. Circulating concentrations of LH start to rise 15 minutes after the start of copulation, peak at approximately 2 to 4 hours, and decrease to basal values by 6 hours after copulation.[5,6] Based on daily ultrasonography,[1,7] ovulation occurred with remarkable consistency (96% of the llamas) by the second day after the first of two matings (4 to 8 hours apart) with either a vasectomized or intact male. The mean diameter of the ovulatory follicle on the day before ovulation was 10 mm and it ranged from 7 to 14 mm. In a more recent study involving ultrasonography every 4 hours,[8] the interval from mating to ovulation was 30.0 ± 0.5 hours (mean ± SEM), and was not different from the interval to ovulation following gonadotropin-releasing hormone (GnRH) or LH treatment.

Interestingly, it appears that a unique ovulation-inducing factor (OIF) is present in the seminal plasma of camelids. In a preliminary study,[9] alpacas were selected (n = 58) when a growing follicle of 8 mm or more in diameter was detected, and were assigned to groups treated with seminal plasma or saline intramuscularly or by intrauterine infusion. Ovulation was detected only in alpacas given seminal plasma intramuscularly (13 of 14, 93%). It was concluded that alpaca seminal plasma contains an OIF that acts via a systemic route. Bactrian camels are the only other species in which an OIF has been reported.[10] The importance of OIF relative to physical stimuli for inducing ovulation during natural mating awaits further investigation.

Unmated females remain in a follicular phase characterized by more or less constant sexual receptivity,[11,12] but sexual behavior does not appear to be related to follicle size because females are sexually receptive with follicle diameters ranging from 5 to 12 mm.[13] However, follicle size is related to circulating estrogen concentrations[5] and ovulatory responsiveness.[14] Females with small follicles (4–5 mm) did not ovulate after copulation, whereas females with follicles 7 mm and larger and in

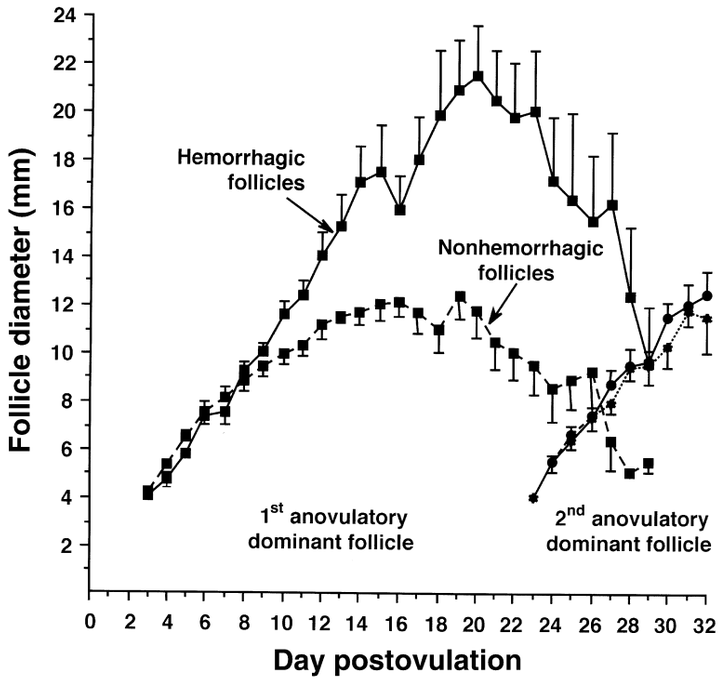

Fig. 118-2 Mean (±SEM) diameter of the corpus luteum and the concentration of plasma progesterone in nonpregnant (vasectomy-mated) and pregnant (intact-mated) llamas from day 6 (day 0 = ovulation) to day 30. (From Adams GP, Sumar J, Ginther OJ: Form and function of the corpus luteum in llamas. *Anim Reprod Sci* 1991;24:127–138.)

the growing phase, or females with mature follicles (8–12 mm) did ovulate after copulation. Regressing dominant follicles did not ovulate after copulation or LH administration.

Even in the presence of a mature follicle, ovulation does not always occur after copulation. Ovulation failure occurs in approximately 20% of pasture-mated females[15] and 10% of hand-mated females.[6] This may be due to inadequate amounts of LH released by the pituitary gland. In this regard, it has been reported that a second copulatory period at 6, 24, or even 48 hours after the first copulatory period did not invoke more release of LH.[6] Correspondingly, an injection of GnRH at 6, 24, or 48 hours after copulation did not invoke more LH release.[6] It appears that if ovulation is to occur at all, it will occur subsequent to the first copulatory stimulus or GnRH/LH administration. The incidence of spontaneous ovulation has been reported to be 4% to 8%.[4,7,16] In some instances, spontaneous ovulation may be associated with the presence of males, owing to visual, olfactory, and auditory stimuli.

LUTEAL DYNAMICS

The characteristics of the luteal phase after natural induction of ovulation have been well described in llamas and alpacas.[1,17–19] Based on daily ultrasonography of the ovaries and every-other-day blood sampling after natural mating in llamas[20] (Fig. 118-2), maximum corpus luteum (CL) diameter and plasma progesterone concentration were detected at day 8 after mating (day 0 = mating). The first significant decrease in CL diameter and plasma progesterone profiles during luteolysis in nonpregnant females occurred on days 11 and 10 after mating and reached their nadir on days 15 and 14, respectively. Similarly, maximum plasma progesterone concentrations occurred on day 8 after human chorionic gonadotropin (hCG) treatment or mating, followed by a decrease beginning on day 13 in nonpregnant alpacas.[14] Luteolysis was temporally associated with pulsatile release of prostaglandin F_2 alpha ($PGF_{2\alpha}$) from the uterus around days 8 to 10 after mating.[17,19]

In pregnant llamas, a transient drop in plasma progesterone concentration was detected between days 10 and 12 after mating, and was followed by a rebound on day 14[20] (Fig. 118-2). Luteal diameter and plasma progesterone in pregnant llamas continued to increase until maximum on days 23 and 27, respectively. It should be remembered that progesterone indicates the presence of a functional CL, but it does not necessarily indicate pregnancy. Elevated concentrations of serum progesterone (>2 ng/ml) or urinary PdG (>1.5 ng/mg Cr) at 7 days after mating are only an indication of ovulation. Furthermore, serum progesterone concentrations of greater than 1 ng/ml at 21 days after mating are only an indirect indication of pregnancy.

CLINICAL IMPLICATIONS

Clinical implications of the endogenous ovarian rhythm involve the timing and control of the follicular wave pattern, induction of ovulation, and control of the luteal phase. At any given time, one may expect to find a follicle of at least 6 mm in one of the ovaries, but to determine whether the follicle is growing (viable) or regressing (dying) would require more than one examination. Such a determination is of importance for breeding management because the immature follicle (<6 mm) and the

overmature (regressing) follicle are not be capable of ovulation and normal luteal development subsequent to copulation. Regarding ovarian synchronization, a recent study was designed to determine the effects of steroids (estradiol plus progesterone [E/P]), gonadotropin (LH), and ultrasound-guided follicular ablation on follicular wave dynamics in lactating and nonlactating llamas, and to determine the effects of these treatments on pregnancy rates after fixed-time natural mating.[21] The intervals from treatment to follicular wave emergence and to the day on which the new dominant follicle reached 7 mm (large enough to ovulate), respectively, did not differ between the LH (2.1 ± 0.3 days and 5.2 ± 0.5 days, respectively) and follicle ablation groups (2.3 ± 0.3 days and 5.0 ± 0.5 days), but both were shorter and less variable than in the control group (5.5 ± 1.0 days and 8.4 ± 2.0 days), while the E/P group (4.5 ± 0.8 days and 7.7 ± 0.5 days) was intermediate. A single, fixed-time natural mating was permitted 10 to 12 days after treatment and although ovulation rates did not differ among groups (control, 93%; E/P, 90%; LH, 90%), the pregnancy rate was higher for synchronized llamas (76%) than for nonsynchronized llamas (54%). The results clearly demonstrate that follicular wave emergence can be induced electively, and animals can be synchronized sufficiently to permit fixed-time insemination without the necessity of testing behavioral receptivity.

OVARIAN IRRREGULARITIES

In general, 15% to 20% of females exhibit some reproductive abnormality.[22] Hypoplastic ovaries, hemorrhagic follicles, cystic follicles, and ovulation failure have been described. Ovarian hypoplasia was the most common ovarian anomaly recorded in a study of slaughterhouse specimens.[22] Hypoplastic ovaries are small (1 × 1.5 cm) and follicular development is suppressed or completely absent. Consequently, estrogen production is impaired and urinary estrone sulfate concentrations are only one third that of normal animals.[23]

The existence of a condition similar to cystic ovarian degeneration, as described in cattle, remains equivocal in camelids on the basis of studies done to date. Based on older literature,[24] follicles greater than 12 mm in diameter were considered "cystic" and therefore subject to hormone treatment to correct the condition. However, based on later ultrasound studies, it appears that cystic follicles in llamas may have been overdiagnosed and overtreated in the past. The normal range in follicle diameter extended to 16 mm and the mean (±SEM) maximum diameter of the dominant follicle was 12.1 ± 0.4 mm.[1] In one study,[25] females that were not exposed to a male (i.e., no sexual stimulation) frequently (16% of nonovulatory follicles) developed oversized follicles (≥25 mm in diameter; Fig. 118-3). These oversized follicles were found to contain bloody fluid and were, therefore, termed *hemorrhagic follicles*. It appears that a vascular accident occurs in some nonovulatory follicles as they near the end of their growing phase, resulting in leakage of blood into the follicle and causing it to balloon to an oversized state. The ultrasonic appearance was characterized as scattered free-floating echogenic spots within the follicular antrum which swirled upon ballottement, similar to that described for hemorrhagic follicles in mares. The antral contents appeared to become organized and did not swirl after follicle growth ceased. Hemorrhagic follicles became very large (up to 35 mm) and persisted for a prolonged period (weeks); however, they resolved spontaneously, they did not disrupt ovarian function, and they were not associated with infertility. Hence, treatment for hemorrhagic follicles does not appear necessary. Clearly, the diagnosis of a follicular cyst cannot be based on size alone and further study is required to critically document the existence of cystic ovarian disease in llamas and alpacas.

Primary ovulation failure has been reported in females that have apparent normal follicle development but do not ovulate after repeated copulation.[23] Attempts to overcome this condition by natural mating or GnRH treatment have been unsuccessful. Although the condition

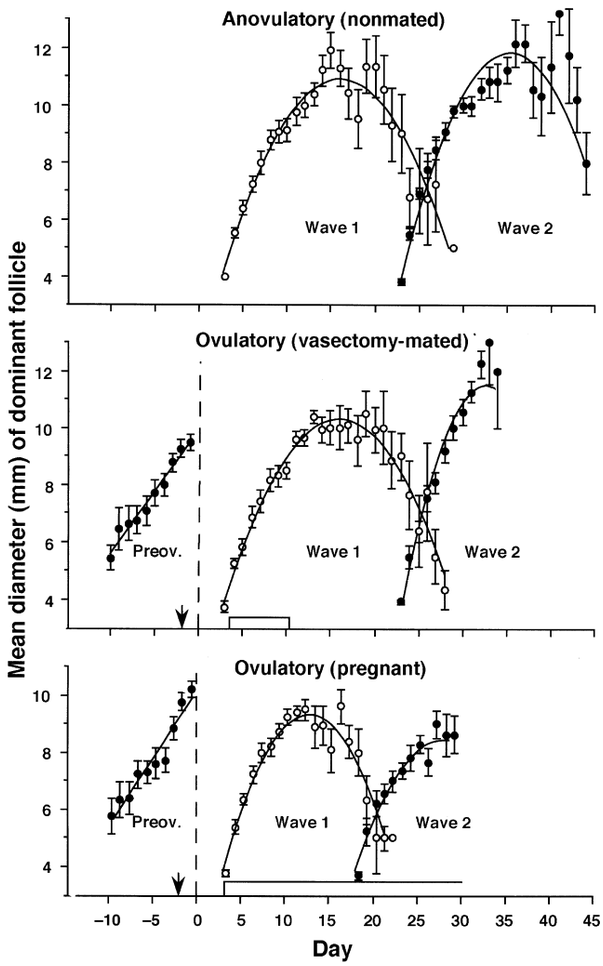

Fig. 118-3 Diameter profiles (mean ± SEM) of successive anovulatory dominant follicles of llamas in which a hemorrhagic follicle was detected *(solid lines)* and llamas in which it was not detected *(broken lines)*. (From Adams GP, Sumar J, Ginther OJ: Hemorrhagic ovarian follicles in llamas. *Theriogenology* 1991;35:557–568.)

has not been systematically studied, it appears that in some cases the pituitary is unable to secrete LH. The obvious solution in such cases is the administration of hCG or LH at the proper time to induce ovulation.[23]

CONCLUSION

Llamas and alpacas have unique reproductive characteristics that differ markedly from other domestic livestock. They are induced ovulators and the ovarian cycle may be conveniently divided into follicular and luteal phases. Follicular waves develop at regular intervals regardless of reproductive or lactational status. The dominant follicle of each wave is anovulatory unless an ovulatory stimulus is provided. Ovulatory stimuli include physical factors, as well as a unique ovulation-inducing factor (OIF) present in the seminal plasma. Ovulation-inducing stimuli trigger LH release from the pituitary within 2 hours of mating followed by ovulation at 30 hours. It appears that a single stimulus is enough to provoke ovulation in the presence of a mature follicle. Circulating progesterone concentrations are correlated with ultrasonographically detected CL diameter. In nonpregnant females, luteolysis begins by day 10 after mating and is complete by day 14, whereas in pregnant females, the CL is maintained throughout gestation. Based on endogenous ovarian patterns, effective protocols have been developed to synchronize follicular waves for fixed-time mating. Ovarian hypoplasia, hemorrhagic follicles, and ovulation failure are the most common ovarian irregularities.

CHAPTER 119

Breeding Soundness Evaluation and Subfertility in Female Llamas and Alpacas

AHMED TIBARY

Reproductive medicine is most likely the single most common veterinary call in alpaca and llama practice. This is due in part to the difficulty for most breeders to understand the intricacies of reproductive physiology in this species. In addition, the long pregnancy length, the constraint to breed at specific times of the year in order to avoid winter and summer, and the desire to breed to outside males make female reproductive evaluation of paramount importance for the success of a breeding operation. This chapter reviews the standard protocol for the evaluation of the reproductive function in the female lamoids as well as the reproductive disorders and diagnostic approach to infertility.

BREEDING SOUNDNESS EVALUATION OF THE FEMALE LAMOID

Breeding soundness examination of the lamoid female is requested as part of a prepurchase examination or for the diagnosis of the cause of reproductive failure. The protocol adopted in this species is similar to that used for the equine. Routine techniques of examination include history and general physical examination, per rectum palpation and ultrasonography of the genitalia, vaginoscopy, and uterine culture and cytologic examination. In selected cases uterine biopsy, endocrinologic evaluation, hysteroscopy, laparoscopy, and cytogenetic evaluation may be required to reach a diagnosis or prognosis for fertility. Some of these techniques may require sedation (palpation, hysteroscopy), epidural anesthesia (palpation, evaluation of perineal laceration), or general anesthesia (laparoscopy).

History and General Physical Examination

General and reproductive history should cover all parameters that may have an impact on reproductive performance including age, type of animal, and breeding management system. A history of previous illnesses and treatments is important because of their possible effect on reproductive performance, and the information helps identify females with high-risk pregnancies. Complete clinical evaluation of the female, including body condition and actual weight, should be done before any manipulation of the genital tract.

Female behavior provides a relatively accurate and inexpensive means for pregnancy diagnosis.[1] The behaviors most indicative of reproductive status are spitting and attempting to escape, which are consistent with the presence of a corpus luteum.[2] Receptivity on the other hand is not well correlated with ovarian status.[2,3] Absence of rejection of the male (spitting) strongly suggests nonpregnancy.[4]

Per Rectum Palpation and Ultrasonography

Transrectal ultrasonography of the genital tract is performed using a 7.5-MHz or 5-MHz linear transducer. For alpacas, the transducer is mounted on a handle to allow manipulation without inserting the hand in the rectum. Ultrasonography allows a more precise evaluation of follicular and luteal activity within the ovary. In the early stage of the follicular wave, the ovary appears elliptical with several small (2 to 5 mm in diameter) follicles disposed along the periphery in a diadem fashion. Dominance is established when follicular diameter reaches 6 mm. The dominant follicle continues to grow steadily until it reaches its maximal size of 9 to 14 mm in llamas and 8 to 12 mm in alpacas.[5,6] Visualization of the corpus luteum after mating is possible within 3 days.[5] The corpus luteum is less echogenic than the ovarian stroma. It appears as a protruding round structure, sometimes with a central cavity. In other cases, the mature corpus luteum has a dense, hyperechoic central area in the shape of a star. The diameter of the mature corpus luteum varies between 11 and 13 mm.

Pathologic changes of the ovaries detected by ultrasonography include cystic changes (anovulatory or hemorrhagic follicles), inflammation, and tumors. Hypoplastic ovaries are very small and the condition is suspected if ovaries cannot be visualized. In Camelidae, development of large anovulatory hemorrhagic follicles is common in the absence of ovulation-inducing stimulus. Periovarian cysts are not rare and should be differentiated from enlarged oviducts. Ovarian inflammation (oophoritis) is suspected when the ovarian size is normal or slightly increased and does not show clear delineation from the rest of the tissue. Ovarian tumors are suspected when the ovary is enlarged and show an abnormal echotexture with no clear follicular dynamic. The ultrasono-

graphic appearance of the ovary depends on the type of neoplasm.

During the follicular phase, the uterus is contracted and the uterine horns are straight. The echotexture of the uterus is usually heterogeneous and shows increased edema of endometrial folds. During the luteal phase, the uterus is relaxed and homogeneous with a medium degree of echogenicity. Abnormalities can be of two types: abnormal uterine echotexture (endometritis, metritis, neoplasm) and abnormal uterine content (pyometra, mummification, maceration, embryonic death).[7,8] Evaluation of the uterine wall can be facilitated by ultrasonography while the uterus is being flushed.

Vaginal Examination

The vulva is inspected for any discharge or lesions and its size and conformation are evaluated. The size of the vulva in Camelidae is relatively small compared to other species. Females presenting increased size and edema of the vulva should be examined for recent parturition or abortion. Abnormal size and position of the vulva in maiden females may suggest presence of congenital abnormalities or intersexuality. Intersexed animals present ambiguous external genitalia sometimes with a rudimentary penis. The distance from the anal sphincter to the vulvar opening is usually increased and the animal shows urinary difficulties.[9] Copious vaginal discharge beyond 7 days post partum is almost always pathologic. Vaginal discharge is suspected upon observation of dried material on the ventral aspect of the tail or by matting of the wool around the tail and perineal area.

Digital examination of the vestibulovaginal area should be performed on all maiden females (persistent hymen and segmental aplasia) and females with pyometra or hydrometra (vestibular or vaginal adhesions). Open-sided specula are helpful if a biopsy punch or a culture swab needs to be guided into the cervix. The most frequent abnormalities encountered in the vagina and cervix are inflammations or adhesions. Vaginal adhesions are a frequent cause of pyometra or mucometra and inability to copulate.[1] The most frequent development abnormality of the cervix in camelidae is the presence of a double cervix.[1] In some cases a thorough vaginal and cervical evaluation requires the use of a flexible endoscope.

Uterine Cytologic Examination and Culture

Endometritis is a common cause of infertility in Camelidae. It is confirmed by uterine cytology and culture. Samples should be taken from the uterine cavity using a double guarded swab. Swabs are examined routinely for aerobic and anaerobic bacteria, Ureaplasma, Mycoplasma, and fungus.[10] The bacteria responsible for endometritis in camelids are essentially those found in the equine and bovine species. Uterine culture may be negative in many cases of chronic endometritis. In the experience of the author, endometrial samples for cytologic examination are best obtained using a cytobrush instead of a swab.

Uterine Biopsy

Uterine biopsy is used to detect inflammatory, degenerative, or neoplastic changes in the endometrium.[11] The technique is similar to that used in the equine. The cervix can be opened by administration of estradiol (0.5 mg) 6 to 8 hours before biopsy. Larger doses of ECP may produce excessive edema and are often counter-productive. The author prefers to perform all manipulation requiring bypassing the cervix without the use of estrogens. This can be accomplished if examination is done when the female has a preovulatory follicle. Evaluation of the specimen should be done by a person familiar with the normal histologic features of the camelid endometrium. Degenerative changes are mainly due to the presence of periglandular or perivascular fibrosis. In severe cases, nesting with cystic dilation of the endometrial glands or lymphatic cysts is observed. A classification of lamoid endometrial biopsies has been proposed.[11]

Endocrinologic Evaluation

Determination of progesterone levels in blood is probably the most widely used hormone assay in Camelidae.[12] Progesterone levels above 1.5 ng/ml indicate the presence of a functional corpus luteum or luteinized anovulatory follicle. The assay is commonly used to determine occurrence of ovulation in bred females. Pregnancy is suspected if progesterone level remains high in a second sample taken 2 to 3 weeks after breeding. This method of pregnancy diagnosis is relatively precise if breeding history is accurate. Plasma estrogens levels above 10 pg/ml in plasma indicate presence of follicular activity.

Hysteroscopy

Hysteroscopy is easily performed using a 9-mm diameter flexible videoendoscope. The cervical canal and uterine cavity can be evaluated for the presence of adhesions, cystic dilation, or abnormal content. Targeted biopsy may be performed during hysteroscopy.[1,13] The papilla at the uterotubal junction is prominent and easily identified. The most common lesions seen at this level are cysts and inflammation of the papillae.

Laparoscopy and Laparotomy

Laparoscopy is an invaluable technique for the confirmation of lesions suspected by ultrasonography or palpation (ovarian hypoplasia, hydrosalpinx, segmental aplasia, periuterine adhesions, etc.), particularly in alpacas.[1,14–16] Selected cases for these procedures include alpacas with suspected ovarian hypoplasia, ovarian masses, hydrosalpinx, pyosalpinx, ovarian and uterine adhesion, and segmental aplasia of the uterus and uterine tubes. Laparotomy is indicated for oviductal flushing to verify the patency of the uterine tube.

Cytogenetic Evaluation

All Camelidae have the same number of chromosomes (n = 74). Abnormal karyotype has been associated with

different forms of reproductive problems in Camelidae. Cytogenetic studies should be considered when external sexual characteristics are ambiguous or when there is extreme aplasia of the ovary or genitalia. Cytogenetic abnormalities described in camelids include XO, XXX, XXY, XX/XY, and XX sex reversal.[1,9] A minute chromosome has been described in several lamoids, but its significance in infertility is not yet known (L. Buoen and A. Weber, personal communication).

COMMON COMPLAINTS IN THE FEMALE LAMOID

The primary complaints in lamoid infertility seen in the author's practice are repeat breeding (75.6%), early pregnancy loss (18.3%), visible abnormalities of the genitalia (4.9%), and continuous rejection of the male (2.4%).[1] Abortion and stillbirth should be considered as part of the subfertility complex. Arriving at a precise diagnosis of the cause of subfertility or pregnancy loss requires a thorough evaluation that should include history and physical examination as well as a complete evaluation of the reproductive organs.[17] In many cases diagnosis of the cause of infertility may require monitoring the female over at least one reproductive cycle (from follicular growth to mating and pregnancy diagnosis). The objectives would be to answer the following questions: What is the expertise of the breeder? Is the male fertile? Does the female have normal genitalia? Is the female ovulating? Judicious choice of examination technique and interpretation allows obtaining an accurate diagnosis.[1] The diagnostic approach to each of these complaints will vary according to the most likely rule-outs for each complaint. In some cases, the approach will vary, depending on whether the female in question is a maiden female or has previously given birth normally.

Lack of Receptivity to the Male

Female reluctance to breed may be due to pregnancy (first rule-out). Behavioral problems are relatively common and may be associated to dominance or sexual differentiation disorders. Reluctance to breed may be caused by pain during mating.

Persistent corpora lutea are rare in the female Camelidae. However, the condition has been suspected in llamas on the basis of prolonged periods of high progesteronemia without pregnancy.[1,18] Many of these conditions may not be truly "persistent corpora lutea" but rather persistent luteinized hemorrhagic follicle. These structures may respond to prostaglandin F ($PGF_{2\alpha}$), but injection may need to be repeated.

Lack of ovarian activity (anestrus or ovarian hypoplasia) does not necessarily translate to lack of receptivity, as many females with these conditions may continuously accept the male.

Repeat Breeding Syndrome

Repeat breeding syndrome can be due to many factors, some of which are pathologic while others are management errors. The pathologic factors involved in repeat breeding include all conditions that may affect gametes or early embryo survival. Management of reproduction in Camelidae is complicated because the signs of estrus are not very reliable and the timing of breeding in relationship to growth and size of the follicle are very critical for induction of ovulation. Diagnosis of the cause of repeat breeding can be challenging and a diagnosis can be achieved only with a complete and sound approach to the problem.

In normal camelid females, fertilization rates are generally greater than 85%. In a trial on 132 normal alpaca females all but 6 females (95.4%) were pregnant on day 12 after a single mating when the dominant follicle was between 8 and 10 mm in diameter (Tibary, unpublished). Failure of fertilization can be due to management errors, ovulation failure, male infertility, and conditions that may hinder semen/ovum transport or survival.

Survival of spermatozoa is reduced in the case of uterine infection. Fertilization takes place in the lower third section of the uterine tube. Ova transport can be impaired by several pathologic processes in the bursa and uterine tube.

Inability to complete copulation is a frequent cause of fertilization failure. This is due to either lack of or partial intromission without ejaculation. Difficulties in intromission are encountered in the presence of vaginal or vestibular anomalies (i.e., partial or total adhesions or persistent hymen) or discrepancies in size between the male and female. An experienced breeder can easily identify these problems.[1]

Management errors account for a significant number of cases of infertility due to repeat breeding syndrome. Male infertility should be always considered when dealing with the infertile females and is discussed in detail elsewhere in this publication. Management errors pertain mainly to inefficient use of males, breeding at the wrong time of follicular development, or overbreeding. Lamoids may be receptive over a wide range of situation as far as follicular development, and many breeders using in-hand mating systems may be confused as to the proper management of breeding. Given the length of follicular wave (8 to 12 days), it is usually recommended to breed every 7 days until the female spits off the male. Using this schedule one breeding should necessarily fall at the right time (presence of a mature follicle capable of ovulation). Once a female has ovulated, the "cycles" become more predictable and the next opportunity for a female to have a dominant follicle is usually 12 to 14 days after ovulation. Daily breeding is not recommended because it may cause uterine inflammation.

Accurate diagnosis requires monitoring the female over at least one reproductive cycle (from follicular growth to mating and pregnancy diagnosis).

Congenital Problems Leading to Fertilization Failure

Congenital causes of fertilization failure include those conditions that may affect behavior, normal follicular development, or gamete transport.

Intersex

Most intersexed animals will show some degree of male-like behavior, but some may still show receptivity, get bred, and fail to get pregnant. Diagnosis of these conditions is based on thorough external and internal examination of the genitalia.

Ovarian Hypoplasia

Ovarian hypoplasia is a common cause of reproductive failure in maiden females. This condition was reported in 16.8% on postmortem examination of 155 infertile alpaca females.[19] Monitoring ovarian activity by ultrasonography every 2 to 3 days for 10 days allows diagnosis of such disorder. Follicular development may be seen in some females, but the follicles fail to develop to an ovulatory size.[20] The overwhelming majority of the cases seen by the authors were bilateral. Various cytogenetic abnormalities were found in about 40% of the animals. Confirmation of the diagnosis can easily be made by laparoscopic examination.[1]

Segmental Aplasia

Segmental aplasia has been described in various portions of the tubular genitalia (uterine tube, uterus, cervix, and vagina). The most common congenital abnormalities of the uterus in Camelidae are segmental aplasia, uterus unicornis, and infantilism.[1,19] Segmental aplasia can affect any part of the genitalia from the vestibulum to the oviduct. Aplasia of the posterior part of the tubular genitalia (cervix, vagina, or vestibulum) may be associated with mucometra or pyometra. Uterus unicornis may be diagnosed by palpation, ultrasound, or hysteroscopy. Pregnancy is possible, but breeding of animals presenting such a condition is strongly discouraged because of the risk of genetic transmission of the abnormality.[1,21] Segmental aplasia of the uterine tube may require laparoscopy for definitive diagnosis.

Acquired Problems Resulting in Fertilization Failure

Ovulation Failure

Failure of ovulation is a common problem in Camelidae.[20,22] Ovulation failure may be due to inadequate LH (luteinizing hormone) release after copulation.[20] It has been suggested in the Bactrian camel that some males with low fertility have a lower concentration or potency of the GnRH (gonadotropin-releasing hormone)-like ovulation-inducing substance.[23] Assessment of ovulation by ultrasonography or progesterone assay should be an integral part of the reproductive management of the female camelid.

Detection of ovulation failure is based on ultrasound management of breeding followed by progesterone evaluation 6 to 8 days after mating. Induction of ovulation may be enhanced by administration of human chorionic gonadotropin (hCG) (500 to 1000 IU, IV) of GnRH (8 μg to 50 μg IM) following mating.

Ovarian Cystic Conditions

Cystic conditions of the ovaries have been described in llamas and alpacas.[19,20] The term cystic ovaries may not always apply to camelidae because a large proportion (30–40%) of nonmated females develop some form of follicular cyst.[1,18] The role of ovarian cysts as a cause of infertility is not well known. An incidence of 4.7% was reported in a random sample of slaughtered alpacas, while a higher frequency of 8.3% was reported in specimens collected from infertile animals.[19] There are few studies dealing with the endocrinology of cystic conditions of the ovaries. Animals with cystic follicles (>12 mm) show a decrease in estrogen secretion.[20]

Therapeutic approaches used are similar to those described in the bovine and consists of administration of hCG or GnRH followed by an injection of PGF_2 analogues 8 to 10 days later. In some situation of luteinized hemorrhagic follicles, females may become nonreceptive for a variable length of time. Administration of $PGF_{2\alpha}$ analogues may help resolve some of these luteinized structures but may need to be administered on several occasions. Daily administration of progesterone in oil (50 mg) seems to regulate the follicular wave and prevent development of new anovulatory hemorrhagic follicles.

Other Ovarian Diseases

Failure of ovulation despite breeding has also been associated with inflammation of the ovaries (oophoritis) due to an extension of a peritonitis or perimetritis. This condition is characterized by loss of follicular activity because of the presence of adhesions between the ovarian surface and the surrounding tissues including the ovarian bursa, uterine tube, and sometimes extending to include some intestinal loops. Definitive diagnosis is made by laparoscopy.

Ovarian tumors have been reported in infertile lamoids and most are teratomas.[19] A case of bilateral teratoma has been described recently in an alpaca. Unilateral ovariectomy followed by partial ovariectomy has been successful in removing the tumor and restoring fertility.[24] Granulosa thecal cell tumors are rare but have been diagnosed in alpacas and can be detected by their ultrasonographic appearance and elevated serum inhibin concentrations.

Endometritis and Metritis

Uterine infection is the most commonly diagnosed reproductive problem resulting in infertility.[10] Uterine infection should be suspected in animals that have a history of repeat breeding or early embryonic death following at least one normal pregnancy. It is important to consider that endometritis may be secondary to overbreeding resulting from ovulation failure or lack of ovarian activity. In fact, in most of maiden females presented to the author for treatment of endometritis the primary cause of infertility was ovulation failure due to ovarian hypoplasia. Diagnosis of endometritis should be based on clinical examination of the animal (vaginal discharge, uterine wall thickening, presence of intrauterine fluid) and confirmed by uterine culture, uterine cytologic examination, and eventually uterine biopsy. Treatment approaches are similar to those described for the equine and consist of uterine flushing followed by daily infusion of antibiotics of choice for 3 to 5 days. Flushing is accom-

plished by placing a Foley catheter (Fr 12 or 14 for alpacas and Fr 18 for llamas) into the uterus and lavage using LRS or DPBS containing antibiotics. Local infusion of the antimicrobial of choice may be applied using infusion pipette or by placing a ram-horn indwelling catheter into the uterus. However, this author is not in favor of the indwelling ram-horn catheter because of the likelihood of complications from irritation. Systemic antimicrobials for 10 to 14 days may be helpful in managing endometritis and metritis in females if catheterization of the cervix is not easy. Treated animals should be sexually rested for 2 weeks. Minimizing number of mating and breeding during the period of the follicular wave most likely to result in ovulation improves fertility and reduces chance of recurrent endometritis.[10]

Uterine infections may result from postpartum complications such retained placenta, dystocia, and uterine prolapse. Postpartum metritis may have systemic effect on the dam or go unnoticed until breeding. Aggressive treatment with uterine lavage and systemic antimicrobials as well as supportive therapy helps to prevent further complications.

Pyometra

This condition has been reported in lamoids.[1] Pyometra with an open cervix and vaginal discharge is observed primarily in the puerperium period and is due to a postpartum complication (retained placenta, dystocia, uterine prolapse) resulting in delayed involution due to infection and accumulation of fluid. Closed pyometra is usually associated with cervical adhesions or prolonged progesterone therapy.

Other Uterine Disorders

Other reported diseases of the uterus include uterine cysts, uterine abscesses, periuterine adhesions, polyps, and uterine neoplasm.[1,11,19,21] Periuterine adhesions are suspected in llamas if difficulty is encountered when attempting to retract the uterus by palpation per rectum. These adhesions are usually a consequence of peritonitis and may originate from postsurgical complications. Uterine neoplasia (adenocarcinoma) has been described in the llama.[11]

Salpingitis, Hydrosalpinx, Pyosalpinx

The most common disorders of the uterine tube in Camelidae are inflammations or pyosalpinx or hydrosalpinx.[1,19] The enlarged uterine tube can be visualized by ultrasonography. In severe cases, the ovary and ovarian bursa may be involved and adhere to each other. Mucosal cysts and microabscesses are reported but relatively rare. Diagnosis of these afflictions requires endoscopic evaluation of the uterine tube papillae or laparoscopy. Prognosis for all these afflictions is poor if bilateral and guarded if unilateral.

Cervical Diseases

Double cervix with some degree of didelphia (double vagina) has been described in llamas and alpacas.[1,19,25] The major complaints are infertility with a persistent vaginal discharge or repeat breeding. Diagnosis of the condition is made after vaginal examination using a speculum and confirmed by direct examination of the genitalia after ovariohysterectomy.

Cervicitis is due to overbreeding, injuries during parturition, or gynecologic manipulations. Cervicitis is usually associated with uterine infections and vaginal mucopurulent or bloody discharge. Other acquired anomalies of the cervix include cervical adhesions or lacerations resulting from a complication of birth or excessive trauma during manipulation.

Complete Vaginal or Cervical Adhesions

All diagnosed cases of pyometra seen by the author were associated with either cervical or vaginal adhesions or with prolonged progesterone treatments. The main cause of cervical or vaginal adhesions is lengthy or inappropriate obstetrical manipulations.

EARLY EMBRYONIC DEATH

Early embryonic death is commonly reported in llamas and alpacas. Incidence of early embryonic death in these species can be as high as 57.8%.[4,26] Most of the early embryonic loss occurs before day 45, and embryonic loss is suspected when the female becomes receptive again or fails to show signs of advanced pregnancy. Some of the possible etiologies of embryonic death in Camelidae include genetic or environmental factors, corpus luteum dysfunction, and uterine pathology such as infection or fibrosis.

Deficiencies in vitamin A, vitamin E, or selenium have been incriminated in increased early embryo loss. Increased early embryonic death has been associated with early postpartum breeding (before 3 weeks).[27] Reduced ovulation rate and embryonic viability may be seen in females in a negative energy balance due to heavy milk production.

Camelids require ovarian progesterone throughout pregnancy; therefore, any alteration of the corpus luteum function either by disturbance of maternal recognition of pregnancy or implantation and iatrogenic administration of luteolytic drug will result in early pregnancy loss. Progesterone supplementation in the form of implants or injections has been advocated as a method for maintaining pregnancy in females with uterine fibrosis or luteal insufficiency. Although there are several anecdotal reports on the efficacy of these treatments, there are no reports on controlled experiments using this therapy. Preliminary results of experiments in the author's laboratory show that progesterone in oil and hydroxyprogesterone caproate are efficacious in maintaining pregnancy, whereas altrenogest is not. Hydroxyprogesterone caproate may be given at a dose of 250 mg every 2 weeks. If progesterone replacement therapy is used to maintain pregnancy, the dose should be gradually decreased or completely stopped 2 to 3 weeks before due date. It is important to monitor fetal well-being by ultrasonography throughout the pregnancy.

ABORTION

Abortion rate after 100 days of pregnancy ranges from 2% to 15%. Known causes of infectious abortion include toxoplasmosis, chlamydiosis, listeriosis, and leptospirosis. Brucellosis *(B. melitensis)* has been reported in South America. Leptospirosis has been incriminated in some abortion storms in llamas and alpacas. Neosporosis (*Neospora caninum*) has been reported recently as a cause of abortion in lamoids. Diagnosis of the cause of abortion is very frustrating and the approach is similar to principles used in other species. Collection of maternal, placental, and fetal samples may improve the chances in reaching a diagnosis.

Iatrogenic causes of abortion include injection of prostaglandin $F_{2\alpha}$ or its analogues, stressful conditions, and administration of corticosteroids even at small doses. Administration of eye ointments containing corticosteroids has been associated with abortion in the last half of pregnancy.

CHAPTER 120

Ovarian Synchronization and Induction of Ovulation in Llamas and Alpacas

JANE VAUGHAN

Control of ovarian folliculogenesis in South American camelids would improve efficiency of supervised matings and facilitate the development of assisted breeding in all camelids. Conception due to a single mating may be maximized by inducing emergence of a new dominant follicle at a known time to allow mating to be scheduled when the dominant follicle is capable of ovulating a competent oocyte.

Real-time ultrasonography has allowed investigators to observe ovarian follicular dynamics reliably, to establish the presence of follicular waves, and to determine appropriate times of exogenous hormone treatment in domestic livestock including South American camelids.[1–6] Unfortunately, it is not possible to identify whether a follicle is growing or regressing on the basis of a single ultrasonographic examination, and multiple examinations may be impractical and uneconomical. It would be an advantage to control ovarian follicular growth using exogenous hormones so that a dominant follicle develops at a specific, repeatable time after completion of a treatment protocol, which may reliably be induced to ovulate and release an oocyte of relatively high fertility.

The complex control mechanisms that regulate the development of ovarian follicles through different physiologic stages has delayed development of a simple exogenous hormonal treatment that gives a synchronized new wave emergence in animals regardless of stage of follicle wave at the time of treatment.[7] The antral follicle of spontaneously ovulating mammals has a changing dependency on follicle-stimulating hormone (FSH), luteinizing hormone (LH), and other growth factors as it develops during a follicular wave.[8] The development of sensitive FSH and LH assays in camelids would allow investigators to examine the characteristics of gonadotropin secretion and determine whether the assumptions that FSH and LH work in a similar fashion in induced and spontaneous ovulators are valid. If the assumptions are correct, the response of the ovary to endogenous or exogenous hormones would depend on the stage of follicular development and the physiologic status of the ovaries at the time of treatment.

Maximum fertility in female South American camelids has been proposed to occur when the dominant ovarian follicle is greater than 6 mm in diameter and capable of responding to an ovulatory stimulus, and either growing or mature but not regressing.[2,9] Follicular growth is similar from day 0 to day 10 after new wave emergence in alpacas, regardless of subsequent interwave interval and the newly emerged follicle attains an average diameter of 7 mm, 6 days after new wave emergence.[6] Pregnancy rates are reduced in cattle when aged oocytes are ovulated from dominant follicles that are persistent for longer than 10 days.[10] Reduced fertility may also be associated with oocyte aging in camelids that ovulate when the dominant follicle is postmature.[7]

Removal of the existing dominant follicle may be achieved hormonally in domestic species either by inducing atresia or ovulation. Both mechanisms result in a decline in plasma estradiol and inhibin concentrations followed by a surge in FSH and emergence of a new follicular wave.[7]

INDUCTION OF FOLLICULAR ATRESIA

Estradiol

Exogenous 17β-estradiol and estradiol benzoate have been used in cattle and sheep to transiently suppress plasma FSH concentrations in a dose-dependent manner, thus exerting an atretogenic effect on FSH-dependent follicles early in the follicular wave and provoking synchronous emergence of a new wave.[11–13]

A single intramuscular dose of 0.5 mg or 2 mg 17β-estradiol apparently induced follicle regression and new wave emergence in alpacas regardless of the stage of follicular development, suggesting that estradiol has a role in gonadotropin regulation in this species.[14] However, subsequent studies in alpacas treated at random stages of ovarian follicular development have shown that a single intramuscular injection of 1 mg 17β-estradiol or 2 or 5 mg estradiol benzoate (Cidirol: InterAg), with or without simultaneous injection of progesterone (Progesterone: Jurox), had no effect on follicular wave turnover.[6])

Progesterone

Various doses and delivery methods of progesterone have been tested in camelids in attempts to manipulate follicular waves, based on the observations that dominant follicles in llamas are smaller in diameter, exhibit a shorter interwave interval, and produce less estradiol during the

Table **120-1**

Exogenous Progesterone Treatments Used in Llamas and Alpacas

Reference	Species	Source of Progesterone
Bourke et al. 1992[18]	Llama	(a) endogenous progesterone (corpus luteum) (b) 3 mg norgestamet implant SC for 7 days (c) 2 × CIDR 0.3 g progesterone for 9 days
Correa et al. 1994[19]	Llama/alpaca	12.5 mg progesterone IM once a day for 12 days
Bourke et al. 1995[20]	Llama	(a) endogenous progesterone (corpus luteum) (b) 3 mg norgestamet implant SC for 7 days
Aba et al. 1999[21]	Llama	120 mg MPA intravaginal sponge for 9 days
Cancino et al. 1999[22]	Llama	6 mg norgestomet implant SC 9 days plus 3 mg norgestomet and 5 mg estradiolvalerate IM on day 0
Ferrer et al. 1999[23]	Llama	120 mg or 240 mg MPA intravaginal sponge for 13 days
Aba et al. 2000[16]	Llama	120 mg MPA intravaginal sponge for 9 days
Vaughan 2001[6]	Alpaca	25 mg twice a day, 50 mg once a day, 100 mg every other day, or 200 mg every other day progesterone IM 4–21 days
Chaves et al. 2002[24]	Llama	330 mg progesterone CIDR 8 or 16 days
Aller et al. 2002[25]	Llama	1.9 g progesterone CIDR-B 8 days

CIDR, controlled internal drug releasing; IM, intramuscular; MPA, medroxyprogesterone acetate; SC, subcutaneous.

luteal phase.[2,15,16] These features of follicular growth in llamas in the presence of a corpus luteum may be due to the negative feedback effects of progesterone on LH secretion, as demonstrated in female cattle, in which follicular growth may be suppressed in a dose-dependent manner using exogenous progesterone.[10,17]

Intravaginal Progestagen Devices

Different intravaginal devices such as progesterone-releasing intravaginal devices (PRID), controlled internal drug releasing (CIDR) devices, and sponges have been used to deliver progesterone or progestagen to camelids (Table 120-1).

However, only one study has been conducted on the plasma progesterone levels obtained in South American camelids after device insertion. CIDRs (CIDR: InterAg) containing 330 mg progesterone were used in llamas for 8 or 16 days.[24] Plasma progesterone concentrations were similar to luteal-phase levels in llamas for the first 3 days after CIDR insertion, and subluteal thereafter. Variation in plasma progesterone following CIDR insertion was evident in the llamas studied, possibly due to wide variations in ability to metabolize progesterone rather than variation in amount of progesterone released from the device.[26]

During the intravaginal presence of some PRIDs and sponges, some camelids have ovulated in the absence of mating. These devices have been implicated in inducing ovulation or luteinization by their physical presence, usually at the time of insertion or removal.[21,27,28] Endogenous progesterone production may then potentially compromise exogenous hormone protocols. There have also been problems with device retention. CIDRs were expelled by some llamas, or caused vaginal discharges severe enough to necessitate their removal.[18] PRIDs were expelled by some camels and one failed to retain the device at all.[27] Sponges containing 0, 120, and 240 mg of medroxyprogesterone caused severe hemorrhagic, purulent, ulcerated vaginitis in llamas.[23]

CIDR devices. In a recent study, llamas were each treated with a CIDR device containing 330 mg of progesterone (CIDR-G: InterAg) for 16 ($n = 6$) or 8 ($n = 16$) days.[24] In animals with follicles greater than 6 mm prior to device insertion, a significant decrease in follicular diameter resulting in minima (mean 4–6 mm) between days 5 and 7. Follicular diameter began increasing on day 10 in those animals treated with a device for 16 days, but was not reported in females with a device for 8 days. In 3 of 4 animals with a follicle less than 6 mm at CIDR insertion, follicle size remained small and relatively unchanged in the presence of the device.

Follicular waves generally overlap in camelids,[2] but Chaves and co-workers also demonstrated that a CIDR device inserted into each of 6 llamas for 16 days apparently prevented emergence of a new follicle until day 12 after insertion.[24] This suggested that progesterone may exert a suppressive effect on FSH secretion, but FSH assays need to be improved before this can be shown.

Sponges. Intravaginal sponges containing 120 or 240 mg medroxyprogesterone acetate (MPA) have been used in llamas to synchronize follicle growth with mixed success. Aba and co-workers inserted one 120 mg MPA sponge (120 mg MPA: Syntex SA) for 9 days with 100% ovulation rates in 22 animals treated with the gonadotropin-releasing hormone (GnRH) analogue, given buserelin (Receptal: Hoechst), or mated with a vasectomized or intact male 6 days after sponge removal.[21] Plasma estradiol declined to basal levels 3 days after sponge insertion, then steadily increased thereafter until ovulation induction on day 16. No ultrasonography was performed to monitor follicular growth patterns in response to the progestagen, but 5 out of the 10 females conceived after mating.

Ferrer and co-workers used intravaginal sponges containing 0, 120, or 240 mg MPA in llamas for 13 days and

monitored follicle activity using transrectal ultrasonography.[23] Neither dose of MPA inhibited follicular development as follicles of 7 mm diameter were observed in each group. Every llama in the group in which a 240 mg MPA sponge was used developed hemorrhagic follicles 9 days after sponge removal.[23]

Subcutaneous Progestagen Implants

Subcutaneous implants offer an alternative method of progestagen delivery and avoid the problems of induction of ovulation or vaginal discharges associated with intravaginal devices. Two commercially available types of implant have been used in camelids. The first consists of 3 mg norgestomet in a silicone matrix in which progestagen is released relatively slowly, and the second consists of 6 mg norgestomet in a hydron polymer in which progestagen is released relatively rapidly.[26]

Bourke and co-workers used a single 3-mg norgestomet-silicon implant (Crestar: Intervet) for 7 days in llamas as part of a multiple ovulation and embryo transfer (MOET) program.[18,29,30] Ultrasonography of ovarian structures indicated that recipients showed synchrony of follicular development with donors.[18] They also used a single 3-mg norgestomet silicone implant in llamas for 7 days as part of another MOET program,[20] but follicular development was not suppressed regardless of whether follicles were growing or regressing at the start of progestagen treatment. Reasons for differences in follicular development in the two studies were not apparent.

Cancino and co-workers used a single 6 mg norgestomet-hydron implant (Syncro-Mate-B) for 9 days in llamas combined with an IM injection of 3 mg norgestomet and 5 mg estradiol valerate at the time of implant insertion.[22] Ovarian structures were not observed over the first 7 days of implant placement. A follicle greater than 6 mm was present approximately 10 days after implant removal in 23 of 46 females, 18 of which ovulated in response to treatment with the GnRH agonist buserelin.[22]

Vaughan used one or two subcutaneous 3-mg norgestomet implants (Crestar: Intervet) in alpacas but did not consistently induce regression of the existing dominant follicle nor induce controlled emergence of a new follicular wave, even though implants were used for a longer duration and at a higher dose rate than previous workers had used in llamas.[6,18,20] Maximum follicular diameter was reduced on the day of implant removal and 5 days later in females that received two implants, but follicular waves continued to emerge in the presence of norgestomet. The continuation of follicular waves during norgestomet treatment meant synchronous emergence of a new wave at implant removal was not possible.

Progesterone Injections

The intramuscular administration of 25 mg progesterone (Progesterone: Jurox) twice daily, 50 mg progesterone once daily, or 100 mg or 200 mg progesterone every second day was effective at inducing regression of the existing dominant follicle and preventing new wave emergence in alpacas.[6] Follicles that emerged after progesterone treatment ceased exhibited diameters and interwave intervals that were not different to those of control females. The most practical protocol for ovarian follicular control in female alpacas was provided by injecting 200 mg progesterone intramuscularly on days 0, 2, and 4. This protocol induced regression of the existing dominant follicle and allowed synchronous emergence of a new follicular wave, so that by day 16, all females exhibited a follicle with a diameter capable of ovulation. Following use of the day 0 to 4 progesterone protocol, it was established that females were able to ovulate and conceive when mated on day 16; however, pregnancy rates were not different than those currently achieved by random pen-mating.[6]

A combination of progesterone and estradiol may potentiate the effects of progesterone on LH suppression in camelids as has been observed in cattle.[33] However, 2 mg estradiol benzoate administered alone or at the beginning of progesterone treatment had no effect on follicular regression above and beyond the effect achieved by progesterone treatment alone in alpacas.[6]

Summary of Progestagen Use in Camelids

Norgestomet implants, along with intravaginal progestagen-containing devices such as CIDRs, PRIDs, and sponges (in conjunction with exogenous prostaglandin to remove the endogenous source of progesterone) are used in sheep, cattle, and goats to produce subluteal/luteal plasma progesterone concentrations that suppress pituitary LH production. In turn, LH suppression suppresses follicular growth and estradiol production. Despite these suppressive effects, these implants/devices do not inhibit emergence of follicular waves. Instead, follicular waves continue in their presence, but ovulation is prevented until their removal. In sheep, cattle, and goats, other hormones such as different esters of estradiol and GnRH are used with progestagen treatment to control follicular wave emergence. Upon removal of the progesterone/progestagen implant/device, the existing dominant follicle responds to the increasing LH pulses by producing increasing amounts of estradiol until an LH surge is induced and spontaneous ovulation follows. The purpose of using progestagen-containing devices in alpacas is to provide a simple method to induce regression of the existing dominant follicle regardless of its age, and allow synchronous emergence of a new follicular wave following device removal. However, claims of success in controlling follicular growth or improving fertility in camelids using subcutaneous and intravaginal progestagen devices need to be assessed cautiously. At any given time during nonovulatory follicular waves in untreated alpacas and llamas, one would expect to find a follicle of at least 6 or 7 mm diameter and single random matings produce ovulation rates exceeding 80% and pregnancy rates over 50%.[2,6,15,21,31,32] It appears that progestagen treatment only partially controls follicular development in camelids and does not improve ovulation and pregnancy rates above these levels.

INDUCTION OF OVULATION

An alternative method of removing an existing dominant follicle involves induction of ovulation or luteinization of that follicle to permit emergence of a new follicular

wave. Mating with a vasectomized male, or injection of exogenous GnRH, LH, or human chorionic gonadotropin (hCG) in the presence of a growing or mature follicle 7 mm or more in diameter may be used to induce ovulation 28 to 30 hours after injection in South American camelids.[31,36–38] It appears that the hypothalamus or pituitary gland then undergoes a period of refractoriness for 24 hours following the endogenous LH surge, possibly due to depletion of pituitary LH or down-regulation of GnRH receptors in the pituitary gland.[39]

The GnRH analogue buserelin (Receptal: Hoechst) has been administered intramuscularly at a dose rate of 8 µg (range, 4 to 12 µg) for many years in llamas and alpacas to induce ovulation in the presence of an ovulatory-sized follicle.[20–22,29,32,38] More recently LH (Lutropin-V: Vetrepharm) has been used intramuscularly in llamas at a rate of 2 mg.[38,40]

The dose of hCG (Chorulon: Intervet) to consistently induce ovulation in llamas or alpacas with a follicle considered capable of ovulation ranges from 500 to 750 IU administered intramuscularly or intravenously.[41–43] However, multiple injections of hCG over time should perhaps be avoided. England and co-workers treated female llamas intravenously with doses of hCG ranging from 25 to 500 IU.[44] Females were used one or more times in eight trials in summer and autumn and results indicated that higher doses of hCG (100–300 IU) were required in autumn to elicit ovulation compared with a lower dose (25–50 IU) in summer.[44] Antibody formation in response to repeated use of hCG in cattle has been reported and may have been responsible for the increasing hCG dose required to induce ovulation in llamas used repeatedly by England and co-workers.[44,45]

Failure of ovulation occurs in approximately 10% of females and may be related to timing of administration of the ovulatory stimulus. If the dominant follicle (or that which is subsequently selected as dominant) is immature and lacking LH-responsiveness at the time of stimulus, as in cattle, ovulation failure may result.[46] Others have proposed a lower LH release in females with small follicles due to reduced estradiol priming of the hypothalamus and pituitary.[9] Aging follicles may not respond to an ovulatory stimulus either. In camels, there is a sharp decrease in the effectiveness of a single intravenous injection of GnRH or hCG to induce ovulation when dominant follicles age and exceed 20 mm diameter.[47]

If control of follicular dynamics is to be achieved by induction of ovulation in South American camelids, further studies are required to establish whether growth of the newly emerged follicular wave after induction occurs so that the dominant follicle attains a diameter considered capable of ovulation at a consistent time. In one study, workers observed the emergence of a new follicular wave immediately after ovulation in llamas.[2] The dominant nonovulatory follicle in the first wave after an infertile mating appeared between 1 and 5 days after ovulation, was 7 mm or greater at the time of luteal regression 10 days after ovulation, and reached a maximum diameter about 15 days after ovulation.[2] A subsequent treatment with prostaglandin may be necessary to induce luteolysis at a consistent time following induction of ovulation if the optimal time of mating is determined to be less than 2 weeks after ovulation, as natural luteolysis varies from 8 to 13 days after mating in alpacas and llamas.[3,48]

In alpacas, 100 µg cloprostenol IM given more than 4 days after ovulation induced luteolysis.[49] In llamas, 250 µg cloprostenol IM given 6 to 8 days after ovulation successfully induced luteolysis.[3,20,29,36,40] However, Smith and co-workers report the erratic response of corpora lutea in pregnant llamas to a single injection of cloprostenol (Estrumate: Miles Inc.), with some females requiring two to four injections of cloprostenol to induce luteolysis.[50] Prostaglandin $F_{2\alpha}$ toxicity and death have been reported in llamas following intramuscular use of dinoprost tromethamine,[51] but Smith and co-workers did not observe any adverse reactions using two doses of 250 µg cloprostenol IM 24 hours apart in 53 llamas.[50]

The disadvantages of inducing ovulation as a method of controlling subsequent new wave emergence in camelids at the present time include a lack of knowledge in the timing of new wave emergence, the poor success with hCG in some animals, inconsistent luteolysis in response to a single dose of prostaglandin, and risk of animal toxicity using prostaglandin.

CONCLUSIONS

In summary, progesterone may be used to suppress folliculogenesis in South American camelids; however, further research is required to develop a practical treatment that increases reproductive efficiency by reducing the number of matings per conception and increasing pregnancy rates in comparison to randomly mated females. Induction of ovulation may be a simpler and more effective approach to follicular wave synchronization in camelids, but again, further studies are required to elucidate follicular growth characteristics following induction of ovulation. The ability to predict new wave emergence and subsequent follicular growth following atresia or ovulation of an existing dominant follicle will allow improved efficiency of supervised matings and the development of reliable artificial breeding technologies.

CHAPTER 121

Pregnancy Diagnosis in Llamas and Alpacas

GREGG P. ADAMS and MIGUEL DOMÍNGUEZ

Diagnosis of pregnancy in llamas and alpacas can be performed by indirect or direct means. The aim of indirect methods is to distinguish between the follicular versus luteal phase of the ovarian cycle, and usually involves assessment of sexual receptivity using a "teaser" male, or measurement of progesterone concentration in blood or milk. Direct methods involve palpation, ballottement, and ultrasonography of the conceptus and associated fluid. Tactful use of indirect and direct methods of assessing pregnancy status will provide the clinician a broad array of breeding management schemes that may be adapted to suit the needs of the individual producer.

THE EARLY EMBRYO

The early embryo resembles that of other ruminant species (Fig. 121-1), but cells of the morula have a darker cytoplasm, and hatching from the zona pellucida usually occurs before the embryo reaches the uterus. Though initially spherical (at ≤7 days after mating), the hatched blastocyst quickly elongates into a delicate filamentous embryonic vesicle that occupies most of one uterine horn by 10 days after mating (Fig. 121-1). Camelids have a diffuse chorioepithelial type of placenta. The chorionic membrane has unbranched villi that form an intricate interdigitation with corresponding undulations in the endometrial epithelium.

SEXUAL BEHAVIOR AND SYSTEMIC PROGESTERONE

It is convenient to consider sexual behavior in parallel with systemic concentrations of progesterone as indicators of pregnancy status in llamas and alpacas because a causal relationship exists between the two. By inference from the results of a number of studies in llamas and alpacas,[1–6] systemic concentrations of progesterone are inversely related to sexual receptivity. That is, females under the prevailing influence of progesterone are nonreceptive to sexual advances of a male.

In an often-cited study of the sexual behavior of alpacas,[6] it was stated that estrus may last for 21 to 36 days with occasional short periods (≤48 hours) of nonreceptivity. In a more critical study in llamas,[3] however, periods of constant estrus of at least 30 days were observed (end of observational period), but extended to at least 90 days in some individuals. No mention was made of short periods of nonreceptivity, other than a prolonged period of diestrus. In nonmated females, follicular waves emerge at regular periodic intervals without interruption by ovulation or luteal gland development.[7] Circulating concentrations of estrogen wax and wane in correspondence with growth of the dominant follicle of each wave;[8] however, no obvious relationship between estrogen concentration and sexual receptivity has yet been detected.[8] The relationship between follicular growth, estrogen concentration, and sexual receptivity has not been quantitatively evaluated and warrants further research, but it is clear that in the absence of progesterone, female llamas and alpacas are more or less receptive continuously.

Based on the assumption that sexual non-receptivity is a reflection of elevated systemic progesterone concentration, the strategy for testing receptivity is similar to that for testing systemic progesterone concentration as an indicator of pregnancy status (Fig. 121-2). Ovulation

CHAPTER 121

Pregnancy Diagnosis in Llamas and Alpacas

GREGG P. ADAMS and MIGUEL DOMÍNGUEZ

Diagnosis of pregnancy in llamas and alpacas can be performed by indirect or direct means. The aim of indirect methods is to distinguish between the follicular versus luteal phase of the ovarian cycle, and usually involves assessment of sexual receptivity using a "teaser" male, or measurement of progesterone concentration in blood or milk. Direct methods involve palpation, ballottement, and ultrasonography of the conceptus and associated fluid. Tactful use of indirect and direct methods of assessing pregnancy status will provide the clinician a broad array of breeding management schemes that may be adapted to suit the needs of the individual producer.

THE EARLY EMBRYO

The early embryo resembles that of other ruminant species (Fig. 121-1), but cells of the morula have a darker cytoplasm, and hatching from the zona pellucida usually occurs before the embryo reaches the uterus. Though initially spherical (at ≤7 days after mating), the hatched blastocyst quickly elongates into a delicate filamentous embryonic vesicle that occupies most of one uterine horn by 10 days after mating (Fig. 121-1). Camelids have a diffuse chorioepithelial type of placenta. The chorionic membrane has unbranched villi that form an intricate interdigitation with corresponding undulations in the endometrial epithelium.

SEXUAL BEHAVIOR AND SYSTEMIC PROGESTERONE

It is convenient to consider sexual behavior in parallel with systemic concentrations of progesterone as indicators of pregnancy status in llamas and alpacas because a causal relationship exists between the two. By inference from the results of a number of studies in llamas and alpacas,[1–6] systemic concentrations of progesterone are inversely related to sexual receptivity. That is, females under the prevailing influence of progesterone are nonreceptive to sexual advances of a male.

In an often-cited study of the sexual behavior of alpacas,[6] it was stated that estrus may last for 21 to 36 days with occasional short periods (≤48 hours) of nonreceptivity. In a more critical study in llamas,[3] however, periods of constant estrus of at least 30 days were observed (end of observational period), but extended to at least 90 days in some individuals. No mention was made of short periods of nonreceptivity, other than a prolonged period of diestrus. In nonmated females, follicular waves emerge at regular periodic intervals without interruption by ovulation or luteal gland development.[7] Circulating concentrations of estrogen wax and wane in correspondence with growth of the dominant follicle of each wave;[8] however, no obvious relationship between estrogen concentration and sexual receptivity has yet been detected.[8] The relationship between follicular growth, estrogen concentration, and sexual receptivity has not been quantitatively evaluated and warrants further research, but it is clear that in the absence of progesterone, female llamas and alpacas are more or less receptive continuously.

Based on the assumption that sexual non-receptivity is a reflection of elevated systemic progesterone concentration, the strategy for testing receptivity is similar to that for testing systemic progesterone concentration as an indicator of pregnancy status (Fig. 121-2). Ovulation

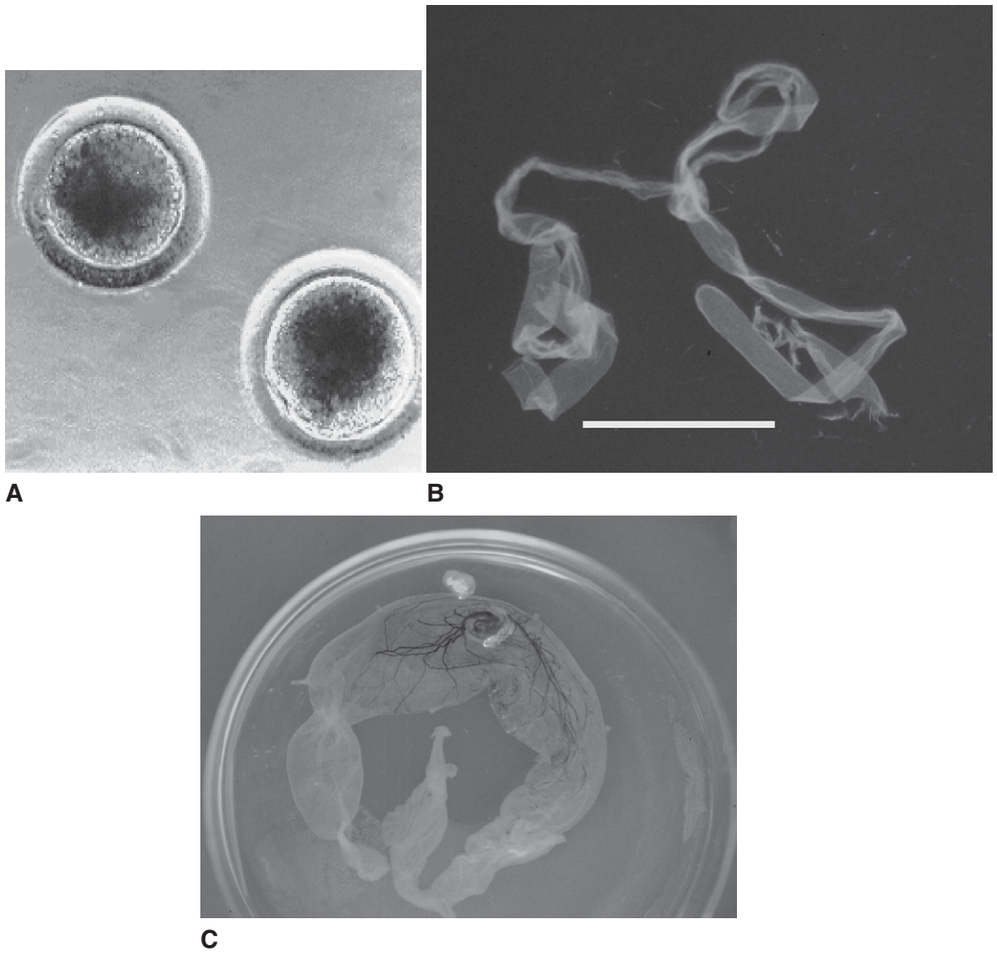

Fig. 121-1 Embryos collected from llamas 3 days after mating **(A)**, 10 days after mating (**B**; scale bar = 1 mm), and 24 days after mating **(C)**. Specimen in a glass Petri dish.

occurs very consistently 1 to 2 days (mean, 30 hours) after the first mating (see Chapter 118), but plasma progesterone does not rise significantly until 4 days after mating.[2] Plasma progesterone concentration peaks 7 days after first mating and decreases rapidly thereafter in nonpregnant animals to a nadir at 11 days after first mating. During the first 3 to 4 days after mating, when the corpus luteum (CL) is forming and progesterone concentrations are low, some females remain receptive to the male. In pregnant animals, plasma progesterone concentration will remain elevated until the last 2 weeks of gestation, at which time it begins to decline to a nadir 24 hours before parturition.[9] In one study, plasma progesterone did not exceed 0.4 ng/ml in nonmated nonovulatory llamas, but it remained in excess of 2 ng/ml in all pregnant llamas after day 11 after mating.[2] In the same study, CL diameter assessed by transrectal ultrasonography was highly correlated with plasma progesterone concentration (r = 83%; $P < 0.0001$) with the caveat that progesterone decreased 1 to 3 days before CL diameter decreased, at the time of luteolysis (see Fig. 122-2). Interestingly, a decrease in mean plasma progesterone concentration was detected between 9 and 11 days after mating in pregnant llamas, as well as subtle decrease in luteal diameter.[2] The transient drop in progesterone was coincident with the initiation of uterine-induced luteal regression in nonpregnant animals and it was suggested that the rescue and resurgence of the corpus luteum between 9 and 1 days after mating represents luteal response to pregnancy (or maternal recognition of pregnancy).[2] Measurement of progesterone concentration in the milk of pregnant and nonpregnant llamas and alpacas during the first 14 days after mating also revealed a parallel relationship with the concentration of progesterone in the blood.[10]

Based on these observations, a diagnosis of ovulation may be made between 4 and 8 days after mating by (1) behavior assessment, (2) measurement of progesterone concentration in blood or milk, or (3) measurement of CL diameter. A diagnosis of *nonpregnancy* may be made by day 11 after mating by detecting behavioral receptivity or basal progesterone concentrations and a regressing CL (see Fig. 121-1).

Test of sexual receptivity is an indirect test of the presence of progesterone, and measurement of systemic

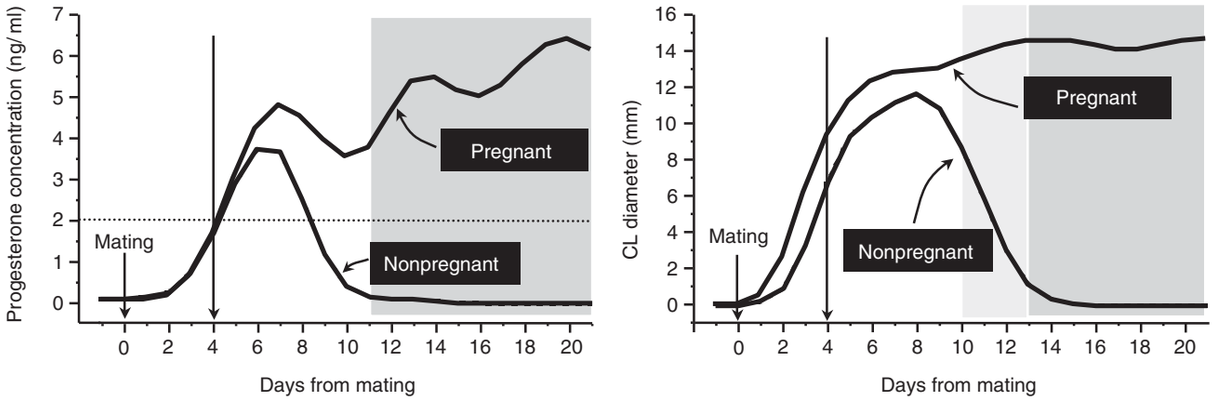

Fig. 121-2 Plasma progesterone concentration and corpus luteum (CL) diameter in nonpregnant and pregnant llamas. The short arrow indicates time of mating, and the long arrow indicates the day of first significant increase in progesterone (day 4). The light shaded area indicates the period when mean CL diameter is significantly different between statuses, and the dark shaded area indicates the period when individual test results will consistently distinguish between nonpregnant and pregnant animals, assuming that pregnancy is the cause of luteal maintenance. Pregnant llamas usually have plasma progesterone concentrations in excess of 2 ng/ml (horizontal dotted line). (Adapted from Adams GP, Sumar J, Ginther OJ: Form and function of the corpus luteum in llamas. *Anim Reprod Sci* 1991;24:127–138.)

progesterone is a measurement of luteal function—*neither* are direct indicators of pregnancy. Hence, behavior assessment and progesterone testing may be more appropriately referred to as methods of diagnosing *nonpregnancy* because luteal gland function may be elicited by factors other than pregnancy. Spontaneous ovulation has been reported in approximately 10% of females not exposed to a male[5,7,11] and may result in a false positive diagnosis of pregnancy. Pathologic processes such as luteal cysts,[4,12] embryo/fetal loss,[1] and abnormalities of the tubular genitalia may result in a prolonged luteal phase and a false positive diagnosis of pregnancy. In one llama that was ultrasonically monitored daily after embryonic loss, luteal regression had not occurred by the end of the observational period (70 days; G.P. Adams, unpublished). Based on repeated ultrasonographic examinations and final inspection at the time of ovariohysterectomy, a clinical diagnosis of a persistent corpus luteum was made in one llama with closed pyometra (cervical adhesions) and in another llama with congenital segmental aplasia and mucometra (G.P. Adams, unpublished). In both instances, the animals were assumed to be pregnant based on behavior and repeated measurement of plasma progesterone during the preceding months. Plasma progesterone concentrations remained above 2 ng/ml, and were unusually high (8 ng/ml) in some samples. The pathogenesis of these irregularities has not been explored and the predictive value of subnormal or supranormal levels of progesterone is unknown. Depending on the range of normal values established by the respective laboratory, progesterone values between 1 and 2 ng/ml are equivocal and warrant repeated measurement.

In a study of the accuracy of behavior testing as an indicator of pregnancy status,[13] the proportion of correct diagnoses ranged between 84% and 95% in llamas and alpacas at 70 to 125 days of gestation. Although convenient and useful, assessment of sexual behavior is confounded by its subjectivity. Submissive behavior in llamas and alpacas is similar to receptive behavior; aggressive behavior in a male or timid behavior in a female may result in submission to mating and mask nonreceptive behavior. Conversely, an inexperienced male may be easily intimidated by a dominant female, and occasionally, inexperienced females refuse to adopt a prone position and need to be restrained for mating. Although behavior and progesterone testing can be extremely useful management tools, they must be used strategically and only for presumptive diagnosis of pregnancy.

OTHER ENDOCRINE INDICATORS OF PREGNANCY

In a study to assess potential endocrine indicators of pregnancy, urine and blood samples were collected throughout pregnancy from 8 llamas and 11 alpacas to measure estrone sulfate and relaxin concentrations.[14] Estrone sulfate concentration in urine and serum peaked twice during pregnancy; at 21 days after mating and again during the last month of gestation. It was concluded, however, that the use of estrone sulfate concentration to diagnose pregnancy is highly dependent on the time of sampling. Measurement of serum relaxin concentration was considered a superior indicator of pregnancy after the second month of gestation because it represents an interaction between mother and fetus (pregnancy-specific) and concentrations were greater than basal values for the majority of gestation.

PALPATION AND BALLOTTEMENT

Scientific reports on palpation and ballottement as methods of diagnosing pregnancy in llamas and alpacas

are scarce. Only one study was found in which an attempt to critically document the accuracy of transrectal palpation was made.[13] Transrectal palpation was possible in 20 of 20 llamas and in 41 of 50 (82%) of alpacas; the rectum of 9 alpacas (18%) was too small to permit palpation. A correct diagnosis was made at 165 days after mating in all animals large enough to permit palpation (100% accuracy). With experience, transrectal palpation can be used to detect pregnancy as early as 35 days after mating, based on marked asymmetry of the uterine horns (conceptus is invariably maintained in the left horn), fluid fluctuance, and in later gestation, palpation of fetal parts. The placenta has a diffuse epithelio-chorial attachment; therefore, a fetal membrane slip characteristic in cattle cannot be felt. No specific reports on the use of transabdominal ballottement were found, but apparently some Peruvian herdsmen are quite skilled and it is used quite commonly after 8 months of gestation.

DIAGNOSTIC ULTRASONOGRAPHY

Two modalities of diagnostic ultrasound have been used for pregnancy diagnosis in llamas, A-mode (amplitude modality) and B-mode (brightness modality). The utility of A-mode ultrasonography for determining pregnancy status was investigated in one study[13] in which alpacas (n = 50) and llamas (n = 20) were examined at 10-day intervals from 70 to 160 days after mating. The transducer was placed in the sparsely haired inguinal region cranial to the udder on either side of midline. Accuracy was 90% to 95% initially but dropped to approximately 65% to 70% after 145 days. In a direct comparison, the accuracy of A-mode ultrasonography for detecting pregnancy was not different from that of behavior testing, but was significantly lower than that of palpation.[13]

With the availability of portable, real-time scanners designed for on-farm use, B-mode ultrasound imaging has become a common tool in veterinary practice. A thorough understanding of anatomy and the principles of ultrasonography are required, but practical capability can be achieved rapidly. For imaging the reproductive organs, the transducer may be placed on the outside of the body and directed dorsally or obliquely across the abdomen (transabdominal approach) or placed within the rectum and directed ventrally (transrectal approach). The transabdominal approach is useful for diagnosing pregnancy after approximately 60 days after mating and was used to generate a graph for estimating gestational age based on biparietal diameter of the fetus.[15] However, the fiber, skin, fat, and muscle of the body wall, and the depth of penetration required causes attenuation of the ultrasound signal and limits the resolution of images.

The transrectal approach involves the insertion of a gloved hand and transducer into the rectum. Because the reproductive organs are located immediately beneath the rectum with very little intervening tissue, the transrectal approach offers better access and a better image than the transabdominal approach. A clear image of the ovaries, uterus, and cervix can be achieved at any time during pregnancy or nonpregnancy. Although the transrectal approach is preferred, some llama and alpaca owners as well as their veterinarians are hesitant to use it. Indeed, physical limitations (i.e., relatively small rectum) may preclude this approach in some individuals. The author estimates that over 90% of mature llamas and over 75% of mature alpacas are able to accommodate the transrectal approach (glove size, $7^1/_2$). A rigid or semirigid probe extension may be used to permit external manipulation of an intrarectally placed transducer in individuals too small to accommodate the operator's hand. Transrectal ultrasonography is a safe procedure, but as with any other diagnostic procedure, it has attendant risks. The most serious risk is trauma or perforation of the rectum, which must be handled as a surgical emergency.[16] Although not critically studied, the incidence of trauma as a result of transrectal examination is apparently no greater in llamas and alpacas than in other large domestic species in which the procedure is routine (e.g., horses and cattle).

The ultrasonographic appearance of the conceptus at different stages of pregnancy, and growth characteristics of the embryo are shown in Figures 121-3 and 121-4. In an ultrasonographic evaluation of 60 llamas during the first 60 days of pregnancy[17] there was no difference in the proportion of left-sided versus right-sided ovulations, but serial examinations revealed that the early embryonic vesicle could be detected in any segment of either uterine horn—ipsilateral or contralateral to the side of ovulation. After day 20, however, the embryo appeared to become fixed in place and was most frequently observed in the middle portion of the left uterine horn, where development continued. After 26 days of pregnancy, the developing embryo/fetus was invariably observed in the left uterine horn (60 of 60 pregnancies). After day 45 the fetus appeared to be laying on its side on the ventral wall of the uterine horn with its head pointing toward the tip of the left horn while the umbilical cord extended toward and sometimes through the uterine bifurcation. In very few instances was the fetus observed hanging from the top of the uterine horn.[17] The embryonic vesicle was first detected as an irregular collection of fluid as early as 12 days after first mating (2 to 4 mm in diameter), and the beating heart of the embryo was first detected by 26 days after mating. In an ultrasound study of 19 alpacas, the embryonic vesicle was first detected in 30% of pregnancies at 10 days after mating, in 50% at 15 days, and in 100% at 23 days.[18] In another ultrasound study of 40 alpacas, the embryonic vesicle was first detected in 50% of pregnancies at 12 days after mating, in 83% at 14 days, and in 100% at 16 days.[19] A reasonable time for initial pregnancy diagnosis, therefore, is about 16 days after mating, depending on examination conditions and the experience of the clinician.

