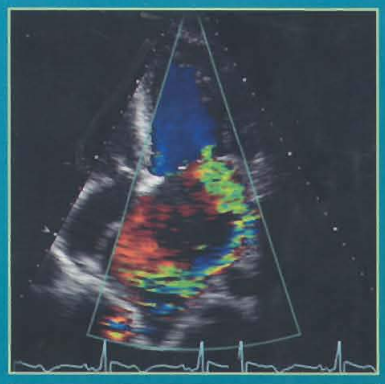
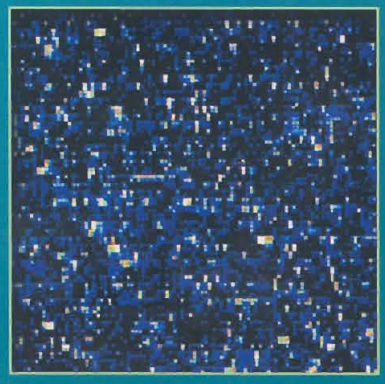
Textbook of CRITICAL CARE

FIFTH EDITION





Mitchell P. Fink
Edward Abraham
Jean-Louis Vincent
Patrick M. Kochanek

مرکز خدمات فرهنگی سالکان

همگام با توسعه علمی و فرهنگی جهان معاصر و استفاده روزافزون کامپیوتر در بین جوامع بشری خصوصاً رشته‌های مختلف علوم و استفاده بهینه از آخرین یافته‌های پزشکی دنیا و ارائه این یافته‌ها در قالب نرم‌افزارهای پزشکی (*ebook* ، *VCD* ، *DVD* ، *VHS* و ...) ما را بر آن داشت که با گردآوری و ارائهٔ این یافته‌ها گامی کوچک در راه ارتقاء سطح علمی متخصصین کلیه رشته‌های پزشکی کشور به صورت سمعی و بصری برداریم. امید است مشوق ما در این راه باشید.

لذا علاقمندان می‌توانند برای دریافت هر یک از محصولات ارائه‌شده به ازاء هر *CD* مبلغ ۵۰۰۰ تومان به حساب جاری ۱۳۲۴۳۶ بانک رفاه کارگران شعبه میدان انقلاب کد شعبه ۱۱۲ به نام مرکز خدمات فرهنگی سالکان واریز و پس از فاکس فیش فوق به همراه نشانی دقیق نسبت به خرید اقلام و دریافت کالای مورد نظر خود اقدام نمایند.

لازم به ذکر است در صورت نیاز به هرگونه اطلاعات تکمیلی می‌توانید به نشانی مرکز مراجعه و یا با تلفن زیر تماس حاصل نمایید.

نشانی مرکز: تهران، میدان انقلاب – خ کارگر جنوبی – خ لبافی‌نژاد بین کارگر و جمالزاده بن‌بست سیمین پلاک ۳۳۹

TEXTBOOK OF CRITICAL CARE ISBN 0-7216-0335-1

NOTICE

Critical care is an ever-changing field. Standard safety precautions must be followed, but as new research and clinical experience broaden our knowledge, changes in treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current product information provided by the manufacturer of each drug to be administered to verify the recommended dose, the method and duration of administration, and contraindications. It is the responsibility of the treating physician, relying on experience and knowledge of the patient, to determine dosages and the best treatment for each individual patient. Neither the publisher nor the editor assumes any liability for any injury and/or damage to persons or property arising from this publication.

DEDICATION

To my beloved wife, Jan, and my two wonderful children, Emily and Matt, for tolerating my long hours away from home; and to my wonderful parents, Walter and Betty Fink, for providing me with a stable and supportive environment during my formative years.

–Mitchell P. Fink

To Norma-May, the love of my life, and to Claire and Erin, who bring me the greatest joy each day.

–Edward Abraham

To Hac and Amélie, hoping for better care of the critically ill throughout the world.

–Jean-Louis Vincent

To my parents, Stella and Julius Kochanek, for leading by example on the value of hard work; to my wife, Denise, and my children, Ashley, Stanton, and Jillian, for their many sacrifices; and to the late Dr. Peter Safar, for encouraging each of us to bring promising new therapies to the bedside of the critically ill.

–Patrick M. Kochanek

CONTRIBUTORS

Edward Abraham, MD
Roger Sherman Mitchell Professor of Pulmonary and Critical Care Medicine; Vice Chair, Department of Medicine; Head, Division of Pulmonary Sciences and Critical Care Medicine, University of Colorado Health Sciences Center, Denver, Colorado
Regulation of Gene Expression

Kareem Abu-Elmagd, MD
University of Pittsburgh Health System, Pittsburgh, Pennsylvania
Intestinal and Multiple Organ Transplantation

Yasir Abu-Omar, MB, ChB
Department of Cardiothoracic Surgery, MRI of the Brain, John Radcliffe Hospital, Oxford, United Kingdom
Atheromatous Embolization

Carlos Agustí, MD, PhD
Consultor, Servei Pneumologia, Hospital Clinic, Barcelona, Spain
Pulmonary Infections in the Acute Immunocompromised Patient

William C. Aird, MD
Department of Medicine, Beth Israel Deaconess Medical Center and Harvard Medical School, Boston, Massachusetts
Thrombocytopenia; Coagulopathy

Louis H. Alarcon, MD
Assistant Professor, Departments of Critical Care Medicine and Surgery, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania
Paracentesis and Diagnostic Peritoneal Lavage

Jorge E. Albina, MD
Professor, Brown University School of Medicine; Director, Division of Surgical Research, Department of Surgery, Rhode Island Hospital, Providence, Rhode Island
Apoptosis in the Critically Ill

Rakesh Alva, MD
Fellow in Critical Care Medicine, Department of Critical Care Medicine, Montefiore Medical Center, Albert Einstein College of Medicine, Bronx, New York
Disaster Medicine for the ICU Physician

Derek C. Angus, MD, MPH
Professor of Critical Care Medicine and Health Services Administration, and Vice-Chair of Research, Department of Critical Care Medicine, University of Pittsburgh, Pittsburgh, Pennsylvania
Evidence-Based Critical Care

Nicole T. Ansani, PharmD
Clinical Education Consultant, Pfizer, Inc., Pittsburgh, Pennsylvania
Principles of NSAID Therapy in Critical Care Medicine

Massimo Antonelli, MD
Associate Professor of Intensive Care and Anesthesiology and Director, General Intensive Care Unit, Policlinico Universitario A. Gemelli, Universita Cattolica del Sacro Cuore; Associate Editor of *Intensive Care Medicine*, Rome, Italy
Fiberoptic Bronchoscopy

Anastasia Antoniadou, MD, PhD
Lecturer of Internal Medicine, Athens University Medical School; Infectious Diseases Specialist and Attending Physician, 4th Department of Internal Medicine, Attikon University General Hospital, Athens, Greece
Infectious Endocarditis

Anupam Anupam, MBBS
Attending Physician, Department of Medicine, Advocate Illinois Masonic Medical Center, Chicago, Illinois
Sudden Deterioration in Neurologic Status

Andrew Charles Argent, MD
Associate Professor, Division of Paediatric Critical Care and Children's Heart Disease, School of Child and Adolescent Health, University of Cape Town; Medical Director, Paediatric Intensive Care, Red Cross War Memorial Children's Hospital, Cape Town, South Africa
Metabolic and Endocrine Crises in the Pediatric Intensive Care Unit

John H. Arnold, MD
Associate Professor, Department of Anesthesia (Pediatrics), Harvard Medical School; Associate Director, Medical Surgical ICU, Children's Hospital; Medical Director, Department of Respiratory Care, Children's Hospital, Boston, Massachusetts
Acute Parenchymal Disease in Infants and Children

Vicente Arroyo, MD
Professor, Department of Medicine, University of Barcelona; Chief of Liver Unit, Hospital Clinic; Research Member, IDIBAPS, Barcelona, Spain
Hepatorenal Syndrome

Karen Ashworth, MD
Senior Registrar in Anesthesia and Intensive Care, Chelsea and Westminster Hospital, London, United Kingdom
Bedside Pulmonary Artery Catheterization

Mark E. Astiz, MD
Professor of Medicine, New York Medical College; Chief, Section of Critical Care Medicine, Saint Vincent's Hospital, New York, New York
Pathophysiology and Classification of Shock States

Todd L. Astor, MD
Assistant Professor of Pediatrics; Medical Director, Lung Transplant Program; Assistant Professor, Section of Pulmonary Medicine, Columbus Children's Hospital, The Ohio State University, Columbus, Ohio
Oxidative Lung Injury

Alfred Ayala, PhD
Professor, Brown University School of Medicine, Division of Surgical Research, Rhode Island Hospital, Providence, Rhode Island
Apoptosis in the Critically Ill

Iyad M. Ayoub, MD
Research Instructor, Department of Medicine, Rosalind Franklin University of Medicine and Science, North Chicago Veterans Affairs Medical Center, North Chicago, Illinois
Transvenous and Transcutaneous Cardiac Pacing

Élie Azoulay, MD, PhD
Service de Réanimation Médicale, Hôpital St. Louis, Paris, France
Specific Facets of Managing Neutropenic Cancer Patients in the Intensive Care Unit; Hematologic Malignancies in the Intensive Care Unit; Organ Toxicity of Cancer Chemotherapy

David B. Badesch, MD
Professor of Medicine, Clinical Director, Pulmonary Hypertension Center, Division of Pulmonary Sciences and Critical Care Medicine, University of Colorado Health Sciences Center, Denver, Colorado
Pulmonary Hypertension

Anna Kathryn Baer, MD
Fellow in Cardiovascular Medicine, Department of Internal Medicine, Division of Cardiology, University of Virginia Health System, Charlottesville, Virginia
Acute Coronary Syndromes: Pathophysiology and Diagnosis

Omer A. Bajwa, MD
Senior Fellow, Department of Critical Care Medicine, University of Pittsburgh; Pulmonary Fellow, Department of Pulmonary Medicine, Allegheny General Hospital, Pittsburgh, Pennsylvania
The Management of Gastrointestinal Bleeding

Marie R. Baldisseri, MD
Associate Professor of Critical Care Medicine, University of Pittsburgh School of Medicine; Medical Director, Intensive Care Unit, Magee-Women's Hospital, Pittsburgh, Pennsylvania
Cardiovascular and Endocrinologic Changes Associated with Pregnancy; Hypertensive Disorders in Pregnancy; Postpartum Hemorrhage

Zsolt Balogh, MD
Assistant Professor, Department of Traumatology, University of Szeged, Hungary
Abdominal Compartment Syndrome

Rasheed A. Balogun, MD
Assistant Professor of Medicine, Division of Nephrology, University of Virginia; Medical Director, Renal Unit and Extracorporeal Therapies, University of Virginia Health Systems, Charlottesville, Virginia
Lithium

Vishal Bansal, MD
Chief Resident, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania
Ileus; Diarrhea; Ileus and Mechanical Small Bowel Obstruction

Joel Edward Barbato, MD
General Surgical Resident, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania
Thrombolytics

Carol A. Barch, MN, CRNP, CNRN
Program Coordinator, Stroke Institute, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania
Management of Acute Ischemic Stroke

Philip Steven Barie, MD
Professor of Surgery and Public Health, Departments of Surgery and Public Health, Weill Medical College of Cornell University, New York, New York
Peritonitis and Intra-abdominal Abscess

Brendan J. Barrett, MB, MSc, MRCPI, FRCPC
Professor of Medicine, Division of Nephrology and Clinical Epidemiology Unit, Memorial University of Newfoundland; Active Staff, Internal Medicine and Nephrology, Health Care Corporation of St. John's, St. John's, Newfoundland, Canada
Contrast Dye-Induced Nephropathy

John G. Bartlett, MD
Professor of Medicine, Department of Medicine, Johns Hopkins University School of Medicine; Chief, Infectious Diseases, Johns Hopkins Hospital, Baltimore, Maryland
Clostridium difficile *Colitis*

Robert H. Bartlett, MD
Professor, Department of Surgery; Director, Surgical Intensive Care Unit; Division Chief, Critical Care, University of Michigan Health Systems, Ann Arbor, Michigan
Extracorporeal Life Support

Sarice L. Bassin, MD
Clinical Assistant Professor, The Queens Medical Center, Neuroscience Center, Honolulu, Hawaii
Seizures in the Critically Ill; Lumbar Puncture; Intracranial Pressure Monitoring

Daniel G. Bausch, MD, MPH
Associate Professor, Department of Tropical Medicine, Tulane School of Public Health and Tropical Medicine, Department of Medicine, Section of Infectious Diseases, Tulane University School of Medicine, New Orleans, Louisiana
Malaria and Other Tropical Infections in the Intensive Care Unit

Hülya Bayır, MD
Assistant Professor, Department of Critical Care Medicine, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania
Key Issues in Pediatric Neurointensive Care

David T. Bearden, PharmD
Clinical Assistant Professor, Department of Pharmacy Practice, College of Pharmacy, Oregon State University, Portland, Oregon
Macrolides

Yanick Beaulieu, MD
Fellow, Department of Critical Care Medicine, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania
Bedside Ultrasonography

Gregory J. Beilman, MD
Associate Professor, Department of Surgery and Anesthesia, University of Minnesota; Director of Surgical Critical Care, Fairview University Medical Center, Minneapolis; Director of Trauma Research, North Memorial Health Center, Robbinsdale, Minnesota
Management of Patients with Kidney, Pancreas, or Kidney-Pancreas Transplantation

Giuseppe Bello, MD
Research Fellow, Istituto di Anestesiologia e Rianimazione, Policlinico Universitario A. Gemelli, Universita Cattolica del Sacro Cuore, Rome, Italy
Fiberoptic Bronchoscopy

Rinaldo Bellomo, MBBS, MD, FAACP, FRACP
Associate Professor, Department of Intensive Care, Austin and Repatriation Medical Centre, University of Melbourne, Heidelberg, Melbourne, Australia
Renal Replacement Therapy in the ICU

E. David Bennett, MD
Professor of Intensive Care Medicine, Department of Intensive Care, St. George's Hospital, London, United Kingdom
Hemodynamic Monitoring

Tomas Berl, MD
Professor of Medicine, Department of Medicine, and Head, Division of Renal Disease, University of Colorado, Denver, Colorado
Disorders of Water Balance

Gordon R. Bernard, MD
Professor of Medicine, Allergy, Pulmonary and Critical Care Medicine, Vanderbilt University Medical Center, Nashville, Tennessee
Acute Lung Injury and Acute Respiratory Distress Syndrome

Anatole Besman, MD
Assistant Professor of Surgery, University of Connecticut School of Medicine, Hartford Hospital, Hartford, Connecticut
Pelvic and Major Long Bone Fractures

Joost Bierens, MD
Department of Anesthesiology, VU University Medical Center; Professor of Emergency Medicine, Medical Commission International Life-Saving Federation; Advisory Board Member Maatschappij tot Reding van Drenkelingen, Amsterdam, The Netherlands
Drowning

Walter L. Biffl, MD
Chief, Division of Trauma and Surgical Critical Care, Rhode Island Hospital; Associate Professor of Surgery, Brown University School of Medicine, Providence, Rhode Island
Apoptosis in the Critically Ill; Thoracic Trauma

Thomas P. Bleck, MD, FCCM
Louise Nerancy Eminent Scholar in Neurology and Professor of Neurology, Neurological Surgery, and Internal Medicine, and Director, Neuroscience Intensive Care Unit, University of Virginia, Charlottesville, Virginia
Seizures in the Critically Ill; Neuromuscular Disorders in the ICU; Botulism; Lumbar Puncture; Intracranial Pressure Monitoring; Determination of Death by Neurologic Criteria

Thomas A. Bledsoe, MD
Clinical Assistant Professor, Brown University School of Medicine, Providence, Rhode Island
Ethical Issues in the Intensive Care Unit

Karen C. Bloch, MD, MPH
Assistant Professor of Medicine and Preventive Medicine, Vanderbilt University School of Medicine, Nashville, Tennessee
Central Nervous System Infections

Frank Bloos, PhD, UWO
Senior Physician, Department of Anesthesiology and Critical Care Medicine, University Hospital Jena; Member of the Medical Study Coordination for the German Compedence Network Sepsis (SEPNET)
Pathophysiology of Sepsis and Multiple Organ Dysfunction

Desmond J. Bohn, MB, BCh, MRCP, FRCPC, FRA
Professor of Pediatrics and Anesthesia, University of Toronto; Chief, Department of Critical Care Medicine, The Hospital for Sick Children, Toronto, Ontario, Canada
Fluids and Electrolytes in Pediatrics

Nicole C. Bouchard, MD
New York City Poison Control Center, New York, New York
Opioids

Arthur Boujoukos, MD
Associate Professor of Critical Care Medicine; Director, Cardiovascular Intensive Care Unit; Vice Chair, Clinical Operations, Department of Critical Care Medicine, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania
Tachycardia and Bradycardia; Management of Patients after Heart and Lung Transplants

Alessandro Bozzano, MD
Tutor (Cardiology Specialization), Department of Clinical Medicine, Prevention, and Applied Biotechnologies, University of Milan-Bicocca, Milan; Cardiologist, Cardiology and Coronary Care Department, San Gerardo Hospital, Monza (Mi), Italy
Pericardiocentesis

William J. Brady, MD
Associate Professor of Emergency Medicine and Clinical Internal Medicine, and Vice Chair, Department of Emergency Medicine, University of Virginia School of Medicine; Medical Director, Life Support Learning Center, University of Virginia Health System, Charlottesville, Virginia
Acute Coronary Syndromes: Pathophysiology and Diagnosis

Serge Brimioulle, MD, PhD
Associate Professor of Medicine, School of Medicine, Free University of Brussels; Staff Physician, Department of Intensive Care, Erasme University Hospital, Brussels, Belgium
Diabetes Insipidus

Daniel E. Brooks, MD
Assistant Professor, University of Pittsburgh Medical Center; Medical Toxicologist, Pittsburgh, Pennsylvania
Calcium Channel Blocker Toxicity

Richard C. Brundage, PharmD, PhD
Associate Professor and Director, Center for Drug Forecasting, College of Pharmacy, Graduate Program in Experimental and Clinical Pharmacology, University of Minnesota, Minneapolis, Minnesota
General Principles of Pharmacokinetics and Pharmacodynamics

Frank Martin Brunkhorst, MD
Oberarzt, Friedrich Schiller University, University Hospital Jena, Jena, Germany
Pathophysiology of Sepsis and Multiple Organ Dysfunction

D. Patrick Bryant, MD
Assistant Professor of Surgery, Penn State University, College of Medicine, Penn State M.S. Hershey Medical Center, Hershey, Pennsylvania
Hypomagnesemia

Timothy G. Buchman, MD, PhD
Professor, Department of Surgery, Washington University School of Medicine, St. Louis, Missouri
Indications for and Management of Tracheostomy

Jeffrey P. Burns, MD, MPH
Clinical Director, Medical-Surgical ICU; Program Director, Fellowship in Pediatric Critical Care Medicine, Children's Hospital; Associate Professor of Anesthesia and Pediatrics, Harvard Medical School, Boston, Massachusetts
Ethical Controversies in Pediatric Critical Care

Belén Cabello, MD
Resident, Critical Care, Medica Intensiva, Hospital San Pau, Barcelona, Spain
Acute Weaning from Mechanical Ventilation

Karen Calhoun, MD
Professor and Chair, Department of Otolaryngology, Head and Neck Surgery, University of Missouri, Columbia, Missouri
Epistaxis

Clifton W. Callaway, MD
Center for Emergency Medicine, Department of Emergency Medicine, Safar Center for Resuscitation Research, University of Pittsburgh, Pittsburgh, Pennsylvania
Cardiopulmonary-Cerebral Resuscitation

Peter M. A. Calverley, MD, MBChB, FRCP
Professor of Pulmonary Medicine, Department of Medicine, University of Liverpool; Honorary Consultant Physician, University Hospital Aintree, Liverpool, United Kingdom
Chronic Obstructive Pulmonary Disease

A. John Camm, MD, FRCP, QHP, FESC, FACC, FAHA
Professor of Clinical Cardiology, and Division Head, Division of Cardiac and Vascular Sciences, St. George's Hospital Medical School, London, United Kingdom
Supraventricular Arrhythmias

Sean M. Caples, DO
Division of Pulmonary and Critical Care Medicine, Mayo Clinic College of Medicine, Rochester, Minnesota
Respiratory System Mechanics and Respiratory Muscle Function

Diane M. Cappelletty, PharmD
Associate Professor of Pharmacy Practice, University of Toledo, College of Pharmacy, Toledo, Ohio
Agents with Primary Activity Against Gram-Positive Bacteria

Joseph A. Carcillo, MD
Associate Professor, Department of Critical Care Medicine, University of Pittsburgh School of Medicine, Associate Director, PICU, Children's Hospital of Pittsburgh, Pittsburgh, Pennsylvania
Sepsis and Multiple Organ System Failure in Children

Franco N. Carnevale, RN, PhD
Associate Professor, Faculty of Medicine (Pediatrics); Associate Professor, School of Nursing; Adjunct Professor, Counselling Psychology; and Affiliate Member, Biomedical Ethics Unit, McGill University, Montreal, Quebec, Canada
Key Issues in Critical Care Nursing

Emily E. Castelli, PharmD
Assistant Professor of Pharmacy and Therapeutics, University of Pittsburgh; Clinical Pharmacist, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania
Digitalis

Edward D. Chan, MD
Associate Professor of Medicine, University of Colorado Health Sciences Center; Staff Physician, National Jewish Medical and Research Center, Denver, Colorado
Tuberculosis

Jean Chastre, MD
Professor of Medicine, University Paris; Medical ICU, Groupe Hospitalier Pitie Salpetriere, Paris, France
Nosocomial Pneumonia; Bronchoalveolar Lavage and Protected Specimen Bronchial Brushing

Robert Chavko, MD
Fellow, Department of Critical Care Medicine, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania
Management of the Brain-Dead Organ Donor

Lakshmipathi Chelluri, MD
Associate Professor, Departments of Critical Care Medicine and Medicine, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania
Acute Respiratory Failure

Augustine M.K. Choi, MD
Professor of Medicine, and Chief, Pulmonary, Allergy, and Critical Care Medicine, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania
Carbon Monoxide and Heme Oxygenase-1

Chun-Shiang Chung, MD
Division of Surgical Research, Assistant Professor of Surgery, Department of Surgery, Brown University School of Medicine and Rhode Island Hospital, Providence, Rhode Island
Apoptosis in the Critically Ill

T. Philip Chung, MD
Department of Surgery, Division of General Surgery, Washington University School of Medicine, St. Louis, Missouri
Molecular and Biochemical Monitoring

Robert S.B. Clark, MD
Associate Professor, Department of Critical Care Medicine, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania
Biochemical, Cellular, and Molecular Mechanisms of Neuronal Death and Secondary Brain Injury in Critical Care; Key Issues in Pediatric Neurointensive Care

J. Perren Cobb, MD
Associate Professor of Surgery, Washington University; Injury Genomics Group, Cellular Injury and Adaptation Laboratory, St. Louis, Missouri
Molecular and Biochemical Monitoring

Jonathan D. Cohen, MD
General Intensive Care Department, Rabin Medical Center, Beilinson Campus, Petah Tiqwa, Israel
Indirect Calorimetry and Metabolic Monitoring

Steven M. Cohen, MD
Dr. Witten B. Russ Professor and Chairman, Department of Surgery, University of Texas Health Science Center, San Antonio, Texas

Assistant Professor, University of Colorado School of Medicine, National Jewish Medical and Research Center, Denver, Colorado
Cellular Signaling

Ericka L. Fink, MD
Fellow, Department of Critical Care Medicine, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania
Key Issues in Pediatric Neurointensive Care

Mitchell P. Fink, MD
Professor and Chair, Department of Critical Care Medicine, and Watson Professor of Surgery, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania
Fever and Hypothermia; Hyperbilirubinemia; Cytopathic Hypoxia: Mitochondrial Dysfunction in Sepsis

Douglas N. Fish, PharmD
Associate Professor of Pharmacy, University of Colorado Health Sciences Center; Clinical Specialist in Critical Care/Infectious Diseases, University of Colorado Hospital, Denver, Colorado
Antimicrobials in Chemotherapy Strategy; Fluoroquinolones

Bradley D. Freeman, MD
Assistant Professor of Surgery, Washington University School of Medicine, St. Louis, Missouri
Indications for and Management of Tracheostomy

John J. Fung, MD, PhD
Chairman, Department of General Surgery, and Director, Transplant Center, The Cleveland Clinic Foundation, Cleveland, Ohio
Clinical Use of Immunosuppressants

Richard L. Gamelli, MD, FACS
The Robert J. Freeark Professor and Chairman, Department of Surgery; Director, The Burn Shock Trauma Institute; Chief, The Burn Center, Loyola University Medical Center, Maywood, Illinois
Burns and Inhalation Injury

Raúl J. Gazmuri, MD, PhD, FCCM
Professor, Department of Medicine; Associate Professor, Physiology and Biophysics, Rosalind Franklin University of Medicine and Science; Section Chief, Critical Care Medicine; ICU Director, North Chicago Veterans Affairs Medical Center, North Chicago, Illinois
Ventricular Arrhythmias; Cardioversion and Defibrillation; Transvenous and Transcutaneous Cardiac Pacing

Robert Geelkerken, MD
Vascular Surgeon, Medisch Spectrum Twente, Department of Surgery, Enschede, The Netherlands
Splanchnic Ischemia

Todd W.B. Gehr, MD
Professor of Medicine, Division of Nephrology, Virginia Commonwealth University Health System, Richmond, Virginia
Clinical Assessment of Renal Function

Herwig Gerlach, MD
Professor of Anesthesiology, Critical Care Medicine, and Physiology, Humboldt University; Director and Chairman, Department of Anesthesiology, Critical Care, and Pain Management, Vivante-Klinikum Neukoelln, Berlin, Germany
Adrenal Insufficiency

Chris A. Ghaemmaghami, MD
Associate Professor of Emergency Medicine and Clinical Internal Medicine, University of Virginia School of Medicine, Charlottesville, Virginia
Acute Coronary Syndromes: Pathophysiology and Diagnosis

Helen Giamarellou, MD, PhD
Professor of Internal Medicine, Infectious Diseases Specialist, and Head, 4th Department of Internal Medicine, Athens University Medical School, Athens, Greece
Infectious Endocarditis

Fredric Ginsberg, MD
Assistant Professor of Medicine, Robert Wood Johnson Medical School at Camden, University of Medicine and Dentistry of New Jersey (UMDNJ), Camden, New Jersey
Myocarditis in the Intensive Care Unit

Debbie S. Gipson, MD, MS
Assistant Professor, Division of Nephrology and Hypertension, Departments of Medicine and Pediatrics; Adjunct Assistant Professor, Department of Epidemiology, School of Public Health, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina
Glomerulonephritis and Interstitial Nephritis in the ICU

Andrew Githaiga, MD
Department of Medicine, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania
Infections in the Immunocompromised Patient

Thomas Gleason, MD
Division of Cardiothoracic Surgery, Department of Surgery, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania
Mechanical Support in Cardiogenic Shock

Jacques P. Goldstein, MD, PhD
Professor, Department of Cardiac Surgery, AZ Vrije Universiteit Brussels, Brussels, Belgium
Cardiac Surgery: Indications and Complications

Rene M. Gonzales, MD
Staff Anesthesiologist, St. Luke's Coordinated Health Network, Bethlehem, Pennsylvania
Difficult Airway Management for Intensivists

Prabhakaran P. Gopalakrishnan, MD
Hospitalist, John Peter Smith Hospital, Fort Worth, Texas
Ventricular Arrhythmias

John Gorcsan III, MD
Associate Professor of Medicine, Director of Echocardiography, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania
Bedside Ultrasonography

Yaacov Gozal, MD
Senior Lecturer in Anesthesiology, Anesthesiology and Critical Care Medicine, Hebrew University–Hadassah Medical School; Director, Operating Room and PACU, Anesthesiology and Critical Care Medicine, Hadassah University Hospital, Ein Karem, Jerusalem, Israel
Arterial Cannulation and Invasive Blood Pressure Measurement

Jeremy D. Gradon, MD, FACP, FIDSA
Associate Professor of Medicine, Johns Hopkins University School of Medicine; Attending Physician, Department of Medicine, Division of Infectious Diseases, Sinai Hospital, Baltimore, Maryland
Head and Neck Infections

Cornelia R. Graves, MD
Associate Professor, Director, Critical Care Obstetrics, and Chief, Maternal Medicine, Division of Maternal-Fetal Medicine, Department of Obstetrics and Gynecology, Vanderbilt University, Nashville, Tennessee
Acute Pulmonary Complications in Pregnancy

Cesare Gregoretti, MD
Servizio di Anestesiologia e Rianimazione, Dipartimento di Discipline Medico-Chirurgiche, Universita di Torino, Ospedale S. Giovanni Battista, Torino, Italy
Patient-Ventilator Interaction

Robin L. Gross, MD
Assistant Professor of Medicine, Robert Wood Johnson Medical School; Division of Pulmonary and Critical Care Medicine, Cooper University Hospital, Camden, New Jersey
Arterial Blood Gas Interpretation

Michael R. Grounds, MD
Reader in Intensive Care Medicine, St. George's Hospital, London, United Kingdom
Hemodynamic Monitoring

Patricia S. Grutkoski, PhD
Instructor, Brown University School of Medicine; Division of Surgical Research, Rhode Island Hospital, Providence, Rhode Island
Apoptosis in the Critically Ill

Paul O. Gubbins, PharmD
Associate Professor, Department of Pharmacy Practice, College of Pharmacy, University of Arkansas for Medical Sciences, Little Rock, Arkansas
Fungal Infections

Kyle J. Gunnerson, MD
Assistant Professor, Department of Anesthesiology and Critical Care and Department of Emergency Medicine, VCURES Laboratory (VCU Reanimation Engineering Shock Center), Virginia Commonwealth University Health System, Richmond, Virginia
Low Systemic Arterial Blood Pressure

Weidun Alan Guo, MD, PhD
Surgical Critical Care Resident, Department of Surgery, Ohio State University, Columbus, Ohio
Infections of Skin, Muscle, and Soft Tissue

Ali Hallal, MD
Surgical Critical Care and Trauma Surgery Fellow, University of Miami, Ryder Trauma Center, Miami, Florida
Anemia of Critical Illness

Mitchell L. Halperin, MD
Division of Nephrology, St. Michael's Hospital, University of Toronto, Toronto, Ontario, Canada
Disorders of Plasma Potassium Concentration

Perry V. Halushka, MD, PhD
Dean, College of Graduate Studies, and Professor, Departments of Pharmacology and Medicine, Medical University of South Carolina, Charleston, South Carolina
Prostaglandins, Thromboxanes, Leukotrienes, and Other Products of Arachidonic Acid

Brian G. Harbrecht, MD
Associate Professor of Surgery, and Medical Director, Trauma Services, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania
Chest Tube Placement, Care, and Removal

Mary E. Hartman, MD
Fellow, Department of Critical Care Medicine, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania
Evidence-Based Critical Care

Maurene A. Harvey, RN, MPH, CCRN, FCCM
President, Educator, Consultant, Consultants in Critical Care Inc., Glenbrook, Nevada
Building Bedside Collaborative Practice

Michelle Hayes, MD
Consultant in Anaesthesia and Intensive Care, Chelsea and Westminster Hospital, London, United Kingdom
Bedside Pulmonary Artery Catheterization

Jan A. Hazelzet, MD, PhD
Sophia Children's Hospital, Erasmus University Medical Center, Rotterdam, The Netherlands
Sepsis and Multiple Organ System Failure in Children

Stephen O. Heard, MD
Chair, Department of Anesthesiology, University of Massachusetts Medical School, and Chairman, Department of Anesthesiology, University of Massachusetts Memorial Medical Center, Worcester, Massachusetts
Management of Acute Pain in the Intensive Care Unit

Paul C. Hébert, MD
University of Ottawa Center for Transfusion Research and the Clinical Epidemiology Program of the Ottawa Health Research Institute, Ottawa, Ontario, Canada
Anemia and Red Blood Cell Transfusion in Critically Ill Patients

John A. Henry, MD, FRCP, FFAEM
Professor, Academic Department of Accident and Emergency Medicine, Imperial College School of Medicine at St. Mary's, and Honorary Consultant, Department of Accident and Emergency, St. Mary's Hospital, London, United Kingdom
Hydrocarbons

Elizabeth D. Hermsen, PharmD, MBA
Adjunct Assistant Professor, University of Nebraska Medical Center College of Pharmacy, and Antimicrobial Pharmacist and Research Associate, The Nebraska Medical Center, Omaha, Nebraska
Metronidazole and Other Antibiotics for Anaerobic Infections

Daniel Herzig, MD
Chief Resident, Department of Surgery, Brown University Medical School, Providence, Rhode Island
Thoracic Trauma

Daren K. Heyland, MD, FRCPC, MSc
Department of Medicine, Queen's Hospital, Kingston, Ontario, Canada
Critical Care Nutrition

Robert W. Hickey, MD
Associate Professor of Pediatrics, Division of Emergency Medicine, Children's Hospital of Pittsburgh, Pittsburgh, Pennsylvania
Key Issues in Pediatric Neurointensive Care

Thomas L. Higgins, MD, MBA
Associate Professor of Medicine and Anesthesiology, Tufts University School of Medicine, Boston; Chief, Critical Care Division, Departments of Medicine, Surgery, and Anesthesia, Baystate Medical Center, Springfield, Massachusetts
Severity of Illness Indices and Outcome Prediction: Development and Evaluation

Nicholas S. Hill, MD
Chief, Pulmonary Critical Care, and Sleep Division, Tufts-New England Medical Center; Professor of Medicine, Tufts University School of Medicine, Boston, Massachusetts
Noninvasive Positive-Pressure Ventilation

Roman Hlatky, MD
Assistant Professor, University of Texas Health Science Center, San Antonio, Texas
Advanced Bedside Neuromonitoring; Jugular Venous and Brain Tissue Oxygen Tension Monitoring

Steven M. Hollenberg, MD
Professor of Medicine, Robert Wood Johnson Medical School/UMDNJ; Director, Coronary Care Unit, Cooper Hospital/University Medical Center, Camden, New Jersey
Acute Coronary Syndromes: Management and Complications

Nathaniel L. Holzman, MD
Department of Surgery, Tufts-New England Medical Center, Tufts University School of Medicine, Boston, Massachusetts
Gastrointestinal Hemorrhage

David T. Huang, MD, MPH
Assistant Professor, Departments of Critical Care Medicine and Emergency Medicine, University of Pittsburgh; Attending Physician, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania
Chest Pain

Rolf D. Hubmayr, MD
Professor of Medicine, Division of Pulmonary and Critical Care Medicine, Mayo Clinic College of Medicine, Rochester, Minnesota
Respiratory System Mechanics and Respiratory Muscle Function

John T. Huggins, MD
Assistant Professor of Medicine, Medical University of South Carolina; Senior Fellow, Division of Pulmonary and Critical Care Medicine, Allergy and Clinical Immunology, Medical University of South Carolina, Charleston, South Carolina
Pleural Disease in the Intensive Care Unit

Russell D. Hull, MBBS, MSc
Professor of Medicine, and Director, Thrombosis Research Unit, University of Calgary, Foothills Hospital, Calgary, Alberta, Canada
Pulmonary Embolism

Sabah N.A. Hussain, MD, PhD
Professor of Medicine, Critical Care and Respiratory Divisions, Department of Medicine, McGill University Hospital Centre, Montreal, Quebec, Canada
Nitric Oxide

James P. Isbister, MD
Consultant in Haematology and Transfusion Medicine, Royal North Shore Hospital of Sydney; Clinical Professor of Medicine, University of Sydney; Adjunct Professor, University of Technology, Sydney, St. Leonards, NSW, Australia
Blood Component Therapy

Rao R. Ivatury, MD
Professor, Department of Surgery, Virginia Commonwealth University, Medical College of Virginia, Richmond, Virginia
Peritonitis and Intra-abdominal Abscess

Connie A. Jastremski, RN, MS, MBA, ANP
Chief Nursing Officer and Vice President, Patient Care Services, Bassett Healthcare, Cooperstown, New York
Building Bedside Collaborative Practice

Larry Jenkins, PhD
Associate Professor, Department of Neurosurgery, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania
Biochemical, Cellular, and Molecular Mechanisms of Neuronal Death and Secondary Brain Injury in Critical Care

Mariell Jesup, MD
Division of Cardiothoracic Surgery, Departments of Surgery and Medicine, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania
Mechanical Support in Cardiogenic Shock

Paul Jodka, MD, BS
Assistant Professor of Anesthesiology and Medicine, Tufts University School of Medicine, Boston; Attending Physician, Adult Critical Care Division, Baystate Medical Center, Springfield, Massachusetts
Management of Acute Pain in the Intensive Care Unit

Robert G. Johnson, MD
C. Rollins Hanlon Professor and Chair, St. Louis University; Chief of Surgery, Saint Louis University Hospital/Tenet, St. Louis, Missouri
Mediastinitis

Vern C. Juel, MD
Associate Professor of Medicine, Division of Neurology, Duke University Medical Center, Durham, North Carolina
Neuromuscular Disorders in the ICU; Botulism

Rose Jung, PharmD
Assistant Professor, Department of Clinical Pharmacy, School of Pharmacy, University of Colorado Health Sciences Center, Denver, Colorado
Aminoglycosides

Allen B. Kaiser, MD
Professor and Vice-Chairman, Department of Medicine, Vanderbilt University School of Medicine, Nashville, Tennessee
Central Nervous System Infections