TWINNING AND EMBRYO LOSS

Double ovulation and twin pregnancies do occur in llamas and alpacas, but the birth of twins is rare. Double ovulation was detected in 1 of 83 ovulations (1.2%) in a Peruvian group of llamas, and 5 of 312 (1.6%) in a North American group of llamas.[17] Of the 6 llamas with double ovulations, 5 developed twin pregnancies, 3 singletons were born, and no twins were born. Information about changes in the size and morphology of the developing conceptus is sparse; however, preliminary studies have

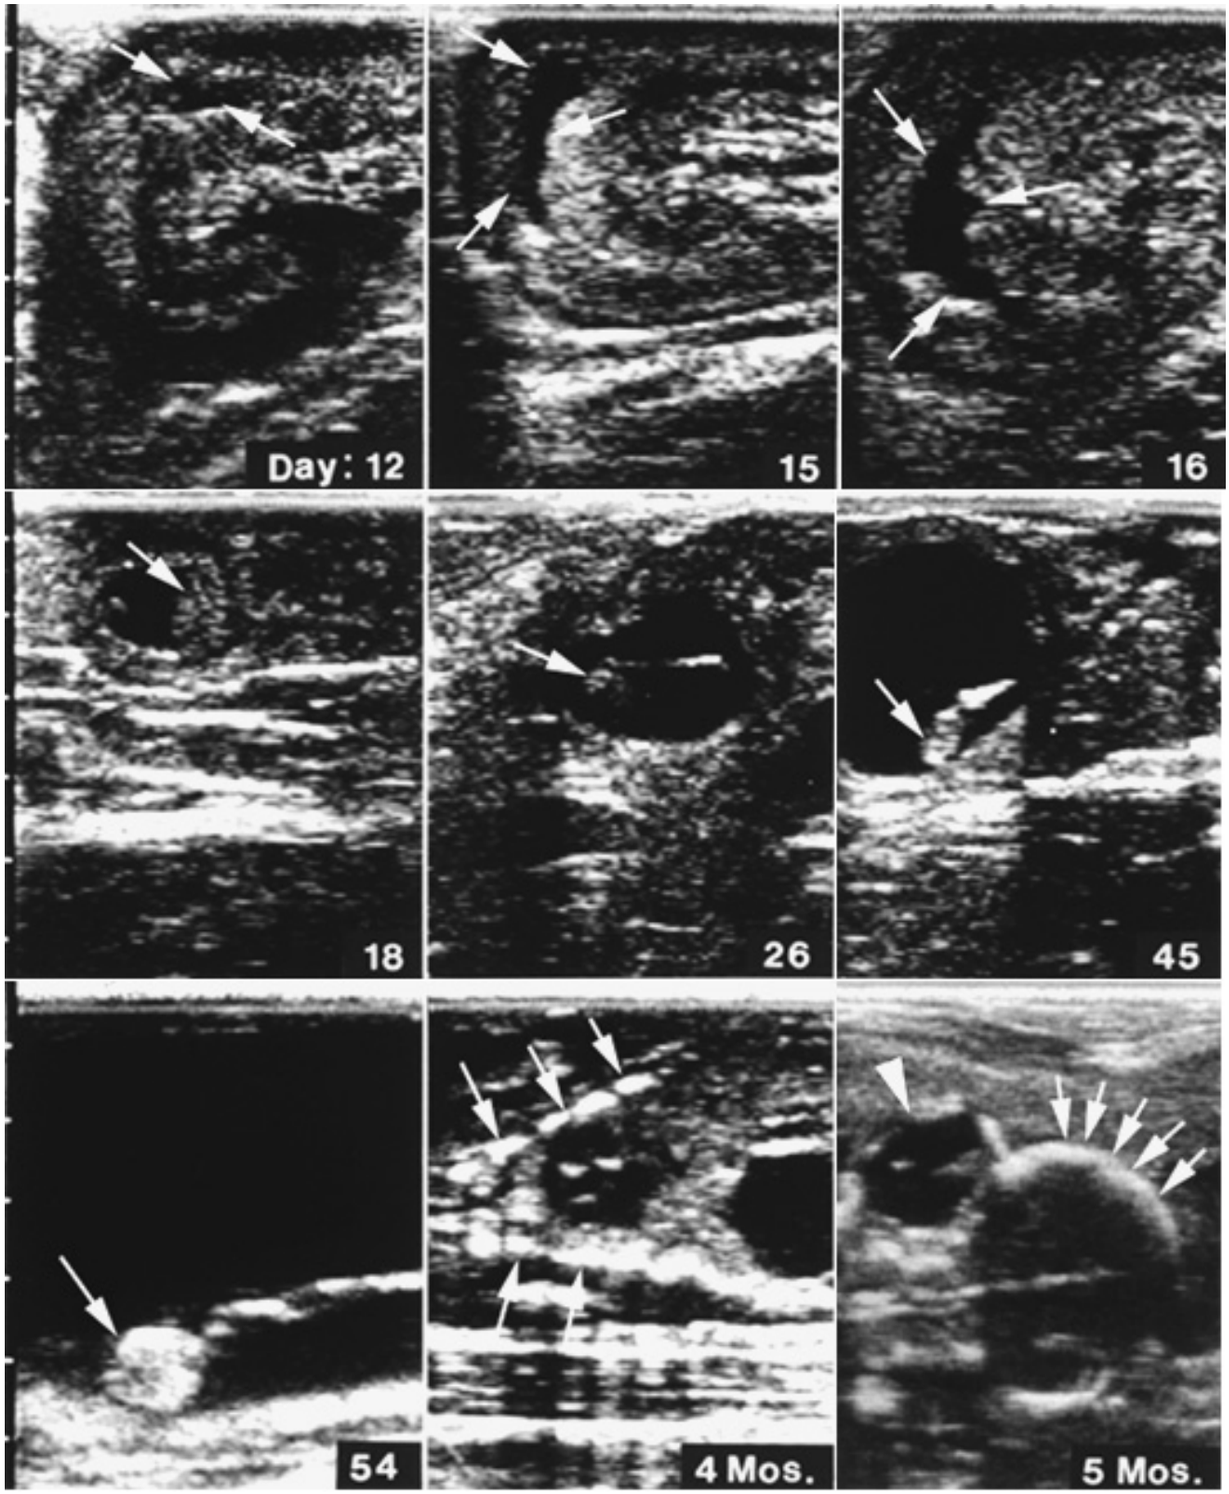

Fig. 121-3 Ultrasonic images of pregnancy in llamas at different stages of gestation (day 0 = ovulation). Note the fluid *(black)* of the embryonic vesicle in the longitudinal sections of the curled uterine horn (days 12, 15, and 16), and the embryo proper *(arrows)* in the cross sections of the uterine horn (days 18, 26, 45, and 54). The fetal chest is recognized by the ribs *(arrows)* and the heart (4 months), and the fetal head *(arrows)* is shown (5 months) with the fluid-filled eye uppermost *(arrowhead)*. (From Adams and Domínguez, unpublished data.)

yielded data on the crown-rump length, dimensions of the fetal eye, twinning, and pregnancy loss (Figs. 121-4 and 121-5).

The nature and rate of pregnancy loss in llamas and alpacas has not been well documented. In an ultrasound study, 83 pregnancies resulted from 123 ovulations (67%) after a single mating session (two matings, 4 to 8 hours apart).[17] Eleven percent of llamas diagnosed as pregnant by ultrasonography at 20 days or sooner lost the conceptus by 40 days after mating, and no further losses were recorded up to 60 days. It seems reasonable, therefore, to monitor the developing conceptus more frequently during early pregnancy (e.g., days 25, 40, and 60) and less frequently thereafter (e.g., at 3, 6, and 9 months and at term).

CHAPTER 122

Eutocia, Dystocia, and Postpartum Care of the Dam and Neonate

PATRICK LONG

IMPENDING PARTURITION

Impending delivery in camelids is difficult to discern. External signs normally seen in other species are not readily apparent in camelids. There are minimal changes in udder development and virtually no vulvar relaxation discernible prior to delivery. In addition, there is a great deal of variability in gestation length, ranging from 330 to 365 days in both llamas and alpacas. In a study of the effects of season on gestation length,[1] fall mating was associated with a gestation length 12 days shorter than spring mating. This may be an evolutionary trait to ensure that the crias will be born in the summer season and thus have the greatest chance of survival. An unusual feature of the domestic and wild species of South American camelids is that most births (>90%) occur between sunrise and mid-day.[6] This is thought to be an evolutionary process to ensure neonatal survival. Females starting first-stage labor late in the afternoon warrant careful examination because a high percentage will be dystocias.

NORMAL PARTURITION

As in other species, parturition is divided into three stages. First stage of labor should not exceed 4 to 6 hours, second stage of labor should not exceed 30 to 45 minutes, and the third stage of labor (characterized by delivery of the placenta) should be completed by 4 to 6 hours.

Typical first-stage labor signs are restlessness, loss of appetite, increased humming, and frequent trips to the dung pile with or without urination or defecation. Many times these signs are subtle and will be missed by all but the most observant owner. Increased rolling or lying in lateral recumbency may be noted during this time. First-stage labor lasting more than 4 to 6 hours warrants rectal or vaginal examination.

Second-stage labor is marked by the appearance of fetal body parts, discharge of amniotic fluid, or appearance of placenta. This stage should progress very rapidly and normally will not exceed 30 to 45 minutes. If the cria is not delivered within 45 minutes of the initiation of second-stage labor, intervention is indicated. Because of the long

CHAPTER 122

Eutocia, Dystocia, and Postpartum Care of the Dam and Neonate

PATRICK LONG

IMPENDING PARTURITION

Impending delivery in camelids is difficult to discern. External signs normally seen in other species are not readily apparent in camelids. There are minimal changes in udder development and virtually no vulvar relaxation discernible prior to delivery. In addition, there is a great deal of variability in gestation length, ranging from 330 to 365 days in both llamas and alpacas. In a study of the effects of season on gestation length,[1] fall mating was associated with a gestation length 12 days shorter than spring mating. This may be an evolutionary trait to ensure that the crias will be born in the summer season and thus have the greatest chance of survival. An unusual feature of the domestic and wild species of South American camelids is that most births (>90%) occur between sunrise and mid-day.[6] This is thought to be an evolutionary process to ensure neonatal survival. Females starting first-stage labor late in the afternoon warrant careful examination because a high percentage will be dystocias.

NORMAL PARTURITION

As in other species, parturition is divided into three stages. First stage of labor should not exceed 4 to 6 hours, second stage of labor should not exceed 30 to 45 minutes, and the third stage of labor (characterized by delivery of the placenta) should be completed by 4 to 6 hours.

Typical first-stage labor signs are restlessness, loss of appetite, increased humming, and frequent trips to the dung pile with or without urination or defecation. Many times these signs are subtle and will be missed by all but the most observant owner. Increased rolling or lying in lateral recumbency may be noted during this time. First-stage labor lasting more than 4 to 6 hours warrants rectal or vaginal examination.

Second-stage labor is marked by the appearance of fetal body parts, discharge of amniotic fluid, or appearance of placenta. This stage should progress very rapidly and normally will not exceed 30 to 45 minutes. If the cria is not delivered within 45 minutes of the initiation of second-stage labor, intervention is indicated. Because of the long

slender body of crias, dystocias from an oversized fetus are rare. As in other ruminant species, the normal presentation is anterior in a dorsosacral position with extended forelimbs. The nose and feet appear almost simultaneously. The chest is the biggest part of the cria, and second-stage labor may appear to stop at this point. Females that stop labor at this point may need assistance if labor doesn't progress within 5 minutes. Females will alternate between standing and lateral recumbency, and final delivery of the fetus may be accomplished in either position. Crias are born with a thin epidermal membrane that does not interfere with breathing or mobility.[3]

Delivery of the placenta, or third-stage labor, is usually completed within 6 hours. Female llamas and alpacas may show abdominal distress until the placenta is passed and may be reluctant to allow the cria to suckle until passage of the placenta. Lochia is commonly found by owners on or near the dung pile for 7 to 10 days post partum. This discharge is reddish brown, is gelatinous, and has no odor.

Retained placentas are uncommon and generally treated if not passed within 24 hours. Treatment consists of injections of oxytocin (5–10 units) at 10-minute intervals with or without gentle traction.[4] Strenuous traction may induce uterine prolapse. If the placenta cannot be delivered with this technique, uterine flushes with dilute iodine solutions may be used to facilitate passage of the placenta.

DYSTOCIA

Uterine torsion, breech or posterior presentation, and abnormalities of posture constitute most of the causes of dystocia in llamas and alpacas. Although the reported incidence varies, most authors cite an approximate 5% dystocia rate.

Uterine Torsion

Uterine torsions may occur as early as 7 to 9 months of gestation, but most occur during the last month. Behavioral signs of uterine torsion are often confused with that of gastrointestinal disorders.[2] Severe abdominal pain, violent rolling, and general restlessness are the typical presenting signs for uterine torsion. Causes of uterine torsion are unknown, but factors such as genetic predisposition, rolling, right side ovulation, increased fetal size, and increased fetal activity have been hypothesized.[4] Diagnosis of uterine torsion may be made with a thorough history of breeding dates, a complete physical examination, and rectal or vaginal examination. In a recent report,[2] 95% of torsions in llamas and alpacas were clockwise (or to the right when viewed from the rear). This is consistent with the author's experience with over 40 cases of uterine torsion.

A complicating issue in alpacas is that rectal examination may not be possible because of their small size. Depending on the location of the torsion, a vaginal examination may lead to the diagnosis. Rectal examination will be necessary to diagnose a torsion cranial to the cervix. When palpating the broad ligament, in a clockwise or torsion to the right, the ligament on the right side will be pulled ventral and medial. The ligament on the left side will be pulled to the right and over the top of the uterus. Palpation of these ligaments will cause pain and noticeable discomfort to the dam. Conversely, a torsion to the left or counterclockwise will result in a reversal of position of the ligaments. Vaginal examination will permit diagnosis of a torsion that is caudal to the cervix; the torsion will cause a twisting of vaginal tissues that is apparent during manual palpation.

Correction of a torsion can be accomplished by rolling the animal, transvaginal manipulation, or laparotomy.[2] Correction for the majority of uterine torsions can be performed with a rolling technique described for horses, except that a plank is not required. Sedation of the female with xylazine at a dose of 0.1 mg/kg intravenously will result in lateral recumbency in most females. If the torsion is clockwise, or to the right, the animal is placed in right lateral recumbency. If the torsion is counterclockwise, or to the left, the animal is placed in left lateral recumbency. One person is needed to flex the rear legs, another is needed to control the front legs and head, and a third person is needed to stabilize the fetus. The female is rolled while the fetus is held stationary. If the torsion is greater than 180 degrees, a second rolling procedure may be needed. After rolling, a rectal examination is performed to ensure that the torsion has been corrected. If corrected, a vaginal examination is performed to see if cervical dilation has occurred. When the cervix is dilated, delivery of the cria may then be assisted. In the author's experience, over 50% of cases of uterine torsion occur at full term and delivery is assisted after correction of the torsion. If there is no cervical dilation, the female is allowed to recover and is monitored closely for recurrence.

If the cervix is open at the time of initial examination, grasping the fetus and rotating it into the correct position can be accomplished. Laparotomy is indicated in longstanding torsions or if one suspects that the uterine wall is compromised. Decisions must be made at the time of surgery if a cesarean section or simple correction of the torsion will be done. Gestation length, fetal size, uterine wall integrity, duration of clinical signs, and presence of colostrum are all factors to consider in this decision.

Multiple episodes of uterine torsion can occur in the same pregnancy and some females have a torsion in subsequent pregnancies.[2] Multiple torsions in a late-term female may necessitate a cesarean section. The prognosis is good for the dam and cria if the torsion and subsequent correction are performed in a timely manner. Future reproductive ability is generally good if the diagnosis and correction are achieved promptly.

Clinical Approach to Dystocia

When dystocia is suspected and intervention is needed, preparation and planning are important. Even though camelids seldom need sedation for examination and manipulations, adequate restraint facilities are required. Animals should be haltered and placed where restraint is adequate. Many animals will lie down when manipulations begin, so be sure that ample space is available to perform the manipulations if this occurs. Many times,

securing the animal to the corner of a stall or pen is sufficient. Placing the animal in a narrow restraint chute with immovable sides is not advised for obstetric manipulations as many females will lie down and make further treatment much more difficult. Tail wrapping is recommended; the tail can be held by an assistant or tied forward. Cleanliness of both the dam and the veterinarian is important. The dam should be thoroughly cleansed as well as the hands and arms of the obstetrician. Adequate lubrication should be used when starting the examination. Damage to the cervix is one of the major causes of infertility subsequent to a dystocia in multiparous females.

A thorough examination should reveal the nature of the dystocia and general principles of mutation and traction used in other species will allow for correction and subsequent delivery of the fetus. In rare instances dilation of the vagina may be incomplete, and a few minutes spent with gentle massage to dilate the vagina before attempting delivery is time well spent. Many times repulsing the fetus cranially will allow sufficient space to reposition an abnormal posture. Most common abnormalities encountered are one leg flexed or both legs flexed. The most difficult corrections involve a ventral or lateral deviation of the head and neck. If there is not adequate lubrication, correction can be very difficult. Many of these cases will require the obstetrician to insert both arms to simultaneously repel the cria and manipulate the neck dorsally and the nose ventrally to extend the neck.

If the presentation is breech, it is important to have adequate dilation of the birth canal before delivery is attempted. Owing to the comparative small size of the fetus and ease of repelling the cria cranially, extending the rear legs is usually accomplished with relative ease. Again, adequate lubrication is important. Placing lubrication into the birth canal and around the cria will greatly assist the delivery process.

A prolapsed uterus is relatively uncommon, but there is a higher incidence after dystocia. Owners should be warned to monitor these animals closely for several hours after an assisted delivery. If a prolapse occurs, owners should be advised to keep the animal calm and the uterus as clean as possible until treatment can be instituted. Treatment of a prolapsed uterus will require caudal epidural anesthesia and light sedation. Extending the dam's rear legs caudally will aid in replacing the uterus. Cleansing the exposed uterus as thoroughly as possible and placing the female on systemic antibiotics after repositioning the uterus will help ensure continued fertility. Administration of oxytocin and systemic antibiotics are indicated. In the author's experience, owners can easily confuse a retained placenta for a uterine prolapse. It is important to question the owner carefully if either is suspected.

Birthing Trauma and Metritis

Cervical trauma at the time of birthing is a major cause of infertility in llamas and alpacas. Care must be taken when performing any obstetric manipulations to avoid damage to the cervix. A complete vaginal examination should be done after prolonged dystocia or extensive fetal manipulations to check for damage. Postpartum metritis can occur as a complication of prolonged dystocia, contaminated birthing area, or retained placenta.[4] Clinical signs include a vaginal discharge and occasionally systemic illness. Uterine lavage and systemic antibiotics are indicated.

POSTPARTUM CARE OF THE NEONATE

A thorough examination of the cria shortly after birth is important. Alpacas and llamas have a high rate of congenital defects that range from minor to life-threatening.[3] Reported defects include choanal atresia, atresia ani, wry face, heart murmurs, polydactyly, syndactyly, cataracts, cleft palate, and umbilical hernia. If still present, removal of the epidermal membrane can be accomplished with gentle rubbing.[4] Meconium staining of the epidermal membrane can be an indicator of fetal stress.

Crias should attempt to stand within 15 to 30 minutes of birth. There should be no respiratory distress and the cria should attempt to nurse within 2 hours. Normal birth weights will range from 9 to 18 kg for llamas and 5.5 to 10 kg for alpacas. Weak flexor tendons, ears that are not erect, and teeth that have not yet erupted are all signs of a premature or dysmature cria. Initial treatments should include treatment of the umbilicus with 7% tincture of iodine or a 0.5% chlorhexidine solution. This should be repeated two to three times in the first 24 hours, especially if the cria is born in a contaminated area. Clients should be instructed to weigh crias and record the weight. Weight gain and activity are the primary signs that clients can use to monitor the health of the cria. Expect that most crias will lose weight in the first 24 hours and then start gaining. It is not unusual for alpaca crias to lose 0.12 to 0.25 kg and llamas to lose 0.25 to 0.50 kg in the first 24 hours of life. After 24 hours, crias should gain the aforementioned weights daily. Most crias will double their birth weight by 1 month of age. Body temperature of the cria should be 37.7° to 38.9°C (100–102°F). The heart rate varies between 60 and 90 beats per minute and the respiratory rate ranges from 10 to 30 breaths per minute.[5] Nursing frequency will vary with the cria's age. Newborns suckle frequently (hourly) but for a very short time. This frequency decreases with age. If the cria is born in a selenium-deficient area, 0.5 to 1 mg of injectable selenium may be given.

Failure of Passive Transfer

Early and frequent nursing is desired, because no passage of antibodies occurs across the placenta. Causes of failure of passive transfer (FPT) include lack of intake, poor production by the dam, and failure of absorption from the cria's intestinal tract. Risk factors for FPT include dystocia, premature or dysmature crias, primiparous females, and females with a history of previous FPT. Immunoglobulin levels should be determined at 24 to 36 hours of age using llama-specific radioimmunodiffusion (RID) assay kits. These kits are available from two commercial sources (Triple J Farms, Redmond WA; Bethyl Labs, Montgomery, TX). The commercially available RID plates vary in their reading[6]; using the Triple J plates, levels greater

Table **122-1**

Interpretation of Assays for Measurement of Passive Transfer of Antibodies in Neonatal Llamas

	IMMUNOGLOBULIN CONCENTRATION (mg/dl)	
Classification	**Triple J Farms**	**Bethyl Laboratory**
Complete failure of passive transfer	<400	<200
Suspect	400–1000	200–500
Adequate IgG concentration	>1000	>500

Table **122-2**

Comparative Milk Composition in the Llama, Goat, Sheep, and Cow

Animal	Water (%)	Protein (%)	Fat (%)	Energy (kcal/L)
Llama[16]	86.2	4.3	5.7	822
Llama[17]		3.4	2.7	
Goat	87.0	3.3	4.0	680
Sheep	81.0	6.2	7.9	1138
Cow	87.3	3.3	3.6	653

Data taken from Morin DE, Hurley WL, Rowan LL, Braselton WE: The composition of llama milk. VIth Congress of the ISACB, Guelph, CA, August 1994, poster 5–23.

than 800 mg/dl are considered adequate and levels less than 400 mg/dl would indicate FPT (Table 122-1). The kits are specific for llama IgG and should not be used if the cria has been supplemented with colostrum of cow, goat, or some other species. If cow or goat colostrum has been supplemented, a sodium sulfite turbidity test can be used (VMRD, Pullman WA). Measurement of total serum proteins can also be done, with the results expected to be greater than 5 g/dl. If this test is used, it is important to evaluate the total protein level and the hydration status of the cria. Dehydration and the resulting high protein level can lead to a false sense of security. It is important to note that test kits used in the equine species are not valid for assessing passive transfer in llamas and alpacas. When using the turbidity test kits, 800 mg/dl is considered adequate passive transfer for camelids.

If FPT has occurred, plasma transfusions can be given either intravenously or intraperitoneally. Llama plasma is commercially available (Triple J Farms, Redmond, WA) or can be obtained from other animals on the farm. If crias are active and not already on IV fluids, introduction of a catheter into the peritoneal cavity is a rapid and relatively stress-free procedure. A small area on the ventral midline is scrubbed and draped. A local anesthetic can be used to desensitize the area. Warmed plasma (350 to 500 ml) can be given over a period of 10 to 15 minutes. The plasma should have a concentration of at least 2500 mg/dl of IgG as measured by the Triple J plate. If an IV catheter is in place, the plasma should be infused over a 2- to 4-hour period.

If the cria is weak at birth or does not nurse vigorously or if the dam has had a history of FPT, supplemental feeding of colostrum is advised. Maintaining a bank of llama colostrum is not always feasible. Cow or goat colostrum is an acceptable substitute. Follow guidelines for other ruminant species when obtaining and handling colostrum. Advise clients that it is ideal to obtain their colostrum from multiparous females and that the first milk after birthing will generally have the highest levels of antibodies. If frozen, the colostrum should be thawed slowly in a warm water bath and not in a microwave oven. When crias are too weak to suckle or if the dam has little or no colostrum, it is advisable to feed at least 10% of the cria's body weight in the first 24 hours. Although there will be little absorption of antibodies from the gut after 24 hours, feeding colostrum, if available, for the first 3 days is advised. Supplemental feeding of the cria should be frequent and in small volumes (e.g., for an 11-kg cria, at least 8 feedings of 150 ml in the first 24 hours).

After the first 1 to 3 days of colostrum supplementation, several options are available if continued supplemental feeding is needed. Whole cow milk supplemented with yogurt (for additional calories) is a good choice. Adding 15 ml of plain yogurt to each 240 ml of milk will provide additional calories without greatly increasing the volume. Various milk replacers have also been used as long-term supplements. Goat milk or goat milk replacer appears to be the best choice for long-term supplementation (Table 122-2).

Choanal Atresia

Choanal atresia is a congenital defect characterized by either a membranous or osseous separation of the nasal and pharyngeal cavities at the level of the choanae.[5] This separation may be unilateral, bilateral, partial, or complete. As obligate nasal breathers, this condition is life-threatening and prevents the cria from suckling and breathing at the same time. Clinical signs are open-mouth breathing with marked flaring of the nostrils; there will be marked dyspnea with complete bilateral choanal atresia. Signs will be less marked if there is a partial or unilateral atresia. Airflow through the nostrils may be tested by placing a dry glass slide under the nostril to check for fogging. Conclusive diagnosis can be done by placing contrast medium in the nasal cavity and tilting the head caudally. Radiographs will demonstrate that the contrast medium will still be present in nasal cavity after 2 to 5 minutes. This will also help differentiate bilateral versus unilateral choanal atresia. Various corrective surgical procedures have been described, but all have high complication rates.[5] Many animals can survive with partial or unilateral choanal atresia, but most cases are complete and bilateral. Euthanasia for humane reasons is recommended in case of the latter.

POSTPARTUM CARE OF THE DAM

Examination of the placenta should be done to ensure that it is totally delivered. The color should be a homogeneous reddish brown. Check the portion of the placenta corresponding to the distal ends of the horns to ensure that the placenta is complete. Postpartum vulvar swelling can be marked, particularly in primiparous females. This swelling normally dissipates within 24 hours. Examine the vaginal tract for excessive bruising or tearing. Hemorrhage should be minimal after delivery of the placenta. Check the mammary glands to ensure that colostrum is present. Agalactia is uncommon in llamas and alpacas, but milk letdown may not occur until the placenta has been delivered. Many primiparous females will be reluctant to allow the cria to suckle until the placenta has been delivered. Light sedation with 5 mg butorphanol IM in alpacas or 10 mg butorphanol IM in llamas will generally facilitate the nursing and bonding process. If the primiparous female is reluctant to allow the cria to suckle, milking 60 to 90 ml of colostrum and feeding the cria with a bottle can be very helpful. Gently wash the udder with warm water and remove waxy plugs if present.

Lactation places peak nutritional demands on llamas and alpacas and most females will lose weight during the lactation period. Protein and energy levels in the feed should be increased over maintenance levels in the last 2 months of pregnancy and during lactation (Table 122-3).

Mastitis

Reports of mastitis are rare in llamas.[7] Clinical signs include reluctance to allow the cria to nurse, swollen and warm udder, and failure of growth by the cria. Milk from affected quarters may be pinkish in color and may be abnormal in consistency. Cultures should be taken and the female should be treated with the appropriate antibiotics. Intramammary infusions are difficult because of the small openings in each teat. Supplemental feeding of the cria may be needed until the infection is resolved.

Table **122-3**

Nutrient Recommendations for Late-Term Pregnancy and Lactation for Alpacas and Llamas

Nutrient	Llama	Alpaca
Protein (%)	12	15
Total digestible nutrients (%)	55–60	60–65
Crude fiber (%)	25	25
Calcium (%)	0.8–1.0	0.8–1.0
Phosphorus (%)	0.4–0.6	0.4–0.6

Adapted from Long P: *J Camel Pract Res* 1999, vol 6.

Agalactia

Agalactia may be caused by systemic diseases, mammary diseases, nutritional deficiencies, or feed toxins.[8] Agalactia in primiparous females immediately after birth may be temporary and resolve within a few hours. It is not uncommon to see milk production begin a few hours after stage three labor is complete. In such cases, oxytocin treatment may help induce milk letdown. It is speculated that females that are overconditioned during their prepubertal life may have large amounts of fat in the mammary tissue and thus have inadequate milk production. Although not proved, many speculate that there is a heritable basis for poor milk production. As in most other species, most primiparous females will have less milk production than multiparous females. Supplemental feeding of crias will be needed if there is inadequate weight gain.

Various herbal remedies are available to stimulate milk production (Llama and alpaca herbal lactation stimulator, Valley of the Llama Ranch, Sonora, CA). The author has used these stimulators with some success. Certain types of grasses contain a mycotoxin that can decrease milk production. This should show up as a herd problem, not just an individual animal problem, but small farms may only have one or two crias per season. When purchasing hay or grass seed to plant in pastures, advise owners to ask for "endophyte-free" seed. When in doubt, many forage labs can assess hay samples for endophyte levels.

CHAPTER 123

Embryo Technologies in South American Camelids

MARCELO H. RATTO and GREGG P. ADAMS

The application of reproductive biotechnology is in the formative stages for the domestic species of South American camelids (llama and alpaca) and is virtually nonexistent for the wild species (guanaco and vicuña). Llamas and alpacas represent a valuable economic and biologic resource for Peruvian, Bolivian, and Chilean people living in the high plains of the Andes,[1] and have become a consistent feature of North American livestock production. World production of fiber from alpacas exceeds 4 million kilograms, worth more than $12 million ($US).[2] Peru has over 3 million alpacas and 1 million llamas, Bolivia has more llamas (2 million) than alpacas (325,000), and Chile has the smallest number of animals (33,000 alpacas and 67,000 llamas). There are more than 150,000 registered llamas and alpacas in North America.

Embryo transfer technologies and superstimulatory treatments have been studied intensively in other domestic species. At present, these methods are applied on a commercial basis in cattle and sheep industries to accelerate genetic improvement of the herds. Although there has been much interest, particularly from owners of valuable breeding stock in North America, little has been published on embryo transfer in South American camelids. Relatively poor results have tempered the initial enthusiasm for embryo transfer in llamas and alpacas in the early 1990s. Reasons for limited success in the use of embryo technologies in llamas and alpacas are the lack of effective superstimulatory treatments, low embryo recovery, and scanty knowledge of embryo physiology.

An overview of the current state of embryo technology in llamas and alpacas is presented herein. Ovarian superstimulation, embryo collection, and embryo transfer will be discussed as well as oocyte collection, in vitro fertilization, and embryo cryopreservation.

OVARIAN SUPERSTIMULATION

Results of studies on ovarian superstimulation and embryo production in llamas and alpacas are summarized in Table 123-1. Superstimulation has been attempted using equine chorionic gonadotropin (eCG) and follicle-stimulating hormone (FSH) during a luteal phase (induced by eliciting ovulation or by progestogen treatment) or during the sexually receptive phase. After superstimulatory treatment, the females were mated and given gonadotropin-releasing hormone (GnRH) or human chorionic gonadotropin (hCG) to induce ovulation. Superstimulatory treatment schemes may be summarized as follows:

1. **Luteal phase induced by ovulation.**[3] GnRH or hCG was given when a follicle of at least 9 mm was present (day 0). At day 7, 1000 IU of eCG was administered intramuscularly. At day 9, a luteolytic dose of prostaglandin was given, and finally, to induce ovulation, 750 IU of hCG was given when follicles reached a diameter of 9 to 13 mm.
2. **Luteal phase simulated by progestogen treatment.**[4–6] The luteal phase has been simulated either by the application of a controlled intravaginal drug-releasing (CIDR) device, norgestomet, or daily progesterone treatment for 7 to 12 days. Gonadotropin treatments consisted of 20 mg pFSH (NIH-FSH-P1) IM every 12 hours for 5 days (total dose of 200 mg) or 1000 IU of eCG, starting 48 hours before progestogens are removed. Finally, 750 IU of hCG or 8 μg of GnRH were administered to induce ovulation.
3. **Sexually receptive phase.**[7,8] Females that displayed continuous sexual receptivity for 5 days received 20 mg pFSH (NIH-FSH-P1) IM every 12 hours for 5 days (total dose of 200 mg). After the last injection of FSH, females were treated with 750 IU of hCG to induce ovulation.

The preoccupation with inducing a luteal phase before or during superstimulation in camelids is enigmatic, but may simply reflect an empirical bias to conventional methods used in other ruminants. The number of ovulations or corpora lutea (CL) varies widely among studies, ranging from 2 to more than 11 per animal. Much of the variation may be attributed to the variation in follicular status at the time superstimulatory treatments were initiated. Presumably, follicular dominance will suppress the superstimulatory response in llamas and alpacas, as it does in cattle, but this remains to be tested. In a recent study[9] comparing the efficacy of FSH and eCG, treatments were initiated at the time of wave emergence and both hormones effectively induced ovarian superstimulation. FSH treatment induced the growth of 18 follicles (≥6 mm) per animal, on average, and eCG induced the growth of 17.

Table **123-1**

Superovulation Schemes Used in South American Camelids

Species	No. of Animals	Physiologic Status	Hormone	Viable Embryos per Donor	Reference
Llama	6	Luteal (hCG)	eCG	2.3	Bourke et al, 1995[3]
Llama	24	Luteal (GnRH)	eCG	1.4	Bourke et al, 1995[3]
Llama	5	Luteal (CIDR)	eCG	2.0	Bourke et al, 1994[5]
Llama	17	Luteal (norgestomet)	eCG	1.3	Bourke et al, 1995[3]
Llama	4	Luteal (norgestomet)	FSH	0	Bourke et al, 1995[3]
Llama/alpaca	4/4	Luteal (progesterone)	eCG	0	Correa et al, 1994[6]
Llama/alpaca	4/4	Luteal (progesterone)	FSH	0.5	Correa et al, 1994[6]
Llama	19	Luteal (GnRH)	eCG	1.6	Bourke et al, 1995[3]
Llama	17	Luteal (norgestomet)	eCG	1.3	Bourke et al, 1995[3]
Llama	20	Sexually receptive	FSH	1.8	Correa et al., 1997[7]; Ratto et al, 1997[8]

CIDR, controlled intravaginal drug releasing; eCG, equine chorionic gonadotropin; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; hCG, human chorionic gonadotropin.

EMBRYO COLLECTION AND TRANSFER

Researchers from Peru reported the first collection of zygotes from the oviducts of alpacas after spontaneous ovulation and from superovulated females by laparotomy 3 days after ovulation.[10] The flushes were done normograde, from the ovarian end of the oviduct to the uterine end; authors suggested that the muscular uterotubal junction made retrograde flush impossible.[11] Embryos have been collected on various days after breeding, using surgical or nonsurgical techniques in unstimulated alpacas and guanacos and superstimulated alpacas and llamas (Table 123-2).

The nonsurgical method of embryo collection is similar to that used in cattle and consists of the introduction of a catheter through the cervical canal and placement of the cuff just cranial to the internal cervical os. Both uterine horns are flushed simultaneously by infusing collection medium until the horns are distended and then the medium is collected by aspiration or gravity flow. The process is repeated several times until 500 to 1000 ml of medium are recovered.[4,12–15] Uterine flushing has been done on days 6.5 to 12 after mating, but embryo recovery has been frustratingly variable. Generally less than 50% of the zygotes have been recovered, based on CL counts, regardless of the method of embryo

collection.[12] The recovery of embryos by surgical flushing of the oviduct and uterus 7 days after mating in 20 llamas treated with pFSH is summarized in Table 123-3. Llamas were mated either 0 hours or 36 hours after the last pFSH treatment.[16]

Embryo Transfer

Over the past 30 years, approximately 13 crias have been born throughout the world as a result of embryo transfer techniques[12] (Table 123-4). The first birth of an alpaca using surgical collection and transfer techniques was reported in 1974.[11] Of 44 recipients, 4 became pregnant, 3 aborted, and 1 gave birth. The first llama born using nonsurgical collection and transfer was reported in a study done in North America[17] in which collection and transfer were done 7 days after GnRH treatment. In 1987, the birth of 2 alpacas was reported in Peru through the use of nonsurgical collection and transfer.[18] Six live cria were born in the United Kingdom during 1992 to 1995, from 27 embryos transferred nonsurgically to 21 synchronized recipients.[4,5] Interestingly, only recipients synchronized with GnRH became pregnant; no pregnancies resulted in those that received progestagen implants. In Chile, the birth of 1 llama cria after 2 nonsurgical embryo transfers was reported in 1994.[19] More recently, Canadian scientists reported the recovery of 23 embryos from 5 superstimulated llamas,[20] and an American study reported the recovery of 37 embryos from 47 unstimulated donors (79%), 41% of which established pregnancies after transfer to recipients.[21] The first report of successful interspecies transfer in camelids appeared in 2001 after 2 alpaca crias were born to llama recipients.[22]

Table **123-3**

Ovarian Response (Mean ± SD) and Ova/Embryo Collection Rate after Flushing the Oviduct and Uterus in Llamas Mated 0 Hours or 36 Hours after the Last FSH Administration*

End Point	Mating at 0 Hours	Mating at 36 Hours
Number of llamas	10	10
Number of corpora lutea	4.5 ± 4.2	13.8 ± 8.4
Number of follicles ≥ 8 mm	6.5 ± 5.4	7.5 ± 8.3
Embryo collection rate	27/45† (60%)	27/138† (20%)
Embryo collection from uterus	17/27 (63%)	16/27 (60%)
Embryo collection from oviduct	10/27 (37%)	11/27 (40%)
Number of blastocysts from uterus	17	16
Number of blastocysts from oviduct	3	0
Number of unfertilized oocytes	7	11

*Given every 12 hours for 5 days, total dose of 200 mg Folltropin.
†Total number of corpora lutea.
From Ratto MH: Induction of superovulation in llamas. Master's thesis, Universidad Austral de Chile, Valdivia, Chile, 1995.

Embryo Morphology

Camelid embryos collected from superovulated females 6 to 7 days after mating vary in size from 0.1 mm to 1 mm and are usually found as hatched expanded blastocysts (Fig. 123-1). From a total of 163 llama embryos and 19 alpaca embryos, the mean diameter of the embryo was 527.1 ± 168.0 μm and 534 ± 151.4 μm, respectively.[22] In addition, great variation was noted in the diameter of successive single embryos collected from the same female in successive collections.[22] About 35% of recovered embryos were small (≤450 μm in diameter), 40% were medium (451–650 μm), and 24% were large (≥651 μm). The size distribution was almost identical for alpacas.

It appears that embryos develop more rapidly in llamas and alpacas than in other species. Morulae have been recovered from llama oviducts as early as day 3 after insemination and we have recovered a blastocyst from a llama oviduct (Adams, unpublished). Trophoblast expansion ranged from a mean of 1.2 mm in diameter on day 6.5 to 7.5, to 83 mm in length on day 13 to 14. This accelerated rate of embryo development may be related to the apparent early maternal recognition of pregnancy in these species.[24,25]

Table **123-4**

Embryo Transfer Results in South American Camelids 1968–2001

Country	Year	Species	Number of Donors	Number of Recipients	Number Pregnant	Number Born
Peru	1968	Alpacas	3	3	0	0
Peru	1974	Alpacas	15	44	4	1
US	1985	Llamas	2	2	1	1
Peru	1987	Alpacas	2	3	3	2
UK	1991	Llamas	33	11	3	2
Chile	1994	Llamas	1	2	1	1
UK	1995	Llamas/guanacos	12	10	5	4
US	2000	Llamas	47		15	
US	2001	Alpacas/llamas				2

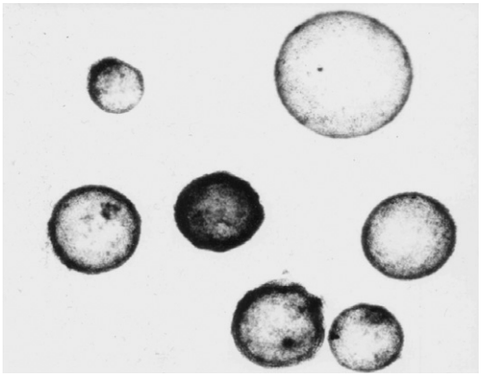

Fig. 123-1 Expanded hatched blastocysts recovered 7 days after mating by nonsurgical uterine flushing of one llama after superovulatory treatment. (From Ratto MH, Gatica R, Correa J: Timing of mating and ovarian response in llamas *(Lama glama)* treated with pFSH. *Anim Reprod Sci* 1997;48:325–330.)

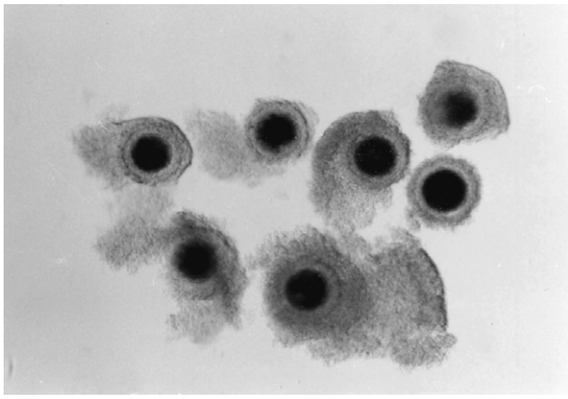

Fig. 123-2 Immature compact cumulus oocyte complexes recovered from excised ovaries of llamas by follicle aspiration using a 21-gauge needle. Note that the ooplasm is very dark, presumably due to high lipid content. (From Ratto MH, Berland M, Gomez C, et al: In vitro maturation of llama oocytes. II World Congress of South American Camelids, Cusco, Peru, 1999, p 80.)

Oocyte Collection

Oocyte recovery rate after follicular aspiration by laparotomy in 4 alpacas treated with FSH and 7 alpacas treated with eCG was 83% (105/127) and 82% (163/198) of the total follicles aspirated, respectively.[26] The proportion of expanded cumulus oocyte complex (COC) that had reached the second metaphase in the two groups was 18/45 (40%) and 16/61 (26.2%), respectively. Ultrasound-guided follicle aspiration has become commonplace as a repeatable procedure for oocyte collection in cattle, but the first report of this technique for any species of camelid appeared in a recent study in llamas.[27] The technique was used in another recent study in llamas (n = 40) to ablate all follicles 5 mm and larger in order to induce new wave emergence before superstimulation, and to aspirate oocytes from the ovaries after superstimulation.[28] An average of 15 follicles per animal were aspirated and an average of 11 oocytes per animal were collected (73% collection rate). Interestingly, administration of luteinizing hormone (LH) before oocyte collection permitted the recovery of a preponderance (~80%) of expanded COC in metaphase II; presumably these COC may be used directly for in vitro fertilization (i.e., in vitro maturation not required).

In Vitro Fertilization

In a morphologic study of the mature ovarian follicle and its contained COC,[29] growing follicles were spherical and 85% of their surface protruded from the surface of the ovary. Because llama and alpaca COCs were dark in color, they were easily distinguished through the follicle wall during transillumination,[29] and the attached COC in lamas was found to be located in the hemisphere containing the expected ovulation point. Oocytes collected from follicles 2 to 11 mm in diameter ranged from 172 to 200 µ (mean ± SD, 183 ± 14; Fig. 123-2). Immature oocytes had a very distinct and large germinal vesicle with a dark nucleolus; the metaphase plate was surrounded by a dark area easily located at 20× to 40× magnification. A greater number of oocytes was collected by mincing the ovary with a razor blade (average 27 oocytes/llama) than by aspiration of follicles between 1 and 6 mm in diameter (6.4 oocytes/llama).[30,31]

The first successful in vitro maturation and in vitro fertilization in llamas was reported in 1992 and 1994, respectively, using ovaries collected from a slaughterhouse.[30,31] Authors reported that 62% of oocytes achieved metaphase II after 36 hours of culture, and 57% of the matured oocytes displayed signs of fertilization after in vitro culture with epididymal sperm. Of 234 oocytes placed in llama oviductal epithelial cell (LLOEC) coculture for 9 days, 32% cleaved, 5.6% reached the morula stage, 6% reached the early to expanded blastocyst stage, and 4.7% reached the hatched blastocyst stage. In a more recent study of in vitro maturation using slaughterhouse ovaries,[28] maturation was complete by 28 hours; that is, there was no difference in the proportion of oocytes that progressed to the second metaphase after 28, 30, or 36 hours of culture in vitro.

Embryo Cryopreservation

The effects of two cryoprotectants, propylene glycol and ethylene glycol, on post-thaw reexpansion and morphology of blastocysts have been compared.[20] After 12 hours of culture only blastocysts preserved in ethylene glycol reexpanded, and although transfers were not attempted, authors concluded that ethylene glycol may be the cryoprotectant of choice in this species. Recently, vitrification of llama embryos has been attempted using an open pull straw (OPS) method.[32] Embryos ranging from 0.3 to 0.8 mm were exposed in one step to a high concentration of cryoprotectant (40% ethylene glycol) and then submerged directly into liquid nitrogen. In vitro reexpansion

of embryos after thawing was acceptable, but no pregnancies resulted after transfer of embryos into two recipients. High lipid content in the cytoplasm of camelid oocytes and embryos may contribute to low survival after cryopreservation.[27,32]

CONCLUSION

Traditional approaches of superovulation and embryo transfer in South American camelids have resulted in limited success primarily because of a poor understanding of reproductive physiology, puberty, and seasonality in these species. Although progress is being made, the inconsistency of reported information on the male and the limited success of semen collection and cryopreservation remain major impediments to the use of artificial insemination and embryo transfer techniques. Recent successes in embryo transfer demonstrate the promise of this technology. Interspecies transfer may be critically important for propagating threatened wild species (guanaco and vicuna). Breakthroughs in techniques for in vitro embryo production in llamas and alpacas are imminent and present many opportunities for genetic improvement of domestic herds and preserving endangered populations.

There is still much to be learned before these technologies are commonplace in camelid breeding. Little or nothing is known about camelid diseases and the potential for disease control (or transmission) with semen and embryos. To our knowledge, no cria have been produced after transfer of cryopreserved embryos or oocytes, and although preliminary data suggest that ethylene glycol may be an effective cryoprotectant, no other data are available as yet. This will provide a very important first step for assisted reproduction in exotic and endangered species and provides opportunities for movement of gametes between countries around the world.

CHAPTER 124

Surgery of the Reproductive Tract in Lamoids

AHMED TIBARY

Surgery of the reproductive tract in camelids includes most of the elective procedures as well as therapeutic surgical techniques considered for other domestic species. As the practice of theriogenology in lamoids has developed in recent years more information has become available on the specific considerations in reproductive surgeries in llamas and alpacas pertaining to anesthesia, surgical approach choices, and pre- and postoperative management. The objective of this chapter is to review the most important reproductive surgeries in lamoids, including laparoscopic techniques.

GENERAL CONSIDERATIONS

As for any surgery, complete physical examination and assessment of the patient should be performed whenever it is possible and is a necessity in compromised patients. This assessment should include at least determination of packed cell volume, total protein, complete cell count (CBC), and fibrinogen. Serum biochemistry may be indicated in some patients (geriatric, depressed, or severely compromised patients), which may require fluid therapy. A jugular vein catheter should be placed in any compromised animal. Elective surgeries should be deferred if the animal shows clinical signs of illness. An accurate estimation of body weight is very important for calculation of medication (sedatives and anesthetics) dosage.

For minor elective surgeries, fasting for 12 hours and water deprivation for 6 to 8 hours is recommended before anesthesia. For more involved surgeries such as ovariectomy or ovariohysterectomy and laparoscopic techniques, food and water should be withheld for 24 and 12 hours before surgery, respectively.

During anesthesia, the most commonly encountered problems in camelids are bradycardia, excessive salivation, bloat, regurgitation, and aspiration. In the recumbent animal the poll of the recumbent camelid should be elevated by 10 cm above the rostral portion of the oral cavity to prevent pooling of regurgitated material in the pharynx and allow the excess saliva to run down freely. Bradycardia can be managed by administration on atropine (0.02 mg/kg IV or 0.04 mg/kg IM). Excessive saliva or regurgitated material may be removed by suction. Placement of nasogastric tube may help to reduce bloating.

Presurgical antimicrobials are commonly used by several practitioners.

ANALGESIA AND ANESTHESIA

Healthy subjects are generally easy to anesthetize in the field. Problems arise when the patient is compromised. For these compromised patients injectable anesthesia may not be the most appropriate choice, and gas anesthesia in a hospital setup should be considered.

Local Anesthesia

The most common local anesthesia used in reproductive surgery is epidural anesthesia and local blocks. Although lumbosacral epidural anesthesia has been described by some authors, it is rarely used because it causes muscle weakness and presents the risk of cranial spread to T10-11. Epidural anesthesia is generally performed in the sacrococcygeal space or between the first and second coccygeal vertebrae and provides perineal analgesia without

Healthy subjects are generally easy to anesthetize in the field. Problems arise when the patient is compromised. For these compromised patients injectable anesthesia may not be the most appropriate choice, and gas anesthesia in a hospital setup should be considered.

Local Anesthesia

The most common local anesthesia used in reproductive surgery is epidural anesthesia and local blocks. Although lumbosacral epidural anesthesia has been described by some authors, it is rarely used because it causes muscle weakness and presents the risk of cranial spread to T10-11. Epidural anesthesia is generally performed in the sacrococcygeal space or between the first and second coccygeal vertebrae and provides perineal analgesia without

locomotion compromise. The intervertebral space is easily identified by palpation while moving the tail up and down. The skin is shaved and aseptically prepared. An 18-gauge, 1.5-inch needle is placed on dorsal midline with the bevel facing cranially and at a 60-degree angle to the tail head. The hub of the needle is filled with the solution and advanced until the solution is pulled into the epidural space.

The duration of analgesia depends on the drug used. In the case of 2% lidocaine (0.2 mg/kg with a maximum of 1 ml per 50 kg of body weight), onset of analgesia is seen 5 minutes after administration and lasts about 1 hour to $1^1/_2$ hours. Administration of xylazine (0.1 mg/kg) provides up to 3 hours of anesthesia and the association of xylazine and lidocaine provides up to 6 hours of analgesia.

Local blocks are usually performed for abdominal surgeries with lidocaine 2% HCl. It is generally recommended to dilute this drug to 1% using isotonic bicarbonate or saline. The total dose should not exceed 4.4 mg/kg body weight (1 ml of 2% lidocaine per 5 kg of BW) to prevent lidocaine toxicity.

Sedation and Tranquilization

Sedation of the patient is accomplished easily by administration of the drug of choice intramuscularly. The most commonly used sedatives in lamoids are the alpha-2 agonists xylazine and medetomidine[1] (Table 124-1). Llamas are more sensitive to these sedatives than alpacas. Analgesia and sedation are increased by combination with butorphanol. Acepromazine is occasionally used for sedation but should be avoided in compromised animals because of its hypotensive effects and lack of reversal agents.

General Anesthesia

An association that works well in the field for anesthesia lasting 20 to 30 minutes consists of a combination of xylazine (100 mg/ml), ketamine (1000 mg/10 ml), and butorphanol (10 mg/ml). This mixture is administered intramuscularly at the dose of 1 ml/50 lb in llamas and 1 ml/50 lb plus an additional milliliter for alpacas. In pregnant animals, this association can be used for induction at half dose or with xylazine (0.05–0.1 mg/lb SQ or IM) + butorphanol (0.03–0.06 mg/lb IM).

The most commonly used induction agent is ketamine. This drug has minimal effect on the cardiovascular system, does not depress reflexes, and provides some analgesia. The major problem is that it causes muscle rigidity and increased salivation. It is better used in combination with xylazine, xylazine and butorphanol, diazepam, or guaifenesin to improve muscle relaxation (see Table 124-1).

In pregnant animals (correction of uterine torsion or cesarean section), anesthesia is generally induced with propofol (3.5 mg/kg IV) and diazepam (0.5 mg/kg IV) or guaifenesin and maintained with isoflurane in oxygen.[2] These drugs have minimal effect of the neonate. Propofol is rapidly redistributed and metabolized and diazepam has minimal placental transfer. Isoflurane is rapidly eliminated, making it well suited for cesarean section in most species.

Table **124-1**

Sedatives and Injectable Anesthetics Used in Camelids

Agent	Dose	Effect	Indications
Xylazine*	0.1–0.3 mg/kg IV 0.3–0.5 mg/kg IV	Mild to profound sedation, mild to moderate muscle relaxation, mild to moderate analgesia.	Genital manipulation, perineal surgery
Medetomidine*	0.01–0.02 mg/kg IV		
Butorphanol	0.1–0.3 mg/kg IM	Analgesia 2–4 h	Castration
	0.05–0.1 mg/kg IV	30–45 min	Preanesthetic
Butorphanol	0.05–0.1 mg/kg IM	20 min	Castration, genital examination
Xylazine	0.1 mg/kg IM		
Medetomidine	60–80 µg/kg IM	15 to 20 min	Genital examination, perineal surgery
Ketamine	2 mg/kg IM		
Detomidine	0.02–0.04 mg/kg IM	15 to 20 min	Genital examination, perineal surgery
Ketamine	2–4 mg/kg IM		
Xylazine	0.2–0.3 mg/kg IV	Anesthesia 20–30 min	Castration, laparoscopy
Ketamine	2–4 mg/kg IV		
Xylazine	100 mg	IV to effect, approximately 1–2 ml/min/50 kg body weight	Induction of general anesthesia
Ketamine	500 mg		
Guaifenesin	500 ml at 5%		
Diazepam	0.2 mg/kg IM	Immobilization 20 min	Castration, laparoscopy
Ketamine	2–4mg /kg IM		
Propofol	2–6 mg/kg IV	15–20 min	Induction for cesarean section, laparotomy
Diazepam	0.2–0.5 mg/kg IV		
Diazepam	0.1–0.5 mg/kg IV		Use in sick animals

*Reversal agents (IV): tolazoline 1–2 mg/kg, yohimbine 0.12 mg/kg, atipamezole 0.1–0.15 mg/kg.

In field practice and for rapid surgeries in healthy subjects the combination ketamine/xylazine is sufficient. The combination of butorphanol (0.1 mg/kg), xylazine (0.2 mg/kg), and ketamine (1.5 mg/kg IV) provides approximately 20 minutes of useful anesthesia for surgical procedures such as castration and testicular biopsy. I prefer to administer this combination IM. Ketamine may cause profound respiratory depression.

Triple drip (ketamine/xylazine/guaifenesin) can be administered to effect for longer duration surgeries, but anesthesia time should not exceed 1 hour. Maintenance of anesthesia can be accomplished by halothane or isoflurane in oxygen.

During recovery, the patient should be placed in sternal recumbency as soon as possible following surgery. The neck and head should be supported to prevent injury. Reversal agent should be administrated if the patient is still too sedated (see Table 124-1).

SURGERY OF THE MALE REPRODUCTIVE TRACT

Surgical procedures in the male lamoids include castration and vasectomy as well as procedures to relieve urolithiasis such as urethrotomy and tube cystomy.

Castration

Castration is the most commonly performed elective surgery in camelids. As for many species castration is indicated to prevent aggressive behavior and eliminate nondesirable males from the genetic pool. Castration may also be indicated in cases of testicular diseases.

Castration of the Normal Male

Much debate is ongoing about the most appropriate age for castration of lamoids. This is due to the effect of castration before puberty on bone growth and predisposition to arthritis. Castration at early age has been shown to delay closure of the long-bone physes, resulting in tall, straight-legged geldings and a predisposition to early onset of degenerative osteoarthritis. It is recommended that male lamoids be castrated no earlier than 15 months of age for alpacas and 18 months for llamas.[3]

Precastration considerations include thorough examination for testicular descent, lesions, and scrotal and testicular adhesions as well as evaluation of the male temperament. Presurgical administration of tetanus toxoid vaccination and antimicrobial therapy is recommended. Procaine penicillin G is generally given at 22,000 U/kg before castration and daily for 3 days.

Two techniques are used for castration of the male lamoid: scrotal and prescrotal. Prescrotal technique requires more time to complete, but is more esthetic and less painful.[3,4]

Scrotal technique. This technique is performed on the male either in the standing position or in lateral recumbency.[5,6] It is the author's preference to use the standing procedures on llamas and lateral recumbency in alpacas as the latter tend to cush, which makes manipulation and surgery very difficult and presents a risk for contamination. For standing castration sedation and analgesia is obtained by using butorphanol alone with local scrotal and testicular infiltration of lidocaine[5] or by administration of a combination of butorphanol and xylazine. Some practitioners prefer administration of an epidural, but this is generally not necessary. For recumbent patient castration a combination xylazine/ketamine or xylazine/ketamine/butorphanol is indicated. Local anesthesia of the scrotum is provided by injection of 1 to 2 ml of lidocaine 2% as a line block along the raphe median.

Fig. 124-1 Castration: scrotal incision.

Fig. 124-2 Castration: stripping of testicular cord.

The technique is not different from that described for other species. The scrotum is prepared for aseptic surgery and an incision is made along the most ventral aspect of the scrotum by holding the testicle firmly into the scrotum to make the scrotal skin tight (Fig. 124-1). The extent of the incision is determined by the size of the testicles and is generally continued until the testicle and its envelopes protrude under pressure from the skin incision. The testicle is exteriorized and held with a towel clamp while the testicular cord is gently stripped from fat and connective tissue using a piece of gauze (Fig. 124-2). The testicle is removed using an emasculator (adult llamas) or after transfixation ligation of the spermatic cord with No. 0 chromic gut (llamas) or No. 2-0 polyglactin 910 (young llamas and alpacas) (Fig. 124-3).

Fig. 124-3 Castration: placement of transfixing suture and transection of testicular cord.

Prescrotal technique. This approach requires the animal to be in a dorsal recumbency position under general anesthesia.[4] The animal is maintained in a frog-leg position by means of ropes or straps. Strict aseptic technique is critical to prevention of infection. The skin is incised on the ventral midline immediately cranial to the ventral base of the scrotum.

In the llama a 5-cm skin incision is located 2 to 3 cm cranial to the scrotum. The left testis is moved cranially by digital pressure, and a skin incision is made directly over it. The skin and subcutaneous tissues are incised to expose the parietal vaginal tunic. The tissue surrounding the tunic is bluntly dissected to free the testis and spermatic cord, which are then retracted out of the incision. The cord is ligated proximally using No. 2 chromic gut suture material and sharply incised distal to the ligature. The contralateral testis is exteriorized through the same skin incision by manipulation into the cranial position and under the penis using digital pressure and blunt dissection and incised in the same manner. Subcutaneous fascia is closed with absorbable suture (No 3-0 polyglecaprone or No. 2-0 polydioxanone) placed in a simple continuous pattern. The skin is closed with the same absorbable suture material in a continuous subcuticular fashion.

Postoperative care for castration includes antimicrobial therapy and confinement in a small pen for 24 hours. Topical antiseptic and fly spray are indicate under farm conditions. The animal should be observed for excessive bleeding or swelling, exudative discharge due to infection, and difficulty urinating. However, postcastration complications are rare, and excessive bleeding can be managed by scrotal packing with gauze. It is important to warn the client that some males may continue displaying copulatory activity even after castration.

Castration of the Cryptorchid Male

Cryptorchidism is relatively rare in lamoids but has been reported in llamas, alpacas, and vicunas. There are very few reports on surgical removal of the retained testis. Two approaches can be utilized: parainguinal approach[7] or a laparoscopic approach (see under laparoscopic surgery).

The parainguinal cryptorchidectomy approach requires the animal to be in dorsal recumbency under general anesthesia. The inguinal area is prepared and draped for aseptic surgery. The inguinal canal is located by palpation and a 1-cm skin incision is made medial to the caudal border of the external inguinal ring and extended cranially 3 to 4 cm. The incision is continued carefully through all tissue layers into the peritoneum. The abdominal cavity is entered using two fingers and the retained testicle is identified by palpation of the area around the incision. The cryptorchid testicle lies usually just lateral to the vaginal ring. Once identified the testicle is grasped and brought up to the incision site. The spermatic cord is ligated with 2-0 polyglactin 910 and resected. The internal abdominal oblique muscle is closed with 0 polyglactin 910 in a continuous pattern. The fascia of the external abdominal oblique muscle is closed with 1 polyglactin 910 in a simple interrupted or simple continuous pattern. A subcuticular closure is provided by 2-0 polyglactin 910 in a simple continuous pattern, which apposed the skin edges. Postoperative care includes limited exercise and antimicrobial therapy for 5 days.

Vasectomy

Vasectomy is mainly used for the preparation of teasers for the induction of ovulation in camelidae for the purpose of scientific studies. However, because of its esthetic advantages some breeders may opt for this technique rather than castration to sterilize males that are undesirable for reproduction.[3]

Vasectomy can be performed in the llama in a sitting or standing position after sedation, but the dorsal recumbency is the preferred position in alpacas. The scrotal skin is prepared by clipping and surgical scrubbing. Surgical drapes are placed around the scrotum. A 2- to 4-cm vertical scrotal skin incision is made slightly medial on the cranial surface of the neck of the spermatic cord. The spermatic cord is freed by blunt dissection and exteriorized with the help of hemostatic forceps (Fig. 124-4). The vas deferens can be easily identified by palpation or visually by its white color and the presence of adjacent vein and artery. The vas deferens is exteriorized using forceps or a spay hook through a small nick made in the vaginal tunic. A 3-cm portion of the vas deferens is removed after ligating each end (Fig. 124-5). The vaginal tunic does not need to be sutured. The skin is sutured, and the same procedure is repeated on the other side. Excised tissue should be submitted for histologic confirmation.

Another approach to vasectomy is to make the incision near the inguinal canal. This technique provides an easier identification of the vas deferens, particularly in individuals that have a short testicular cord. A subcuticular suture provides closure of the surgical site. Alternatively, a 2-cm segment of the ductus deferens may be excised via standard laparoscopy using a forceps scissors[8] (see discussion of laparoscopic surgery).

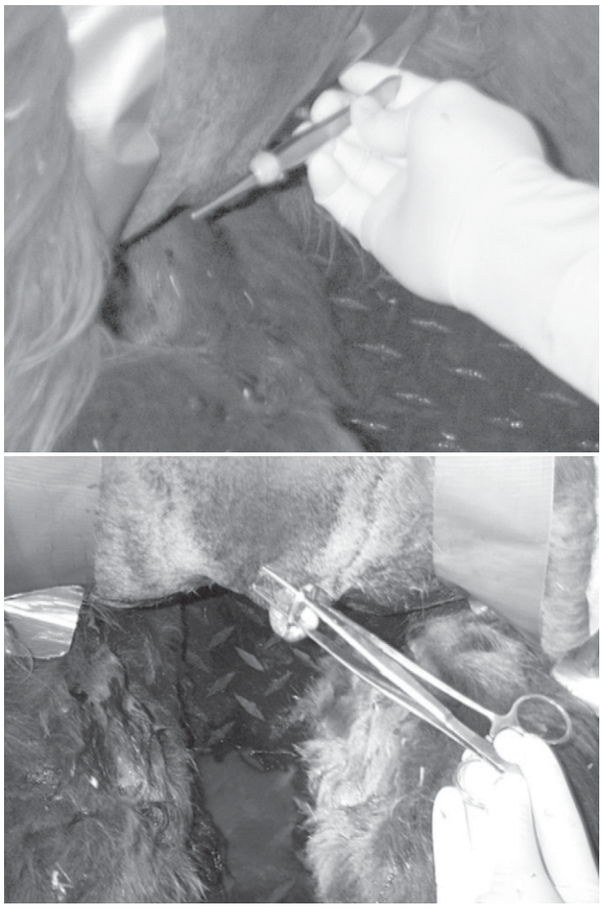

Fig. 124-4 Vasectomy: exteriorization of the testicular cord.

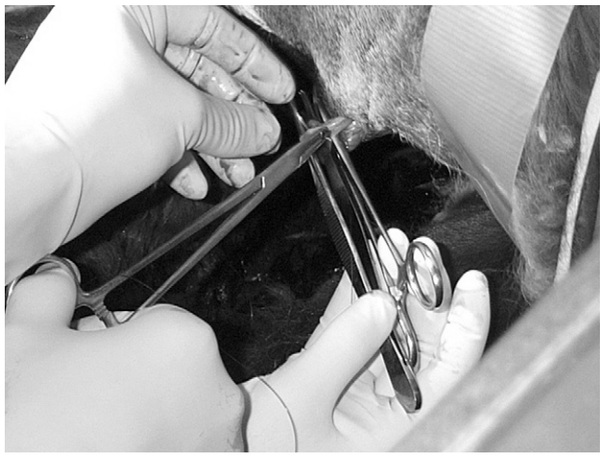

Fig. 124-5 Vasectomy: ligation and transection of vas deferens.

SURGERY OF THE FEMALE REPRODUCTIVE TRACT

Cesarean Section

Cesarean section is indicated if vaginal delivery is impossible. The most common causes of dystocia requiring cesarean section include failure of cervical dilation, uterine torsion, and fetal malpresentation. In alpacas, delivery by cesarean section may be indicated even if the fetus is dead because of the difficulty of manipulation and procedures such as fetotomy. Damage to the cervix or uterus is more likely to occur when trying to force manipulation of the fetus because of inadequate space or cervical dilation. The decision to proceed with a cesarean section should be made relatively quickly in order to improve the chances of fetal and maternal survival. If the size of the dam precludes transvaginal palpation, immediate cesarean section should be chosen.[9]

The health and degree of compromise of the parturient female and the fetus should be assessed. I recommend placing a jugular vein catheter in all females presented for dystocia. Females presenting with cardiovascular shock, dehydration, and hypotension should receive crystalloid fluids and nonsteroidal anti-inflammatory drugs. Presentation, position, and posture of the fetus may be determined by vaginal or rectal palpation. It is preferable to perform these examinations after epidural anesthesia. Viability of the fetus may be determined by transabdominal ultrasonography. However, in many cases there is no time to proceed with fetal evaluation.

Two approaches are utilized for cesarean section in lamoids: the ventral midline approach and the left paralumbar approaches.[9,10]

Ventral Midline Approach

The ventral midline approach has been suggested as the preferred approach for alpacas and llamas. This allows simple access to the abdominal cavity and complete exteriorization of the uterus with minimal hemorrhage. Anesthesia is generally induced with propofol and diazepam (0.5 mg/kg IV) or guaifenesin. Although some have used halothane, maintenance of anesthesia is usually provided by isoflurane in oxygen.[11] The patient is placed in dorsal recumbency and the ventral midline is prepared aseptically. A midline celiotomy incision (25 cm in alpacas and 35 to 40 cm in llamas) is made through the skin, subcutaneous fat, cutaneus trunci muscle, and linea alba from the cranial border of the mammary gland extending cranially (Fig. 124-6). The uterus is identified by direct palpation and exteriorized from the abdomen.[11]

An incision is made through the uterine wall over the hindlegs along the greater curvature. The cria is removed and the umbilicus clamped and transected. If the placenta is still adhered to the uterine wall, it should be left in place but peeled off along the uterine incision to provide adequate hemostasis and closure. Because of the type of placentation mural bleeding may be a problem. The margins of the uterine incision are oversewn with a continuous interlocking pattern using resorbable suture

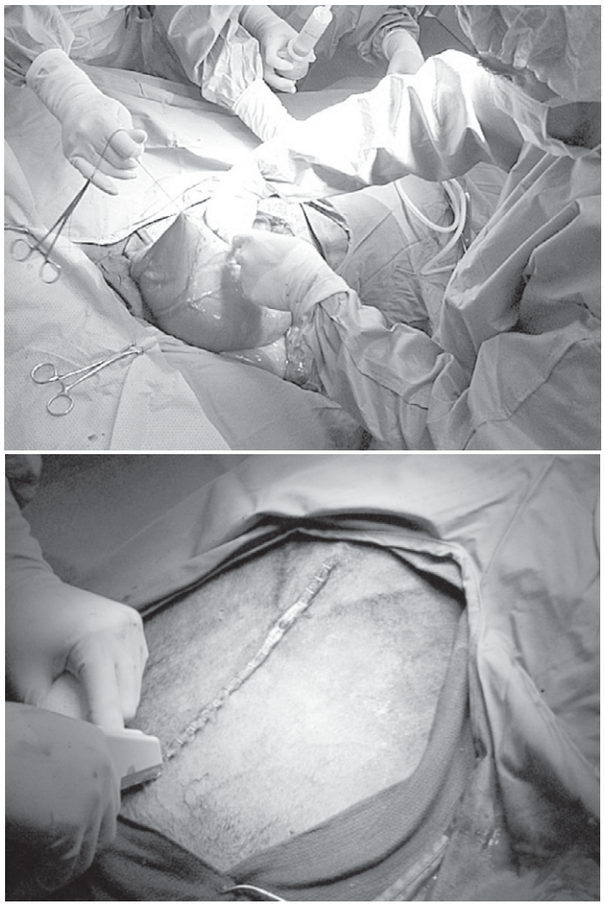

Fig. 124-6 Cesarean section: midline ventral abdominal approach; skin incision.

material (No. 1 chromic gut or smaller in alpacas) to control bleeding before closure of the uterus (Fig. 124-7). The uterine serosa is closed using No. 0 Vicryl, No. 0 polydioxanone or polyglecaprone in alpacas or No. 2 chromic gut (llamas) in a simple Cushing or Utrecht. Some practitioners prefer to administer 10 to 20 IU oxytocin in the uterine wall. The uterine wall and abdominal cavity may be lavaged with warm saline solution containing antibiotics (1 L isotonic saline solution containing antibiotics (K-penicillin G 22,000 U/kg body weight, sodium ampicillin 20 mg/kg, or sodium ceftiofur 1 mg/kg), anti-inflammatory drugs (flunixin 1 mg/kg), and heparin (20 to 40 units/kg). Carboxymethyl cellulose (CMC 14 ml/kg body weight, intraperitoneally) may be used to prevent postoperative adhesions but this has not been thoroughly evaluated in llamoids.[11,12]

The linea alba is closed by appositional pattern with interrupted horizontal mattress sutures, cruciate pattern sutures, or continuous suture pattern. In alpacas various suture materials can be used: No. 2 polyglycolic acid, No. 1 polydioxanone or polyglactin 910, No. 2 Vicryl. Closure of the skin may be done with staples, or 2 PDS horizontal mattress suture pattern, or preferably a subcuticular suture pattern (No. 2-0 polyglactin 910 or polyglecaprone); do not use skin sutures.[12]

Paralumbar Technique

The animal is sedated and restrained in a sitting sternal position. In some females only physical restraint and line or inverted "L" block anesthesia are needed. Epidural anesthesia may help restrain the animal in selected cases. The surgical site is clipped and shaved over an area extending vertically from the processes of lumbar vertebrae down and horizontally from the last rib to the hip (Fig. 124-8). The skin incision is oblique, extending from the angle formed by the hip to the bottom of the last rib. The incision line should be parallel to the direction of the thighs while the animal is sitting in the sternal position (Fig. 124-9). The muscle layers are opened by blunt dissection in a grid fashion. The peritoneum is incised and the hand of the operator is introduced into the abdominal cavity and directed caudally to the pelvic region where the uterus is identified by direct palpation. The gravid uterine horn (nearly always the left) is grasped around a fetal limb and gently exteriorized from the incision (Fig. 124-10). Uterine incision, exteriorization of the fetus, and uterine closure is conducted in the same manner described previously.[9]

The abdominal cavity is closed in three layers: (1) The peritoneum and the transverse abdominal muscle *(m. transversus abdominis)* are closed together with a simple continuous suture. (2) The internal and external abdominal muscles (*m. obliquus internus abdominis* and *m. obliquus externus abdominis*) and the subcutaneous fascia are closed in a second layer with a simple continuous suture. The suture is anchored every 2 to 3 cm to the transverse muscle to remove any dead space and prevent formation of pockets. (3) The skin is closed using a continuous interlocking suture pattern (Fig. 124-11).

Some practitioners prefer to close all muscles in one layer to provide a better support and decrease tension on each individual layer and prevent herniation. This is provided by a simple continuous suture pattern or cruciate suture pattern using No. 1 PDS or No. 1 polyglactin 910 suture.

Postoperative Care and Complications

Postoperative care includes pain management using butorphanol tartrate (0.05 mg/kg, IV) or flunixin meglumine (1 mg/kg IV, once daily) and antimicrobials in the form of benzylpenicillin (20 mg/kg IV four times daily), gentamicin sulfate (6.6 mg/kg IV once daily), or ceftiofur sodium (5 mg/kg IV twice daily). Flunixin meglumine is continued for 3 days. Antimicrobial prophylaxis should be continued for 5 to 7 days depending on the condition of the uterus and fetus at the time of surgery. Ulcer prophylaxis (e.g., omeprazole, 2 mg/kg, PO, every 12–24 hours for 5 days) is routinely administered after surgery. Fluid therapy may be indicated in some cases. The dam should be monitored for postpartum metritis and toxemia. The placenta is generally expelled within a few hours if the cervix is open or 2 to 4 days if it was closed at the time of surgery. Oxytocin administration (20 to

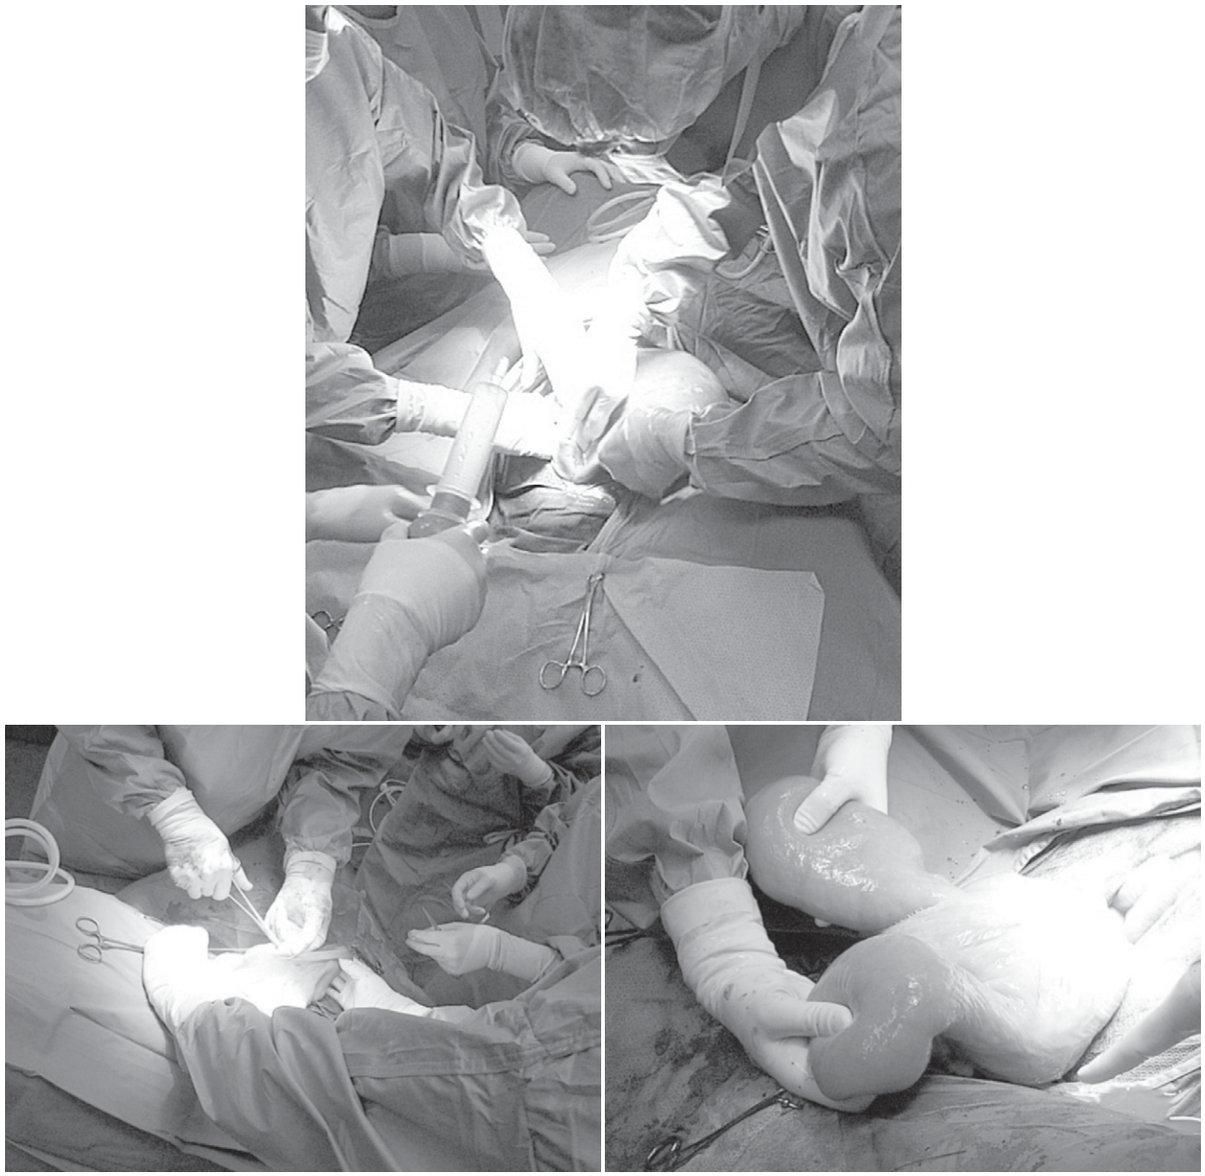

Fig. 124-7 Cesarean section: midline ventral abdominal approach; exteriorization and suture of the uterus.

30 IU, IM) every 6 hours during the first 24 hours after surgery is advocated by some practitioners.

Information regarding success rates and complications associated with cesarean section in llamas and alpacas is limited. Some of these complications include incision infection, hernia, peritonitis, intestinal adhesions, and infertility. However, these complications are very minimal when the surgery is performed early in dystocia and sterile technique is used. The rebreeding success rate is excellent, and most females will be rebred within the first 4 months after surgery.

Ovariectomy

Ovariectomy is usually performed for convenience to prevent sexual activity or eliminate pregnancy or to remove diseased organs (ovarian masses). In camelids, ovariectomy can be done via a parainguinal, ventral midline, or flank approach. The choice of a particular technique depends on the age of the animal, the side of the ovary concerned (unilateral or bilateral), and the situation of the ovary (normal versus abnormal). The flank approach can be used in multiparous animals because the

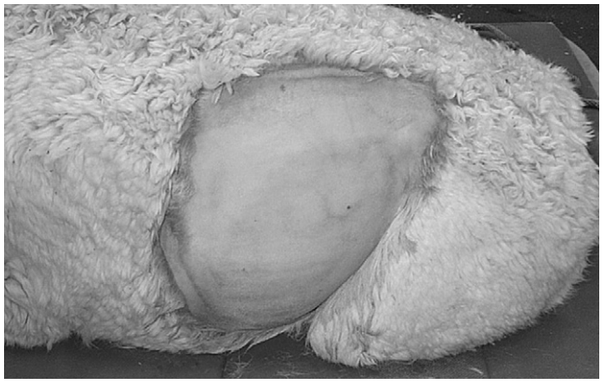

Fig. 124-8 Cesarean section: paralumbar approach; surgical site preparation.

Fig. 124-9 Cesarean section: paralumbar approach; skin incision.

Fig. 124-10 Cesarean section: paralumbar approach; exteriorization of the uterus.

Fig. 124-11 Cesarean section: paralumbar approach; skin closure.

genital tract is sufficiently developed to allow exteriorization via the flank. In young animal ovariectomy or in presence of large ovarian masses or when both ovaries need to be removed, the ventral midline approach is the preferred technique.[9] Because the uterus is extremely contracted during the follicular phase the author has found that ovariectomy and ovariohysterectomy are best accomplished after a period of progesterone therapy to simulate a luteal phase (progesterone 50 mg IM per day for 10 days). Anesthesia and preparation of the animal for ovariectomy is similar to the technique described for cesarean section. A small incision (4 to 6 cm in alpacas and 6 to 8 cm in llamas) is made through the skin and all layers of the ventral midline starting just cranial to the udder and continuing cranially. The surgeon introduces two fingers into the abdominal cavity (Fig. 124-12). The urinary bladder is identified by palpation, and the uterus is recognized in its dorsal aspect by following one of the horns to the uterine bifurcation. One of the uterine horns is grasped between the fingers and pulled toward the surgical incision. Both horns are exteriorized by gentle traction (Fig. 124-13). The ovary is exteriorized from the incision site by applying gentle traction. The vascular pedicle (proper ligament) of the ovary is isolated by passing forceps through the mesovarium and clamped with hemostatic forceps, making sure to incorporate the ovarian artery and vein. The ovary is transected after transfixion ligation with absorbable suture material. Closure of the surgical site and postoperative care are performed as described for cesarean section.[9]

Ovariohysterectomy

Ovariohysterectomy is indicated when there is uterine pathology. The procedure is done under general anesthesia with the animal in dorsal recumbency. The animal should be fasted 24 to 48 hours and receive systemic antibiotics 12 hours before surgery. Although a parainguinal approach has been described, in the author's

Fig. 124-12 Ovariectomy, incision site.

Fig. 124-13 Ovariectomy, exteriorization of the uterine horns and ovary.

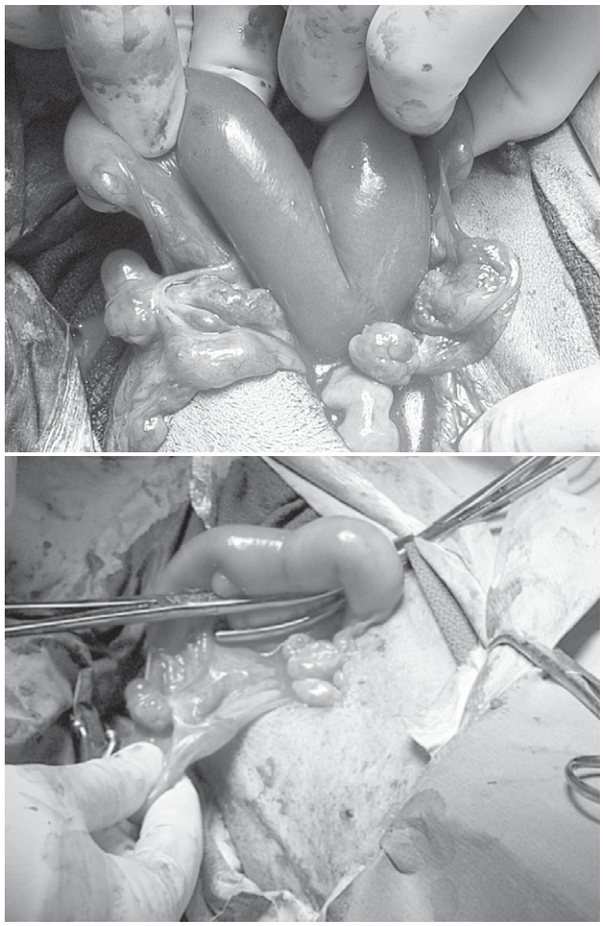

Fig. 124-14 Ovariohysterectomy: transfixion and resection of the uterus.

opinion the best surgical approach to ovariohysterectomy is the ventral midline approach. The animal is prepared as for a cesarean section. A skin incision is made from the cranial border of the mammary glands toward the umbilicus. The extent of the incision depends on the size of the uterus. The uterus is completely exteriorized from the surgical opening and all fluids present are drained with a large-bore needle attached to a flexible tube. The uterus should be flushed with saline solution and antibiotics and then sutured to avoid contamination of the abdominal cavity. All blood vessels including the ovarian and cranial uterine arteries are identified and ligated (double ligation). The broad ligament of the uterus can then be transected to allow manipulation of the uterus at the cervical level. Transfixation ligatures are placed proximal to the cervix, making sure to include the large uterine vessels located on each side. The uterus is transected at the level of the body between two hemostatic forceps (Fig. 124-14). A circumferential ligature of absorbable suture material is placed close to the cervix. If the remaining portion of the uterine body is large, it should be closed with an inverting suture pattern before replacing it in the abdomen. The vagina should be closed with overlapping mattress sutures with catgut or Vicryl. The reproductive tract is amputated proximal to the mattress sutures. The serosal surfaces of the stump are apposed by simple interrupted sutures. The abdomen is closed in the same manner as for cesarean section.[9]

Perineal Laceration Repair

Perineal lacerations are relatively uncommon but do occur in lamoids. They are usually classified using the same grading system used in the equine species.[13] The author has seen mainly third-degree and occasional second-degree perineal lacerations. The occurrence of third-degree laceration is probably due to the small perineal body, which is characteristic of this species.[13]

Superficial lacerations can be repaired quickly under local anesthesia using Caslick's procedure if the tear has already epithelialized. Second-degree laceration requires

reconstruction of the perineal body, generally after sedation and epidural anesthesia.

Repair of the third-degree perineal laceration and rectovaginal fistulae should be delayed until the tissue has granulated and epithelialized. Although some practitioners perform this operation as early as 2 weeks after injury, it is generally recommended to wait until 4 to 8 weeks post partum. Repair of third-degree laceration is preferably done on the standing sedated patient; however, the practitioner should be aware that many animals, particularly alpacas, have the tendency to go down in a sternal position during surgery. Epidural anesthesia is helpful because the rectal and vulvar tissues need to be retracted using suture or retractors. Repair techniques are similar to those described for the mare and consist of dissection of the rectal and vaginal walls with the goal of creating a new separate rectal floor and vestibular roof and reconstruction of the anus.[13]

Fig. 124-15 Truss (shoelace suture) for vaginal prolapse.

Vaginal and Uterine Prolapse

Vaginal prolapse occurs in lamoids during the last few weeks of pregnancy. Predisposing factors are age, parity, and obesity. Different degrees of vaginal prolapse may be observed, ranging from small protrusion of the vestibular area when the female is in the sitting position to permanent vaginal prolapse. Management of the condition consists of cleaning and replacement of the exposed area. The vaginal tissue is retained by truss (shoelace) pattern. This is accomplished by placing three loops of suture on each side of the vulvae and running an umbilical tape through the loops in a shoelace manner (Fig. 124-15). The manipulation may be done after epidural anesthesia or local block, depending on the extent of tissue to be replaced.

Uterine prolapse occurs in lamoids, but there are no precise data on the incidence of this problem. Most of the cases seen by the authors occurred with 2 hours of normal birth or after induction of abortion. The condition is suspected to be associated to hypocalcemia. Uterine prolapse is replaced in the same manner described for other species after epidural anesthesia. The placenta is gently peeled off the endometrium before if still present. Truss pattern is placed on the vulva to prevent recurrence of the prolapse. Prognosis for fertility depends on the health of the uterine tissue at the time of diagnosis. Complications include uterine blood vessel rupture, uterine wall laceration, and cervical laceration. Large-spectrum prophylactic antimicrobials should be administered for 5 days to prevent infectious complications. Nonsteroidal anti-inflammatory drugs may be used in the first 2 days.

Vaginal Stricture

Vaginal strictures can be congenital or acquired. Thorough evaluation of the vestibular and vaginal cavity requires sedation and epidural anesthesia. A videoendoscopy of the area may be required for completeness of evaluation. Acquired vaginal strictures are usually due to vaginal and vestibular adhesions. Congenital vaginal strictures include imperforated hymen and other serious congenital anomalies such as vaginal hypoplasia or aplasia. When evaluating vaginal strictures, it is important to keep in mind that double vagina (didelphys) may be perceived as a stricture. "Persistent" hymen may be ruptured by manual dilation or scissors. In some instance the author has used different size bougies to evaluate and expand the narrowing of the vestibular area.

Acquired vaginal adhesions may be due to traumatic lesions following dystocia. Complete vaginal occlusions are associated with pyometra or mucometra. Drainage of the uterine content can be attempted by surgical or laser removal of the adhesion. Thickness of the adhesion should be evaluated. One technique used by the author is to place a Foley catheter with the fluid-filled balloon completely against the vaginal occlusion and evaluate by transrectal ultrasonography the distance from the caudal aspect of the uterine/vaginal fluid to the wall of the balloon.

LAPAROSCOPY AND LAPAROSCOPIC SURGERY IN LAMOIDS

Laparoscopic techniques are becoming commonplace in many hospitals and referral centers for evaluation of the reproductive tract or reproductive surgeries. Laparoscopy can be performed with the animal standing or in dorsal recumbency.[14]

Standing Laparoscopy

Standing laparoscopy is performed mainly in llamas for in situ observation of the genital organs or ovariectomy. Food is withheld generally for 24 hours and water is withheld for 12 hours before surgery, respectively. Llamas are restrained in stocks and sedated with butorphanol tartrate (0.1 mg/kg BW IV). The left paralumbar fossa is prepared for aseptic surgery and 2 % lidocaine is infused into the subcutaneous and muscular tissues in an inverted "L" pattern to desensitize the region.[15]

A small (10 to 15 mm) skin incision is made in the craniodorsal portion of the fossa 4.5 cm caudal to the twelfth rib and 8 cm ventral to the transverse processes of the lumbar vertebrae. This provides a portal for a 30-degree laparoscope, which is placed after penetrating the abdominal cavity through the abdominal muscle and peritoneum using an appropriate trocar. The abdomen is distended with carbon dioxide to a pressure of 10 mm Hg. Each ovary is identified by following the respective uterine horn craniad. This manipulation may be difficult if the urinary bladder is distended. Once the genital tract has been located and inspected a second incision is made in the skin of the caudodorsal portion of the left paralumbar fossa 10 cm caudal to the twelfth rib and 10 cm ventral to the transverse process of the lumbar vertebrae. This incision will provide the portal for a manipulation instrument (grasping forceps) inserted through a cannula fitted with a sharp trocar. A small incision is then made in the skin of the caudoventral region of the left paralumbar fossa 6 cm caudal to the twelfth rib and 15 cm ventral to the transverse processes of the lumbar vertebra to provide a portal for the introduction of a ligature guide holding a loop of size 0 polydioxanone. The ovary is grasped with the forceps through the suture loop. The ligature is pushed to the level of the ovarian pedicle and tightened around it. The ligature guide is removed and scissors are introduced to cut the end of the ligature and transect the ovarian pedicle at the base of the ovary. The ovary is removed from the abdomen with the grasping forceps. All instruments are removed and excess gas expelled. The portal incisions are closed (external oblique muscle with a single cruciate 3-0 polyglyconate and skin is closed with a single cruciate suture 3-0 monofilament nylon).

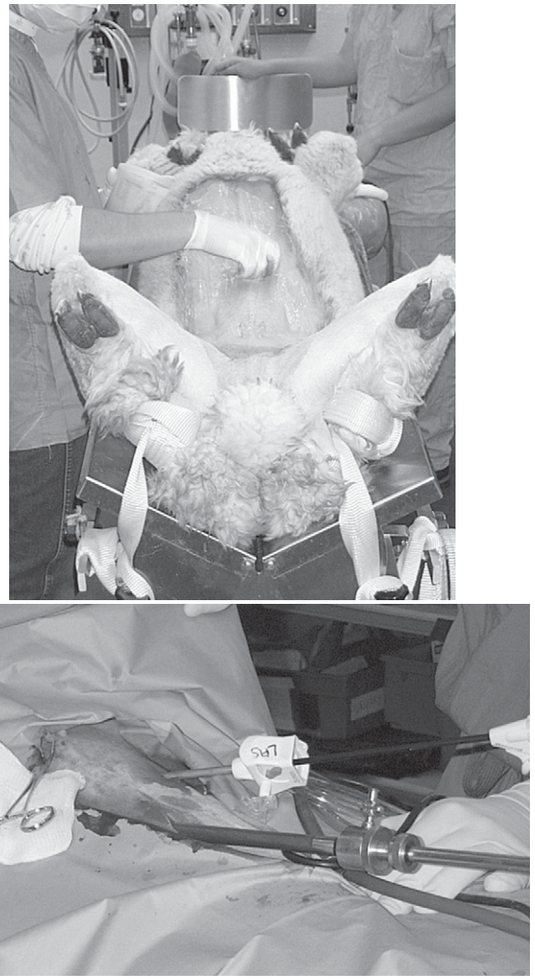

Fig. 124-16 Laparoscopy, ventral midline approach.

Ventral Abdominal Approach

This approach is very useful for examination of the reproductive tract, insemination, oocyte collection, and embryo transfer as well as ovariectomy and ovariohysterectomy.[11,14] The technique is performed under general anesthesia in a dorsal recumbency position. Quick visualization of the reproductive tract for the purpose of inspection and insemination may be done with sedation and local block.

Feed is withheld for 24 hours before surgery and antimicrobial therapy (PPG 22,000/kg IM) is given every 12 hours before and up to 72 hours after laparoscopy. Anesthesia is induced with an intravenous combination of xylazine hydrochloride (0.25 mg/kg) and ketamine hydrochloride (3.5 mg/kg) and maintained with isoflurane.

The ventral abdomen is clipped and surgically prepared from the cranial edge of the mammary gland to the xiphoid (Fig. 124-16). A small skin incision (size depending on the diameter of the laparoscope) is made in the midline at the level of the umbilicus or 3 to 5 cm caudal to it (see Fig. 124-14). The abdomen is perforated with a teat cannula and insufflated with CO_2 to a partial pressure of 10 to 20 mm of Hg. The laparoscope trocar and cannula are inserted at this level through the linea alba and peritoneum into the abdomen. The trocar is removed and replaced with a laparoscope. The pelvic inlet is identified by tilting the surgical table to 30 degrees to elevate the hind legs and displace the abdominal viscera cranially. The instrument portals are made on the left and right side of the midline midway between the scope portal and the caudal aspect of the fold of the flank.

The uterus is located under the urinary bladder and each uterine horn is followed to its tip and elevated to allow visualization of the corresponding ovary (Fig. 124-17). Atraumatic grasping forceps are used to manipulate the uterus and bladder for location of the ovaries.

For ovariectomy, the ovary is dislodged from the ovarian bursa by gentle manipulation until the mesovarium and proper ligament of the ovary are isolated. Hemostasis may be provided by two Hulka clips across the mesovarium or proper ovarian ligament or a suture loop placed around these structures. The proper ligament is incised with scissors proximal to the clips or suture.[11]

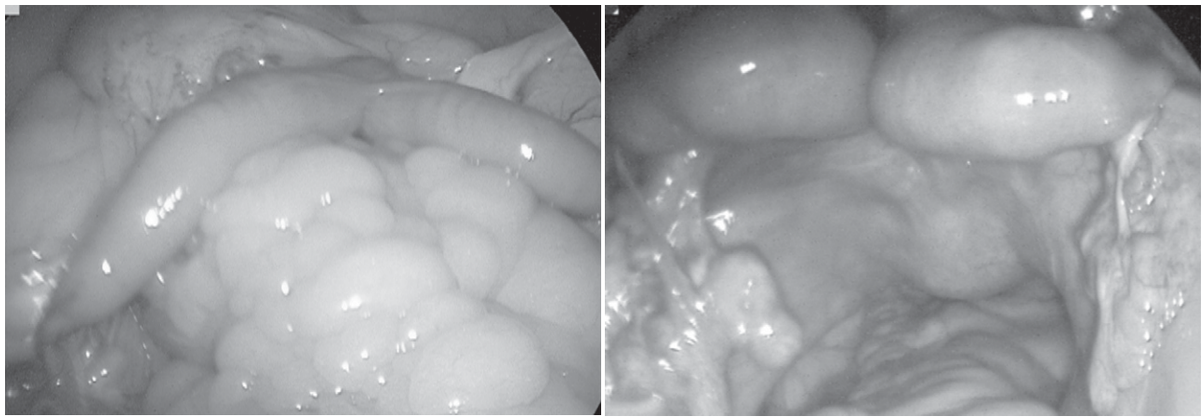

Fig. 124-17 Laparoscopy, visualization of the uterus and ovary.

Each portal, the linea alba, and the external sheath of the external abdominal muscle are closed with one simple cruciate suture of 0 polyglycolic acid and the skin is closed with 2-0 polypropylene using a simple cruciate suture.

Laparoscopic ovariohysterectomy has been described and requires good practice in the manipulation of suture and dissecting instruments through a laparoscope. The female is prepared in the same manner as for ventral midline laparoscopic ovariectomy. The procedure starts with ligation of the ovarian vessels. The mesovarium is exposed and incised after hemostasis has been ensured by a series of clips using a Ligaclip inserted into the left portal. The broad ligament is transected close to the uterine horn but avoiding the uterine artery. The broad ligament is cut caudal to the uterine body. The same procedure is repeated on the other side. Once both uterine horns are freed a ligature loop is introduced and the uterine horns and ovaries are passed through all the way to the uterine body and tightened. A second ligature loop is placed in the same manner around the uterine body to provide hemostasis. The uterus is transected after a third loop is placed along the portion of the uterus to be removed to prevent uterine content spillage. The uterus and ovaries are removed from the abdominal cavity from one of the instrument portals after increasing its size.[14]

Laparoscopic Vasectomy

Laparoscopic vasectomy has been reported in llamas and alpacas. The technique is performed on the patient in dorsal recumbency after sedation.[8] The author prefers to operate under general anesthesia. The surgical table is tilted to 45 degrees with the hindquarters elevated. Depending on the length of instrument the laparoscope portal can be at the level of the umbilical scar or more caudal while the manipulation and incision instrument portals are placed on each side of the penis about 5 cm to the rudimentary teats. The incisions for the instrument portals may be made in such a way that the skin incision is not parallel to the abdominal incision.

The ductus deferens is located at the site where it emerges through the inguinal ring where it joins the contralateral ductus deferens dorsal to the urinary bladder and 2 to 3 cm of the ductus deferens are resected between these sites.

Portal incisions are closed with simple interrupted pattern. Examination of ejaculate at 15 days and 30 days showed presence of sperm cells but no motility; after 45 days no sperm cells were found.

Laparoscopic Cryptorchidectomy

Laparoscopic cryptorchidectomy is modified from a technique described in stallions. Feed is withheld for 48 hours before surgery. Antibiotic preventive therapy consisting of IM injection of procaine penicillin G (22,000 IU/kg every 12 hours) was started 2 hours before surgery and continued for 72 hours. Anesthesia is induced with a mixture of ketamine hydrochloride/xylazine/butorphanol and maintained with isoflurane in oxygen. The patient is positioned in dorsal recumbency. The abdominal area from the xiphoid process to the inguinal region is clipped and aseptically prepared and draped for surgery.

A 5-mm stab incision is made at the umbilicus and a teat canula is inserted into the abdomen for insufflation with carbon dioxide (CO_2) to a pressure of 15 mm Hg. The laparoscope is inserted as described previously, and the surgical table is inclined in the head-down position to allow cranial displacement of the abdominal viscera and localization of the retained testis. Three instrument portals are used: two are located on the same side as the retained testis and one is on the opposite side and more cranial. All instrument portals are located within the axial one half of the rectus abdominis muscle and lateral to the midline. The portals are created by making a 1.5-cm incision through the skin and the external rectus sheath. Blunt penetration through the remaining abdominal wall is performed with a 5-mm conical tip obturator. Instruments are subsequently placed through these portals without using an outer cannula.

Once the testis is located and isolated with a manipulation rod, a grasping forceps is introduced through the

cranial portal, and a laparoscopic ligature is introduced the caudal portal. The laparoscopic ligature loop is made of polyglactin 910 (Vicryl), and modified Roeder knot is tied forming a loop. The long tail of the suture loop is threaded through a hollow steel push rod that serves to advance and tighten the slipknot (Fig. 124-18). The push rod is made by drilling a 1.2-mm hole in the end of a 10-gauge, 26.5 cm bitch catheter. The push rod and ligature is inserted into the caudal portal through an introducer sleeve. The grasping forceps is passed through the loop of ligature, and then the Chambers catheter is used to manipulate the testis into position for the grasping forceps. The testis is grasped near the head of the epididymis and elevated from the surrounding tissues. The ligature is then advanced around the testis and pedicle to a point just proximal to the epididymis. When the ligature is correctly positioned, the push rod is advanced while pulling the long tail of the loop to advance the knot and tighten the ligature. The testicle is divided distal to the ligature using scissors placed through the opposite portal. The suture material is cut approximately 1 cm from the knot. After transection, the ligated pedicle is observed for hemostasis. The scissors and push rod were removed from the abdomen. A pair of forceps is passed through the caudal portal, and the testis is transferred to them and removed from the abdomen. After removal of the testicle, the abdomen is decompressed and the operative table returned to a horizontal position. The laparoscopic portal is closed with polyglactin 910 in a figure 8 pattern. All skin incisions were apposed with a subcuticular, simple continuous pattern of polyglyconate, then sealed by application of cryoacrylate, taking care not to interpose the glue between wound edges. Skin adhesive is applied around the incision sites to facilitate application of elastic bandage tape.

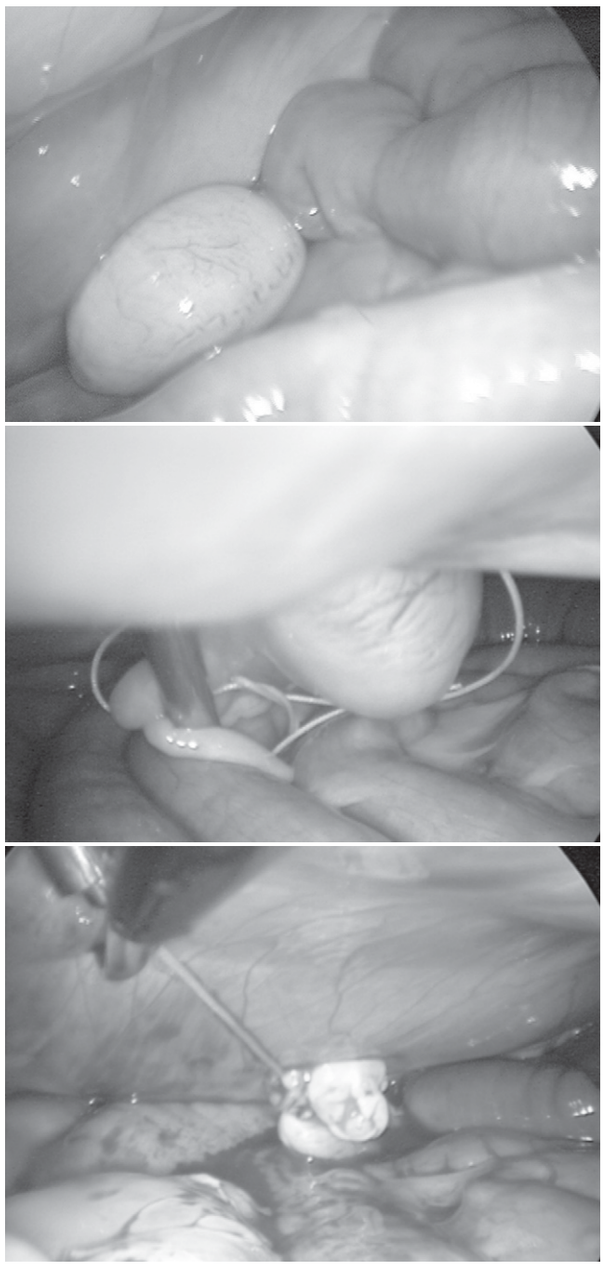

Fig. 124-18 Laparoscopic cryptorchidectomy.

SURGERY FOR SPECIAL REPRODUCTIVE PROCEDURES

The surgical techniques described so far are standard technique to access any part of the cranial reproductive tract in the female Camelidae and can be used for some special reproductive procedures such as direct transfer of embryos in the uterine lumen (surgical embryo transfer), collection of early stages of development of embryo from the uterine tube, gamete intrafallopian transfer (GIFT), and follicular aspiration for oocyte collection, although this latter technique is quickly being replaced by ultrasound-guided transvaginal aspiration.

Collection of oviductal stage of embryo development and GIFT are easily accomplished when the ovary, ovarian bursa, and uterine tube are exteriorized. Transfer of gametes is readily accomplished by injecting them directly into the uterine tube after catheterization. The oviduct is catheterized by placing a plastic catheter from the infundibular end and maintaining it in place with forceps. Oviductal flushing may be used to evaluate uterine tube patency in females with longstanding infertility.

Embryo collection is generally done under general anesthesia. An area similar to that described for ovariectomy or ovariohysterectomy is prepared for surgery and draped. The uterus and ovaries are located and exteriorized as described earlier. The ovaries are inspected for numbers of corpora lutea (Fig. 124-19). During the procedure, the uterine horn should not be allowed to dry out. This is accomplished by lavage with sterile saline. Each horn is flushed separately. A small incision is made at the base of the horn, and a Foley or Argyle silicon No. 10 catheter is introduced and maintained in place

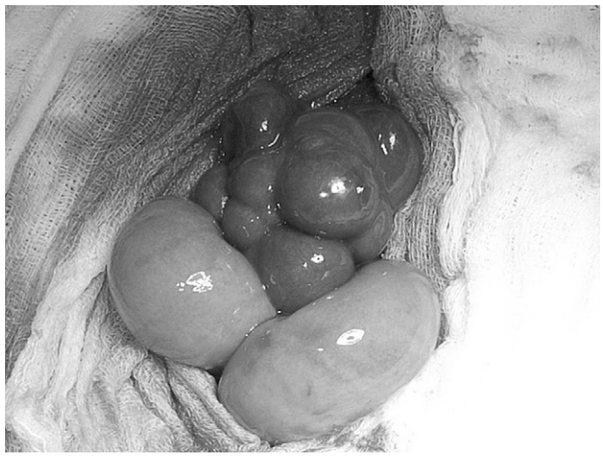

Fig. 124-19 Surgical embryo transfer collection, corpora lutea.

Fig. 124-20 Surgical embryo transfer, uterine flushing.

by inflating the cuff (Fig. 124-20). The uterine horn is flushed from the uterotubal junction toward the base. There is no need to suture the uterus if the suture in the endometrium is not prolapsing through the uterine incision. The linea alba, subcutaneous tissues, and skin are closed routinely as described earlier.

CHAPTER 125

Reproductive Cycles in Female Cervids

GEOFFREY WILLIAM ASHER

The cervids are a complex assemblage of taxa that include 43 species and 206 subspecies[1] characterized by extreme diversity in morphology, physiology, ecology, and geographic distribution. It is important to recognize that in any consideration of reproductive functions no one species represents a "typical" deer. For example, some cervids exhibit highly seasonal patterns of births in cool temperate climes, and others are completely aseasonal in equatorial regions. Furthermore, many species are strictly monovular and bear single offspring annually, whereas others are normally polyovular and bear multiple offspring.

An increased understanding of reproductive function in cervids over the last few decades stems largely from the growing importance of various deer species in agriculture (e.g., deer farming) and ex situ conservation efforts (e.g., captive breeding of endangered species). In general, the research has been directed toward successful application of assisted reproductive technologies to manipulate the genetic constitution of populations (e.g., selection for improved performance traits; avoidance of inbreeding depression) or to increase rates of propagation of specific genetic lineages. There is also a growing awareness of understanding reproductive patterns to assist in the management of under- or overabundant wild deer populations.

However, it should be emphasized that studies to date have focused on a few key species that do not necessarily reflect the full range of cervid physiology. For example, considerable research investment has been directed at the reproductive and genetic management of farmed deer, such as European red deer (*Cervus elaphus* spp. *scoticus, hippelaphus*), North American wapiti (*Cervus elaphus* spp. *nelsoni, roosevelti, manotobensis*), European fallow deer *(Dama dama dama),* chital deer *(Axis axis),* and rusa deer *(Cervus timorensis).* All tend to be genotypes that exhibit notable gregariousness and are adapted to mixed browsing/grazing. Farmed species, therefore, represent a specific subset of the entire cervid genome biased toward the larger-bodied, monovulatory species with a high degree of behavioral plasticity. Many other cervid species not used for agricultural purposes exhibit different behavioral and reproductive characteristics, particularly smaller-bodied, forest-dwelling browsing cervids of tropical regions.

REPRODUCTIVE STRATEGIES

Seasonal Breeding

The necessity for most cervid species to give birth at an appropriate time of year for optimal survival and growth of offspring has exerted considerable influence on their reproductive physiology. Species of northern temperate origin, which constitute the majority of farmed deer, typically conceive in autumn and calve in summer, whereas species of tropical origin exhibit limited seasonality or are completely aseasonal.[2]

The endogenous mechanisms governing seasonal reproductive patterns in temperate species are robust, being manifest rigorously when animals are transferred between localities despite subtle variations in climate and seasonal feed supply. Furthermore, transference across the equator results in an exact 6-month phase change, even though the relationship between season and feed production differs considerably between continental Northern Hemisphere and insular Southern Hemisphere environments.[3]

It is now well established that entrainment of seasonal reproductive cycles of temperate cervid species is affected by endogenous recognition of photoperiodic changes, with the majority of species initiating mating activity during decreasing day length of late summer and autumn. Variations in the actual mating season between species of up to 8 weeks usually offsets genetically determined species differences in duration of gestation, such that parturition in most species occurs in midsummer.

The translocation of cervid species outside their natural latitudinal ranges is often associated with reproductive maladaptation to the new environment, even after decades of acclimatization. There have been recent attempts to establish temperate species, such as red deer and fallow deer, in equatorial zones (despite the presence of locally adapted cervid species). Anecdotal evidence indicates that removal of photoperiodic signals has had a marked effect on the overall physiology of these deer. For example, fallow deer translocated from New Zealand to southeast Asia exhibited apparent "desynchronization" to the extent that 70% of does became anovulatory at the time of joining during their "normal"

breeding season. This situation was subsequently corrected by strategic administration of melatonin implants for periods of 2 to 3 months.

Even the translocation of temperate species back into different temperate environments can be associated with a degree of reproductive maladaptation. For example, red deer and fallow deer of northern continental origin have frequently been translocated to Southern Hemisphere environments over the last century. Despite this period of acclimatization and the obvious successes in colonizing new habitats, reproductive patterns still strongly adhere to ancestral adaptations. Such reproductive seasonality has obvious beneficial consequences for the species within their traditional environment. However, translocation to more moderate, insular Austral environments has been associated with a degree of misalignment between reproductive seasonality and seasonal changes in feed availability. This has been particularly noticeable for deer farmed on pastoral environments in which peak feed production generally occurs 2 to 3 months before calving/lactation.[3]

Prolificacy and Fecundity

With few exceptions, cervid species generally reproduce annually, irrespective of whether they are seasonal or aseasonal breeders. Therefore, variation between species in reproductive prolificacy largely reflects species differences in fecundity (e.g., ovulation rate, litter size). Some species are strictly monotocous (bear singleton offspring) and others are polytocous (capable of bearing multiple offspring). This divergence in reproductive productivity has been linked to the overall life strategies of the various species, based on the principles of "r" and "k" selection.[4] In general, the monotocous "k-selected" species represent the larger-bodied, long-lived, later-maturing roughage feeders (i.e., grazers) and include most species within the genera *Cervus* (red deer, wapiti), *Dama* (fallow deer), *Axis* (chital deer), and *Rangifer* (reindeer, caribou). These species characteristically form stable populations within climax vegetation zones (e.g., grasslands). Although twinning has been recorded in these species, its incidence is generally below 1% of all births.

The polytocous "r-selected" species generally represent the smaller-bodied (moose are the obvious exception), shorter-lived, early-maturing selective browser/concentrate feeders and include most species within the genera *Odocoileus* (white-tailed deer, black-tailed deer, mule deer), *Alces* (moose), *Capreolus* (roe deer), etc. These species are characterized by their ability to rapidly infiltrate and populate disturbed habitats (e.g., seral vegetation communities) but are generally displaced within climax communities. In many such species, twins and triplets are the norm if environmental conditions (e.g., feed supply) favor investment into high reproductive rates (e.g., white-tailed deer, *Odocoileus virginianus*). These species also tend to be short-lived and are generally more susceptible to diseases than "k-selected" species.

ESTRUS AND OVULATION

The processes of estrus and ovulation are closely aligned, both physiologically and temporally, to ensure fertilization of ova. Recent studies of red deer, wapiti, and fallow deer have demonstrated that the temporal sequence of ovarian and endocrine events associated with estrus/ovulation share considerable similarity to those observed in other ruminant species.

The preovulatory period (up to 48 hours before ovulation) is characterized by a number of precisely orchestrated events: (1) the demise of luteal tissue (luteolysis) from a previous ovulation (often a "silent" ovulation, see later discussion) that causes a rapid decline in blood progesterone concentrations; (2) the emergence of a dominant estrogenic follicle that progressively secretes estradiol into the peripheral circulation; and (3) a subtle but perceptible change in the dynamics of pituitary secretion of luteinizing hormone (LH) in response to follicular estradiol secretion.

The onset of behavioral estrus in all species studied coincides with a marked elevation in plasma estradiol concentrations in the peripheral blood and the onset of the preovulatory LH surge (i.e., a massive, sustained increase in plasma LH concentrations that ultimately leads to follicular rupture/ovulation) (Fig. 125-1). It is highly likely that, as in other ruminants, secretion of estradiol by the emergent follicles attains a plasma threshold that instigates both estrus and the LH surge. Such elevations in peripheral blood have also been observed in white-tailed deer, reindeer, and axis deer. In fallow deer, in addition in increased estradiol secretion, a notable increase in plasma androstenedione concentrations has been observed at the onset of estrus. This weak androgen is also likely to be of follicular origin and may have a role in estrous behavior in this species.

Although behavioral estrus is usually terminated at copulation (i.e., within a hour of onset) in studied cervid species, the preovulatory LH surge persists for ~18 hours, reaching a peak 10- to 20-fold higher than basal values, 3 to 8 hours after the onset of estrus (see Fig. 125-1). The LH surge is a mandatory prerequisite for follicular rupture, which has been timed in both red deer and fallow deer to occur 24 hours after the onset of estrus/LH surge. This timing is in very close agreement with studies on sheep and cattle.

Estrous Cycle

With few exceptions (e.g., roe deer), female cervids are polyestrous, and nonpregnant animals are capable of exhibiting either continuous estrous cycles (e.g., some tropical species) or, more commonly, alternating periods of estrous cyclicity and anestrus (Fig. 125-2). Estrous cycles have been characterized for a number of cervid species based on studies on recurrent estrous behavior and luteal secretion of progesterone in nonpregnant females (Table 125-1).

The estrous cycle consists of a number of discrete luteal events of highly specific duration. Although there is a high degree of similarity in luteal events among various cervid species, there are subtle variations in the time courses that give rise to differences in species–specific estrous cycle lengths (i.e., the interval between two successive estrous episodes) (see Table 125-1).

Luteinization of postovulatory follicles (i.e., luteal phase) is associated with increased secretion of

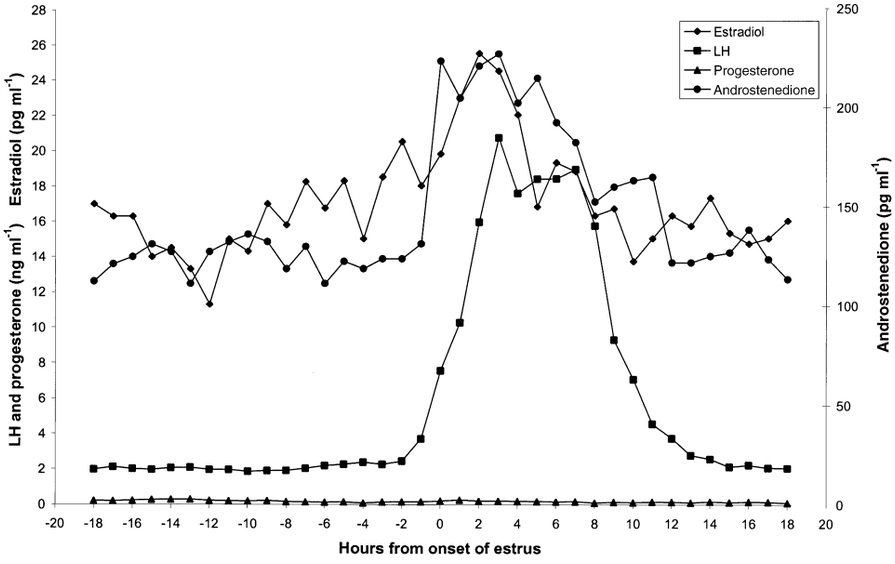

Fig. 125-1 Mean plasma concentrations of luteinizing hormone (■), progesterone (▲), estradiol (◆), and androstenedione (●) around the onset of estrus of a fallow deer doe. (From Asher GW, Barrell GK, Peterson AJ: Hormonal changes around estrus of farmed fallow deer, *Dama dama*. *J Reprod Fertil* 1986;78:487–596.)

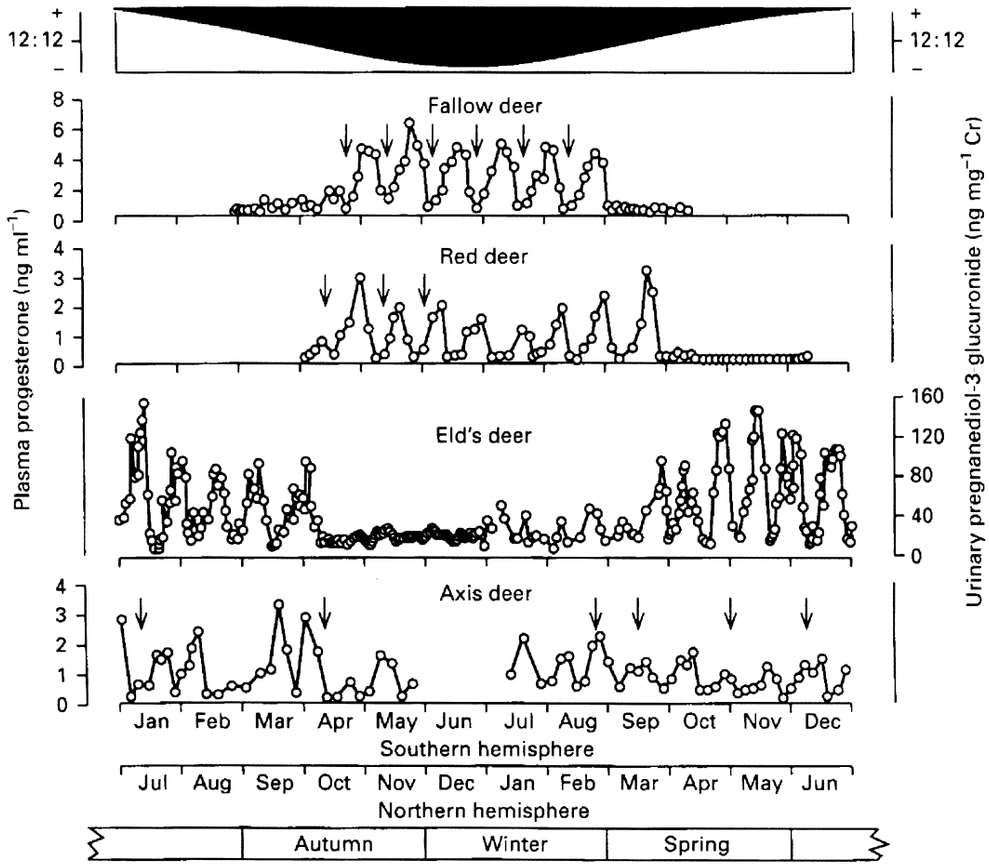

Fig. 125-2 Estrous/luteal cycles in temperate (fallow deer, red deer) and tropical (Eld's deer, chital deer) species in temperate environments, as defined by peripheral plasma progesterone concentrations or urinary pregnanediol metabolite concentrations during the annual cycle of nonpregnant females. The data have been normalized about common hemispheres and placed in relation to relative annual changes in photoperiod. Arrows indicate observed estrous behavior. (From Asher GW, Montfort SL, Wemmer C: Comparative reproductive function in cervids: implications for management of farm and zoo populations. *J Reprod Fertil Suppl* 1999;54:143–156.)

Table **125-1**

Summary of Reproductive Parameters for Various Cervid Species

Species	Common Name	First Estrus of Season*	Estrous Cycle Length (Days)	Potential Cyclicity (Months)	Birth Period*	Gestation Length (Days)	Notes
Cervus elaphus	Red deer	Oct	18–19	5	June	234	Estrous cycle length increases during the season
Cervus elaphus	Wapiti	Sept/Oct	19–20	5	June	247	
Cervus elaphus	Red deer × wapiti	Sept/Oct	19	5–6	June	240	
Elaphurus davidianus	Pere David's deer	Aug	19.5	5–6	May	284	Unusually long gestation length
E. davidianus × *C. elaphus*	PD × red deer	Sept/Oct	19.6	5	June	240–274	Highly variable gestation length
Dama dama dama	European fallow deer	Oct	21–24	5–6	June	234	Estrous cycle length increases during the season
D. d. mesopotamica	Mesopotamian fallow deer	Sept	20–22	—	May	~234	
D. d. dama × *D. d. mesopotamica*	Fallow deer hybrids	Sept/Oct	20–23	5–6	May/June	226–240	
Cervus unicolor	Sambar deer	Jan–March	20	4–5	Oct–Dec	247	Tropical species studied in temperate zones
Cervus timorensis	Rusa deer	Jan–March	18	—	Oct–Dec	249	Tropical species studied in temperate zones
Cervus eldi	Eld's deer	Jan–March	18.5	7.8	Aug–Oct	236	Tropical species studied in temperate zones
Axis axis	Chital deer	All months	18–19	Year round	Year round	235	Tropical species studied in temperate zones
Cervus nippon	Sika deer	Oct/Nov	21	—	June	224	
Odocoileus virginianus	White-tailed deer	Oct/Nov	21–30	6–7	May/June	200	Species occupies a wide latitudinal zone
Odocoileus hemionus	Black-tailed deer	Nov	21–26	4–5	June	201	Estrous cycle length increases during the season
Alces alces	Moose	Oct	24	5–6	May/June	231	North American subspecies
Capreolus capreolus	Roe deer	July/Aug	Monovulatory	—	May/June	259–300	Exhibits delayed implantation
Rangifer tarandus	Reindeer	Sept/Oct	21	>5	May/June	216	Domesticated form of caribou
Muntiacus reevsi	Reeve's muntjac	All months	14–15	Year round	Year round	210	Tropical species studied in temperate zones
Pudu pudu	Pudu	Sept/Nov	~11	—	April/Aug	200	Wide breeding seasons

*Season given as Northern Hemisphere equivalent for species studied in the Southern Hemisphere.
Data in table compiled from multiple reference sources.

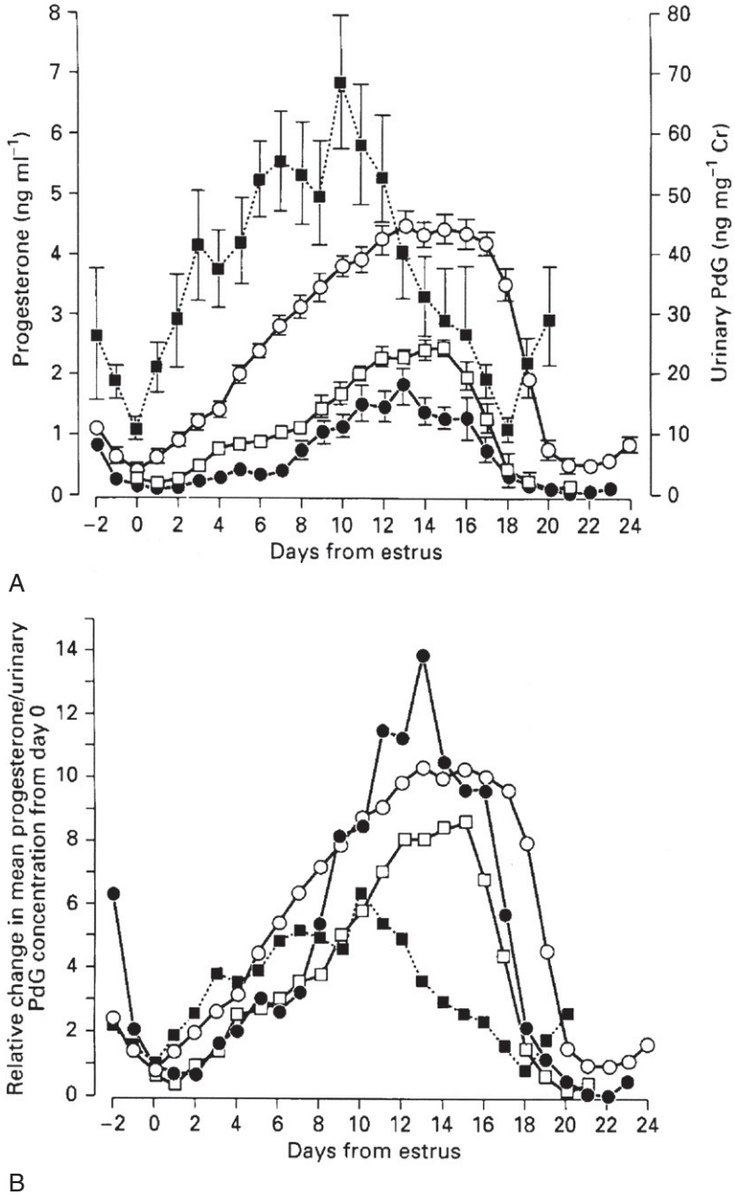

Fig. 125-3 Profiles of mean peripheral plasma concentrations of progesterone *(solid line)* or urinary concentrations of pregnanediol metabolite *(dashed line)* during the cervid estrous cycle for fallow deer (○), red deer (□), axis deer (●), and Eld's deer (■). **A,** Mean (±SEM) values. **B,** The same data presented as relative change in mean concentrations from day 0. (From Asher GW, Montfort SL, Wemmer C: Comparative reproductive function in cervids: implications for management of farm and zoo populations. *J Reprod Fertil Suppl* 1999;54: 143–156.)

progesterone, with maximal output occurring between days 10 and 16 of the estrous cycle (day 0 = estrus). In the absence of a preimplantation embryo, the new corpus luteum then undergoes luteolysis between days 16 and 23 in response to an interplay between luteal secretion of oxytocin and uterine secretion of prostaglandin $F_{2\alpha}$ (as demonstrated for red deer, fallow deer, and reindeer). This causes a rapid drop in peripheral blood progesterone levels, leading ultimately to estrus/ovulation. Although absolute plasma progesterone concentrations during the estrous cycle vary among species (Fig. 125-3, *A*), the relative changes from day 0 are quite similar between species (Fig. 125-3, *B*). Average duration of the normal estrous cycle ranges from 17 days in some tropical species of deer to 18 to 20 days in red deer, 21 to 23 days in fallow deer, and 24 to 27 days in moose and black-tailed deer (see Table 125-1). The mean duration of the estrous cycle tends to increase progressively during the breeding season in red deer, fallow deer, and black-tailed deer. In a number of species occasional "long-cycles" (two to three times normal duration) have been observed, but their significance is unknown.

The transition into the breeding season is characterized by "silent ovulations" (i.e., ovulations not preceded by overt estrus) and short-lived (8–10 days) corpora lutea in most species studied. In fallow deer, multiple successive silent ovulations leading up to the start of the breeding season have been observed. The transient nature of the preliminary corpora lutea may actually serve to promote within-herd synchrony of first overt estrus of the season.

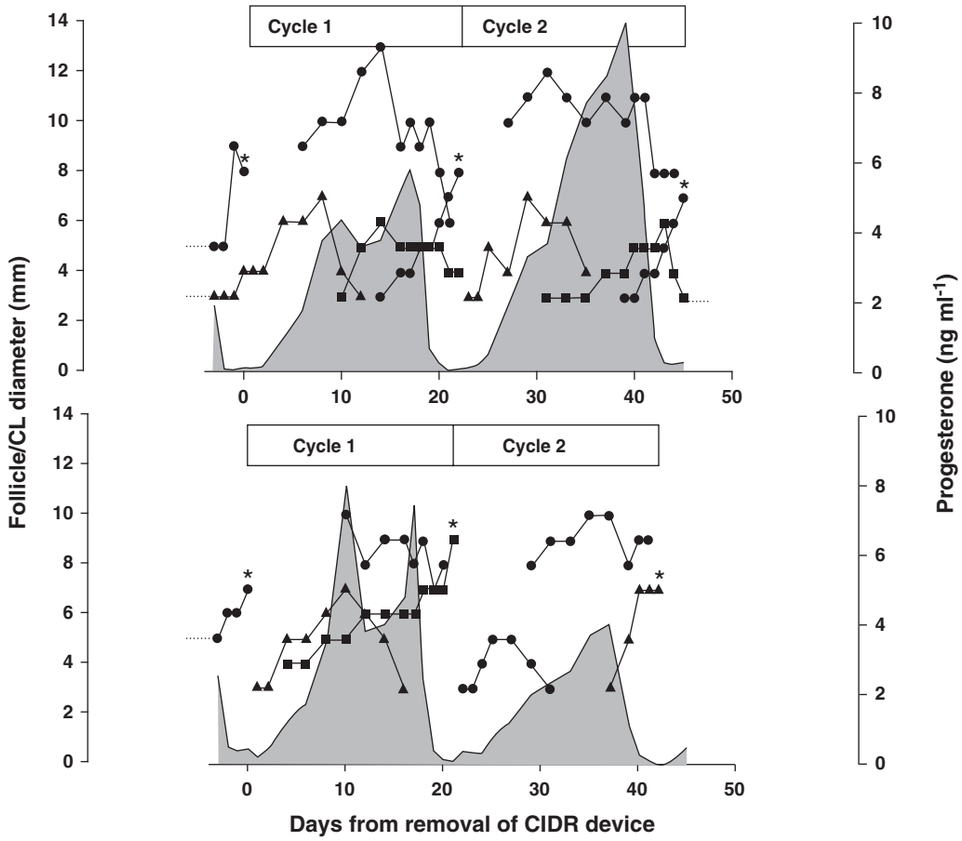

Fig. 125-4 Profiles for fallow deer does of plasma concentrations of progesterone *(shaded profiles)* and diameters of corpora lutea (○, ▲, ■) during two consecutive estrous cycles. Asterisks denote abrupt follicular disappearance indicative of ovulation. (From Asher GW, Montfort SL, Wemmer C: Comparative reproductive function in cervids: implications for management of farm and zoo populations. *J Reprod Fertil Suppl* 1999;54:143–156.)

When considering cervid estrous cycles it is important to maintain the perspective that continuous estrous cyclicity is not a normal phenomenon for most female cervids, particularly those species that exhibit highly seasonal breeding seasons. Although a return to estrus/ovulation following conception failure increases opportunities to establish a later pregnancy, evolutionary pressures for maintaining a highly synchronous calving season at an optimal time of year are very rigorous. The penalties, in terms of neonate death, for conceiving and calving later in the season are often high, particularly in harsh environments. Therefore, many seasonally breeding cervids exhibit exceptionally high rates of conception to their first estrus of the breeding season (~85% in red deer and fallow deer), and subsequently terminate further ovulatory activity for the season.

Ovarian Follicular Dynamics

The patterns of ovarian follicular turnover during the estrous cycle and anestrous period have been described from recent ultrasonographic studies on red deer, wapiti, and fallow deer. Understanding these patterns will assist in future development and fine tuning of assisted reproductive technologies.

Follicle changes during the estrous cycle of deer have shown considerable similarity to those of cattle. Discrete, nonrandom patterns of follicle emergence, growth, and regression are indicative of the existence of (1) strong dominance by a single follicle and (2) discrete dominant follicle waves within the estrous cycle. In the case of red deer, normal estrous cycles were characterized by a variable number (one to three) of dominant follicle waves within each cycle, with only the final dominant follicle present during luteolysis ovulating. In fallow deer and wapiti, estrous cycles were observed to have two to four dominant follicle waves (Fig. 125-4), with the number of waves correlated with cycle length (ranging from 21–23 days). Emergence of new small follicles generally occurred only following the demise of the larger dominant follicles, particularly after ovulation (i.e., during the early luteal phase of the new estrous cycle) when progesterone secretion was minimal.

The anestrous period in nonpregnant red deer is generally characterized by anovulation, the complete absence of luteal tissue and minimal blood progesterone concen-

trations (exceptions to this include persistent corpora lutea remaining from the end of the breeding season in some nonpregnant hinds). However, anestrus, from late spring through to early autumn, is a very dynamic state, as evidenced from studies on pituitary LH secretion. This is reflected strongly in patterns of follicle turnover. Ultrasonographic scanning in early, mid-, and late anestrus has revealed markedly differing patterns of follicle emergence, growth, and regression. In particular, mid-anestrus appears to be a state of more rapid turnover of smaller follicles than during periods of transition in or out of the breeding season. The implications of such observations on control of seasonal breeding patterns remain to be seen.

PREGNANCY AND PARTURITION

Fertilization and Embryonic Development

Few studies have focused on aspects of fertilization and early embryonic development in deer. Recent research on red deer reflects the growing importance of this species in agriculture. These studies have largely sought to characterize the natural (in vivo) developmental sequences (Table 125-2) in order to successfully develop assisted reproductive technologies (e.g., embryo transfer, IVEP) to facilitate genetic management of farmed red deer.

In red deer, oocyte nuclear maturation prior to ovulation appears to be similar to that of other ruminant species. Oocytes are ovulated at the MII stage 20 to 24 hours after the onset of the preovulatory LH surge. A polar body is clearly visible in the perivitelline space. The surrounding *corona radiata* cells appear to be lost within 6 hours of ovulation.

Motile spermatozoa have been seen in the red deer oviduct as early as 8 hours after coitus, but probably actually reach the oviduct within minutes of mating. Fertilization and pronuclei formation are quite rapid. As with cattle, syngamy has been observed within 13 hours of ovulation.

Embryonic development up to days 5 to 6 from estrus (i.e., up to 16 cell/morula stages; see Table 125-2) occurs in the oviduct. Thereafter, the embryo enters the uterus to complete its development. This is later than occurs in sheep but is similar to horses. Subsequent embryo

Table **125-2**

Sequence of Events and Embryonic Development in Red Deer

Time from Onset of Estrus	EVENT/CONCEPTUS STAGE		
	Study 1	*Study 2*	*Study 3*
20–24 h	Ovulation	—	—
29–33 h	Fertilization	—	—
30–38 h	Male and female pronuclei formed	—	—
90 h (4 d)	8-cell embryo	—	—

2. Peterson AJ, Ledgard AM, Berg DK: Conceptus development and associated fertility in red deer *(Cervus elaphus)* from days 11 to 25 after mating. *Theriogenology* 1997;47(1):402.

3. Demmers KJ, Jabbour HN, Deakin DW, Flint APF: Production of interferon by red deer *(Cervus elaphus)* conceptuses, and the effects of roIFN-t on the timing of luteolysis and the success of asynchronous embryo transfer. *J Reprod Fertil* 2000;118:387–395.

development (see Table 125-2) follows a similar pattern to other ruminant species.

Interestingly, conception rates in red deer are some of the highest recorded for domesticated ruminants, being in the order of 80% to 85% within 7 days of mating. Furthermore, subsequent embryo survival rates up to 20 days from mating are very high (probably >95%). No distinguishing features of early embryonic development explain the differing fertility among ruminant species.

Maternal Recognition of Pregnancy

Almost all cervids exhibit estrous cycles that may be terminated by successful conception. Repeated cycles reflect cyclic formation and destruction of corpora lutea, whereas pregnancy blocks the luteolytic process and allows persistence of corpora lutea. Luteolysis is the result of interplay between the hormones oxytocin and prostaglandin. In red deer, the end of the luteal phase (days 16–18 of the estrous cycle) is associated with increased uterine oxytocin sensitivity leading to a cascade of pulsatile release of oxytocin and prostaglandin $F_{2\alpha}$. This ultimately precipitates luteal regression and the concomitant decline in progesterone secretion. The pulsatile release of these two hormones is suppressed in the presence of a preimplantation embryo, presumably as a consequence of the release of an embryonic signal. As in other ungulate species, this signal is believed to be a specific form of interferon. This is supported by studies showing that uterine flushings from pregnant red deer hinds contain interferon and the preimplantation embryo secretes the interferon molecule following in vitro culture for 24 hours. In addition, administration of exogenous interferon in the mid-late luteal phase of the estrous cycle extends the luteal lifespan by suppressing uterine oxytocin sensitivity and pulsatile release of prostaglandin $F_{2\alpha}$.[11]

Postconception Ovulation

Postconception ovulation, leading to the development of accessory corpora lutea, is a phenomenon observed in red deer, wapiti, white-tailed deer, and sika, but does not appear to have been seen in fallow deer. Its incidence is particularly high in wapiti (~60–80% of pregnancies). Accessory corpora lutea are noticeably younger than corpora lutea derived from the "estrous" ovulation, and appear to form from ovulations occurring during the later preimplantation embryo development phases. The mechanisms and functions of postconception ovulation and luteal development are unknown for deer. It does seem likely, however, that the additional luteal tissue assists in pregnancy maintenance by increasing circulating peripheral concentrations of progesterone.

Embryonic Implantation

Based on two studies on red deer only, embryonic implantation in cervids occurs about 20 to 21 days after mating. At this stage of development, embryonic expansion is complete and the trophoblast is in close apposition over the entire surface of the endometrium and the head and tail regions of the neural tube remain open with 12 to 15 pairs of somites. The yolk sac has vascularized and a two-chambered beating heart can be observed. The allantois is just visible as a club-like protuberance from the hindgut (see Table 125-2).

Placentation and Fetal Development

Ruminant placentation is typically superficial (the blastocyst elongates, filling both uterine horns, and the trophoblast attaches to the uterine epithelium) and polycotyledonary. In most cervid species studied, placentation is oligocotyledonary, with 6 to 12 placentomes formed, and synepitheliochorial (six tissue layers separate the maternal and fetal circulation). Fetal and placental growth has been most intensively studied in red deer, based on accounts of dissection and real-time ultrasonography.[12,13] The gestational period from days 27 to 55 is arguably the most interesting in terms of fetal development and placentation.

Following embryonic implantation around 20 to 21 days from mating, the trophoblast expands and infiltrates both uterine horns. By day 27 the fetus is about 6 mm long and has a discernible two-chambered heart. The amnion and yolk sac are present, but there is little evidence of placentomes at this stage. By day 34, at about 13 mm in length, the fetus has undergone considerable development, with limb buds and head prominent. The yolk sac has diminished and the allantois fills the entire chorion. Plaques are appearing on the trophoblast, adjacent to caruncles. Erythrocytes can be seen invading the caruncular area. By day 41, at about 28 mm crown-rump length, the fetus shows clear evidence of skeletal primordia. The heart is now four-chambered and the stomach (with ruminant chambers) is emerging. The metanephros and gonads are also evident. Cotyledons have formed on the trophoblast, with cotyledonary villi penetrating developing caruncular crypts. By day 48, at about 38 mm crown-rump length, the fetus exhibits considerable lengthening of the limbs, and has pronounced snout, eyelids, and hooves. The gonads are large but undifferentiated, and the adrenal glands are clearly evident. Placentomes have formed in most caruncles and some additional placentomes have formed. By day 55, at about 55 mm in length, the fetus is very "deer-like" in appearance. The limbs and skull have lengthened, the sex organs have differentiated, and the kidneys are evident. There are also prominent pedicle swellings becoming apparent on the skull (i.e., pedicle/antler primordia). Placentation is well developed by this stage, with the full complement of placentomes present (although the actual number varies with each conceptus).

It seems likely that the aforementioned pattern of red deer fetal and placental development within the 80 to 90 days of pregnancy is similar across cervid species, irrespective of adult livemass. This is certainly true for fallow deer, which are less than 50% of the adult livemass of red deer, but exhibit virtually identical growth of the fetus in the first 55 days of pregnancy.

Fetal and placental development in the latter stages of pregnancy have, again, been well documented for red deer, and appear to follow patterns that are fairly typical

for ruminants. These have been described as Gompertz equations of growth for gestational age.[14] As cervids in general share a degree of commonality in gestation length (i.e., 200–250 days; see Table 125-1), it is likely that fetal and placental growth follow similar patterns across species, albeit different trajectories according to species-specific birth weight ranges. As is typical of all ruminant pregnancies, conceptus growth trajectory is most rapid during the last third of pregnancy.

Although twinning is uncommon for red deer, there are numerous documented cases in both wild and farmed populations (many of those among farmed red deer have been artificially induced with exogenous gonadotropins during artificial breeding programs). It has recently become apparent that female red deer calves born from disex pairs exhibit a high degree of freemartinism. This indicates a degree of shared fetal placentation in red deer. However, naturally twinning species (e.g., white-tailed deer) do not exhibit freemartinism, suggesting a trend toward complete isolation of fetal placentation.

Although trends in fetal growth trajectory have been generalized for red deer, it is important to recognize the possible influences of extrinsic factors on rates of fetal development, particularly during the last third of pregnancy. For example, recent studies have shown that the level of nutrition to hinds during late pregnancy significantly influences fetal/conceptus growth rate (see later). Also, there may be pronounced intrinsic (e.g., genetic) influences, particularly in the case of hybridization between taxa (e.g., red deer × wapiti hybrids).

Role of the Corpus Luteum during Pregnancy

There is variation among ruminant species as to the role of the corpus luteum in maintaining the viability of pregnancy. Some species (e.g., goats) rely entirely on luteal production of progesterone throughout pregnancy, and others (e.g., sheep) instigate placental synthesis that supersedes ovarian production within the first trimester of pregnancy. Little is known about the influence of luteal and placental progesterone on pregnancy in cervids. Numerous studies across a number of cervid species have demonstrated physiologically significant quantities of progesterone in the peripheral circulatory system during the entire term of pregnancy. However, the relative contributory roles of luteal and placental tissues in its synthesis and secretion have yet to be fully determined.

In white-tailed deer, ovariectomy during various stages of pregnancy invariably resulted in fetal death and abortion within 48 to 96 hours. However, in red deer, wapiti, and reindeer, ovariectomy or luteectomy (removal of the corpus luteum) resulted in abortion in most, but not all, pregnant females. This indicates the possibility of extraovarian sources of progesterone supporting pregnancy.

Treatment of pregnant red deer and reindeer hinds with prostaglandins again caused fetal loss in most, but not all, cases. However, failure to abort may have been due to incomplete luteal regression and subsequent luteal regeneration. This indicates a degree of luteal refractoriness to prostaglandins during pregnancy, rather than indicating an extraovarian source of progesterone synthesis.

Gestation Length

Species-specific gestation lengths tend to be positively correlated with adult body mass in mammals generally. Although known gestation lengths for various cervid species (see Table 125-1) are also correlated to body size, cervid gestation lengths are relatively long (200–250 days) compared to those for other ruminants of similar size (e.g., sheep and goat species; ~150 days). The imperatives of highly synchronized annual reproduction necessitate prewinter rutting/conceptions and summer calving, the consequence of which is a relatively long gestation. The fact that one species, the roe deer, employs delayed implantation in order to "extend" gestation length highlights the importance of appropriate seasonality of conceptions and birth.

Although gestation length is clearly under a high degree of genetic control, variation in actual lengths are evident within each species. The highly variable gestation lengths recorded for hybrids between red deer and Pere David's (PD) deer indicates strongly that relatively few genes control species-specific gestation length. The two parental species have widely differing pregnancy durations (234 versus 284 days), and the backcross hybrids (e.g., 75% red deer, 25% PD deer) exhibit very wide variation (240–274 days) typically seen in genetic traits in which there is random segregation of alleles at relatively few gene loci.

However, there is little doubt that various extrinsic factors contribute to some variation in gestation length. For example, the average length for European red deer is 234 days. However, the observed range is 224 to 250 days. Recent studies on pregnant red deer hinds have shown that the level of nutrition over the last third of pregnancy can influence gestation length in this species. Hinds under moderate nutritional stress exhibited retardation of conceptus growth but appeared to compensate for poor fetal development by delaying parturition by up to 7 to 15 days. In this way they appeared able to maintain viable calf birth weights. The mechanisms by which this occurs remain unknown but may involve an effect of fetal growth rate on maturation of the fetal adrenal glands.

Parturition and Lactogenesis

Little is known about the physiologic mechanisms controlling parturition in cervids. Studies on a number of species (red deer, fallow deer, white-tailed deer) have shown a precipitous decline in blood progesterone concentrations in pregnant females around the day of parturition, reflecting demise of the corpus luteum or placental progesterone source. An elevation in blood estrogen levels has also been observed around birth in white-tailed deer.

There is some evidence that parturition is mediated, at least partly, by the fetus. Red deer hinds carrying wapiti × red deer or PD deer × red deer fetuses tend to exhibit longer gestation lengths than hinds carrying red deer fetuses. Pregnancy durations tend to be intermediate between the gestation lengths to parental taxa, indicating fetal expression of birth processes. In other examples of more extreme hybridization of red deer involving

species of different karyotype (e.g., sambar deer, rusa deer), hinds carrying hybrid fetuses generally exhibit excessively long gestations (i.e., often exceeding the mean length of both parental species by 10–30 days), failure of lactogenesis, dystocia, and high levels of neonate nonviability. This suggests a complex role of the fetus in parturition that is severely perturbed by hybridization.

Lactogenesis occurs in red deer and fallow deer very late in pregnancy, with females showing virtually no palpable or visible udder development before 30 to 40 days before parturition. First calving (i.e., pubertal) red deer hinds may show no signs of udder development until just 3 to 4 days before calving. This renders udder checking an unreliable method of pregnancy diagnosis.

There is growing evidence that lactogenesis in red deer and fallow deer is strongly influenced by prevailing photoperiod (i.e., normally increasing day length) during the last few months of pregnancy. Fallow does subjected to complete reversal of photoperiod during early pregnancy, due to translocation between hemispheres, exhibited a very high level (>95%) of failure of lactogenesis at parturition. Furthermore, treatment of pregnant red deer hinds with melatonin implants starting 80 days before birth (designed to induce an early return to estrus following calving) resulted in complete failure of all hinds to undergo lactogenesis. Interestingly, however, hinds similarly treated from 40 days before birth exhibited full lactation following calving. These observations indicate photoperiod responsiveness of mammary tissues, and that the critical window of lactogenesis lies 40 to 80 days before parturition.

LACTATION

Udder Development and Milk Composition

Irrespective of litter size, the typical cervid udder has four quarters, each with a single teat-canal. In the nonlactating state, the mammary tissue is well regressed into the inguinal region and the four teats are barely visible. However, in the fully lactating state (especially immediately prior to and after parturition), the udder is fully developed to its maximal size and the teats are extended. The udder often extends backward slightly, being very obvious below the vulval region. In red deer, wapiti, and fallow deer, which normally rear singleton offspring, only one or two quarters tend to dominate milk production during the entire lactation.

Little is known about the dynamics of milk production, storage, and let-down in cervids. However, there have been a number of studies on milk composition. Because most deer hide their calves for several weeks after birth, nursing is infrequent and the milk is rich compared with that of large grazers such as cattle (Table 125-3). The colostrum is particularly concentrated and rich in immunoglobulins, which protect the offspring while its immune system is maturing.

Milk production increases to a peak of about 2.5 L per day in red deer and 4.0 L per day in wapiti at about 40 days from birth, declining gradually as long as there is a suckling stimulus.[15] In the wild, this may occur throughout the calf's first winter, although volumes ingested are probably small. Thus, lactation in red deer can last 7 to 9 months in the absence of enforced weaning (as often occurs on deer farms).

Control of Lactational Yields

In red deer, well-fed lactating hinds can produce milk yields of 1400 to 2000 g/day early in lactation. However, nutrition to the hind exerts considerable influence over actual yields, with hinds on restricted food intake producing as little as 50% of the peak yield of hinds on unrestricted intakes.[16] Similarly, range conditions affect feed intake and have considerable bearing on milk production. In one study of red deer in Scotland, hinds on fertilized pasture exhibited milk yields 50% higher than hinds on poor quality hill pastures.[17] This nutritional effect flows through to calf growth rates, and is very well known to red deer and wapiti farmers in New Zealand and Australia. Summer drought conditions in Southern Hemisphere regions often have a negative impact on lactational yields and, ultimately, calf growth.

Other determinants of lactational yields in some cervid species may include genetics of the fetus. It has been a well-established practice in red deer farming in New Zealand to mate red deer hinds with wapiti bulls to produce fast-growing hybrid calves from (relatively) small hinds. The lactational demands on red deer hinds to raise hybrid offspring, which have growth rates twice that of red deer calves, are quite daunting. However, they are

Table **125-3**

Composition of Ruminant Milks

	Solids %	Fat %	Protein %	Lactose %	Ash %	MJ/L %
Cattle	12.6	3.7	3.4	4.8	0.7	3
Sheep	8.4	7.4	5.5	4.8	0.7	5
Bison	13.9	3.5	4.5	5.1	0.8	3.4
Wapiti/red deer	22.3	8.0	8.0	5.0	1.3	5.3
Moose	22.9	10.0	8.4	3.0	1.5	6
White-tailed/mule deer	25.3	10.9	7.6	5.4	1.4	6.7

From Haigh JC, Hudson RJ: *Farming wapiti and red deer.* St. Louis: Mosby, 1993.

capable of doing so if nutrition is not limiting. This suggests that either the hinds are capable of greater milk yields when bearing and raising hybrid offspring or the hybrid calves are capable of greater efficiency of converting milk solids into body growth. In all likelihood, both factors apply, and there is the intriguing possibility that the genotype of the fetus may influence lactogenesis and subsequent lactational yields.

Influence of Lactation on Ovulation

Given the unusually long gestation length of cervids and the imperatives of annual reproduction cycles, the interval between parturition and reestablishment of pregnancy is relatively short (3 to 4 months in most species). As lactation normally persists for up to 7 to 9 months, there is an overlap between calf rearing and reinstigation of ovulatory cycles. The influences of lactation on the incidence and timing of ovulation have received much speculation but are not well studied for cervids. Studies on red deer in Scotland showed that hinds on poor quality pasture had lower milk yields and higher plasma prolactin concentrations than hinds on better quality pasture. The higher prolactin levels were associated with a greater suckling frequency and a later return to estrus compared with the hinds on better pastures.[17] However, this study did not take into account differences in hind body condition (i.e., weight, fatness) that might also influence the onset of ovulatory activity.

Farmed red deer and wapiti are often weaned prior to the autumn rut to facilitate feeding and mating management. This effectively curtails lactation early. Several studies in New Zealand and Canada have compared the effects of pre-rut and post-rut calf weaning on ovulatory activity. In both cases, early cessation of lactation has been associated with advanced ovulatory activity of approximately 12 days in red deer and 5 days in wapiti.[18,19] Although it is difficult to argue that cessation of lactation per se was a causal factor in the breeding advancement, as early weaned hinds generally exhibited dynamic improvements in body condition, there is little doubt that lactation does influence reproduction by some means.

CHAPTER 126

Reproductive Anatomy and Physiology of Male Wapiti and Red Deer

JERRY C. HAIGH

REPRODUCTIVE ANATOMY

The reproductive organs of the male members of the genus *Cervus* consist of the testicles, epididymides, ductuli deferentia, accessory glands, and the penis and the prepuce[1–3] (Fig. 126-1). The testicles are located in a dependent scrotum between the hind legs.

The penis is a fairly simple rod-shaped structure that undergoes very little increase in circumference during erection, but increases in length by about 40%.[1] There is no sigmoid flexure (see Fig. 126-1). The urethra, which lies on the ventral surface of the penis through its length, curves dorsally at its extremity, and permits the ejection of urine and a few sperm cells in an upward direction, which is important during "thrash-urination" activity indulged in by rutting males as they spray upward almost at right angles onto their ventral abdomens, neck, and throat[1] (Fig. 126-2).