Richard Kallet, MS, RRT, FAARC
Clinical Research Coordinator, Critical Care and Respiratory Care Division, Department of Anesthesia and Perioperative Care, University of California at San Francisco General Hospital; Clinical Resident Coordinator, Cardiovascular Resident Institute, University of California, San Francisco, San Francisco, California
Bedside Monitoring of Pulmonary Function

Edo Kaluski, MD, FACC
Cardiology Department, Assaf-Harofeh Medical Center, Zerifin; Sackler Faculty of Medicine, Tel-Aviv University, Tel Aviv, Israel
Pulmonary Edema

Kamel S. Kamel, MD
Associate Professor of Medicine, University of Toronto; Attending Staff, Chief, Division of Nephrology, Department of Medicine, Toronto, Ontario, Canada
Disorders of Plasma Potassium Concentration

Sandra Kane-Gill, PharmD, MSc
Assistant Professor, Center for Pharmacoinformatics and Outcomes Research, University of Pittsburgh, Pittsburgh, Pennsylvania
Pharmacoeconomics in Critical Care

Jeffrey P. Kanne, MD
Department of Radiology, Harborview Medical Center, University of Washington, Seattle, Washington
Imaging of the Chest in the ICU

Lionel Karlin, MD
Medical Intensive Care Unit, Hôpital Saint Louis and Paris University VII, Paris, France
Organ Toxicity of Cancer Chemotherapy

Manoj Karwa, MD
Assistant Professor of Medicine, Department of Critical Care Medicine, Montefiore Medical Center, Albert Einstein College of Medicine, Bronx, New York
Disaster Medicine for the ICU Physician

Kenneth D. Katz, MD
Assistant Professor, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania
Calcium Channel Blocker Toxicity

David Charles Kaufman, MD, FCCM
Associate Professor of Surgery, Medicine, Anesthesia and Medical Humanities, University of Rochester; Medical Director, Surgical Intensive Care Unit, Strong Memorial Hospital, Rochester, New York
Hepatopulmonary Syndrome

Catherine Kelleher, MD
Assistant Professor of Medicine, Denver Health Medical Center, Denver, Colorado
Hypertensive Crisis and Urgency

John A. Kellum, MD
Associate Professor of Critical Care Medicine, University of Pittsburgh; Staff Intensivist, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania
Polyuria; Oliguria; Acid-Base Disorders; Evidence-Based Critical Care

Aktar S. Khan, MD
Assistant Professor of Surgery, Thomas E. Starzl Transplantation Institute, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania
Management of the Brain-Dead Organ Donor

Richard J. King, MD
Fellow, Surgical Critical Care, Penn State/M.S. Hershey Medical Center, Hershey, Pennsylvania
Hypocalcemia and Hypercalcemia

Rick Kingston, PharmD
Vice President/Senior Clinical Toxicologist with the PROSAR International Poison Center; Associate Professor of Pharmacy at the University of Minnesota, College of Pharmacy, Department of Clinical and Experimental Pharmacology, Minneapolis, Minnesota
Pesticides and Herbicides

Orlando Kirton, MD, FACS, FCCM, FCCP
Ludwig J. Pyrtek Chair in Surgery, and Director of Surgery and Chief, Division of General Surgery, Hartford Hospital; Professor of Surgery and Associate Program Director, Integrated General Surgery Residency, and Vice Chair, Department of Surgery, University of Connecticut School of Medicine, Hartford, Connecticut
Pelvic and Major Long Bone Fractures

Jason Knight, MD
Physician, Department of Emergency Medicine, Maricopa Medical Center, Phoenix, Arizona
Conduction Disturbances and Cardiac Pacemakers

Patrick M. Kochanek, MD
Director, Safar Center for Resuscitation Research; Professor and Vice Chairman, Department of Critical Care Medicine, Professor of Pediatrics and Anesthesiology, University of Pittsburgh School of Medicine and Children's Hospital of Pittsburgh, Pittsburgh, Pennsylvania
Key Issues in Pediatric Intensive Care; Biochemical, Cellular, and Molecular Mechanisms of Neuronal Death and Secondary Brain Injury in Critical Care

W. Andrew Kofke, MD, MBA, FCCM
Professor, Anesthesia and Neurosurgery, and Director of Neuroanesthesia, Department of Anesthesia, University of Pennsylvania, Philadelphia, Pennsylvania
Critical Neuropathophysiology

Jeroen J. Kolkman, MD
Gastroenterologist, Medisch Spectrum Twente, Enschede, The Netherlands
Splanchnic Ischemia

Robert L. Kormos, MD
Director, Thoracic Transplantation and Artificial Heart Program, Medical Director, McGowan Institute for Regenerative Medicine, University of Pittsburgh, Pittsburgh, Pennsylvania
Ventricular Assist Devices

Larry W. Kraiss, MD
Associate Professor of Surgery, and Chief, Division of Vascular Surgery, University of Utah School of Medicine, Salt Lake City, Utah
Endothelial Function

David J. Kramer, MD
Professor of Medicine, Mayo Clinic College of Medicine; Director, Transplant Critical Care, Mayo Clinic, Jacksonville, Florida
Liver Transplantation

John W. Kreit, MD
Associate Professor of Medicine, Division of Pulmonary, Allergy, and Critical Care Medicine, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania
Antidepressant Drug Overdose

James A. Kruse, MD
Chief, Critical Care Services, Mary Imogene Bassett Hospital, Cooperstown, New York
Ethanol, Methanol, and Ethylene Glycol

Vladimir Kvetan, MD
Professor of Anesthesiology and Clinical Medicine, Associate Professor of Surgery, and Director of Critical Care Medicine Service and Fellowship, Department of Critical Care Medicine, Montefiore Medical Center, Bronx, New York
Disaster Medicine for the ICU Physician

Jacques R. Lacroix, MD
Professor of Pediatrics, Universite de Montreal; Pediatrician, Hospital Sainte-Justine, Montreal, Quebec, Canada
Hematology and Oncology in Children

Yi-Chen Lai, MD
Research Scholar, Physical Care Medicine, NRSA Fellow, NICHD/NIH, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania
Biochemical, Cellular, and Molecular Mechanisms of Neuronal Death and Secondary Brain Injury in Critical Care

Fred J. Laine, MD
Radiology Associates of Richmond, Richmond, Virginia
Neuroimaging

David Laithwaite, MD
Clinical Research Fellow, Division of Vascular Medicine, University of Nottingham, Southern Derbyshire Acute Hospitals Trust, Derby, United Kingdom
Peripheral Arteriopathies Including Embolism

Gilles Lebuffe, MD, PhD
Anesthesiologist and Intensivist, Clinique d'Anesthésie et de Réanimation, Hôpital Claude Huriez, Centre Hospitalier Universitaire de Lille, Lille, France
Resuscitation from Circulatory Shock

James A. Lederer, MD
Associate Professor, Harvard Medical School; Associate Professor of Surgery, and Brook Investigator, Brigham and Women's Hospital, Boston, Massachusetts
Lymphocyte Function after Injury

Moshe Levi, MD
Division of Renal Diseases and Hypertension, Department of Medicine, University of Colorado Health Sciences Center, and Denver Veterans Affairs Medical Center, Denver, Colorado
Disorders of Calcium and Magnesium Metabolism

Allan D.O. Levi, MD, PhD
Chief of Neurosurgical Services, University of Miami School of Medicine, Miami, Florida
Spinal Cord Injury

Phillip D. Levin, MA, MB, BChir
Research Fellow, Department of Critical Care, Sunnybrook and Women's College Health Sciences Centre, Toronto, Ontario, Canada; Staff Anesthetist, Department of Anesthesiology and Critical Care Medicine, Hadassah Hebrew University Hospital, Jerusalem, Israel
Arterial Cannulation and Invasive Blood Pressure Measurement; Beyond Technology: Caring for the Critically Ill

Mitchell M. Levy, MD
Brown University School of Medicine; and Rhode Island Hospital, Department of Pulmonary and Critical Care Medicine, Providence, Rhode Island
Ethical Issues in the Intensive Care Unit; End-of-Life Issues in the Intensive Care Unit

Scott Liebman, MD
Assistant Professor of Medicine, University of Rochester School of Medicine and Dentistry; Assistant Professor of Medicine, Strong Memorial Hospital, Rochester, New York
Urinary Tract Obstruction

Stuart L. Linas, MD
Director, Renal Fellowship Program, Rocky Mountain Kidney Research Center, University of Colorado Health Sciences Center; Chief of Nephrology, Denver Health Medical Center, Denver, Colorado
Hypertensive Crisis and Urgency

Peter K. Linden, MD
Professor, Department of Critical Care Medicine, University of Pittsburgh School of Medicine; Director, Abdominal Organ Transplant ICU, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania,
Fulminant Hepatic Failure Including Acetaminophen Toxicity

Krishna Lingam, MD
Consultant Vascular Surgeon, Derby Hospitals NHS Foundation Trust, Derby, United Kingdom
Peripheral Arteriopathies Including Embolism

Gregory Y.H. Lip, MD, FRCP
Professor of Cardiovascular Medicine, University of Birmingham, and University Department of Medicine, City Hospital, Birmingham, United Kingdom
Severe Heart Failure

Pamela A. Lipsett, MD, FACS
Professor of Surgery, Anesthesia, Critical Care Medicine, and Nursing, Johns Hopkins University Schools of Medicine and Nursing; Fellowship Director, Surgical Critical Care, and Co-Director, Surgical Intensive Care Units, Johns Hopkins Hospital, Baltimore, Maryland
Acute Pancreatitis

Alan Lisbon, MD
Assistant Professor of Anesthesia, Harvard Medical School; Department of Anesthesia and Critical Care, Beth Israel Deaconess Medical Center, Boston, Massachusetts
Management of the Postoperative Cardiac Surgical Patient

Raghu S. Loganathan, MD
Fellow in Critical Care Medicine, Department of Critical Care Medicine, Montefiore Medical Center, Albert Einstein College of Medicine, Bronx, New York,
Disaster Medicine for the ICU Physician

Adriana M. Lopez, MD
Pediatric Critical Care Fellow, University of Arkansas for Medical Sciences, Arkansas Children's Hospital, Little Rock, Arkansas
Pediatric Intensive Care Procedures

John M. Luce, MD
Professor of Medicine, Division of Pulmonary and Critical Care Medicine, Department of Medicine, University of California, San Francisco, School of Medicine; Associate Director, Medical and Surgical Intensive Care Units, San Francisco General Hospital, San Francisco, California
Human Immunodeficiency Virus Infection

Courtney H. Lyder, ND, GNP, FAAN, RN
Professor of Nursing, Professor of Internal Medicine and Geriatrics, Acting Chair of the Department of Acute and Specialty Care, and Gerontology Consultant, University of Virginia Medical Center, Charlottesville, Virginia
Pressure Ulceration

Andrew I.R. Maas, MD
Department of Neurosurgery, Erasmus Medical Center, Rotterdam, The Netherlands
Intensive Care after Neurosurgery

Neil R. MacIntyre, MD
Professor of Medicine, Duke University Medical Center, Durham, North Carolina
Assist-Control Mechanical Ventilation

Duncan J. Macrae, MBChB, BMSc, FRCA, FRCPCH
Director of Paediatric Intensive Care, Royal Brompton Hospital; Honorary Senior Lecturer, Imperial College, University of London, London, United Kingdom
Acquired and Congenital Heart Disease in Children

Stefano Maggiolini, MD
Tutor (Cardiology Specialization), University Department of Clinical Medicine, Prevention, and Applied Biotechnologies, University of Milan-Bicocca, Milan; Cardiologist, Cardiology and Coronary Care Unit Department, San Gerardo Hospital, Monza (Mi), Italy
Pericardiocentesis

Vinay Maheshwari, MD
Clinical Associate, Pulmonary, Critical Care and Sleep Medicine, Tufts-New England Medical Center; Clinical Instructor, Tufts University School of Medicine, Boston, Massachusetts
The Hematopoietic Stem Cell Transplantation Patient

Bernhard Maisch, MD, FESC, FACC
Professor and Chairman, Department of Internal Medicine and Cardiology, and Dean of Medical Faculty, Phillips University; Director of the University Hospital Departments of Internal Medicine and Cardiology, Marburg, Germany
Pericardial Diseases

Ajai K. Malhotra, MD
Assistant Professor, Trauma, Virginia Commonwealth University's Medical College of Virginia Hospitals, Richmond, Virginia; Clinical Instructor in Surgery, University of Tennessee, Memphis, Tennessee
Peritonitis and Intra-abdominal Abscess

Jordi Mancebo, MD
Associate Professor, Department of Medicine, Universitat Autonoma de Barcelona; Unit Chief, Medicina Intensiva, Hospital San Pau, Barcelona, Spain
Acute Weaning from Mechanical Ventilation

Henry J. Mann, MD
Professor, College of Pharmacy, and Director, Center for Excellence in Critical Care, University of Minnesota, Minneapolis, Minnesota
General Principles of Pharmacokinetics and Pharmacodynamics

John A. Mannick, MD
Moseley Distinguished Professor of Surgery, Harvard Medical School; attending, Brigham and Women's Hospital, Boston, Massachusetts
Lymphocyte Function after Injury

Sanjay Manocha, MD
Post-Doctoral Fellow of the CIHR IMPACT Program and Michael Smith Foundation for Health Research, Critical Care Research Laboratories, Centre for Cardiovascular and Pulmonary Research, St. Paul's Hospital, Vancouver, British Columbia, Canada
Adjunctive Respiratory Therapy

Eric L. Marderstein, MD
Department of Surgery and Critical Care Medicine, University of Pittsburgh Health System, Pittsburgh, Pennsylvania
Placement of Feeding Tubes

Daniel R. Margulies, MD
Director of Trauma, Department of Surgery, Cedars-Sinai Medical Center; Assistant Clinical Professor of Surgery, David Geffen School of Medicine, University of California, Los Angeles, Los Angeles, California
Percutaneous Dilatational Tracheostomy

Paul E. Marik, MD, FCCM, FCCP
Professor, Pulmonary and Critical Care Medicine, Thomas Jefferson University; Chief, Pulmonary and Critical Care Medicine, Jefferson Medical College, Philadelphia, Pennsylvania
The Management of Gastrointestinal Bleeding; Aspiration Pneumonitis and Pneumonia

John J. Marini, MD
Professor of Medicine, University of Minnesota, Minneapolis; Director of Translational Research, Regions Hospital, St. Paul, Minnesota
Principles of Gas Exchange

Donald W. Marion, MD, FACS
Senior Research Fellow, The Brain Trauma Foundation, New York, New York
Traumatic Brain Injury

Steven J. Martin, PharmD, BCPS, FCCM
Associate Professor of Pharmacy, and Co-Director, The Infectious Disease Research Laboratory, Department of Pharmacy Practice, College of Pharmacy, University of Toledo, Toledo, Ohio
Beta-Lactam Drugs Used in Critical Care

Mark L. Martinez, MD
Fellow, Department of Internal Medicine, Division of Pulmonary and Critical Care, University of Utah School of Medicine, Salt Lake City, Utah
Endothelial Function

Michael A. Matthay, MD
Professor of Medicine and Anesthesia; Senior Associate, Cardiovascular Research Institute; Associate Director, Intensive Care; and Director, Critical Care Medicine Training Program, Department of Medicine, University of California, San Francisco, San Francisco, California
Lung Epithelial Function

Gary R. Matzke, BS Pharm, PharmD
Vice-Chairman and Professor, Department of Pharmacy and Therapeutics, School of Pharmacy; Professor, Renal and Electrolyte Division, Department of Medicine, School of Medicine, University of Pittsburgh, Pittsburgh, Pennsylvania
Drug Dosing in the Patient with Renal Failure

Addison K. May, MD
Associate Professor of Surgery, Department of Surgery, Vanderbilt University, Nashville, Tennessee
Peritonitis and Intra-abdominal Abscess

George V. Mazariegos, MD
University of Pittsburgh Health System, Division of Transplant Surgery, Pittsburgh, Pennsylvania
Intestinal and Multiple Organ Transplantation

Clyde E. McAuley, MD, FACS
Associate Professor, Department of Surgery, Northeastern Ohio Universities College of Medicine, Rootstown; Trauma Surgeon, St. Elizabeth Health Center, Youngstown, Ohio
Vascular Catheter-Related Infections

Stephen A. McClave, MD
Professor of Medicine, Division of Gastroenterology/Hepatology, Department of Medicine, Louisville School of Medicine, Louisville, Kentucky
Critical Care Nutrition

Michael McCready, MD
Chief Cardiology Fellow, Department of Cardiovascular Sciences, University of Calgary, Calgary, Alberta, Canada
Sudden Cardiac Death: Implantable Cardioverter-Defibrillators

Kenneth R. McCurry, MD
Assistant Professor of Surgery, University of Pittsburgh; Director, Adult Lung and Heart-Lung Transplantation; Surgical Director, Pediatric Lung and Heart-Lung Transplantation, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania
Cannulation for Extracorporeal Membrane Oxygenation

John K. McIlwaine, MD
Section of Critical Care Medicine, Department of Anesthesiology, Dartmouth-Hitchcock Medical Center, Lebanon, New Hampshire
Hypernatremia and Hyponatremia

Dieter Mesotten, MD, PhD
Resident, Department of Intensive Care Medicine, University Hospital Gasthuisberg, Catholic University of Leuven, Leuven, Belgium
Hyperglycemia and Blood Glucose Control in the Intensive Care Unit

Isabelle Michaud, MD
Senior Instructor, Department of Medicine, Pulmonary and Critical Care, University of Rochester Medical Center, Rochester, New York
Hepatopulmonary Syndrome

Eric B. Milbrandt, MD, MPH
Assistant Professor, Department of Critical Care Medicine, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania
Agitation and Delirium; Management of Pain, Anxiety, and Delirium

Marek Mirski, MD, PhD
Director, Neuroscience Critical Care Unit; Chief, Division of Neuroanesthesiology; Associate Professor of Anesthesiology and Critical Care, Johns Hopkins Medical Institutions, Baltimore, Maryland
Anticonvulsants in the Intensive Care Unit

Xavier Monnet, MD
Assistant Professor, Paris XI University; Medical Intensive Care Unit, Bicêtre University Hospital, Paris, France
Inotropic Therapy in the Critically Ill

Frederick A. Moore, MD
Chief, General Surgery and Trauma/Critical Care Medicine, and Professor and Vice-Chairman, University of Texas at Houston Medical School, Houston, Texas
Abdominal Compartment Syndrome

Theo J. Morales, MD
Division of Respiratory Medicine, Department of Pediatrics, The Hospital for Sick Children, and Department of Medicine, Division of Respirology, The University of Toronto, The Toronto General Hospital Research Institute of University Health Network, Toronto, Ontario, Canada
The Neutrophil: Balancing Antimicrobial Effectiveness and the Potential for Damage to the Host

Delphine Moreau, MD
Assistant Professor, University of Paris VII; Medical Intensive Care Unit, Saint Louis Hospital, Paris, France
Hematologic Malignancies in the Intensive Care Unit