The prepuce has well developed muscles that are responsible for the remarkable rapid forward and backward movement, often called palpitation, of this region seen during the rut[1] (Fig. 126-3). This behavior, and the degree of development of these muscles, has not been reported from any other genus.

Scrotal circumference increases markedly and peaks at about the time of the onset of the rutting season. A threefold increase in size between early summer and autumn has been noted in red deer stags, and the scrotal circumference of male elk increases by about 50% during this period[4] (Fig. 126-4). After this it declines fairly steadily until it reaches its nadir in spring.[4] The percentage of normal sperm in ejaculates, the scrotal circumference, and the concentrations of serum testosterone undergo annual changes in synchrony.[4]

Cellular changes in the testis and the production of spermatozoa occur seasonally. As testosterone levels rise after the summer solstice, activity within the testicular parenchyma increases. The diameter of seminiferous tubules increases and the development cycle of seminiferous epithelium occurs. As these events take place, so the testicular size changes.[2,4]

At the onset of the rut, the interstitial cells of the testis are of maximum size and number, as is the activity of the seminiferous tubules. When reproductive activity has ceased, in the spring at about the time of antler casting, the interstitial cells are small and inactive, no mature spermatozoa are visible in the lumen, and the cells of the seminiferous epithelium show almost no differentiation beyond the very earliest forms of sperm precursor.[1,2] These changes are reflected in the measurements of scrotal circumference (see Fig. 126-4). Thus, the stag undergoes testicular and hormonal changes similar to puberty on an annual basis.

The epididymis also undergoes seasonal changes. In autumn it is lined by a tall pseudostratified columnar epithelium. By spring the height of this epithelium declines sharply and the nuclei of the epithelial cells are condensed. In autumn the cauda epididymidis is densely packed with sperm. In early summer no sperm are visible in the lumen.[1,2]

Accessory Glands

The accessory glands include paired ampullae, paired vesicular glands, both a body and disseminate part of the prostate, and small bulbourethral glands[3] (Fig. 126-5).

At their distal ends the ductuli deferentia enlarge to form the ampullae. These organs lie in close apposition to one another throughout most of their length in a common bundle of connective tissue. They are 4 to 5 cm long and about 1 cm in diameter at their widest in wapiti. Each ampulla opens separately into the duct of the adjacent seminal vesicle, forming short ejaculatory ducts.[3] Their epithelium exhibits changes that are correlated with the sexual cycle. Histologically the ampullae have the appearance of a branched tubular gland with sac-like dilatations, the crypts of which contained secretion. In May the epithelial height has not changed, but the nuclei have condensed. At this time some crypts contain densely packed degenerative sperm.[1]

The paired seminal vesicles are attached to the anterior end of the pelvic urethra, lateral to the ampullae, and are joined medially by a genital fold. They are 6 to 7 cm long and have a slightly lobulated appearance.[1] In autumn they contain a thick yellow secretion. Each gland opens separately into one of the paired ejaculatory ducts. The glands show increased epithelial height from July into the rutting period in October. They regress by November and contain little or no secretion in spring.[1,2]

The prostate gland consists of two parts. It has a discrete, bilobed body lying anterior to and continuous with

(Redrawn from Haigh JC, Cates WF, Glover GJ, et al: Relationships between seasonal changes in serum testosterone concentrations, scrotal circumference and sperm morphology of male wapiti (*Cervus elaphus*). *J Repro Fertil* 1984;70:413–418.)

the disseminate prostate. This body is visible on the dorsal part of the pelvic urethra as two small discrete hemispherical masses just caudal to the ligamentous band that connects the vesicular glands. It opens ventrally into the pelvic urethra. The epithelium of the prostate body is of a tall, columnar type during the rut and shortens markedly, appearing cuboidal by November.[1,2] The disseminate part of the prostate can be identified throughout most of the pelvic urethra, underlying the urethral muscle. It has numerous ducts opening into the urethra.[1] There appears to be little seasonal change in epithelial height.[1,3]

The bulbourethral glands are extremely small, the combined weight being 0.6g in wapiti. They are found at the junction of the urethral and bulbourethral muscles under a layer of connective tissue on either side of midline. In one study comparing epithelial heights before and after the rut, no differences were found.[3]

Spermatozoa

The spermatozoa of the elk and red deer have the same general appearance as those of other ruminants.[4] Collection of semen on a year-round basis shows that it is possible to obtain ejaculates with a high percentage of abnormal forms in July and August (Northern Hemisphere), but that by the beginning of September ejaculates of mature elk bulls contain a high proportion of normal sperm[4] (see Fig. 126-4). For evaluation of reproductive soundness, and for artificial insemination, semen should be collected from just before the autumnal equinox until a short time after the winter solstice, with highest sperm concentrations expected around and soon after the time of the equinox. From about the time of the spring equinox and for a few weeks afterward wapiti males may be azoospermic. A wide range of spermatozoal abnormalities have been found in both wapiti and red deer that are similar to those seen in domestic bulls, and the same classifications can be used for them.

REPRODUCTIVE CYCLES

All the physiologic events of the reproductive cycle are tied to gestation length, which in wapiti and red deer is timed for delivery of a calf in late spring/early summer.

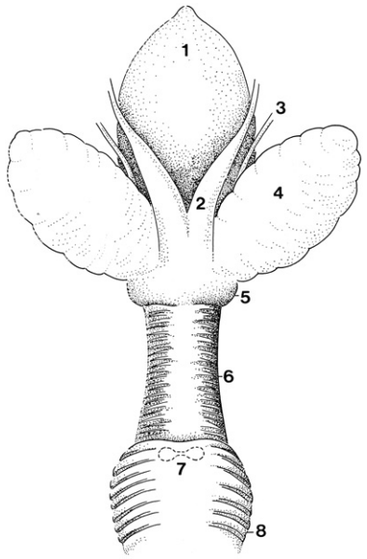

Fig. 126-5 Pelvic organs and accessory glands of the wapiti. *1*, urinary bladder; *2*, ampulla; *3*, ureter; *4*, vesicular gland; *6*, urethral muscle surrounding disseminate prostate and bulbourethral gland distally; *7*, bulbourethral gland; 8, bulbospongiosus muscle. (From Haigh JC, Hudson RJ: *Farming wapiti and red deer.* St. Louis: Mosby, 1993.)

This is late enough to avoid inclement weather and to ensure plenty of high-quality forage, but early enough for the calves to attain sufficient weight to survive the subsequent winter. In the natural ecosystems this occurs at the end of May or early June in the Northern Hemisphere. There are, however, minor modulations in season that are governed by other factors that account for the minor year-to-year variation in rutting and calving dates.[5] Weather or forage quality and availability leading up to the rut are likely factors. Even when members of these species are kept outside the latitude zones in which they evolved they retain the same seasonal breeding pattern.

When these temperate zone deer are taken across the equator they shift their cycles of antler development, breeding, hair coat, appetite, and energy expenditures.[6] This change does not occur immediately, or in all animals at the same time, but usually is complete within 2 years of translocation. The change can be accelerated by the appropriate use of endogenous melatonin.

Puberty

Puberty in the male has been defined as the period when secondary sexual characteristics and accessory organs develop under the influence of the testis.[7] It is a continuous process that begins when the stag has reached a critical weight and is reflected in the initiation of growth of the antler pedicle.. Its onset at this stage is more related to body weight than photoperiod and there are records of undernourished free-ranging red deer not reaching puberty until 3 years of age.[7,8]

Suttie and associates[9] have described the events that occur in the testis of young red deer stags. In the autumn of its first year of life, when the male calf is about 3 months old, testicular diameter begins to increase. The following spring the increase is arrested, but size does not decline. About midsummer at the start of the second year, testicular size again starts to increase as the calf approaches puberty.[9]

From the time that the calf is 3 months of age, pulses of luteinizing hormone (LH) increase to about three per 24-hour period and lead to discrete pulses in testosterone. From the time of the summer solstice the number of pulses of both hormones increases to about eight per day. There is then a decline in spring, and after the spring equinox, by the time that the animals are 11 months old, pulsatile secretion of LH is almost undetectable. After the summer solstice when males were 13 months old, frequent low amplitude pulses of LH are accompanied by frequent discrete pulses of testosterone. In late summer LH frequency is maximal and is accompanied by frequent large-amplitude pulses of testosterone that persists for 2 months.[9]

Although 15-month-old stags may be fertile, they are usually not able to breed successfully in the presence of older males.[7,8] However, in experimental situations they can and will breed hinds in estrus.[10] Indeed, many deer farmers use 1-year-old stags as sires, but with only small numbers of hinds (e.g., 10–15).

Subsequent Cycles

The annual change from an inactive and infertile state to full reproductive readiness has been likened to a seasonal puberty.[2,7,11] The exact details of physiologic activity after puberty have been described in red deer. Elk follow the same pattern, but events occur some 2 weeks earlier as the gestational length is that much longer.

It is also important to note that juvenile animals develop their sexual activity more slowly than do adults, at least until they reach 3 years of age.[2,11,12] When a wapiti reaches the "teen" age (2–5 years) his semen production rises from year to year; more semen can be stored in the epididymis and a progressively greater volume of fertile semen can be ejaculated. These increases continue until the testicle growth is completed and the animal is in its prime.[13] With these facts in mind the sequence of events in an individual mature wapiti bull can be summarized as follows.

At the spring equinox pituitary activity and testosterone concentrations are minimal. At about the summer solstice, the weight of the pituitary gland begins to increase, and with it the output of gonadotropin-releasing hormone (GnRH). Approximately 2 months after the summer solstice pituitary weight is at its maximum, as are LH concentrations. Testosterone concentrations begin to rise in response to the LH activity. Around the autumnal equinox while LH levels are not as high, the responsiveness of the target cells in the testis to LH is much more marked, and serum testosterone levels are at a peak at this time when testicular testosterone concentrations may be 1000 times higher than those measured in spring and early summer. Trials with synthetic

GnRH have shown that the pituitary gland will respond to injections of this hormone at any time of year, but that these responses are greatest just before and at the time of antler velvet cleaning. The consequent testosterone increases occur most markedly at the time of the rut, to a limited extent while the animal is in hard antler, and hardly at all between casting and antler cleaning.[14] Within a month of the autumnal equinox testosterone levels have declined to near baseline levels, where they remain for most of the rest of the winter. Seasonal reproductive changes are more striking in the male than in the female, not least because the most visible secondary sexual characteristic is the presence of antlers, which are used to establish dominance and breeding privileges during the rut. Preceding the rut, testosterone concentrations, scrotal circumference, and percentage of normal sperm increase sharply, reaching a peak just before the rut itself (Fig. 126-4). Other secondary sexual characteristics also change throughout the year. In preparation for rutting battles, the neck swells owing to massive development of the muscles, giving the rutting stag a very distinctive appearance.[11,15]

Although the rapid change in serum testosterone concentrations in later summer is clearly seen, there is a much more subtle and transient elevation after the winter solstice in both wapiti and red deer.[4,16] These elevations correspond to the two annual increases in size of the testicular interstitial cells of red deer.[17] Biannual increases in testosterone have also been seen in several other deer species.

It is commonly observed on deer farms that wapiti and red deer stags that are well nourished will exhibit two rutting seasons a year. The principal one occurs in autumn, and the second one in which some fighting and bugling is heard for a brief period of about 10 to 14 days occurs about 1 month to 6 weeks after the winter solstice. It has been found that the quality of the nutrition influenced the levels of testosterone, and that well-nourished red deer stags can rut twice a year.[16] This is not commonly observed overtly on deer farms, and generally does not cause management problems.

The duration of daylight is the same at this time as it is after the summer solstice, and it may be that the light signal during this period is stimulatory until its increasing duration is recognized and no longer acts as a stimulant. When animals are transferred across the equator the stimuli are reversed.

It has been shown that in the red deer there are seasonal fluctuations of prolactin receptors in the testis and epididymis. The role of prolactin in the testis has not been fully determined, but it may have both stimulatory and inhibitory functions. In the epididymis a receptor was detected only during the breeding and early nonbreeding season.[18]

It is likely that other reproductive hormones also exhibit dual annual cycles. Bubenik and associates[19] reported dual elevations of estradiol-17β in white-tailed deer that occurred in April/May and October/November.

BEHAVIORAL CHANGES

Reproductive behavior is discussed in Chapter 127.

CHAPTER 127

Reproductive Behavior of Red Deer and Wapiti

GEOFFREY WILLIAM ASHER, JERRY C. HAIGH, and PETER R. WILSON

As with other ruminants, female cervids exhibit estrus rather than continual sexual receptivity. In most species, estrus is restricted to the "rutting" season, a period of hypersexual activity during which males contest access to females for mating.[1] Thus, female sexual activity is closely synchronized with that of males, especially in temperate species.*

STAG BEHAVIOR

During the period in which antlers are in velvet stags do not normally engage in any sexual behavior. If stags or bucks are competing while their antlers are in velvet they will normally do so by rising on their hind legs and engaging in boxing activity. However, the presence of hinds in estrus outside the normal breeding season will induce a full range of mounting and mating activity. Normally hinds would not be in estrus at this time, but this type of behavior has been seen when hinds are brought into estrus out of season by artificial hormonal means, or when animals have been transferred across the equator and have not yet adjusted to the new photoperiod. Resumption of rutting behavior occurs late in winter if a female loses a conceptus and begins to cycle again, or begins estrous cyclicity particularly late.[2]

The behavior of stags changes quite abruptly at about the time that antler velvet is shed and antlers become fully calcified. Wapiti gestation is about 2 weeks longer than that of red deer and fallow deer, and so the changes occur that much earlier (for more on the relationship of antlers to reproduction see Chapter 133).[3] They take place, in mature males, about 3 to 4 weeks before the onset of the rut (mating season) itself. Younger males start rutting behavior a little later than mature adults. The behaviors at this time include antler rubbing or thrashing, wallowing, preputial palpitation with or without urine spraying, bugling or roaring, dominance displays, and sparring in wapiti and red deer.[4] At this time, stags become extremely aggressive toward one another and often toward humans in a farming environment. Antler rubbing and thrashing serve to both mark territory and remove the dried velvet tissue on the surface of the hard antler. The thrashing may be accompanied by rubbing of the neck on vegetation, fence posts, or other wooden structures and is probably a form of scent marking. At this time, in male-only mobs, the fighting mode changes from boxing to a complex of displays that may culminate in clashes that involve the use of the head. In single sire mating mobs fighting is not seen, but fence pacing with parallel walking displays projected at males across fence lines, or at people, are common. Males will also face directly up to people at fence lines and carry out head threats that involve a rapid dip. If stags (also called bulls in wapiti) are placed in adjacent paddocks, fighting through the wire will occur.

In *Cervus* males the underside of the belly, the forelegs, and the neck are often darkly stained during the rut and for a period thereafter. This is due to the frequent spraying of fluid from the penis, usually accompanied by preputial palpitation, that is known in elk as "thrash urination," and which is almost certainly used as a scent marker.[4,5] The urethra at the tip of the elk's penis points upward, which allows for a spray that is almost at right angles to its long axis.[6] This ensures that the entire belly and neck can efficiently be scented. The smell of the fluid, and the smell of the stag himself, is particularly strong at this time of year.[4,6] When this fluid has been collected it has not been shown to contain sperm.[7] Thrashing is sometimes accompanied by wallowing. If there is a convenient wet or damp spot, a stag will often choose it for a wallow. He will scrape with his feet in the ground, sometimes will use his antlers, and often will urinate as well. He will then usually roll in the wallow and cover both his belly and neck with the mixture.[4,6]

On deer farms stags have usually been "placed" or "joined" with hinds just before velvet cleaning, or very soon after it occurs in order to take advantage of the well-recognized "stag effect." It has been shown that the stag's rutting behavior advances the onset of estrus if introduced to the female about 3 weeks before onset of estrous cyclicity in the absence of stags.[6,8] The array of behaviors described serves to stimulate and synchronize the hinds during the phase of transition between the anestrus period of summer and the active breeding season. Hinds may go through a silent heat and both hormonal activity and follicular wave activity increase until an ovulatory cycle occurs.[1] A "dormitory effect" is also recognized to occur among hinds, and silent heat may further

*Note on terminology: Female red deer are called hinds, as are wapiti (North American elk) in some texts. Most industry people call wapiti females cows. The males of the two subspecies are technically both called stags, which is in common use for red deer; the more common term for wapiti is bulls.

synchronize estrus among a group of hinds, thus shortening the rut and calving period.

The intensity of stag behavior increases gradually until the animals are in full-blown rut. The rut is defined as the period of maximum reproductive activity.[2] It is timed to meet the evolutionary pressures that have dictated parturition onset to meet the optimal forage availability in the following year.

Sparring

Sparring encounters, when antlers are engaged and pushing matches occur, are a common feature of the rut in free-ranging animals. They are most intense in mature individuals and are unusual if males are of different ages. However, they are usually preceded by a series of ritualized behaviors during which males size one another up. Stags may break off an encounter before engaging in physical contact.[7]

Vocalization

The calling sound made by rutting males is known as roaring in red deer, and bugling in wapiti. By the onset of the rut mature stags have been calling for at least 2 or 3 weeks. Stags will call whether or not they are placed with hinds. If the weather is cool (<10° C) during the day, calling may occur as often as twice a minute throughout the 24-hour day, but if temperatures exceed 20° C the frequency declines during the middle of the day. The sounds are most commonly heard before 9 AM and after 5 PM.[4,9] In red deer frequency increases to as many as eight roars per minute preceding a fight.[9] In red deer it has been shown that the frequency of roaring may affect the success that a stag has in maintaining his harem.[9] It is rare to hear a yearling wapiti bugle at all.

Heterosexual Behavior

Hinds tend to move into rutting areas held by dominant stags over this period. While they are nonestrous, hinds remain subordinate to the stag, displaying characteristic submissive behaviors whenever approached. These behaviors include a head lowering and neck stretching posture associated with jaw chattering. Hinds will often run short distances to avoid the stag. Stags frequently display to hinds, particularly if they appear to be moving outside the stag's rutting area. Such displays include standing side-on to the hind with chin raised. The stag will often raise and stamp a front foot, emitting a deep guttural bark at the same time. This is usually sufficient to direct the hind back to the core rutting area or to join the other hinds. The stag will frequently wander among resting and grazing hinds, sniffing each hind's perianal region for signs of impending estrus. Hind urine is often tested with displays of flehmen.[6,10]

In natural mating systems wapiti and red deer hinds form groups of several animals and these are "rounded up" by rutting stags. The amount of time spent herding females increases steadily from the time that velvet is cleaned off, and within about 2 weeks has become a major activity.[4] Rutting bulls will spend up to 40% of their time herding their females on farms, even chasing them away from water or feed troughs.[6] Most of the herding behavior is seen in the early morning up to 9 AM or in the evening as during the hottest part of the day stags and hinds may spend up to 60% of their time resting. The threat employed by stags that are herding hinds is usually extension of the head and neck such that the head is level with or slightly below the shoulders. This posture, held while the stag runs toward a hind that is trying to leave the herd, often stimulates the hind to rejoin the group, whereupon herding activity ceases.[4]

Yearling males may not show full rutting behavior for as much as a month later than older ones and may be seen making homosexual mounts, but they are capable of breeding if older males are not present.[2,11,12]

Throughout the rut the stags can be seen periodically checking the hinds, both by smelling their perineal regions or faces and by sniffing their urine and performing "flehmen," or lip curl.[10] The stag may walk among a group of resting hinds carrying out these checks and if a hind is coming into estrus the stag will pay more attention to her, sometimes separating her from the herd.

The hinds show little overt behavior related to reproduction in the period preceding the peak of the rut. Only the most vigilant observer will be able to detect when a hind is in heat. There is little or no vulval swelling, and although it does occur, hind mounting of other hinds is unusual. The well-known research team on the island of Rhum have reported that red deer hinds give off a distinctive odor during the time that they are in estrus.[2] The interaction of a hind with the stag is the best indicator of her reproductive state. Hinds may exhibit different behavior if they are kept separate from stags.[13] They would approach fences separating them from the male, frequently reaching through to lick him, while he became agitated and ran along the fence bugling frequently. Hinds approaching estrus may spend an increasing amount of time paying attention to the stag, or there may almost no interaction between them until the moment of coitus.[13]

The range of behaviors that are engaged in by elk and red deer have been extensively studied by many observers. One of the earliest "textbook" references was published in 1576 and is an account by Turbevile of many aspects of hunting and the biology of deer.[12] A section of his chapter on the "Vault of Hartes"* bears quoting as it cannot be much improved upon today.† The second paragraph quoted contains what is probably the most lyrical description of flehmen ever penned:

> Harts do beginne to Vault about the middeft of September, and their Rut doth continue about two monethes, and the older that they be, the hottere they are, and the better beloued of the Hyndes. The old harts go fooner to vault than the yong, and they are fo fierce and fo proude, that vntil they haue accomplyfhed their luft, the yong Harts

*Hartes (or harts) is the medieval English term for a mature red deer stag.

†Note that in medieval English f (without the full horizontal bar, so it cannot be properly represented on modern keyboards) is often used for the modern s, and u is used to represent v.

Table **127-1**

Time Sequence of Breeding Behavior in Red Deer

Action	Hours before Mating
Sniff-approach by stag	22
Short chase by stag	17
Long chase by stag	6
Low mount	45 min
Mount by hind Copulation	20 min

From Veltman CJ: The mating behavior of red deer. Proceedings of the 2nd Deer Course For Veterinarians, Deer Branch of the NZ Veterinarian Association, 1985, pp 135–142.

Table **127-2**

Breeding Parameters of Wapiti and Red Deer[6,13,14]

Parameter	Measurement
Average low mounts per copulation	4 (1–16)
Duration of low mount	15 sec
Duration of copulation, mount included	5 sec
Repeat breeding (some hinds only)	0.3–7 h
Duration of postcopulatory straining	3.2 min
Time taken by hind to return to herd	9 min
Duration of estrus	6–30 h
Estrus interval	21.2 (19–25) (wap), 18 days
Gestation length	247 ± 5 (wap) days

> dare not come neare them, for if they do, they beate them and dryue them away. The yong Deere haue a maruellous craft and malice, for when they perceiue that the olde Hartes are wearie of the Rut and weakened in force, they runne vppon them, and eyther hurt or kyll them, caufing them to abandon the Rut, and then they remayne maifters in their places.
>
> Hartes doe muche foner kyll each other when there is fcarcitie of Hyndes, for if there be Hyndes plentie, then they feparate them felues in one place or other. It is a pleafure, to beholde them when they goe to Rutte and make their vaute. For when they smell the Hynde, they rayfe their nofe vp nto the ayre, and look aloft, as though they gaue thankes to nature which gaue them fo great delight.

More modern descriptions of breeding behavior differ only in detail from those of Turbevile. Some of them are indicated in Tables 127-1 and 127-2.

Precopulatory Behavior

In free-ranging situations, for about a 12-hour period before estrus the hind and stag may be seen resting near one another, often within 10 or 15 m, and the stag appear to be guarding her.[14] As estrus approaches in a hind, the stag may single the hind out and initiate short (10–20 m) intensive chase sequences, usually with his neck stretched forward and with rapid tongue movements directed toward the hind's rear (Fig. 127-1). Such chases usually end with the hind remaining within 5 to 10 m of the stag. These sequences have been observed to occur anywhere between 6 hours and a few minutes from the onset of estrus (actual receptivity).

Fig. 127-1 Stag and hind in a chase sequence. (From Haigh JC, Hudson RJ: *Farming wapiti and red deer*. St Louis: Mosby, 1993.)

On farms, where mating groups are not as free to move about, this behavior may not be observed, especially if large numbers of hinds are run with a single stag and he may be mating with an average of three or four a day. The stag will, from time to time, approach a hind that is coming into estrus while stretching his head and elevating his tail. The hind may move away and the stag chases her for short distances and then appears to lose interest.[10,14] The chases increase in length as the hind approaches standing estrus and solicitation by hinds may also be seen. They may stop, arch their backs, and elevate their tails. The gait may change to a prancing walk.[10]

Mounting and Copulatory Behavior

Depending upon his level of experience and the number of hinds that he has to breed, a stag may perform so-called low mounts.[6,10,13,14] During these he will mount the hind and lay on her back. His penis protrudes from the sheath, but no intromission occurs. The low mounts may be seen as much as 12 hours before mating, but usually this time is less than 6 hours (Fig. 127-2). In an extreme case 34 low mounts by a single red deer stag were seen.[14]

Hinds in estrus may sometimes mount stags or other hinds and spend a good deal of time rubbing themselves over the rump or under the neck of the stag.[6,10,13,14] There is a considerable difference among individual hinds as to the degree of estrus behavior shown. Some are served only once at a given estrus and may show only the most subtle signs of being in heat. Others may be served four or five times and show conspicuous estrus behavior.[13,14]

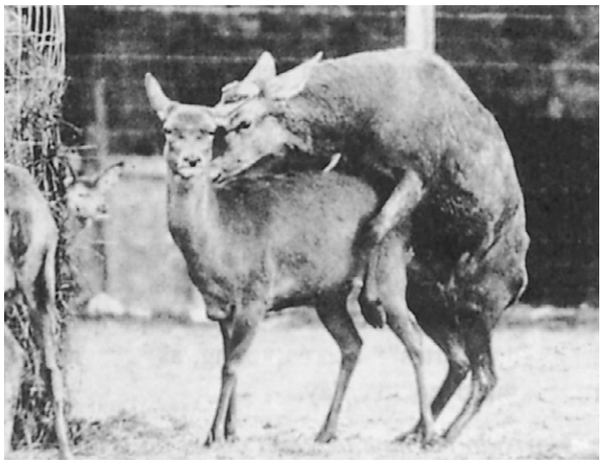

Fig. 127-2 Low mount without intromission. (From Haigh JC, Hudson RJ: *Farming wapiti and red deer*. St Louis: Mosby, 1993.)

Estrus onset is often quite sudden, at which point the hind stops abruptly during a chase sequence and allows the stag to mount. She may even take several steps backward with her tail raised and wagging.[13] When this happens still the stag will show great excitement, his tongue will often flick in and out, and he will arch his neck over the back and neck of the hind.[6,10,13,14] One or two low mounts then usually occur in quick succession, followed by the ejaculatory mount. Prolonged mating sequences, involving many noncopulatory mounts, can occur. Under these circumstances, the total duration of courtship may last several hours and the hinds often exhibit more obvious signs of estrus. Such behaviors include self-grooming by rubbing her chin over her flanks, similarly grooming the stag, mounting or being mounted by other hinds, and mounting the stag. The hind will generally remain very close to the stag until copulation occurs.

The actual moment of copulation and ejaculation lasts only a few seconds. The hind stands after a brief chase and the stag mounts and then thrusts upward in a single motion. He places almost no weight on the hind's back, but the force of the thrust usually drives the hind forward a few paces. This strong physical thrust has been reported to occasionally cause vaginal tearing or rupture, and may be responsible for penile injury in some instances.

There are differing reports on the time of day at which copulation occurs. There do not appear to be any reports that describe continuous observation over a prolonged period of both night and day in natural breeding situations, most studies involving either only daylight hours or specific times of day.[6,10,13,14] Marking of hinds by raddle painted stags occurs throughout the 24-hour day,[6,14] but Veltman has reported that 75% to 90% of hinds were mated during dawn-to-dusk watches.[10] In one study of synchronized hinds continuously observed for 72 hours, using night vision equipment between dusk and dawn, coitus was observed during both night and day.[6]

Postcopulatory Behavior

After dismounting the stag will often roar or bugle before walking away and apparently losing interest. Just after mating the hind will adopt a squatting stance and strain. Both urine and mucoid fluid are passed from the vagina.[4,10,13,14] This posture is not seen at other times.[10] After a few minutes the hind will rejoin the herd. She may breed again with the stag, even after a few hours, and copulation intervals in excess of 24 hours have been recorded.[14] Some hinds terminate estrus at copulation, but 30% to 40% will re-mate 6 to 12 hours later. The average time for a red deer hind to be in estrus is 18 hours. Up to four copulations per estrus have been observed.

Although this pattern of estrous and mating behavior is typical for red deer, there is considerable variation on the theme, particularly in relation to the duration of events and the number of noncopulatory mounts.

The End of the Rut

The rut may last for only a few weeks with a peak activity of as little as 20 days.[4] A resurgence of activity may occur if hinds do not conceive during the first period.[6] In free-ranging situations, if a stag is exhausted during this time he will be usurped by another.[4] As indicated previously and noted by Turbevile, the young stags come into the peak of their rut later than the mature ones.[12]

Rutting stags spend little time feeding, and a mature stag may lose as much as 25% of his body weight in 6 weeks, and losses of 30% have been recorded.[2,4] Bulls or stags that are markedly debilitated after rutting must soon regain some condition in order to survive harsh winters.

HIND BEHAVIOR

Calving/Fawning

The birthing process of red deer and white-tailed deer has been well described, based on behavioral observations on parturient females. The process is similar to many other ruminant species. However, some key features are relevant to cervid species. Even in gregarious species (e.g., red deer, fallow deer), parturient females seek isolation from herd mates for the birth process. In farmed red deer, preparturient females are often observed to frantically pace fence lines in an effort to isolate themselves from other hinds. The frequency of "fence pacing" decreases with increased paddock area and decreased stocking density, indicating that the behavior is strongly motivated by a desire to seek an isolated birthing environment. Such behavior is observed anywhere up to 48 hours before parturition, but is intensified in the 24 hours leading up to birth.

Actual parturition is similar to that seen in other domestic and wild ruminants. The process from initiation of labor (i.e., abdominal straining) to expulsion of the calf/placenta can occur over periods of 30 minutes to 6 to 8 hours, but normally takes 2 to 3 hours. Considerable variation in the timing of these events has been observed in wapiti.[15] All remnants of afterbirth are ingested by the females.

Posterior presentation is not considered as an abnormality in *Cervus* to the same extent as it is in other domestic species. It has been observed to proceed to normal unassisted birth in a high proportion of cases,[6] Details on timing of calving events are provided.[15]

Placentophagia

It is common to see hinds turning back and ingesting any part of the placental membranes that they can reach, as well as licking and chewing any fluids or tissues that have fallen to the ground, even before calf delivery (Figs. 127-3 to 127-5). Placentopahgia is a normal event in mammalian life, and it has been suggested that it is related to several factors. The commonest is that it is a predator defense mechanism. Other, unsubstantiated, reasons suggested include that this tissue may act in aiding milk let-down, or may provide a substantial supply of nutrients after a period of reduced intake.[16] The most detailed explanation comes from work in rats, in which it has been shown that the fetal fluids and placenta contain placental opioid-enhancing factor, a protein that enhances endogenous opioid-mediated analgesia evident at the end of pregnancy and during delivery.[16,17]

Bonding

Usually, as soon as the calf is born the mother starts to attend to it, especially licking and drying it and eating the remains of the afterbirth, even if this is expelled some time after the actual delivery, but the hind may rest if parturition has been prolonged.[1]

Free-ranging deer tend to leave the herd and deliver their calves in isolation, only rejoining the herd after a period of several days once they have bonded with the calf. In farm situations this option is not available to them, and this may explain the observed occurrence of cross-mothering that is recognized in red deer and wapiti.[6]

In farm situations a dominant hind experiencing second stage labor may find a newborn calf hiding in the paddock and adopt it. When her own calf is born some time later she may abandon one of the two, or her own calf may be taken by the subordinate hind that has been driven off and is still seeking a juvenile to raise.[18]

Lactation

Most species of deer nurse their newborn calves for a few hours after birth, during which time dam/calf bonding occurs. This may sometimes take place when the hind is lying down (Fig. 127-6). Thereafter, the dam leaves the calf hidden at or near the birth site, returning only a few times per day during the first 2 to 3 weeks to suckle the calf. Calves follow their dams, often returning to the herd, after this initial "hide-out" period. Anecdotal evidence suggests that in farm situations the hide-out period

may be shorter in later born calves within a single paddock. Exceptions to this general pattern do occur among cervids; reindeer and caribou calves generally follow their dams within a few hours of birth, owing to the migrating and wide-ranging nature of this species.

CHAPTER 128

Reproductive Management of Farmed Red Deer and Wapiti

PETER R. WILSON and JERRY C. HAIGH

Currently, the various races or subspecies of red deer, and the wapiti (or North American elk), which is found in eastern Asia as well as North America, are all considered to belong to one species, *Cervus elaphus*.

The historical range of red deer stretches from Scotland to China, with perhaps as many as 22 subspecies recognized.[1] Red deer have been introduced into the wild in numerous countries. They have been domesticated as a livestock species in many countries, but particularly in New Zealand, where approximately 2.3 million animals were farmed in the year 2001.

Wapiti, of which at least 10 subspecies are recognized, range, in Asia, from the Tien Shan mountains of Russian Turkestan and the Altai mountains of Russia and Mongolia through China and Manchuria into North Korea.[1] In North America they were formerly found throughout much of the continent. Their range was reduced through overhunting in the late 19th century, but numerous reintroductions have occurred since. They are now found, both free-ranging and on ranches and farms, in many areas.[1]

Reproductive management of *C. elaphus* varies somewhat according to the region or country in which these animals are farmed and is influenced both by market forces and by climate. The numerous subspecies can interbreed freely. For this discussion, crosses between them are referred to as crossbreds, rather than the more commonly used, but technically incorrect term, hybrids.[1] One anomaly discussed in more detail in these pages is that red deer and wapiti respond differently to ovarian superstimulation.[1]

Fundamentally, the species is described as seasonally polyestrous, or a short-day breeder, with the onset of fertility and the rut occurring in autumn. The timing of onset of the breeding season has evolved by the need to deliver calves at a time when grazing conditions are optimum for milk production and calf well–being, in early summer. Gestation of wapiti is slightly longer (247 ± approx. 5 days) than that of red deer (233 ± approx. 7 days).[1,2] For this reason wapiti stags clean the velvet antler (an event closely linked to elevated testicular testosterone concentrations) and display aggressive behavior prior to the rut, about 2 weeks earlier than red deer.[1]

Use of the larger wapiti stags, or their F_1 cross red deer male progeny, as terminal sires (those whose progeny are destined for venison production) over the smaller red deer hind developed in New Zealand to increase the biologic efficiency of the production system. Most red deer hinds weigh 90 to 120 kg, whereas mature wapiti hinds weigh 250 to 300 kg. Progeny growth rate increase is related to the proportion of wapiti genes present. Because the progeny grow fast, more venison can be supplied to meet the seasonal Northern Hemisphere market.

In New Zealand management is also designed to bring forward the median herd calving date as much as possible to take advantage of early spring grass growth.

BODY CONDITION AND BODY CONDITION SCORING

Body condition score (BCS) is an important tool for management of dairy and beef cattle. BCS systems have been developed for both red deer and wapiti.[3–5] Scoring charts have been developed with scores ranging from 1 (lean, or very poor condition) to 5 (fat, or very good condition) with half-unit increments[3,5] or from 1 (thin or emaciated) to 9 (fat or obese).[4] For the purposes of the following discussion the 5-point scale of Audigé and associates[3] is used. It is essential that palpation be employed for accurate estimation of condition, particularly in winter when coat obscures the body contour. As the winter coat is usually well developed by the onset of the rut, the time when a BCS is most relevant, care must be taken to avoid missing subtle changes.[6,7] Eye appraisal of animals in the paddock may estimate herd status to within one score, but is inadequate for individual animal condition scoring.

In the most objective study reported, in which deer were palpated,[3] showed repeatability was 0.91 and 0.89, while reproducibility was 0.81 and 0.79 for yearlings (primiparous) and adult hinds, respectively. There were significant variations among hinds according to season and farm.

Although the only data on BCS in deer have related to reproductive outcomes, it is likely that health and mortality rate are also related to body condition, since low BCS is an indicator of nutritional status.

Stags

Males should enter the rut with a BCS as close as possible to 5 because they will lose from 25% to 30% of their pre-rut weight, even if offered grain and good quality hay, often resulting in a BCS of 1.5 or 2 in the early winter. In mature stags this change is seen even if the stags do not have access to hinds, as they spend considerable amounts

of time engaging in rutting behavior. Yearling stags (18 months of age) do not lose appreciable weight or BCS during this period, and 2- and 3-year-old stags lose about 15% of body weight.

Stags require a high plane of nutrition immediately after the rut to recover adequate condition before winter, to reduce the risk of death due to exposure. Grain or concentrates or high pasture allowances should be provided for at least 6 weeks before the winter solstice. By this time, animal and human safety is usually not a problem, as aggressive behavior has subsided. A useful target by the winter solstice is a recovery of 25% to 30% of the body weight lost, or a BCS increase of 1 point. Gradual increase in grain allowance avoids grain overload and laminitis, to which deer are particularly susceptible.[1]

Hinds

Body Condition Score and Conception

In red deer, premating BCS is significantly associated with conception rate, conception date, and weight of weaned offspring, while BCS during pregnancy is associated with dystocia and ability of the red deer hind to rear a calf to weaning.[3,8]

Guidelines for achievement of optimal reproductive performance have been proposed. In general, hinds with a BCS of 2.5 or more have a greater chance of conception per se, and have an earlier conception date. Pregnancy rates of hinds in good condition (3–5) are likely to be 10% greater than hinds in poor condition (<2.5).[9] However, it has been observed that overfat primiparous hinds (>BCS 4) were at increased risk of failure to conceive.[6,7,10] However, Beatson and associates[11] were unable to verify this relationship.

If the production target is "optimal" reproductive success, defined by an early mean conception date and high conception rate, individual hind BCS should be greater than 2.5 before mating and should either be stable or increased during the mating period.[6,7] Indeed, Audigé and associates[3] propose that for optimal reproductive performance from hinds, their body condition should remain stable throughout the year at scores between 2.5 and 4. Recent studies have shown that a delay in mean conception date of 12 days was associated with late weaning, resulting in an average loss of 0.5 BCS.[12] The pattern of change during the mating period is also important. Beatson and associates[9,11] showed that hinds below a BCS of 2.5 before mating, but increasing BCS during the mating season, have a higher conception rate than those staying below 2. Those at or above BCS 2.5 that gained in BCS during mating had no improvement in conception date or rate, confirming that BCS 2.5 or greater is optimal. However, these authors demonstrated that hinds losing BCS from any premating score showed a lowered conception rate. These observations confirm the value of BCS as a predictor of reproduction outcomes, and as a tool for determining when management changes are appropriate if optimal reproductive performance is desired.

Similar criteria for wapiti have not yet been verified, but the principles are likely to be the same. Although 2-year-old wapiti hinds (jinnocks) calved (in the Northern Hemisphere) later than adult hinds (mean 11 June versus 6 June), hind pre-rut weight influenced calving dates.[13] This finding confirms that there is an interaction between BCS and body weight, particularly in primiparous hinds.

Body Condition Score and Dystocia

It has been generally believed that the fat, unfit hind is more likely to suffer dystocia than one that is physically fit and in optimal body condition.[1] Recent research has shown associations between BCS and dystocia in red deer herds.[8] Hinds with a BCS of 4 or more shortly before calving were 2.7 times as likely to experience dystocia than hinds with lower scores. An increase in BCS late in gestation also increased the risk of dystocia. There was an interaction between BCS and topography, with hinds with a high BCS but grazed on steep hill pastures being at lower risk of dystocia than hinds of the same BCS grazing flat pastures.

GENETIC SELECTION

Selection criteria for red deer have been developed, to some extent, in New Zealand. For practical purposes, the selection criteria applied by most deer farmers are quite basic. For hinds and stags, temperament is a prime determinant. This is judged by ease of handling for routine procedures such as yarding, vaccination, parasite control, ultrasound scanning, and for stags, velvet antler removal. An important consideration is aggression, both toward handlers and toward other deer. The heritability of temperament not known, and traits may be learned rather than genetic. However, farmers report a significant improvement in achieving calm, amenable deer as a result of culling animals that do not confirm to requirements. Selection of hinds for ability to conceive, as shown by ultrasound scanning early in gestation, and rear a calf to weaning, determined by lactational status, is also widely practiced. Audigé and associates[6] demonstrated that hinds that reared a calf to weaning were 3.1 times as likely to conceive early, and 3.7 times as likely to conceive at all in the subsequent breeding season than hinds not rearing a calf to weaning. Some farmers using individual sire mating systems will select stags on the basis of their apparent fertility, measured by conceptions or calves born.

Body size is also a selection criterion, and many farmers use crossbreeding between red deer and wapiti to achieve increased size compared with purebred red deer. However, this may reduce the biologic efficiency of feed conversion to venison, because hind maintenance constitutes a higher proportion of total feed requirement for the combined mother-offspring unit. Alternatively, use of wapiti/red deer hybrid stags mated to pure red deer hinds improves the biologic efficiency of a venison production system because of the greater potential for growth of the crossbred offspring, thus increasing the proportion of total energy consumption of the mother-offspring unit partitioned to venison production.

Selection of sire stags for velvet antler production is commonly practiced, and this has the potential for significant improvement in antler production because the heritability is about 0.43. Currently, phenotypic

characteristics of weight and conformation are the main criteria. Calculation of breeding values based on individual animal recording is only recently being adopted by some deer stud farmers in New Zealand. Sire referencing now needs to be undertaken to improve the rate of genetic gain.

No such criteria exist for wapiti. Until subspecies, races, and bloodlines have been sufficiently studied to establish true genetic differences, there is little basis for designing complex breeding programs. Until referencing schemes, such as ones initiated in New Zealand, have been developed, selection will inevitably be based upon phenotypic characteristics.

Hinds may be selected for temperament, body size, and appearance. These selection criteria need not have any basis in genetic performance, which can only be judged from progeny. However, some of these have been put to use. Culling has been based on infertility, repeated difficulty with calving, poor temperament, or other undesirable features as criteria.

In North America the driving force behind the wapiti industry has been the single characteristic of antler size, without regard to pharmaceutical quality. Some differentiation between so-called "velvet" character and "hard antler" character has begun to develop. The former products are used in the neutraceutical trade in the Orient, and to an increasing extent in North America. Hard antler (also known, inaccurately, in the trade as "hard horn") size and length is the character sought in the hunt ranch market. Stags may also be selected for bloodline and relationship to hinds in a group as well as phenotypic characteristics such as size, appearance, and temperament.

HERITABILITY

There have been a few studies of heritability in red deer in New Zealand and the United Kingdom. Where stag herds are farmed for velvet antler production, producers are interested in selection of stags for superior lifetime performance and selection of sires and dams to produce improved sons and management of the stag herd to increase returns from velvet antler.[14] These authors found that the heritability of antler production studied among over 2000 stags on five farms ranged from 0.43 (±0.09 SE) to 0.85 (±0.33 SE). The average estimated genetic correlation between velvet weights in successive years was 0.97 (±0.07 SE) but declined to 0.76 (±0.29 SE) as the number of years between harvests increased.[14]

Live weights have moderate to high heritabilities in both sexes and at all ages with estimates ranging from 0.48 (±0.36) to 0.80 (±0.12)[14] and 0.31 to 0.49, 0.22 to 0.89, 0.33 to 0.48, 0.37 to 0.45, and 0.37 to 0.90 for birth weight, weaning weight, midwinter weight, turn-out weight, and other weights, respectively.[15] On one property where inbreeding was recognized as a factor, heritability estimates were very low (<0.08).[15] Heritabilities for date of calving were low on seven of the eight farms (<0.05), and repeatabilities were low to moderate (0.06 to 0.37).[15]

Animals whose bloodlines originated in the forests of Eastern Europe (Yugoslavia, Hungary, Germany) were heavier at all stages, indicating their usefulness as "terminal sire" breeds, confirming the potential usefulness of the larger mainland European red deer.[15] Hinds of mainland European parentage also tended to calve earlier.[15]

There is only limited information on heritability of production traits in wapiti. One study of heritability of antler traits in over 12,700 stags showed a moderately heritable figure of 0.27 (±0.03 SE).[16] Antler yield can therefore be expected to respond to selection to some degree, but nonadditive and environmental effects can also influence production.

Crossbreeding involving mating animals of different breeds or races is prohibited in some jurisdictions (e.g., Alberta and Manitoba, Canada, and several states in the United States).

MATING MANAGEMENT

Decisions about mating management determine the likely pattern of reproductive outcomes. One of the most important considerations in deciding a breeding strategy is the choice made by the farmer as to how long a calving season is tolerable, and therefore at what date the stag is withdrawn from the hinds. As productivity and growth rates of calves is governed by birth dates, the earlier that hinds deliver, the higher are progeny weights. For most practical purposes a 6- or 8-week calving season is acceptable, although on well-managed properties most of the calves delivered in the second month will be born to 2-year-old animals calving for the first time.

To achieve the maximum benefit of the "stag effect," in which the sight, sound, and smell of the stag will both synchronize and stimulate the onset of estrus in hinds, it is advisable to introduce a breeding male to a hind mob 2 or 3 weeks before the expected date of breeding. In practical terms this is best accomplished by introduction late August, and before the end of the first week in September in the Northern Hemisphere.

Although some producers do request a prebreeding sire evaluation, the semen testing of stags just before the rut is probably not a common practice, despite the fact that infertility in stags is recognized. *Brucella ovis* has become recognized in New Zealand as a pathogen that affects the reproductive system of stags and is capable of causing infertility.[17]

Stag/Hind Ratio

The mating capacity of stags is not well documented but is an important consideration in determining pregnancy dates and herd conception patterns. The average stag/hind ratios for adult and yearling red deer in New Zealand were 1:40 (range 8–82) and 1:27 (range 1–51), respectively. The most recent data has shown pregnancy rates and dates were similar for more than 80 groups of red deer hinds mated at single sire ratios as low as 1:140.[11,18] Thus, the mating capacity of stags is greater than commonly utilized. It is recommended that all management factors for achieving pregnancy, as described elsewhere,[6] be optimal when large numbers of hinds are mated to an individual stag. There are obvious advantages to the use of large mating groups. The number of

paddocks needed is reduced, more hinds can be mated to superior sires, and the number of breeding stags required is reduced. However, as Beatson and associates[9] suggest, the use of large breeding mobs increases the risk of financial loss if, in a single sire mating system, a stag is either infertile or subfertile. Stag failures do occur, regardless of breeding group size, so the use of back-up stags should be standard practice if the risk is to be reduced.[1,9] There are no data to indicate a usable maximum number of hinds per stag on wapiti farms.

Despite the observation of a greater mating capacity of stags than commonly believed, it has become common practice to manage breeding groups with about one mature stag to 60 red deer hinds[6] and about a maximum of 35 or 40 wapiti hinds. In the most extensive investigation to date, over 3600 red deer hinds over 2 years of age, and more than 1100 yearling hinds were mated in each of 3 successive years. The number of hinds per stag was classified as 0–60, 61–100, and above 100. The variations in calving dates about a median were 10.0, 10.3, and 11.3 days, respectively.[9]

In general, much smaller numbers of hinds are mated to yearling stags if they are used as single sires. Groups of less than 10 hinds per stag are commonly used, although no data are available to justify this practice. In New Zealand it is not uncommon to breed yearling hinds in mobs that include several yearling males.

Manipulation of the Natural Cycle

The median calving date in New Zealand averages November 30 (range 11/26 to 12/6) for adult hinds, and December 13 (range 11/26 to 12/15) for primiparous hinds. In many temperate climates this is an ideal situation that ensures that the best possible quality of feed is available to the hinds to meet the demands of lactation. In some parts of the world, particularly New Zealand, the best quality forage is available slightly earlier in the year, and research efforts have been directed to finding ways of inducing early reproduction so that hinds will calve when forage is at its best.[1] In such areas it has the added advantage that calves born early in the year may attain heavier weights at a set time, and potentially provide better returns at market.

The technique has been investigated in New Zealand, but in North America, it is only likely to be of use in the warm wet climatic regions of the west coast and more southern areas where good quality fodder is available for long periods of the year. This may also be true of areas where irrigated grazing is practiced.

There are a number of practical methods of inducing early estrus in deer herds. The most commonly used regimen is a combination of a controlled intravaginal drug (progesterone)-releasing (CIDR) source for about 12 days, followed by intramuscular injection with 200 IU pregnant mare serum gonadotropin (PMSG) or synthetic gonadotropin-releasing hormone (GnRH) at the time of CIDR withdrawal. This regimen is also used for estrus synchronization for artificial insemination (AI) and embryonic transfer (ET) programs. An additional observation is that hinds in contact with treated animals are induced to come into estrus early, presumably due to a "dormitory effect" of the type that has been reported in other animals, including humans. The "stag effect," achieved by early introduction of stags to hind groups prior to the mating season, is also known to be a powerful inducer of estrus in hinds and one that can be enhanced further by advancement of rutting behavior of stags using melatonin. Advancement of the median conception dates of 8 to 10 days has been achieved using this technique. The sight, sound, and smell of the stag all serve to stimulate reproductive activity in the females.

If significant advancement of estrus is induced in hinds, similar advancement of stag reproductive activity is necessary. In natural systems, the cycle of sperm production among stags is geared to a calendar that more or less matches that of the hinds coming into estrus. The best quality semen is only present about 2 weeks before the rut, as it takes around 60 days for the testicle to go from its quiescent state around the longest day of the year to the production of fully mature spermatozoa. If hinds are artificially induced into estrus very early, the stags may be subfertile. Melatonin treatment of stags can resolve this problem. Alternatively, artificial insemination using frozen semen can be undertaken.

The other method for estrus advancement that has proved successful is use of melatonin. The advantage of melatonin is that it can be used upon both hinds and stags, either in the feed or as implants, so that both sexes come into reproductive readiness together. A melatonin implant has been approved for commercial use in Australia and New Zealand. It is recommended for use in yearling hinds in the first year. It is not commonly used with adult hinds because they are calving at the time when administration is needed. If administered to pregnant hinds it may cause prolonged pregnancy. The recommended regimen involves monthly treatments starting 3 to 4 weeks before the longest day. This will advance the reproductive season by approximately 3 to 6 weeks. Treatments started later than about 10 days before the longest day may advance calving by approximately 2 to 3 weeks. Treatments earlier than recommended are contraindicated and may suppress the ability of both stags and hinds to respond. Only those stags that are to be used in early breeding programs should be treated, as their performance if used later during the regular season may be less than optimal.

Melatonin induces not only early reproductive activity but also visible effects, including an early molt to winter coat, a reduced milk yield in the hinds, and an earlier than usual decline in appetite.

Pregnancy Determination

Details of techniques for pregnancy determination of both cervids and bison are provided in a separate chapter.[19–21] They include manual palpation, ultrasound scanning, and methods involving blood or fecal sampling.

Pregnancy Profiling

One advanced application of ultrasound to pregnancy diagnosis and assessment of fetal aging as a tool for

measuring reproductive performance has been described as pregnancy profiling.[18] Data have demonstrated the range of reproductive patterns that provide a benchmark for farmers wishing to improve reproductive performance. Pregnancy profiles for individual deer herds are becoming common on New Zealand deer farms, allowing managers to define not only pregnancy rate but also other reproductive outcomes such as first and last expected calving dates, median and mean conception dates, and the pattern of conceptions. Management decisions, as discussed elsewhere in this chapter, can be targeted to achieve the desired outcome.

PARTURITION

A distended abdomen is one of the few visual clues of impending parturition in red deer and wapiti.[1] In adult hinds the udder may begin to enlarge as much as 4 weeks before calving, while in primiparous hinds, this development may not be seen until 2 weeks prior to parturition.[1]

Restlessness, a characteristic fence-pacing activity, and solitude seeking are characteristic of imminent parturition. New Zealand workers recognized two such behaviors.[1] This behavior is not always seen, and may, in part, be a herd density–dependent phenomenon. In the wild, hinds usually isolate themselves as parturition approaches and do not rejoin the herd until about 2 weeks after calving.[22] Fence pacing appears to be an attempt to find a more suitable location for calving or to get away from pen mates. As few as 30% of farmed wapiti exhibit fence-pacing activity if they are at a density of less than three hinds per acre and have some measure of isolation from one another through either topography or the presence of cover.[23] However, age and experience of the hind does not seem to be a factor, and those that fence pace are not necessarily the same individuals each year.

By the end of first-stage labor the parturient hind will usually separate from the herd. As labor advances she may look at her flanks and frequently change position. She may even start to strain, stop and move away, and then graze briefly before starting again. Close observation of the events at calving have demonstrated that there is considerable variation in timing (Table 128-1).[24]

The normal fetal delivery presentation is anterior dorsal, similar to that of cattle, with the forefeet coming first, followed by the head.[1] However, a posterior presentation is not uncommon. During parturition the hind will turn and lick herself or the emerging calf or ingest fetal fluids that have splashed on the ground, as well as the placenta.[1] In normal parturition, passing the calf's head through the pelvis is the rate-limiting step, with complete delivery usually occurring in a matter of seconds thereafter. Final delivery may take place when the dam is either lying or standing.

Disturbance of a hind during parturition may delay the process considerably, and particularly in primiparous hinds, may predispose to dystocia. Hinds may rejoin the herd and subsequently seek a new calving site. Furthermore, primiparous hinds may leave the calving site altogether and abandon the calf if disturbed.[1]

Table **128-1**

Calving Sequence and Calf Vitality in Farmed Wapiti Observed at the Ministik Wildlife Research Station from 1988 to 1993

Observations	*n*	Range	Mean ± SEM
Stages of Parturition		**Time before Delivery (min)**	
First stage			
Pacing	27	91–902	365 ± 38
Second stage			
Contractions first seen	31	15–720	122 ± 24
Appearance of amniotic sac	12	27–238	97 ± 22
Bursting of amniotic sac	30	<1–355	79 ± 17
Appearance of calf	55	<1–193	45 ± 5
Calf Development		**Time after Birth (min)**	
Third stage			
First stand	58	13–271	49 ± 5
First suckle	58	28–223	76 ± 5

From Church JS, Hudson RJ: Calving behaviour of farmed wapiti (*Cervus elaphus*). *Appl Anim Behav Sci* 1996;46:263–270.

Calving Dates

The peak of the calving season in the wild and on game farms is the first of June (12/1 in Southern Hemisphere), although variations from year to year and from place to place may occur. At least in wapiti, male calves tend to be born several days later than female calves but this might be due to the slightly greater proportion of male calves born to first-time calvers. This seems contrary to the sex ratio bias on the Isle of Rhum, where sons predominate among older dominant hinds.[22]

Most deer farmers find it advantageous to have calving synchrony. Although breeding seasons can be synchronized or even significantly advanced by hormonal treatments, the simplest way to achieve synchrony is by optimal mating management, including maintaining optimal BCS, early weaning, early stag introduction, early removal of the stag, and culling of late-breeding hinds. For optimal calving spread, stag withdrawal should be by November (May). However, for red deer farming in New Zealand, normal practice shows a mean mating termination date of May 10 (Southern Hemisphere).[6] Those authors showed a median calving date of November 30 for adult hinds and December 13 for primiparous hinds, but considerable variation exists among farms.[6] These data confirm that few farmers achieve the biologic potential reproductive performance from their deer.

Birth Weights

Management of hind weight during gestation has a direct effect upon birth and weaning weights of wapiti. Thorne and associates[25] observed that when hinds lost more than 3% of body weight during the second and third trimesters, calf weights were below 16 kg.

Birth weights average about 9 kg in red deer and 18 kg in wapiti, with crossbred calves being intermediate,

dependent on the proportion of wapiti genes present. Male calves tend to be larger than females, as are calves from older hinds. Birth weight is a good predictor of neonatal survival and weight at weaning. Wapiti calves less than 11.4 kg at birth have a less than 50% chance of survival.[25] A similar relationship has been shown for fallow deer.

If hinds are fed to excess during pregnancy, calving difficulties may ensue, due to both oversize of calves and overfat hinds. Underweight calves, usually due to hind malnutrition, should be the exception on farms, although extremes in the wild are evident. In the wild there is often ample opportunity for the hind to regain condition between the flush of vegetation in mid-April and calving in late May or early June. Consequently, it appears safe, if not desirable, to feed to maintenance or even allow a 5% to 10% weight loss of pregnant hinds through the winter feeding period before they are turned out onto spring pasture. However, a lowered weaning rate has been described in red deer if body weight was lost during gestation.[28]

Bonding

Deer calves are "hider" animals and may be separated from the mother for long periods of time. During a 24-hour period the calf may only spend a few minutes with its mother, during four to seven sucking bouts that last a short time. It is therefore important for both animals to establish recognition of one another. Bonding is initiated when the hind first licks the calf after birth, but is reinforced on subsequent occasions. After a feeding bout the hind attempts to lead the calf away with repeated vocalizations and nose-to-nose contact. At some point the calf will leave its mother and seek cover. After grazing, the hind may return to the calf and initiate contact with a soft mewing. Alternatively, the calf may squeak and even stand up when seeking its mother. If it does this, several hinds may approach and sniff it to identify it. It is possible that a hind may have "labeled" her calf with saliva so that she can recognize it later.[1] However, on farms it is not uncommon to find that a significant number of calves are nursed by females other that their mothers, and that a considerable amount of cross-mothering occurs.[29] Hinds that have lost calves may be willing to let other calves suck, and may even "adopt" a calf.[1]

An on-farm survey to determine the reproductive performance of farmed wapiti among 50 producers in Alberta involving 1084 wapiti hinds reported a calving rate of 81% and 96% for 2-year-old and adult hinds joined with the stag, respectively, giving an average of 93%.[13] Overall calf mortality rate was 5.2% in the survey, with a trend for 2-year-olds to experiencing losses of 9.5% and adult hinds 4.4% of progeny born. Similar surveys of farmed red deer in New Zealand observed calf mortality rates between birth and weaning of 6% to 8% for adult and 12% to 16% for primiparous hinds.[9,28] Dystocia accounted for two thirds of the total calf deaths reported in the survey,[13] but that cause was significantly lower for red deer in New Zealand.[8]

Twinning

Twinning in red deer and wapiti is not common. One set of triplets and three sets of twins gave a multiple birth ratio of 1 in 271 calvings in a Canadian survey of wapiti, while no instance of twinning was confirmed in a New Zealand red deer survey.[13,28] Other data for red deer suggest a twinning rate of between 1:600 and 1:2000. Twinning is common for some other species of deer, including white-tailed deer.

Management at Calving

Prospective dams should be assembled in calving paddocks several weeks before the expected normal calving season to allow time to adapt to the environment and social changes often associated with altering mob composition in preparation for calving. For wapiti in western Canada, an appropriate date is about 10 May. The paddock should provide some cover for the newborn calves but remain sufficiently open and heavily stocked so that the dams can detect and drive out intruding coyotes. Adequate cover near the middle of the paddock keeps calves from bedding along the fence line where they may get tangled in the netting or encounter predators. If the calving paddock is large, strips may be mowed to ensure that vehicles do not drive over hiding calves. Most farmers like to hold their nursery herd near the farmhouse so they can more closely monitor progress and respond to any emergency.[1] However, other studies of red deer suggest that disturbance during calving may increase the risk of "mismothering" and calf loss.

When red deer were first established on farms in New Zealand, losses of calves due to aggression from hinds other than their dams (termed "rogue hinds") were believed significant. Losses were reduced by culling or providing cover (e.g., brush piles or hay coils), but the problem subsided as the breeding herd settled into farm life. Many farmers provide artificial cover in uniform, heavily grazed calving paddocks for thermal amelioration as well as security.

Pasture rotation is advisable to provide the best quality forage available. However, to avoid leaving a newborn behind, the nursery herd should not be moved until the calves have abandoned their lying-out behavior and joined the herd. Supplemental feeds usually are offered to maintain tractability and integrate the calves into the farming operation.

Calving Difficulties

The most common causes of dystocia are overfatness and unfitness.[8] Audigé and associates described higher dystocia rates in hinds with a BCS of 4 or more on flat pastures than on hill pastures. Fat hinds have reduced pelvic passage dimensions and may also bear larger calves, both exacerbating the situation. There has been natural selection for ease of calving because farmed deer have only recently been adapted from feral populations; thus, dystocia rates are lower than in some other classes of domesticated livestock. However, dystocias can be a problem in some poorly managed intensively farmed herds. Occa-

sional incidents of dystocia caused by malpresentations that are not related to mismanagement can occur. Data show dystocia rates on commercial deer farms to average less than 1%, although rates of up to 10% have been observed.[8,26,27] Primary risk factors were high BCS prior to calving, rapid weight gain prior to calving, and topography.

Animals that are timid or are kept in large paddocks, particularly on hills, where they get ample exercise, seldom experience calving difficulties. But the problem may be seen in settled herds that are content to laze around feed bunks throughout pregnancy.[1] Farmers with docile hinds on supplemental feed in the early spring period often encourage animals to be more active in search of emerging spring growth, or force them to exercise to reduce the risk of dystocia. The dystocia rate is higher in primiparous hinds, due to both size factors and their more insecure nature at that age, making them more prone to disturbance during parturition.

Dystocia may also be caused by either fetal or maternal abnormalities. Fetal abnormalities may include congenital conditions but are most commonly either relative fetal oversize or abnormalities of presentation or position as delivery commences. Many dystocias are associated with fetal malpresentation.[8,26,27] Dystocia may be attributable to relative maternal undersize, which may occur if wapiti stags are bred to red deer hinds, or particularly if purebred wapiti embryos are implanted into red deer hinds.

Excessive or inappropriate interference with calving hinds can actually create difficulties. Farmers who enter paddocks where hinds are in second stage labor may disrupt the process and cause hinds to stop and move from the intended birthing site. This is particularly important with primiparous hinds and can cause calf abandonment. The most useful pieces of equipment during the calving season are a vehicle with which the stock are familiar and a good spotting scope or pair of binoculars. With these, paddocks can be observed from a distance. Observation three or four times a day is probably sufficient to detect dystocias in time to allow successful intervention if necessary. However, it is common practice on large commercial deer farms for managers not to observe hinds intensively during calving, because the risk of dystocia in well-managed herds is low, and the risk of disturbance causing dystocia and mismothering problems is high.

A key decision is when to intervene in difficult births. The farmer should be familiar with the chain of behavioral events that occur in normal parturition. If an individual starts the straining characteristic of second stage labor, she should calve within 2 hours if she has had a calf previously, and within 3 hours if she is calving for the first time. A good rule of thumb is that if there is no progress over a 30-minute period, intervention should be considered. The straining may be intermittent, but delay of delivery beyond these times may mean that assistance is required. However, this is not a hard rule, and it is not uncommon to start preparation of the handling shed, only to return half an hour later to find a newborn calf on the ground.

With binoculars, it may be possible to discern whether or not a calf is being normally presented. The normal position, as for most classes of livestock, is an anterior presentation in which the head is preceded by two forefeet. Occasionally, a posterior presentation with only two hind feet showing, may proceed to an unassisted birth. Other presentations should be considered abnormal and intervention should proceed before the usual 2-hour waiting period.

The hind experiencing difficulty should be herded into the handling yards. Although she will most probably have isolated herself from other animals in the calving paddock, and can often be moved on her own, other hinds may move into the yards with her. These animals should be returned to the calving paddock as soon as possible after the parturient dam has been isolated.

It is common for hinds experiencing dystocia to isolate themselves from the herd. She should be yarded and maneuvered so that she can safely be approached initially from the side to avoid being kicked while she is examined. Manual restraint may be adequate, although modern hydraulic restraining devices are excellent in providing both restraint and standing support and are safer for the people involved, particularly with the larger wapiti. Thorough disinfection of the entire perineal area, as well as the hands and arms, and use of copious quantities of obstetric lubricant are essential before any examination of the reproductive tract. If there is any possibility of brucellosis or leptospirosis or other zoonotic disease in the herd, the operator should wear protective gloves and sleeves. The first step is thorough examination of the calf and the hind to ensure that the tract has not been damaged or that the head and feet presented are all from the same calf, or that one forefoot and one hind foot are not being simultaneously presented. Note that twinning in red and wapiti deer is uncommon, but when it occurs, the risk of dystocia is higher. Epidural analgesia and uterine relaxant drugs may be advantageous if manipulations are restricted by abdominal straining or uterine contractions, which may be particularly intense in deer.

Once positional abnormalities have been corrected and it has been determined that the relative sizes of dam and calf will permit vaginal delivery, traction can be applied. This should neither be continuous nor overzealous. Calving chains placed above the fetlock joint of each leg, and if possible behind the ears and through the mouth, the latter to prevent strangulation and ensure that the head is pulled in a straight line, should be pulled both outward and downward. Intermittent traction on alternate legs with steadier traction on the head will usually effect delivery. Overzealous use of chains or ropes can easily lead to limb fractures or uterine rupture, especially among inexperienced operators who are more used to assisting the more robust bovine calves at delivery.

The calf should be quickly removed to an area close to the chute where fresh dry bedding has been prepared. Other than clearing its airways and ensuring that it is breathing, the operator should not interfere with it. Breathing can be stimulated by inserting a finger, or a

short piece of straw, gently into the nostril of the calf to stimulate sneezing. If necessary, intravenous or intracardiac cardiopulmonary stimulant drug may be used. Drying with cloths is contraindicated. Cleaning of the calf should be left to the mother, to assist with calf recognition and bonding.[1] A segment of fetal membrane should be placed on the newborn. If later observation shows the membrane to be still present, this is an indication that bonding or acceptance has not occurred. The hind should be quietly moved to the segment of the handling system where the calf has been left and the two should be left strictly alone for an hour to ensure "mothering up." Rarely, an inexperienced hind may attack a calf, so a brief period of observation of the pair should be carried out. Such an attack would normally take place within a short time (<1 minute).

If immobilizing drugs have been used to restrain the dam, both calf and dam should be treated with an appropriate antagonist, as immobilizing drugs will cross the placental barrier and sedate the calf before delivery.

Once the hind and calf have imprinted for about an hour, a check should be made. If bonding has started, the hind will have licked the calf dry and removed the membrane by this time and it may even try to stand and search for the udder. If the calf is still wet, and the hind shows no interest in it, it must be removed for artificial rearing. Colostrum may be collected as described later. If all is well, gates from the shed back to an adjacent paddock can be left open and the pair should again be left alone, for several hours if possible. Allowing a hind to move her calf in a passive manner is a better option than moving the calf, as the hind may refuse to accept it once she is out in the open and has not seen it lie down.

Elective cesarean section is an alternative delivery for red deer hinds used as surrogate mothers for purebred wapiti calves implanted by embryo transfer. The ethical issues surrounding this practice should be considered. It is also an option when vaginal delivery is not possible for other reasons. In most situations, this operation will be carried out under general anesthesia, although the use of epidural xylazine has been described.[1] In most cases resulting calves will be artificially reared, and the caveat on the dangers of rearing male cervid calves must be issued.

In the event that a dead calf is delivered, or if artificial rearing is necessary, colostrum may be collected from the hind. If a hind is recumbent after a cesarean section or mildly sedated while standing in a chute, she can be treated with oxytocin. A short while later colostrum can readily be collected with a 60-ml syringe with the hub end cut off and the plunger reinserted from the cut end, not the flange end. The flange end is then placed over the teat after greasing the udder to allow a seal, and gentle suction applied. Alternatively, a human breast pump may be used. As much as 750 ml has been collected at one time.[1]

WEANING

Choice of early weaning (pre-rut), late weaning (post-rut), or no weaning will depend on the individual farm and policies. All options have advantages and disadvantages, which relate to desired reproductive outcomes the following season, feed management, animal health program implementation, labor, etc. Thus, the decision is based on the aims and objectives of the individual farm. One reason for weaning is the age-specific difference in winter feed requirements between calves and adults, but pre-rut weaning is claimed to tighten the synchrony of breeding and calving. Weaning may be done when the calves are about 3 months old, in the first week or 10 days of September in the Northern Hemisphere. By this time, they will have been supplied with a creep feed arrangement and will be able to manage for themselves.[1]

Effects of Weaning on Reproduction

The advantages to a breeding program that accrue from early pre-rut weaning of red deer are that the hinds will have about a 3- to 5-week period before the onset of the rut. This will give them the opportunity to recover from the stress of the weaning itself, which lasts a few days, and from the nutritional burden imposed by the demands of lactation. They will be able to start putting on some weight and will be in the best possible nutritional condition at the start of the rut. This topic is covered more fully in the preceding section on body condition scoring. It has been reported that hinds weaned after the rut, and therefore lactating during the rut, were 0.5 of a BCS lower than pre-rut weaned hinds.[12] This, along with the possible effects of lactational hormones on ovulation, resulted in a delay in conception date of 12 days, but did not alter conception rate per se, although if early removal of the stag is desired, pregnancy rate may fall. Those authors noted that body weight and growth rate of post-rut weaned progeny were higher than those weaned pre-rut. However, in absolute terms, in the following season it is likely that the weights of progeny of pre-rut weaned hinds the year before will be equivalent because they would have been born earlier, and therefore be heavier at a given date as a function of birth weight. It is likely that feed quantity and quality will also influence the magnitude of differences between early and late weaning on a seasonal basis. Early weaning also increases breeding synchrony among hinds. This will bring forward the mean calving date, and in turn give the calf of the following year more time to grow to optimal weight before weaning. This reinforces the view that management decisions about reproduction should consider all implications and consider effects over two breeding seasons.

The longer gestation period of the wapiti relative to the red deer (247 ± 5 days versus 233 ± 7 days, respectively, in well-nourished hinds), and earlier rut onset, means that weaning at or about the beginning of September only provides the hind about 10 days to 2 weeks for recovery before the start of the rut. However, pre-rut weaning was associated with an advance in caving dates of 5 days as well as other benefits to the farming program, which included improved calving (3.3%), better weaning rates (2.6% in adult hinds and 13.4% in young hinds), decreased calf mortality rates (3.2%), and improved growth to 200 days (8%).[13]

Weaning Practices

Weaning can be pre-rut, post-rut, or natural (no management-imposed separation). A survey of wapiti farming practice in western Canada shows that both pre- and post-rut weaning is carried out, and that some farmers do not wean at all. It is common practice on intensively managed red deer farms to wean calves before the rut, and this is considered essential if hinds are to be entered into an artificial breeding program. Hinds in poor body condition, due to undernutrition, or that have been permitting multiple suckling should definitely have progeny weaned if they are to conceive in the early part of the breeding season.[9,12]

Three techniques for pre-rut weaning have been investigated. In remote weaning, which has been the traditional practice among beef farmers, and was adopted by wapiti and red deer farmers, calves are abruptly weaned at about 100 days of age and removed to a location remote from their dams. Interval weaning involves the shifting of a few hinds each day over a 10-day period to an adjacent pasture, and then to a remote pasture. Contact weaning involves weaning of the calves into a paddock with which they have been previously familiarized, adjacent to the paddock in which their dams are held, separated only by a reliably calf-proof fence. In two separate studies, interval and contact weaning were reported to be more welfare-friendly than remote weaning, with calves demonstrating fewer signs of distress. However, no differences in calf performance between trial groups were reported.[30,31] When comparisons were made between remote weaning, and calves weaned into unfamiliar paddocks, separated by 100 m from their dams, the latter showed more signs of distress than those moved a distance of 2 km.[32]

Weaning Rates

Weaning rates, for practical purposes, may be described as calves weaned/hinds joined to the stag, calves weaned/hinds pregnant at scanning early in gestation, or calves weaned/calves born. Each ratio gives different information. It is important to standardize terminology when comparing rates between farms, age groups, and species, because the effects of gestational and perinatal losses may be significant on many farms.

Data for New Zealand red deer farm weaning rates (calves weaned/hinds scanned pregnant) from 81 herds reported in several large surveys show primiparous hinds weaned at an average of 86.2% ranging from 64% to 100% between herds.[11,28] By comparison, adult hinds weaned at an average of 91.5% (range 78% to 100% between herds). When the effect of pregnancy rate is included, overall reproductive efficiency (calves weaned/hinds joined to stag) averaged 63% to 77% and 81% to 89%, respectively, for primiparous and adult hinds over 2 years.[28] Similar data from another study show ranges of 68% to 75% for primiparous hinds, and 80% to 88% for adult hinds, respectively.[11] Thus, there is enormous variation in reproductive efficiency among farms, ranging from 25% to 92% and 69% to 94%, for primiparous and adult hinds, respectively, indicating that management plays a pivotal role in reproductive outcomes.[27] Loss rates during gestation ranged from 0% to 2.5% (average 1%), indicating that the majority of losses between conception and weaning are periparturient.[11,28]

Data on weaning rates have not been as extensively studied in North America. In an on-farm survey of performance of farmed wapiti among 50 producers in Alberta involving 1084 hinds, weaning rates of 73% for 2-year-old and 91% for adult hinds resulted in an 88% weaning rate overall.[13]

CHAPTER 129

Reproductive Management of Fallow Deer

ROBERT C. MULLEY

Fallow deer are the most widely distributed deer in the world and are primarily farmed for meat. Venison from fallow deer is fine grained and cut sizes are particularly suited to the restaurant trade, which usually prefers chilled rather than frozen product. To provide year-round availability of chilled product of consistent quality, a range of reproductive management strategies and production techniques, including selective slaughter of males and females at different times of the year, castration of some males for slaughter during the breeding season, and the use of hybridization, is required.

Genetic selection for reproductive success and growth and development to suit market criteria will further contribute to economic success provided that animal health and husbandry benchmarks for a particular region are adhered to.

Velvet antler is regarded as a by-product of fallow deer farming, but the amount of velvet antler produced by an adult buck each year rarely exceeds 500 g, and the financial return to the farmer after the costs of removal from the animal and sale levees make it a low return product. However, for management reasons (e.g., injury to breeding females, animal handlers in yards, etc.) the antler should be removed from fallow bucks anyway, and if this procedure coincides with antler growth at a highly saleable grade, then the price differential between costs and returns may favor the farmer. The antler cycle is strongly linked with reproductive cycles, and effective management of this species for production of venison necessarily involves consideration of the antler cycle in reproductive management strategies.

A number of factors need to be considered for the development of an efficient fallow deer farm. Assessment

CHAPTER 129

Reproductive Management of Fallow Deer

ROBERT C. MULLEY

Fallow deer are the most widely distributed deer in the world and are primarily farmed for meat. Venison from fallow deer is fine grained and cut sizes are particularly suited to the restaurant trade, which usually prefers chilled rather than frozen product. To provide year-round availability of chilled product of consistent quality, a range of reproductive management strategies and production techniques, including selective slaughter of males and females at different times of the year, castration of some males for slaughter during the breeding season, and the use of hybridization, is required.

Genetic selection for reproductive success and growth and development to suit market criteria will further contribute to economic success provided that animal health and husbandry benchmarks for a particular region are adhered to.

Velvet antler is regarded as a by-product of fallow deer farming, but the amount of velvet antler produced by an adult buck each year rarely exceeds 500 g, and the financial return to the farmer after the costs of removal from the animal and sale levees make it a low return product. However, for management reasons (e.g., injury to breeding females, animal handlers in yards, etc.) the antler should be removed from fallow bucks anyway, and if this procedure coincides with antler growth at a highly saleable grade, then the price differential between costs and returns may favor the farmer. The antler cycle is strongly linked with reproductive cycles, and effective management of this species for production of venison necessarily involves consideration of the antler cycle in reproductive management strategies.

A number of factors need to be considered for the development of an efficient fallow deer farm. Assessment

of body score of both breeding and slaughter stock combined with information on nutritional requirements of different age and sex classes of stock at various stages of the production cycle are essential elements of reproductive management on both stud and commercial farms. The integration of information on reproductive biology, behavior, nutrition, genetics, lactation, and animal management of farmed fallow deer provided in this chapter will assist practitioners to advise owners of both small and large farms on how to optimize production for maximum profit.

THE BREEDING SEASON

Fallow deer exhibit highly seasonal patterns of reproduction calibrated by photoperiod. They are short-day breeders, with the rut (peak of mating activity) occurring in October/November in the Northern Hemisphere (NH) and April/May in the Southern Hemisphere (SH). Breeding pattern within regions is highly synchronized in any one year, and reproductive management of this species on pastoral farms must therefore align feed supply with seasonal demands of late pregnancy and lactation. Patterns of reproduction also vary slightly at different latitudes, and local benchmarks for reproductive behavior and onset of the rut need to be established. Description of the estrous cycle, estrus, length of the breeding season, and gestation length are provided by Asher in Chapter 123.