Alison Morris, MD, MS
Assistant Professor of Medicine, Division of Pulmonary and Critical Care Medicine, Department of Medicine, Keck School of Medicine, University of Southern California, Los Angeles, California; Adjunct Assistant Professor of Medicine, Division of Pulmonary, Allergy, and Critical Care Medicine, University of Pittsburgh, Pittsburgh, Pennsylvania
Human Immunodeficiency Virus Infection

Michele Moss, MD
Professor and Vice Chair of Pediatrics, University of Arkansas for Medical Sciences, Arkansas Children's Hospital, Little Rock, Arkansas
Pediatric Intensive Care Procedures

Claus-Martin Muth, MD
Assistant Professor of Anesthesiology and Staff Anesthesiologist, Sektion Anesthesiologische, Pathophysiologie und Verfahrensentwicklung, Universitaet Ulm; Assistant Professor of Anesthesiology, Universitaetsklinik für Anesthesiologie, Universitaetsklinikum, Ulm, Germany
Other Embolic Syndromes

Kurt G. Naber, MD
Professor and Head of Urology, Hospital St. Elisabeth, Teaching Hospital of the Technical University Munich, Straubing, Germany
Infections of the Urogenital Tract

Lena M. Napolitano, MD
Professor of Surgery, University of Maryland School of Medicine; Division Chief, Surgical Critical Care and General Surgery, and Deputy Chief, Surgical Care Clinical Center, Virginia-Maryland Healthcare System, Baltimore, Maryland
Ascites

Stanley A. Nasraway, Jr., MD
Associate Professor, Departments of Surgery, Medicine and Anesthesia, Tufts University School of Medicine; Director, Surgical Critical Care, Tufts-New England Medical Center, Boston, Massachusetts
Gastrointestinal Hemorrhage

Magdaline Ndirangu, MD
Department of Medicine, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania
Infections in the Immunocompromised Patient

Lewis S. Nelson, MD
Department of Emergency Medicine, New York University, and New York City Poison Control Center, New York, New York
Opioids

Jerry A. Nick, MD
Associate Professor, National Jewish Medical and Research Center, University of Colorado Health Sciences Center, Denver, Colorado
Cellular Signaling

Michael S. Niederman, MD
Chairman, Department of Medicine, Winthrop University Hospital, Mineola; Professor of Medicine and Vice-Chairman, Department of Medicine, SUNY at Stony Brook, Stony Brook, New York
Community-Acquired Pneumonia

Scott Norwood, MD, FACS, FCCP
Clinical Associate Professor of Surgery, Department of Surgery, University of Texas School of Medicine, Houston; Director, Trauma Services, Department of Surgery, East Texas Medical Center, Tyler, Texas
Vascular Catheter-Related Infections

Beatrice Nyakonu-Schwake, PharmD
Critical Care Resident, Regions Hospital, St. Paul, Minnesota
Toxic Inhalations

Juan B. Ochoa, MD
Associate Professor, Departments of Surgery and Critical Care Medicine, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania
Ileus; Diarrhea; Ileus and Mechanical Small Bowel Obstruction; Placement of Feeding Tubes

Mark D. Okusa, MD
Professor of Internal Medicine and Attending Physician, University of Virginia Health System, Charlottesville, Virginia
Lithium

Keith M. Olsen, PharmD, FCCP, FCCM
Professor of Pharmacy, Department of Pharmacy Practice, University of Nebraska Medical Center, Omaha, Nebraska
Theophylline and Other Methylxanthines

James P. Orlowski, MD
Division of Pediatrics, Department of Pediatric Critical Care Medicine, University Community Hospital, and Department of Pediatrics, Critical Care Medicine and Medical Ethics, University of South Florida, Tampa, Florida
Drowning

Richard Orr, MD
Associate Professor, Departments of Critical Care Medicine and Pediatrics, University of Pittsburgh School of Medicine; Associate Director, Pediatric Intensive Care, and Medical Director, Pediatric Critical Care Transplant, Children's Hospital of Pittsburgh, Pittsburgh, Pennsylvania
Transport Medicine

Catherine M. Otto, MD
Professor of Medicine and Director, Cardiology Fellowship Training Programs, University of Washington School of Medicine; Co-Director, Adult Congenital Heart Disease Program, and Associate Director, Echocardiography Laboratory, University of Washington Medical Center, Seattle, Washington
Emergent Valvular Disorders

Heleen M. Oudemans-van Straaten, MD, PhD
Internist-Intensivist, Department of Intensive Care, Onze Lieve Vrouwe Gasthuis, Amsterdam, The Netherlands
Toxic Megacolon in Critically Ill Patients

Joseph E. Parrillo, MD, FCCM
Professor of Medicine, Robert Wood Johnson Medical School at Camden, UMDNJ; Head, Division of Cardiovascular Disease and Critical Care Medicine, and Director, Cooper Heart Institute and Cardiovascular and Critical Care Services, Cooper University Hospital, Camden, New Jersey
Myocarditis in the Intensive Care Unit

Amit Patel, MD
Department of Cardiac Surgery, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania
Ventricular Assist Devices

David L. Paterson, MD
Department of Medicine, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania
Infections in the Immunocompromised Patient; Acute Viral Syndromes

Donna M. Paulnock, PhD
Professor, Department of Medical Microbiology and Immunology, University of Wisconsin Medical School, Madison, Wisconsin
Macrophage Function

Andrew B. Peitzman, MD
Professor, Department of Surgery, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania
Abdominal Trauma

Judith Pepe, MD
Associate Professor of Surgery, University of Connecticut School of Medicine, Farmington; Associate Director, Surgical Critical Care, Hartford Hospital, Hartford, Connecticut
Central Venous Catheterization

Andrew D. Perron, MD
Attending Physician and Program Director, Department of Emergency Medicine, Maine Medical Center, Portland, Maine
Acute Coronary Syndromes: Pathophysiology and Diagnosis

Bradley Peterson, MD, FCCM
Director, Pediatric Intensive Care Unit, Children's Hospital of San Diego, San Diego, California
Pediatric Trauma

Graham F. Pineo, MD
Professor of Medicine and Director, Thrombosis Research Unit, University of Calgary; Acting Head, Division of Hematology, Foothills Hospital, Calgary, Alberta, Canada
Pulmonary Embolism

Michael R. Pinsky, MD
Professor, Departments of Critical Care Medicine, Bioengineering and Anesthesiology, University of Pittsburgh School of Medicine; Attending Physician, University of Pittsburgh Medical Center and Magee Women's Hospital, Pittsburgh, Pennsylvania
Heart-Lung Interactions

Didier Pittet, MD, MS
Professor, Faculty of Medicine, University of Geneva; Director, Infection Control Program, and Professor, Division of Infectious Diseases, Department of Internal Medicine, University of Geneva Hospitals, Geneva, Switzerland
Acute Bacteremia

Fred Plum, MD
Professor Emeritus, Department of Neurology and Neuroscience, Weill Medical College of Cornell University, New York, New York
Coma

Murray M. Pollack, MD, MBA
Executive Director, Center for Hospital Based Specialties; Division Chief, Critical Care Medicine, Children's National Medical Center; and Professor of Pediatrics, The George Washington University School of Medicine, Washington, DC
Evaluating Pediatric Critical Care

Brian D. Poole, MD
Division of Renal Diseases and Hypertension, University of Colorado School of Medicine, Denver, Colorado
Acute Renal Failure

Mordecai M. Popovtzer, MD, FACP
Professor of Clinical Medicine, Department of Medicine, Section of Renal Disease, University of Arizona Health Sciences Center; Professor of Clinical Medicine, Southern Arizona Veterans Affairs Health Care System, Tucson, Arizona
Disorders of Calcium and Magnesium Metabolism

Stephen M. Prescott, MD
Department of Internal Medicine, University of Utah; Executive Director, Huntsman Cancer Center Institute, Salt Lake City, Utah
Endothelial Function

Peter J. Pronovost, MD
Associate Professor, Departments of Anesthesiology and Critical Care, Surgery, and Health Policy and Management, and Medical Director, Center for Innovations in Quality Patient Care, The Johns Hopkins University School of Medicine, Baltimore, Maryland
The Pursuit of Performance Excellence

Juan Carlos Puyana, MD
Associate Professor, Departments of Critical Care Medicine and Surgery, University of Pittsburgh School of Medicine; Director, Surgical/Trauma Intensive Care Unit, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania
Resuscitation of Hypovolemic Shock

Murugan Raghavan, MD, MRCP(UK)
Fellow, Critical Care Medicine, Department of Critical Care Medicine, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania
Fulminant Hepatic Failure Including Acetaminophen Toxicity

Thomas G. Rainey, MD
Director, Critical Care, Suburban Hospital; Chairman, Idealized Design of the Intensive Care Unit, Institute for Healthcare Improvement/Voluntary Hospitals of America; and President, Critical Medical Inc., Bethesda, Maryland
The Pursuit of Performance Excellence

Thomas Rajan, MD
Fellow, Pulmonary Critical Care and Sleep Division, Tufts-New England Medical Center, Tufts University School of Medicine, Boston, Massachusetts
Noninvasive Positive-Pressure Ventilation

V. Marco Ranieri, MD

PREFACE

The fifth edition of the *Textbook of Critical Care* continues the tradition of excellence established by the earlier editions but embodies a number of new features that should make it easier to use by both trainees and experienced clinicians and more likely to remain up-to-date. Several features of the fifth edition warrant special comment.

- Because critical care medicine is now a mature specialty that is practiced all over the world, the experts selected to write chapters for the fifth edition are an international group.
- The opening section of the book consists of short chapters that provide a brief overview of clinical problems, such as acute respiratory failure or diarrhea, that are commonly encountered in the management of patients with critical illness.
- Although the book contains extensive citations to the medical literature, both the bulk and the cost of the resulting volume have been decreased by providing most of the references on a CD-ROM rather than in the text per se. The most important citations are provided in the text with some annotation to help readers understand why the selected references are particularly noteworthy.
- Most chapters include a list of key points. A quick glance at this list will help readers remember the "take home" messages for the chapter.
- New pediatric content of the textbook is also international in scope and addresses key topics within each area of pediatric critical care that are germane to the broader readership of the book.
- Because the basic science that underlies the practice of critical care medicine is advancing rapidly, the editors have included an entire section devoted to key topics in areas of fundamental biology that are relevant to the field.

A new feature of the fifth edition is a dedicated website, www.criticalcaretext.com, which has been launched at the same time the book published. This website will be updated every week throughout the life of this edition. The website features the full text and illustrations of the fifth edition of the *Textbook of Critical Care* and is fully searchable. You can even download the illustrations to PowerPoint to enhance your presentations or lectures. Another added-value feature on the website is the inclusion of critical care calculators. References are linked to Medline or directly to full-text articles where available, which will expand your search capabilities. However, the absolute key feature of the website is the regular weekly updates from experts in the field, so that the text is consistent with the best information available in the scientific literature. The latest issues of the major medical journals might contain an article that will fundamentally change the standard of care for the management of a disease or syndrome encountered in the care of critically ill patients. If this happens, the relevant chapter(s) will be updated immediately, so that this work can stay current year after year. The book and the website can be purchased either separately or together as an **e-dition** package, giving you unprecedented reference power.

The fifth edition of this textbook would not have been possible without the enormous contributions made by the prior editors. We express our gratitude to Will Shoemaker, Steve Ayers, Ake Grenvik, and Peter Holbrook for the opportunity and great honor to follow in their footsteps.

We want to thank the many people who were instrumental in helping us assemble the text you are now holding in your hands. Specifically, we wish to thank Ms. Janice Knapp, editorial assistant to Dr. Fink; Marci Provins, editorial assistant to Dr. Kochanek; Dr. Karen Pickett and Ms. Marie-Rose Andre, who assisted Dr. Vincent; and Kelly Kast and Katie Overdier, who assisted Dr. Abraham.

COMMON PROBLEMS

Chapter 1
SUDDEN DETERIORATION IN NEUROLOGIC STATUS

Joseph M. Darby • Anupam Anupam

Patients admitted to the intensive care unit (ICU) with critical illness or injury are at risk for neurologic complications.[1-5] A sudden or unexpected change in the neurologic condition of a critically ill patient often heralds a complication that may cause direct injury to the central nervous system (CNS). Alternatively, such changes may simply be neurologic manifestations of the underlying critical illness or treatment that necessitated ICU admission (e.g., sepsis). These complications can occur in patients admitted to the ICU without neurologic disease and in those admitted for the management of primary CNS problems (e.g., stroke). Neurologic complications also can occur as a result of invasive procedures and therapeutic interventions performed. Commonly, the recognition of neurologic complications is delayed or missed entirely because ICU treatments (e.g., intubation, drugs) interfere with the physical examination or confound the clinical picture. In other cases, neurologic complications are not recognized because of a lack of sensitive methods to detect the problem (e.g., delirium). Morbidity and mortality are increased among patients who develop neurologic complications; therefore, the intensivist must be vigilant in the evaluation of all critically ill patients for changes in neurologic status.

Despite the importance of neurologic complications of critical illness, few studies have specifically assessed their incidence and impact on outcome among ICU patients. Available data are limited to medical ICU patients; data regarding neurologic complications in general surgical and other specialty ICU populations must be extracted from other sources. In studies of medical ICU patients, the incidence of neurologic complications is 12.3% to 33%.[1,2] Patients who develop neurologic complications have increased morbidity, mortality, and ICU length of stay. Sepsis is the most common problem associated with the development of neurologic complications (sepsis-associated encephalopathy). In addition to encephalopathy, other common neurologic complications associated with critical illness include seizures and stroke. As the complexity of ICU care has increased, so has the risk of neurologic complications. Neuromuscular disorders are now recognized as a major source of morbidity in severely ill patients.[6] Recognized neurologic complications occurring in selected medical, surgical, and neurologic ICU populations are shown in Table 1–1.[7-41]

TABLE 1–1. NEUROLOGIC COMPLICATIONS IN SELECTED SPECIALTY POPULATIONS

Medical	
Bone marrow transplantation[7,8]	CNS infection, stroke, subdural hematoma, brainstem ischemia, hyperammonemia, Wernicke's encephalopathy
Cancer[9]	Stroke, intracranial hemorrhage, CNS infection
Fulminant hepatic failure[10]	Encephalopathy, coma, brain edema, increased ICP
HIV/AIDS[11,12]	Opportunistic CNS infection, stroke, vasculitis, delirium, seizures, progressive multifocal leukoencephalopathy
Pregnancy[13,14]	Seizures, ischemic stroke, cerebral vasospasm, intracranial hemorrhage, cerebral venous thrombosis, hypertensive encephalopathy, pituitary apoplexy
Surgical	
Cardiac surgery[15-19]	Stroke, delirium, brachial plexus injury, phrenic nerve injury
Vascular surgery[20,21]	
Carotid	Stroke, cranial nerve injuries (recurrent laryngeal, glossopharyngeal, hypoglossal, facial), seizures
Aortic	Stroke, paraplegia
Peripheral	Delirium
Transplantation[10,22-25]	
Heart	Stroke
Liver	Encephalopathy, seizures, opportunistic CNS infection, intracranial hemorrhage, Guillain-Barré syndrome, central pontine myelinolysis
Renal	Stroke, opportunistic CNS infection, femoral neuropathy
Urologic surgery (TURP)[26]	Seizures and coma (hyponatremia)
Otolaryngologic surgery[27,28]	Recurrent laryngeal nerve injury, stroke, delirium
Orthopedic surgery[29]	
Spine	Myelopathy, radiculopathy, epidural abscess, meningitis
Knee and hip replacement	Delirium (fat embolism)
Long bone fracture/nailing	Delirium (fat embolism)
Neurologic	
Stroke[30-34]	Stroke progression or extension, reocclusion after thrombolysis, bleeding, seizures, delirium, brain edema, herniation
Intracranial surgery[35]	Bleeding, edema, seizures, CNS infection
Subarachnoid hemorrhage[32,36-38]	Rebleeding, vasospasm, hydrocephalus, seizures
Traumatic brain injury[32,39,40]	Intracranial hypertension, bleeding, seizures, stroke (cerebrovascular injury), CNS infection

Continued

IMPAIRMENT IN CONSCIOUSNESS

Global changes in CNS function, best described in terms of impairment in consciousness, are generally referred to as encephalopathy or altered mental status. An acute change in

TABLE 1–1. NEUROLOGIC COMPLICATIONS IN SELECTED SPECIALTY POPULATIONS—CONT'D

Cervical spinal cord injury[41]	Ascension of injury, stroke (vertebral artery injury)

CNS, central nervous system; HIV/AIDS, human immunodeficiency virus/acquired immunodeficiency syndrome; ICP, intracranial pressure; TURP, transurethral prostatic resection.

the level of consciousness undoubtedly is the most common neurologic complication that occurs after ICU admission. Consciousness is defined as a state of awareness (arousal or wakefulness) and the ability to respond appropriately to changes in environment.[42] For consciousness to be impaired, global hemispheric dysfunction or dysfunction of the brainstem reticular activating system must be present.[43] Altered consciousness may result in a sleeplike state (coma) or a state characterized by confusion and agitation (delirium) (Table 1–2).

When an acute change in consciousness is noted, the patient should be evaluated, keeping in mind the patient's age, the presence or absence of coexisting organ system dysfunction, the patient's metabolic status and medication list, and the presence or absence of infection (Table 1–3). In patients with a primary CNS disorder, deterioration in the level of consciousness (e.g., from stupor to coma) frequently represents the development of brain edema, increasing intracranial pressure, new or worsening intracranial hemorrhage, hydrocephalus, CNS infection, or cerebral vasospasm. In patients without a primary CNS diagnosis, an acute change in consciousness is often due to the development of infectious complications (i.e., sepsis-associated encephalopathy), drug toxicities, or the development or exacerbation of organ system failure. Nonconvulsive status epilepticus is increasingly being recognized as a cause of impaired consciousness in critically ill patients.[44-53]

States of altered consciousness manifesting as impairment in wakefulness or arousal (i.e., coma and stupor) and their causes are well defined.[42,43,54,55] Much confusion remains, however, regarding the diagnosis and management of delirium, perhaps the most common state of impaired CNS functioning in critically ill patients at large. When dedicated instruments are used, delirium can be diagnosed in more than 80% of critically ill patients, making this condition the most common neurologic complication of critical illness.[56-58] Much of the difficulty in establishing the diagnosis of delirium stems from the belief that delirium is a state characterized mainly by confusion and agitation and that such states are expected consequences of the unique environmental factors and sleep deprivation that characterize the ICU experience. Terms previously used to describe delirium in critically ill patients include ICU

TABLE 1–2. STATES OF ACUTELY ALTERED CONSCIOUSNESS

State	Description
Coma	Closed eyes, sleeplike state with no response to external stimuli (pain)
Stupor	Responsive only to vigorous or painful stimuli
Lethargy	Drowsy, arouses easily and appropriately to stimuli
Delirium	Acute state of confusion with or without behavioral disturbance
Catatonia	Eyes open, unblinking, unresponsive

TABLE 1–3. GENERAL CAUSES OF ACUTELY IMPAIRED CONSCIOUSNESS IN THE CRITICALLY ILL

TABLE 1–3. GENERAL CAUSES OF ACUTELY IMPAIRED CONSCIOUSNESS IN THE CRITICALLY ILL—CONT'D

Miscellaneous
Fat embolism syndrome
Neuroleptic malignant syndrome
Thiamine deficiency (Wernicke's encephalopathy)
Psychogenic unresponsiveness

CNS, central nervous system.

psychosis, acute confusional state, encephalopathy, and postoperative psychosis. It is now recognized that ICU psychosis is a misnomer; delirium is a more accurate term.[59]

The currently accepted criteria for the diagnosis of delirium include an abrupt onset of impaired consciousness, disturbed cognitive function, fluctuating course, and the presence of a medical condition that could impair brain function.[60] Subtypes of delirium include hyperactive (agitated) delirium and the more common hypoactive or quiet delirium.[58] Impaired consciousness may be apparent as a reduction in awareness, psychomotor retardation, agitation, or impairment in attention (increased distractability or vigilance). Cognitive impairment can include disorientation, impaired memory, and perceptual aberrations (hallucinations or illusions).[61] Autonomic hyperactivity and sleep disturbances may be features of delirium in some patients (e.g., those with drug withdrawal syndromes, delirium tremens). Delirium in critically ill patients is associated with increased morbidity, mortality, and ICU length of stay.[62-64] In general, sepsis and drugs should be the primary etiologic considerations in critically ill patients who develop delirium.