REPRODUCTIVE BEHAVIOR

Bucks

The breeding season is enormously stressful for fallow bucks. Potential sire bucks should be clinically examined by a veterinarian well before the start of the rut for detection of abnormalities, because once the rut commences they become extremely aggressive toward other deer if confined in handling yards and injuries can occur. Bucks will fight vigorously during the pre-rut period to establish dominance, and in very large paddocks and in the wild will sometimes establish stands, which they mark by thrashing small trees and digging rutting scrapes. In confinement bucks will walk the boundary of their fence line incessantly, especially in small paddocks (1–3 hectares) and can cause deep erosions from this activity in wet conditions. In small enclosures bucks give the impression that they are herding does because there is no real opportunity for lekking to occur. Even when the herd of does is resting the dominant buck will be moving continually to defend the harem against competitor bucks or to check does for estrus.

If bucks are placed in adjoining paddocks they will fight vigorously through a fence and can make large holes in it. The fighting will also create holes in the top soil on either side of the fence, as the bucks attempt to hold ground during their pushing and shoving. This enormous energy expenditure leads to rapid weight loss, and adult bucks can lose 20 to 30 kg in a period of 6 to 8 weeks just prior to and during the rut. This equates to a change in body condition score from 3.5 to 1.5 (on a scale of 5) and leaves the buck vulnerable to winter death syndrome if low body condition is combined with poor quality feed and cold-snap weather conditions.[7] Losses among sire bucks can be minimized by providing high-quality feed to sires immediately following the rut. This ensures protection of valuable genetics in preparation for subsequent breeding seasons.

Bucks are capable of breeding past the age of 15 years, but in the wild and on farms in competition with other bucks, they are unlikely to hold a harem beyond 7 to 8 years of age. Rapid turnover of breeding bucks on farms is desirable to reduce the intergeneration interval and maximize genetic gain through selection.

Does

Fallow does reach puberty weight prior to 16 months of age, but usually do not conceive until that age because of the acutely seasonal photoperiod effect that induces the onset of estrus. Occasionally precocious females will reach puberty weight by 8 months of age and conceive, but this should be avoided by careful management because of the impact of pregnancy on growth of the doe and the long-term impact on lifetime reproductive performance.

Estrous behavior in does appears quite passive compared with that of other livestock species.[1] It is rare for does in estrus to mount other does or be mounted, and the most obvious characteristic of fallow deer estrus is simply that a doe will stand to be mounted by the buck. A nonestrous doe will generally avoid close contact with the rutting buck and will run short distances if a buck approaches.

The onset of estrus can be very abrupt, although self-grooming, more activity than normal in the form of walking and fence-pacing, and reduced time spent feeding are indicative signs. Does can cycle for 3 to 6 months if not mated, at intervals of 21 to 25 days from early to later in the breeding season, respectively. Interest shown by both bucks and does in mating wanes remarkably after about the fourth estrous cycle of the breeding season, and it is uncertain whether this is due to weakening pheromonal signals associated with estrus or some other reason.

REPRODUCTIVE BIOLOGY

Fallow deer have a highly synchronized mating season. The does are polyestrous but most (~95%) conceive in their first or second estrous cycle. Pregnancy testing using ultrasonography is 100% accurate from 50 days of gestation, and a high level of accuracy is achievable earlier than this by experienced operators. Rapid fetal growth takes place in the third trimester of pregnancy when daily energy requirements increase by 25%. Basic information on the reproductive biology of fallow deer is presented in Table 129-1.

The buck-doe ratio used by most fallow deer farmers is 1:40 for experienced adult bucks and 1:20 for rising 2- and 3-year-old bucks. Higher buck-doe ratios can lead to subfertility in males and prolong the breeding season. This may lead to the birth of late fawns (conceived in

Table **129-1**

Fallow Deer Reproduction

Feature	Description
Onset of puberty	Does: 16 months (weight dependent, 35 to 40 kg) Bucks: 14 months (motile sperm first detected)
Onset of breeding season	Mid-April Southern Hemisphere, mid-October Northern Hemisphere
Duration of breeding season	6 estrous cycles in adult does 4–5 estrous cycles in younger does
Duration of rut	6 weeks (2–3 estrous cycles)
Length of estrous cycle	21 ± 0.6 days (1st cycle of breeding season) 25 ± 1.5 days (last cycle of breeding season)
Length of estrous	12 to 24 hours
Matings per estrous	Repeated mounting (16 ± 7) prior to final ejaculatory mount
Courtship	4 to 50 minutes (mean ± SD = 15 ± 10)
Gestation length	234 ± 2 days
Onset of fawning	Last week of spring
Duration of parturition	30–180 minutes from appearance of membranes
Fawning rate	88–92% of does joined
Male-female ratio at birth	1 : 1
Weaning rate	80–84% of does joined
Birth weight	Females: 4–4.2 kg Males: 4.2–4.6 kg
Twinning rate	<1 : 200

fourth or fifth estrous cycle), and these fawns will grow slower than their counterparts, be subject to winter conditions earlier in their development, and usually do not attain the adult body weights expected. Late fawns might not conceive at 16 months of age as expected, because their body weight will not be sufficiently high by then to support the onset of puberty, pregnancy, and then lactation. Fallow does are highly fertile and will continue to breed after 12 years of age, depending on conditions, although there is some evidence that they are most efficient between 3 and 8 years of age.[10]

Fallow does will usually miss one or more breeding seasons throughout their reproductive life even when environmental conditions seem favorable.[10] Stress may play a role in inducing this reproductive spell, and may originate from the heavy demands of lactation in drought years or from feeding the rapidly growing male fawn through to weaning the previous year, from introducing deer to new surroundings at the start of the rut, or changed environmental conditions.

Fawn growth rates between 100 and 200 g/head/day are usually attained in the first 12 weeks of life, but slow to average between 50 and 100 g/head/day for the following 9 months up to yearling age. Growth profiles for female and male fawns up to 12 months of age are shown in the annual management calendar in Table 129-2. Castration of males at 6 months of age reduces growth rate by 10% compared with their male counterparts, but this is compensated for by increasing ease of management of slaughter animals during the following breeding season.

Accurate records of reproductive performance and growth rates of progeny are essential for selection of high-producing animals and for sire comparisons in single-sire mating systems. Breeding does should be replaced at the rate of 20% per annum, and the intergeneration interval for breeding bucks should be as low as is feasible to maximize the genetic gains resulting from genetic selection.

WEANING

Weaning is a management procedure that separates breeding females from their progeny, and is usually carried out to (i) simplify management of doe mating groups over the rut, (ii) provide preferential feeding for juvenile animals during the winter, and (iii) allow easy access to young animals for animal health and welfare management once they are nutritionally independent of their dam, without disturbance to breeding herds.

Weaning can be carried out pre-rut or later in the breeding season in fallow deer, as lactation does not appear to inhibit ovulation and conception. However, the procedure should not be carried out without consideration of factors/stressors that can impact on behavioral and growth changes in weaned animals and their dams, such as unfavorable weather patterns (drought, wet, cold), body condition of dam or fawn, and introduction to unfamiliar surroundings of fawns, in particular after separation from their mother. If does become emaciated due to poor nutrition during lactation, it is probable that subsequent reproductive performance will be low if poor body condition is maintained throughout the rutting period, and pre-rut weaning is recommended under such conditions.[1] Studies have shown positive effects of pre-rut weaning on hind conception date and hind condition in red deer in New Zealand, but it was acknowledged that weaned calves grew more slowly.[14]

Weight loss occurs in fawns immediately after weaning and persists for 2 to 3 weeks whether the procedure occurs pre-rut or post-rut. Comparative evaluation of weight recovery in fallow deer weaned pre-rut compared with deer weaned post-rut has shown no difference between the groups by 12 to 14 months of age owing to compensatory weight gains that occurred during spring (9–12 months of age).[11] However, the availability of nutritious feed during this time is necessary to facilitate weight recovery. Minimization of weight loss at weaning is assisted by (i) weaning dams from their fawns so that fawns remain in familiar surroundings, (ii) adding two or three older animals of quiet temperament and who are used to human contact to the group of weaned deer, to assist in training of weaned deer to use of laneways, gates, and concentrate feeding points if required, and (iii) moving dams out of calling range of their fawns for 3 to 4 weeks. This may not be possible if deer are being weaned indoors, where appropriate strategies may need to be developed according to the size of the facility.

Controlled mating practices may require considerable pre-rut sorting and handling of breeding stock, and under

Table **129-2**

Annual Management Calendar

Month	Adult Bucks	Adult Does	Rising 2-Year-Olds	Fawns
1st month of summer: December (SH) June (NH)	Velvet bucks at "A" grade stage of growth Remove velvet from 2-year-old stud bucks	Monitor fawning and ensure adequate high-quality feed Lactation requires 20–24 MJME/head/day Record birth weights for stud records	Remove velvet from 2-year-old bucks Last year's fawns now regarded as rising 2-year-old animals	Sell animals reaching BCS and market weight requirements Weigh animals for selection data New fawns now being born
2nd month of summer: January (SH) July (NH)	Remove antler regrowth Veterinary examination of breeding bucks Record weight and BCS Vasectomize teaser bucks for use in AI program if needed.	Lactating does need 20–24 MJME/head/day. Provide feed supplement if required Catch, ear tag and weigh fawns born late	Remove antler spikes Record weight and BCS of deer to be sent for slaughter	Fawns start eating hard feed from 7 weeks of age
3rd month of summer: February (SH) August (NH)	Provide quality feed to bucks in preparation for the rut Bucks easily stressed late in month Yarding and handling procedures should be minimized	Lactating does need 24 MJME/head/day Provide feed supplements if required, to maintain BCS 2.5–3	Weigh and BCS animals for slaughter Provide high-quality feed (10 MJME/head/day) to does about to be mated for the first time	Fawns eating up to 5 MJME/head/day hard feed plus milk Growth rates of buck fawns 180–280 g/day Growth rates of doe fawns 120–200 g/day
1st month of autumn: March (SH) September (NH)	Select breeding bucks and introduce to does in mating groups Avoid placing bucks in adjoining paddocks with shared fence line as they will fight incessantly	Pre-rut wean Vaccinate does Record lactation status (wet and dry) of does Cull dry and poor temperament does Build doe BCS to 3 prior to joining Regular handling of does for AI to habituate to yards and quieten	Weigh and BCS does to be joined Minimum weight for European does is 38 kg, and hybrid does 40 kg Sell surplus does and castrated bucks for venison	Wean fawns if this procedure is carried out pre-rut Wean all fawns over 16 kg, vaccinate with polyvalent clostridial vaccine Weigh, sex, and tag animals if not done at birth Provide high-quality feed. Fawns now eating 10 MJME/head/day
2nd month of autumn: April (SH) October (NH)	Mating commences Provide high-quality feed to standby bucks and breeding bucks even though their VFI is greatly reduced Put teaser buck with does being prepared for AI	Feed high-quality feed to maintain BCS 3 at joining Natural mating commences Insert progesterone devices for synchronization of estrus in does for use in AI program Does will lose weight for 2–3 weeks after weaning	Minimum weight of 38 kg and BCS of 2.5 for does to be joined Sell castrated bucks and surplus does for venison	Best feed available for weaned fawns 10 MJME/head/day and 15% protein for best growth Will lose weight for 2–3 weeks after weaning 2nd vaccination with polyvalent clostridial vaccine Anthelmintic drench may be required in wet years
3rd month of autumn: May (SH) November (NH)	Replace breeding bucks with replacement buck for third estrous cycle Keep teaser buck with does that have had AI for 2 weeks after procedure, then replace with entire buck	Maintain does at BCS 3 Remove devices for synchronizing estrus and AI does Sell cull does for venison	Sell surplus does and castrated bucks for venison	High-quality feed to maintain growth rates of 80–100 g/day (bucks) and 65–85 g/day (does) Anthelmintic drench in wet years if required

Table **129-2**

Annual Management Calendar—cont'd

Month	Adult Bucks	Adult Does	Rising 2-Year-Olds	Fawns
1st month of winter: June (SH) December (NH)	Remove all breeding bucks from mating groups in first week of month High-quality feed for rest of winter to ensure survival and optimum velvet production	Doe mating groups can be combined for ease of management Monitor BCS closely and feed to maintain at score 3	Sell surplus does and castrated bucks for venison	Castrate bucks for slaughter in following winter Weigh and calculate growth rate since weaning Animal health check Feed supplement if required
2nd month of winter: July (SH) January (NH)	Provide quality feed to ensure optimum velvet production and recover BCS post-rut Require 20 MJME/head/day	Pregnancy test does and cull dry does Feed >10 MJME/head/day to all pregnant does Supplement if required	Feed 10 MJME/head/day to all pregnant does Supplement if required	Best available feed to maximize growth Weigh and record growth for selection
3rd month of winter: August (SH) February (NH)	Feed to appetite with high-quality feed Protect from weather extremes Record dates of antler casting	Regular check of BCS of does, any decline to be addressed with high-quality supplement Pregnancy test does that were not detectably pregnant last month	As for adult does All surplus castrates to be sold	Weigh and record growth Health check Record spike initiation on bucks
1st month of spring: September (SH) March (NH)	Record antler casting dates Provide high-quality feed	Sell cull does for venison Monitor BCS and maintain at 3 with supplements if necessary	Sell culls for venison Pregnant does treated same as adult does	Weigh and record growth and development of antler spikes
2nd month of spring: October (SH) April (NH)	Separate bucks into velvet mobs on basis of antler casting dates Give high-quality feed for optimum velvet production	Vaccinate with polyvalent clostridial vaccine Separate into fawning mobs Keep AI groups separate for ease of fawn identification Feed requirement now 13 MJME/head/day	As for adult does	Remove early antler spikes
3rd month of spring: November (SH) May (NH)	Velvet bucks at "A" grade stage of velvet growth Maintain on high-quality feed Sell cull and surplus breeding bucks	Maintain feed at >13 MJME/head/day Place does in fawning paddock early in month Ensure adequate shelter and water First fawns born in last week of month Record birth weights for stud records	As for adult does	Sell precocious bucks and hybrids for venison Remove antler spikes Weigh for selection data

AI, artificial insemination; BCS, body condition score; MJME, Megajoules of metabolizable energy; NH, Northern Hemisphere; SH, Southern Hemisphere.

these circumstances fawns are better removed from the breeding herd. The opportunity to preferentially feed weaned deer, and to carry out routine animal health management, without disturbance to breeding animals is facilitated by pre-rut weaning. In situations where concentrate feeding of deer is routinely practiced such as in-winter systems and indoors it is likely that young animals will not compete equally for feed with adult animals and their growth and development will not be optimal unless they are managed separately to adult stock. However, under extensive pastoral conditions where access to feed is not a limiting factor, where the mating policy involves joining a number of breeding bucks with the total breeding herd, and where reproductive performance data are not routinely recorded, separation of sub-yearling animals can take place in late winter/early spring without apparent production consequences.

There is little evidence in fallow deer to support the notion that either pre-rut weaning or post-rut weaning leads to improved reproductive management, if feed is available and disease or husbandry and management do not create stress that compromises growth and development in fawns or reproductive performance in does. Seasonal conditions and production targets should therefore dictate when weaning takes place under pastoral conditions.

DYSTOCIA

Dystocia is not common in fallow deer, and is most likely to be seen in does fawning for the first time. Birth weight in fallow deer is usually 9% to 11% of doe mating weight but may be as high as 12% in some animals. This proportionate weight appears to be easily accommodated by the dam at parturition, and birth usually occurs between 30 and 120 minutes from the appearance of membranes. Disturbance of the herd will prolong parturition, and intervention should not be considered within 3 hours. Where intervention is required the doe should be quietly isolated from the rest of the mob if possible, as major disturbance can lead to complications with the rest of the does, including mismothering or interrupted parturition.

Does with dystocia may need to be tranquilized before assistance is given, and it is usual in such cases that little interest is shown in the fawn if born alive. The fawn can be artificially reared (see lactation), and goat colostrum is a good substitute if deer colostrum is unavailable from the doe. If the doe is strong enough after delivery of the fawn and shows interest in grooming it, she should be left alone in a quiet place for bonding to occur. Fallow does are good mothers and once bonding has occurred, the doe and fawn can be returned to the rest of the herd.

NUTRITION AND BODY CONDITION SCORE

The interrelationships between nutrition, body condition score (BCS), and reproductive performance are well established for ruminants, including deer. The highly seasonal reproductive patterns in temperate species of deer leads to predictable body weight fluctuations at certain times of each year in adult animals, particularly males, and lactation also corresponds with dry summer conditions in many areas of the world where deer are farmed. Farmers must therefore set minimum body condition scores at strategic points of growth and reproduction to maximize overall productivity. Setting target or minimum body condition scores provides constant feedback on nutritional adequacy and also provides farmers with an insight to future feed requirements. The use of strategic feeding in conjunction with routine evaluation of body condition score promotes efficient resource management and should lead to higher profitability resulting from more consistent reproductive performance and slaughter animals grown to specification.

Seasonal variations in energy intake, and the annual energy intake for European fallow deer (E) bucks, does, and haviers (castrated male deer) and $^1/_4$ bred hybrids ($^3/_4$ European and $^1/_4$ Persian) (H) between 10 and 21 months of age are shown in Table 129-3, and daily energy intake and live weight change for the same animals are shown in Figure 129-1. The pronounced reduction in voluntary feed intake and associated reduction in live weight in bucks during autumn corresponds with the rut (peak

Table **129-3**

Seasonal Variation in Energy Intake (MJME/day) for Fallow Deer*

Sex of Animal		Mean Live Weight at 10 Months Old (kg)	Spring	Summer	Autumn	Autumn	Annual Intake (365 days)	Mean Live Weight at 10 Months Old (kg)
				MJME/day			MJME/head	
Bucks	E	33.0	14.5	14.3	12.1	13.4	4986	51.8
	H	38.5	14.9	15.8	13.2	15.1	5431	60.8
Does	E	26.5	8.8	9.3	10.1	7.1	3201	32.2
	H	28.3	9.6	11.6	11.2	8.2	3710	35.2
Haviers	E	28.6	12.3	10.9	10.3	10.8	4047	47.0
	H	29.8	12.8	12.7	11.1	11.8	4446	48.8

*For deer of different sexes from 10 to 21 months of age. Data for European (E) and hybrid (H) ($^3/_4$ European, $^1/_4$ Persian) genotypes are represented.
MJME, Megajoules of metabolizable energy.

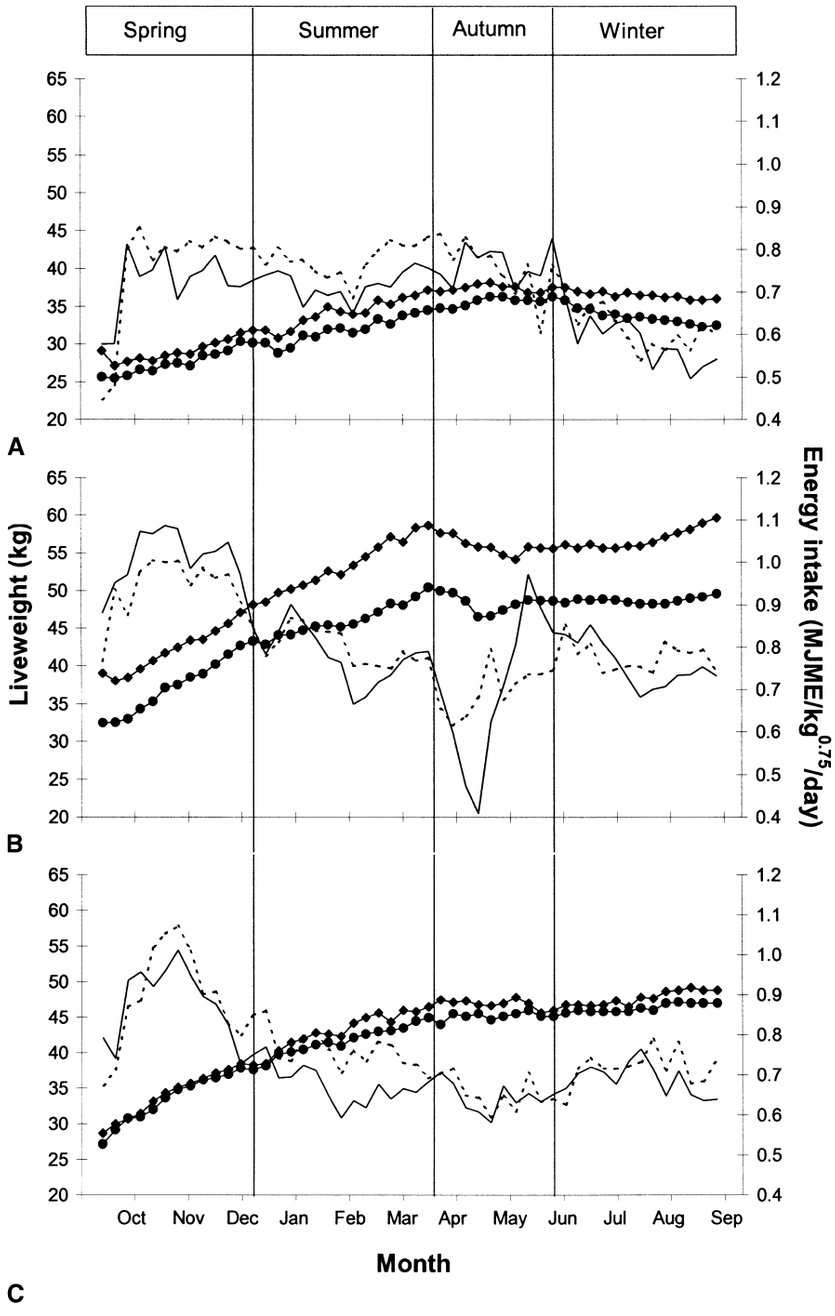

Fig. 129-1 Mean live weights and energy intakes of individually penned (A) does, (B) bucks, (C) haviers of the European (E) and $^1/_4$ bred Persian hybrid (H) genotypes of fallow deer over four seasons: live weight (kg). ●E; ◆H: Energy intake (MJME/kg body weight$^{0.75}$/day).

breeding period), and this reduction is significantly increased in older males, particularly those being used for breeding when up to 30% of live weight may be lost during this time. Calculated energy requirements for adult fallow bucks of different ages and weights over seasons of the year are shown in Table 129-4, although these data are interpolated from information derived for red deer stags in the winter in New Zealand.[3]

The metabolizable energy (ME) requirements for European and hybrid fallow does between 45 and 55 kg live weight in the last two trimesters of pregnancy and the first 12 weeks of lactation are shown in Figure 129-2. Accelerated energy intake in the third trimester corresponded with rapid fetal growth, and the total ME intake during the first 12 weeks of lactation is more than double the requirement for adult does in midpregnancy (winter). Feed supply in late pregnancy and lactation is critical for maintenance of optimal reproductive performance, and recent work with red deer showed that restricted daily energy intake during late pregnancy was associated with loss of body condition score and increased gestation length.[7]

Table **129-4**

Calculated Energy Requirements (MJME/day) for Breeding Bucks*

Age of Sire Bucks (Years)	March Live Weight (kg)	Autumn 100 days	Winter 65 days	Spring 100 days	Summer 100 days
Rising 3	65	17.0	16.1	18.1	18.1
Rising 4	85	20.7	19.6	20.3	20.3
Rising 5	105	24.3	23.0	24.1	24.1

MJME, Megajoules of metabolizable energy.

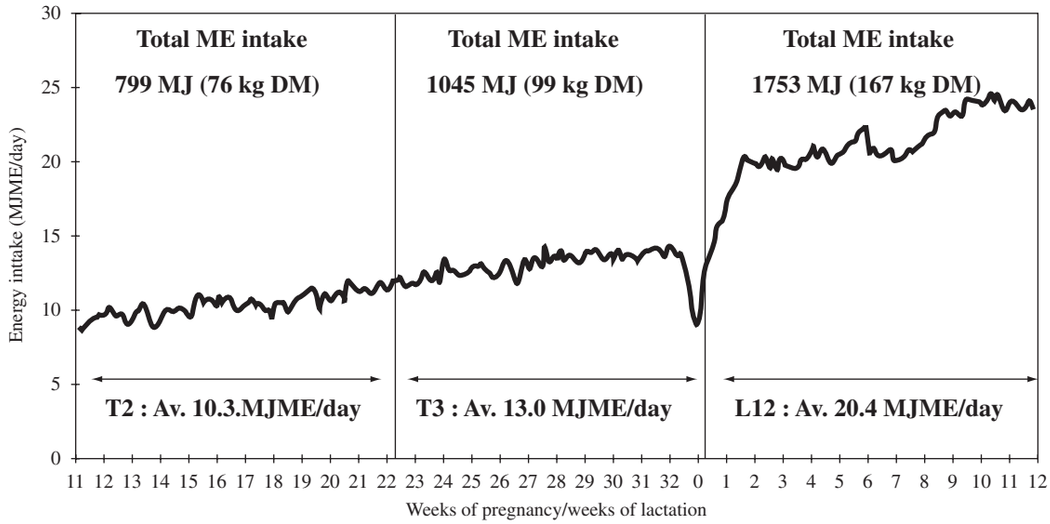

Fig. 129-2 Metabolizable energy intake of fallow does over the second (T2) and third (T3) trimesters of pregnancy and first 12 weeks of lactation (L12). (From Flesch JS: Nutritional requirements of pregnant and lactating fallow deer (*Dama dama*). Doctoral thesis, University of Western Sydney, Sydney, Australia, 2001.)

Low quality feed during late pregnancy and lactation in fallow deer has been shown to be correlated with the occurrence of fawns of low birth weight and lower than expected survival to weaning.[6,9] However, recent attempts in fallow deer and red deer to affect fetal growth by restricting feed intake to does in mid- to late pregnancy were unsuccessful unless body condition scores were lowered significantly, because of strong intrinsic mechanisms to compensate for environmental extremes. Condition score monitoring needs to be done on a regular basis to be effective, as the manifestation of poor nutrition may not be detected until it is too late to address.

Weaned fallow deer commence eating hard feed from 6 weeks of age, and by 16 weeks will consume 10 megajoules of metabolizable energy (MJME)/head/day, or 0.95 MJME/kg$^{0.75}$/day of feed comprising 14 MJME/kg dry matter and 15% protein if available to them. The feed intake associated with rapid growth in this age group equates to 3.4% of body weight for 25-kg animals. Hence, it is possible that on less palatable and low digestibility feeds, "gut fill" may prohibit fawns from ingesting sufficient feed to extract the required ME and crude protein for optimal growth.[7] The high daily feed requirement of weaned fallow deer from 16 weeks of age has seldom been accurately estimated by farmers in the past, and feed budgets for autumn and winter in particular, when rapidly growing weaned deer are being fed through their first winter, need to be carefully calculated.

Adult breeding bucks in low body condition following the rut require careful management and access to high-quality feed. Inappetence during the rut may reduce the live weight of a 100-kg buck pre-rut to 70 kg post-rut, and reduce the condition score from between 4 and 5 in late summer (5 point scale) to 2 or lower post-rut. Any reduction below a body condition score of 2 increases the vulnerability of breeding bucks to winter death syndrome, which refers to death resulting from a combination of poor quality feed, low body condition score, and cold-snap weather conditions. Valuable genetics in breeding bucks must be protected by availability to high-quality

feed and careful management post-rut to avoid such losses.

A body condition scoring system for fallow deer has recently been developed and this will greatly assist animal health professionals, wildlife biologists, and deer farmers to manage herds of fallow deer for production and reproductive performance.[7]

Body Condition Score

A 5-point body condition scoring system for a fallow deer has been developed and can be summarized as follows[7]:

GRADE 1: Very Poor Condition (Emaciated)
Animals in this category are emaciated through malnutrition, old age, or parasitism, disease, or injury. The wings of the pelvis are extremely prominent with no palpable fat over the rump, which is concave in appearance with little muscle coverage. The spine is highly palpable, giving the body an angular appearance. The ribs may also be palpable or visible through the skin. Does in this condition are usually infertile.

GRADE 2: Poor Condition (Lean)
Animals in this category are also obviously thin. Adult bucks are usually BCS 2 after the rut, and lactating does may be seen in BCS 2 in times of feed shortage. As with BCS 1, the wings of the pelvis are prominent and easily palpable. Rump areas are flat with slight tissue coverage. Sacral spinous processes are easily palpable, with the saddle having a slightly angular appearance.

GRADE 3: Moderate Condition
Animals in this category, are not undernourished as described in BCS 1 and 2, but still do not display prominent deposits of fat in certain areas of the body. BCS 3 should be a minimal score for breeding stock. The wings of the pelvis are not as prominent as BCS 1 and 2, but are still palpable with slight finger pressure. The spine is also palpable, but is slightly enveloped in tissue. The body has a more rounded appearance. The rump is still flat, although a greater mass of muscle tissue is felt with firm pressure.

GRADE 4: Good Condition
Animals in this category are considered to be in good condition. The wings of the pelvis are rounded, and can be palpated under a thin layer of fat. The spine is also enveloped in fat, and may be felt only with firm finger pressure. The body now has a rounded appearance over the saddle, with no clear delineation between the torso and pelvic area of the animal. The rump has considerable fat coverage, and is slightly convex. Brisket fat is now visible and easily palpated. Adult bucks usually reach and may exceed BCS 4 in late summer. Adult breeding does will reach BCS 4 in late spring or when not pregnant and lactating for at least 12 months.

GRADE 5 Very Good Condition (Fat)
Animals in this condition are considered too fat for commercial purposes. The metabolic debt of pregnancy and lactation usually prevents does from attaining this degree of condition, although bucks with abundant feed may reach BCS 5 over summer. Castrates, if not slaughtered by their second summer, may also reach this level of fatness. The wings of the pelvis are concealed in fat and cannot be palpated. Spinal processes are also enveloped in a layer of fat and not felt at palpation, giving the animal a very rounded appearance. The rump is extremely well covered and convex. Brisket fat is highly visible and easily palpated from the thorax to the distal end of the sternum.

GENETIC SELECTION

Genetic variation is the most important precondition for any selective breeding program, but it has been shown that there is very little genetic heterozygosity in fallow deer world wide.[13] Further, for recently domesticated species such as deer, heritability of production traits will depend on the genetic history of the species, both in terms of its previous abundance and the selective forces that it has experienced in the past. Although there is little genetic variation in fallow deer, some quantitative progeny test data collected in New Zealand show that there is enough genetic variation in the population for traits of economic value and for some traits the heritability (h^2 estimate) is similar to that found in other farm animals[4] (Table 129-5). Although pelage color is 100% heritable in fallow deer, there is no evidence that coat color variation is linked to production traits that a farmer might want.

Although complex economic traits are controlled by many genes it is clear that increased selection intensity (i.e., selection of very few sire bucks from a large pool) and reduced generation interval (i.e., rapid introduction of young bucks and does to breeding herd, and turnover of older animals) will lead to cumulative genetic improvement in fallow deer. The ongoing improvement of breeding value in a line of animals can be quantitatively defined if desired production traits are accurately measured and recorded. However, as for other animal production systems, genetic selection will only achieve results if the following occurs:

- The breeding objectives are clearly defined.
- Only two or three breeding objectives are tested at once.

Table **129-5**

Heritability Estimates for a Range of Traits in European Fallow Deer

Trait	h^2 Estimate	
Pelage color	1.0	High heritability
Growth traits	0.2–0.4	Inadequate heritability
Antler size	0.3–0.4	Moderate heritability
Carcass fatness	0.3–0.4	Moderate heritability
Fawn survival	0.1–0.2	Low heritability

From Asher GW, Langridge M (eds): *Progressive fallow deer farming*, 2nd ed. Hamilton, NZ: Ruakura Agricultural Centre, 1992, pp 79–94.
h^2, The efficiency of transmission of parental phenotypic superiority to the next generation.

- The traits are easily and accurately measured.
- The traits are inherited.
- The selection pressure on breeding stock is high.

Environment (E) and in particular nutrition play a major role in whether valuable genes (G) are expressed optimally. Breeding value is best determined through use of progeny testing where possible when purchasing breeding stock; otherwise, it is possible to pay large amounts for E when the cumulative and permanent G is sought.

Rapid genetic improvement for some commercially desirable traits may be more easily achieved through crossbreeding, and hybridization between the European fallow deer (*Dama dama dama*) and the larger Persian fallow deer (*Dama dama mesopotamica*) is now commonly practiced in commercial fallow deer farms for production of animals for meat, and for production of breeding does with larger body size that can produce fawns with higher birth weights.

Reproductive success of farmed deer is often related to quiet temperament, and the quietest deer are also often the heaviest. Therefore, selection on temperament may produce larger and quieter deer, and if temperament is partly genetic, then the manifestation of this selection pressure is permanent.

HYBRIDIZATION

There are only two subspecies within the genus *Dama*, European fallow deer (*Dama dama dama*) and Persian fallow deer (*Dama dama mesopotamica*). Persian fallow deer readily hybridize with European fallow deer, and the mature body size of Persian fallow deer (adult males 145–150 kg; adult females 70–75 kg) is significantly larger than their European counterparts. Hybridization capitalizes on additive genetic effects from combining two genotypes, as well as the potential effects of heterosis.

Four additive breed effects result from hybridization of these two subspecies:

- Faster growth rates
- Larger mature body weight
- Increased weight at puberty
- Slaughter weight reached sooner

The hybrid progeny also show no difference in body composition or dressing percentage and hybrid breeding does are slightly more efficient in terms of feed utilization than their European counterparts.[12] Furthermore, concerns about the occurrence of dystocia resulting from mating large Persian bucks over the smaller European does were ill-founded, although this practice should take place only with mature adult does and not rising 2-year-old does.

The term hybridization should not be used when referring to crosses between European fallow deer sourced from different geographic locations world wide, such as England, Denmark, Hungary, Australia, New Zealand, etc. Although there may be some merit in accessing animals of exceptional quality from these various locations for use in breeding herds, they are merely geographic variants of European fallow deer. As stated earlier, there is only one hybridization opportunity within the genus *Dama*, and that is between the European and Persian subspecies.

FETAL AGING

Pregnancy diagnosis using ultrasonography is a routine procedure in fallow deer, especially in controlled breeding programs or for culling of dry does. Fetal and placental measurements can assist practitioners in determining gestational age, which can be used to inform management practices. Detection of pregnancy using ultrasound is possible in fallow deer after 30 days in the hands of experienced operators, but for most commercial purposes results obtained at 50 days or greater are unequivocal. The data in Table 129-6 provide some fetal and placental measurements for fallow does scanned at 50 and 65 days of gestation. After 65 days the fetus has usually descended into the abdomen of the doe, and measurement by ultrasound is no longer possible. However, necropsy of does at known gestational ages (Table 129-7) provides insight into fetal and placental growth that takes place later in pregnancy, and this information may be useful for veterinarians and wildlife managers investigating outbreaks of disease.

There is evidence that nutritional stress (30% reduction of voluntary feed intake per day) in fallow does in the last trimester of pregnancy affects fetal growth and significantly affects doe body condition score. This leads to the occurrence of fawns of low birth weight that are too weak to stand and suckle, and that die within 24 to 48 hours after birth. Greater than 50% of fawns less than 3.5 kg at birth die within 48 hours after parturition. There is no evidence that poor nutrition in late pregnancy prolongs gestation length in fallow deer, as has been shown in red deer.[2]

FAWNING

The fawning season of fallow deer is generally condensed into the last 2 weeks of spring and the first 4 weeks of

summer owing to the high fertility of this species and highly synchronized start to the breeding season. Studies have shown that 95% of fallow does conceive in either their first or second estrous cycle of the breeding season, thus leading to the concentrated fawning pattern referred to. Fawns can be born later than this if bucks remain with does throughout the autumn and winter months, when persistently cyclic does can conceive at their fourth or fifth estrus, or if precocious doe fawns left unweaned from their mothers reach puberty weight by 8 months of age. However, fawns born in late summer/early autumn as a result of these late conceptions have low survival rates, grow significantly more slowly than their cohort counterparts if they do survive, and complicate management. It is becoming common practice for managers to remove sire bucks from breeding herds in early winter, effectively giving does only two to three chances to conceive.

An understanding of the normal parturient and maternal behavior patterns of fallow does is necessary in order to detect abnormal situations requiring attending. Fallow does go off their feed 2 to 3 days before parturition, and become increasingly restless until parturition. They will often disassociate from the main herd, pace the fence line in smaller paddocks, and as birth becomes more imminent, frequently lick their vulval region.[1] Does in small paddocks can be disturbed by curious or passing deer and this can prolong parturition, but this is unlikely in larger paddocks with lower stocking rates. However, parturition to completion of grooming of the newborn fawn usually takes 60 to 180 minutes on average, and if parturition is taking longer than this, obstetric intervention may be required.

Fawns will suckle within the first hour after birth, and will then find a resting place, which is usually some distance away from the doe. This is normal behavior and fawns found on their own should not be considered to have been abandoned. Does will return several times during each day to suckle their fawn. Under intensive conditions this could occur as often as seven to eight times during daylight hours, and four to five times under more extensive pastoral conditions.

In some parts of the world where deer are farmed, fawning coincides with deteriorating pasture quality and this can lead to poor growth rates and severe decline in doe body condition. Poor feed quality prior to parturition can also reduce fetal growth in the last trimester of pregnancy, leading to production of fawns of low birth weight. The strong correlation between low birth weight and perinatal death in fallow deer is well established.[1,6] Other causes of perinatal death in fallow deer are presented in Table 129-8.[6]

Table **129-8**

Causes of Perinatal Deaths and Associated Birth Weights of Fallow Deer Fawns

Cause of Death (Class)	Number	%	Birth Weight (kg) ± SD
1A	16	11.1	1.99 ± 1.05
1B	6	4.2	3.80 ± 0.48
1C	7	4.9	3.43 ± 0.87

Total	**134**	**100.0**	**3.01 ± 1.07**

Key: 1A, anteparturient death; 1B, parturient death, birth trauma obvious; 1C, parturient death, no obvious birth trauma; 1D, premature; 2, birth trauma, lungs aerated; 3, misadventure; 4, exposure/starvation; 5, mismothering; 6, infections; 7, malformations; 8, undiagnosed.

As a general principle, does should be familiar with their fawning paddock and given at least 2 weeks to acclimatize prior to the commencement of fawning. The fawning paddock should contain sufficient ground cover for fawns to hide in, and to be protected from environmental extremes of heat or cold. Feed available to does in early lactation needs to be abundant and of high quality to accommodate the twofold increase in energy intake that occurs immediately after parturition. Proximity to

water is also a key point and lactating animals should not have to go too far for water. Does will stay in close proximity to where their fawn is hiding for at least the first 10 days after birth.

In some circumstances it may be necessary to hand-rear a fawn, and this is easily accomplished. However, it is necessary to warn against hand-rearing of buck fawns, as they do not have any fear of humans as adults (from 16 months of age) and can be particularly dangerous with or without antlers. Hand-reared does remain very quiet and can be used to show leadership in laneways and sheds when training weaner age deer.

The composition of milk from does has been reviewed by Whitehead.[15] Compared with the domestic cow, deer produce a milk rich in energy, fat, and protein, but similar in lactose concentration. Cervid milk contains 19% to 26% dry matter, 6% to 11% fat, 6% to 10% protein, 3% to 5% sugar, and 1% to 2% ash. When compared at peak lactation, cervid milks are all reasonably similar in gross composition and more concentrated than domestic bovid milks. If a newborn deer has not had colostrum, then goat colostrum is a good substitute and can be readily stored in the freezer for anticipated use. A simple but proven formula for hand-rearing fallow fawns comprises 100 g milk replacer per 100 ml of water, 1 egg yolk, 5 g neosulphetan or tribisson, 20 g dextrose, 5 ml cod liver oil, and 5 ml multivitamin solution. Feed several times per day via bottle or bowl, at 30° to 40° C. Additional water should be provided at all times to prevent dehydration, especially in very hot climates or if alternative and more concentrated mixtures are used.

VENISON PRODUCTION

The usual measure of efficiency in a meat production system is the kg/ha turnoff of meat per annum. A slight complication in the production of venison from deer is that much of the product is ready for slaughter at the same time each year because of the acutely seasonal breeding pattern. To overcome this clustering of product availability, a range of strategies can be employed to provide carcasses of consistent quality year round. These strategies include hybridization, selective slaughter of surplus female stock, and castration.

Hybridization between European fallow deer and Persian fallow deer produces offspring that reach slaughter weights up to 2 months sooner than purebred European fallow deer for both males and females. Hence, from 9 months of age precocious hybrid bucks ($^1/_4$, $^3/_8$, and $^1/_2$ bred) are available for slaughter and produce carcasses from 27 to 30 kg. European fallow bucks reach equivalent slaughter weights from 11 to 12 months of age and hybrid does from 12 to 14 months of age. If a proportion of hybrid and European bucks are castrated each year, they produce venison of excellent quality and can be easily handled through slaughter premises during the breeding season when entire bucks are difficult to handle and produce venison of variable quality. Use of breeding and management strategies such as these allows producer flexibility to provide fresh or chilled product of consistent quality to the market year round. Preslaughter assessment of body condition score should be combined with animal live weight to ensure that only the animals suited to market specifications are slaughtered.

ANTLER MANAGEMENT

Antlers are grown annually by fallow bucks and are normally removed from animals on intensive farms for management reasons. If harvested at the required stage of growth, the entire growing antler, known as velvet, can be sold. Bucks with full hard antler can inflict serious if not lethal damage to other deer and livestock managers, can do enormous damage to trees by continual rubbing and territory marking during the breeding season, and can easily get caught up in stock fencing, which occasionally will lead to serious injury or death of the animal. In breeding bucks this is a serious and costly loss of genetic capital.

If velvet antler is to be removed, either for commercial gain or simply for ease of management, it must be done humanely by trained operators, and in many countries this requires veterinary supervision. Harvesting necessarily involves analgesia and standardized techniques for removal and animal restraint. However, even with good facilities and experienced personnel antler is easily damaged as a result of yarding. In one study 27 of 227 (11.9%) fallow deer handled through the yards for velvet antler removal had damaged antlers as a result of yarding.[8] Of deer with damaged antlers, 4 of 27 (14.8%) had damaged both antlers. Significantly more antlers (22/220 or 10%) harvested from 2-year-old bucks were damaged, compared with older bucks, and this reflects their relative lack of habituation to the process of yarding and handling. Saleable "A" grade velvet, as standardized by the market, can be harvested in late spring/early summer from adult bucks 2 years old or older, about 45 ± 3 days following antler casting. In this study the weight of "A" grade velvet antler harvested from fallow bucks increased annually until a peak at 6 years of age.[8] The data indicate that the average age of fallow bucks in herds developed for velvet production should be 5 years to achieve a sustained maximum harvest and to allow for development of replacement animals before the rapid fall-off in velvet yield after 6 years. The low annual yield of "A" grade velvet antler from fallow bucks and variable marketability of this product strongly influence whether the species is useful commercially for velvet production and for this reason it is not usual to see herds of fallow bucks kept for this purpose. However, given that the antlers should be removed from adult breeding bucks for management and safety reasons, they should be removed at the most commercially saleable stage to recoup the costs of antler removal and maintenance feed costs. Velvet antler weight approximately doubled between 2 and 5 years of age (Table 129-9).

The yields shown in Table 129-9 are baseline data and more highly selected strains of deer are now producing greater annual yields than those shown. Mature bucks of Danish and Hungarian strains in particular are likely to yield more.

Bucks grow an antler spike in their first year of life and this must also be removed for safe handling of deer to

Table **129-9**

The Mean (± SD) Weight and Length of Velvet Antler Harvested From Fallow Bucks of Known Age

Age (Years)	No. of Bucks	Mean Antler Weight (g)	Mean Antler Length (cm)
2	110	246 ± 50	13.4 ± 2.6
3	35	282 ± 64	14.2 ± 2.1
4	25	365 ± 54	14.1 ± 1.9
5	32	445 ± 72	16.4 ± 1.0
6	15	486 ± 72	16.3 ± 0.5
7	5	365 ± 43	12.7 ± 0.8
8	5	333 ± 36	

slaughter. Effective methods of removal include use of rubber ligatures in early growth phases in spring, lopping using long-handled horticulture cutters or a surgical saw after application of local analgesic in spring, or lopping of the calcified spike in midsummer using cutters. Local laws must be consulted prior to implementation of antler management procedures.

ANIMAL HEALTH

Deer are only recently domesticated to intensive agriculture. Fallow deer have adapted well to domestication and are now well established in a wide range of environmental and pastoral conditions world wide. They have adapted just as well to intensive indoor conditions as they have to extensive pastoral conditions, although different animal health and stress management procedures need to be applied. In general, fallow deer are susceptible to most of the diseases of other domesticated ruminants but appear to be remarkably disease resistant at this point in their domestication. This innate disease resistance is more fragile as stocking rate increases, and disease from parasites and other infectious diseases are more likely to impact on management systems with high stock density. Diseases such as acute parasitism, pasteurellosis, necrobacillosis, leptospirosis, and clostridial diseases have been recorded more frequently in fallow deer herds managed under intensive conditions. Conversely, fallow deer appear not to be susceptible to malignant catarrhal fever, which is a major disease threat in many other deer species, and also appear less susceptible to yersiniosis and lungworm. Facial eczema and ryegrass staggers also cause significant problems in fallow deer in many parts of the world, and need to be carefully monitored.

Owing to their recent status as domesticated animals, fallow deer still retain some of their "wildness" and need to be handled in specifically built facilities by experienced and confident livestock handlers to reduce stress. Habituation to the process of moving through yards and laneways is particularly important if stress-related injuries and production losses are to be minimized. This is particularly important for animals being prepared for use in artificial breeding programs in which expensive techniques and valuable genetics are being used. A high success rate (>75% conceptions) can be achieved using artificial insemination in fallow deer providing the deer are calm and well habituated to their surroundings and handling procedures.[5] Younger animals are usually more prone to stress, and combining older, experienced animals with good temperament into mobs of younger deer for initial training can be extremely beneficial.

KEY POINTS

- Fallow deer exhibit highly seasonal patterns of reproduction controlled by photoperiod.
- The rut is an enormously stressful period for bucks, and careful management and feeding of deer during the breeding season is required.
- Approximately 95% of fallow does conceive at either their first or second estrous cycle of the breeding season, at buck-doe ratios of 1:40.
- There is little difference between pre-rut weaning and post-rut weaning on fawn growth and doe fertility.
- Does should weigh 38 to 40 kg prior to mating at 16 months of age
- Fawn survival is strongly linked to birth weight, and weights below 3.5 kg are unacceptably low. Fawns over 4 kg at birth have 95% chance of survival to weaning.
- Body condition score rather than birth weight is the best indicator of nutritional sufficiency and reproductive capacity in adult deer.
- Hybridization of European fallow deer and Persian fallow deer provides farmers with increased production options for efficient venison production.
- Artificial insemination techniques for fallow deer are very effective and proved under commercial conditions, and are now a commonly used tool in genetic improvement programs.
- Strategic feeding of fallow does in the third trimester of pregnancy and during lactation is recommended for maintenance of long-term reproductive performance.

CHAPTER 130

Reproductive Management of White-Tailed Deer

HARRY A. JACOBSON

Among deer, the whitetail is unique. Its reproductive timing can vary by as much as 6 months or more within the same hemisphere, it has a higher fecundity rate than most species of deer, it can reach puberty in its first year of life, and it can alter its fertility to meet favorable and unfavorable environmental conditions.

As with other deer species, reproductive timing is regulated to a large extent by photoperiod, and it has been demonstrated that photoperiod sets the endogenous clock of the whitetail. However, research also has demonstrated that the whitetail's reproduction is governed by a genetic clock. Because the whitetail has a geographic distribution that extends across two hemispheres and has adapted to dramatically different environments, ranging from tropical to desert to temperate to boreal forest, it above all deer has perhaps the most complex reproductive adaptations.

FUNDAMENTALS AND BIOLOGY

Puberty

Puberty can be reached as early as 6 months of age. Studies have demonstrated that, depending on nutritional conditions, up to 80% of doe fawns can conceive during their first year of life. Such rates have been common in the Midwestern farm belt.[1] However, in the southeastern United States, this rate drops to an average of 40% or less.[2] At the extremes of the range, puberty is generally delayed to the yearling age class. Nutrition is important and onset of puberty for fawns is dependant on body size. For northern races of deer, fawns must reach 80 to 90 lb, and for smaller southern races, body size of 70 lb or more seem to be required for puberty to occur in the first year of life.[3] Both protein and energy are

CHAPTER 130

Reproductive Management of White-Tailed Deer

HARRY A. JACOBSON

Among deer, the whitetail is unique. Its reproductive timing can vary by as much as 6 months or more within the same hemisphere, it has a higher fecundity rate than most species of deer, it can reach puberty in its first year of life, and it can alter its fertility to meet favorable and unfavorable environmental conditions.

As with other deer species, reproductive timing is regulated to a large extent by photoperiod, and it has been demonstrated that photoperiod sets the endogenous clock of the whitetail. However, research also has demonstrated that the whitetail's reproduction is governed by a genetic clock. Because the whitetail has a geographic distribution that extends across two hemispheres and has adapted to dramatically different environments, ranging from tropical to desert to temperate to boreal forest, it above all deer has perhaps the most complex reproductive adaptations.

FUNDAMENTALS AND BIOLOGY

Puberty

Puberty can be reached as early as 6 months of age. Studies have demonstrated that, depending on nutritional conditions, up to 80% of doe fawns can conceive during their first year of life. Such rates have been common in the Midwestern farm belt.[1] However, in the southeastern United States, this rate drops to an average of 40% or less.[2] At the extremes of the range, puberty is generally delayed to the yearling age class. Nutrition is important and onset of puberty for fawns is dependant on body size. For northern races of deer, fawns must reach 80 to 90 lb, and for smaller southern races, body size of 70 lb or more seem to be required for puberty to occur in the first year of life.[3] Both protein and energy are

important. Protein is obviously critical to reaching minimum body size. However, it has been demonstrated that female fawns on high-energy diets had significantly higher levels of progesterone than did fawns on low-energy diets, regardless of protein levels in the diet.[4]

At the extremes of the range, whitetails may be programmed to delay puberty. Michigan researchers demonstrated that even when supplement-fed, doe fawns in the Upper Peninsula of Michigan did not become pregnant, whereas 60% or more of doe fawns in the farmlands of the Lower Peninsula commonly were pregnant.[5]

Buck fawns can be expected to show similar rates of puberty to those of doe fawns. In buck fawns, puberty is indicated by the appearance of small calcified antler buttons in their first winter. Because of the relationship between testosterone production and hardened antlers, these calcified antlers indicate puberty has occurred and these animals are normally capable of breeding and producing offspring. However, with both buck and doe fawns, timing of puberty and ability to breed and conceive offspring are generally much later in the year than is the case with the onset of adult breeding. In general, yearling does normally have fawns at least a month or more later than do adult does.

Seasonal Changes in Sexual Characteristics

Because the whitetail is a seasonal breeder there are marked changes in both secondary reproductive characteristics and reproductive anatomy. In effect, the white-tailed deer and other deer undergo pubertal changes every year of their existence. These changes are readily evident in secondary sex characteristics of the male with the onset of increased body size, swollen neck, and development of large antlers. As with other deer species, the annual calcification of antlers and the rub-out of velvet signal readiness to breed.

Changes in the reproductive anatomy of males are characterized by annual increases and decreases in secondary sex glands and the testes and epididymis (Fig. 130-1). These changes occur earlier in 2-year-old or older bucks than they do in yearling bucks (Fig. 130-2).

Changes in female reproductive characteristics are less obvious than in males. Enlargement of the ovaries, vagina, and uterus do occur just prior to the rut. Changes are most pronounced in fawn and yearling does, but enlargement and increased elasticity are also noticed in the primary reproductive organs of adult females. The uterus of the white-tailed doe is bifurcate. Ovulation is said to occur from 12 to 14 hours after estrus.[6] Implantation occurs about 30 days after conception.[3] Following ovulation, normally from one to three corpora lutea are readily visible as ovarian swellings on one or both ovaries. Corpora albicantia of pregnancy are readily visible as large pigmented scars in formalin-fixed and sectioned ovaries of does for at least 3 months following parturition. Corpora albicantia of pregnancy from previous years are often visible as smaller pigmented scars in fixed tissue. Corpora albicantia from does not conceiving during their cycle are generally visible only as nonpigmented granular tissue in the ovaries for a few weeks following their formation.

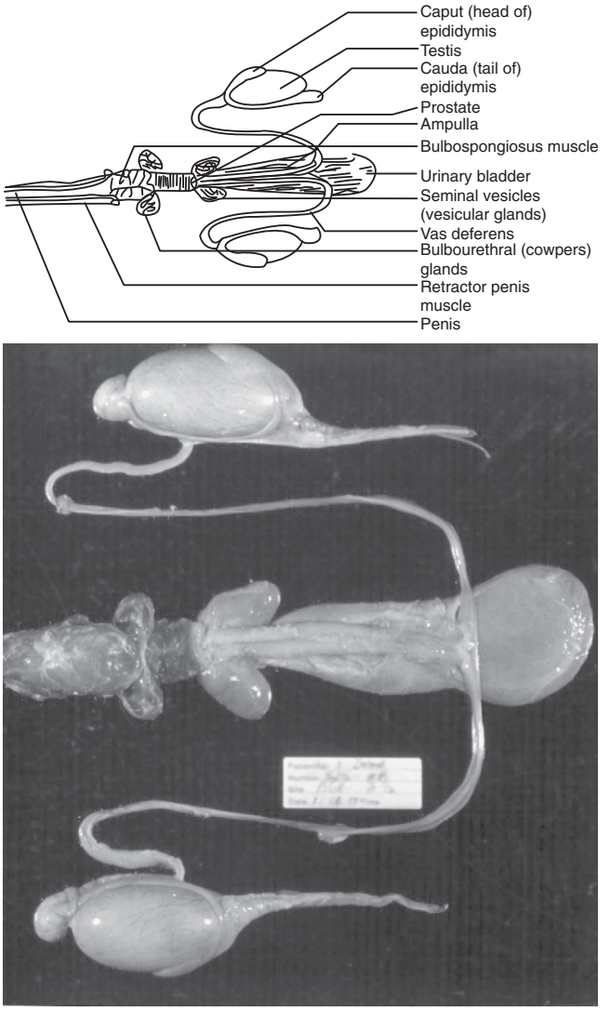

Fig. 130-1 Line drawing of reproductive tract of male white-tailed deer and photograph of the tract during November, when the rut is close to the peak.

Reproductive Timing

Breeding dates of the white-tailed deer change markedly across its range (Fig. 130-3). Initiation of the rut is photoperiod-related. This influence was illustrated most aptly by translocation of white-tailed deer from North America to New Zealand. Following translocation, reproductive activity of white-tailed deer including antler growth, velvet shedding, antler casting, and fawning all occurred about 180 days later than in the Northern Hemisphere.[7] However, white-tailed deer also are known to have an endogenous circannual clock that can regulate reproduction in the absence of photoperiod cues.[8] Genetics also is an important regulator, and different subspecies at the same latitude are known to have different rut timing. This difference can be as much as 2 months or more, and depending on the North American location, white-tailed deer have been documented to breed in

every month of the year.[9] The interrelationship of genetics and photoperiod was further shown by a study involving translocation of deer from Mississippi to Michigan and vice versa.[10] In this study, deer shifted their reproductive patterns about 3 weeks earlier or later, depending on whether in Michigan or Mississippi. However, regardless of geographic location, the rut of Mississippi deer was about 7 weeks later than that of the Michigan deer. This genetic linkage was further confirmed by the crossbred offspring of these animals which, regardless of paternal or maternal lines, had intermediate rut timing between that of the two different parent lines.

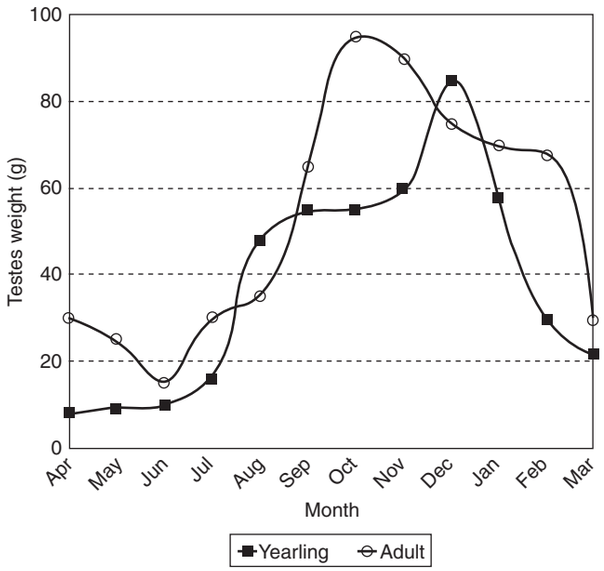

Fig. 130-2 Seasonal changes in testes weight of yearling and adult bucks. (From Griffin RN: Characteristics and management implications of the male reproductive cycle of the white-tailed deer in Mississippi. Master's thesis, Mississippi State University, 1980.)

Rut

The rut is initiated by the receptivity of the doe. However, it has been demonstrated that presence of mature males can induce earlier initiation of estrus than when does are confined with only yearling males present.[11] Adult sex ratios, which are close to 1:1, may also be important. Improvement of male-to-female sex ratios along with increased presence of mature males has shown that presence of mature males resulted in earlier breeding dates for wild populations. In two separate studies, one involving deer in South Carolina and one in Mississippi, it was demonstrated that when sex ratios of adult males to adult females was increased, the peak of rut was shifted by more than 3 weeks earlier in these populations.[12]

Estrus in the white-tailed doe normally lasts about 24 hours, and if conception does not take place, the doe will repeat the cycle at 21- to 29-day intervals.[3,13] Several copulations can occur within one estrus and multiple parenthood of the same litter can occur.[14,15] There also is evidence that a silent estrus can precede the first estrus cycle when copulation is allowed.[16]

Gestation

Gestation length normally averages about 200 days and can range from 187 to 222 days.[3] Gestation appears to be slightly longer in northern deer than southern. In Michigan, known gestation lengths averaged 199 days, whereas in Mississippi known gestation lengths of captive deer averaged 196 days.[3,17] Fetuses may develop in either or both uterine horns. The number of caruncles in the pregnant doe is variable with an average of 6 and a range of 4 to 19.[18]

The number and sex of fetuses depends on both age and nutrition. Generally, yearling does (bred as fawns) have only one fawn, 2-year-old does average 1.3 to 1.6 fawns, and prime-age does average 1.5 to 1.8 fawns.[3,9] Triplet fawns are not uncommon in well-nourished deer herds and can occur in about 3% of pregnancies, although usually one or more of the triplets have low

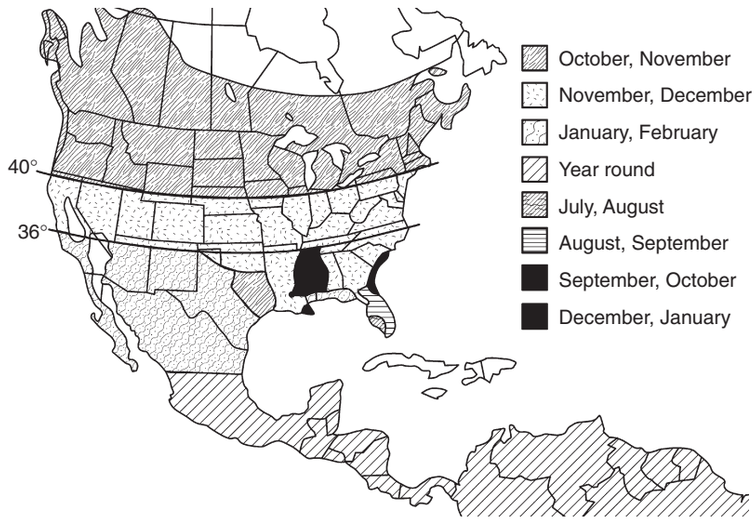

Fig. 130-3 Timing of the rut in different geographic regions of North America.

birth weights and it is unusual for all three to survive. Sex ratios favor males for yearling does and in adult does under poor nutrition, but favor females in adult does under good nutrition.[3,9] Gestation can be altered slightly by nutritional plane with does under poor nutrition having slightly longer gestation length than well-nourished does.[14] However, does with poor nutrition are also more likely to have fawns with low birth weights and to abort or abandon their fawns at birth.[19]

Parturition

Does seek seclusion just prior to parturition. Prime-age does have high fidelity to birthing sites that normally are the best fawning grounds, and consequently, they have higher survival rates for their fawns.[20] The birthing process can last up to 12 hours or more and does are known to be able to stop the process if disturbed.[2] As parturition nears, does can be seen to increase restlessness and seek out fawning cover. Does also show a peculiar gait and often hold their tails in an extended crocked position at this time.[2] Following birthing the doe usually licks her fawns dry and ingests the placenta. Twin fawns are bedded separately by the doe shortly after birth and usually remain separated until 3 or more weeks of age.[19]

REPRODUCTIVE MANAGEMENT

Genetics and Selection

Theoretically, heritable traits such as body weight, antler size, reproductive timing, and disease resistance can all be selected for through reproductive management. With wild populations this is feasible only through introduction of new animals with desirable traits or by selective removal from the breeding pool of animals with undesirable traits. For this to occur, desirable traits must be both readily identifiable and highly heritable. The most common traits selected for wild populations are those involving antler characteristics. Mature bucks have been shown to have antler heritability (h^2) estimates of from 0.03 to 0.43, with antler weight having the highest heritability, followed by antler points, beam circumference, and beam length.[10]

With captive populations selective breeding can be conducted by single sire mating and though artificial breeding techniques. Unfortunately, most traits that are of management interest have high environmental variability, and often animals may be selected for breeding because of phenotypic characteristics, which may not represent genotypic breeding value. For this reason, it is recommended that selection of breeding stock for individual traits should be on the basis of pedigree rather than phenotypic traits of individual animals.

Nutrition

Pregnant does require 155 to 160 kcal per kilogram of body weight$^{0.75}$ per day for maintenance and 131 kcal of metabolizable energy per kilogram of body weight$^{0.75}$ per day.[21] Energy requirements of does during the peak of lactation are increased about 150% of that required during gestation.[22] Protein requirements have been variously stated to be as low as 8% to 10% crude protein (dry matter basis) for body maintenance during the winter months coinciding with gestation and as approximating the growth requirements of fawns (14–22%) for lactating does.[3] Macronutrient requirements are stated as being between 0.12% and 0.29% for phosphorus, 0.64% for calcium, and 0.20% for magnesium.[23] Other nutritional requirements are not well described, but generally the most important considerations for nutrients of the white-tailed deer relate to protein and energy. Although protein and energy deficiencies have often been reported, there are few known reports of other nutrients being deficient for wild or captive white-tailed deer.

Artificial Breeding

Artificial insemination has now become fairly common for breeders of captive white-tailed deer. Vaginal insemination is routinely conducted on sedated or tranquilized does, or on does held in restraint chutes. Published data on conception success following hormone induction is lacking, although high (>65%) conception rates have been obtained with does inseminated following natural cycles and estrus detection with a vasectomized buck.[24] However, conception success following vaginal insemination of hormone-induced does rarely exceeds 40%.[17] Intrauterine insemination may result in higher conception rates than vaginal insemination, but studies on this are unknown.

Semen processing is relatively routine for white-tailed deer and conception success has been documented from both electroejaculated bucks and from postmortem collection.[24] Variation in fertility between individual bucks is unknown at present, but undoubtedly is a factor in conception rate success.

Procedures for semen processing and electroejaculation have been described.[24] Sedation with xylazine hydrochloride (2.2 mg/kg) and telazol (3.6 mg/kg) and reversal with tolazine (recommended manufacturer's dose rate) has been used successfully for electroejaculation of adult bucks.[17] Operator experience is critical and use of inappropriate sedation, ejaculation of animals with elevated respiration or hyperthermia, or use of excessive voltage can lead to stress-related death.

Although successful embryo transfer has been achieved, at present it does not appear in practical use.[25] Realistically, embryo transfer for white-tailed deer requires high cost, and the cost-to-benefit ratio is offset by high natural twinning rates and early reproductive maturity seen in this species of deer.

CHAPTER 131

Reindeer Reproductive Management

JOHN E. BLAKE, JANICE E. ROWELL, and MILAN P. SHIPKA

Rangifer, a relatively new genus in the deer family, is indigenous to holarctic northern latitudes. Reindeer and caribou are both members of the same species, *Rangifer tarandus,* which has been subdivided into two main groups, based on antler morphology and habitat, with seven extant subspecies.[1] Reindeer and caribou can interbreed, producing reproductively viable hybrids. Nonetheless, behavioral and physiologic differences remain between the subspecies, especially in the timing of reproductive events.

Reindeer have been semidomesticated for centuries and are an economic mainstay for many native populations. Throughout most of their history they have been raised in extensive, free-ranging systems. More recently, there has been a move toward intensive reindeer farming using traditional agricultural practices, which requires a more in-depth knowledge of reproductive management.

HAREM FORMATION AND MANAGEMENT OF BREEDING REINDEER COWS

Estrous Cycles

Reindeer are seasonally polyestrous, short-day breeders, with an estrous cycle length of approximately 24 ± 3.4 days (range: 18–29 days).[2] The endocrine changes during the estrous cycle have been described in detail and are very similar to other deer species. Primiparous Norwegian reindeer exhibited considerable variation in estrous cycle length (19.4 ± 5.7 days) at the onset of the breeding season.[3] This contrasts to our work with reindeer at a similar latitude in Fairbanks, Alaska, where estrous cycle length did not vary significantly from the beginning to the end of the breeding season or among individuals. Seasonal ovarian activity among females penned without a bull is initiated in late August.[2,4] Like other ruminant species, a small transient progesterone rise, lasting between 4 and 9 days, precedes the first full-length estrous cycle of the breeding season, and reindeer may experience two or more short cycles before the onset of full-length cycles.[2] Even though an estradiol and luteinizing hormone (LH) peak may precede short cycles, these hormonal events have not been clearly linked to estrous behavior. However, the possibility that males may detect these initial endocrine changes and attempt to mount cows at this time could explain the numerous earlier reports of a 10- to 12-day cycle length.

Females left open will continue to cycle well into spring (April), having 6 to 8 estrous cycles over the winter.[2] The transition to anestrus in five adult females was characterized by either an abrupt cessation of luteal activity in April (n = 2) or the formation of a persistent corpus luteum (CL) (n = 3) beginning in late February or March. Sampling did not continue long enough to evaluate the lifespan of the prolonged CL in two cases, but from previous work, it is known that persistence into the next breeding season can occur.[4] Further investigation is needed to assess the potential effect of a persistent CL on breeding synchrony and timing of mating.

Antlers and the Onset of Estrus

Reindeer and caribou are the only members of the deer family in which females grow antlers. Although males depend on rising testosterone to harden and clean the antlers, increasing estradiol at the onset of the breeding season is responsible for female antler cleaning.[5] Anecdotal information suggests that antlers are cleaned 2 to 3 weeks before the onset of estrus, but there is no clear documentation on the interval between antler cleaning and first ovulation. Although preliminary work cannot predictably link antler cleaning with ovulation, polished antlers are a useful criterion for timing harem formation.[6]

Puberty

Recommendations generally suggest that harem cows be at least 1.5 years old or a have a body weight of at least 60 kg. Yearling and adult females initiate the first full-length cycle at approximately the same time,[2,4] suggesting that once pubertal weight is attained, age differences in body weight have little effect on the onset of breeding readiness. Both males and females can reach sexual maturity at 6 to 8 months of age, and there are numerous reports of females producing their first offspring as yearlings. However, calf pregnancies have resulted in reduced postpartum growth rate of the young females, low birth weight calves, and high offspring mortality rates. Although male reindeer can attain physiologic puberty in their first year, their subordinate position in a herd generally precludes them from breeding. If isolated with receptive females though, larger male calves can take over a dominant role and successfully breed.

Bull Introduction

In the absence of a bull, adult cows in good body condition will come into estrus, the timing of which may vary

with latitude.[2] However, introduction of a bull to a group of females before the initiation of estrous cycles significantly hastened the onset of ovarian activity by approximately 2 weeks and resulted in synchronized calving the following spring.[4]

Estrous Behavior and Detection

Behavioral estrus can be subtle, and published descriptions are inconsistent. Various authors report dilation of the preorbital glands and upright position of the tail, especially in response to touching of the perineal region. Redness and swelling of the vulva, accompanied with a mucous discharge, is not always apparent.[3] Anecdotal descriptions of cows appearing restless, searching for a bull, and mounting other cows can be found in the husbandry literature. The behavior of the male toward the female is probably the most frequently used indicator of estrus. However, there are problems with consistency and precision here, too. Once-a-day observations or observations collected only during daylight hours may not be frequent enough to detect all instances of mating.

There are few reports on the use of artificial aids for the detection of estrus. Heat mount strips and vasectomized, marked bulls have been occasionally used with variable success. We recently investigated the use of a radiotelemetric estrous detection system in reindeer. In two separate studies, successful detection of estrus and breeding was 70% ($n = 10$) and 42% ($n = 19$), respectively. The former study was the only one in which we encountered two false positive mounts, at 18 and 21 days after conception.[2] Collective radiotelemetric data indicate that individual mounts are swift, lasting 3 to 9 seconds and estrous females are mounted one to three times over a 24-hour period. The brief mount duration coupled with the low frequency of mounting most likely contributed to the poor success rate of radiotelemetric or visual estrus detection. Studies to improve mount detection with radiotelemetry are ongoing.

Estrous Synchronization and Superovulation

Interest in truncating the breeding season and artificial insemination has focused attention on synchronizing estrus. Among captive reindeer in Fairbanks, two 15-mg IM injections of $PGF_{2\alpha}$ (Lutalyse , Pharmacia and Upjohn Company, Kalamazoo, MI 49001, USA) administered 10 days apart, caused luteolysis in cycling reindeer, while a single 15-mg injection at 6 weeks after conception terminated pregnancies.[6,7] Polished antlers among a group of cows are an indication that most of the females are cycling and, hence, a reasonable cue for initiating a synchronizing protocol dependent on a normal CL. However, it does not preclude the fact that some cows may be experiencing sequential short cycles and fail to respond appropriately to prostaglandin.[7] In addition, care must be taken to ensure that the full dose is delivered into the muscle and not into the substantial subcutaneous fat. Conception following successful synchronization with $PGF_{2\alpha}$ was 88% with mounting occurring 44 to 56 hours after the end of treatment.[7]

The use of goat controlled intravaginal drug release (CIDRg: 0.33 g progesterone) is common in Europe, although very little has been published. In Finland, 8 of 10 females conceived following a 14-day treatment regimen with CIDRg devices. Mating occurred 43 hours after CIDR removal. Concurrent superovulation with follicle-stimulating hormone (FSH) resulted in an embryo recovery of only 20%.[8]

Gestation Length

Published estimates of gestation length for reindeer and caribou range from 198 to 240 days. This variability in reported gestation length may be partially explained by the limited reliability of behavioral observations of estrus and breeding, thus producing inaccurate estimates of conception. Our accumulated data, using only individuals with conception dates verified by endocrine data, provide a gestation length of 216.9 ± 6.8 days ($n = 39$). In one study, gestation length among eight captive reindeer, housed and managed identically throughout gestation, differed by 23 days and conception date was negatively correlated with gestation length ($r^2 = -0.98$, $P < 0.0001$). A Norwegian study has also reported a negative correlation between gestation length and conception date.[9] More information on the variability in gestation length and its association with calf viability and growth is clearly warranted and our current studies are addressing this phenomenon.

Calving

Pending parturition can be difficult to identify unless the reindeer are being observed on a regular basis. Udder development in reindeer is variable and may start as early as 2 weeks before parturition, although noticeable udder growth usually occurs during the last 24 hours before parturition. Like other species, reindeer females become restless during this time and will separate themselves from the herd. If there is an opportunity, she will hide to give birth. The sequences of events during parturition are similar to those described in domestic livestock and other cervidae. Calving occurs quickly, and careful observation is required to witness a birth. Normal fetal presentation is anterior with the front hooves and nose entering the birth canal. The time from visualization of a foot or nose to having a calf on the ground is anywhere from a few minutes to approximately half an hour. The cow usually lies down through parturition but may rise and lie down repeatedly. Once born, the cow will lick and may consume the membranes still clinging to the calf. A healthy calf will be standing and trying to nurse within 10 to 60 minutes. The placenta is expelled shortly after parturition, but this can take up to 2 hours. Retained placenta is rare following a normal birth but is relatively common after an abortion.

In our experience, calving difficulties in reindeer are very uncommon, but assistance is necessary if part of the calf has been visible for over 30 minutes without being born or if the cow has been straining for more than an hour with no results. Dystocia in reindeer usually results from an abnormal presentation; most commonly one leg,

or the head, is back. Posterior presentations (rear hooves presenting first in the birth canal) occur infrequently and should not necessitate assistance. We have observed a true breech position (tail and hips presenting in the birth canal with the hind legs still deep in the uterus) only with the first calf during twinning; the second twin presented in the normal anterior position. Dystocia due to an oversized calf is extremely rare, even among reindeer giving birth as yearlings.

Reindeer normally have a single offspring although twin fetuses have been found in 17.8% of harvested, free-ranging reindeer.[10] In Fairbanks, two cases of male pseudohermaphroditism have been recorded, with one occurrence being a presumed freemartin. Although confirmation via chromosome evaluation is lacking, this calf was born co-twin with a normal male. These observations suggest that twinning in reindeer is not a highly selected trait and attempts to promote it may be detrimental.

Abortion, Stillbirth, and Neonatal Death

Other than infection with *Brucella suis* biovar 4, few other infectious causes of abortion, stillbirths, or neonatal death in reindeer have been reported. However, with increasing numbers of reindeer being raised under intensive management systems and the higher number of interactions with domestic livestock, reports of infectious causes of reproductive disorders may increase. Poor feeding practices, malnutrition, and stress have been implicated in fetal and early neonatal death, but this has been poorly characterized in the literature. Accurate diagnostics are a crucial management tool, especially now that reindeer are being raised in nontraditional areas and in close contact with domestic livestock.

Early neonatal death in reindeer has also been associated with attempts to increase the prevalence of white-coated animals in Alaskan reindeer herds. Selective breeding practices have successfully generated more white-coated calves, but these calves are frequently born with multiple congenital anomalies that lead to death by predation or starvation within days of birth. These anomalies include brachygnathia, osteopetrosis, and eye malformations causing blindness.

Pregnancy Detection

The endocrinology of pregnancy has recently been described in both Norwegian[9] and Alaskan reindeer.[2] In the latter study peripheral progesterone concentrations increase immediately after conception to mean (±SE) levels of 5.89 ± 0.09 ng/ml; range 2.40 to 14.28 ng/ml (n = 10) where it remains until parturition, producing a progesterone profile consistent with species dependent on luteal progesterone throughout gestation. Although the placenta produces progesterone, this contribution is not clearly evident in the progesterone profile. Nonpregnant females will continue to cycle throughout the winter, as will cows that undergo early embryonic loss. Cyclic levels of progesterone overlap those of pregnancy throughout gestation, making peripheral progesterone a poor candidate for pregnancy detection.[2]

Plasma estradiol-17β (E_2), estrone (E_1), and estrone sulfate (E_1S) remain at baseline levels until the last 2 to 4 weeks of gestation when they increase dramatically until parturition. Significant concentrations of E_1S are not quantifiable until the final weeks of gestation, rendering the hormone of little use for pregnancy determination or as an indirect measure of placental health in the latter part of pregnancy.[2,9]

Pregnancy-specific protein B (PSPB) has been successfully used to detect pregnancy in wild caribou, extensively ranched reindeer, and captive reindeer and caribou. In both caribou and reindeer, PSPB appeared in maternal plasma 4.4 weeks (range 4–5 wks, n = 6) after mating and disappeared between 4 and 7 days following an injection of $PGF_{2\alpha}$ at 6 weeks of gestation.[6] For PSPB pregnancy determination, blood samples should be collected 6 weeks after breeding (if breeding dates are known) or after harems have been broken up.

Among captive reindeer habituated to handling and restraint, transrectal ultrasonography has been used to detect pregnancy between 35 and 60 days of gestation, although earlier detection, as in other cervidae, is probably achievable. The small size of these animals requires the use of a probe extender (a piece of slightly curved, fitted plastic pipe used to stabilize the probe and cord), thus allowing the operator to guide the probe with minimal discomfort to the animal. As in other species, rectal ultrasonography loses accuracy later in pregnancy once the gravid uterus drops over the pelvic brim and the fetus attains a position lower in the abdominal cavity. Transabdominal ultrasonography is successful only if adequate contact between the skin and the transducer can be achieved. Unfortunately this is difficult to accomplish with reindeer, even if the hair is shaved, because of air pockets within the hair shaft.