As has been noted, nonconvulsive status epilepticus is increasingly recognized as an important cause of impaired consciousness in critically ill patients. Although the general term can encompasses other entities, such as absence and partial complex seizures, in critically ill patients, nonconvulsive status epilepticus is often referred to as "status epilepticus of epileptic encephalopathy."[53] It is characterized by an alteration in consciousness or behavior associated with electroencephalographic evidence of continuous or periodic epileptiform activity without overt motor manifestations of seizures. In one study of comatose patients without overt seizure activity, nonconvulsive status epilepticus was evident in 8%.[51] Nonconvulsive status epilepticus can precede or follow an episode of generalized convulsive status epilepticus; it can also occur in patients with traumatic brain injury, subarachnoid hemorrhage, global brain ischemia or anoxia, sepsis, and multiple organ failure. Despite the general consensus that nonconvulsive status epilepticus is a unique entity responsible for impaired consciousness in some critically ill patients, there is no general consensus on the electroencephalographic criteria for its diagnosis or the optimal approach to treatment.[65]

STROKE AND OTHER FOCAL NEUROLOGIC DEFICITS

The new onset of a major neurologic deficit that manifests as a focal impairment in motor or sensory function (e.g., hemiparesis) or results in seizures usually indicates a primary problem referable to the cerebrovascular circulation. In a study evaluating the value of computed tomography (CT) in medical ICU patients, ischemic stroke and intracranial bleeding were the most common abnormalities associated with the new onset of a neurologic deficit or seizures.[66] Overall, the frequency of new-onset stroke is between 1% and 4% in medical ICU patients.[1,2] Among general surgical patients, the frequency of perioperative stroke ranges from 0.3% to 3.5%.[67] Patients undergoing cardiac or vascular surgery and surgical patients with underlying cerebrovascular disease can be expected to have an increased risk of perioperative stroke.[19]

The frequency of new or worsening focal neurologic deficits in patients admitted with a primary neurologic or neurosurgical disorder varies. For example, as many as 30% of patients with aneurysmal subarachnoid hemorrhage develop delayed ischemic neurologic deficits.[36] Patients admitted with stroke often develop worsening or new symptoms as a result of stroke progression, bleeding, or reocclusion of vessels previously opened with interventional therapy. In patients who have undergone elective intracranial surgery, postsurgical bleeding or infectious complications are the main causes of new focal deficits. In trauma patients, unrecognized injuries to the cerebrovascular circulation can cause new deficits. Patients who have sustained spinal cord injuries, and those who have undergone surgery of the spine or of the thoracic or abdominal aorta, can develop worsening or new symptoms of spinal cord injury. Early deterioration of CNS function after spinal cord injury usually occurs as a consequence of medical interventions to stabilize the spine, whereas late deterioration is usually due to hypotension and impaired cord perfusion. Occasionally, focal weakness or sensory symptoms in the extremities occur as a result of occult brachial plexus injury or compression neuropathy. New cranial nerve deficits in patients without primary neurologic problems can occur after neck surgery or carotid endarterectomy.

SEIZURES

The new onset of motor seizures occurs in 0.8% to 4% of critically ill medical ICU patients.[1,2,68] The new onset of seizures in general medical-surgical ICU patients is typically caused by narcotic withdrawal, hyponatremia, drug toxicities, or previously unrecognized structural abnormalities.[3,68] New stroke, intracranial bleeding, and CNS infection are other potential causes of seizures after ICU admission. The frequency of seizures is higher in patients admitted to the ICU with a primary neurologic problem, such as traumatic brain injury, aneurysmal subarachnoid hemorrhage, stroke, or CNS infection.[69] Because nonconvulsive status epilepticus may be more common than was previously appreciated, this problem should also be considered in the differential diagnosis of patients developing new, unexplained, or prolonged alterations in consciousness.

GENERALIZED WEAKNESS AND NEUROMUSCULAR DISORDERS

Generalized muscle weakness often becomes apparent in ICU patients as previous impairments in arousal are resolving or sedative and neuromuscular blocking agents are being discontinued or tapered. Polyneuropathy and myopathy associated

with critical illness are now well recognized as the principal causes of new-onset generalized weakness among ICU patients being treated for non-neuromuscular disorders.[5,70-73] These disorders also may be responsible for prolonged ventilator dependency in some patients. Patients at increased risk for these complications include those with sepsis, systemic inflammatory response syndrome, and multiple organ dysfunction syndrome, as well as those who require prolonged mechanical ventilation. Other risk factors include treatment with corticosteroids or neuromuscular blocking agents. In contrast to demyelinating neuropathies (e.g., Guillain-Barré syndrome), critical illness polyneuropathy is primarily an axonal condition. Critical illness polyneuropathy is diagnosed in a high percentage of patients undergoing careful evaluation for weakness acquired while in the ICU. Because primary myopathy coexists in a large number of patients with critical illness polyneuropathy, ICU-acquired paresis[72] or critical illness neuromuscular abnormalities[5] may be better terms to describe this problem. Although acute Guillain-Barré syndrome and myasthenia gravis are rare complications of critical illness, these diagnoses should also be considered in patients who develop generalized weakness in the ICU.

NEUROLOGIC COMPLICATIONS OF PROCEDURES AND TREATMENTS

Routine procedures performed in the ICU or in association with the evaluation and treatment of critical illness can result in neurologic complications.[4] The most obvious neurologic complications are those associated with intracranial bleeding secondary to the treatment of stroke and other disorders with thrombolytic agents or anticoagulants. Other notable complications are listed in Table 1–4.

TABLE 1–4. NEUROLOGIC COMPLICATIONS ASSOCIATED WITH ICU PROCEDURES AND TREATMENTS

Procedure	Complication
Angiography	Cerebral cholesterol emboli syndrome
Anticoagulants/ antiplatelet agents	Intracranial bleeding
Arterial catheterization	Cerebral embolism
Bronchoscopy	Increased ICP
Central venous catheterization	Cerebral air embolism, carotid dissection, Horner's syndrome, phrenic nerve injury, brachial plexus injury, cranial nerve injury
DC cardioversion	Embolic stroke, seizures
Dialysis	Seizures, increased ICP (dialysis disequilibrium syndrome)
Endovascular procedures (CNS)	Vessel rupture, thrombosis, reperfusion bleeding
Epidural catheter	Spinal epidural hematoma, epidural abscess
ICP monitoring	CNS infection (ventriculitis), hemorrhage
Intra-aortic balloon pump	Lower extremity paralysis
Intubation	Spinal cord injury
Left ventricular assist devices	Stroke, seizures
Lumbar puncture or/drain	Meningitis, herniation
Mechanical ventilation	Cerebral air embolism, increased ICP (high PEEP and hypercapnea), seizures (hypocapnea)
Nasogastric intubation	Intracranial placement

CNS, central nervous system; DC, direct current; ICP, intracranial pressure; ICU, intensive care unit; PEEP, positive end-expiratory pressure.

EVALUATION OF SUDDEN NEUROLOGIC CHANGE

A new or sudden change in the neurologic condition of a critically ill patient necessitates a focused neurologic examination, a review of the clinical course and the medications administered before the change, a thorough laboratory assessment, and appropriate imaging or neurophysiologic studies when indicated. The type and extent of the evaluation depend on the clinical context and the general category of neurologic change occurring. The history and physical examination should lead the clinician to the diagnostic approach best suited to the individual patient.

The essential elements of the neurologic examination include an assessment of the level and content of consciousness, pupillary size and reactivity, and motor function. Additional evaluation of the cranial nerves and peripheral reflexes and a sensory examination are conducted as indicated by the clinical circumstances. If the patient is comatose on initial evaluation, a more detailed coma examination should be performed to help differentiate structural from metabolic causes of coma.[43,55] When the evaluation reveals only a change in arousal, without evidence of a localizing lesion in the CNS, a search for infection, discontinuation or modification of drug therapy, and a general metabolic evaluation may be indicated. Lumbar puncture to aid the diagnosis of CNS infection may be warranted in selected neurosurgical patients and immunocompromised individuals. Lumbar puncture to rule out nosocomially acquired meningitis in other patients is generally not rewarding.[74] Electroencephalography should be performed in patients with clear evidence of seizures, as well as when the diagnosis of nonconvulsive status epilepticus is being entertained. Continuous electroencephalography should be considered when the index of suspicion for nonconvulsive status epilepticus remains high and the initial electroencephalographic studies are unrevealing.

CT is indicated for non-neurologic patients with new focal deficits, seizures, or otherwise unexplained impairments in arousal.[66] In patients with primary neurologic disorders, CT is indicated if worsening brain edema, herniation, bleeding, and hydrocephalus are considerations when new deficits or worsening neurologic status occurs. In some cases, when the basis for a change in neurologic condition remains elusive, magnetic resonance imaging (MRI) may be helpful. In particular, the diffusion-weighted MRI technique can reveal structural abnormalities, such as hypoxic brain injury, fat embolism, vasculitis, cerebral venous thrombosis, or multiple infarcts following cardiopulmonary bypass, that are not apparent by standard CT or conventional MRI.[75-80] MRI may be the imaging modality of choice in patients with human immunodeficiency virus (HIV) and new CNS complications.[75] For patients who develop signs and symptoms of spinal cord injury complicating critical illness, MRI or somatosensory evoked potentials can be used to further delineate the nature and severity of the injury. For patients who develop generalized muscle weakness or unexplained ventilator dependency,

electromyography and nerve conduction studies can confirm the presence of critical illness polyneuropathy or myopathy.

MONITORING FOR NEUROLOGIC CHANGES

The common occurrence of neurologic changes in critically ill patients emphasizes the need for vigilant monitoring. A variety of clinical techniques, such as the Glasgow Coma Scale, National Institutes of Health Stroke Scale, Ramsay Sedation Scale, Richmond Agitation-Sedation Scale, and Confusion Assessment Method for the Intensive Care Unit (CAM-ICU) can be used to monitor clinical neurologic status.[57,58,81-86] Neurophysiologic methods such as the bispectral index may provide more objective neurologic monitoring in the future for patients admitted to the ICU with and without primary neurologic problems.[87-89] For patients admitted to the ICU with a primary neurologic disorder, a variety of monitoring techniques, including measurements of intracranial pressure, near infrared spectroscopy, brain tissue Po_2, transcranial Doppler, and electroencephalography, are available.[90]

ANNOTATED REFERENCES

In an effort to dispel the myth that environmental conditions lead to "ICU psychosis," the authors of this article argue that ICU psychosis is more appropriately described as delirium. The etiology and management of delirium in critically ill patients are reviewed.

Naik-Tolani S, Oropello JM, Benjamin E: Neurologic complications in the intensive care unit. Clin Chest Med 1999;20:423-434.

The authors of this article present an overview of central nervous system (CNS) complications of critical illness and ICU procedures in critically ill patients without primary disorders of the CNS.

Sundgren PC, Reinstrup P, Romner B, et al: Value of conventional diffusion- and perfusion-weighted MRI in the management of patients with unclear cerebral pathology, admitted to the intensive care unit. Neuroradiology 2002;44:674-680.

This retrospective study of 21 critically ill patients undergoing MR imaging because of a disparity in clinical neurologic findings and CT imaging revealed that additional useful diagnostic and prognostic information can be obtained, especially when diffusion and perfusion weighted MR sequences are obtained.

Chapter 2
AGITATION AND DELIRIUM

Eric B. Milbrandt • E. Wes Ely

Agitation and delirium are commonly encountered in the intensive care unit (ICU). They are more than an inconvenience; these conditions can have deleterious effects on patient and staff safety and contribute to poor outcomes. It is important for clinicians to have an organized approach for the evaluation and management of agitation and delirium.

AGITATION

Agitation is a state of extreme arousal, irritability, and motor restlessness that results from an internal sense of discomfort or tension. It is the behavioral response to physical or emotional distress, including pain, dyspnea, and anxiety, although the most common cause of agitation in the ICU is probably delirium.[1] Agitation is characterized by repetitive, nonproductive movements that may appear purposeless, although careful observation of the patient sometimes reveals an underlying intent. Agitation may be mild, characterized by increased movements and an apparent inability to get comfortable. Severe agitation can be life-threatening, leading to removal of life-saving devices as well as hypoxia, barotrauma, and hypotension due to patient-ventilator asynchrony. Indeed, recent studies have shown that agitation contributes to ventilator asynchrony, increased oxygen consumption, and inadvertent removal of devices and catheters.[2-5]

DELIRIUM

Delirium is an acute, fluctuating change in mental status, with inattention and altered level of consciousness. Delirium is an objective sign of cerebral insufficiency or acute cognitive dysfunction. It should be thought of as a form of organ dysfunction, much like shock and hypoxemia are considered evidence of dysfunction of the cardiovascular and pulmonary systems, respectively. Delirium has myriad causes, including pain and anxiety, medications, toxins, and metabolic derangements. Also known as acute encephalopathy[6] or ICU psychosis,[7] delirium occurs in as many as 80% of mechanically ventilated ICU patients and has recently been shown to be associated with increased length of stay, medical complications, and poor outcomes, including an increased 6-month mortality.[8-12] Furthermore, delirium can adversely affect the quality of life in survivors of critical illnesses, because a significant percentage of individuals who develop delirium in the hospital continue to demonstrate symptoms of delirium after discharge.[13-16] These patients manifest decreased cerebral activity and increased cognitive deterioration, and they are more likely to develop dementia than are patients without delirium. Finally, patients who develop delirium have a greater rate of decline on cognitive tests than do nondelirious patients.[13-16]

Delirium can be hypoactive or hyperactive. Patients with hypoactive delirium are calm but inattentive, and they manifest decreased mobility. Patients with hyperactive delirium are agitated and combative. Inattention is the hallmark feature of both types of delirium. Patients with hyperactive delirium are at risk for self-extubation, loss of catheters, and patient-ventilator asynchrony. Because of these risks, patients are often given high doses of sedatives that commit them to continued mechanical ventilation. Despite the dangers of hyperactive delirium, hypoactive delirium may actually be associated with a worse prognosis.[17-20]

Because the majority of patients manifest hypoactive delirium instead of the more obvious hyperactive type,[18,21-25] delirium frequently goes unrecognized in the ICU. Furthermore, up to 40% of alert or easily arousable patients who are usually assumed to be "cognitively intact" by ICU personnel may actually be delirious.[10] Even when ICU delirium is recognized, most clinicians consider it an expected event that is often iatrogenic and without consequence.[26]

CAUSES AND RISK FACTORS

The list of causes and risk factors for agitation and delirium is long, and the causes of the two conditions overlap to a large extent (Table 2–1). Fortunately, there are several mnemonics that can aid clinicians in recalling the list; two common ones are IWATCHDEATH and DELIRIUM (Table 2–2). In practical terms, the risk factors can be divided into three categories: the acute illness itself, patient factors, and iatrogenic or environmental factors. Importantly, a number of medications that are commonly used in the ICU are associated with the development of agitation and delirium (Table 2–3). A thorough approach to the treatment and support of the acute illness (e.g., controlling sources of sepsis and giving appropriate antibiotics), as well as minimizing the iatrogenic component (e.g., avoiding excessive sedation), can help reduce the incidence and magnitude of delirium and its attendant complications.

ASSESSMENT

There are many scales available for the assessment of agitation and sedation, including the Ramsay Scale,[27] the Riker Sedation-Agitation Scale (SAS),[28] the Motor Activity Assessment Scale (MAAS),[29] and the Richmond Agitation-Sedation Scale (RASS).[30] Each has good reliability and validity

TABLE 2–1. CAUSES OF AND RISK FACTORS FOR AGITATION AND DELIRIUM

Age >70 years	BUN/creatinine ratio ≥18
Transfer from a nursing home	Renal failure, creatinine >2.0 mg/dL
History of depression	Liver disease
History of dementia, stroke, or epilepsy	Congestive heart failure
Alcohol abuse within past month	Cardiogenic or septic shock
Tobacco use	Myocardial infarction
Drug overdose or illicit drugs	Infection
HIV infection	Central nervous system pathology
Medications	Urinary retention or fecal impaction
Hypo- or hypernatremia	Tube feeding
Hypo- or hyperglycemia	Rectal or bladder catheters
Hypo- or hyperthyroidism	Physical restraints
Hypothermia or fever	Central line catheters
Hypertension	Malnutrition or vitamin deficiencies
Hypoxia	Procedural complications
Acidosis or alkalosis	Visual or hearing impairment
Pain	Sleep disruption
Fear and anxiety	

BUN, blood urea nitrogen; HIV, human immunodeficiency virus.

among adult ICU patients and can be used to set targets for goal-directed sedative administration. The SAS, which scores agitation and sedation using a 7-point system, has excellent interrater reliability (kappa = 0.92), and it is highly correlated (r^2 = 0.83 to 0.86) with other scales. The RASS (Table 2–4), however, is the only method that has been shown to detect variations in the level of consciousness over time or in response to changes in sedative and analgesic drug use.[31,32] The 10-point Richmond scale has discrete criteria to distinguish levels of agitation and sedation. Patient evaluation consists of a three-step process. First, a patient is observed to determine whether he or she is alert, restless, or agitated (0 to +4). If the patient is not spontaneously alert, the patient's name is called and the duration of eye contact is measured (−1 to −3). If there is no eye contact with verbal stimulation,

TABLE 2–2. MNEMONICS FOR REMEMBERING CAUSES OF DELIRIUM AND AGITATION: IWATCHDEATH AND DELIRIUM

IWATCHDEATH	DELIRIUM
Infection	**D**rugs
Withdrawal	**E**lectrolyte and physiologic abnormalities
Acute metabolic	**L**ack of drugs (withdrawal)
Trauma/pain	**I**nfection
Central nervous system pathology	**R**educed sensory input (blindness, deafness)
Hypoxia	**I**ntracranial problems (CVA, meningitis, seizure)
Deficiencies (vitamin B_{12}, thiamine)	**U**rinary retention and fecal impaction
Endocrinopathies (thyroid, adrenal)	**M**yocardial problems (MI, arrhythmia, CHF)
Acute vascular (hypertension, shock)	
Toxins/drugs	
Heavy metals	

CHF, congestive heart failure; CVA, cerebrovascular accident; MI, myocardial infarction.