Antler retention is not always a reliable predictor of pregnancy status. Nevertheless, retention of antlers by pregnant cows has long been a technique used by wildlife biologists to assess near-term pregnancy status in wild caribou. This practice is based on the assumption that pregnant females retain their antlers until calving, or shortly thereafter, whereas nonpregnant females cast antlers 1 to 2 months earlier. It has also been suggested that well-fed, pregnant females cast antlers before calving. Neither of the above assumptions are supported by our captive animal data. In Fairbanks, where caribou and reindeer are reared together under identical conditions, 89% of the reindeer retain their antlers until after calving compared to only 32% of caribou. All that can be said with any certainty is that antler retention into mid-April can be used to infer pregnancy, although the converse is not true; a certain percentage of pregnant animals may cast before calving. Early bilateral casting, as well as asynchronous antler casting, occurs periodically in response to multiple factors related to the overall health of individual animals. This may include concurrent systemic or localized infectious disease as well as stress.

BREEDING BEHAVIOR AND MANAGEMENT OF BULLS

Rutting and Breeding Behavior

An early and very clear sign of the pending rut is the cleaning of velvet antlers. In Fairbanks, this generally

starts in mid-August with all adult male reindeer being in hard antler by the end of August. Antler cleaning in male calves is delayed until late September/early October and is not always complete. Among castrates cleaning is a protracted and incomplete event. Increasing levels of testosterone cause the antlers to harden and the velvet to split and shed, a process that can be completed within a day. The muscles of the neck thicken and the distinctive mane develops. Aggressive behavior toward other males increases, along with herding and chasing of females. Older, mature males initiate this process first, giving them a distinct advantage in establishing dominance. Males will use their antlers to threaten other males and even females during the early rut period. Rut-related behaviors of the dominant males include urination on their hind feet, a self-marking display termed tramping-urination, accompanied by distinctive vocalizations, referred to as panting or barking. Bulls will rub and scent mark shrubs and trees and thrash trees and bushes (and fences) with their antlers. Intense aggressive displays may result in the digging and marking of pits using both forelegs and antlers. Fights between equally matched males can be vicious and result in death. Male aggression directed toward uncooperative females, usually early in the season, has resulted in fatal injuries both in the wild and in captivity. In intensive farming situations where pasture space may be limited, males should be separated from females before calving and remain separated during the early rut period. This avoids potential injury to unreceptive females. It also allows managers to take full advantage of the bull effect, which requires a period of isolation between the sexes for maximum effect.[4] It is critical to recognize that males who are normally docile, friendly, and cooperative toward people and handlers become extremely dangerous and cannot be trusted until rut has ended.

Rutting Physiology

With advancing rut, voluntary food intake decreases and, at the height of the rut, males cease eating altogether.[11] Over a 77-day rut period males lost 35% of their ingesta-free mass. Of this, lean mass and body protein were depleted by 23%, whereas 78% of the fat reserve was expended with a daily energy deficit equivalent to 90% of the standard metabolic rate. This loss of mass and other physiologic changes occurred in all males 2 years of age and older, regardless of dominance status or whether or not they were penned with females This implies that all males, whether they are in bull pens or with harems, need to be carefully managed during the rut period.

The substantial energetic cost to these males puts them at higher risk of acquiring life-threatening infections during and shortly after the rut. We have observed relatively minor injuries in rutting bulls develop into extensive infections, frequently leading to septicemia. Moreover, the nature of these animals at this time makes clinical management difficult. Likewise, use of sedatives and anesthetic agents in rutting *Rangifer* during this period of physiologic change requires careful monitoring by a veterinarian. The unpredictability of anesthesia in rutting males of any species is well recognized; however, we have observed a very transient period in rutting *Rangifer* when they are extremely sensitive to the effects of cyclohexamines (ketamine and tiletamine) and alpha-2 agonists (xylazine and medetomidine). Although a combination of xylazine and ketamine is an excellent and cost-effective anesthetic agent in captive reindeer, we have encountered prolonged anesthesia (5 to 24 hours) with severe bradycardia (<30 beats/minute) and a weak pulse in rutting bulls receiving minimal anesthetic doses. A single dose of 15 mg of xylazine caused a life-threatening level of anesthesia (heart rate of 25 beats/minute) that was refractory to repeated doses of yohimbine in an adult bull that 3 weeks previously easily tolerated a dose four times that level with an additional 1 g of ketamine. Both immobilizing events occurred while the bull was in rut, providing no external means of discriminating when the animal became hypersensitive (Blake, unpublished observations). Although this case is an extreme example, it is not an isolated incident. Intensive management of rutting bulls is thus best handled by a "hands-off" approach. If handling of rutting bulls is necessary, well-constructed runways, chutes, catch pens, and crushes are vital. Movement of bulls through facilities can be accomplished using habituation techniques before the onset of rut, baiting with an estrous female and provision of catwalks.

Post-rut management requires careful dietary consideration. Some bulls come out of rut in very poor body condition and may continue to be anorexic for a short time. Careful observation is advised because these poorly conditioned animals may simply continue to starve, or equally problematic, they may suddenly gorge on available feed, which can also lead to death.

Male Dominance

Dominant males in free-ranging systems are generally between 6 and 10 years old with body size, antler size, and antler branching correlated with dominance. Reindeer husbandry practices in Norway recommend 1.5-year-old males for breeding. Because of increasing aggression with age and subsequent difficulty in handling, few herders use bulls for more than 2 or 3 seasons or older than 4 to 5 years of age. Among Alaskan reindeer producers, deantlered 1.5-year-old male reindeer have served as highly effective breeding bulls when provided exclusive access to a harem. Information on quantitative assessment of bull fertility is lacking, and bull selection is frequently based on desirable yet fairly superficial qualitative characteristics and suitable rutting behavior. As a minimum, evaluation of potential breeding bulls must include checking for descent of both testicles. Bilateral cryptorchidism occurs in reindeer and can result in an animal that behaves appropriately but is incapable of impregnating cows.

Even though removing the antlers from a dominant male can result in his losing superiority, antlers alone do not assure dominance. Age, body size, strength, and experience combine to produce dominance in deantlered males. For management purposes, antlers may be removed either while in velvet or as hard antler. However, cutting antlers close to the pedicle increases the risk of the bull acquiring head injuries which, if untreated, can lead to septicemia and death. Self-inflicted trauma to the

head is reduced if the antlers are cut above the brow tine. The brow tine appears to provide important protection to the face. Deantlered, rutting bulls are just as damaging to fences as antlered deer.

There are few studies on the optimal number of females per breeding male. The husbandry literature suggests 4 to 6 bulls per 100 cows, although some have suggested that a mature bull can cover 50 cows or more. In most captive situations, a ratio of one bull for 10 to 20 cows is the general practice. The condition of the bull during the breeding season must also be considered. A mature bull may be able to cover 20 cows, but it may be at the expense of his own condition and survival. Some management systems incorporate close observation with replacement of weakening or spent bulls with a "back-up" bull to ensure that all cows are covered.

Hormonal Control of Rut

There is abundant anecdotal information on the use of medroxyprogesterone acetate (Depo-Provera, Pharmacia and Upjohn Company, Kalamazoo, MI 49001) to reduce aggression in male reindeer. Although not approved for use in reindeer, this compound has been administered in a series of two injections (generally one in August and the second in October) in doses ranging from 200 to 400 mg per animal. In most cases it is used to reduce aggression in nonbreeding males or given to males following breeding. Anecdotal information suggests that the drug produces very tractable males who retain their antlers and go on to breed normally in subsequent seasons, but no studies have specifically addressed the impact of the drug, drug dose, or chronic use on spermatogenesis, semen quality, and fertility. The potential of the drug to help manage rutting bulls needs more thorough investigation.

Although reindeer broadly conform to many of the principles and practices of deer farming, they do represent a species that is frequently the exception to the rule. Response to the demand for reindeer-specific information is just emerging, and knowledge in this area will not only improve our ability to farm reindeer, but will add significantly to the general understanding of this species and their unique adaptations to the Arctic.

CHAPTER 132

Reproductive Management of Axis Deer (*Axis axis*)

ANTHONY W. ENGLISH

Chital deer are one of six species of deer found in the wild in Australia.[1] There was early interest in their potential as a farmed species with the trapping of small numbers in Queensland in the early 1970s. Chital are among the most attractive of deer, and produce excellent venison, but they soon acquired a reputation as a nervous animal that was difficult to handle in captivity. There were also problems with high rates of perinatal mortality on farms, and it became apparent that there were both economic and animal welfare issues to be addressed if chital were to be successfully farmed. A program of intensive research on the species was undertaken at the Deer Research Unit, Camden, between 1985 and 1995 that resulted in the development of highly successful management strategies for this species under Australian conditions.[2] In particular, there was an opportunity to compare and contrast the needs of chital deer with those of fallow deer (*Dama dama*), a species of temperate origin and therefore a strictly seasonally polyestrous breeder with all conceptions occurring in the autumn. This is in marked contrast to chital deer, which were known to produce calves in all months of the year in herds where mating was not controlled in any way. The major thrust of the studies at Camden was to determine the factors that needed consideration in order to farm chital deer as successfully as fallow deer. Thus, studies were conducted on the biology and behavior of chital deer, including ways to minimize handling problems, on the reproductive physiology of both stags and hinds, and on carcass quality and body composition. There was development of effective programs of artificial insemination as well as ultrasonic fetal aging and pregnancy diagnosis.[3–5]

BIOLOGY AND BEHAVIOR

A major difference between chital deer and fallow deer is the temperate origins of the latter, whereas chital deer originate in India, Nepal, Bhutan, and Sri Lanka.[6] As a tropical species it was believed that their major attribute would be their ability to breed all year round, with the potential for chital hinds to produce three offspring in 27 months. This is in contrast to fallow deer that produce only one offspring annually, with strict reproductive seasonality imposed by photoperiodic variation. However, it soon became apparent that chital deer on farms in southern Australia were not realizing this high reproductive potential, partly because of the high perinatal mortality rate. Many calves born in the winter months died within a day or so of birth, especially in very inclement weather. In addition, there were often major problems when attempts were made to handle groups of chital deer on farms, given that such groups almost invariably contained all age classes, including antlered stags. With the timorous nature of the species and their often panic-stricken reaction to being closely approached, there were frequent losses from trauma and postcapture myopathy.

During the studies on chital deer at Camden it became apparent that chital deer were quite readily yarded and handled after a suitable "training and taming" process, especially once the deer were segregated into appropriate gender and age groups for management purposes.[7] Studies on the physiologic responses of chital deer to regular handling confirmed that this taming process did occur.[8] To reduce the risks of traumatic injuries during yarding, antler growth is always prevented by velvet antler removal or surgical polling. Well-trained chital deer can in fact be yarded and handled as readily as can fallow deer, through identical facilities.[2]

REPRODUCTION

It had been noted that chital hinds were capable of producing calves in every month of the year in India, Nepal, Hawaii, and Texas as well as in Australia.[6,9–11] However, when data were collected at Camden over several years it was found that there was a preponderance of calves born in the second half of the year.[3] This fitted well with observations made on the antler cycles of chital stags, with a high level of synchrony in their cycles being noted. Most stags cast their antlers in late winter and early spring, between August and October, with the subsequent development of hard antlers and other secondary sexual characteristics and a period of rutting behavior in January to June. This fitted with observations that showed that chital hinds cycle all year round if unmated, with an estrous cycle length of 19.3 ± 1.3 days and a gestation period of 234.5 ± 3.0 days. Moreover, chital hinds were known to conceive quite quickly after parturition, and it was revealed that the interval from calving to conception ranged from 18 to 118 days, with an average of 48.1 ± 27.8 days.[12] Subsequent work showed that the first detected estrus occurred at a mean time of 26.9 ± 3.0 days after parturition. Furthermore, hinds in contact with a stag in this study had a significantly shorter interval from parturition to first ovulation compared to hinds not in contact with a stag (93% compared to 43%, respectively).[13]

MATING MANAGEMENT

Intensive observation of chital stags showed that they were capable of producing viable semen even during the velvet antler phase, although the quality of the semen at that time was reduced.[4] Thus, even though a majority of conceptions occur when stags are in hard antler, there is always the potential for some hinds to conceive at other times. In herds when no mating management is practiced there are likely to be some young calves in the group at any time of the year. It was this fact that was at the heart of many of the handling difficulties that had been encountered with chital deer, with too many opportunities for misadventure when hinds and very young calves were yarded with larger groups, including adult stags. An obvious solution is to practice some form of restricted mating, to ensure that conceptions do not occur all year round. This should be routinely practiced with farmed chital deer, with births timed to coincide with optimal pasture conditions in spring, and much earlier in the pasture growing season than can ever be achieved with fallow deer. Not only does this allow the appropriate management of pregnant and lactating hinds and their young calves, with calving avoided in the winter months when perinatal mortality rate can be high, but it also offers a definite advantage in a venison production system. There is then the potential to produce prime venison at times when it may not be possible with deer of temperate origin.

In restricted mating systems that are designed to produce calves at a particular time of year it is preferable to select stags that are in hard antler, because this ensures the best possible chance of good semen quality in those animals. Routine collection of semen for evaluation would not normally be carried out on commercial farms, but it could be done if there was a need to make absolutely certain that semen quality was not likely to be a limiting factor in a breeding program. It would be prudent not to anesthetize a stag for this examination closer than 1 week to the mating commencement date.

Stag/hind ratios of 1:30 have been found to produce good conception rates but this can be varied from as low as 1:10 up to 1:50 with good results. It was found that chital stags when confronted with a number of estrous hinds were able to modify their mating behavior to cope with this situation.[3] In unrestricted, all-year-round calving groups the dominant stag is able to spend many hours tending a hind that is coming into season, until she finally accepts him. In restricted mating systems the stag will tend each estrous hind only for a short period before mating with her and moving on to another female, with good conception rates.

ENHANCED REPRODUCTION

Artificial breeding protocols developed in red deer and fallow deer have been modified for use in chital deer, with only moderate success. Artificial insemination has been quite successful, but embryo transfer has not—or at least not as successful as in red deer, but approaching the results obtained in fallow deer.

The components of an artificial insemination program are collection of semen, freezing and storage of semen, synchronization of estrus in hinds, and deposition of frozen-thawed semen in the hind. Semen can be collected from chital stags by electroejaculation, using chemical immobilization (4 mg/kg xylazine plus 4 mg/kg ketamine intramuscularly, with reversal of xylazine using yohimbine at 0.5 mg/kg IM). Chital semen is readily frozen using extenders based on TRIS-egg yolk-citrate, and thawed in a water bath for subsequent insemination.[14] Laparoscopic and cervical insemination of CIDR (controlled intravaginal drug release)-synchronized chital hinds has produced conception rates that are generally lower than for fallow deer using similar techniques, and more research is required.[4]

PERINATAL DEATH

The problem of perinatal death in calves born in winter was confirmed in studies at the DRU, Camden. There was a 48% death rate in calves born to 45 chital hinds over 4 years, with the majority of the deaths in the winter months. This compares unfavorably with a rate of 18% in fallow deer fawns at the same location.[15] The most frequent cause of calf death was found to be a complex of mismothering, fox predation, and exposure/starvation. Chital hinds are sensitive to the presence of humans when there are very young calves in the herd, and the calves are best ear-tagged at weaning, at about 3 months of age. Chital calves are somewhat smaller at birth than are fallow fawns, with females weighing 3.4 ± 0.5 kg and males 3.6 ± 0.4 kg. They can often move through gaps which will stop fallow deer fawns, which have birth weights of 3.97 ± 0.53 kg and 4.27 ± 0.70 kg, respectively.[15] This may result in mismothering and the death of calves if fences are poorly maintained.

One unforeseen cause of perinatal death in captive chital deer was the strong tendency of some adult stags to attempt to mate with hinds that were actually calving, or just after calving. When this occurs the neonate can be knocked aside and there is certainly the potential for injuries to occur. Given that a hind cannot readily escape this attention from a stag when they are in an enclosure together, it would be good management not to have adult stags in the same enclosure as hinds that are due to calve.[3]

Restricting the birth season to those times of the year when weather conditions are favorable for calf survival and when abundant high-quality pasture is available for lactating hinds has been shown to greatly reduce the problem of perinatal death in chital deer.[2]

CONCLUSION

There is no doubt that the use of chital deer on deer farms in Australia, Texas, or elsewhere can be an effective venison production system, if appropriate management strategies are put in place. Although the principles of management that have been developed for fallow deer apply equally to chital deer, some specific differences in biology and behavior do need to be taken into account when working with this beautiful species. This applies especially to differences in reproductive biology due to

the tropical origins of the chital deer, and the specific reproductive management issues that flow from this.

CHAPTER 133

Antlers and Reproduction

MURRAY R. WOODBURY and JERRY C. HAIGH

Antlers are only indirectly involved in the outcome of the reproductive process, but they are so intimately involved with, and affected by, the sexual seasonality of cervids that it becomes essential to discuss them and the effects that sex hormones have on their growth and annual cycle.

ANTLER DEFINITIONS

Antlers are unique in the animal world and therefore the jargon used in antler discussions is also unique.

The term "velvet" refers to the skin covering a growing antler. It describes the fuzzy texture provided by many fine hairs growing on the surface. "Velvet antler" refers to the entire antler when it is in the growth phase. At this stage it is soft and lacks the mineralized characteristics of hard antler, which is nothing less than bone. Frequently "velvet" and "velvet antler" are used interchangeably to refer to the antler in its growth phase.

Antler grows from discrete areas on the frontal bone of the skull called pedicles. They are permanent features of the skull and remain after the antler is cast off in the fall as the perennial source of the regenerating antler.

The antler-pedicle junction is called the coronet, or the "burr," due to the circumferential growth of irregular knobs and pearls of antler at the junction. In first-growth antlers the coronet is less prominent, becoming more distinct with advancing maturity.

"Spikers" are yearling stags with first-growth, single-spike antlers. Spike antlers are sometimes branched, depending on the month of birth and the nutrition available for growth. Early born stags on good levels of nutrition frequently grow branched antlers in the first year. The presence of such antlers is not necessarily predictive of future antler growth.

The generic antler is composed of a major beam, with branches or tines arising from the beam. The

the tropical origins of the chital deer, and the specific reproductive management issues that flow from this.

CHAPTER 133

Antlers and Reproduction

MURRAY R. WOODBURY and JERRY C. HAIGH

Antlers are only indirectly involved in the outcome of the reproductive process, but they are so intimately involved with, and affected by, the sexual seasonality of cervids that it becomes essential to discuss them and the effects that sex hormones have on their growth and annual cycle.

ANTLER DEFINITIONS

Antlers are unique in the animal world and therefore the jargon used in antler discussions is also unique.

The term "velvet" refers to the skin covering a growing antler. It describes the fuzzy texture provided by many fine hairs growing on the surface. "Velvet antler" refers to the entire antler when it is in the growth phase. At this stage it is soft and lacks the mineralized characteristics of hard antler, which is nothing less than bone. Frequently "velvet" and "velvet antler" are used interchangeably to refer to the antler in its growth phase.

Antler grows from discrete areas on the frontal bone of the skull called pedicles. They are permanent features of the skull and remain after the antler is cast off in the fall as the perennial source of the regenerating antler.

The antler-pedicle junction is called the coronet, or the "burr," due to the circumferential growth of irregular knobs and pearls of antler at the junction. In first-growth antlers the coronet is less prominent, becoming more distinct with advancing maturity.

"Spikers" are yearling stags with first-growth, single-spike antlers. Spike antlers are sometimes branched, depending on the month of birth and the nutrition available for growth. Early born stags on good levels of nutrition frequently grow branched antlers in the first year. The presence of such antlers is not necessarily predictive of future antler growth.

The generic antler is composed of a major beam, with branches or tines arising from the beam. The

Table **133-1**

Major Differences Between Antlers and Horns

Feature	Horn	Antler
Tissue of origin	Skin	Bone
Composition	Keratin	Multiple tissue types
Persistence	Permanent	Deciduous
Innervation	Lacks innervation	Highly innervated when growing
Vascularization	Nonvascular	Highly vascular when growing

number, configuration, and spatial orientation of tines is species-specific.

Antlers are often unknowingly referred to as horns. Antlers are quite distinct from horns and have several features that distinguish them from horns, including their ability to regenerate. In fact, antler is the only mammalian tissue besides the placenta that is entirely shed and subsequently regenerated. The major differences between antlers and horns are listed in Table 133-1.

ANTLER GROWTH

Most of the available information on antler growth and control deals with deer from temperate regions. The timing and regulatory mechanisms of antler cycles in tropical deer can be somewhat different than those found in temperate zones and are illustrated in Figure 133-1. However, the basic mechanisms of antlerogenesis and its regulation provided here are common to most cervids.

Antler pedicles develop from osteogenic centers on the frontal bone area. They begin growth when sexual differentiation of the fetus occurs. Testosterone is required for pedicle formation and growth. It does not directly stimulate growth, but increases the sensitivity of antlerogenic tissue to undetermined growth factors.[1] Pedicle growth is sufficient to support antler growth at about 6 to 10 months of age and is a continuous process in the first antler cycle.[2]

Hummels are antlerless red deer stags. This abnormality has been attributed to poor feeding conditions resulting in the formation of incomplete pedicles without the potential to develop normal antlers. Presumably, nutritional cues act synergistically with androgens to permit the development of this secondary sex characteristic of red deer.[2]

At the distal pedicle, mesodermal cells derived from the skin or the pedicle, or both, multiply and differentiate to make new antler tissue. At the point of growth hyperplastic fibroblasts deposit collagen, forming a well-vascularized mass on the pedicle. The new antler elongates as this growth continues in the outermost layers of the tip. Further differentiation of cells into chondroblasts and chondrocytes associated with the formation of cartilage occurs in the portions closer to the antler base. Subsequently, the antler continues to enlarge by the differentiation process at the tip and by elaboration of fibrocartilage underneath those portions. Growth is very rapid; a wapiti antler is capable of growing more than 2 cm in a 24-hour period. After a period of about 80 days a mature wapiti stag can be expected to grow immature, still uncalcified antlers in excess of 15 kg. Subsequent growth is slowed as antler maturation proceeds and full growth is achieved after approximately 120 days. Readers requiring a more detailed description of basic antler development and growth are referred to the paper by Chapman.[3]

Primary ossification of antler occurs through the process of modified endochondral ossification whereby cartilage is directly converted to bony tissue by the deposition of mineralized material within the cartilaginous matrix.[4] Chondrocytes exhibit alkaline phosphatase activity leading to the formation of trabeculae and spongy reticulum. The reticulum is then strengthened by osteoblastic activity laying down bone on the surfaces of the trabeculae (intramembranous ossification).[4] This activity eventually leads to the hardening of the entire mature antler. The calcification and ossification process proceeds up the antler from the base to the tip. The thickening of the trabeculae eventually results in the typical hard antler, consisting of thick compact bone covering a sponge-like core.

Antler metabolism is largely under the control of hormones, such as insulin-like growth factor (IGF), but antler mineralization and ossification are influenced by testosterone.[5] As photoperiod decreases the antler becomes more sensitive to the increasing presence of testosterone, resulting in completely mineralized and polished antlers at the time of rut.[6] Figure 133-1 illustrates the circannual antler growth pattern in deer from temperate zones.

Coincidental to advancing antler calcification the skin covering the antler begins to die. The exact mechanism of velvet shedding is poorly understood, but there is no doubt that vascular changes initiate the process, with velvet death due to avascular necrosis. Typically velvet shedding occurs at the same time as testosterone levels are rising. Administration of exogenous testosterone (or estrogen) will cause premature shedding of antler velvet.[6]

The hardened and cleaned antler does not die but appears to remain alive like other bones in the body. In the fallow deer a well-developed system of microscopic nutrient canals is evident, and there are living osteocytes, osteoblasts, osteoid seams, and microcallus formations indicating bone remodeling activity present until at least 3 weeks before casting.[7]

The annual loss of the antler from the pedicle in late winter or early spring is called casting. Casting is associated with diminishing testosterone levels resulting from the increasing photoperiod of spring. The line of future separation between the antler and pedicle is called the abscission line and is indicated microscopically by a narrow transverse band of minute blood vessels. Osteoclastic activity across this line is responsible for the eventual release of the antler from the pedicle. After casting the ingrowing skin-derived tissue fuses with the mesodermal tissue from the vascular channels of the pedicle,

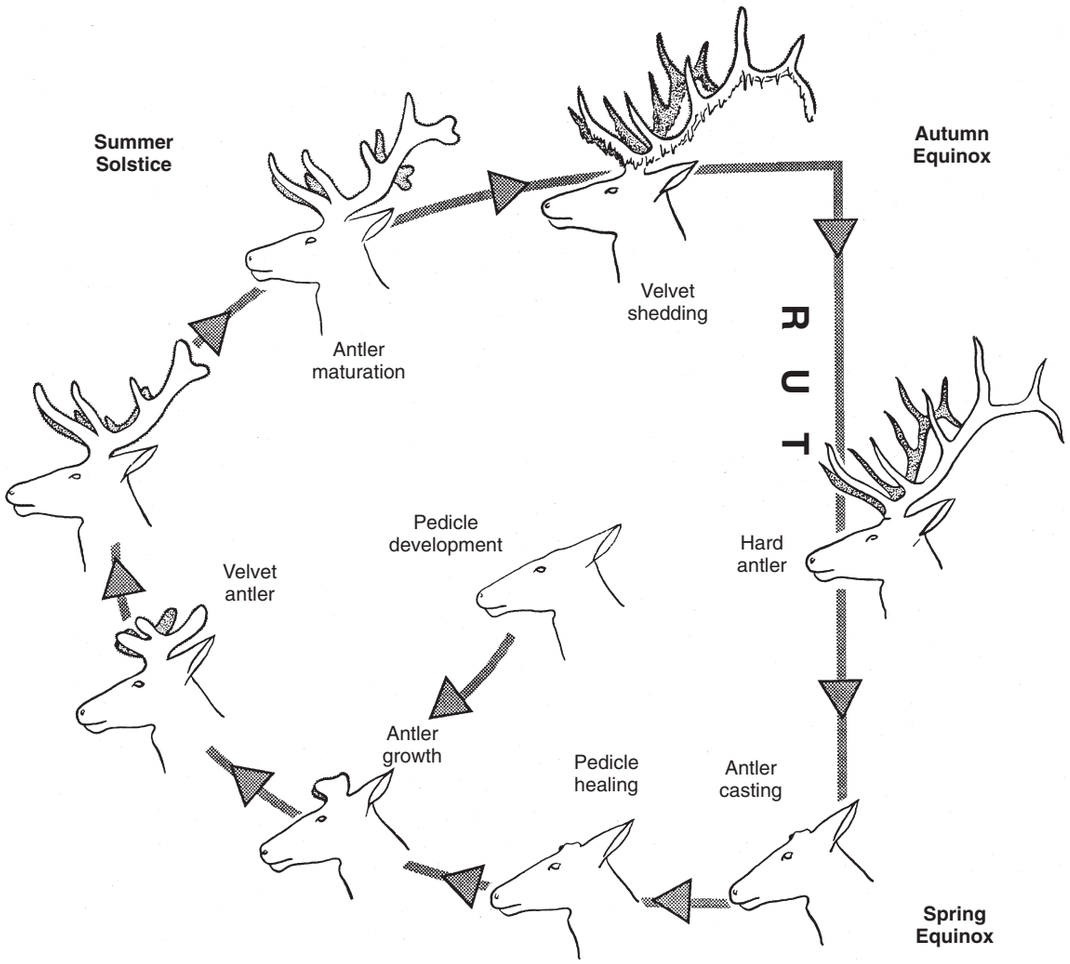

Fig. 133-1 The antler cycle. (From Haigh JC, Hudson RJ: *Farming wapiti and red deer*. St Louis: Elsevier, 1993.)

giving rise to a developing antler bud under the scab covering the pedicle.[8]

THE ANTLER CYCLE

Antler growth cycles are closely related to sexual cycles in stags and are directly attributable to variations in seasonal photoperiod influencing gonadal steroidogenic activity. The seasonal onset of reproductive activity (rut) in stags is associated with rising circulating levels of gonadotropins and consequently testosterone secretion. Readers requiring a more detailed description of neuroendocrine regulation of the antler cycle are referred to the book chapter by Bubenik.[9]

Photoperiod and Melatonin

Natural circadian rhythms of the individual are responsible for the timing of events during antler growth, but experimental evidence points to the pineal gland and its response to light as being the modulator of those mechanisms responsible for gonadotropic control and hormonal control of the antler cycle and the male and female reproductive cycle.[9] When the duration of daylight reaches a peak and the length of darkness is least the pineal gland responds by elaborating very little melatonin. As day length decreases and the period of darkness increases the pineal gland responds by secreting increasing levels of melatonin. Melatonin production is greatest when day length is decreasing to the lowest annual levels.

Gonadotropins

Rising levels of melatonin act on the pulse generator of the hypothalamus, causing the pulsatile production and release of gonadotropin-releasing hormone (GnRH). The appropriate frequency and amplitude of the GnRH pulses causes the pituitary to produce and secrete gonadotropins, meaning luteinizing hormone (LH) and follicle-stimulating hormone (FSH). These hormones regulate the testicular output of testosterone, which is thought to ultimately control the timing of the antler cycle along with the male reproductive cycle.[10]

Testosterone

As day length decreases, testosterone secretion increases in response to rising LH levels and reaches a peak immediately prior to the rut. Thereafter, levels begin to decline until spring when a rapid decline in circulating testosterone is associated with antler casting. While testosterone levels remain low new antlers begin to grow. When antler growth nears completion the testosterone levels are once more rising. High levels of testosterone are associated with hardening and cleaning of the antler, coinciding nicely with the behavioral need for antlers during the rut.

Exogenous testosterone administration during the velvet phase results in calcification and cleaning of the antler. Administration during the hard antler phase results in retention of the antler. Therefore, high concentrations of testosterone promote calcification and velvet shedding as well as prevent casting of hard antler. Sustained high concentrations of testosterone also prevent the growth of new antlers.

The hormonal control of the antler cycle in reindeer differs somewhat from that in other cervids. In female reindeer estrogen appears to regulate the antler cycle in a manner similar to that of testosterone in males. In both sexes there appears to be an auxiliary control mechanism operative in the absence of gonads. There appears to be sufficient adrenal production of sex hormones such that antler production and regulation, although altered, can occur in ovariectomized or castrated animals.[11]

FUNCTION OF ANTLERS IN REPRODUCTION

Although students of deer behavior agree that antlers are important in intraspecific combat,[12,13] there is some debate about other roles of these structures in the life of different deer species. For instance, a role in estimation of social class and rank between individual conspecifics is suggested.[14,15] On the other hand Clutton-Brock examined five possible functions for antlers and argued that virtually their only role is for use in fights between competing males seeking access to females.[12]

Actual decisive fighting, as opposed to sparring[14,16] is likely to occur for three reasons: (1) between two closely matched stags who are competing for access to females, (2) between males that do not know one another and do not know each other's rank, and (3) in asymmetrical contests when an inexperienced young male enters the rutting ground of a prime male and fails to recognize or heed warning threats.[17]

There have been many suggestions that antlers, used as displays or advertisements of dominance among males, will permit stags to assess each other without fighting.[15,17–19] Stags appear to evaluate each other based mostly on antler size.[17,18] The length of the antler beam in elk indicates that antlers are a long distance, visual signal. The slightest head nodding is reinforced visually by movement of the elongated antlers, reinforcing the stag's presence and rank. Changes in the shape or size of the antler structure of breeding males through accidental fracture or experimental trials can lead to alterations in the stag's position in the hierarchy because such stags are immediately challenged by subordinates.[15,17,18]

There is also evidence that elk hinds in estrus will seek out the stag with the largest antlers, indicating a male-female interaction dependent on antlers in addition to the male-male interaction.[17]

Antlers also have an olfactory role in the sex life of deer. During bouts of thrash urination rutting behavior, elk and red deer spray heavily scented urine on their sideways tilted antlers.[18] The dorsal location of the urethral tip on the penis is an adaptation of elk and red deer that allows urine to be directed slightly above the horizontal as it is ejected cranially from the erect penis. The bull can scent himself on the belly, forelegs, long hairs of the neck, and the antlers.[20] Antlers are also used during the rut for making scrapes and wallows in the ground and for territorial marking by thrashing of vegetation and destruction of small trees and bushes.

Although antlers provide a visible expression of dominance, other social and individual factors are of similar importance. For example, antlerless stags will successfully defend a harem and breed. That the absence of antlers in no way inhibits the ability to breed is an important factor for the deer farmer as an antlerless stag is considerably easier to manage during the rut than one with a full head and inflicts less damage to fences, other deer, and humans.

ANTLER MANAGEMENT

Effects of Castration on Antler Growth

Testosterone promotes pedicle growth but interferes with antler growth.[9] It is required for pedicle development and the initiation of the first antler cycle. Castration prior to first antler growth results in the complete and permanent inhibition of pedicle growth. Once pedicles are developed and antler growth has been initiated, castration does not prevent antler growth. Because antler growth in the intact male occurs in the absence of significant testosterone levels, castration will not interrupt antler growth once it has begun.

Castration of postpubertal males in velvet will result in the retention of the velvet antlers without maturation. The outcome is continuously growing antlers that never mineralize, shed their covering of skin, or cast normally in the fall. Castration of animals in hard antler will result in casting of the antlers within 2 or 3 weeks, followed by the growth of abnormal antlers described earlier.

The effects of castration on antler growth and maturation can be reversed with exogenous testosterone. Weekly intramuscular 2 mg/kg injections of testosterone cypionate, enanthate, or propionate will result in mineralization of the antler and shedding of the antler skin.[21] Use caution when handling these animals as they will become aggressive and show the typical behavioral signs of rut. Testosterone injections can be stopped when the antlers are hard and polished. The subsequent abrupt fall in testosterone levels will result in shedding of the polished antlers, followed of course by the regeneration of abnormal antler growth.

Reindeer are an exception to the principles of antler growth. In this species, both males and females develop antlers soon after birth and prior to puberty. Removal of the testes or ovaries before puberty does not block growth or annual regeneration of antlers.[22] When castrated during the period of velvet antler growth, the developing male antlers are retained throughout the fall and winter but do not become overgrown. These antlers fail to fully mineralize and shed their skin, but are cast in the spring, initiating new antler growth. Reindeer antlers are renewed annually despite castration. Behavioral signs of rut in intact male reindeer can be diminished or removed by an injection of 200 to 300 mg of medroxyprogesterone acetate (Depo-Provera, Pharmacia & Upjohn).

Antler Removal

Velvet antler removal from farmed elk and deer for commercial purposes is widely practiced. Soft, growing antler harvested from elk, red deer, sika deer, and other species is processed and used in traditional Chinese medicine and as modern nutraceuticals for its benefits in treating chronic disease and tonic effect.[23] Velvet antler's reputation as an aphrodisiac is undeserved and its reported effects on human sexual function are largely organ-based rather than psychological.

Antler harvesting can be accomplished only on suitably restrained animals, especially with large cervids like elk. In the recent past chemical immobilization with general anesthetic drugs was widely used. More recently, modular handling facilities with hydraulic cradles have been developed to safely and securely hold fully awake animals for antler removal.

Modern farming practice involves the administration of local anesthesia to the nerves serving the antler and pedicle, followed by amputation of the antler just above the antler-pedicle junction.[24,25] Hemostasis is achieved by a tourniquet around the pedicle. Amputation is easily performed using any coarse saw that can be repeatedly sanitized with chemical disinfectants. Ancient methods did not involve the use of analgesia, but more modern techniques have incorporated the subcutaneous infiltration of lidocaine in a ring block at the base of the antler pedicle. Because of industry concern about chemical residues in antler products, experimental and unproven methods such as transcutaneous electrical nerve stimulation (TENS), also known as electroanesthesia, and compression of the pedicle are also used. Their effectiveness and worth have yet to be scientifically established.[26]

For safety reasons, hard antler is also commonly removed from farmed deer. Antlerless stags are easier to handle and much less dangerous to humans and herd mates during the rut. "Thrashing" behavior, using antlers as instruments of aggression on inanimate objects, often ruins fences, waterers, and hay racks. In the instance of hard antlers, anesthesia of the antler after restraint is not necessary. Animal handling and physical or chemical restraint is much easier to accomplish if antler removal is performed prior to the rut. A saw cut approximately 2 cm above the pedicle junction with a Gigli wire or fine-toothed saw will easily take the hard antler off cleanly.

CHAPTER 134

Cervid Semen Collection and Freezing

MIKE J. BRINGANS, CLAIRE PLANTE, and JOHN POLLARD

SEASONALITY

The cervid species mentioned in this section (wapiti, red deer, white-tailed deer, fallow deer, and sika deer) are all seasonal breeders. Because of the relationship between changing daylight length and fertility, there is a limited window of opportunity to collect viable semen[1,2] (Fig. 134-1).

This window can be manipulated early via artificial lights or the use of melatonin implants. Melatonin implants have been successfully used to advance the breeding season of red deer.[1] Starting 3 months before the normal breeding season, using one implant of Regulin (Regulin, Schering Agrochemical, Ltd., NSW, Australia) per month, it was possible to obtain good quality semen 1 month before other untreated bulls of the same age.[2]

However, there were undesirable side effects. These bulls rutted early when the temperatures were hot, and then changed into a summer coat in late winter when the temperatures were cold. They also showed irregular antler growth, going through two antler cycles in 1 year.[2]

At the beginning of the breeding season, a higher percentage of secondary abnormalities can be seen in the semen sample. The timing of this varies between individual males. Similarly, individual males will display a higher percentage of secondary abnormalities toward the end of the breeding season. In some instances an excess of 50% of sperm in one ejaculate will show distal droplets before cessation of viable sperm production.[1]

METHOD OF COLLECTION

Some workers have reported collections from dummy mounting, as well as indwelling condoms in ovariectomized females treated with estrogen, but realistically electroejaculation is the most accepted method. There are two methods of collecting semen by electroejaculation.

Under Anesthetic

Initially most cervid species were collected this way.[1] However, from the late 1980s onward the method of choice to collect red deer and wapiti semen involved the use of no drugs, and a squeeze or chute.[1]

If wapiti or red deer are in full antler it may still be necessary to tranquilize or anesthetize them. Drugs used to induce lateral recumbency are listed in Table 134-1. They are either narcotic-based mixtures or a mixture of xylazine HCl and Telazol.[1,3]

Fentazine or the carfentanyl/xylazine mix is reversed with tolazoline hydrochloride (Tolazine, Lloyd Laboratories, Shenandoah, Iowa) (2–4 mg/kg, given half IM, half IV) or yohimbine hydrochloride(Antagonil, Vetrepharm, London, Ontario, Canada) (1.0–1.25 mg/kg) to reverse the xylazine, as well as Narcan (Naloxone hydrochloride injection, DuPont Pharmaceuticals, Dorval, Quebec City, Canada) to reverse the narcotic (Table 134-2). The more nervous smaller cervid species are best done under anesthesia. The drug combination of choice for white-tailed deer bucks is xylazine/Telazol mix. This is reversed with

CHAPTER 134

Cervid Semen Collection and Freezing

MIKE J. BRINGANS, CLAIRE PLANTE, and JOHN POLLARD

SEASONALITY

The cervid species mentioned in this section (wapiti, red deer, white-tailed deer, fallow deer, and sika deer) are all seasonal breeders. Because of the relationship between changing daylight length and fertility, there is a limited window of opportunity to collect viable semen[1,2] (Fig. 134-1).

This window can be manipulated early via artificial lights or the use of melatonin implants. Melatonin implants have been successfully used to advance the breeding season of red deer.[1] Starting 3 months before the normal breeding season, using one implant of Regulin (Regulin, Schering Agrochemical, Ltd., NSW, Australia) per month, it was possible to obtain good quality semen 1 month before other untreated bulls of the same age.[2]

However, there were undesirable side effects. These bulls rutted early when the temperatures were hot, and then changed into a summer coat in late winter when the temperatures were cold. They also showed irregular antler growth, going through two antler cycles in 1 year.[2]

At the beginning of the breeding season, a higher percentage of secondary abnormalities can be seen in the semen sample. The timing of this varies between individual males. Similarly, individual males will display a higher percentage of secondary abnormalities toward the end of the breeding season. In some instances an excess of 50% of sperm in one ejaculate will show distal droplets before cessation of viable sperm production.[1]

METHOD OF COLLECTION

Some workers have reported collections from dummy mounting, as well as indwelling condoms in ovariectomized females treated with estrogen, but realistically electroejaculation is the most accepted method. There are two methods of collecting semen by electroejaculation.

Under Anesthetic

Initially most cervid species were collected this way.[1] However, from the late 1980s onward the method of choice to collect red deer and wapiti semen involved the use of no drugs, and a squeeze or chute.[1]

If wapiti or red deer are in full antler it may still be necessary to tranquilize or anesthetize them. Drugs used to induce lateral recumbency are listed in Table 134-1. They are either narcotic-based mixtures or a mixture of xylazine HCl and Telazol.[1,3]

Fentazine or the carfentanyl/xylazine mix is reversed with tolazoline hydrochloride (Tolazine, Lloyd Laboratories, Shenandoah, Iowa) (2–4 mg/kg, given half IM, half IV) or yohimbine hydrochloride(Antagonil, Vetrepharm, London, Ontario, Canada) (1.0–1.25 mg/kg) to reverse the xylazine, as well as Narcan (Naloxone hydrochloride injection, DuPont Pharmaceuticals, Dorval, Quebec City, Canada) to reverse the narcotic (Table 134-2). The more nervous smaller cervid species are best done under anesthesia. The drug combination of choice for white-tailed deer bucks is xylazine/Telazol mix. This is reversed with

yohimbine or tolazoline hydrochloride (doses as previously given).

Cervids collected under anesthetic are in lateral recumbency with an assistant holding the back legs and another assistant holding the head.[1]

More electroejaculation stimulation is needed than in standing collection. Anesthetized males are more likely to spoil the collection with urine contamination or accessory sex gland contamination with this method.

A cleaner collection can be obtained by initially snaring the penis with a cotton bandage and directing it into a collection vessel, so as to avoid preputial contamination. Care is taken to collect the ejaculate in fractions, so that every collection can yield some viable sperm. If contamination from urine or accessory sex glands occurs, then that affected fraction is discarded.

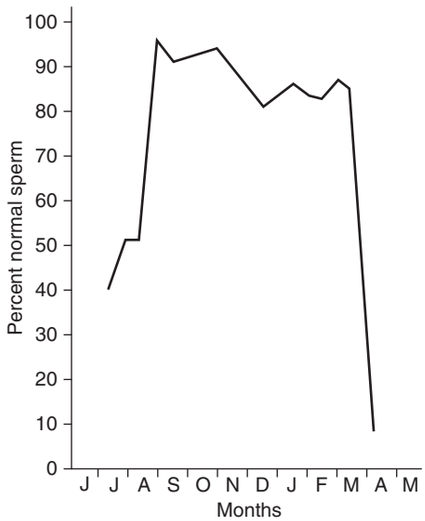

Fig. 134-1 Spermiogram of adult wapiti bulls in the northern hemisphere. (Adapted from Haigh JC, Barth AD, Cates WF, et al: Electro-ejaculation and semen evaluation of wapiti. In Fennessy PF, Drew KR: *Biology of deer production.* Wellington: The Royal Society of New Zealand, 1985, pp 197–203.)

Standing Collection

With standing collection the male is immobilized with a squeeze or crowding gate. The rectum is evacuated manually. During this process the penis can be snared with a section of gauze bandage for easier collection. The preputial area is cleaned before collection. Tranquilization may be needed in rare instances. Xylazine (30 mg total dose) can be used in red deer and wapiti. Reversing this dose is unnecessary.

EQUIPMENT

The group uses a Lane Pulsator III electroejaculator (Lane Pulsator III, Lane Manufacturing Inc., Aurora, CO) on all species. A sheep probe is ideal for the smaller species, and hand-crafted probes are used for wapiti and red deer (size 4 cm diameter for red deer and 6 cm diameter for wapiti). These can have two or three ventrally placed electrodes.[4]

Collection vessels used are normally specially blown bell-shaped glasses with a protective water jacket kept at 36° C. Thick glass-bottom shot glasses can be used in warmer climates. Standard bovine rubber collection sheaths and test tube combinations can also be used, but

Table **134-1**

Drugs Used to Induce Lateral Recumbency

Anesthetic	Wapiti (400 + kg)	Red Deer (220 kg)	White-tailed Deer (100 kg)
Fentazine*	3 ml	2 ml	
Carfentanyl* (0.06 mg/ml) and xylazine* (100 mg/ml)	2 ml mixture	1 ml mixture	
Xylazine (100 mg/ml) and tiletamine HCl (50 mg/ml) and zolazepam HCl* (50 mg/ml)			1–2 ml mixture

*Fentazine, Parnell Laboratories, Ltd., Alexandria, NSW, Australia; Wildnil (carfentanyl), Wildlife Pharmaceutical Canada, Inc., Callander, Ontario, Canada; Rompun (xylazine), Bayer, Inc., Etobicoke, Ontario, Canada; Telazol (zolazepam), Wapitiins-Sinn, Inc., Cherry Hill, NJ.

Table **134-2**

Drugs Used to Reverse Anesthetics

	Wapiti (400 kg)	Red Deer (220 kg)	White-Tailed Deer
Yohimbine (5 mg/ml)	3–5 ml	3–5 ml	3–4 ml
Tolazine hydrochloride (100 mg/ml)	3–5 ml	3–5 ml	3–4 ml
Narcan (0.4 mg/ml)	1 ml to be used in conjunction with one of the above	1 ml to be used in conjunction with one of the above	

these are more prone to extra contamination from the prepuce and abdomen. The collection vessels can be kept in a water bath or an incubator and returned quickly to either, as the fraction is collected.

TECHNIQUE

Initially begin pulsing (3 sec on, 3 sec off) at low voltage (±1 volt) and gradually build the voltage up to $2^1/_2$ volts. Normally a male will have ejaculated in a 1- to 5-minute period.[2]

With standing collections in wapiti and red deer, in most cases, it is normal to see clear seminal fluid initially. This is not normally kept to be included in the semen to be processed. This volume can be 1 ml to 10 ml. Soon after the ejaculate becomes cloudy, the white semen will be evident. After the semen rich fraction is collected it is common to see cloudy and then clear seminal fluid again. Only the semen-rich fractions (1–8 ml) are processed. Care must be taken to avoid the yellow vesicular fluid, because this is toxic to sperm (Fig. 134-2). This is more commonly seen early in the breeding season. Semen can be salvaged if inadvertently mixed with vesicular fluid, if it is quickly pipetted off the yellow viscous solution.

With both anesthetized cervids and those done standing, a second ejaculate can be obtained 5 to 10 minutes after the first. It will yield approximately the same volume and number of sperm cells. With the smaller cervid species, such as white-tailed and fallow deer, a smaller volume, higher density ejaculate is more common.

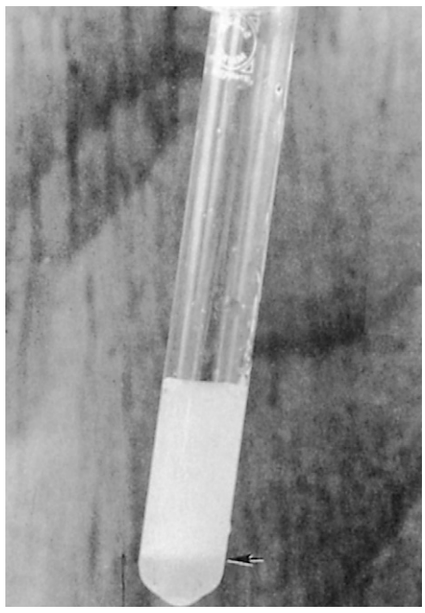

Fig. 134-2 Ejaculate in which vesicular gland secretion has been collected. The upper portion contains creamy white semen. The lower one sixth, below the separation line *(arrow)* is bright yellow. The semen should be carefully decanted before extension or freezing. Note arrow dividing line between sperm fraction (*upper*, white) and vesicular gland fraction (*lower*, yellow). (From Haigh JC, Hudson RJ: *Farming wapiti and red deer*, St Louis: Mosby, 1993.)

Extender that has been kept at the same temperature is added to the semen-rich fraction immediately, at a ratio between 1 : 1 and 1 : 3 semen/extender, depending on perception of color and density. This is pipetted into a sealed test tube and put in a water jacket (water volume 150 ml) at the same temperature as the water bath. This water jacket is placed in another container at 4° C and the semen will cool to 4° C over 1.5 hours.

The typical number of sperm cells per collection is 4000 million with red deer or wapiti, and 3500 million with whitetailed deer. The semen is placed in 0.5- or 0.25-ml straws at 30 million to 40 million sperm cells per straw for wapiti and red deer and 50 million per straw for white-tailed deer.

There are no data available on minimum doses necessary for optimal conceptions. This would have to be done on an individual male basis, as fertility varies among animals having equivalent semen quality. The lowest number of sperm cells in wapiti I have used is 300,000 live sperm per dose, which achieved a 50% conception rate in 10 wapiti cows.

The typical collection yields of 470 collections from wapiti over a 4-year period are represented in Table 134-3 and collections for white-tailed deer are in Table 134-4.

EXTENDERS

The extender used most commonly is a one-step TRIS extender with a gentamicin, tylosin, Lincospectin anti-

Table **134-3**

Semen Collection from Wapiti

Age	No. of Collections	No. of Doses*	Average†
2-year-olds	29	12–132	51
3-year-olds	21	19–229	74
Adults	420	8–248	98

*Each frozen dose contained an estimated 40 million sperm/0.25 ml straw.
†Adult red deer averaged 130 over the same period as wapiti.
Note re collection failures: 20 of 470 resulted in zero saleable semen; 11 collections were discarded because the prefreeze motility was below 70% or the post-thaw motility was below 40%; 3 were contaminated by urine; 4 were contaminated by vesicular fluid; 1 was discarded due to a high percentage of secondary abnormalities.

Table **134-4**

Semen Collection from White-Tailed Deer

Age	No. of Collections*	No. of Doses†	Average
2-year-olds	10	14–130	45
Adult	38	13–128	70

*Two of the 38 adult collections were discarded.
†Each frozen dose contained an estimated 50 million sperm/0.25 ml straw.

biotic mix (One Step Tris Extender, Gencor, Guelph, Ontario, Canada). This has been used successfully in wapiti, red deer, white-tailed deer, fallow deer, and sika deer. However, some collections of certain individual males will not freeze in such an extender with acceptable results. Other extenders can be used in these cases. For example, of 210 wapiti bulls collected, six did not freeze acceptably in the TRIS extender (Citrate extende) Two of these bulls produced good quality semen frozen in Biociphos Plus (Biociphos Plus, manufacturer IMV, France; Canadian distributor, Gencor, Guelph, Ontario, Canada) only. Triladyl (Triladyl, Minitube, Ingersoll, Ontario, Canada.) is also a good alternative extender for most cervid species, and semen from two of the "problem" bulls froze in Triladyl with acceptable results. A step A (no glycerol) and step B citrate extender can also be used. It is technically more difficult to use but is also worth trying if a bull's ejaculate fails to consistently freeze well in a one-step extender. The other two of our problem bulls had semen successfully frozen in this.

FREEZING

After cooling to 4°C, the semen is extended further to give the required dose per straw. A minimum of 4 hours after collection, it is packed into straws and frozen. The level in the vapor rack is at –140°C. The freezing box temperature is wafted up to –100°C, and the straws are placed in it. The temperature in the box will rise to –35°C and then fall at 10°C per minute to –160°C over a period of 13 minutes. The semen is then plunged into liquid nitrogen.

ANALYSIS

Each batch of semen frozen should be analyzed by thawing two straws. An immediate post-thaw motility reading is done and usually a 2-hour incubation motility reading is done after this. This gives a good indication of the percentage of live, progressively motile sperm cells in the sample. A morphologic examination is done after staining and primary and secondary abnormalities are noted.

Except for the beginning and end of normal breeding seasons, very few secondary abnormalities are seen (usually less than 1%). Of all cervid collections done, I have seen only one subfertile red stag and two subfertile wapiti males with more than 50% secondary abnormalities, at mid-breeding season. All three had histories of poor conceptions with natural matings.[2]

Most primary abnormalities seen are bent tails, usually the result of cold shock. If most of the sperm cells are affected this way it can also be from urine contamination changing the pH of the extender. A count with a hemocytometer is done to check concentration.

FREQUENCY OF COLLECTIONS

Wapiti and red deer can have their semen collected on 2 consecutive days or weekly, without any reduction in sperm numbers. Often a collection attempted on the third consecutive day will give a reduction in sperm numbers of approximately 50%. It is not recommended to collect semen on 2 consecutive days with smaller deer species, such as white-tailed deer, because of the anesthetic risk. This can routinely be done weekly without a noticeable decrease in sperm numbers.

SUCCESS OF COLLECTIONS

The success of collections varies from month to month. The peak breeding season for female wapiti in North America is early September. Some adult wapiti bulls can have their semen collected as early as the first week of August. "Pre-rut" collections generally become more successful as collections are done closer to the breeding season. For best results 2- and 3-year-old bulls are generally left until the last week of August and 1-year-old bulls are left until early September or until after the rut.

Adult bulls that are used for natural breeding generally produce less freezable semen immediately after their breeding than they do pre-rut and one or more months later. We prefer to collect semen at least 2 weeks after the bull has been removed from the cows (Table 134-5). This recommendation also applies to red deer and white-tailed deer.

"Fresh" Semen Collections and Artificial Insemination

It is routine to collect semen from wapiti, red deer, or white-tailed deer, extend the semen, cool, and inseminate immediately. I have used Triladyl, and Tris One Step extenders for this with acceptable pregnancy results[2] (Table 134-6). The part A citrate extender can also be used successfully for this.

Postmortem Semen Collection

Of eight postmortem collections done, seven gave viable sperm capable of fertilizing. It is important to handle the testicles correctly to achieve a useful collection. On the dead animal, the testicles should be pushed down into the scrotum and then the whole scrotal sac removed close to the abdomen. This is placed into a cooler at 4°C. This

Table **134-5**

Collections of Adult Wapiti Bulls, 1999–2001

Month	Average No. of Straws (40 million/straw)	No. of Collections
Aug.	96	82

*Younger wapiti bulls sometimes will not produce freezable semen in January and February. Adult white-tailed deer bucks can be successfully collected until up to 1 week after antler casting.

Table **134-6**

Fresh Semen Collections and Artificial Insemination

Year	Numbers	Overall Conception (%)	Percentage of Heifers that Conceived When Inseminated with Frozen Semen*	Percentage of Heifers that Conceived When Inseminated with Fresh Semen*
1997	23	78%	70%	85%
1998	31	81%	72%	85%
1999	42	70%	60%	80%
2000	67	73%	67%	80%

*Semen at the same property over a 4-year period.

can be transported in this situation for a number of hours. The longest time frame I experienced, which still resulted in a successful collection, was 18 hours from time of death to freezing.[2]

The testicles are removed from the scrotum at the time of collection. The temperature of the tail of the epididymis is measured with a thermocouple and the extender is heated or cooled to the same temperature. The tail of the epididymis is dissected off. The first 8 cm of the epididymis is flushed with 5 ml extender, and then a syringe with 10 ml of extender is used to wash each tail (after parallel cuts are made 1 mm apart with a scalpel blade through it).

The semen/extender mix is kept at 4° C for 3 hours and then frozen. The average number of sperm cells collected with this method was 2000 million per male. The majority will have distal droplets, but of the semen collected with this method, conceptions ranged from 30% to 60%.

Complications

Of all the collections done to date we have not experienced any deaths as a result of semen collection. However, anesthetic deaths are possible in the smaller deer species, so care should be taken to monitor anesthetic depth. Preputial erosions and prolapses are common in wapiti males and may have to be resected before collection. I have also seen a rectal prolapse subsequent to semen collection that had to be repaired. At rut time this is a difficult procedure because the bugling vocalization produces intra-abdominal pressure that tends to cause a recurrence of the problem.[2]

CHAPTER 135

Estrous Synchronization and Artificial Insemination in Domesticated Cervids

CLAIRE PLANTE, JOHN POLLARD, and MIKE J. BRINGANS

A powerful and well-respected tool for disseminating the genetics of select sires in cattle that have superior traits of economic importance is artificial insemination (AI). It is believed that this same AI technique has the potential to rapidly improve genetic gain within the cervid industry. One of the primary requirements for the success of AI with both species, however, is the identification of elite sires. In the deer industry, this is currently a limiting factor. Phenotypic characteristics such as antler size and body weight are generally reviewed and measured in assessing elite sires with the goal of improving the herd genetic makeup. The reality is that these same characteristics are governed not only by genetic makeup, but also by management techniques and nutritional condition. Standards that have been determined and tracked in cattle that reflect performance recording and analysis must likewise be developed for the cervid industry for both males and females if AI is to reach its full potential with this species.

The interest in AI in the cervid industry continues to grow as a result of the developments and refinement of reliable transcervical AI techniques in larger deer species, and minimally less invasive surgical techniques (smaller deer species) and availability of good quality frozen semen. This chapter will give a brief review of the AI techniques used in the various deer species.

In the mid-1970s, Polish scientists reported the first successful use of surgical AI of red deer.[1] In this trial, three calves were produced from 12 hinds. Likewise, successful nonsurgical AI with wapiti (*Cervus elaphus canadensis*) was reported in 1984.[2] In 1984, Haigh[3] inseminated two white-tailed deer (*Odocoileus virginianus*) with fresh-cooled semen utilizing the techniques of placing a bovine insemination pipette through a disposable vaginal speculum and depositing the semen at the os cervix. The result of this procedure was that both females delivered two live fawns. Likewise, successful surgical AI has also been reported in reindeer (*Rangifer tarandus*).[4] Today, there are reliable transcervical techniques that minimize the stress on the donors and make the AI procedures more accessible and available to everyone at a reasonable cost.

ESTROUS SYNCHRONIZATION

Owing to the seasonality of the female of the cervid species, it is standard practice to use AI early in their breeding season. The female's transition into the breeding season is characterized by silent ovulations and short-lived (8–10 days) corpora lutea, followed by the first true cycle in most deer species. The goal, therefore, is to coincide AI with the normal expected first cycle peak. General practice would follow the pattern of introducing a sire into the group 10 to 14 days after AI. This sire would be kept with the females for a minimum of at least two further cycles. The female, if not bred, will continue to cycle until such time that she conceives or the extending daylight length of late winter "switches" her cycling off. Generally, however, it is common practice for farmers to remove the male from the breeding group to avoid late calves.

The success of any AI program is to breed the female at the most ideal time for conception. In cervids, this ideal is between 18 and 36 hours after the beginning of a standing heat. The challenge in achieving this is due to the difficulties faced in trying to observe the heat signs in the female. These signs are very subtle and often occur away from observers. Unfortunately, the most successful method of heat detection (the female being mounted by the male) is impractical in a field situation. A vasectomized male that has been marked with paint or oil both under the brisket and inside his front leg may be placed with the females. However, nobody goes through this trouble. There are two signs that are most certainly difficult to determine in a field situation, but should be evaluated at the time of AI. These signs are vaginal discharge of mucus and hair rubbed off the rump (Fig. 135-1). These signs do not have to be present in each female but it does help in assessing if the overall group of females is in good standing heat.

Because of the limitations of accurately identifying standing heat in the females, it is now an accepted standard practice to program the females with a progesterone device and perform time breeding after the removal of the device (Table 135-1). The CIDR (controlled intravaginal drug release) is the most commonly used progesterone-releasing device in the deer industry. Generally, when synchronizing wapiti or red deer crosses, the CIDR-b (1.9 g progesterone) is utilized, whereas the CIDR-g (0.33 g progesterone) is being used for smaller deer. Dependent upon the species, the device is left in between 10 and 14 days and then removed manually. Once the CIDR device is withdrawn, the blood progesterone levels

A B

Fig. 135-1 Two heat signs that should be observed by the inseminator at the time of breeding: **A,** vaginal discharge of mucus and **B,** hair rubbed off the rump. These signs do not have to be present in each female, but it does help in assessing if the overall group of females is in good standing heat.

Table **135-1**

Recommendations for Estrous Synchronization in Various Deer Species

Species	Progestin Device	CIDR Duration	eCG Dose (I.U.*)	Time for AI after CIDR Removal
Wapiti	CIDR-b	12–14 days	190–200	60–66 hr
Red deer	1 or 2 CIDR-g	10–12 days	150–200	56–60 hr
Sika deer	CIDR-g	12–14 days	50	58–62 hr
Fallow deer	CIDR-g	12–14 days	0	63–67 hr
White-tailed deer	CIDR-g	12–14 days	100–150	60–65 hr
			200	50–52 hr

AI, artificial insemination; CIDR, controlled intravaginal release; eCG, equine chorionic gonadotropin.

drop, causing a luteinizing hormone (LH) surge and ovulation. Equine chorionic gonadotropin (eCG) or pregnant mare serum gonadotropin (PMSG) is often used in varying doses related to the different species, ensuring that synchronizing is tight. eCG tightens up the window of estrus by reducing the mean interval to the onset of estrus[5,6] and may reduce the spread of ovulation.[5]

ARTIFICIAL INSEMINATION PROCEDURES

Traditional transcervical insemination techniques have been utilized in the breeding of wapiti and red deer hybrids since the 1980s, and just in the last few years for red deer. Purebred hinds can be transcervically inseminated with purebred wapiti semen, and this approach can be very effective in producing hybrids.[7] To accomplish AI with these species, the use of a chute system or squeeze to restrain the female is required. This minimizes, or eliminates, the need for any tranquilization. The goal is to introduce the semen directly into the body of the uterus, just in front of the cervix. With the unusual problem females, the semen could be placed intracervically, and a pregnancy rate of 20% to 50% (depending on the semen quality) can still be achieved. Last year on 1491 transcervically inseminated wapiti females, an overall calving rate of 71.8% was achieved, with a 4.7% twinning rate. A similar calving rate of 73.5% on 950 red deer hinds was obtained, with a twinning rate of 4.1%.

Smaller deer are primarily inseminated laparoscopically. Laparoscopic AI is done with the tranquilized hind secured to a "stretcher table." The pelvic area is lifted to a 40- to 60-degree angle, and through the laparoscope, the semen is deposited at the tip of the horn, ipsilateral to the preovulatory follicle, or half the dose of semen being deposited at the tip of both horns if ovaries are not visualized. The procedure requires only minutes to do, after which the tranquilizer is reversed and the female immediately walks away. This laparoscopic technique is a less invasive technique than the traditional laparotomy; however, the technician's skills play a major role in the success of this technique. There are slight possibilities of

adhesions and scar tissue formation, which might interfere with future conception or complicate a pregnancy. The personnel required and the cost of AI is increased with this technique, and the success rate is expected to be around 70%.

Recent breeding results in white-tailed does, utilizing nonsurgical techniques, are also encouraging. White-tailed does appear to be highly fertile and some females will become pregnant if the semen is deposited at the os cervix. However, better results will be obtained if cervical intraluminal semen deposition is achieved over a short space of time. The cervix is visualized through a vaginal speculum and a bovine embryo transfer pipette is fed through the cervix, into the uterus if possible (Fig. 135-2). White-tailed does are inseminated with this technique with or without synchronization. If no synchronization is used, a teaser buck is mixed with the females. When the doe "stands," she is then inseminated. Results have been quoted as high as 80%, although they are quite variable. Last year, 35 does were inseminated 62 to 63 hours post-CIDR removal. Twenty-four females delivered at least one fawn (68.5% fawning rate), of which two carried twins, three carried triplets, and one carried quadruplets (but all died as stillborn) to term. This was the only farm that confirmed the parentage based on DNA testing. Another group has been inseminating the does at 50 to 52 hours after CIDR removal with an injection of 200 IU of eCG.[8] Over the last 2 years, this group has inseminated over 1800 does, with variable results, being from almost 0% to almost 100% fawning rate, with an overall mean of 65%. This program produces about 3% multiple births with 5 fawns and average of 2.8 fawns per doe.

Factors Affecting Success

Well-documented results are available supporting the success of AI in deer. Experienced technicians should average results around 70% pregnancy rate, with transcervical and laparoscopic techniques, with any of the deer species. The following will describe some factors influencing the AI success rate, especially related with the transcervical AI technique in wapiti and red deer. As found by other commercial AI centers, there is an extreme variation among farms (Fig. 135-3). The success rate of an AI program is affected by several factors and based on the analyzed data; some of these variations will be discussed here.

Male Effect and Semen Quality

There is great variability among wapiti bulls and stags in spermatozoal ability to maintain fertilizing capacity following thawing of frozen semen. Although there are no standards or minimum criteria used by commercial centers, it seems to be a minimum of 40% progressively motile sperm with greater than 30 million total sperm per insemination dose. Post-thawing evaluation criteria are generally done by estimating the progressive motility of the sperm. It is becoming relatively common to evaluate the longevity of motility 2 to 3 hours after thawing. It is understood that frozen-thawed semen having greater longevity tends to have better pregnancy rates when used for insemination, at least in the equine and bovine industry. Unfortunately, motility, besides being a fairly subjective measure of quality, is a very poor predictor of actual fertility.

Another important aspect affecting the quality of frozen semen is the quality of the raw ejaculate and especially the constituents of the seminal plasma at that time. Excessive seminal fluid or presence of the gel fraction has a detrimental effect on the freezability of the semen. A male will produce better quality semen for freezing if he has bred a few females earlier, or if he was collected once or twice before freezing the semen. However, at the time of thawing the semen, there is no test that can assess if the frozen semen has been compromised by excessive seminal fluid at the time of freezing.

A challenge remains to ensure proper handling and preparation of frozen semen to ensure best possible results at the time of AI. The thawing of semen is usually done at 35° to 37°C for 30 seconds. Straws should be sorted and identified only when totally submerged in

Fig. 135-2 Transcervical insemination of a white-tailed doe. The cervix is visualized through a vaginal speculum and a bovine embryo transfer pipette is fed through the cervix, into the uterus if possible.

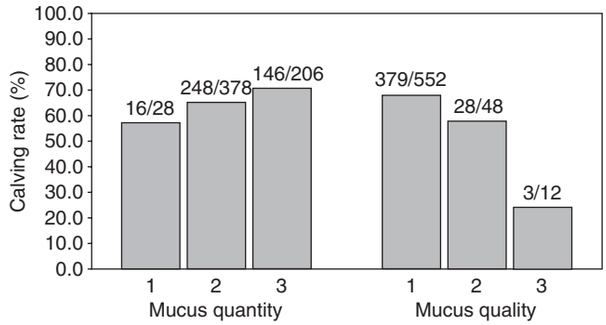

Fig. 135-3 Influence of quantity and quality of mucus at the time of artificial insemination on calving rate. This survey was performed on 612 elk cows.

liquid nitrogen. In many cases good semen is seriously damaged during handling, during shipping, and by inadequate tank maintenance.

Female Selection

Careful female selection for entry into an AI program is essential for acceptable results. The ideal females to select are the ones with a strong genetic background, calm temperament, who have produced calves every year, without calving problems and without any strange abnormalities in the pelvic area (urine poolers, etc.). These females are also in good body condition (2.5 to 3.5 BCS) and have a post-calving interval of more than 60 days. Any cow that did not calve in the previous year should not be used, nor should females that had calving problems or a dead-born calf. Females that are in poor body condition (too thin or overly fat) and calve only "every other year" should also be rejected from the AI program.

Yearling females can be used in an AI program if their weight is over 180 kg (400 lb) for a wapiti female or 70 kg (150 lb) for a red deer hind. The farm can achieve a decent pregnancy rate with AI on heifers, if the farm is successful in getting the yearling pregnant with natural cover. Usually, the yearlings enter an AI program a few weeks after the mature females, giving them a chance to have a better first cycle. First-calf heifers must be fed extra to avoid lowered pregnancy rates due to nutritional stress, and if too thin at the time of AI, they should be rejected from the program.

AI of yearling red deer hinds should be by either laparoscopic or transcervical techniques, depending upon pelvic size. An inseminator with a size 6 hand should be able to inseminate transcervically around 80% to 90% of yearling red deer hinds.

Estrous Synchronization and Quality of Heat

In any synchronization program, the application of an intravaginal device for 10 to 14 days increases the risk of local vaginal infection, which, at the worst, creates an ascending infection to the uterus, causing endometritis-pyometra. Strict hygiene must be observed at CIDR application and withdrawal. New latex gloves should be worn for each CIDR application and the applicator disinfected between each use (e.g., with Virkon). A disinfectant ointment (e.g., Hibitane cream) is also applied over the CIDR and applicator. When the CIDR devices are withdrawn, a new glove is used for the next CIDR. Care should be given at the time of injection of eCG that the female receives the full dose.

A survey was performed on 612 wapiti cows to evaluate the effect of the mucus on the success of AI. At the time of AI, the quality and amount of vaginal mucus present was evaluated and tracked to evaluate the state of the heat at time of breeding. The amount of mucus was evaluated from 1 to 3: 1, no mucus, very dry; 2, some mucus on the AI rod; and 3, mucus pouring out. The quality of mucus was also recorded: 1, clear; 2, cloudy; and 3, pus-like. A cow that was very dry at the time of AI had a 57% chance of getting pregnant, whereas a cow presenting a higher amount of mucus had 66% to 71% chance of getting pregnant (Fig. 135-3). There was a marked drop in calving rate when the females presented a cloudy/pus-like mucus at the time of breeding.

Effect of Intrauterine and Intracervical Semen Deposition

Theoretically, semen should be deposited in the uterine body, just in front of the internal cervical os. However, this task may be impossible with females with smaller cervices. At the time of breeding, the site of the semen deposition was recorded as: 0, semen deposited in the vagina, around the external cervical os; 0.75, being at least 75% down the length of the cervix; and 1, in the uterine body. On a survey performed on 413 wapiti cows, 5 of 5 cows did not get pregnant if the semen was deposited less than halfway through the cervix, and 12 of 27 cows (44.4%) got pregnant if the semen was placed 75% into the cervix; of the remaining cows, 73% (289/396) got pregnant and carried an offspring to term when inseminated into the uterine body.

Facilities

The best facility design is the one that is managed by a qualified and experienced handler who knows both the animals and the system. The handling system should allow the animals to be brought into the crush with the least amount of stress and excitement. The best "crush" for the transcervical AI is one that holds the female with a minimum of pressure. The female should not be able to "crawl" ahead in the crush and should not go down. If the crush is designed properly, a "kick-board" is not necessary, as the operator can stand to one side. The female should not be able to back out of the crush. There are a great variety of systems that can be used. Systems that allow too much movement can prove to be dangerous to the female and the technician. Inadequate restraint can result in lowered pregnancy rates, especially if the semen cannot be smoothly and properly placed immediately after thawing. Sudden movement from the female could also cause damage to the uterus while the pipette is in the uterus and cervix causing a cervical or uterine perforation, especially if the cow suddenly backs against a crush door.

CONCLUSIONS

The success of AI in cervids assures this industry future growth. With decreasing cost of semen and AI services, and a broader access to estrous synchronization supplies, the demand for AI is sure to continue and increase. Within the industry itself, herdsmen are being "pushed" to improve their herd genetics beyond what may be available within their own herd to ensure the top breeding stock is developed and maintained; otherwise, they will not be able to compete in the market.

Veterinary medicine will need to grow with this industry. There is a role with assisting the herdsman in selecting the best cows for the AI program, in overseeing the herd health and nutrition management, and coordinating the estrous synchronization program.

CHAPTER 136

Application of Embryo Biotechnologies in Farmed Cervids

JOHN POLLARD, CLAIRE PLANTE, and MIKE J. BRINGANS

Farmed cervids represent newly adapted species to domestication possessing unique reproductive characteristics and husbandry requirements. High relative market value, demand for rapid genetic advancement, and international genetic exchange have all promoted significant interest in the development of embryo-based reproductive technologies in these species. Embryo biotechnologies have proved themselves as exceptionally valuable tools for use by progressive animal breeders in other domestic livestock species. Although a myriad of technologies currently exist by which embryos can be either created or modified, all embryo biotechnologies applied to the production of living progeny must end in the transfer of embryos to suitable recipients. The basic processes of embryo recovery, manipulation, and transfer referred to collectively as embryo transfer, brings with it powerful production and clinical benefits related to maximizing female reproductive capacity, advancing the rate of genetic progress through shortening of generation intervals, lessening the cost of genetic transport and threat of disease transfer, as well as the intentional elimination of specific environmental pathogens from infected donor populations. The adaptation of embryo biotechnologies for use in farmed cervids has been

ongoing for a number of decades. Recent advances in transcervical artificial insemination, embryo recovery, and embryo transfer technologies in red deer, as well as the development of in vitro embryo production systems, is continuing the clinical development of embryo transfer in cervid species. This chapter will describe the current status of embryo biotechnology development and use in farmed red deer and wapiti (North American elk) and give effective clinical methodologies where available.

CERVID BIOLOGY, REPRODUCTION, AND EMBRYOLOGY

Collectively, cervids have experienced a long and complex association with humans, inspiring study and pursuit as a primary food source over the millennia. Only in recent history have we attempted to domesticate and selectively breed a limited number of cervid species for agricultural purposes. Chief among those selected for domestication have been members of the *Cervus elaphus* family. Members of the *Cervus elaphus* family, including European red deer (*Cervus elaphus elaphus*), North American elk (*Cervus elaphus nelsoni*, *manitobensis*, and *roosevelti*), and Siberian elk (*Cervus elaphus siberi*), while broadly spread both in terms of their geographic distribution and phenotypic appearance, interbreed readily, producing fertile hybrids. Wapiti and red deer exhibit a seasonally restricted polyestrous form of reproduction in which unmated females ovulate a single oocyte at intervals averaging 18 days in red deer and 21 days in wapiti (see Chapter 125). Wapiti and red deer have additionally evolved naturally to calve in sequence with the flush of grass growth in the spring. Calving in conjunction with spring grass growth requires successful conception to occur in September-October in North America, as gestation lengths average 233 days in red deer and 245 days in wapiti. A return to cyclicity in mature females and the initiation of cyclicity in yearlings occurs in response to decreasing daylight length. In North America, wapiti generally begin to exhibit fertile estrous cycles in the middle of September, while red deer hinds begin to cycle in early October. In unmated females, ovulations may continue to occur through March or April. Such a period of extended cyclicity rarely occurs, however, as the high natural fertility exhibited in wapiti and red deer receiving adequate nutritional support generally leads to a high percentage of females conceiving (>85%) on their first estrous cycle. In both wild and farmed wapiti and red deer, breeding activity is thus concentrated to a very restricted period in the early fall.

Embryonic development in wapiti and red deer takes place in the oviduct and the uterus. The first, second, third, fourth, and often fifth embryonic cell cycles transpire within the lumen of the oviduct in close association with the mucosal epithelium. Wapiti and red deer embryos appear to first enter the uterine lumen approximately 6 days following ovulation. Coincident or just prior to their entrance into the uterus, wapiti and red deer embryos undergo a process of cellular compaction during the fifth cell cycle, which leads to development of distinct inner and outer cell groups. Compaction is followed by the formation of the fluid-filled cavity known as the blastocelic cavity within the embryo. Formation of this blastocelic cavity coincides with the initial differentiation of epithelial cells from pluripotent embryonic cells and denotes transformation from the compact morula to blastocyst stage. Cellular differentiation and cavitation occur around 6.5 days after ovulation in both red deer and wapiti. Wapiti and red deer embryos are generally darker in color than bovine or ovine embryos at both the compact morula and blastocyst stages. Hatching of blastocyst stage embryos can occur as early as 7.5 days following ovulation, with elongation occurring between days 13 and 16.[1] Elongated red deer blastocysts signal their presence to the maternal system through the secretion of antiluteolytic interferon between days 16 and 22.[2] Attachment of blastocysts occurs by day 30 of gestation.[1] Fetal growth in wapiti and red deer is linear between days 30 and 50 of gestation with significant differences in both fetal size and placentome development at each of these gestational time points readily apparent by ultrasound examination.[3] Cervid artificial breeding programs involving group synchronization make use of these differences by delaying the introduction of backup bulls or stags for at least 10 days following artificial insemination (AI) or 4 days following the transfer of embryos so as to clearly distinguish between artificially and naturally sired conceptions.