TABLE 2–3. COMMONLY USED DRUGS ASSOCIATED WITH DELIRIUM AND AGITATION

Benzodiazepines	Antibiotics
Opiates (especially meperidine)	Corticosteroids
Anticholinergics	Metoclopramide
Antihistamines	Muscle relaxants
H_2 blockers	Lidocaine

the shoulder is shaken or the sternum is rubbed, and the response is noted (−4 or −5). This assessment takes less than 20 seconds and correlates well with other measures of sedation (e.g., Glasgow Coma Scale, bispectral electroencephalography, neuropsychiatric ratings).

Until recently, there was no valid and reliable way to assess delirium in critically ill patients, many of whom are nonverbal owing to sedation or mechanical ventilation. The Confusion Assessment Method for the ICU (CAM-ICU) (Table 2–5) is a delirium measurement tool that was developed by a team of specialists in critical care, psychiatry, neurology, and geriatrics.[8-12] Administered by a nurse, the evaluation takes only 1 to 2 minutes to conduct and is 98% accurate for detecting

TABLE 2–4. RICHMOND AGITATION-SEDATION SCALE

+4	Combative	Combative, violent, immediate danger to staff
+3	Very agitated	Pulls or removes tube(s) or catheter(s); aggressive
+2	Agitated	Frequent nonpurposeful movement; fights ventilator
+1	Restless	Anxious, apprehensive, but movements not aggressive or vigorous
0	Alert and calm	
−1	Drowsy	Not fully alert but has sustained (>10 sec) awakening (eye opening/contact) to voice
−2	Light sedation	Drowsy; briefly (<10 sec) awakens to voice or physical stimulation
−3	Moderate sedation	Movement or eye opening (but no eye contact) to voice
−4	Deep sedation	No response to voice, but movement or eye opening to physical stimulation
−5	Unarousable	No response to voice or physical stimulation

Procedure for Assessment

1. Observe patient
   Is patient alert, restless, or agitated? **(Score 0 to +4)**
2. If not alert, state patient's name and tell him or her to open eyes and look at speaker.
   Patient awakens, with sustained eye opening and eye contact. **(Score −1)**
   Patient awakens, with eye opening and eye contact, but not sustained. **(Score −2)**
   Patient does not awaken (no eye contact) but has eye opening or movement in response to voice. **(Score −3)**
3. Physically stimulate patient by shaking shoulder and/or rubbing sternum.
   No response to voice, but response (movement) to physical stimulation. **(Score −4)**
   No response to voice or physical stimulation **(Score −5)**

Am J Respir Crit Care Med 2002;166:1338-1344; Ely EW, Truman B, Shintani A, et al: Monitoring sedation status over time in ICU patients: Reliability and validity of the Richmond agitation-sedation scale (RASS). JAMA 2003;289:2983-2991.

TABLE 2–5. CONFUSION ASSESSMENT METHOD FOR THE INTENSIVE CARE UNIT

1. Acute Onset or Fluctuating Course	Absent	Present
A. Is there evidence of an acute change in mental status from baseline?		
OR		
B. Did the (abnormal) behavior fluctuate during the past 24 hours, that is, tend to come and go or increase and decrease in severity, as evidenced by fluctuation on a sedation scale (e.g., Richmond Agitation-Sedation Scale), Glasgow Coma Scale, or previous delirium assessment?		

2. Inattention	Absent	Present
Did the patient have difficulty focusing attention, as evidenced by a score of less than 8 on either the auditory or visual component of the Attention Screening Examination?		

3. Disorganized Thinking	Absent	Present
Is there evidence of disorganized or incoherent thinking, as evidenced by incorrect answers to 2 or more of the 4 questions or the inability to follow commands?		

Questions (use either set A or set B):

Set A	Set B
1. Will a stone float on water?	1. Will a leaf float on water?
2. Are there fish in the sea?	2. Are there elephants in the sea?
3. Does 1 pound weigh more than 2 pounds?	3. Do 2 pounds weigh more than 1 pound?
4. Can you use a hammer to pound a nail?	4. Can you use a hammer to cut wood?

Other:

1. Are you having any unclear thinking?
2. Hold up this many fingers. (Examiner holds two fingers in front of patient.)
3. Now do the same thing with the other hand. (Do not repeat the number of fingers.)

4. Altered Level of Consciousness	Absent	Present
Is the patient's level of consciousness anything other than alert, such as vigilant, lethargic, or stuporous (i.e., Richmond agitation-sedation score other than 0 at time of assessment)?		

Alert: spontaneously fully aware of environment and interacts appropriately

Vigilant: hyperalert

Lethargic: drowsy but easily aroused; unaware of some elements in the environment or not spontaneously interacting appropriately with the interviewer; becomes fully aware and appropriately interactive when prodded minimally

Stuporous: becomes incompletely aware when prodded strongly; can be aroused only by vigorous and repeated stimuli, and as soon as the stimulus ceases, lapses back into the unresponsive state

Overall Assessment: Presence of Features 1 and 2 and Either Feature 3 or Feature 4?	Yes	No

delirium as compared with a full *Diagnostic and Statistical Manual of Mental Disorders* IV assessment by a geriatric psychiatrist.[8,10] Delirium is diagnosed when a patient demonstrates an acute change or fluctuating changes in mental status, inattention, and either disorganized thinking or altered level of consciousness. National guidelines recommend the routine use of this method for delirium assessment in all critically ill patients.[32]

MANAGEMENT

Agitation is expected in a newly intubated patient. However, when agitation or delirium develops in a previously comfortable patient, a search for the underlying cause should be undertaken before attempting pharmacologic intervention. A rapid assessment should be performed, including vital signs and physical examination, to rule out life-threatening problems (e.g., hypoxia, self-extubation, pneumothorax, hypotension) or other acutely reversible physiologic causes (e.g., hypoglycemia, metabolic acidosis, stroke, seizure, pain). The previously mentioned IWATCHDEATH and DELIRIUM mnemonics can be particularly helpful in guiding this initial evaluation.

After correcting any identifiable contributing factors, pharmacologic treatment is often required. If pain is present, an analgesic should be the initial drug of choice. Although benzodiazepines are the most commonly used drugs for the treatment of agitation, they are not recommended for the management of delirium because they can paradoxically exacerbate confusion. Patients who manifest delirium should be treated with a traditional antipsychotic medication (e.g., haloperidol). When given intravenously, these medications exert a calming effect, flattening the affect and diminishing psychomotor agitation without suppressing respiratory drive or affecting hemodynamics. Haloperidol and related drugs achieve this effect by blocking dopamine receptors in the central nervous system. With acute delirium, haloperidol should be given in doses of 2 to 10 mg i.v. every 20 to 30 minutes until delirium is controlled. Subsequently, 25% of the total loading dose should be administered every 6 hours.[32] The dose should then be tapered over several days. Despite their favorable safety profile, antipsychotic medications can cause extrapyramidal reactions, neuroleptic malignant syndrome, and QT interval prolongation leading to torsades de pointes. These adverse effects are thought to be dose related, leading some experts to question the safety of the rapid-loading approach. According to this view, patients should receive no more than 20 mg/day of haloperidol.[33] Anecdotally, the use of atypical antipsychotics, such as risperidone, olanzapine, or ziprasidone,[34] is in vogue. However, their effectiveness in treating ICU delirium has not been evaluated systematically and, like haloperidol, these agents have the potential for QT interval prolongation.

For nondelirious agitated patients, benzodiazepines and propofol are the drugs of choice in the ICU. These agents are most effectively administered using standardized nurse-driven protocols with a clearly stated target level for sedation. Benzodiazepines bind to gamma-aminobutyric acid receptors in the central nervous system, leading to sedation, anxiolysis, hypnosis, muscle relaxation, anticonvulsant activity, and amnesia.[35] Benzodiazepines do not relieve pain, but their anxiolytic and amnestic properties may improve pain tolerance by moderating the anticipatory pain response.[36] Benzodiazepines can cause hypotension when given as a bolus dose, particularly in hypovolemic patients who may not tolerate the reduction in sympathetic vascular tone associated with benzodiazepine-induced anxiolysis. Further, by reducing inhibitions, these agents can sometimes cause paradoxical increases in agitation and aggressiveness. Of the benzodiazepines that are currently available, diazepam, midazolam, and lorazepam are the preferred agents in the ICU. The onset of action of diazepam is 2 to 5 minutes, making it useful for rapidly sedating acutely agitated patients. However, its long half-life makes prolonged sedation a risk with repeated use, particularly in patients with renal or hepatic dysfunction. To control acute agitation, it is given in doses of 2 to 6 mg every 5 to 15 minutes until the event is controlled. Continuous infusions are not recommended. Midazolam is also useful for acute agitation because it has a rapid onset (2 to 5 minutes) and short duration of action. It is given as bolus injections of 2 to 5 mg every 5 to 15 minutes. When used for long-term sedation (>48 to 72 hours), it tends to produce unpredictable awakening times, especially in patients who are obese or who have low serum albumin concentrations or renal failure.[32] Lorazepam has a slower onset of action (5 to 20 minutes), making it less helpful for acute agitation; however, it is less lipid-soluble and has no active metabolite, making it the preferred agent for long-term administration in most critically ill patients. Intermittent doses of 1 to 4 mg are given every 2 to 6 hours, or continuous infusions may be used.

Propofol is an intravenous anesthetic whose mechanism of action is not known. It is quite popular in the ICU owing to its rapid onset of action (1 to 2 minutes) and short duration of action (2 to 8 minutes). It is the preferred sedative when rapid awakening is important, such as for neurologic assessment or pending extubation.[32] When used for long-term (>48 to 72 hours) sedation, the short duration of action does not translate into a reduced duration of mechanical ventilation or a shorter ICU stay.[37] Propofol can cause hypotension due to vasodilatation-related loss of preload and myocardial depression.[38] High-dose continuous infusions have been associated with lactic acidosis in children and with metabolic acidosis, arrhythmias, and cardiac arrest in adults.[39-41] Consequently, providers should consider alternative sedative agents for any patient receiving high-dose propofol infusions who develops unexplained metabolic acidosis, arrhythmias, or cardiac failure.

At times, mechanical restraints may be needed to ensure patient and staff safety while waiting for medications to take effect. It is important to keep in mind, however, that restraints can actually increase agitation and delirium, and their use may have adverse consequences, including strangulation, nerve injury, skin breakdown, and other complications of immobilization.

SUMMARY

Agitation and delirium are very common in the ICU, where their occurrence puts patients at risk for self-injury and poor clinical outcomes. Through a systematic approach, life-threatening problems and other acutely reversible physiologic causes can be rapidly identified and remedied. Recognizing and treating agitated delirium with antipsychotic medications may reduce the use of sedative medications and decrease the risk of prolonging the ICU stay due to oversedation.

Chapter 3

MANAGEMENT OF ACUTE PAIN IN THE INTENSIVE CARE UNIT

Paul Jodka • Stephen O. Heard

Acute pain often occurs in patients who are cared for in the intensive care unit (ICU). Acute pain and discomfort can have multiple causes in this setting, including surgical and post-traumatic wounds and injuries, the use of invasive monitoring devices and mechanical ventilators, prolonged immobilization, and routine nursing care (e.g., dressing changes, airway suctioning).[1-4] Pain is defined as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage."[5] The experience of pain and any related suffering differs among patients,[6,7] but the physiologic sequelae of inadequately treated pain are relatively predictable and potentially deleterious. Such physiologic responses to acute pain and stress are mediated by neuroendocrine activation and increased sympathetic tone. As a consequence, the patient develops tachycardia, increased myocardial oxygen consumption, immunosuppression, hypercoagulability, persistent catabolism, and numerous other metabolic alterations.[8,9] Additional morbidity may be incurred by pain-related functional limitations affecting, for example, pulmonary mechanics[10] and the timing of ambulation.

ACUTE PAIN ASSESSMENT

A variety of scales, such as the visual analog scale and the numeric rating scale, have been used as pain assessment tools in the ICU, although they have not been formally validated for such use (Fig. 3–1). Unfortunately, many ICU patients cannot provide full (or even partial) information regarding their pain. As a consequence, caregivers must sometimes use signs of heightened sympathetic activity (e.g., hypertension, tachycardia, lacrimation, diaphoresis, restlessness) as surrogate markers for the presence of pain; trends in such signs provide a measure of the success of a given intervention. Behavioral-physiologic scales have been described and compared with the visual analog and numeric rating scales.[11,12] These scales, however, are not specific enough to eliminate the subjective component of pain assessment in ICU patients. Thus, pain assessment in critically ill patients remains an inexact science requiring an individualized approach. Assessments must be made consistently and repeatedly and documented in the medical record.

OPTIONS FOR ACUTE PAIN THERAPY

Acute pain is triggered by stimulation of peripheral nociceptors in the skin or deeper structures and is a complex process, involving multiple mediators at various levels of the neuraxis (Fig. 3–2).[5] Different parts of the pain pathway can be targeted either individually or as part of a comprehensive strategy aimed at multiple sites for additive or synergistic effects. Thus, nociception can be influenced peripherally by the use of nonsteroidal anti-inflammatory drugs (NSAIDs) and nerve blocks, at the spinal cord level by the use of epidural or intrathecal medications, and centrally by the use of systemic medications.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Drugs in this class inhibit cyclooxygenase (COX) enzymes, which are involved in prostaglandin synthesis and related inflammation in response to injury. COX-1 is a constitutive enzyme that is present in most tissues and, through the production of prostaglandins E_2 and I_2, serves homeostatic and protective functions.[13] COX-2 is an inducible enzyme that is expressed in response to inflammation. Nonsteroidal anti-inflammatory drugs (NSAIDs) are commonly used in conjunction with other agents, such as opioids, to take advantage of different side effect profiles and possible synergistic efficacy. As a class, NSAIDs may cause adverse effects that include nausea, gastrointestinal bleeding, inhibition of platelet function, operative site bleeding, renal insufficiency, and bronchospasm in aspirin-sensitive patients (triad of asthma, nasal polyposis, and aspirin allergy).[1,5,14,15]

Currently, ketorolac tromethamine (Toradol) is the only parenteral NSAID available in the United States. It has been

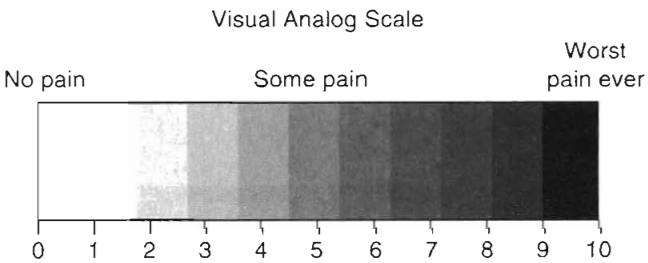

FIGURE 3–1. Visual analog scale. Pain can be rated between 0 (no pain) and 10 (extreme pain). Use of a graphic such as this allows an intubated patient to indicate his or her level of discomfort by pointing. Other scales use cartoon faces that are either smiling or frowning. (From Higgins TL, Jodka PG, Farid A: Pharmacologic approaches to sedation, pain relief and neuromuscular blockade in the intensive care unit. Part II. Clin Intensive Care 2003;14[3-4]:91-98.)

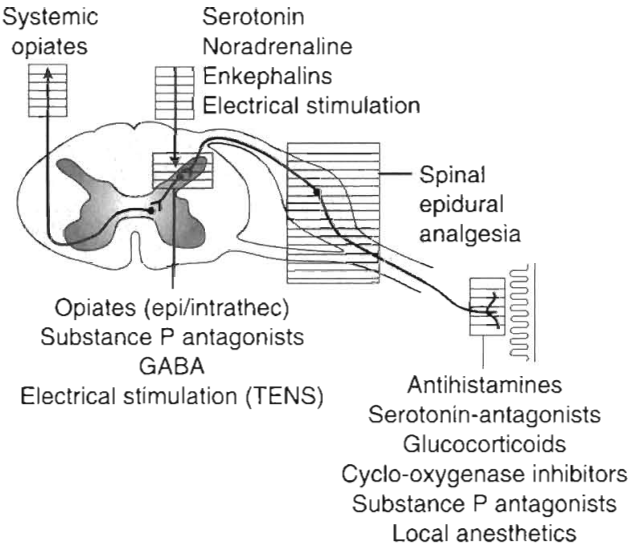

FIGURE 3–2. A "map" of the path of nociceptive information from the periphery to the central nervous system. Modification of that information can occur at any point of information transfer. GABA, gamma-aminobutyric acid; stim, stimulation; TENS, transcutaneous electric nerve stimulation. (From Kehlet H: Modification of responses to surgery by neural blockade: Clinical implications. shown to reduce postoperative opioid requirements and does not cause respiratory depression.[16,17] However, prolonged use has been associated with a significant incidence of the aforementioned side effects (primarily bleeding and renal failure)[18,19]; consequently, ketorolac therapy should be limited to a maximum of 5 days.[1] In addition, ketorolac should be used at decreased dosages, or avoided altogether, in patients at higher risk of such complications owing to advanced age, hypovolemia, and preexisting renal insufficiency. This caution also applies to enterally administered NSAIDs.

Selective COX-2 inhibitors such as celecoxib (Celebrex) and rofecoxib (Vioxx) are available for enteral administration, and injectable COX-2 agents are being studied primarily for the management of acute postoperative pain.[13] The main advantage of these agents over their nonselective relatives lies in the promise of decreased gastrointestinal side effects. However, because COX-2 inhibitors reduce the formation of prostaglandin I_2 (a vasodilating prostaglandin) without affecting the production of thromboxane A_2 (a vasoconstricting prostaglandin), the potential for cardiovascular toxicity exists.[13] Clinical trials are under way to determine the efficacy, cost-effectiveness, and safety of these drugs in the perioperative arena. As with NSAIDs overall, this class of drugs has yet to be formally evaluated in the ICU setting.

OPIOID ANALGESICS

A number of opioids are available(Table 3–1), and this drug class remains the mainstay of ICU analgesia. Morphine, hydromorphone (Dilaudid), and fentanyl are commonly used in ICUs in the United States and have been recommended as first-line narcotic analgesic agents.[1] Opioids bind to a variable degree with various opioid receptor subtypes (μ, δ, κ) located in the brain, spinal cord, and peripheral sites and modulate the transmission and processing of nociceptive signals.[5] The clinical and pharmacologic properties of opioids depend on several variables, such as chemical and solubility properties, dosing regimen (dose, route, and duration of administration), patient characteristics (Table 3–2), and presence of active metabolites. Drugs that are often thought of as short-acting (e.g., fentanyl) actually have a markedly prolonged duration of action if given repeatedly or as an infusion (Fig. 3–3).

Opioids are excellent analgesics, but they are not amnestic agents. As a class, opioids can suppress respiratory drive and promote sedation, gastrointestinal symptoms (ileus, nausea and vomiting, constipation), urinary retention, pruritus, or hypotension. Morphine can cause hypotension by triggering the release of histamine. High doses of meperidine can cause myocardial depression and lead to hypotension on this basis. Hypotension can also be caused by the ablation of pain-mediated sympathetic stimulation, or it may be multifactorial.[20] In actual practice, however, opioids are relatively neutral regarding their hemodynamic effects, if they are used judiciously in euvolemic patients. Of note, coadministration of other central nervous system–active agents (such as benzodiazepines) tends to accentuate opioid-induced side effects, specifically those of sedation, respiratory depression, and hypotension.

Opioids are most commonly administered intravenously in critically ill patients and titrated to effect, either on a scheduled, intermittent basis or as a continuous infusion following a loading dose to achieve analgesia.[1] This strategy avoids concerns regarding unpredictable bioavailability associated with intramuscular, enteral, or transdermal administration and favors more stable analgesic drug concentrations. The benefits of administering analgesics (and sedatives) in such a fashion are several, but they must be balanced against the possibility of inadvertent excess dosing, which may result in prolonged mechanical ventilation and longer hospital stays.[21] It has been reported, however, that scheduled daily interruption of sedative-analgesic drug infusions can help minimize this problem and may actually lead to a shorter duration of mechanical ventilation and a shorter ICU stay.[22]

Morphine is a naturally occurring narcotic analgesic.[1,20] It is metabolized mainly by the liver to an active compound (morphine-6-glucuronide) that can cause a prolonged drug

TABLE 3–1. COMMONLY USED OPIOIDS

Agent	Intermittent Dose	Continuous Dose	Metabolism	Precautions
Fentanyl	0.35–1.5 μg/kg i.v. q 0.5–1 h	0.7–10 μg/kg/h	Oxidation	Rigidity with high doses
Hydromorphone	10–30 μg/kg i.v. q 1–2 h	7–15 μg/kg/h	Glucuronidation	
Morphine	0.01–0.15 mg/kg i.v. q 1–2 h	0.07–0.5 mg/kg/h	Glucuronidation	Histamine release
Meperidine	Not recommended	Not recommended	Demethylation and hydroxylation	Avoid with MAOIs and SSRIs

MAOI, monoamine oxidase inhibitor; SSRI, selective serotonin reuptake inhibitor.

TABLE 3–2. FACTORS INFLUENCING NARCOTIC PHARMOCOKINETICS

Age (increased sensitivity in elderly)
Acid-base status (increased arterial pH increases brain penetration)

Liver disease
Renal disease (active metabolites may accumulate)
Other central nervous system depressants
Acute and chronic tolerance

effect in patients with renal insufficiency. Onset of action after intravenous administration is relatively slow (5 to 10 minutes) owing to low lipid solubility, and the duration of clinical effect is long enough to permit its use as either an intermittent injection or an infusion. Morphine can cause histamine release and vasodilatation, resulting in hypotension, so it should be used with caution in hypovolemic and hemodynamically unstable patients. Dosing requirements vary significantly from patient to patient and must be individualized (see Table 3–1).

Hydromorphone is a semisynthetic narcotic that, compared with morphine, has a similar duration of action, is a more potent analgesic, does not release histamine, and lacks an active metabolite. These properties make it an attractive alternative to morphine in patients with hemodynamic instability or significant renal impairment.[1] Hydromorphone is also best administered by either infusion or intermittent injection.

Fentanyl is a synthetic narcotic with a potency about 100 times that of morphine. Fentanyl does not cause histamine release, has no active metabolites, and generally has minimal effects on hemodynamics. It is very lipophilic, leading to a rapid onset of action. Fentanyl can accumulate in fat, however, giving rise to a prolonged drug effect if it is given in very high doses or for a lengthy period, even in patients without significant renal or hepatic dysfunction.[1] Rapid high-dose fentanyl injection can cause chest rigidity that may interfere with ventilation, even in intubated patients, necessitating temporary use of a paralytic agent. On balance, however, fentanyl is a good choice for the analgesic needs of unstable ICU patients, provided the aforementioned pharmacokinetic properties are kept in mind.[1]

Meperidine (Demerol) is a synthetic opioid that is about one tenth as potent as morphine. Meperidine is metabolized by the liver into several compounds that are cleared by the kidneys; these compounds tend to accumulate in the setting of renal insufficiency or after repeated administration in patients with normal renal function. Normeperidine is a primary and neuroexcitatory metabolite of meperidine that has been reported to cause seizures.[23] Additionally, meperidine can cause tachycardia[24] due to anticholinergic effects and also may cause myocardial depression at higher doses. Given these concerns and the ready availability of alternative agents, it is difficult to justify the use of meperidine in the ICU.

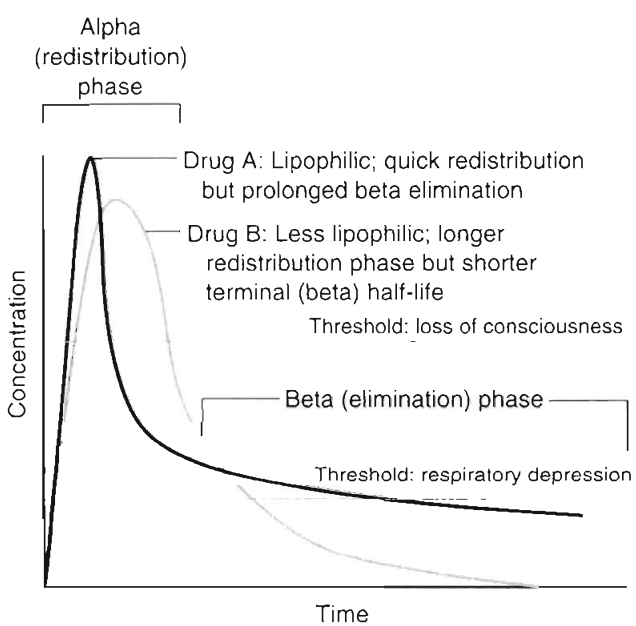

FIGURE 3–3. Pharmacokinetics. A lipophilic drug (drug A) may have a rapid onset and an initially quick distribution but a prolonged beta-elimination (metabolism) phase, resulting in respiratory depression with repeated doses or constant infusion. A less lipophilic drug (drug B) may take longer to redistribute, giving the impression of a prolonged initial duration of action, but does not accumulate, owing to a shorter elimination half-life. Fentanyl is like drug A, whereas morphine is more similar to drug B. (From Higgins TL, Jodka PG, Farid A: Pharmacologic approaches to sedation, pain relief and neuromuscular blockade in the intensive care unit. Part II. Clin Intensive Care 2003;14[3-4]:91-98.)

OTHER NARCOTIC ANALGESICS

Many other opioids are available for clinical use, such as alfentanil, sufentanil, and remifentanil. Comparative data on the use of these drugs in critically ill patients are lacking, and the use of a given agent is determined largely by a given practitioner's experience and practice patterns.

NEURAXIAL ANALGESIC TECHNIQUES

The administration of narcotics, local anesthetics, and other agents via intrathecal or epidural catheters targets the processing of pain signals at the level of the spinal cord or nerve root.[5,25] Intrathecal analgesic techniques are most appropriate for the acute perioperative setting, with limited applicability to the general ICU population. The use of epidural catheters for regional analgesia in ICU patients may be quite useful, assuming that the pain pattern is regionalized and that there are no contraindications to catheter placement (e.g., coagulopathy, uncontrolled infection, unstable spinal skeletal structures). In some patients, epidural analgesia may be preferable to intravenously administered medications, because this approach affords dense regional pain control[5] while largely avoiding the sedative and respiratory side effects of systemic medications. Because there are multiple factors related to the feasibility and utility of neuraxial techniques in ICU patients, consultation with a pain management specialist is advised when such an approach is being considered.

ANNOTATED REFERENCES

Carroll KC, Atkins PJ, Herold GR, et al: Pain assessment and management in critically ill postoperative and trauma patients: A multisite study. Am J Crit Care 1999;8:105-117.

A descriptive, correlational study of pain management in 213 patients in 13 ICUs. The authors found that patients were generally satisfied with their pain management, despite being in pain. They concluded that patient satisfaction alone is not a reliable means of gauging the effectiveness of pain management.

Desbiens NA, Wu AW, Broste SK, et al: Pain and satisfaction with pain control in seriously ill hospitalized adults: Findings from the SUPPORT research investigations. Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatment. Crit Care Med 1996;24:1953-1961.

In the Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatment (SUPPORT), approximately 50% of patients experienced pain, 15% reported extreme or moderate amounts of pain, and 15% were dissatisfied with their pain management. Patients were more likely to be dissatisfied if they had severe pain, greater anxiety, depression, and alteration of mental status.

The ICU environmental stressor scale was administered to patients, families, and ICU professionals during a patient's first week of care. Pain, inability to sleep, and having tubes in the mouth were the most important stressors identified by the three groups.

Chapter 4
FEVER AND HYPOTHERMIA

Mitchell P. Fink

Fever is defined as an increase in body temperature. Normal body temperature is 36.8 ± 0.4° C. Normally, body temperature varies in a circadian fashion by about 0.6° C, being lowest in the morning and highest in the late afternoon or early evening. Fever is triggered by the release of various cytokines—notably, interleukin-1 beta, tumor necrosis factor, and interleukin-6—that are capable of causing secretion of prostaglandin E_2 in the hypothalamus. Prostaglandin E_2 binds to prostaglandin receptors on neurons in the ventromedial preoptic area and the median preoptic nucleus.[1,2] Activation of these receptors triggers a number of neurohumoral and physiologic changes that lead to increased body temperature.

Body temperature can be measured using an oral, axillary, or rectal mercury-filled glass thermometer. These traditional approaches, however, have been largely replaced by a variety of safer and more environmentally friendly methods. These approaches use thermistors located on catheters or probes situated in the pulmonary artery, distal esophagus, urinary bladder, or external ear canal.[3] Infrared detectors can also be used to measure tympanic membrane temperature. Forehead skin temperature can be measured using a temperature-sensitive patch. A core (i.e., rectal, pulmonary artery, esophageal, bladder, or tympanic membrane) temperature greater than 38.3° C should be regarded as evidence of fever.

Fever is a cardinal sign of infection. Accordingly, the new onset of fever should trigger a careful diagnostic evaluation, looking for a source of infection. The diagnostic evaluation should be thorough and tailored to the recent history of the patient. For example, the possibility of a central nervous system infection should receive greater attention in a patient with recent or ongoing central nervous system instrumentation. By the same token, if a patient recently underwent a gastrointestinal surgical procedure, the clinician should have a high index of suspicion for an intra-abdominal source of infection. Key elements in the assessment of new-onset fever in the intensive care unit (ICU) are listed in Table 4–1. Common sources of infection in ICU patients are listed in Table 4–2.

Although fever in the ICU is most commonly due to infection, myriad noninfectious causes of systemic inflammation can also result in hyperthermia. Important noninfectious causes of fever in ICU patients are listed in Table 4–3. Some authors claim that noninfectious causes of fever rarely result in a core temperature greater than 38.9° C,[4,5] although rigorous data in support of this view are lacking. By the same token, infections are rarely, if ever, associated with core temperatures greater than 41.1° C. When the core temperature is this high, the clinician should suspect malignant hyperthermia, neuroleptic malignant syndrome, or heat stroke.

In general, fever should not be treated using antipyretics. This view is based on data that suggest that hyperthermia is an adaptive response that enhances the host's ability to fight infection.[6,7] In addition, body temperature is an unreliable clinical parameter when patients are receiving antipyretic therapy. These considerations notwithstanding, antipyretic therapy should be administered to selected patients with fever. Among such patients are those with acute coronary syndromes (i.e., myocardial infarction or unstable angina), because the tachycardia that usually accompanies the febrile response can exacerbate imbalances between myocardial oxygen delivery and demand. Febrile patients with head trauma, subarachnoid hemorrhage, or stroke should receive antipyretics to prevent temperature-related increases in cerebral oxygen utilization. Children with temperatures greater than 40° C or a history of seizures should also be treated.

Hypothermia blankets are often used to lower the core temperature in febrile ICU patients; however, hypothermia

TABLE 4–1. KEY ELEMENTS IN THE EVALUATION OF NEW-ONSET FEVER IN ICU PATIENTS

Be familiar with the patient's history. Pay particular attention to possible predisposing causes of fever.
Perform a careful physical examination. Pay particular attention to surgical wounds and vascular access sites. Look for evidence of pressure-induced skin ulceration. In patients with recent median sternotomy, evaluate the stability of the chest closure. Perform a careful abdominal examination.
Obtain or review a recent chest x-ray, looking for evidence of new infiltrates or effusions.
Obtain appropriate laboratory studies. At a minimum, these studies should include a peripheral white blood cell count and cultures of blood and urine. If the patient is endotracheally intubated or has a tracheotomy, obtain a sample of sputum for Gram stain. In some centers, sputum is routinely cultured. In other centers, bronchoalveolar lavage or bronchial brushing for quantitative microbiology is performed using blind or bronchoscopic methods.
Central venous catheters that have been in place for longer than 96 h should be removed. The tip should be submitted for semiquantitative microbiology.
In patients receiving antibiotics for more than 3 days, a stool sample should be analyzed for the presence of *Clostridium difficile* toxin.
More extensive diagnostic evaluation should be considered in a graded fashion based on history, physical examination findings, laboratory results, persistence of fever despite presumably appropriate antimicrobial chemotherapy, or clinical instability. These additional tests and procedures include diagnostic thoracentesis, paracentesis, and lumbar puncture. Imaging studies should be considered, including abdominal or cardiac ultrasonography and head, chest, or abdominal computed tomography.

blankets are no more effective in cooling patients than are antipyretic agents.[8] Hypothermia blankets can cause large temperature fluctuations and are associated with rebound hyperthermia when removed.[8] Additionally, external cooling can augment hypermetabolism and actually promote persistent fever. Lenhardt and colleagues demonstrated that active external cooling in volunteers with induced fever increased oxygen consumption by 35% to 40% and was associated with a significant increase in circulating epinephrine and norepinephrine concentrations.[9]

In view of the preceding, when treatment of fever is warranted, administration of an antipyretic agent is the recommended approach. Commonly used antipyretics include isoform nonselective cyclooxygenase inhibitors, such as ibuprofen or aspirin, or acetaminophen. Although acetaminophen is not a cyclooxygenase inhibitor, it is converted in the central nervous system to a metabolite with activity against this enzyme. Cyclooxygenase inhibitors treat fever by inhibiting the formation of prostaglandin E_2. Because corticosteroids, such as hydrocortisone or methylprednisolone, are potent anti-inflammatory agents, these drugs can suppress the febrile response to infection. Other anti-inflammatory agents have a similar effect. Therefore, absence of fever should not be used to rule out infection, especially in patients receiving corticosteroids or other potent anti-inflammatory drugs.

A reasonable approach for evaluating fever in ICU patients was described by Marik.[4] As depicted in Figure 4–1, blood cultures should be obtained whenever an ICU patient develops a new fever. A comprehensive physical examination should be carried out, and a chest x-ray obtained and reviewed. Noninfectious causes of fever should be excluded. In patients with an obvious focus of infection, a directed diagnostic evaluation is necessary. However, if there is no obvious source of infection and the patient is not deteriorating clinically, it is reasonable to obtain blood cultures and observe the patient for 48 hours before ordering additional diagnostic studies or starting empirical antibiotics. This approach is not reasonable, however, if new fever is accompanied by other signs of worsening clinical status such as arterial hypotension, oliguria, increasing confusion, rising serum lactate concentration, falling platelet count, or worsening coagulopathy. Nor is this approach reasonable if the core temperature is greater than 39° C but less than 41.1° C. Patients in this category should receive empirical antimicrobial chemotherapy while aggressive attempts are made to diagnose the source of infection. All febrile neutropenic patients should receive broad-spectrum empirical antimicrobial chemotherapy after appropriate cultures are obtained.

Chapter 5

VERY HIGH SYSTEMIC ARTERIAL BLOOD PRESSURE

Michael Donahoe

Very high systemic arterial blood pressure is a common problem in the ICU. The intensivist must distinguish conditions requiring prompt intervention from clinical situations in which aggressive blood pressure control could lead to an adverse outcome. This distinction cannot be based solely on the level of arterial blood pressure elevation.

The Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure described two acute conditions of elevated systemic arterial pressure.[1] A *hypertensive emergency* is a rare clinical situation that requires immediate blood pressure reduction (not necessarily to normal ranges) within minutes to hours. Hypertensive emergencies are defined by the presence of new or progressive end-organ damage of the neurologic, cardiovascular, or renal systems (Table 5-1).

In contrast, *hypertensive urgencies* are characterized by elevated systemic arterial pressure without evidence of end-organ damage. In these cases, a gradual reduction of blood pressure over several hours to days is the goal because there is no proven benefit to more rapid reduction of blood pressure in asymptomatic patients. Cerebral or myocardial ischemia or infarction can be induced by aggressive antihypertensive therapy if the blood pressure decreases to less than a level that supports adequate tissue perfusion.[2] Hypertensive urgencies are not to be ignored, however, because they can progress to end-organ damage if blood pressure remains uncontrolled over a sustained interval.

Another term, *accelerated hypertension*, also implies end-organ damage. In this case, the clinical markers of damage are pathophysiologic changes involving the retina of the eye, including exudates, hemorrhages, arteriolar narrowing, and spasm. The term *malignant hypertension* is characterized by the additional retinal finding of papilledema. Both of these conditions are often associated with vascular injury to the kidney, termed *malignant nephrosclerosis*, and to other target organs. Two large series confirmed that specific retinal findings do not predict the outcome in patients with elevated systemic arterial pressure.[3,4] This chapter uses the term *hypertensive emergency* to identify acute increases in systemic blood pressure that mandate prompt intervention by the intensivist.

PATHOPHYSIOLOGY

An acute elevation in systemic arterial blood pressure most frequently results from increased systemic vascular resistance. Increased vascular resistance can be precipitated by increased circulating concentrations of catecholamines, increased activity of the sympathetic nervous system, or activation of the renin-angiotensin system. Less commonly, hypertension occurs in the setting of significant volume expansion or augmented contractility of the left ventricle or both.

Two crucial components in the pathophysiology of organ dysfunction associated with accelerated hypertension include the development of obliterative vascular lesions and disordered vasoregulation. The vascular changes of the retina, in accelerated and malignant hypertension, are mirrored by similar changes in the kidney and other organs, leading to a proliferative arteritis and, in advanced stages of the process, fibrinoid necrosis. Presumably, vasoactive mediators play a key role in this process, but the mechanisms underlying these pathologic changes due to severe hypertension remain to be elucidated. A state of relative ischemia is produced in affected organs, resulting in end-organ dysfunction. Early recognition and control of elevated blood pressure are crucial to prevent progression to this more advanced stage of disease.