APPLICATION OF ARTIFICIAL BREEDING TECHNOLOGIES IN WAPITI AND RED DEER

The wapiti and red deer breeding industries have been expeditious in their acceptance of reproductive biotechnologies. This rapid uptake of reproductive technology use has been encouraged by inherent factors unique to this industry, including a high level of natural fertility in red deer and wapiti, the co-advent of commercial wapiti and red deer farming with the evolution of commercially useful reproductive biotechnologies, as well as the ubiquitous pursuit of genetic advancement by breeders and the resulting competitive nature of the respective industries. The principal reproductive technology in clinical use within this species, as with other livestock species, is artificial insemination (see Chapter 134). Unique to the wapiti and red deer industries, however, is the universal use of a single timed insemination of cryopreserved semen at the beginning of the breeding season. As a carryover from their recent adaptation from the wild state, reproductive function in red deer hinds and wapiti cows suffers significantly from excessive handling. A single timed insemination allows for a reduction in handling stress to a minimum and the simultaneous concentration of management resources. The remarkable natural fertility of this species has permitted the evolution of a breeding system in which the timed insemination of a single straw of cryopreserved semen results in mean calving rates above 75%. The evolution of a timed single insemination system in wapiti and red deer has proved itself as an invaluable asset to the pursuit of genetic advancement and will serve as a model system for the development of all future reproductive technologies in this species. Of particular interest to the wapiti breeding industry is the

production and clinical concern related to the successful covering of cows as early in the breeding season as possible. Though, as discussed previously, wapiti cows may exhibit fertile estrous cycles from September through April if left unmated, the natural condition of this species is for a very high percentage of wapiti cows to conceive at their first ovulation if covered successfully. Wapiti breeders generally wish to mimic this natural pattern of reproduction as closely as possible in farmed animals, as the value of calves is at least partially determined by their birth dates, with late-born calves (calves born after June) severely discounted. A further physiologic complication, adding to the restricted breeding season, is the rapid accumulation of internal fat that can occur in wapiti cows if left unbred. Prolonged intervals between weaning and breeding can lead to excessive deposition of pelvic fat that can negatively impact both the ability of cows to be artificially inseminated and dystocia rates at parturition. These combined factors are of such importance to the industry that all reproductive technologies applied to this species must be designed to be implemented in the 5-week period beginning in the middle of September. In the case of embryo-based biotechnologies, this concentration of breeding activity has acted to severely restrict the time available to the practitioner for donor manipulation, as breeders generally wish for donors themselves to conceive successfully within this same 5-week period. This has proved a most challenging restriction, as the hormonal manipulation of donors in preparation for embryo production often proves stressful and disruptive to donor cyclicity over an extended period following treatment. Reproductive technologies intended for use in cervids must thus be designed from their onset to be both limited in treatment duration and minimally invasive so as not to disrupt normal estrous cyclicity in the manipulated females immediately following treatment.

Embryo Biotechnologies

Any discussion pertaining to the application of embryo biotechnologies to farmed cervids must begin with appropriate recognition given to this species group for the pivotal role it has played in the study of mammalian embryology. In 1651, William Harvey, following careful dissection of reproductive tracts obtained from red deer hinds harvested by King Charles I, produced evidence that mammalian gametes and embryos exist in a free and unattached state during the first weeks of life. The recognition of this developmental period in red deer, during which embryos remain unattached and therefore available for recovery, manipulation, and transfer, was critical to the advent of embryo biotechnologies in mammals. Developing embryo biotechnologies such as embryo transfer, embryo cryopreservation, in vitro embryo production, intracytoplasmic sperm injection, and adult animal cloning have the potential to dramatically alter the very manner in which we view our own reproductive capacity and that of the animals under our care.

Prehatching stage embryos possess several unique characteristics that make them effective for use in advancing genetic change and health-related biosecurity. Chief among these beneficial characteristics are that they are very small (averaging ~150 μm in diameter) and are encased within an impermeable protective shell. This glycoprotein shell, referred to as the zona pellucida, is equivalent to the shell on the familiar chicken egg, in that it completely encases the developing embryo and is impermeable to bacterial and viral pathogens. Because of the impermeability of the zone pellucida, zona intact embryos can be washed free of contaminating pathogens and thereafter be certified free of disease.[4] While it is confined within the zona pellucida, mammalian embryos remain very small (~150 μm in diameter) and are therefore very economical to transport to distant locations. It is the significant size advantage of the embryo that in fact grants embryo transfer systems their principal economic advantage over conventional live animal transport systems. Many hundreds and even thousands of embryos can be transported for less than the cost of a single airline ticket. An entire herd of deer or wapiti could be shipped using these methods to any location across the globe. These combined economic and health advantages make embryo transfer a logical choice for the safe international exchange of cervid genetics.

Embryo transfer is the process by which embryos are recovered from one female (the donor) prior to their attachment to her uterus, and thereafter transferred to the reproductive tract of another female (the recipient) for full-term development to live offspring. During the process of embryo transfer, there remains full genetic linkage between the donor female and the embryos that she produces for transfer and the progeny ultimately produced by the recipients. In contrast, there is no genetic relationship established, at all, between the recipient and the offspring as a result of embryo transfer, though there is a significant health status relationship established in utero between the recipient and the progeny of the embryo transfer donor. The success of embryo transfer (pregnancy to term) is dependent upon the recovery of embryos from the donor and the proper interaction between the transferred embryo and the recipient's reproductive tract. This interaction depends on the health of the transferred embryo, the health of the recipient's reproductive system, and their synchrony at the time of transfer.

The potential power of embryo transfer within cervid production rests within two technologic pivot points on which both the genetic makeup and health status of selected animals can be manipulated. The first pivot point exists within the relationship between the biologic donor and the embryos that she produces. Within this relationship, while there is full genetic linkage between the biologic dam and her embryos, there is no health status relationship. By this we mean that although embryos inherit all their genes from their sire and dam, they inherit none of their biologic parents' contaminating pathogens over the first week of life. The second pivot point exists within the relationship between the recipient female and the embryo transfer derived progeny that she produces. In this relationship, there is no genetic relationship between the recipient and the transferred implanted embryo offspring, but there is complete (or at least partial) health status linkage. This implies that by intentionally selecting recipients of a specific health

status, the breeder may thereby select the desired health status of the offspring she will produce. By putting these two pivot points together within an integrated production system, embryo transfer permits cervid breeders to intentionally, sustainably, and simultaneously manipulate both the genetic composition and health status of animals under selection.

Three principal streams of embryo-based reproductive technologies exist today—multiple ovulation and embryo transfer (MOET) systems, in vitro embryo production (IVP) systems, and somatic cell–based cloning systems. Only MOET and IVP systems will be addressed here, as somatic cell–based cloning systems have not yet evolved to a clinically productive state. MOET and IVP production streams differ only in the manner in which embryos are derived from donor females. In MOET systems, in vivo derived embryos are directly recovered from superovulated donor females following fertilization and before hatching from the zona pellucida. In IVP systems, mature or immature oocytes are recovered from donor females. Recovered oocytes are then fertilized in the laboratory with resulting in vitro derived embryos cultured to a transferable stage of development. Following embryo recovery or production both MOET and IVP systems utilize similar embryo cryopreservation and transfer methods.

Multiple Ovulation and Embryo Transfer Systems

Multiple ovulation and embryo transfer systems involve a three-step process for the in vivo production and recovery of embryos. The initial step in the MOET process involves the synchronization and superovulation of donor females. Superovulation is followed by the breeding of donor females (either by natural cover or artificial insemination) to allow for in vivo fertilization of oocytes. The final step of in vivo embryo production encompasses the recovery of embryos from the donor's uterus or oviducts. MOET has been applied to both red deer and wapiti over the past two decades. Even though red deer and wapiti are part of the same genetic family (*Cervus elaphus*) their response to MOET treatment, and particularly their response to gonadotropin-stimulated superovulation, differs significantly.[5] Superovulation is the process by which females are stimulated with exogenous gonadotropins to increase their ovulation rate above that normally occurring in the species under investigation. During a typical estrous cycle both red deer and wapiti cows normally ovulate only a single oocyte. Superovulation in these species would thus be defined as any treatment that would increase the ovulation rate above a single oocyte. A limited number of experimental studies have addressed superovulation in either red deer hinds or wapiti cows. These studies have demonstrated that while red deer will respond at moderate rates to superovulation treatment with commercially available purified gonadotropin, wapiti cows do not.[5,6] This difference is intriguing because red deer and wapiti interbreed readily, have very similar reproductive patterns, and are considered to be members of the same species.[6] Although earlier attempts to superovulate wapiti utilizing impure preparations of follicle-stimulating hormone (FSH) and miniosmotic pumps were at times successful,[6,7] more recent attempts involving highly purified FSH preparations currently available have met with failure. Wapiti cows treated with purified FSH preparations appear not to respond to exogenous gonadotropin either in the growth of supernumerary follicles or in the ovulation of multiple oocytes. The nonresponsiveness of wapiti to superovulatory treatments may be based either in the biologic incompatibility of commercially available gonadotropin hormones with wapiti FSH receptors, or in yet undiscovered powerful intraovarian control mechanisms that inhibit simultaneous growth in follicular cohorts to ovulatory stages in mature wapiti. Whatever the underlying mechanism, the inability to superovulate wapiti cows has been the primary limiting factor in the development of MOET in farmed wapiti. Of interest to the application of advanced embryo biotechnologies in wapiti is our recent finding that juvenile wapiti donor calves (3- to 4-month-old calves) are responsive to gonadotropin treatment, averaging 7.3 and 15.7 cumulus-oocyte complexes recovered per control and superstimulated wapiti calf, respectively.

In red deer, early superovulation protocols included equine chorionic gonadotropin (eCG) within the treatment regimen, and more modern methodologies have made use of highly purified FSH alone (purified ovine FSH [oFSH, Ovagen, ICP, Inc., Auckland, NZ] has become the commercial gonadotropin of choice in red deer). A synchronization and superovulation protocol that has been extensively tested by our clinical group in the commercial production of red deer embryos in presented in Table 136-1. In brief, the first controlled intravaginal drug release (CIDR-G; Interag, Hamilton, NZ) device is inserted into the vagina of each donor hind on day 0 of treatment. On the ninth day of treatment the initial CIDR-G is replaced by a new CIDR-G in conjunction with the initiation of FSH treatment. The total FSH dosage used for superovulation in red deer is dependent upon the genetic background of the donors in question. English strains are generally very responsive to gonadotropin stimulation, but eastern European strains are not. For English strains a total dose of 0.4 to 0.5 unit Ovagen is commonly

Table **136-1**

Superovulation Protocol for Red Deer Hinds Utilizing a Single Timed Transcervical Insemination

Treatment Day	Treatment
Day 0	Insert CIDR-G
Day 9	Replace CIDR-G; AM and PM injections of oFSH*
Day 10	AM and PM injections of oFSH
Day 11	CIDR-G removal; AM and PM injections of oFSH
Day 12	AM and PM injections of oFSH
Day 13	Artificial insemination at 48 h after CIDR removal
Day 20	Embryos flushed 228 h after CIDR removal

*Ovagen (total dosage dependent upon genetic strain).
CIDR, controlled intravaginal drug release; FSH, follicle-stimulating hormone.

prescribed, but a full 1.0 unit of oFSH (Ovagen) may be required for German, Croatian, or Romanian lines. Regardless of the strain in question, FSH is administered to each donor in eight equal doses or in a declining dose regimen. Injections are administered at 12-hour intervals over a 4-day period. On day 11 of treatment, the second CIDR-G is removed in conjunction with the administration of the sixth FSH injection. Following the final injection of FSH on day 12, donor hinds either are placed with selected stags for natural cover or are artificially inseminated. Although natural cover provides some advantages in terms of maximizing sperm number and viability, it is disadvantaged by the limited selection intensity afforded by resident stags on individual farms, by the number of hinds that can be covered by an individual stag, and by the tendency of red deer stags to focus their attention on individual favored hinds while leaving other unfavored hinds unbred. Alternatively, superovulated red deer hinds may be artificially inseminated using either laparoscopic or transcervical methods. The use of artificial insemination affords significant benefits to breeders, including increased intensity and variety of stag selection, the ability to breed large numbers of hinds to individual stags, and the capacity to assure semen deposition in the uterus of each treated hind. Although laparoscopic insemination has been the traditional technique of choice in red deer (and may still be necessary for smaller yearling hinds), highly effective transcervical insemination techniques have recently been developed in red deer (see Chapter 134).[5] In previous studies, laparoscopic insemination of superovulated hinds was found to decrease both fertilization and transferable embryo recovery rates when compared to naturally covered hinds. In contrast, we have found a single timed (48 hours after CIDR removal) transcervical insemination to be highly effective. Table 136-2 presents embryo production data from red deer donors superovulated utilizing the protocol presented in Table 136-1 and inseminated transcervically with a single dose of cryopreserved red deer semen 48 hours after removal of the second CIDR device. A single timed transcervical insemination allows for a minimum of donor handling and does not require either general anesthesia or abdominal invasion. Overall, fertilization was observed in 89% of the transcervically inseminated superovulated donors with embryo production averaging 4.6 transferable embryos per donor.

Embryos may be recovered from red deer hinds utilizing either surgical or transcervical flushing methodologies and commercial media. Surgical flushing has been effectively employed in red deer for several decades and remains the procedure of choice for use with small yearling hinds or in programs that demand oviductal stage embryos. Transcervical flushing methods have now been developed for red deer, which are equally efficacious to surgical procedures (Table 136-3). Transcervical procedures may soon displace surgical methods as they are significantly less stressful on donor animals and do not require general anesthetics.

The surgical recovery of red deer embryos is accomplished using methods similar to those used for other small domestic ruminants. Surgical flushing is conducted under general anesthesia (water and feed are removed from donor hinds for at least 12 hours prior to surgery) with the reproductive tract exteriorized through a midventral laparotomy. A very effective general anesthetic protocol that has proved to be exceptionally safe for use with both red deer and wapiti is the mixture of xylazine (Bayer AG, Germany) and carfentanil citrate (Wildife Pharmaceuticals, Inc., Fort Collins, CO, US).[6] The mixture of xylazine and carfentanil is administered as an intramuscular injection and is reversed by an intravascular injection of tolazine hydrochloride (Lloyd Laboratories, Shenandoah, IA) and naltrexone hydrochloride (Wildlife Pharmaceuticals, Inc., Fort Collins, CO, US). Once exteriorized, the lumen of each uterine horn is cannulized using a silicon molded Foley catheter (12 F for yearling hinds; 14 F for mature hinds). The catheter is

inserted through a blunt puncture made at the base of each uterine horn with the catheter's balloon subsequently inflated with 4 to 7 ml of air or saline. The endometrium of red deer is quite friable and great care must be taken not to split or damage this tissue during either balloon inflation or medium infusion. With the Foley catheter secured, the infundibulary os is cannulated using a tom-cat catheter attached to a 10-ml syringe. Medium is then gently flushed through the length of the oviduct into the uterus and out the Foley catheter into a collecting dish. As the red deer oviduct is a rather delicate structure, flush medium should be gently pulsed through the tom-cat catheter so as not to rupture the ampullary wall. After the oviduct is flushed with 10 ml of medium, a blunted 20-gauge needle is passed through the uterine wall just caudal to the uterotubal junction. Another 40 ml of medium is then flushed through the cannulated uterine horn. The entire procedure is repeated on the contralateral oviduct and uterine horn. Puncture sites where Foley catheters have been passed through the uterine wall must be secured with inverting sutures, or endometritis may result. The exteriorized reproductive tract should be continually irrigated with warmed saline to reduce the incidence of surgically induced adhesions.

Nonsurgical embryo recovery was initially developed and tested by our working group during the 1999 breeding season. The evolved procedure is identical to transcervical methods ubiquitously used in bovine embryo recovery, save for the size and composition of the flushing catheter and requisite size of the operator's hands. Essential to the recent development of transcervical methods for artificial insemination, embryo recovery, and embryo transfer in red deer was the entrance of highly creative female clinicians possessing diminutive hands talented in palpation. Nonsurgical embryo recovery in red deer is accomplished using a 14-gauge metal flushing catheter passed transcervically into the uterine lumen under the guidance of rectal palpation. After the catheter's balloon is carefully inflated at the base of the respective uterine horn, flush fluid is injected and then withdrawn from the uterine lumen in a manner similar to that used in cattle. A total of 500 ml of medium is flushed per uterine horn. An epidural anesthetic is used to facilitate passage of the flushing catheter through the cervix. As transcervical procedures access the uterine lumen alone, only embryos at or beyond the compact morula stage can be recovered by these procedures. This is generally adequate for commercial embryo recovery programs, however, as compact morulae and blastocysts are the embryonic stages of choice for cryopreservation and transfer. In direct comparisons, transcervical embryo recovery methods have been shown to be as effective and productive as traditional surgical procedures (see Table 136-3) when flushing 9.5 days following CIDR device removal.

Although wapiti cows do not respond to currently available superovulation procedures, individual embryos can be recovered from donors synchronized as for artificial insemination. Such donors will ovulate only a single oocyte, but clinical experience has demonstrated that individual embryos may be collected from a high percentage of the donors (~70%) if flushed 9.5 days following CIDR device withdrawal. Bovine methodologies and equipment for transcervical uterine flushing can be directly applied to wapiti cows, as they are approximately equivalent in size and anatomic configuration.

Methods for the in vivo production of embryos in fallow deer have also been developed.[8] Embryo production from MOET technologies in fallow deer appear intermediate to that of red deer and wapiti. Although fallow deer appear more responsive than wapiti to superovulation, the production of embryos following gonadotropin treatment falls significantly short of that obtained in red deer. Embryo recovery rates have averaged 2.1 embryos per superovulated doe.[8] Superovulation protocols have often included the addition of a low dose of eCG (100–200 IU) to the purified oFSH treatment. Fallow does may be laparoscopically inseminated using a single dose of semen, with embryos recovered surgically using procedures similar to that described previously for red deer. Recovered embryos are transferred to synchronized does using the laparoscopically based minilaparotomy method. Pregnancy rates following the transfer of fresh embryos in fallow deer have been similar to those obtained in red deer. Transcervical embryo recovery and transfer methods have not been developed to clinically productive states in fallow deer due to their diminutive size.

In Vitro Embryo Production

In vitro embryo production technologies allow for the creation of embryos in the laboratory from gametes gathered from either fertile or infertile donors. In vitro embryo production (IVP) is a generalized term referring to a number of associated technologies, including those associated with sperm and oocyte recovery from donors, in vitro oocyte maturation, in vitro fertilization, and the in vitro culture of embryos. In vitro embryo production technologies are among the most interesting and powerful of all the new reproductive technologies, as they empower the practitioner to circumvent infertility. Such infertility may be related to anatomic, pathologic, or human-induced causes in adult animals, or may be related to reproductive incapacity normally present in juvenile animals not yet achieving the age of puberty. Through IVP systems, juvenile donors may be induced to reproduce following the transfer of IVP-derived embryos to suitable mature recipients. Artificial breeding programs utilizing juvenile donors have the capacity to significantly increase the rate of genetic improvement by decreasing the generation interval with the selection program.

The process of IVP begins with the acquisition of gametes from both the dam and sire of interest. In both red deer and wapiti, sperm from desired sires is available in a cryopreserved state. This is advantageous because cryopreserved sperm are always available and the freezing and thawing process facilitates the initiation of in vitro capacitation. Over the past decade, significant progress has been made in the technologies of oocyte recovery from living donors. The technique selected depends upon the donor's species and age. Laparoscopically guided oocyte aspiration can be used for the recov-

ery of oocytes from either adult or juvenile donor females. Transvaginal oocyte recovery techniques utilizing rectal palpation have also been developed for use in mature red deer and wapiti females, by which either immature or mature oocytes may be recovered. Transvaginal oocyte recovery may be conducted under ultrasound guidance or under the guidance of rectal palpation alone (referred to as blind aspiration). Donors in intensive oocyte recovery programs can be repeatedly aspirated over several months without apparent harm or long-term adverse effect on the donor's continued fertility.

In vitro embryo production generally consists of the three-step process of oocyte maturation, oocyte fertilization, and embryo culture. Following recovery, cumulus-oocyte complexes at the germinal vesicle stage of meiosis are placed into medium designed to stimulate maturation to the second-metaphase stage of meiosis. In vitro oocyte maturation generally occurs over a 24-hour period, after which the mature oocytes are exposed to capacitated sperm for an additional 12 to 24 hours. Sperm capacitation can be induced by exposure to various chemical or biologic factors. Following fertilization, presumptive zygotes are generally placed into culture for an additional 5 to 7 days, during which time the developing embryos cleave to stages that can be cryopreserved or transferred to the uterine lumen (compact morulae and blastocysts).

In vitro embryo production systems have been recently developed in red deer.[9–11] Laparoscopically recovered red deer oocyte-cumulus complexes can be matured and fertilized in the laboratory, with the resulting embryos cultured to advanced stages. In vitro maturation procedures have generally mimicked standard bovine or ovine protocols using either purified hormones or biologic fluids as the in vitro gonadotropin source. In vitro sperm capacitation has been induced in red deer sperm with either purified heparin or estrus sheep serum. The culture of in vitro derived presumptive zygotes has resulted in variable results and relatively few embryos developing to advanced embryonic stages. The establishment of embryo transfer–based pregnancies involving red deer IVP embryos has apparently been restricted to the transfer of early stage embryos.[10] The transfer of later stage (morulae and blastocysts) in vitro–derived red deer embryos has thus far not resulted in the establishment of viable pregnancies. As red deer hinds respond at relatively high rates to standard superovulation protocols and with the recent evolution of nonsurgical embryo recovery and transfer systems in this species, the use of developing IVP systems may be restricted to use with either juvenile hinds or in the treatment of infertility.

Because of this inability to successfully superovulate wapiti on a repeatable basis, a significant effort has been put forth toward the development of methods for the in vitro production of wapiti embryos. As even nonstimulated ovaries contain accessible populations of small diameter follicles, immature oocytes derived from these follicles can be matured and fertilized in the laboratory in order to produce viable embryos for transfer. Oocytes can be collected from mature wapiti cows by transvaginal aspiration on a weekly basis without adverse effect on subsequent donor fertility. Early attempts at IVP in wapiti demonstrated that, as in red deer studies, embryos could be successfully produced and that these embryos would result in pregnancies if transferred at very early cleavage stages.[12] In these early studies, IVP wapiti embryos cultured to more advanced embryonic stages were not able to survive cryopreservation nor produce viable pregnancies if transferred. More recently, however, embryo culture systems have been evolved that produce embryos of advanced embryonic stages that are able to produce high pregnancy rates upon transfer and survive cryopreservation. These methods have now been advanced by our group to allow for the production of large numbers of wapiti calves derived from the in vitro fertilization of oocytes recovered from juvenile wapiti donor calves (3–4 months of age). The production of wapiti embryos and resulting embryo transfer calves from oocytes laparoscopically recovered from juvenile wapiti donors, allows for greatly accelerated genetic progress in a species normally possessing long generation intervals. The transfer of embryos derived from oocytes recovered from 3- to 4-month-old heifer calves has resulted in pregnancy rates following surgical transfer to red deer/wapiti hybrid recipients of 65% for fresh embryos and 61% for cryopreserved embryos (Table 136-4). The current state of IVP technology in farmed wapiti allows oocytes recovered laparoscopically from juvenile calves or transvaginally from mature cows to be fertilized and cultured in the laboratory so to produce blastocyst stage embryos that survive cryopreservation and transfer at high rates. No malformations, abnormal birth weights, or lengthened gestations have been observed to date from calves produced from the transfer of IVP wapiti embryos.

Embryo Cryopreservation

Cervid embryos are exceptionally robust and amenable to manipulation including cryopreservation. To date, the vast majority of cervid embryos that have been cryopreserved commercially have and continue to be frozen utilizing glycerol as the cryoprotectant. Standard bovine protocols making use of 1.5 M glycerol cryoprotectant solutions, freezing rates of 0.3 to 0.4°C per minute, and a three-step dilution process have been typically utilized. Although the majority of cervid embryos have been

cryopreserved at the compact morula and blastocyst stages, red deer embryos cryopreserved as early as the 8-cell stage have resulted in the birth of live fawns following transfer. As in other domestic ruminant species, the transfer of cervid embryos cryopreserved in glycerol has typically averaged 55% to 65% pregnancy rates (Table 136-5). A limited number of transfers involving blastocysts have additionally demonstrated that wapiti embryos may be successfully cryopreserved using ethylene glycol as the cryoprotectant for freezing and direct dilution during the thawing process.

Embryo Transfer

Embryos created and recovered by whatever means must be transferred to suitable recipients for viable offspring to be produced through embryo transfer. The overall pregnancy rate resulting from the transfer of cervid embryos is dependent upon a complex interaction of factors, including the health and viability of the transferred embryo, the synchrony established between the age and development stage of the embryo and the recipient's uterine environment, the health and reproductive condition of the selected recipient, and the clinical expertise and skill of the embryo transfer team. Red deer hinds are generally selected as recipients for red deer embryos, and red deer/wapiti hybrids have been primarily utilized as recipients for wapiti embryos. The use of pure red deer recipients for wapiti embryos generally results in increased dystocia rates due to the larger size of wapiti calves at birth in comparison to red deer fawns. Recipient hinds are synchronized using methods identical to those used for artificial insemination. In brief, a single CIDR-G in red deer and either two CIDR-G or a single CIDR-B for red deer/wapiti hybrids is inserted within each recipient on day 0. The CIDR is removed on day 12 in red deer and on day 14 in red deer/wapiti hybrids, with 200 IU of eCG administered intramuscularly. Recipients are synchronized to come into heat ~24 hours behind that of donor hinds or cows (48 hours following follicular aspiration for IVP embryos). The transfer of red deer or wapiti embryos to red deer or red deer/wapiti hybrid recipients has been, until very recently, performed surgically or laparoscopically. Laparoscopic transfer methods in cervids has evolved to a procedure more appropriately termed a laparoscopically guided minilaparotomy. By these methods, a laparoscope is inserted into each recipient's abdomen while it is under general anesthetic (recipient hinds are removed from water and feed for at least 12 hours prior to surgery) in order to visualize both the recipient's ovaries (so to confirm their reproductive status—presence and condition of corpus luteum) and ipsilateral uterine horn to facilitate exteriorization. Once the recipient's reproductive status is confirmed, a small midventral incision (3–4 cm) is then made and the tip of the isolateral uterine horn is exteriorized with atraumatic gasping forceps. A blunted 19-gauge needle is passed through the uterine wall several centimeters caudal to the uterotubal junction, and the embryo is transferred to the recipient's uterine lumen using either a tom-cat or IVF catheter. Pregnancy rates produced by our group between 2000 and 2002 averaged above 55% across several hundred surgical procedures involving the transfer of single cryopreserved embryos to synchronized red deer recipients (see Table 136-5). In contrast, the transfer of single fresh red deer embryo to synchronized red deer recipients generally results in pregnancy rates above 70%.

Our working group has also pioneered and tested the transcervical transfer of cryopreserved red deer or wapiti embryos to nonanesthetized standing pure red deer or hybrid recipients (Fig. 136-1). Recipient hinds

Table **136-5**

synchronized as for surgical transfer are held stationary in a hydraulic crush. An epidural anesthetic is applied and the rectal contents are removed. The ovaries and uterus are rectally palpated to determine the recipient's reproductive status and suitability. A small-gauge blunted metal cannula is passed through the recipient's cervix and into lumen of the isolateral uterine horn. The embryo loaded within a long polyethylene transfer catheter is then injected into the uterine lumen using a minimum volume of fluid. Transcervical transfer of red deer embryos to recipients has resulted in pregnancy rates of ~60% and appears comparable to that following surgical transfer (see Table 136-5). Transcervical embryo transfer benefits both recipient animals and breeders because the procedure is much less stressful and time-consuming for both parties.

FUTURE APPLICATIONS IN CERVID BREEDING

The application of embryo-based biotechnologies to cervids will evolve in response to economic and production forces driving the cervid breeding industries. One such economic force at play in North America is the relative high value of wapiti cows in comparison to either pure red deer or hybrid hinds. As wapiti cows are valued at several times that of hybrid animals, wapiti calf production systems taking advantage of the genetic compatibility between wapiti and red deer through the transfer of pure wapiti embryos to low cost hybrid hinds will continue to develop. Embryo biotechnologies will also contribute by minimizing the cost of genetic transport and risk of disease transmission during domestic and international genetic exchange. The importance of limiting the risk of pathogen transmission in farmed wapiti and red deer during genetic exchange continues to increase owing to the emergence of devastating diseases such as chronic wasting disease and tuberculosis. Embryo biotechnologies will also function to advance genetic improvement in cervids by the shorting of generation intervals through use of juvenile oocyte donors (Fig. 136-2). The innovative nature of the cervid breeding industries, combined with increasing demand for genetic improvement and exchange, as well as the need for pathogen elimination, shall continue to increase the clinical utilization of embryo biotechnologies in this species.

CHAPTER 137

Reproductive Patterns in Female Bison (*Bison bison* sp.)

KAREN L. GOODROWE, GABRIELA F. MASTROMONACO, and LEANNE S. OTHEN

REPRODUCTIVE CHARACTERISTICS

The female bison is seasonally polyestrous, with estrous cyclicity usually beginning in late July or August and conception generally occurring at the first or second estrus and a reported 95% of cows mating only once.[1–4] The length of the bison estrous cycle has been reported to range from 16 to 31 days, with an average length of 20.8, 21.5, and 20.8 days based on behavioral observations, and urine and fecal progestin profiles, respectively.[2,3] Although estrogens can be measured in cycling female bison, the profiles do not provide physiologic indicators of behavioral estrous or ovarian activity.[5] Based on endocrine evaluations of luteal activity, behavioral signs of estrus, and recorded births, females can continue to cycle through December or January.[3,6] Demonstrations of behavioral estrus include homosexual mounting, standing for mounting, flehmen, and tail flagging, and these behaviors coincide with nadir progestin values in cycling animals.[3,5,7] The behavioral ecology of male and female bison, with particular emphasis on reproductive behaviors, has been well described by Berger and Cunningham.[4]

To establish population demographics and reproductive characteristics in bison, historical records from the Toronto Zoo wood bison herd were analyzed from 1978 to 2000.[6] Of the 145 bison calves born during this time, all were singletons. A total of 14 calves (9.6%; 8 males, 4 females, and 2 unknown) either were stillborn or died on the day of birth. Eleven calves (7.6%; 3 males, 8 females) died within 30 days post partum. Parturition most frequently occurred in May (Fig. 137-1, 55.4%). This is consistent with data from free-ranging plains bison; however, animals living at higher latitudes or in areas with more harsh winters have demonstrated a trend to produce calves later in the spring.[4] From the Toronto Zoo records, calves born from August to October had a greater mortality rate (37.5%), compared to those born between April and July (15.5%).[6] The sex ratio of offspring was approximately equal: 51.0% females and 47.6% males. The youngest and oldest age at which a female produced offspring was 2 and 17 years, respectively. The mean age of females producing offspring (from females of known age, $n = 102$) was 6.01 years. On average, both bulls and cows lived between 14 and 17 years.

Calf production in free-ranging plains bison has been reported to be greatest in females aged 5 to 13, with those aged 10 to 13 years being the most fecund, and more than 80% of pregnancies occurring in animals 4 years of age or older.[4,8] Pregnancy rates have been reported in lactating cows and are attributed to ovulation failure.[8] Although rare, yearlings have been reported to conceive.[1,4] Pregnancy rates of 70% have been reported for free-ranging bison.[1] Observations of 16 plains bison births have shown that parturition is rapid, with birth occurring an average of 68 minutes after the amnion was first visible and 13 minutes after the forehooves were first observed.[9] Calves were precocial and stood and nursed 10.8 and 32.2 minutes, respectively, after birth. In open

CHAPTER 137

Reproductive Patterns in Female Bison (*Bison bison* sp.)

KAREN L. GOODROWE, GABRIELA F. MASTROMONACO, and LEANNE S. OTHEN

REPRODUCTIVE CHARACTERISTICS

The female bison is seasonally polyestrous, with estrous cyclicity usually beginning in late July or August and conception generally occurring at the first or second estrus and a reported 95% of cows mating only once.[1–4] The length of the bison estrous cycle has been reported to range from 16 to 31 days, with an average length of 20.8, 21.5, and 20.8 days based on behavioral observations, and urine and fecal progestin profiles, respectively.[2,3] Although estrogens can be measured in cycling female bison, the profiles do not provide physiologic indicators of behavioral estrous or ovarian activity.[5] Based on endocrine evaluations of luteal activity, behavioral signs of estrus, and recorded births, females can continue to cycle through December or January.[3,6] Demonstrations of behavioral estrus include homosexual mounting, standing for mounting, flehmen, and tail flagging, and these behaviors coincide with nadir progestin values in cycling animals.[3,5,7] The behavioral ecology of male and female bison, with particular emphasis on reproductive behaviors, has been well described by Berger and Cunningham.[4]

To establish population demographics and reproductive characteristics in bison, historical records from the Toronto Zoo wood bison herd were analyzed from 1978 to 2000.[6] Of the 145 bison calves born during this time, all were singletons. A total of 14 calves (9.6%; 8 males, 4 females, and 2 unknown) either were stillborn or died on the day of birth. Eleven calves (7.6%; 3 males, 8 females) died within 30 days post partum. Parturition most frequently occurred in May (Fig. 137-1, 55.4%). This is consistent with data from free-ranging plains bison; however, animals living at higher latitudes or in areas with more harsh winters have demonstrated a trend to produce calves later in the spring.[4] From the Toronto Zoo records, calves born from August to October had a greater mortality rate (37.5%), compared to those born between April and July (15.5%).[6] The sex ratio of offspring was approximately equal: 51.0% females and 47.6% males. The youngest and oldest age at which a female produced offspring was 2 and 17 years, respectively. The mean age of females producing offspring (from females of known age, $n = 102$) was 6.01 years. On average, both bulls and cows lived between 14 and 17 years.

Calf production in free-ranging plains bison has been reported to be greatest in females aged 5 to 13, with those aged 10 to 13 years being the most fecund, and more than 80% of pregnancies occurring in animals 4 years of age or older.[4,8] Pregnancy rates have been reported in lactating cows and are attributed to ovulation failure.[8] Although rare, yearlings have been reported to conceive.[1,4] Pregnancy rates of 70% have been reported for free-ranging bison.[1] Observations of 16 plains bison births have shown that parturition is rapid, with birth occurring an average of 68 minutes after the amnion was first visible and 13 minutes after the forehooves were first observed.[9] Calves were precocial and stood and nursed 10.8 and 32.2 minutes, respectively, after birth. In open

habitat, cows tended to remain in groups, whereas in wooded areas, cows tended to give birth in isolation.[9]

PREGNANCY

There are no previous reports documenting hormonal patterns during the entire period of gestation in bison. To establish longitudinal steroid profiles for the wood bison during pregnancy, fecal and urine sample collection was performed at least five times weekly over three reproductive seasons (August until birth) from a captive herd of wood bison at the Toronto Zoo. The actual number of samples for each individual varied, but samples were taken at least once each week. Samples were analyzed for steroid hormone concentrations by enzyme immunoassay (EIA) using previously described methods.[3,5,7] Urine was analyzed for pregnanediol-glucuronide (PdG), estrone conjugates (EC), and cortisol, and feces were analyzed for progestins (P) and EC. Steroid hormones were extracted from feces according to previously described methods and stored frozen until analysis.[5,7] Gestation length was determined from observed mating or last observed estrus until the birth of a calf.

Hormonal patterns were monitored in 11 pregnancies over the 3-year period. One calf from year 1, one calf from year 2, and two calves from year 3 were stillborn, and their respective dams died due to complications during or after calving. Two of the stillbirths were female and two were male. The mean gestation length for the 11 pregnancies was 265.3 ± 2.5 days. This differs from reports of primiparous and multiparous free-ranging bison (287.9 versus 279.9, respectively). Berger and Cunningham have reported adjustment of gestation length in females, with those in good body condition experiencing an ~6 day shortening of gestation.[4] No difference was detected between pregnancies producing live offspring (267.9 ± 1.0 days) and stillbirths (263.2 ± 6.8 days) or between pregnancies carrying male and female calves in the Toronto Zoo wood bison herd. Physical attributes indicative of impending parturition included: vulval swelling 2 to 3 weeks prepartum, mucus secretion approximately 2 weeks prepartum, and udder development. On the day of or just preceding parturition, increased restlessness, separation from the herd, passing of the mucous plug, and contractions were observed.[5]

Live Births

Progestins

Composite weekly PdG and P profiles from the viable pregnancies are shown in Figure 137-2. Urinary PdG concentrations were unchanged from week –37 until week –14, then increased markedly from week –13 to week –7. After week –7, PdG levels declined gradually to 749.0 ± 148.1 ng/mg creatinine at week –5, followed by a more dramatic decrease at week –4, which continued through week 0. Fecal P levels demonstrated a pattern similar to the PdG profile (see Fig. 138-2). Mean P concentrations did not differ from luteal phase values between week –37 and week –12. A significant elevation in P was detected at week –10 (920.56 ± 124.6 ng/g feces). Fecal P values then continued to rise to a peak at week –4, after which time levels markedly declined through week –2 and continued to fall through parturition. Fecal P concentrations had not reached baseline by week 3 post partum.

Estrone Conjugates

A doubling in mean urinary EC from mean nonpregnancy levels of 1.0 ± 0.1 ng/mg Cr to 2.2 ng/mg Cr was detected between weeks –35 to –33 (Fig. 137-3). Urinary EC then remained statistically unchanged, but increased gradually, from week –31 to week –5, then increased rapidly between week –4 to a peak at week –1 (range: 475.2–2272.7 ng/mg Cr). A precipitous decline in urinary EC was observed between week –1 to week 0 and decreased even further by week 3 post partum. Fecal EC concentrations increased markedly from mean nonpregnancy levels (25.4 ± 5.7 ng/g feces) between weeks –30 to –26 (see Fig. 137-3), similar to the pattern observed for urinary EC. Fecal EC concentrations remained statistically unchanged from week –30 to week –5, but also showed a gradual increase over time. A significant elevation in fecal EC concentrations was detected at week –4 (295.5 ± 29.9 ng/g feces) which increased in all females to a peak during week –1. Fecal EC concentrations declined in the week prior to parturition and continued to fall through week 3.

Corticosteroids

Mean urinary corticosteroid levels from the seven viable pregnancies remained consistent throughout gestation,

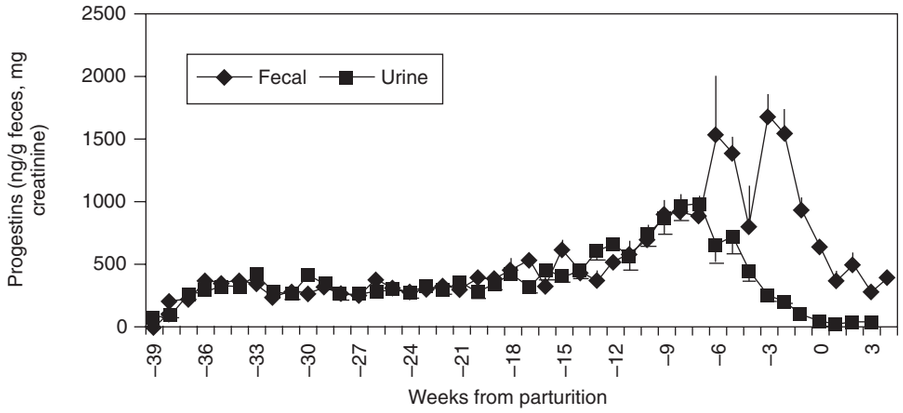

Fig. 137-2 Mean weekly fecal progestin (◆) and urinary pregnanediol-glucuronide (■) concentrations during gestation in seven wood bison at the Toronto Zoo. Data are aligned to the week of parturition (week 0).

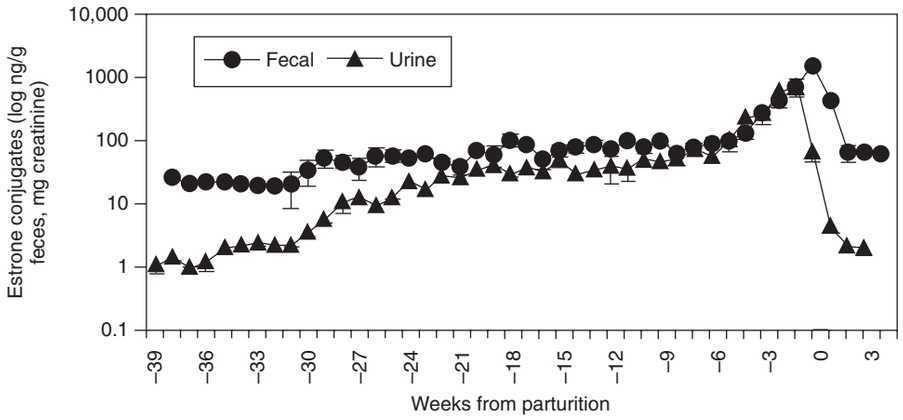

Fig. 137-3 Mean weekly log of fecal (●) and urinary (▲) estrone conjugate concentrations during gestation in seven wood bison at the Toronto Zoo. Data are aligned to the week of parturition (week 0).

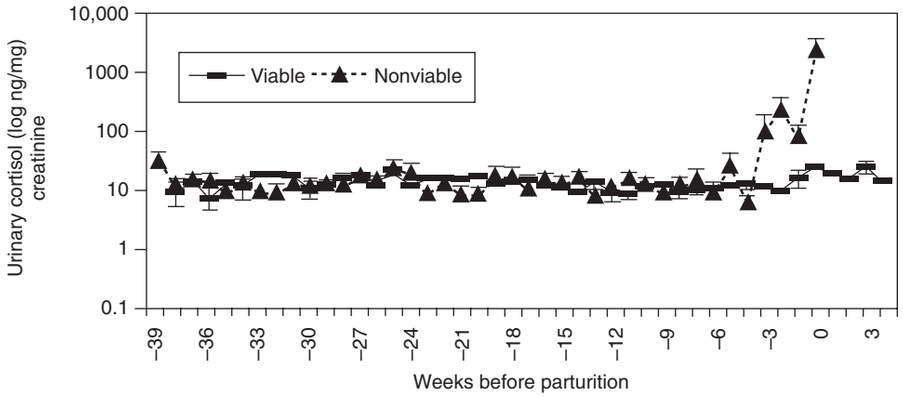

Fig. 137-4 Mean weekly log of urinary corticosteroids during gestation from seven viable (—▬—) and four nonviable wood bison pregnancies (calves stillborn; ▲) at the Toronto Zoo. Data are aligned to the week of parturition (week 0).

with a mean of 14.3 ± 0.5 ng/mg Cr (range 1.8–23.4 ng/mg Cr). During the week prior to parturition, urinary corticosteroids demonstrated a marked elevation to 28.1 ± 6.1 ng/mg Cr (Fig. 137-4). Corticosteroids were not measurable in feces.

Stillbirths

Similar endocrine patterns for PdG, P, urinary EC, and fecal EC were observed among the four females that produced stillbirths, and mimicked those of viable pregnancies. However, significant elevations in corticosteroids (10- to 100-fold greater than values observed in viable pregnancies) were observed in weeks –3 through 0 (see Fig. 137-4). Collectively, this information indicates that both the peak in estrogens and corticosteroids can be used as an indicator of impending parturition, and that corticosteroids may provide insight into the well-being of the fetus up to 14 days prior to parturition.

Table **137-1**

Pregnancy Diagnosis Based on Fecal Estrone Conjugate Analysis*

Estrone Conjugate Levels	Prediction	Outcome
>5 ng/g feces	18 pregnant†	17 pregnant
4.0–4.9 ng/g feces	6 possibly pregnant‡	5 pregnant
<4 ng/g feces	19 not pregnant	21 not pregnant

*Analysis based on 43 female wood bison at approximately week –27 of gestation.
†One false positive.
‡One animal was not pregnant.

Table **137-2**

Pregnancy Diagnosis Based on Fecal Estrone Conjugate Analysis*

Estrone Conjugate Levels	Prediction	Outcome
>25 ng/g feces	29 pregnant	29 pregnant
20–24 ng/g feces	13 possibly pregnant	3 pregnant,† 10 not pregnant
<20 ng/g feces	35 not pregnant	33 not pregnant, 1 abortion,‡ 1 pregnant

*Analysis based on 76 female wood bison at approximately week –14 of gestation.
†The three pregnant animals gave birth later in the year (from July through October), and the 10 animals not pregnant were yearlings.
‡The spontaneous abortion occurred in March.

Pregnancy Diagnosis

Based on the preceding profiles, fecal samples were collected in a single breeding season from 43 wood bison females of the Great Slave Lake herd, Northwest Territories, Canada, to test the feasibility of pregnancy diagnosis based on single samples. The first occasion for sample collection was in November, which retrospectively was (on average) week –27 of gestation. Using the EC assay, fecal samples were analyzed and diagnosis of reproductive status was made using the following criteria: over 5 ng/g feces = pregnant; 4.0 to 4.9 ng/g feces = possibly pregnant; and below 4 ng/g feces = not pregnant (Table 137-1). Over a 2-year period, 77 fecal samples were collected from the same herd of animals in February (at ~week –14 of gestation). Samples were analyzed for fecal EC and evaluation of reproductive status was conducted using the these criteria: over 25.0 ng/g feces = pregnant; 20.0 to 24.0 ng/g feces = possibly pregnant and below 20 ng/g feces = not pregnant (Table 137-2). In animals deemed to be pregnant at week –27, there was a 94.45% accuracy of positive pregnancy detection, but for animals predicted to be pregnant at week –14, there was 100% accuracy. Overall, pregnancy diagnosis performed from fecal samples collected during midgestation was a reliably high predictor of pregnant animals.

Alternatives to fecal hormone analysis for bison pregnancy detection have been described. Kirkpatrick and associates used urine samples collected over a 30-day period to diagnose pregnancy in plains bison.[10] Diagnosis was made based on noncyclic patterns, which demonstrated continually increasing PdG concentrations (>200 ng/mg Cr). The earliest detection of pregnancy in wood bison was between weeks –30 and –26 of gestation using fecal ECs. Urinary ECs also could be used as an indicator between weeks –35 and –33. This is earlier than reported by Kirkpatrick and associates, who were unable to determine pregnancy with urinary EC until 3 to 4 months (weeks –26 to –21) of gestation.[11] The tendency for both urinary and fecal progestin concentrations to remain comparable to peak luteal phase levels for the majority of gestation renders progestins to be less reliable indicators of early pregnancy. Detection of pregnancy in plains bison using total fecal estrogens (>1.09 ng/g feces) and PdG (>57.7 ng/mg Cr) has been found to be 100% accurate after 90 days of gestation, but urinary estrone conjugates (>10 ng/mg Cr) were 89% accurate determining pregnancy in the second month of gestation.[10] Diagnosis of pregnancy in wood bison sampled from November to January has been assessed by radioimmunoassay (RIA) for pregnancy-specific protein B (97% reliable) and by rectal palpation (89% accuracy).[12]

From a herd husbandry perspective, improved understanding of reproductive processes in bison can contribute to more effective management practices. In captive populations, longitudinal monitoring of pregnancy can indicate fetal health, determine abnormalities in gestation, and estimate the date of parturition, enabling appropriate animal care preparations to be made and allowing early problem recognition. Interestingly, the endocrine patterns of pregnancy during gestation in bison do not mimic those of cattle, but rather demonstrate characteristics similar to both sheep and cows.[13] As in sheep, fecal and urinary progestin levels were consistent with peak luteal phase values for the first trimester, became elevated during the second trimester, and declined 3 to 5 weeks before parturition, respectively; whereas estrone conjugate concentrations in feces and urine increased markedly 4 weeks prior to parturition, similar to domestic cattle. This unique hormonal profile suggests that interspecies embryo transfer between bison and cattle would be ineffective, as has been demonstrated for the domestic and Dall's sheep, and further stresses the need to establish species-specific databases, rather than relying on a presumed model.[14]

ASSISTED REPRODUCTIVE TECHNOLOGIES

There is a paucity of information concerning assisted reproductive technologies in bison. Despite reproductive similarities to cattle, reliable and effective methods for estrous synchronization, superovulation, embryo transfer, and artificial insemination have not yet been developed. Rectal ultrasonography can be used to assess ovarian activity in bison.[3,5] This is most successful when

the animals have been habituated to human presence and restraint facilities. Bison ovaries and corpus luteum (CL) average 26 × 18 mm and 22 × 19 mm in size, respectively, and follicles range in size from 7 × 7mm to 10 × 14 mm.[3] In a single report of successful embryo transfer, estrous cycles were synchronized in both donor and recipient cows using Syncromate B implants (SB) with combinations of estradiol valerate (E_2V) and prostaglandin.[15] Superovulation of donor cows was attempted with either pregnant mare serum gonadotropin (PMSG) or follicle-stimulating hormone (FSH). Recipients received either gonadotropin-releasing hormone (GnRH) or human chorionic gonadotropin (hCG) to synchronize ovulation and were artificially inseminated with fresh semen. Only moderate ovarian responses were obtained from donor females, with 28 of 33 attempts to superovulate 16 females resulting in sufficient responses to conduct embryo collections. A total of 20 viable embryos (0.71 embryos/collection attempt), 11 degenerate embryos, and 63 unfertilized ova (2.25 UFO/collection) were collected. Other attempts at synchronization and superovulation have used permutations of the preceding protocols, but with limited success.[3,7,16] Reliability of E_2V in combination with SMB implants from both an ovarian and endocrine response perspective led one group of investigators to choose prostaglandin F over E_2V as a vehicle for estrous synchronization.[7] There are no reports of IVM with bison oocytes, and only two reports of in vitro fertilization (IVF) to produce hybrid embryos using bison sperm to inseminate cattle oocytes.[17,18] In both cases, standard cattle IVF protocols were used for in vitro maturation and IVF. Fertilization rates were moderate, but embryonic development rates were low, indicating that extensive work is necessary to define optimal sperm preparation/processing and culture conditions.

ACKNOWLEDGMENTS

Funding for this project was provided by the W. Garfield Weston Foundation, Mutual of Omaha, and the Toronto Zoo Foundation. Special thanks to the animal care staff of the Canadian Domain section and the veterinary staff of the Toronto Zoo, and to Dr. Margery Hay, Astrid Bellem, Dave Ryckman, Sue Walker, and Kristen Young for their contributions to data collection.

CHAPTER 138

Reproductive Management of Bison

JERRY C. HAIGH and JOHN GRINDE

REPRODUCTIVE BIOLOGY

Bison in North America are seasonal breeders. Using data collected from several different locales in the Northern Hemisphere, Berger and Cunningham reported that in any given year the earliest calves are seen in the first week of April, and that 25% of births had occurred by April 22. The median birth, over a 5-year period, always fell between May 2 and 8, and 80% of all births had taken place within 55 days of the first one recorded.[1] In Northern Alberta the onset of calving often occurs about a week earlier than this. Some later calves may be born in November or even December. A management scheme that describes the events in a bison ranch year is presented in Table 138-1.

Actual mechanisms of control of seasonality have not been studied, and the possibility that the high degree of synchrony is driven by availability of suitable nutrition does exist. Anecdotal evidence from bison ranchers implies that no calvings are seen in the months of January, February, and the first half of March, although such calvings have occasionally been reported.[2]

On average, bison bulls reached puberty at 16.5 months and should be capable of passing a breeding soundness evaluation by 24 months of age.[3]

Bison bulls demonstrate a moderate degree of seasonality that is evident in changes of fecal testosterone, testicular histology, and to a limited degree in semen quality.[4]

Rutley and Rajamahendran,[5] in a study of nine plains bison and five wood bison, found that females are seasonally polyestrous and go through a period of about 3 months when there is no evidence of ovarian activity. Using serum and fecal progestin metabolites as indicators of ovarian activity they found that there was a significant difference in concentrations between periods of anestrus and pregnancy, and that open cows entered a period of anestrus in spring. However, they found considerable overlap between fecal progestins of pregnant animals and those not bred, but exhibiting periodic estrus, and even some overlap between nonbred animals and those in anestrus. A similar study involving behavioral observations and the evaluation of fecal progesterone and urinary pregnanediol glucuronide showed that cyclic activity began in early August and ceased in early December.[6]

Social integration among bison cows can create problems that are not seen in beef herds. When different groups of cows are mixed a change of dominance position can cause delays in the onset of estrus. The animals may take a considerable time to integrate.

PRODUCTIVITY

The calving rate and number of calves per adult cow bison vary widely according to management system, particularly nutritional status.

In some free-ranging herds the productivity is much less than in managed operations. For instance, five parameters of reproductive biology of the free-ranging herds in Yellowstone National Park were examined by Kirkpatrick and associates.[7] They found that lactating cows younger than 5 years of age did not conceive, a fact caused by ovulation failure, and that range condition had an effect upon conceptions in cows 4 years old or younger. The pregnancy rates reported for cows of this age would not be acceptable in commercial herds.

However, calving rates for bison in the National Bison Range, Montana, were between 78% and 100%.[8] Kirkpatrick and associates[7] considered that the three factors of environmental conditions, age, and lactational state influence the overall reproductive performance of the bison in their study, and it is likely that these factors play a role in any mammalian population.

Successful bison managers control parasite loads in their herds either through good pasture management, or the use of anthelmintics at strategic points in the calendar.[9] Of particular concern are the stomach worms of the family Ostertaginae, which have been shown to cause death in both winter and spring, mainly through type II ostertagiasis, or in summer by causing debility and reduced productivity, including reproductive failure.[10]

Good pasture management is essential for the success of breeding programs in bison operations. It is common practice to "flush" bison before the onset of the rut, and ensure that cows enter the breeding season in good body condition.[7] At this time most ranched animals are also feeding calves, and on well-managed properties an objective is to achieve as close as possible to a 100% conception rate, even in lactating animals.

Good nutritional management is also essential in the spring months. Dystocia is reported by bison ranchers, and there is little doubt that overfat cows have an increased risk of dystocia, although this has not been critically tested.[9]

Table **138-1**

Reproductive Management Calendar—Bison

Month	Calves	Cows	Bulls	Nutrition
Jan	Late weaning	Late pregnancy check	Very late breeding	Begin to decrease nutrition
Feb				Aim for BCS of 2.5 at calving
Mar			Semen testing of bulls	
Apr	Calving starts		Semen testing	
May	90–95% calving		Semen testing	Increase plane for cows as they calve
June	Some may go as late as Dec (see text)			Grass ideal
July			Breeding	Aim for BCS of 4.0 for cows through to December
Aug			Breeding	
Sept			Breeding	
Oct	Weaning	At weaning vaccinate and deworm	Breeding (may remove at this time)	
Nov	Weaning	Pregnancy check	Some continue with breeding	
Dec	Late weaning	Pregnancy check		Decrease plane

BCS, body condition score.

Table **138-2**

Body Condition Scoring—Bison

Score	Fat cover	Ribs	Spine	Flank	Inguinal fill	Thurl
1	None	All visible	Very sharp	Empty	Very sharp	Sunken
2	Minimal; at necropsy some fat visible in gastrointestinal tract	All visible	Very sharp	Empty	Sharp	Flat
3	<1 mm backfat	7+ visible (depends on hair coat)	Just visible			Slightly rounded
4	2–12 mm backfat (classifies as A1 on slaughter)	Less than 4 visible	Not visible	Thickened	Rounded	Round
5	>12 mm backfat (usually >20 mm)	1 or 2 may be visible, but covered	Not visible	Full	Deep	Lumpy

BODY CONDITION SCORING

No formal data have been reported for the use of body condition score (BCS) in bison, and the heavy winter coat can confound accurate field examination. However, a field system of scoring can be used (Table 138-2). Palpation is not an option. Using this system a target BCS of 2.5 (on a scale of 5) can be used for animals entering the breeding season.

To understand BCS in bison it must be realized that they deposit fat in a manner more similar to dairy animals than beef cattle. Fat is deposited first (and predominantly) in the interstitial spaces and in the abdominal cavity. With increasing obesity a variable layer of subcutaneous fat, and marbling, is deposited. The subcutaneous layer is not uniform but occurs most commonly over back and loin, dorsal neck, near the tail-head, and in the groin and flank. Back fat measurements of 30 mm are occasionally seen at slaughter. Marbling within muscles is seen only in obese animals.

Animals in a negative energy situation utilize fat reserves. Subcutaneous fat pads (such as those near the tail-head) disappear first, which leads to clearer muscle definition as the body loses condition. This is especially noticeable on the hindquarters in summer. As interstitial fat is removed muscles appear to subside, dorsal spinous processes seem to protrude more, the neck narrows, and ribs and pelvic structures become more visible. In very thin animals all fat has been metabolized and muscle mass is used as an energy source (see Table 138-2 and Figs. 138-1 to 138-4).

FERTILITY TESTING

Bison bulls are often tested for fertility in May before the breeding season, although many farmers do not test bulls more than once in the bull's lifetime. Testing is also carried out at other times of year, for instance, before auction sales. Bison bulls can produce semen year-round

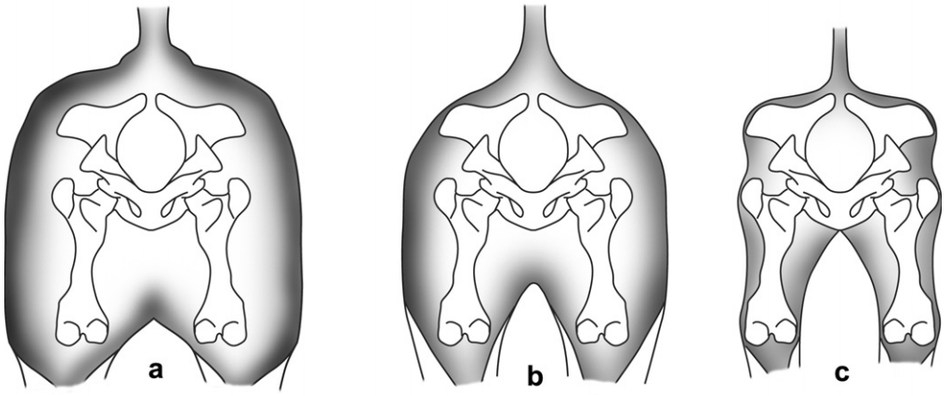

Fig. 138-1 Representation of three body condition scores (BCS) showing view from the rear. Roundness of the hip and buttock region and the angle of the inguinal region indicate gradation from obese (**a,** BCS 5) through "good working condition" (**b,** BCS 3) to extreme emaciation (**c,** BCS 1).

Fig. 138-2 Bison with a BCS of 1. This animal is extremely emaciated. It died within 1 week of the picture being taken.

Fig. 138-4 Bison with a BCS of 4.5 to 5.0. The most noticeable feature is the presence of large irregular masses of fat around the tail-head.

Fig. 138-3 Two bison with BCS of 3.0.

and examinations of seasonal fluctuation in ejaculate quality have shown that fluctuations do occur, which provides a caveat for those conducting test in late winter or early spring.[3] These tests are limited, for the most part, to semen collection by electroejaculation (e-e) followed by its evaluation. Libido testing has not been reported, and it is generally considered too dangerous to carry out scrotal circumference measurements, although these can be done in suitably designed chutes.[11] Bison bulls can kick backward with great force and standing directly behind them is not recommended.

In vitro fertilization with either fresh, or frozen-thawed, semen has been used in the production of bison × domestic cattle hybrid embryos and could be employed as a means of testing semen fertility, but is not practical for the bison rancher.[12]

The only objective report so far published has been the study carried out for 5 consecutive years on a total of 234 bison bulls in the 28- to 30-month-old age group at Custer State Park.[11] The 1992 Society for Theriogenology guidelines for beef cattle semen evaluation and

reproductive tract examination were used. The authors concluded that scrotal circumference (SC) was significantly correlated with body weight, percentage of normal spermatozoa, percentage of primary spermatozoal defects, and percentage of motile spermatozoa. SC was positively associated with increased odds of semen collection, satisfactory motility, satisfactory morphology, and simultaneous satisfactory motility and morphology. Receiver-operator characteristic curve analysis selected 29 cm as the optimal SC cutoff most predictive of simultaneous satisfactory spermatozoal motility and morphology. The authors further concluded that SC is a good indicator of adequate spermatozoal motility and structure in bison.

The authors also pointed out that the study was limited by the fact that all samples were collected in early October, which is essentially after the end of the breeding season, taking no account for possible seasonal variations. They also pointed out that all the animals came from one location.[11]

To accomplish a quality examination, the bull must be restrained in a squeeze that will hold him securely so he will not injure himself or the evaluator. The squeeze must also allow unrestricted access to the rear as well as the lower side of the animal. Many bison bulls have a tendency to squat when held in a chute, and this often means considerable delays in the procedure. Some ranchers have a tendency to apply electric prods randomly over the animal's body in an attempt to make him stand square. This is seldom justified, and usually means that the animal simply becomes obstreperous. If a prod is to be used, its judicious application, with a couple of very brief stimuli to the coronet of the hind foot, will usually make him stand, and a couple of applications, if needed, will often train a bull. A better option is to use a hydraulic chute designed to prevent squatting.

An alternative approach has been employed in a zoo setting, where a small exhibit herd is maintained. The animals are habituated to human presence, and to the chute by keeping it open and allowing them to wander in and out and having the chute associated with the feeding area. This approach generally results in calmer animals when they are handled in the chute for any type of processing.[13]

When semen evaluation is conducted, evacuation of feces from the rectum and palpation of the pelvic accessory sex glands can be carried out from one side. During this examination ampullary massage can be conducted, and this will often aid the entire collection process. After carrying out a rectal examination, an operator may move a hand down to the scrotum in a single continuous move, maintaining contact with the perineal skin, and palpate the scrotum for abnormalities, but caution must be exercised during this procedure. The testicles can be checked for consistency and their sizes can be compared. Any abnormalities, including monorchidism, are noted.

A variety of units are used for electroejaculation, which can be considered part art and part science; thus, some of the variations have to do with operator confidence and experience as much as anything. During the ejaculation process, the penis is visually inspected for damage, defects, or the inability to extend. Handling of semen should follow established techniques used for the domestic bull and at certain times of year may involve the use of a warm-water sleeve outside the collection tube, or a preheated Styrofoam cup. Often the owner needs the information quickly because he is sorting the bulls based on the results of the reproductive evaluation.

Most bison bull semen examination involves the same measurements as used for domestic cattle. Gross motility is scaled either from 1 to 3 or 1 to 5, the highest rating being akin to a mass of swirling clouds, the lowest barely moving.

Individual motility is detected under higher magnification. The minimum requirement for beef animals is 30%. Some veterinarians use this standard for bison as well. It is possible that this standard should be higher for bison. In an evaluation form designed for one client, the minimum accepted standard for individual motility is 50%.[14] However, there are no objective data that confirm or refute this figure. It may be that bulls meeting 30% may be able to breed successfully.

Unlike the beef industry, bison bulls at 18 to 24 months of age can easily be moved into a feeder program rather than being maintained as breeding stock. Some producers prefer to have only the superior bulls used for breeding and therefore request the higher minimum standards.

Morphologic criteria are the same for bison bulls as for domestic cattle. The minimum standard accepted for use of a bull in a breeding program is generally taken as 70% normal cells. Nigrosin-eosin is a useful stain, and a Feulgen stain has been used for the examination of nuclear material.[3,4]

Using Society for Theriogenology beef standards, it has been demonstrated that young bulls do not always pass the first time, as they may not have reached sexual maturity. The commercial bison industry semen tests, and possibly rejects, many developmentally incomplete bulls between 19 and 21 months of age. Studies by Helbig and associates have shown that a failed test at 21 months may be too soon to discard a bull and that those that fail semen tests at this age may be worth testing again at 24 months.[3]

Table 138-3 shows results of semen evaluation with the following minimum requirements: individual motility of 50%, morphology 70% normal.[10,14] No statistical analyses were conducted, but it appears that the percentage of samples rated as satisfactory increases around the age of 2 years.[14]

Keen and associates[11] in their study of the 28- to 30-month-old bulls at Custer State Park found that only

Table **138-3**

Semen Evaluation of Bison Bulls Relative to Age

Age (Months)	Animals Tested	Satisfactory (%)	Unsatisfactory (%)
18 to 24	404	72.28	27.72
24 to 36	107	93.46	6.54
36+	53	94.34	5.66

36.2% were rated satisfactory, despite the lower acceptable motility of 30%. This difference could be due to a variety of circumstances, including nutrition, body weight, differing bloodlines, different operator standards, or other factors.

AGE OF BULLS

Most producers use bulls between 2 and 7 years of age because older animals become difficult to manage and tend to be aggressive toward both humans and younger bulls, especially during the rut. If all bulls are of similar age, above about 5 years, they tend not to cede dominance, and fence damage frequently occurs. If a bull battery consists of animals of staggered ages, this problem does not occur.

BULL-COW RATIOS

Most producers run bison in multisire mating mobs with a bull-cow ratio between 1:10 and 1:15. There are no objective data to support these numbers, but they have no doubt developed from long practice. There appear to be no data that critically test the point at which calving seasons may be prolonged, or percentage of cows calving decline due to an inappropriately low ratio. Some producers, especially those that manage their herds to produce meat for the farm gate sale business, use higher ratios (up to 1:35) that create a prolonged calving season up to 3 or more months in duration.

PADDOCK MANAGEMENT

Management systems vary widely from extensive to intensive. In extensive systems the animals may be run in mobs of several hundred, being moved from large paddock to large paddock every few days.[15] In intermediate and mixed farming systems some degree of supplementary feeding is used, usually in winter.[16] Bison are also managed intensively, with year-round feeding.[17]

In those operations in which bulls are separated from cows for part of the year, the males are generally turned in with the females in late May or early June. The full rut does not start until mid to late July, and extends through August. There do not appear to have been any studies reported on the so-called "ram effect" in bison. Rutting behavior tails off sharply by September, as by then most cows have conceived. However, calves have been born in almost all months of the year, although calving in January, February, and the first half of March is considered exceedingly rare.

REPRODUCTIVE BEHAVIOR

Female bison are gregarious and live in groups with calves and immature individuals throughout the year. When a female is in estrus a male develops a tending bond with her that may last from a few hours to several days.[8,18,19,20] Bison are not harem breeders, and competition among males may be high because only a relatively small number of cows are in heat at one time.

Observation of breeding groups has shown that females may show typical signs of estrus that include a swollen vulva, raised tail-head, and close association with the bull. Bulls demonstrate typical flehmen reactions when tending a cow, and have been seen to actively discourage a cow that is coming into estrus when already tending a cow that is in a more advanced estrous state. Cows also exhibit flehmen toward one another, and it has been suggested that they use this behavior to stimulate the onset of estrus and synchronize the timing of copulation.[21]

During the tending period, which may last from a few hours to several days, the bull and cow adopt a position alongside one another, both facing in the same direction, and if a cow attempts to move away, the bull may swing his head across and intercept her.[18] It has been reported that 95% of bison females copulate only once per estrus period or, if more than once, with only one male.[1]

Aggressive interaction among bulls increases as they mature, and has been reported to peak between 8 and 11 years of age.[22] Commercial ranchers seldom keep bulls up to such a mature age, mainly because they become difficult to manage.

In free-ranging, mixed-age groups immature bulls may not get the chance to breed, because cows are tended and bred by older animals. However, they do breed opportunistically, often without showing any prolonged tending behavior.[22] During the early and middle parts of the rut mature bulls are the most aggressive, but younger bulls become increasingly aggressive as the rut progresses and mature bulls lose condition. If mature bulls are excluded from ranched herds, younger bulls show aggression throughout, but may be more reluctant to engage in behaviors involving risk, such as fighting.[22] For this reason most ranchers do not use fully mature bulls, but tend to use those under 5 years of age. However, a single mature bull in a breeding mob may prevent competition among the younger males while ensuring that they have opportunities to breed.

Mounting among bulls (Buller syndrome) has been observed among bulls up to 4 years of age and is commonly seen in mixed-age bull groups.[19]

PREGNANCY DIAGNOSIS

This subject is covered more fully in Chapter 139.[23] Techniques include rectal palpation, ultrasound imaging, serum sampling for progesterone or pregnancy-specific protein, and fecal sampling for steroid metabolites.

Pregnancy diagnosis is not widely practiced by bison ranchers, although there is no doubt that it would reveal deficiencies unrecognized by ranchers.[2] Both mummified fetus and freemartins have occasionally been recognized.

CALVING MANAGEMENT

There are reports of the killing of newborn calves by young bison bulls, although it is not known if this is due to curiosity or aggression. However, in intensive or semi-intensive operations young bulls should probably be removed from groups of calving cows.

Calving Behavior

Calving in bison is usually rapid, with calves weighing from 18 to 27 kg (about 4.5% to 7% of maternal body weight). They are unusually precocious.[20] The choice of calving site appears to depend on the type of habitat, and perhaps on herd size. In large groups on open grassland, calving commonly occurs within the group, with no attempt to search for isolation. Calving in denser habitat usually occurs in isolation.[10,20]

In general, bison cows have few calving problems. When they do have problems, they are difficult to deal with, and the outcome is seldom good.

One of the first signs of impending labor is that the cow will hold her tail elevated and well away from the vulval opening. The cow may also grunt, roll, paw the ground, or kick at her belly.

As parturition progresses, the cow will usually begin to strain while in a standing position, with her back humped. Shortly after the cow begins to strain, the amnion appears. Occasionally bison cows will deliver their calves standing, but in most cases the cow will lay down on her side with her feet extended. As she strains the cow will often lift her head and look backward. When the calf starts to emerge, the cow will frequently elevate her upper back leg. As soon as the calf is born, the cow will stand over it and lick it continually until it stands and nurses.

Dystocia

Because of the relatively small size of bison calves in relation to their dams dystocia is fairly uncommon, but certainly not unknown. Two causes of dystocia that appear to be of growing concern in the bison industry are fetal oversize and overfat dams.

Fetal Oversize

Within the bison industry, oversized calves have not been a major cause of calving problems in the past. However during the last few years, oversize calves have become a more common cause of dystocia in bison as some producers have followed beef industry management practices and selected on production parameters such as weaning weights, yearling weights, and 2-year-old weights.

Overfat Cows

Free-ranging bison cows lose weight during the winter months, and generally are thin when they enter the calving season. Ranched bison are generally provided with better quality feed than would be available under free-ranging conditions. Some bison producers that experience calving problems may have cows that are overfat at calving season. Target BCS should not exceed 2.5.

Management of Dystocia

It is difficult to make broad recommendations about how long to leave a calving bison cow before trying assist her. Obvious malpresentations require early intervention. In other instances it is not as easy to differentiate between a cow that requires assistance and one that is just taking a long time with a normal delivery.

In one study of free-ranging bison, bison cows took from 18 to 197 minutes to deliver their calf after the amnion was observed. They took from 1 to 40 minutes to deliver their calf after the calf's feet were first visible.[20] If these numbers are applied to farmed animals, it would be recommended that bison cows be allowed a minimum of 3.5 hours to deliver their calf after the amniotic sac is observed, and a minimum of 40 minutes once the calf's feet are observed.

A key component of calving management is that bison cows may delay labor for long periods if they are disturbed. If an observer interrupts the labor process and causes the cow to get up, she will delay the delivery of her calf. Observation of calving bison should be done from a long distance. Binoculars or a spotting scope are vital tools for the bison manager.

The incidence of dystocia in bison cows is low, and bison cows are often able to deliver calves that are in abnormal positions. In particular, presentations in which both back feet are presented first are not uncommon, and cows should be able to deliver such calves without any problems.[10] For these reasons bison producers often allow calving cows a considerable amount of time to work things out before they consider providing assistance.

Some bison producers make a deliberate decision not to interfere in dystocia cases at all. If a cow cannot deliver her calf unassisted, she is considered to be a cull animal and is shot, as leaving her would become a welfare issue.

The major goal of providing assistance to bison cows with dystocia is to save the cow, as the calf is likely to be dead. A major problem that then ensues is the capture and restraint of the cow. Because calving cows have a larger flight zone than noncalving cows, plenty of time should be taken to bait the cow or to slowly and calmly work her into a handling facility.[10] In most cases of calving trouble the calf will be dead before the cow has been identified as having a problem. If the calf is not dead, it will usually not survive the cow being aggressively chased into a handling facility. If the calf is dead, then time is not as critical, and the cow can be left for a period of up to 6 or 8 hours. It is important, however, not to leave the cow for too long as dehydration of the calf and the uterine environment will create serious problems that may make assisted delivery extremely difficult or cause toxemia in the cow.

If a cow must be tranquilized in the field, appropriate drugs must be used. The cow is likely to be stressed, especially if she has been chased, and the use of xylazine alone is unlikely to be effective. Drug combinations involving opioids and xylazine, or xylazine and Telazol are likely to be required.[24]

Once the cow is restrained in a squeeze or is tranquilized, assistance can be provided. Using sound principles of careful manipulation, and great care with the uterine wall, which may be fragile if assisted delivery has been delayed, the calf should be removed from the uterus as quickly as possible to minimize the amount of time the cow spends in the squeeze. The longer she stays in the squeeze the less likely will be her chance of survival.

Bison cows will often lie down if they are held within a squeeze for any time longer than a few minutes. If a hydraulic squeeze is not available, ropes can be tied under the cow's belly to act as a sling that will hold the cow up during the procedure.

If the malpresentation cannot be corrected by manipulation, a fetotomy is an option, but long procedures will reduce the cow's chance of survival.

Cesarean sections should be considered as a last resort. If the cows survive, the chances of them breeding back are limited.

Because of the very aggressive nature of newly calved bison cows, it is difficult to "mother up" calves that have been manually delivered, and we are unaware of any successful mothering up of calves and cows after cesarean section.

GESTATION LENGTH

Based on 261 known calving dates based on observed copulations, the length of gestation ranges from 277 to 293 days.[1]

There is good evidence to show that gestation length in bison varies with nutritional condition as well as date of breeding. Furthermore, primiparous females have longer gestations that multiparous ones (mean 288 versus 280 days).[1] Animals in poor condition will mate later than those in optimal condition, and will have longer pregnancies. However, females in good condition, bred after the median date, will reduce their gestation lengths by an average of 5.9 days, suggesting that they do so in order to synchronize births with other females in the herd.[1]

CHAPTER 139

Pregnancy Determination and Fetal Aging of Farmed Red Deer, Wapiti, and Bison

PETER R. WILSON and JERRY C. HAIGH

Early pregnancy detection in wapiti, red deer, and bison can be accomplished by rectal palpation, rectal ultrasound examination, serum estrone sulfate (E_1S) concentrations, cross-reactivity with bovine pregnancy-specific protein (PSPB), and possibly, fecal hormone evaluation. Pregnancy diagnosis late in gestation is useful to determine if there have been fetal losses from scanning early in gestation. This may be performed by rectal manual or ultrasound examination, transabdominal ultrasound, or hormonal measurements, udder palpation, or observation. In red deer it is also possible to palpate a late-term fetus by abdominal ballottement. The principal requirement is that handling facilities and animal behavior be appropriate to ensure that the animals do not damage themselves, the operator, or the equipment while the examination is being conducted.[1]

MANUAL EXAMINATION

The simplest and least expensive method is rectal palpation, which can only be accomplished in animals large enough to permit the insertion of a hand. It is a relatively easy procedure in wapiti if restraint is adequate, but unless the operator has small hands (surgical glove size 6 or less) the red deer is difficult or impossible to palpate because of its smaller size. The variety of cross-bred animals on farms must be evaluated on an individual basis, and decisions on the advisability of rectal examination should be based upon both human hand size and the experience of the operator. Manual examination of bison for pregnancy determination is governed by the quality of the restraint method.

The cervix of the nulliparous red deer and wapiti is about 5 cm long and 1.5 cm in diameter. This part of the tract enlarges slightly during the first pregnancy and the cervix of multiparous wapiti females is about 5 cm in diameter and 10 cm in length.[1]

The uterus of nonpregnant wapiti lies almost entirely within the pelvic cavity. The yearling nonpregnant uterus is small, with a horn diameter of about 1.5 cm and a length of 8 to 10 cm. Enlargement in the pregnant horn can readily be detected manually by 42 days after conception, at which time it lies over the pelvic brim. At this time the uterus may be about 20 to 25 cm in length, and the first two of the enlarging placentomes on the dorsolateral surface of each horn can be felt. At this stage the wapiti fetus is about 24 mm in length, and can often be felt by finger-tapping of the fluid-filled uterus. The crown-rump (CR) length of the red deer fetus is about 19 mm at this stage of gestation. The fetal membrane slip technique has also been described. By 75 days of gestation the uterus has considerably enlarged, its weight has pulled it down into the abdominal cavity, and the fetus may be as much as 30 cm in length.[2] By 100 days of pregnancy it may be possible to determine only that the cervix lies over the pelvic brim, and that the uterus is out of reach, as it can be difficult for the operator to insert an arm past the elbow, and for some individuals even past the middle of the forearm, even in wapiti of 300 kg body weight.

The reproductive tract of the bison female is readily examined per rectum, in which criteria used have been adopted from cattle.[3,4] A small number of the animals may adopt a "dog-sitting" posture in the chutes, which delays proceedings.

ULTRASOUND

Transrectal Approach

Transrectal ultrasound examination, using a 5-MHz linear transducer on a rigid extender, has proved to be a highly reliable method of pregnancy diagnosis in red deer.[5,6] Although pregnancy confirmation is by observation of the fetal membrane, placentomes or fetal anatomy, the principal challenge for the ultrasonographer is definitive identification of the nonpregnant uterus.[6] A "nil diagnosis" is advised for any animal in which neither a pregnant nor a nonpregnant uterus can be detected, and these animals should be returned for repeat examination.

The fetal heartbeat can first be seen as early as 22 days of gestation in some wapiti, and by 24 days in all.[7] Pregnancy should therefore not be affirmed before 24 days, although other signs, such as the presence of an amniotic vesicle, may be seen before this time.[6] A cut-off of 28 days for confirmation of pregnancy by ultrasound, and a "nil diagnosis," with a second examination to follow, has been suggested as standard procedure for any animal in which a nonpregnant uterus cannot be detected.[8]

For the most accurate estimation of conception date in red deer it is recommended that ultrasonographic pregnancy diagnosis be carried out between approximately 35 and 60 days of gestation. At this time, amnion dimen-

sions and CR length can be measured, and estimates based on these have standard errors of about 2 days.[5] Although conception dates of red deer can be estimated upon measurements made after 60 days of pregnancy, the standard error of the estimate is greater. Up to 13 fetal and uterine dimensions may by used to estimate conception date.[5] Note, however, that fetal aging, while providing an accurate estimation of conception date, cannot be used to accurately predict the calving date of an individual deer, because of the normal variation in gestation length described earlier. However, fetal aging can give an accurate prediction of the pattern of calving of a herd, because variation in gestation length of an individual is random about the mean. Defining the herd pattern of conception and therefore calving dates is known as "pregnancy profiling" in New Zealand.[8]

As pregnancy advances and the uterus moves over the pelvic brim, fetal anatomy may be difficult to scan after about 110 to 130 days in red deer. In wapiti, by 100 days, it may not be possible to determine pregnancy if the uterus has advanced into the abdominal cavity and lies between the posterior face of the rumen and the ventral abdominal muscles, where a probe, even with an extension handle attached, cannot reach it.[1]

Transabdominal Approach

Ultrasound can also be used via the external, transabdominal approach in the later stages of gestation in red deer, by applying the probe to the relatively hairless area immediately adjacent to the udder. A 3.5-MHz sector scanner has been used in New Zealand. This technique can also be used in reindeer in later gestation, but the heavy winter coat limits the site for application of the scanner. A hair-free site between the teats has been used in Norwegian reindeer.[9]

Ultrasound is also becoming established as a useful tool for pregnancy diagnosis in bison, but no data on fetal sizing have been reported.[4]

HORMONE MEASUREMENTS

Hormonal evaluation has been used to determine pregnancy in free-ranging populations of wapiti. Serum progesterone (P4) concentrations are raised during pregnancy, but because progesterone concentrations also rise during the estrous cycle, and the levels during pregnancy and the luteal phase may overlap. Therefore, because wapiti and red deer are polyestrous until after midwinter, if progesterone concentrations are to be used for pregnancy determination in that period, they must be used either in conjunction with other methods of diagnosis, or sampling must be repeated at intervals shorter than the generally accepted estrous cycle length of 18 to 21 days. If carried out after the spring equinox when normal estrous cyclicity has ceased in nonpregnant animals, elevated progesterone concentration in a single sample is diagnostic.[1]

Similarly, hormonal metabolite concentrations of ungulates have been measured in urine and feces to determine reproductive status. Although this technique has not been demonstrated in wapiti or red deer, it has the potential to be of benefit as a noninvasive method of diagnosis. It is most likely to be used in free-ranging populations rather than farmed animals. It is also used in zoo animals when handling facilities may not be available, or caretakers may wish to make determinations in a noninvasive manner.[10]

Estrone sulfate (E_1S) concentrations have also been used in the determination of pregnancy. It has been shown to be 100% effective in distinguishing pregnancy when hinds are more than 100 days pregnant.[11]

PREGNANCY-SPECIFIC PROTEIN

A pregnancy-specific protein in red deer cross-reacts with the pregnancy-specific protein of bovine origin (PSPB).[12,13] Wapiti pregnancy-specific protein has been characterized and shown to have similar properties to that of cattle.[14] The protein, produced by the binucleate cells of the trophoblast, is produced only during pregnancy, and in red deer it is reliably present 33 days after conception.[12]

When PSPB levels were compared to direct uterine examinations, lowering the criterion used to indicate pregnancy from 95% to 93%, binding of wapiti (elk) antiserum to bovine PSPB improved overall pregnancy detection accuracy from 94% to 96% and reduced the rate of false positive tests from 15% to 3%.[15]

Bovine pregnancy-specific protein assays have also been used for pregnancy determination in bison, and have proved to be as accurate as rectal palpation.[3] For more details on pregnancy diagnosis in bison, see Goodrowe and associates.[10]

CHAPTER 140

Brucellosis in Specialized Livestock

LORRY B. FORBES

The genus *Brucella* consists of six formally recognized species of bacteria found in terrestrial mammals (*abortus*, *melitensis*, *suis*, *ovis*, *canis,* and *neotomae*) and a proposed species recently described in marine mammals.[1,2] These gram-negative bacteria are the causative agents of brucellosis in animals. A number of species have more than one biologic variant. There are seven recognized biovars of *B. abortus*, five of *B. suis,* and three serovars of *B. melitensis*.[3] Two distinct strains of *B. canis* have been reported, and there is evidence to suggest more than one biovar for the marine isolates.[2,4] *Brucella ovis* and *B. neotomae* have no reported variants. The preferred hosts for individual species are cattle (*B. abortus*), goats and sheep (*melitensis*), sheep (*ovis*), dogs (*canis*), and wood rats (*neotomae*). *Brucella suis* is notable because it has a wider range of normal hosts than the other species of *Brucella* and these hosts are associated with specific biovars. Thus, the normal hosts for *B. suis* biovars 1 and 3 are swine; for biovar 2, swine and the European hare; for biovar 4, reindeer and caribou; and for biovar 5, rodents. The host specificity of *Brucella* is not always absolute, and it appears that in some cases it is an artifact of normal host range. When a normal and a potential host come in contact through translocation, game farming, extension of agricultural zones into wildlife habitat, or for other reasons, there is an opportunity for interspecific transfer to occur. Examples of this are the spread of *B. abortus* from cattle to bison and *B. ovis* from sheep to red deer. The following sections describe the disease by host for bison, elk, reindeer, caribou, red deer, white-tailed deer, mule deer, moose, and other deer species. Table 140-1 lists the species and biovars of the genus *Brucella*, the normal hosts, and the specialized livestock species that have been infected with brucellosis either in the field or experimentally.

AMERICAN BISON (*Bison bison*)

Brucellosis in bison probably originated from contact with European cattle in the 19th and early 20th centuries.[5] The disease is self-sustaining in bison herds, as evidenced by longstanding infection of relatively isolated populations in Wood Buffalo National Park in Canada, and the greater Yellowstone area of the United States.[5,6] *Brucella abortus* biovar 1 (typical and urease negative) and biovar 2 have been recovered from bison.[7,8] Clinical signs, pathogenesis, and epidemiology of bison brucellosis are similar to those seen in cattle, but serologic tests and vaccines developed for use in cattle do not always give equivalent responses in bison and this needs to be considered in diagnosis and control.

Epidemiology

The epidemiology of brucellosis in bison is not well documented, but the similarities of the clinical disease in bison and cattle and the ability of the disease to sustain itself in infected bison herds suggests that epidemiologic

aspects of the disease are similar, if not identical, in both species.[9] Oral infection is the primary route of infection. Aborted fetuses, placentas, and uterine fluids from infected bison cows can contain high numbers of *B. abortus*, and persistent vaginal shedding may occur for several weeks post partum. Licking and nosing of aborted materials or the genital regions of postabortion females provides ample opportunity to transmit the disease and these behaviors have been observed in domestic bison. In cattle, persistent shedding of *B. abortus* may occur after abortion or following subsequent normal calvings, but successive abortions are uncommon. There are no field infection data for bison, but a vaccine strain (*B. abortus* strain 19) was recovered from a bison cow after her second abortion following vaccination, suggesting that both persistent shedding and successive abortions may occur.[10]

Venereal transmission rarely occurs in cattle, and infected bulls are considered a negligible risk factor. However, transfer of the organism directly into the uterus via artificial insemination will cause disease.[11,12] This is because the vaginal environment is not conducive to survival of *Brucella* sp., whereas the uterine environment provides optimal growth conditions. Bison bulls infected with *B. abortus* are similar to bovine bulls and can shed the organism in semen. This is likely not a significant factor in transmission. Two experimentally infected bison bulls shown to be shedding *B. abortus* in semen were housed with six susceptible bison cows for 10 months. Four cows were successfully bred by one of the bulls and none of the cows or their calves were positive on culture or showed seroconversion.[13]

In cattle, superovulation, artificial insemination, and embryo transfer have been used to produce disease-free calves from brucellosis-infected cows. Similar procedures have been used with infected donor bison cows to produce calves bacteriologically negative for brucellosis.[13] The use of infected cows and bulls for breeding purposes is generally discouraged, but these methods provide an option for the preservation of valuable germ plasm in diseased populations of bison.

Brucella organisms are commonly present in the milk of infected cattle and have been shown to be present in the milk of some experimentally infected bison cows for 3 weeks.[9] Live calves born to infected dams are likely to ingest *Brucella* organisms in milk, but the dose received and the effect of anti-*Brucella* colostral antibodies are complicating factors. The importance of this route of infection among bison is unknown. Meconium from aborted calves contain *Brucella* organisms, as do feces from calves nursing infected dams, and these may be a factor in transmission under conditions of close confinement.[9]

In areas cohabited by bison and cattle, it should be remembered that cattle and bison strains are indistinguishable and that interspecific transmission is possible.

Cattle have been infected with *Brucella* from bison under both field and experimental conditions and *B. abortus* strain 2308 has been successfully transmitted from infected cattle to noninfected bison cohabiting the same pen.[14–16] Experimental infection of six bison with the reindeer strain of brucellosis (*B. suis* biovar 4) showed that this strain is not pathogenic for bison and that reindeer cohabiting range with bison are unlikely to pose a risk.[17]

Pathogenesis

The pathogenesis of brucellosis is similar among hosts despite the different species and biovars found in the genus *Brucella*.[18] Infection proceeds through four stages: mucosal infection, infection of local lymph nodes, bacteremia and secondary localization, and reproductive tract localization. Invasion of the mucosa occurs following exposure and elicits an acute inflammatory response in submucosal tissues characterized by increased numbers of mononuclear, polymorphonuclear, and eosinophilic leukocytes; plasma cells; and focal lymphoid aggregates. *Brucella* sp. are facultative intracellular parasites and likely resist intracellular killing by releasing of 5′-GMP and adenine from their surface, which interferes with degranulation (phagosome-lysosome fusion) and inhibits myeloperoxidase–hydrogen peroxide–halide bacteriocidal activity. Their survival within host leukocytes offers additional protection against other humoral and cell-mediated bacteriocidal responses. Organisms escaping the submucosal response travel to local lymph nodes via lymphatic drainage where they cause enlargement due to lymphoid and reticuloendothelial hyperplasia and the infiltration of inflammatory cells. Survival and multiplication of the organisms in the regional lymph nodes eventually results in spillover into the vascular system and hematogenous spread to other tissues, most notably lymphoid tissues, uterus, and mammary gland in females and testes, epididymis, and accessory sex organs in males. Bones and synovial membranes are less frequently involved and a variety of other tissues and organs can harbor the organism, particularly during the bacteremic phase.

Brucella organisms have an affinity for the placenta, and are found in high numbers in chorionic trophoblasts.[18] Chorionic trophoblasts produce a variety of hormones and secretory proteins and appear to provide the factors necessary to stimulate rapid growth of *Brucella* sp. Localization in the reproductive tract was originally attributed to the presence of erythritol in these tissues, but subsequent studies showed that erythritol was not a critical requirement. Infection may be associated with minimal placentitis or with severe placentitis characterized by widespread destruction of placentomes and fetal membranes. Abortion is a frequent sequela, regardless of the severity of placentitis, and is caused by *Brucella* lipopolysaccharides and lipid A (endotoxins) present in the uterine environment. The exact mechanism causing abortion is not completely understood and is probably due to a combination of factors. Both placental and fetal progesterone are required to maintain pregnancy in cattle and sheep during the second half of gestation. Virulent strains of *Brucella* destroy chorionic trophoblasts in vitro, and if this occurs in vivo, it may disrupt the progesterone balance. Bovine and ovine fetuses infected with highly pathogenic strains of *Brucella* have elevated cortisol levels and this may result in decreased progesterone, increased placental estrogen production, subsequent increases in endometrial prostaglandin (PGF_2), and induction of parturition. This fetal effect does not occur consistently with strains of low virulence (RB51, strain 19). Interestingly, abortions have been associated with *B. abortus* strain 19 vaccination in bison indicating that *Brucella* strains of low virulence for cattle are not necessarily of low virulence for bison.[10]

The pathogenesis of mammary gland infection is not well described, but is associated with focally distributed interstitial infiltrates of plasma cells, lymphocytes, macrophages, and variable numbers of neutrophils.[18] A variety of pathologic changes associated with inflammatory responses can also occur following localization in the male reproductive tract. Orchitis, epididymitis, and seminal vesiculitis have been described, and lesions may range from severe necrotizing pyogranulomatous orchitis to mild seminal vesiculitis.[19]

Localization in the joints probably occurs following traumatic injury or endotoxin-mediated changes to capillary permeability resulting in hemorrhage into the joint. Arthritic lesions in bison were characterized by serous arthritis with lymphoplasmacytic infiltrates and hemosiderin-laden macrophages in synovium and proliferation of synovial villi.[7] Foci of necrosis and mineralization occurred within the synovium and joint capsule, and there was an infiltrate of epithelioid macrophages, macrophages, and lymphocytes and proliferation of fibroblasts.[7]

Clinical Signs

Abortions are readily induced by experimental infection of bison with cattle strains of *Brucella* and abortions due to brucellosis have been described in both wild and ranched bison.[9] Based on the limited evidence available, abortions in bison, as in cattle, tend to occur in the last 3 months of pregnancy. Gross lesions of the fetus are seldom observed. Histopathologically, a mild bronchointerstitial pneumonia characterized by neutrophils, mononuclear cells, and degenerate leukocytes in bronchioles and alveoli has been described in aborted fetuses and infected neonates, as have splenic infarction, splenic necrosis, and purulent nephritis.[8,20] Retained placentas occur in experimentally infected, vaccinated, and field-infected bison cows.[8,9] Metritis in a field-infected bison was associated with a purulent vaginal discharge and necrotic placenta, debris, and purulent exudate in the uterine lumen, all of which were cultured positive for *B. abortus*, and a recently aborting bison cow had a purulent endometritis and necropurulent placentitis.[8,21]

Orchitis, epididymitis, and seminal vesiculitis have been described in bison that were serologically or bacteriologically positive for *B. abortus*.[9] Grossly enlarged scrotums were a common clinical sign. Visible lesions ranged from scrotal sacs filled with purulent exudate and caseous testicular remains to thickened epididymal tissue containing foci of yellowish purulent exudate. Gross lesions

are not always present, but microscopic lesions in the epididymis, seminal vesicle, and ampulla consisting of lymphoplasmacytic infiltrates with neutrophils in the interstitium and glandular lumens have been described. Based on the limited data, the severity of testicular lesions probably varies with the dose and duration of infection and there is no doubt that reproductive performance is affected in some cases.

B. abortus has been recovered from arthritic joints and hygromas in wild male bison.[7] Affected joints may be grossly distended and mobility may be inhibited. Arthritic lesions included loss of articular cartilage with eburnation and lysis of bone, synovial villous hyperplasia, pannus formation, and thickening of joint capsules. Large amounts of translucent viscous yellow fluid containing flecks of debris were present in the joint space and distended tendon sheaths. One bull had a suppurative exudate in the stifle joint. The severity of lesions, and subsequent degree of lameness, likely varies according to the dose and duration of infection.

Diagnosis

Brucellosis should be considered as a differential diagnosis in cases of late stage abortion, testicular enlargement, low conception rate, or lameness of unknown etiology. On a herd basis, brucellosis is easily diagnosed using serologic tests designed for use in cattle. On an individual animal basis, variations in test sensitivity and specificity from that seen in cattle may compromise test interpretation. Culture and recovery of the organism from suspected cases provides the only true definitive diagnosis.

Serology

A number of serologic tests are available for use in cattle, and most, if not all, can be used for bison. These tests include the buffered plate agglutination test (BPAT), rapid screening test, brucellosis card test (BCT), standard tube agglutination test (SAT) , rivanol test, complement fixation test (CFT), particle concentration fluorescence immunoassay (PCFIA), indirect and competitive enzyme immunoassays (iELISA, cELISA), and most recently, the fluorescence polarization assay (FPA).[9,22] The sensitivity and specificity of serologic tests used for bison vary widely, and validation has been hampered by the relatively low number of samples available for study. It has been suggested that serologic responses on some tests are slower to develop in bison than in cattle, and that no serologic test is reliable during the first 8 weeks after infection.[16] In general, the tests reliably recognize bison that are positive on culture (sensitivity from 75% to 100%), but do not consistently predict culture results (specificity 36% to 100%).[9] The BCT is a readily available and easily conducted field assay and has been used as the sole test to successfully eradicate brucellosis from an infected bison herd. Recent validation work has shown an iELISA, cELISA, and FPA test to have a sensitivity of 96.3%, 96.3%, and 96.3% and a specificity of 97.6%, 94.1%, and 97.6%, respectively, making them the tests of choice.[22] The FPA can also distinguish between strain 19 vaccine infection and field infection.[22] However, it should be remembered that in the early stages of infection, vaccination and field infection titers may be indistinguishable.

For practical purposes, the deficiencies of individual serologic test procedures can be overcome by using a battery of different tests and, if necessary, conducting retests at 3- to 4-week intervals. Strong positive reactions on serologic assays are reliable indicators of exposure but do not necessarily mean that individual bison are harboring significant numbers of the organism. Low level reactions must be interpreted with caution, particularly if they occur in only a few animals in otherwise serologically negative herds. For both herd and individual animal testing, the strength of a presumptive diagnosis of brucellosis increases with the number and magnitude of observed serologic responses.

Bacteriology

Recovery of *Brucella* organisms is required for a definitive diagnosis.[3] The success of bacteriologic culture is dependent on the number, type, and quality of samples submitted, the experience of the diagnostic laboratory, and the duration of infection in the animal sampled. *Brucella abortus* is widely distributed in lymph nodes and organs of infected animals, but not necessarily in all these tissues. In chronic infections, only a few tissues may remain infected and these may contain small numbers of the organism. A large selection of samples is required to maximize the sensitivity of bacteriologic culture. Tissues associated with abortion are important for culture. Samples of choice are fetal stomach contents, fetal lungs, and placenta. Fetal spleen, liver, kidneys, and lymph nodes and vaginal exudates are also good candidates. Milk is a useful sample for bacteriologic culture, but shedding of the organism in milk is often erratic. Mammary tissue provides more reliable results. In the male, semen can be cultured, but infected bulls do not always shed in semen. Bacteriologic culture of testicle and epididymis will give more reliable results, particularly if abnormalities are present. The accessory reproductive glands are of lower priority, but should be sampled if lesions are present. In both sexes, lymph nodes draining the head (retropharyngeal, parotid, mandibular) and inguinal region (internal iliac, supramammary in female; superficial inguinal in male) are tissues of choice for culture, but additional body lymph nodes such as the mediastinal, bronchial, mesenteric, hepatic, suprascapular, prefemoral, and popliteal will enhance the sensitivity of bacteriologic culture. Fluid or suppurative material from affected joints of animals with lameness or joint enlargements should be aseptically collected and cultured. Occasionally the organism will be present in nontypical locations, such as bones or kidneys, and any lesions in animals suspected of having brucellosis should be sampled.

Samples for bacteriologic culture should be chilled to 4°C as soon as possible after collection and processed within 72 hours. If processing will be delayed, samples can be frozen at –20°C and stored for several months. *Brucella* sp. are slow growing and compete poorly with contaminant bacteria on commonly used media. In most cases, successful isolation requires specialized media and procedures; therefore, samples should be submitted to

a laboratory familiar with the isolation of *Brucella* sp.[3] Confirmation and biotyping of suspected *Brucella* isolates require specialized chemical reagents, bacteriophages, and antisera and are usually performed by a national or international reference laboratory.[3] Molecular procedures are being developed for the identification and biotyping of *Brucella* isolates.

Treatment and Control

There is no effective and economic antibiotic treatment for brucellosis in cattle, and none has been described for bison. *Brucella abortus* in bison is a reportable disease under national animal health programs and control is by whole herd depopulation or by quarantine, serologic testing, and slaughter.

Vaccines

Brucella abortus strain 19 is a live vaccine that is commonly used in cattle but offers limited protection against infection and abortion in bison. In addition to this, antibodies produced following vaccination with strain 19 are indistinguishable from those produced following field infection and are a confounding factor in serologic diagnosis. In one study, 58% of pregnant bison aborted following strain 19 vaccination, and one of these bison aborted a strain 19 infected calf during her subsequent pregnancy as well.[10] In another study, 61% of vaccinated bison became infected and 33% aborted following challenge with a virulent strain of *Brucella* (*B. abortus* strain 2308).[10] Female bison vaccinated as 8-month-old calves and challenged with *B. abortus* strain 2308 during their second trimester of pregnancy had an infection rate of 91% and an abortion rate of 75%.[23] Seventy-three percent of pregnant bison vaccinated with strain 19 remained positive on a least one serologic test 10 months after vaccination.[10]

Brucella abortus strain RB51 is also a live vaccine and was developed from a mutant strain of *B. abortus* strain 2308 that does not produce the lipopolysaccharide O side chain characteristic of the smooth brucellae. In cattle, this strain protects at least as well as strain 19, does not cause abortion, and does not induce the formation of detectable antibodies on standard serologic tests for brucellosis.[24,25] This vaccine has been approved for use in cattle in the United States. Strain RB51 vaccine is less pathogenic for bison than strain 19 vaccine and is cleared by 30 weeks without shedding or lateral transmission following calfhood vaccination.[26,27] As in cattle, RB51 in bison stimulates a specific cell-mediated immunity that does not interfere with standard serologic tests for brucellosis.[27] Pregnant bison may abort following vaccination using cattle doses, and vaccination of adult bull bison may result in transient shedding of strain RB51 in semen.[28,29] In a study using calfhood vaccination with RB51, 15% (4/27) of vaccinated bison aborted following challenge with *B. abortus* strain 2308 as compared to 62% (4/7) of control subjects.[30] There was a significant reduction in the recovery of strain 2308 from the uterus and mammary gland of the RB51-vaccinated animals. In the field, this would reduce the likelihood of both horizontal transmission via fluids associated with abortion or parturition and vertical transmission via milk. Based on these data, it has been suggested that calfhood vaccination with RB51 would be beneficial in reducing transmission of brucellosis among bison. The duration of immunity is unknown, and initial studies on the safety of revaccinating pregnant bison previously vaccinated as calves are not conclusive.[31]

Zoonotic Potential

All field strains of *Brucella* from bison and *B. abortus* strain 19 vaccine are pathogenic for humans. Vaccine strain RB51 is a rough mutant strain and is likely of low virulence for humans. This is based on the low pathogenicity of other rough species (*B. ovis* and *B. canis*) for humans and case reports of accidental exposure.[32] Until more field data on RB51 are available, it would be prudent to consider it a human pathogen.

NORTH AMERICAN ELK (*Cervus elaphus* subspp.)

Brucellosis in elk (wapiti) caused by *B. abortus* originated from contact with infected cattle and bison during the early 20th century.[33] *Brucella abortus* biovars 1 and 4 have been recovered from elk, and clinical signs and pathogenesis of elk brucellosis are similar to those seen in cattle and bison.[33] Confinement in pens or population concentrations on managed winter feeding grounds during periods when abortions are occurring provide the necessary conditions for transmission. Currently, brucellosis in elk due to *B. abortus* occurs only in the wild elk of the greater Yellowstone area of the United States, and control programs using vaccination and feeding ground–habitat modifications are being attempted.[33]

Epidemiology

Oral exposure is the primary route of infection. Under natural conditions female elk isolate themselves at calving and rapidly consume the products of parturition.[34] This strategy appears effective in preventing intraspecific transmission in wild populations. Elk on feedgrounds or in confinement have been observed to smell, lick, and consume products of parturition from other elk, including aborted fetuses and this provides ample opportunity to transmit the disease. Seventeen of 18 unexposed cow elk and 6 of 6 unexposed bull elk became infected following natural exposure to artificially infected elk, indicating that elk are highly susceptible to infection; and 33% to 100% of naturally or experimentally infected elk were shown to either abort or produce nonviable calves, demonstrating a mechanism for the dissemination of large numbers of organisms into the environment.[33,35] Three successive abortions were reported in one elk cow.[35] In addition to placental and fetal tissue, chorioallantoic fluid is considered a significant source of environmental contamination.[35] Vaginal shedding of *B. abortus* has been reported for up to 17 days following abortion or birth of nonviable calves, and positive vaginal cultures were obtained for up to 9 days following normal parturition in an infected elk cow.[35] The duration of infection under natural conditions is unknown. *B. abortus* has been recovered from experimentally infected elk 56 months after inoculation. Latent infections lasting 23 months (no clinical or serologic evidence of disease) were

observed in two elk cows after which they developed serologic titers and aborted, and latent infections probably occur in some calves born to infected dams.[35]

B. abortus has been recovered from the epididymis, seminal vesicles, ampullae, and semen of experimentally infected elk, but natural breeding of infected bulls to noninfected cows failed to transmit the disease.[35] Venereal transmission is not a significant epidemiologic factor in elk, and this is assumed to be for the same reasons as described for bison and cattle.

Brucella organisms were present in the milk of one of five lactating infected elk, indicating that some calves ingest *Brucella* organisms in milk.[35] The dose received and the effect of anti-*Brucella* colostral antibodies are complicating factors, and the importance of this route of infection among elk is unknown. Meconium from three nonviable calves contained *Brucella* organisms, but feces from calves nursing infected dams did not, and the authors concluded that environmental contamination from elk calf feces was not important.[35]

Historical evidence suggests that appropriate calving management under confinement conditions or the opportunity for female elk to exhibit normal isolation behavior at parturition is sufficient to prevent transmission of disease. Brucellosis was confirmed in the elk and bison of the greater Yellowstone area in the early 1900s, and it is generally agreed that it was present for some time before that. Between 1892 and 1967, over 14,000 wild elk from this area were either given or sold to a variety of private, corporate, and government organizations in 38 states and 3 countries.[36] It is likely that some of these animals had brucellosis, yet there are no reports of this disease in any of the destination herds. This is likely due to a combination of factors. The number of infected elk transported was probably low. Animals for public display were a novelty at their destination and were closely monitored. Under these conditions it is reasonable to assume that transmission was limited by the prompt removal of aborted fetuses or dead calves, and in many cases, by separation of the valuable pregnant females from the rest of the herd. Elk translocated for restocking or otherwise released under range conditions were able to mimic normal wild behavior at parturition and thus effectively block transmission. In contrast, the wild elk of the greater Yellowstone area have been concentrated in high numbers on managed winter feeding grounds. Under these conditions, detection and isolation of aborting females, effective removal of fetuses, and cleanup of contaminated sites is not possible prior to exposure of other elk, and this appears sufficient to maintain the disease in these herds.

Cattle have been infected with *B. abortus* from elk under experimental conditions.[33] In areas cohabited by bison, cattle, and elk, it should be remembered that the *B. abortus* strains infecting these species are indistinguishable and that interspecific transmission is possible (although unlikely unless calving or abortion occurs during cohabitation).

Pathogenesis

The pathogenesis of *B. abortus* infection in elk is as described for cattle and bison. Infection proceeds through four stages: mucosal infection, infection of local lymph nodes, bacteremia and secondary localization, and reproductive tract localization. A detailed description is contained in the preceding section for bison.

Clinical Signs

Abortions in the last 3 months of pregnancy and nonviable calves are the most common clinical signs in both naturally and experimentally infected elk. Fifty-four percent (7 of 13) naturally exposed elk and 61% (40 of 60) experimentally infected elk aborted or had nonviable calves.[33,35] Three consecutive abortions were observed in one elk cow; however, the frequency of repeat abortions under field conditions is unknown.[35] Gross lesions of the fetus have not been reported. Retained placentas occur in cattle and bison, but have not been observed in elk.[35] Infertility in cows is not a common sequela.

Clinical signs and gross lesions of orchitis, epididymitis, and seminal vesiculitis have not been observed in elk, although *B. abortus* was isolated from the epididymis, seminal vesicles, and ampullae of 4, 7, and 6 of 17 experimentally infected bulls, respectively.[35] All tissues of 6 of the 17 infected bulls in this group were negative on culture. There are no confirmed reports of infertility in bull elk associated with *B. abortus* infection.

Carpal bursitis (hygroma) was the second most frequently observed sign in infected elk.[35] It occurred in 12 of 65 elk with experimental infections of at least 1 month duration, although it is usually associated with more chronic infections. Distention was grossly apparent in some cases, and visible only on necropsy in others. This condition was not associated with lameness and often resolved spontaneously. Inflammation of synovial membranes and distention of joint cavities and tendon sheaths, often associated with severe lameness, occurred in 13 of 65 infected elk examined at necropsy.[35] *Brucella abortus* was isolated from the anterior and posterior fetlock, anterior and posterior flexor tendon sheath, and carpal, stifle, and hock joints of these animals.

Diagnosis

Brucellosis in elk caused by *B. abortus* should be considered as a differential diagnosis in cases of late stage abortion or lameness of unknown etiology. On a herd basis, brucellosis is easily diagnosed using serologic tests designed for use in cattle. On an individual animal basis, variations in test sensitivity and specificity from that seen in cattle may compromise test interpretation. Culture and recovery of the organism from suspected cases provides the only true definitive diagnosis.

Serology

A number of traditional serologic tests designed to detect brucellosis in cattle have been used for elk. The complement fixation test (CFT) and agglutination tests such as the standard plate agglutination test (SPT), buffered plate agglutination test (BPAT), and rivanol test (Riv) have been used successfully to detect infected elk.[37] Specificity data for elk are lacking for most of the traditional tests and therefore the incidence of false positive reactions is unknown. The CFT was the most sensitive of these tests,

but the anticomplementary activity frequently observed in serum from cervidae can cause inconclusive results. Indirect and competitive enzyme immunoassays (iELISA, cELISA), and the fluorescence polarization assay (FPA) have recently been validated for detection of *B. abortus* infection in elk and were compared with the CFT.[38] The sensitivity and specificity of the iELISA, cELISA, and FPA exceeded 99% for each test, and the FPA was able to correctly distinguish 84% of 55 *B. abortus* strain 19 vaccinated elk (4 months after vaccination) from infected elk. Test results using a commercially available cELISA kit were 98.6% specific for elk 6 months to 2 years after vaccination with *B. abortus* strain 19 and 100% sensitive in detecting infected animals.[39] However, in elk tested 15 to 43 days after vaccination, specificity dropped to 88%, and the authors suggest that the test not be used within 2 months of strain 19 vaccination.

In general, strong positive reactions on serologic assays are reliable indicators of exposure, particularly if reactions occur in a battery of tests and are present in a number of animals in a herd. However they do not necessarily mean that individual animals are harboring large numbers of the organism. Low level reactions must be interpreted with caution, particularly if they occur in only a few animals in otherwise serologically negative herds. For both herd and individual animal testing, the strength of a presumptive diagnosis of brucellosis increases with the number and magnitude of observed serologic responses.

Bacteriology

Recovery of *Brucella* organisms is required for a definitive diagnosis.[3] As for other hosts, the success of bacteriologic culture is dependent on the number, type, and quality of samples submitted; the experience of the diagnostic laboratory; and the duration of infection in the animal sampled. *Brucella abortus* is widely distributed in lymph nodes and organs of infected animals, but not necessarily in all these tissues. In chronic infections, only a few tissues may remain infected, and these may contain small numbers of the organism. A large selection of samples is required to maximize the sensitivity of bacteriologic culture. Sampling is as previously described for bison except that seminal vesicles and ampullae should be included for male elk.

Treatment and Control

There is no effective and economic antibiotic treatment for brucellosis in elk. *Brucella abortus* in elk is a reportable disease under national animal health programs and eradication is possible using a number of strategies including herd depopulation, isolation of dams at parturition, and serologic testing and slaughter. Since the only known infected elk herds are the wild herds in the greater Yellowstone area, these strategies are not economically or politically feasible. Instead, a program of vaccination and altered winter feeding management has been suggested to control the disease.[33]

Vaccines

Brucella abortus strain 19 is a live vaccine that offers incomplete protection against infection and abortion in elk.[40] Twenty-seven percent of mature elk vaccinated with a cattle dose of strain 19 aborted. Reduced doses (3.7×10^7 to 7.6×10^9) did not cause abortion or result in bacteremia, but 45% (19 of 42) of vaccinated elk and 69% (9 of 13) of nonvaccinated elk became infected following challenge. Sixty-two percent (23 of 37) of strain 19 vaccinates calved successfully as compared to 33% (3 of 9) of nonvaccinates. In a similar study using elk vaccinated as calves with strain 19 and subsequently challenged as pregnant adults, 29% of vaccinates (13 of 45) calved successfully as compared to 5% (2 of 44) of nonvaccinated control animals.[41] However, there was no difference in the number of infected fetuses/calves between the two groups. Simulations indicate that field vaccination of feedground elk with strain 19 is unlikely to reduce infection rates below 20%, and this is supported by limited field data from one herd showing a reduction in the rate of serologic reactions from approximately 46% to approximately 25% after 8 to 9 years of vaccination.[33,42]

Brucella abortus strain RB51, described above for bison, has been assessed as both an oral and intramuscular vaccine in elk.[43–47] Seroconversion does not occur on standard serologic tests for brucellosis, and bulls do not have grossly detectable reproductive lesions or shed the organism in semen. However, in various studies using pregnant elk previously vaccinated with strain RB51, 4 of 8, 5 of 7, 14 of 16, 12 of 16, 16 of 16, and 13 of 14 elk aborted or produced nonviable calves following challenge with *B. abortus* strain 2308.[43,44,46,47] Consequently, strain RB51 vaccine is not recommended for use in elk.

Zoonotic Potential

All field strains of *Brucella* from elk and *B. abortus* strain 19 vaccine are pathogenic for humans. Vaccine strain RB51 is a rough mutant strain and is likely of low virulence for humans. This is based on the low pathogenicity of other rough species (*B. ovis* and *B. canis)* for humans and case reports of accidental exposure.[32] Until more field data on RB51 is available, it would be prudent to consider it a human pathogen.

REINDEER AND CARIBOU (*Rangifer tarandus* subspp.)

Brucellosis in reindeer and caribou is caused by *Brucella suis* biovar 4 and is endemic in the circumpolar Arctic except for Scandinavia, Greenland, and the Canadian Arctic east of Hudson Bay. There is debate as to whether rangiferine brucellosis spread to North America across the Bering Sea land bridge during the last ice age, or if it was introduced in imported Russian reindeer around 1900.[48,49] The pathogenesis of rangiferine brucellosis is similar to that seen with brucellosis in other species but is characterized by a more pronounced granulomatous response, resulting in an increased severity and variety of lesions. Epidemiologically, the disease is similar to that seen in other species. It has been suggested that rangiferine brucellosis has a cyclic component and that latent infection may play an important role, but the existence and significance of this has yet to be determined.

Epidemiology

Oral exposure is the primary route of infection. Aborted fetuses, placentas, and uterine fluids from infected reindeer or caribou contain high numbers of *B. suis* biovar 4.[49,50] Infected females had 10^3 to greater than 10^5 organisms per gram of uterine tissue for at least the 4 weeks following calving or abortion.[50] Licking and nosing of aborted materials or the genital regions of females following abortion or parturition provides ample opportunity to transmit the disease. Females usually abort during the first parturition following infection, but successive abortions are uncommon.[49]

Reindeer and caribou bulls frequently have extensive reproductive tract pathology and shed the organism in semen. However, there is no evidence of venereal transmission, presumably for the same reasons previously described for bison and cattle. In one experiment, a female reindeer inoculated intravaginally with *B. suis* biovar 4 at 3.5 months of gestation calved successfully and had a live calf the following year as well.[48]

Mammary tissue or milk from infected females contained 10^3 to greater than 10^5 organisms per gram for at least 4 weeks following abortion or parturition.[50] Live calves born to infected dams are likely to ingest *Brucella* organisms in milk, but the dose received and the effect of anti-*Brucella* colostral antibodies are complicating factors. The importance of this route of infection in rangiferine species is unknown.

Cattle can become infected with *B. suis* biovar 4 if they are in contact with infected reindeer that are calving. Four of 8 cattle housed with 17 infected reindeer were cultured positive for *B. suis* biovar 4 58 days after the reindeer were removed from their pen.[50]

Pathogenesis

Suppurative lesions are observed more frequently and in a wider variety of tissues in reindeer and caribou than in other species infected with brucellosis.[49,51] The reason for this enhanced inflammatory response is unknown. Otherwise, the pathogenesis of brucellosis in reindeer and caribou is as previously described for bison. Infection proceeds through four stages: mucosal infection, infection of local lymph nodes, bacteremia and secondary localization, and reproductive tract localization.

Clinical Signs

Clinical signs usually involve the reproductive and musculoskeletal systems, and less commonly a variety of other tissues and organs.[49,51–53] Infected females may abort during the last 3 months of pregnancy, or give birth to weak or nonviable calves. Retained placentas and metritis may be present, and mastitis with abscessation of the mammary gland is frequently observed. In some cases of mastitis normal mammary tissue is almost entirely displaced by purulent exudate.

Infected males may have inflammatory lesions in the testicles, epididymides, seminal vesicles, and ampullae. In some cases, the scrotal sac may be grossly distended by swollen testicles or epididymides or by purulent exudate associated with orchitis and epididymitis. Reproductive capacity will be significantly reduced in males with severe bilateral orchitis and sterility is probably the final outcome.

Lameness associated with bursitis or synovitis may be present alone or in conjunction with other clinical signs. Carpal and fetlock joints are the most frequently involved, and affected joints may be grossly distended by serofibrinous or thick purulent exudate. Extension may occur into tendon sheaths and hooves and osteoarthritis may be present in chronic infections.

Abscesses in *Brucellosis*-infected reindeer and caribou often contain an odorless, thick, light green purulent material. In addition to the tissues listed above, abscesses or granulomas have been described in lymph nodes, liver, kidney, spleen. and subcutaneous tissues.

Diagnosis

Brucellosis in reindeer or caribou should be considered as a differential diagnosis in cases of late-stage abortion, testicular enlargement, low conception rate, lameness of unknown etiology, or the presence of suppurative lesions in any tissue. On a herd basis, brucellosis is easily diagnosed using serologic tests designed for use in cattle. On an individual animal basis, variations in test sensitivity and specificity from that seen in cattle may compromise test interpretation and there is evidence to suggest that some female reindeer and caribou with established infections may not be detected at certain stages of the disease.[50,54] Recovery of the organism from suspected cases provides the only true definitive diagnosis.

Serology

A number of serologic tests developed for use in cattle, including the buffered plate agglutination test (BPAT), rapid screening test, brucellosis card test (BCT), standard tube agglutination test (SAT), rivanol test, mercaptoethanol test, antiglobulin test (AGT), and complement fixation test (CFT), have been used successfully to detect rangiferine brucellosis.[50,55] In general, these tests have adequate sensitivity, particularly in acute infections, but fail to detect some animals with established infections. These animals may not be producing sufficient antibody for detection (latent infection), or the *B. abortus* antigen used in these tests (dominant A surface antigen) is not sufficiently sensitive to detect low levels of antibody produced in response to infection with *B. suis* biovar 4 (dominant M surface antigen). The CFT was the most sensitive of these tests, but the anticomplementary activity frequently observed in serum from cervidae may prevent testing of some samples. Specificity data for reindeer and caribou are not available for most of the traditional tests, and therefore the incidence of false positive reactions is unknown.

An indirect and competitive enzyme immunoassay (iELISA, cELISA) and a fluorescence polarization antibody test (FPA) have recently been validated for the detection of brucellosis in various cervids including *B. suis* biovar 4 infection in reindeer and caribou.[38] The sensitivity and specificity of the iELISA, cELISA, and FPA ranged between 98% and 100% for these tests. The FPA was recommended

as a test of choice because it was technically simple, adaptable for field use, and relatively inexpensive to perform.

For practical purposes, the deficiencies of individual serologic test procedures can be overcome by using a battery of different tests and, if necessary, conducting retests at 3- to 4-week intervals. In general, strong positive reactions on serologic assays are reliable indicators of exposure, particularly if reactions occur in a battery of tests and are present in a number of animals in a herd. However, they do not necessarily mean that individual animals are harboring large numbers of the organism. Low level reactions must be interpreted with caution, particularly if they occur in only a few animals in otherwise serologically negative herds. For both herd and individual animal testing, the strength of a presumptive diagnosis of brucellosis increases with the number and magnitude of observed serologic responses.

Bacteriology

Recovery of *Brucella* organisms is required for a definitive diagnosis. As for other hosts, the success of bacteriologic culture is dependent on the number, type, and quality of samples submitted, the experience of the diagnostic laboratory, and the duration of infection in the animal sampled. *Brucella suis* biovar 4 is widely distributed in lymph nodes and organs of infected reindeer and caribou, but not necessarily in all these tissues. In chronic infections, only a few tissues may remain infected and these may contain small numbers of the organism. A large selection of samples is required to maximize the sensitivity of bacteriologic culture. Sampling is as previously described for bison. In addition to tissues with lesions and a wide selection of lymph nodes, seminal vesicles and ampullae should be sampled from male reindeer and caribou. Suppurative material from any location should be cultured.

Treatment and Control

There is no effective and economic antibiotic treatment for brucellosis in reindeer and caribou.

Vaccines

Brucella suis biovar 4 (killed) vaccine is the only vaccine shown to be useful for reindeer.[56] A number of other vaccines have been tried, including *B. melitensis* H38 (killed), *B. abortus* strain 45/20 (killed), *B. abortus* strain 19 (live), and *B. abortus* strain RB51 (live). Four of five reindeer vaccinated with *B. melitensis* strain H38 (killed) and two of three control reindeer either aborted or had nonviable fawns following challenge with *B. suis* biovar 4.[57] One of six reindeer vaccinated with *B. abortus* strain 45/20 (killed) and two of four control reindeer either aborted or had nonviable calves following challenge.[55] Seven of 11 pregnant reindeer vaccinated with *B. abortus* strain 19 (live) and challenged with *B. suis* biovar 4 either aborted, had nonviable calves, or were nonpregnant at the end of the experiment.[58] *Brucella abortus* strain 19 vaccine alone induced abortions, caused long-term infections, and was shed into the environment in sufficient quantities to cause seroconversion in naive reindeer.[59] *Brucella abortus* strain RB51 does not interfere with standard serologic tests for brucellosis, which is a desirable characteristic for control programs. In a preliminary safety trial using RB51, 54.5% (12 of 22) pregnant reindeer cows aborted following vaccination, and this vaccine is not recommended for use in reindeer until additional evaluations are completed.[60]

Zoonotic Potential

Brucella suis biovar 4 can cause severe disease in humans and occurs most frequently in people from Arctic areas who are associated with the slaughter and consumption of caribou or reindeer. *B. abortus* strain 19 vaccine is pathogenic for humans. Vaccine strain RB51 is a rough mutant strain and is likely of low virulence for humans. This is based on the low pathogenicity of other rough species (*B. ovis* and *B. canis*) for humans and case reports of accidental exposure.[32] Until more field data on RB51 are available, it would be prudent to consider it a human pathogen.

RED DEER (*Cervus elaphus* subspp.)

Naturally occurring brucellosis in red deer caused by *Brucella ovis* was first reported in New Zealand in 1996.[61] The causative organism is identical to that causing brucellosis in sheep and the disease in red deer is similar, if not identical, to *B. ovis* infection in sheep. It primarily affects the male reproductive organs and can cause decreased fertility or sterility. It is believed that the disease spread from sheep to red deer, and this is supported by experimental transmission of *B. ovis* from infected rams to noninfected stags.[62] At present, this disease occurs only in New Zealand.

Epidemiology

Oral exposure of stags to infected semen during the rut is the primary mode of transmission.[63] Behavioral studies comparing the homosexual activity of rams and stags indicated that mounting and preputial sniffing and licking occurred less frequently in stags than in rams, but with sufficient frequency to facilitate transmission.[64] It was concluded that sniffing or licking of semen from the preputial area, or from the perineum after one stag has mounted another is a more important route of transmitting disease among stags than rectal copulation. It is presumed that spread from rams to stags takes place in the same fashion. Stag to stag and ram to stag infection studies have shown that animals must be confined together to facilitate transmission.[62,64] The disease was not transmitted under conditions where infected and noninfected stags were rotated through the same pasture or where infected and noninfected stags were separated by a common fence.[65]

Brucella ovis has not been identified as a source of reproductive failure in hinds. In sheep, ewes develop transient infections and can mechanically transmit the disease to clean rams, but do not transmit infection from one season to the next.[66] Experimental studies indicate a

similar situation likely exists with red deer.[67] Under field conditions, the rate of infection for hinds following mating with an infected stag, and the frequency of disease transmission to other stags during the same estrus, the next estrus, or in the following rut appears low, but requires further study.[68,69]

Pathogenesis

The pathogenesis of *B. ovis* infection in red deer is similar to that described for other hosts.[18] Infection proceeds through four stages: mucosal infection, infection of local lymph nodes, bacteremia and secondary localization, and reproductive tract localization. *Brucella ovis* infection is unique because lesions are usually limited to the male reproductive tract. The pathogenesis in stags is probably identical to that described for rams.[66] Localization of *B. ovis* in the epididymis causes perivascular edema and accumulation of lymphocytes, monocytes, and neutrophils in peritubular tissue. The tubular epithelium is eventually destroyed by bacteria or the inflammatory response resulting in an extravasation of spermatozoa. The host response to the spermatozoa leads to the formation of large spermatic granulomas that may completely block the epididymis and cause testicular degeneration and fibrosis.

Clinical Signs

Sperm samples may contain abnormal sperm and sperm may have decreased motility.[70] In severe cases, there may be frank pus in the sperm sample. Fertility may be decreased and some stags may be infertile. Testicular or epididymal lesions may be present, but they are generally small and difficult to detect on scrotal palpation. Clinical signs have not been reported in hinds.

On postmortem examination, suppurative or caseous testicular lesions up to 5 mm in diameter were observed in 10 of 15 stags cultured positive for *B. ovis*.[71] Granulomas and interstitial lymphoid cells were frequently seen on histologic examination.

Diagnosis

Brucellosis in red deer caused by *B. ovis* should be considered as a differential diagnosis in cases of male or apparent female infertility, orchitis, or epididymitis, or where abnormal sperm samples are observed. On a herd basis, the disease is easily diagnosed using serologic tests designed for *B. ovis* in sheep. Serologic tests to detect antibodies to *B. abortus, B. suis,* and *B. melitensis* will not detect antibodies to *B. ovis*. This is because the smooth (A and M) surface antigens of *B. abortus, B. suis,* and *B. melitensis* do not cross-react with antibodies produced against the rough (R) surface antigen of *B. ovis*. Serologic titers have been reported to recede more quickly in infected red deer than in sheep, and this may compromise test interpretation.[64] Culture and recovery of the organism from suspected cases provides the only true definitive diagnosis.

Serology

The complement fixation test for *B. ovis* is the recommended test and is considered highly sensitive in detecting acute infections. It had a specificity of 98.9% based on 183 known negative animals.[64] The gel diffusion test and ELISA test for *B. ovis* may also be used but may be less sensitive.[72] Because extensive validation data are not yet available for these tests, repeat testing, use of a battery of tests, and bacteriologic examination of semen would be prudent in questionable cases, such as a single serologically reacting animal in an otherwise negative herd.

In general, strong positive reactions on serologic assays are reliable indicators of exposure, particularly if reactions occur in a battery of tests and are present in a number of animals in a herd. However, they do not necessarily mean that individual animals are harboring large numbers of the organism. Low level reactions must be interpreted with caution, particularly if they occur in only a few animals in otherwise serologically negative herds. For both herd and individual animal testing, the strength of a presumptive diagnosis of brucellosis increases with the number and magnitude of observed serologic responses.

Bacteriology

Recovery of *Brucella* organisms is required for a definitive diagnosis. As for other hosts, the success of bacteriologic culture is dependent on the number, type, and quality of samples submitted, the experience of the diagnostic laboratory, and the duration of infection in the animal sampled. Based on the disease in sheep, *B. ovis* is probably widely distributed in lymph nodes and organs of infected deer, but not necessarily in all these tissues. In experimental infections of sheep it has been recovered from the liver, kidney, spleen, testicles, epididymides, vesicular glands, bulbourethral glands, ampullae, and iliac, prescapular, precrural, submaxillary, parotid, and retropharyngeal lymph nodes.[66] Since the target organs for *B. ovis* in deer appear to be the epididymides and accessory sex glands, they are the samples of choice for bacteriology, and semen is a useful sample to culture from a live animal. In chronic infections, and cases in which semen culture is negative but the animal remains seropositive, only a few tissues may remain infected and these may contain small numbers of the organism. A large selection of samples will maximize the sensitivity of bacteriologic culture. Sampling in addition to semen sampling should be done as previously described for bison.

Treatment and Control

Test, slaughter, and herd management techniques similar to those used for sheep in New Zealand have been recommended for the control and eradication of *B. ovis* in red deer.[63] Antibiotic treatment has not been evaluated. In sheep, streptomycin plus tetracycline, and dihydrostreptomycin plus oxytetracycline have been used to treat *B. ovis,* and similar regimens may prove useful for salvaging valuable stags.[69] Vaccination using live *B. melitensis* strain Rev. 1 is 74% to 100% protective against *B. ovis* infection in 3- to 5-month old rams but has not been advocated for use in red deer.[69]

Zoonotic Potential

Brucella ovis is not pathogenic for humans.

WHITE-TAILED DEER (*Odocoileus virginianus*) AND MULE DEER (*Odocoileus hemionus*)

Brucellosis does not naturally occur in white-tailed or mule deer. Experimental infections with *B. abortus, B. ovis,* and *B. suis* biovar 4 (rangiferine brucellosis) have been established in white-tailed deer.[73–76] Mule deer have been exposed to *B. abortus, B. suis,* and *B. neotomae* under experimental conditions, but infections have not been confirmed bacteriologically.[77] The possibility of interspecific transmission exists in places where white-tailed deer or mule deer are closely confined with other infected host species.

Epidemiology

White-tailed and mule deer are widely distributed across North America and have cohabited range with infected cattle and bison for decades. A single bacteriologically confirmed field case of *B. abortus* in a white-tailed deer was reported in 1964, but extensive serologic surveys before and after that time have consistently failed to provide evidence of infection with *B. abortus, B. suis,* or *B. melitensis* in deer populations.[78,79]

The few serologic surveys to detect *B. ovis* in white-tailed and mule deer were negative and there is no clinical or pathologic evidence of brucellosis caused by *B. ovis* in these species. In New Zealand, transmission of *B. ovis* from sheep to red deer has been observed, and once established in red deer, intraspecies transmission was similar to that observed in sheep. Experimental infections using *B. ovis* indicate that a similar situation is possible with white-tailed deer and contact spread of *B. ovis* from an infected to a noninfected buck in the same pen has been documented.[75]

White-tailed deer have been experimentally infected with *B. suis* biovar 4.[76] This biovar of *Brucella* normally occurs in reindeer and caribou in Arctic areas where geographic isolation provides a natural barrier to field exposure. Transmission of *B. suis* biovar 4 to a moose (*Alces alces*) under field conditions has been documented, and presumably transmission from reindeer and caribou to other deer species could occur if ranges overlap.[80] There is evidence to support latent infection in reindeer, and this could pose a transmission risk in places where game farmed reindeer and white-tailed/mule deer cohabit the same range.

There is no evidence to indicate that brucellosis is maintained in wild white-tailed or mule deer populations. Oral exposure is the primary route of infection and the browsing characteristics of white-tailed and mule deer under natural conditions probably limit their exposure to *Brucella* sp. by preventing contact with contaminated forage.[79] Under conditions of close confinement, it would be prudent to assume that the mechanisms for transmission of *B. abortus* and *B. suis* biovar 4 are similar to those described for bison, elk, and reindeer, and for *B. ovis*, similar to those described for red deer.

Pathogenesis

The limited experimental data indicate that the pathogenesis of brucellosis in white-tailed and mule deer is similar that described for bison, elk, and reindeer (*B. abortus*, *B. suis* biovar 4) or red deer (*B. ovis*).[73–77] Refer to the preceding sections for bison, elk, reindeer, and red deer.

Clinical Signs

Brucella abortus

No definitive clinical signs were reported in four white-tailed deer or the single mule deer experimentally infected with *B. abortus*, although there was a transient febrile response from days 8 to 15 in the mule deer.[73,74,77]

Brucella suis

Clinical signs were not observed in any of five male white-tailed deer experimentally infected with *B. suis* biovar 4, and no gross lesions were observed at postmortem examination 6 weeks after infection.[76] Four of the five deer were cultured positive for *B. suis* biovar 4 at necropsy. The organism was isolated from lymph nodes, liver, and spleen, but not from testes and epididymides. There are no data on clinical signs in females, intraspecific transmission, or long-term infections.

Brucella ovis

The clinical signs and lesions observed in nine male white-tailed deer experimentally infected with *B. ovis* were similar to those observed in sheep and red deer (see discussion of red deer) infected with the same organism.[75] Varying degrees of epididymal enlargement occurred, and in some cases there was adherence of the tunic to the epididymides and grossly visible cavitations containing creamy white exudate. Lesions were not always present. *Brucella* ovis was recovered from the normal appearing epididymides of a white-tailed buck on PID 429 and positive semen cultures were obtained on PID 102.[75] Intraspecific transmission occurred from an infected buck to an noninfected buck cohabiting the same pen.[75] There are no data on clinical signs in females; however, based on observations in other species infected with *B. ovis*, they are likely to be minimal.

Diagnosis

Brucellosis caused by *B. abortus*, *B. suis* biovar 4, or *B. ovis* is rare, if it occurs at all, in white-tailed and mule deer. However, if clinical signs include one or more of the following: abortion, stillbirth, abnormal sperm, testicular lesions, lameness, mastitis, or multiple granulomatous lesions in various tissues, and the etiology is unknown, brucellosis should be considered. When reviewing the history it is important to determine if affected deer were in contact with known host species for brucellosis such as bison, elk, cattle, reindeer, caribou, red deer, or domestic sheep.

Serology

Serologic tests for cattle have been used to detect antibodies to *B. abortus*, *suis,* or *melitensis* in white-tailed and mule deer but little or no validation data exist for their use in these species. Under experimental conditions standard plate and tube agglutination tests for cattle used on sera from white-tailed deer infected with *B. abortus* had serologic profiles similar to that seen in infected cattle, and the complement fixation test (CFT) was better than the serum agglutination test (SAT), card test, and rivanol test (Riv) for detecting white-tailed deer infected with *B. suis* biovar 4 (four of four bacteriologically positive deer detected).[73,74,76] A number of serologic assays have been evaluated in other cervids, such as elk and reindeer, and are good candidate tests for use in white-tailed and mule deer. The complement fixation test and agglutination tests such as the standard plate agglutination test (SPT), buffered plate agglutination test (BPAT), and rivanol test (Riv) were used to detect elk infected with *B. abortus*.[37] Indirect and competitive enzyme immunoassays (iELISA, cELISA), the fluorescence polarization antibody test (FPA), and the CFT were validated for detection of *B. abortus* infection in elk and *B. suis* biovar 4 infection in reindeer and caribou and had a sensitivity and specificity of ≥99% for each test.[38] It should be remembered that the anticomplementary activity frequently observed in serum from cervidae can cause inconclusive results on the CFT.

Serologic tests for cattle will detect antibodies to *B. abortus, suis,* and *melitensis*, but not to *B. ovis*. If testicular abnormalities are present and contact with sheep (or red deer) may have occurred, the complement fixation test for *B. ovis* should be conducted in addition to the other tests. In nine white-tailed bucks infected with *B. ovis*, the CFT correlated well with isolation results from the semen or epididymides, particularly in older bucks.[75] This is supported by data from red deer in which the CFT for *B. ovis* is considered highly sensitive in detecting acute infections and had a specificity of 98.9% based on 183 known negative animals.[64] The gel diffusion test and ELISA test for *B. ovis* may also be used, but validation data are not available for these tests in white-tailed or mule deer. In questionable cases, such as a single serologically reacting animal in an otherwise negative herd, repeat testing, use of a battery of tests, and bacteriologic examination of semen are advisable.

In general, strong positive reactions on serologic assays are reliable indicators of exposure, particularly if reactions occur in a battery of tests and are present in a number of animals in a herd. However, they do not necessarily mean that individual animals are harboring large numbers of the organism. Low level reactions must be interpreted with caution, particularly if they occur in only a few animals in otherwise serologically negative herds. For both herd and individual animal testing, the strength of a presumptive diagnosis of brucellosis increases with the number and magnitude of observed serologic responses.

Bacteriology

Recovery of *Brucella* organisms is required for a definitive diagnosis. As for other hosts, the success of bacteriologic culture is dependent on the number, type, and quality of samples submitted; the experience of the diagnostic laboratory; and the duration of infection in the animal sampled. *Brucella* organisms are widely distributed in lymph nodes and organs of infected animals, but not necessarily in all these tissues. In chronic infections, only a few tissues may remain infected, and these may contain small numbers of the organism. A large selection of samples is required to maximize the sensitivity of bacteriologic culture. Sampling is as previously described for bison except that seminal vesicles, bulbourethral glands, and ampullae should be included for white-tailed and mule deer bucks. Semen is a useful sample to culture, particularly if *B. ovis* is suspected.

Treatment and Control

Brucellosis in white-tailed and mule deer rarely, if ever, occurs under natural conditions, and no treatment or control programs exist. However, if these deer species are maintained in contact with infected hosts on managed ranges or under game farming conditions, interspecies transmission could occur. Control and treatment strategies would then be based on those developed for cattle, elk, and bison for *B. abortus*, reindeer for *B. suis* biovar 4, and red deer or sheep for *B. ovis*.

Zoonotic Potential

Brucella abortus and *B. suis* biovar 4 are pathogenic for humans. *Brucella ovis* is not a human pathogen.

MOOSE (*Alces alces*)

Experimental and field evidence indicate that *B. abortus* and *B. suis* biovar 4 cause a severe debilitating disease in moose, culminating in death.[80–86] Moose cohabiting areas with brucellosis-infected host species, such as cattle, bison, elk, reindeer, and caribou, are at risk of acquiring brucellosis. Live vaccines for brucellosis have not been tested on moose, and because of their apparent susceptibility to *Brucella* infection, inadvertent or purposeful exposure during routine vaccination programs for other species may cause clinical disease.

Epidemiology

Naturally occurring *B. abortus* infections in moose have been described on four separate occasions, three of which were associated with brucellosis-infected bison or cattle herds.[83–86]

Similarly, the single field case of *B. suis* biovar 4 infection in a moose was associated with infected caribou.[80] Moose and caribou are sympatric in northern areas of North America, and moose with antibodies to *Brucella* are occasionally found in these areas, further supporting occasional field exposure.[87] Moose are likely infected orally through the ingestion of forage or water contaminated with infected products of parturition from normal host species cohabiting the same range. The severe pathologic lesions observed in field and experimental infections and the low number and debilitated condition of field cases indicates that brucellosis in moose is probably

fatal and intraspecific transmission is rare or does not occur.

Pathogenesis

The pathogenesis of *B. abortus* and *B. suis* biovar 4 infection in moose is similar to that observed in the normal hosts for these species of *Brucella*, but the lesions are more extensive and severe.[81,82] The specific anti-*Brucella* cell-mediated immune response associated with protection in other hosts appears to be diminished in moose and results in high numbers of *Brucella* bacteria in tissues and an associated endotoxemia.[81] Experimentally infected moose had a prolonged bacteremic phase (≥166 days for *B. abortus* and ≥103 days for *B. suis* biovar 4) and their lymph nodes frequently contained greater than 4×10^4 bacteria per gram.[81,82] There are no data on the reproductive effects of brucellosis in moose, but considering their susceptibility, it is likely that abortion, orchitis, epididymitis, and other reproductive disorders can occur with a pathogenesis similar to that observed in other species. A variety of lesions occurred in moose experimentally infected with *B. abortus*.[81] Lymph nodes were consistently involved. They varied in size from grossly normal to markedly enlarged. Lesions ranged from mild to moderate follicular hyperplasia with low numbers of giant cells in the sinusoids and subcapsular sinuses to severe follicular hyperplasia, edema, congestion, fibrin deposits within distended subcapsular sinusoids, foci of hemorrhage and cortical necrosis, thrombi, and increased numbers of macrophages and giant cells. Fibrin and fibrous tags were often present on the pulmonary pleura, omentum, various abdominal organs, and in carpal joints. Liver enlargement sometimes occurred, and foci of necrosis and hemorrhage were often present on the capsule. Multiple small foci of necrosis in the hepatic parenchyma and cuffs of macrophages and lymphocytes around the portal triads were present on histologic examination in some cases. Carpal joints were the only affected joints. Lesions in the synovium included hyperemia, hemorrhage, and fibrosis, and fibrin on the surface. Villus hypertrophy and pannus formation were observed. Joint fluid varied from amber-colored to clear, yellow viscous fluid in increased volume. Similar carpal lesions were described in the single field case of *B. suis* biovar 4.[80]

Clinical Signs

Clinical signs did not occur in any of the three moose heavily infected with *B. abortus* and killed at day 70 (two moose) and day 166 (one moose) after infection, which was remarkable considering the extremely high tissue load of *Brucella* in these animals.[81] A fourth *B. abortus*–infected moose with a similar bacterial load exhibited weakness and depression for only 24 hours before dying of acute endotoxic shock 85 days after infection.[81] A single moose infected with *B. suis* biovar 4 was anorexic, depressed, and had a body temperature elevation from 38° to 39.5°C from day 42 to 58 after infection, after which it returned to normal.[82] In four field cases of brucellosis in moose the animals were described as thin, weak, and having abnormal behavior.[83–86]

Clinical Pathology

Clinical chemistry and hematology were not remarkable in four moose experimentally infected with *B. abortus* and did not predict the onset of clinical signs and death or indicate the persistent bacteremia present.[81] It was not until 24 hours before death that one of these moose had clinical pathologic values consistent with endotoxemia and systemic collapse. One week prior to death, this moose had a rise in white blood cell count from 6.2 to 11.5×10^9 cells/L, but the relative proportion of cells in the differential count remained unchanged and this was within the normal range for cattle. A similar rise was seen at day 55 in a single moose infected with *B. suis* biovar 4.[82] It was not associated with clinical signs and was maintained until the moose was killed on day 103.

Diagnosis

Brucellosis should be ruled out when sick, debilitated, or dead moose are encountered in areas where known host species for brucellosis occur. Currently available vaccines for brucellosis have not been evaluated for use in moose, and exposure to live vaccines for brucellosis, such as *B. abortus* strain 19, could cause clinical disease.

Serology

The common serologic tests used for cattle will detect *B. abortus* and *B. suis* biovar 4 infection in moose. Experimentally, there is individual variation in postexposure seroconversion, but by day 21 after infection most moose have a significant response using cattle criteria for interpretation.[81,82] One heavily infected moose did not have a positive CFT result until 43 days after infection.[81] Once seroconversion occurs, antibody titers are maintained at high levels on all tests.[81,82]

Bacteriology

Bacteriologic findings are as described for bison. The organism is present in large numbers in a variety of tissues and is readily cultured. Blood contains much lower numbers of bacteria than lymph nodes, but the prolonged bacteremia makes whole blood a useful sample for a definitive diagnosis of brucellosis in live moose.

Treatment and Control

Antibiotic treatment has not been attempted in moose and the commonly used cattle vaccines (strain 19 and RB51) have not been evaluated for efficacy in moose. Cattle vaccines have either caused disease or been ineffective when used in other species, and this makes them poor candidates for use in moose.[88] At present, the most effective control method would be to ensure that moose do not cohabit range with known infected host species.

Zoonotic Potential

Brucella abortus and *B. suis* biovar 4 are pathogenic for humans. The high bacterial load in the tissues of infected moose poses a significant zoonotic risk to persons

butchering or conducting postmortem examinations on these animals.

OTHER DEER SPECIES

Axis deer (*Axis axis*) appear highly susceptible to experimental infection with *B. abortus*.[89] Thirty days after infection four axis deer had positive results on serologic tests used for cattle, as well as widespread distribution of the organism in tissues, and in milk from a lactating female. The course of infection after 30 days is unknown, but the strong serologic response, systemic involvement, and lack of field survey evidence of disease despite opportunities for exposure suggest that the disease in axis deer may be similar to that seen in moose.

Brucella abortus was isolated from two of 126 roe deer (*Capreolus capreolus*) in Switzerland (reported in 1964), but there have been no reports of brucellosis in roe deer since that time.[90] Serologic surveys for brucellosis have included fallow deer (*Cervus dama*), Japanese deer (*Cervus nippon)*, Muntjac deer (*Muntiacus reevesi*), Chinese water deer (*Hydropotes inermis*), roe deer, pampas deer (*Ozotocerus bezoarticus*), and sambar deer (*Cervus unicolor*).[79,91,92] Titers were rarely demonstrated, and when they occurred, they were usually low. Many of the survey titers were probably nonspecific, as the surveillance tests used were designed for cattle and their specificity in deer is unknown. It is likely that most species of deer are susceptible to brucellosis if appropriate conditions of exposure are met, but these conditions and the progression of disease will likely vary. In places where deer cohabit areas with known infected hosts for brucellosis, abortion, infertility, stillbirths, weak calves, and testicular lesions may indicate brucellosis and should be considered in a differential diagnosis. A wide variety of other lesions, such as those described for reindeer and moose, may also be present and provide additional clinical evidence. It should be remembered that the current serologic tests for *B. abortus, suis*, and *melitensis* will not detect exposure to *B. ovis* and vice versa. In general, the serologic and bacteriologic tests for diagnosis are the same as those previously described for other cervids.

CHAPTER 141

Other Reproductive Diseases of Deer and Bison

JERRY C. HAIGH

Comprehensive information about reproductive abnormalities in deer and bison is not yet available. In this chapter an attempt is made to collate reports form a variety of sources. Some information comes from published literature or the author's own records, but the advent of two list servers, Deermail and ElkMed, has allowed correspondence between farmers and scientists, and some of the information presented here was supplied by several correspondents. It is likely that as time progresses more conditions will be recognized.

INFERTILITY OR SUBFERTILITY

Infertility has been seen following recovery from epizootic hemorrhagic disease in white-tailed deer bucks. These animals also showed external evidence of infertility, as they did not clean the velvet from their antlers and essentially became physiologic castrates.[1]

A variety of sperm defects, similar to those in other species, have been detected in red deer, wapiti, and fallow deer, as well as bison, but there is little work on these defects and their possible relationship to infertility or subfertility.[2] A high proportion of knobbed acrosomes has been observed in a single infertile wapiti stag,[3] and a stump-tail defect that caused infertility and was carried in the female line has been seen, also in wapiti.[4]

Cases of subfertility or infertility have been observed in fallow bucks. In two cases only 5% to 10% of does joined produced fawns, and this was not associated with abortion or other disease entities.[5] Similar unexplained fertility reduction has been seen in white-tailed deer and wapiti. In a herd of white-colored red deer studied over 12 years reproductive rates were below 50%, which was considered to be related to inbreeding.[6]

CONGENITAL DEFECTS

Several congenital defects have been reported. Freemartinism has been reported in red deer, wapiti, and reindeer and in *Cervus* has become more prevalent since the advent of artificial breeding and the use of synchronization techniques that often lead to twinning.[7] Gonadal hypoplasia, brachygnathia, absence of active teats, and intersex cases have been reported. In female fallow and axis deer the following conditions have been seen: nabothian cysts in cervix blocking patency, cystic ovaries (parovarian cysts), pyometra, metritis, and mastitis.

In a 12-year study of red deer in the Czech Republic, and in numerous subsequent instances at the same facility, a variety of reproductive anomalies have been seen.[8,9] Many of these were thought to be associated with specific genetic anomalies in an inbred herd of white-colored red deer.[6,8,9] There were 56 perinatal deaths associated with 176 births, but in only 3.4% (6 animals) could morphologic defects be seen on gross examination. The malformations included anophthalmy (1 case), termination of the digestive tract into the vagina (1), undeveloped anus (1), and shortened legs to about 50% of normal height. There have been numerous cases of brachygnathia, which did not compromise survival.[10]

TRAUMA

A few cases of classic "broken penis" in wapiti, similar to the condition known in cattle, have been reported by clinicians subscribing to the "ElkMed and "Deermail" list servers.[11,12] In one of these, semen collection via electroejaculation was still possible.

Anal intromission during mating leading to death of the hind in one case, and prolonged evidence of pain in another, has been reported in wild red deer.[13] The author has records of a case in which a wapiti stag, penned with a group of four white-tailed deer females in a small enclosure, attempted to mate them and caused extensive internal trauma and death in each of them.[3]

An unusual incidence of rupture of the suspensory ligament of the udder occurred in three white-tailed deer that were held in a drop-floor chute for a few minutes shortly after their fawns were weaned. One animal died acutely after rupturing the mammary artery. In this animal and one other extensive hemorrhage undermined the skin on both hind legs below the stifle joints as far down as the hocks (Fig. 141-1). In the third animal the hemorrhage was not as severe.[3] Deer are routinely handled in such chutes for a variety of purposes, with no ill effects. It was hypothesized that in this case the animals struggled in the chute, thrashing their legs back and forward, damaging the distended udders, which had not been suckled for 24 hours.

In a 15-year study of penned red deer in the Czech Republic, infanticide by incoming males was demonstrated. It was considered that the males thereby improved the fecundity of the females that they were associated with because those females did not have to

nurse dependent young and so gained in body condition and had improved chances of conceiving during the rut.[14]

DISEASES OF THE REPRODUCTIVE TRACT

Two widely recognized sporadic conditions of wapiti, of unknown etiology, are ulceration of the vestibule and posterior vagina and ulceration of the prepuce[2] (Figs. 141-2 and 141-3). It is tempting to think that they may be related, and possibly even a venereal condition, but no confirmation of this hypothesis has been achieved. Attempts at isolation of several different pathogens have not provided a reliably reproducible etiologic agent.

Another theory of causation of this condition proposes that it may be due to chemical burning of the mucous membranes due to excessive protein in the diet and renal excretion of ammonia. The author has seen this condition in males that had been on a 13% protein diet for several weeks and considers this hypothesis of causation unlikely, but there is no clearly demonstrated etiology.

In the female the condition has most often been seen when animals are being synchronized for artificial breeding, and the lesions appear as shallow ulcers varying in size up to as much as 1 cm in diameter. They may be covered in a diphtheritic membrane, and may coalesce if numerous.

In females the condition appears to be self-limiting, and there is no evidence that it causes infertility. It is in the male that the condition is more commonly seen, because it can progress to balanitis with marked swelling of the distal prepuce and secondary bacterial infection. If detected early it is possible that hydrotherapy and the administration of antibiotic may help in clearing up the condition. However, it is often the case that the condition is seen when the animals are in rut, when they are extremely aggressive, making frequent hydrotherapy dangerous for both handler and patient.

Fig. 141-3 Posthitis in a wapiti stag. The preputial tip is swollen and has become infected and necrotic. (Photograph by Colin Mackintosh; from Haigh JC, Hudson RJ: *Farming wapiti and red deer.* St. Louis: Mosby, 1993.)

Many cases in males are seen when there is some degree of preputial prolapse, often accompanied by swelling and bacterial infection. Because of the dependent position of the distal prepuce these cases are seldom resolved with simple measures, and require amputation of the affected portion. This can be accomplished surgically or with the use of compression. For the latter the animal is restrained in a chute. The mucus membrane is exteriorized until healthy tissue is found on the inner surface, and then the compression ring is applied. At least three materials have been used. Tight bandage or a rubber castrating ring has been placed over the tissue while a large syringe case (its end cut off) was held in the lumen of the sheath, or equipment designed to deal with rectal prolapse (Callicrate Smart Bander, No-bull Enterprises, St. Francis, Kansas) was used. After a few days the affected part, which has undergone ischemic necrosis, falls away and recovery is usually complete.

A disease of European bison (*Bison bonasus*) that is characterized by a chronic necrotizing inflammation of

the prepuce and penis has been observed since 1980.[15] More than 30% of male bison in the population were affected in 1997. The histologic and microbiologic results indicate a necrobacillosis with *Fusobacterium necrophorum* as the etiologic agent. The authors suggest that there are probably a variety of factors contributing to the etiology and pathogenesis, and presumably several agents are involved and interact synergistically. This condition has not been reported in North American bison.[15]

Five cases of phimosis, all in related axis deer (*Axis axis*) in a zoo, have been observed. One was treated surgically.[16]

Necrosis of the distal part of the penis has been seen in two red deer. Clinical signs in one of these included severe abdominal pain, and ataxia and paresis of the hind limbs. Pathologic examination showed necrosis of the distal part of the penis, with marked swelling.[16]

MISCELLANEOUS

The author has seen two cases of mummified fetus in wapiti and one in a moose. The moose mummy was delivered within minutes of the birth of a normal, live calf. Both wapiti cases were resolved by the use of two doses of prostaglandin $F_{2\alpha}$ given 30 days apart. In one closely observed instance a vaginal discharge of mucopurulent material occurred over several days after the second injection. The animal did not conceive the following autumn, but went on to calve in subsequent years.[3]

Urinary calculi leading to urethral occlusion has been seen in wapiti at the Western College of Veterinary Medicine. Treatment by urethrotomy alleviated the condition, but is not likely to be of any long-term use. In cattle, treated cases soon proceed to slaughter. In wapiti any thought of keeping the animal for the production of velvet antler in future years has to be tempered by the fact that long-term survival is not likely.

Neoplastic conditions are occasionally seen.

An outbreak of an acute disease of the udder was seen in Mongolian reindeer in the late summer of 2004. Seventeen cases that involved the development of numerous pox-like lesions on the hairless ventral portion were seen (Fig. 141-4). These animals were being milked at the time, and some of the herders developed similar lesions on their hands. A single biopsy was taken from the edge of a fresh lesion, but unfortunately, no diagnosis was possible. Most of the animals were treated conservatively with the application of a zinc-oxide paste. The lesions regressed over the course of about 2 weeks, and no further cases have been reported by the herders.[17]