Aggressive control of elevated systemic arterial blood pressure must be undertaken with caution. There is a rightward shift of the pressure-flow relationship in the central nervous system in patients with long-standing hypertension.[5] Normally, cerebrovascular arteriolar tone is adjusted over a range of perfusion pressures to maintain a constant blood flow. In normal individuals, normal flow is maintained over a range of mean arterial pressure from approximately 60 to 150 mm Hg. A rightward shift in this relationship results in the loss of autoregulation at higher mean arterial pressure values. Aggressive lowering of the blood pressure in patients with an altered autoregulation curve can lead to compromised organ perfusion and ischemia. These pathophysiologic observations are supported by numerous clinical observations. The lower limit of autoregulation is about 20% to 25% below the resting mean arterial pressure. A safe level of blood pressure reduction in the acute setting has been proposed as a 25% reduction of mean arterial pressure or a diastolic blood pressure in the 100 to 110 mm Hg range. This regulated level of blood pressure reduction should maintain critical organ perfusion even in patients with long-standing hypertension.

CEREBROVASCULAR DISEASE

HYPERTENSIVE ENCEPHALOPATHY

Acute elevations in systemic arterial blood pressure can lead to hypertensive encephalopathy. The most common presenting

Miscellaneous Conditions

Eclampsia/preeclampsia
Postoperative hypertension

clinical manifestations include headache, nausea and vomiting, visual disturbances, focal neurologic findings, and seizures. If left untreated, the condition can progress to coma and death. Most patients with hypertensive encephalopathy have a mean arterial pressure significantly greater than the patient's baseline blood pressure, although not in the range typically associated with hypertensive emergency. Retinal findings, including arteriolar spasm, exudates or hemorrhages, and papilledema, are often present. Absence of these findings does not exclude the diagnosis of hypertensive encephalopathy, however. Neuroimaging studies suggest that edema involving the subcortical white matter of the parieto-occipital regions is a characteristic feature of hypertensive encephalopathy; this finding is termed *posterior leukoencephalopathy*.[6] Although the exact mechanism is debated, disordered regulation of vascular flow is believed to contribute to the clinical and radiographic findings. Hypertensive encephalopathy must be distinguished from other acute neurologic conditions associated with hypertension by a thorough evaluation. In general, the neurologic symptoms of stroke or intracranial hemorrhage have a more acute onset than the symptoms associated with hypertensive encephalopathy. The diagnosis of hypertensive encephalopathy is confirmed by the absence of other conditions and the prompt resolution of symptoms with effective blood pressure control. The failure of a patient to improve within 6 to 12 hours of blood pressure reduction should prompt an investigation for an alternative cause of the mental status changes. In most cases, the condition is entirely reversible with no observable adverse outcomes.

ACUTE STROKE

Hypertension is reportedly present in 80% of patients with an acute stroke.[7] The incidence of hypertension is higher in patients with primary intracerebral hemorrhage compared with ischemic disorders.[8,9] Current data suggest that hypertension in the setting of acute stroke is associated with a poor functional outcome.[8,10] Despite this knowledge, the treatment of elevated systemic arterial pressure in acute stroke is poorly investigated and complex.

Two important clinical features complicate the management of hypertension in acute stroke. First, during acute stroke, cerebral autoregulation may be compromised, and lowering of blood pressure may compromise cerebral blood flow further and extend ischemic injury.[11] Second, medications used to treat hypertension may lead to cerebral vasodilation, resulting in increased cerebral blood flow and progression of cerebral edema.[12] Ideally a "correct" level of mean arterial pressure should be maintained in each patient to maintain cerebral perfusion pressure without risking worsening cerebral edema or progression of the lesion, but the clinical determination of this "ideal" value is difficult.

Data are lacking from randomized clinical trials to guide antihypertensive therapeutic decisions in acute stroke. Only a few drug classes have been investigated in this condition, and the total number of patients studied is small. Published guidelines are not based on solid evidence. Using available information, only modest reductions in mean arterial pressure (10% to 15%) are advised in the acute setting of an ischemic stroke. The natural history is for the blood pressure to begin declining shortly after the onset of the acute event and to stabilize within the first 24 hours. Agents that allow titration of therapy (i.e., intravenous medications) may be preferred over oral agents when treatment is necessary, provided that the patient can be monitored carefully in a stroke unit. Also, many patients are unable to tolerate oral medications because of stroke-induced swallowing dysfunction.

For patients with hemorrhagic strokes, the general recommendation is that blood pressure should be reduced to prevent hematoma progression and rebleeding. Even this recommendation is not based on carefully controlled clinical trials, however. Similar cautions to limit the extent of blood pressure reduction (i.e., 15% to 20%) are advised.

SUBARACHNOID HEMORRHAGE

A patient with aneurysmal subarachnoid hemorrhage provides the challenge of an acute neurologic syndrome secondary to an initial insult, followed by the ongoing risk of additional insults over time. These additional insults can include hydrocephalus, rebleeding, and vasospasm. Hemodynamic management is complicated by the competing goals of lowering blood pressure to minimize the rebleeding risk and elevating blood pressure to minimize the risk of cerebral vasospasm and infarction.[13] In general, hypertension is not treated aggressively in this population for fear of precipitating cerebral ischemia. Treatment can be guided by the neurologic condition. For a patient with a normal neurologic picture, small reductions in blood pressure can be accomplished to minimize the risk of rebleeding. For a neurologically impaired patient, aggressive control of blood pressure is avoided to maintain cerebral perfusion pressure.

CARDIOVASCULAR DISEASE

ACUTE CORONARY SYNDROME

Patients presenting with acute myocardial ischemia or infarction frequently have elevated systemic arterial pressure.

The increased afterload increases myocardial oxygen demand. A reduction in myocardial work, achieved by decreasing heart rate and blood pressure, favorably reduces myocardial oxygen demand and infarct size in these patients. A reduction of high systemic arterial pressure in this setting should be done cautiously, however. Potent systemic vasodilation, without coronary vasodilation, can lead to a reduced coronary artery perfusion pressure and infarct extension. For this reason, nitroglycerin, a potent coronary and arterial vasodilator, is often the antihypertensive agent of choice in acute coronary syndromes. In combination with beta-blocker therapy, this approach to reduction in arterial pressure can reduce cardiac workload significantly in the setting of ischemia. Careful monitoring of hemodynamic indices during treatment is paramount.

ACUTE LEFT VENTRICULAR DYSFUNCTION

High systemic arterial blood pressure in a patient with acute pulmonary edema contributes to an increased myocardial workload and diastolic dysfunction. The hypertension may be a primary event with secondary myocardial dysfunction or secondary to the sympathoadrenal response to hypoxemia, increased work of breathing, and anxiety in the setting of acute left ventricular dysfunction. Regardless of the cause, efforts to control elevated systemic arterial pressure are essential. For a critically ill patient, infusion of sodium nitroprusside permits rapid titration of blood pressure. Angiotensin-converting enzyme (ACE) inhibitors, which are available in oral and intravenous forms, are associated with acute and long-term beneficial effects in patients with left ventricular failure.[14,15] Aggressive diuresis before blood pressure control may not be advised. Patients with hypertensive emergencies in particular may have had a natriuresis resulting in elevated levels of renin production by the kidney and increased circulating levels of the potent endogenous vasoconstrictor angiotensin II. Further reduction in renal perfusion can lead to increased production of angiotensin II. Medications that increase cardiac work (e.g., hydralazine) or impair cardiac contractility (e.g., labetalol) also may be contraindicated in this setting.

In contrast, nicardipine, a calcium antagonist, has been associated with reduced systemic arterial pressure with preservation of coronary blood flow, favoring the use of this medication in acute left ventricular dysfunction.[16] Likewise, fenoldopam, a dopamine-1 receptor antagonist, has been associated with preservation of coronary blood flow during treatment to reduce systemic arterial pressure.[17]

ACUTE AORTIC DISSECTION

Aortic dissection is believed to result from an intimal tear in the aortic wall. The primary morbidity and mortality result from extension of that tear. This extension is promoted by factors that increase the rate of change of aortic pressure (dP/dt), including elevation in blood pressure, heart rate, and myocardial stroke volume. Blood pressure should be reduced promptly to near-normal levels. Aggressive control of blood pressure with a vasodilator could precipitate a reflex tachycardia, increasing dP/dt. Combined-modality therapy to promote vasodilation (sodium nitroprusside) and control cardiac contractility (beta blocker) is advocated for this disorder. Alternatively, drugs that do not increase dP/dt, such as trimethaphan, can be used effectively to control blood pressure.

RENOVASCULAR DISEASE

The kidney is a source of the mediators that promote hypertension (i.e., angiotensin II) and a target of high systemic arterial pressure. Chronic hypertension is secondary only to diabetes mellitus as a cause of renal insufficiency. In younger patients, the presence of severe hypertension suggests the possibility of intrinsic renal disease, such as poststreptococcal glomerulonephritis and IgA nephropathy. Renovascular disease is noted in 30% of white patients with severe hypertension and retinopathy.[18]

Elevated systemic arterial pressure should be regulated in patients with underlying renal insufficiency, and a comprehensive workup should be initiated to determine the cause-and-effect relationship. Traditional vasodilator medications, such as labetalol and sodium nitroprusside, are preferred to ACE inhibitors in the acute setting because ACE inhibitors can compromise renal function.[19] The risk of ACE inhibitor–induced renal dysfunction is particularly great in patients with hyperkalemia and acute uremia.[19]

SCLERODERMA RENAL CRISIS

Scleroderma renal crisis is characterized by the development of acute renal failure associated with moderate-to-severe hypertension and a normal to minimally abnormal urine sediment. The most significant risk factor for scleroderma renal crisis is the presence of the diffuse skin involvement characteristic of the disease. The disorder results in marked activation of the renin-angiotensin system. Aggressive control of blood pressure using ACE inhibitors, particularly early in the disease process, can control blood pressure in 90% of patients and promote a greater rate of recovery in renal function.[20] Captopril has been the most extensively studied agent used for treatment of this hypertensive emergency.

POST–KIDNEY TRANSPLANTATION

Hypertension after renal transplantation occurs in a high percentage of patients. In the immediate post-transplantation period, hypertension usually is a manifestation of graft rejection, ischemia, or medication toxicity. Corticosteroids and calcineurin inhibitors promote the development of hypertension. In addition, renal artery stenosis can complicate allograft function and should be evaluated in any patient with resistant hypertension. In the immediate post-transplant period, blood pressure should be regulated at the upper limits of normal to preserve graft function. In the later post-operative period, even more strict control of blood pressure is preferred.[21] The therapy of choice for post–kidney transplantation hypertension is controversial. Calcium channel blockers may reverse cyclosporine-induced renal vasoconstriction; however, outcome trials in this area showed conflicting results.[22,23] ACE inhibitors have the potential to exacerbate renal dysfunction and augment the hyperkalemia induced by calcineurin inhibitors. Either category of medication for blood pressure control could be used with careful monitoring for toxicity.

EXCESS CATECHOLAMINE STATES

PHEOCHROMOCYTOMA

Pheochromocytoma can result in the production of circulating mediators leading to catecholamine excess. These mediators result in hypertension, diaphoresis, tachycardia, and paresthesias of the hands and feet. These attacks can last minutes to days and occur several times a day or once per month. Operative manipulation of the tumor can result in perioperative hypertension. The treatment of hypertension in this disorder must avoid the use of isolated therapy with a beta blocker, a strategy that can lead to unopposed alpha-adrenergic stimulation with the risk of further vasoconstriction and blood pressure elevation. The preferred agent for treatment of hypertension due to pheochromocytoma is phentolamine, a potent alpha-adrenergic antagonist. If necessary, this medication can be combined with a beta blocker, or a combined alpha/beta blocker, such as labetalol, can be used safely.

PHARMACOLOGICALLY MEDIATED

Clonidine withdrawal can mimic the crisis of pheochromocytoma. Clonidine is a centrally acting stimulant of alpha-adrenergic receptors that reduces peripheral adrenergic system activation. Rapid withdrawal or tapering of therapy with this agent has been associated with a hyperadrenergic state, characterized by hypertension, diaphoresis, headache, and anxiety.[24] The syndrome can best be treated by restarting treatment with clonidine. If the symptoms are extreme, treatment can be initiated as outlined for patients with pheochromocytoma. Hypertension also can occur during the withdrawal phase of alcohol abuse[25] and beta-blocker therapy.

Monoamine oxidase inhibitor use can be associated with a marked elevation in the systemic arterial blood pressure, if the patient consumes foods or medications containing tyramine or other sympathomimetic amines. Tyramine-containing foods include champagne, avocados, smoked or aged meats, and fermented cheeses. The monoamine oxidase inhibitor interferes with degradation of the tyramine in the intestine, leading to excess absorption and tyramine-induced catecholamine activity in the circulation. Other medications, including metoclopramide, a dopamine agonist; the calcineurin inhibitors cyclosporine and tacrolimus; and drugs of abuse, such as cocaine, phenylpropanolamine, phenylcyclidine, and methamphetamine, must be considered as possible factors in an ICU patient with elevated systemic arterial pressure.

After spinal cord injury, hypertensive states may occur particularly with stimulation of dermatomes and muscles below the level of the spinal cord injury. Patients with hypertension in this setting typically have lesions above the level of the thoracolumbar sympathetic neurons. Blood pressure elevation is believed to result from excess stimulation of sympathetic neurons. Hypertension is accompanied by bradycardia through stimulation of the baroreceptor reflex. Treatment is focused on minimizing stimulation and providing medical therapy as necessary. Patients with Guillain-Barré syndrome can manifest a similar syndrome.

MISCELLANEOUS CONDITIONS

PREECLAMPSIA/ECLAMPSIA

Preeclampsia/eclampsia is the second most common cause of maternal death in the United States after thromboembolic disease. Hypertension occurs as one manifestation of preeclampsia in a pregnant patient; the other key features are proteinuria and edema. Hypertension in pregnancy also can be seen secondary to chronic hypertension and transient or gestational hypertension. The new onset of hypertension after 20 weeks of gestation is most characteristic of a patient with preeclampsia.

When possible, the optimal treatment of preeclampsia is delivery of the fetus, an approach that prevents progression to eclampsia. Blood pressure should be regulated, however, to prevent end-organ damage. Hydralazine generally is considered the agent of choice in pregnant patients. Sodium nitroprusside (fetal defects), ACE inhibitors (renal dysfunction in fetus), and trimethaphan (meconium ileus) should be avoided because of associated toxicities in pregnant patients. In addition to hydralazine, alternative agents that can be used in this population include labetalol and nicardipine.

POSTOPERATIVE HYPERTENSION

Poorly controlled hypertension preoperatively and intraoperatively is associated with an increased rate of postoperative complications.[26,27] Hypertension in the postoperative period can be seen in 75% of patients, and the risk seems to be greater for vascular surgical procedures, including abdominal aortic aneurysm repair, carotid endarterectomy, and coronary artery revascularization.[28] Postoperative hypertension in these patients can lead to complications, including bleeding from suture lines, intracerebral hemorrhage, and left ventricular dysfunction. Postoperative hypertension can be caused by elevated systemic vascular resistance in response to circulating stress hormones, activation of the renin-angiotensin-aldosterone system, or altered baroreceptor function after certain types of surgery.

Patients with postoperative hypertension must be investigated thoroughly to rule out reversible causes before the institution of drug therapy. Factors such as pain, anxiety, hypervolemia, hypoxemia, hypercarbia, and nausea can contribute to postoperative hypertension. Postoperative hypertension often is limited in duration (i.e., 2 to 12 hours), and aggressive attempts to lower blood pressure acutely can lead to delayed hypotension.

Postoperative hypertension typically is treated by the administration of vasodilators, including sodium nitroprusside and nitroglycerin. Beta blockers can be added for additional control.

ANTIHYPERTENSIVE MEDICATIONS

The goal of antihypertensive therapy in the emergent situation is to lower blood pressure to a safe range as quickly as possible. In general, intravenous medications are preferred, allowing titration of dosing to minimize the risk of excessive hypotension. The precise level of blood pressure reduction necessary to reduce the risk of organ ischemia is not defined. A commonly proposed goal is to lower the mean arterial pressure by approximately 20%, or to reduce diastolic blood pressure to 100 to 110 mm Hg. To monitor carefully the effect of antihypertensive therapy, these patients are best monitored in the ICU.

For hypertensive urgencies, oral therapy generally can be used to lower the blood pressure to safer levels over a 24-hour interval. These patients in general do not require monitoring in an ICU.

TABLE 5–2. INTRAVENOUS ANTIHYPERTENSIVE THERAPY

Medication (Route)	Mechanism	Dosing	Indication	Contraindication
Nitroprusside (i.v. infusion)	Arteriolar and venous vasodilator	0.25-10 µg/kg/min i.v. infusion	Most hypertensive emergencies	Contraindicated in pregnancy. Caution with use in cerebral edema, acute coronary syndrome, or azotemia
Labetalol (i.v. infusion, oral)	Alpha/beta-adrenergic blocker	i.v. bolus 20 mg initially followed by 20-80 mg every 10 min Infusion: 0.5-2 mg/min	Most hypertensive emergencies	Contraindicated in acute heart failure or in patients nontolerant of beta blockers
Nicardipine (i.v. infusion)	Calcium channel blocker	Initial: 5 mg/h Maximum: 15 mg/h	Most hypertensive emergencies	Contraindicated in acute heart failure and caution with use in acute coronary syndrome
Fenoldopam (i.v. infusion)	Peripheral dopamine-1 antagonist	Initial: 0.1 µg/kg/min	Most hypertensive emergencies	Caution in patients with glaucoma
Nitroglycerin (i.v. infusion)	Venodilator	Initial: 0.25-0.5 µg/kg/min Maximum: 8-10 µg/kg/min	Acute coronary syndromes	
Phentolamine (i.v.)	Alpha-adrenergic blocker	5-10 mg every 5-15 min	Pheochromocytoma, catecholamine withdrawal, catecholamine excess	
Enalaprilat	Angiotensin-converting enzyme inhibitor	1.25-5 mg every 6 h	Scleroderma crisis and acute left ventricular dysfunction	Caution with use in acute coronary syndrome
Hydralazine (i.v., oral)	Arteriolar vasodilator	Initial: 10 mg every 20-30 min Maximum: 20 mg	Pregnancy	

Medications available for the treatment of elevated systemic arterial pressure are summarized in Table 5-2. Sodium nitroprusside has been the gold standard for the treatment of hypertensive emergencies because of its short duration of action allowing careful titration. Sodium nitroprusside acts as a direct vasodilator of arterioles and veins. The blood pressure response to nitroprusside infusion is rapid and mandates the use of this medication in a well-monitored environment. The infusion must be provided by a calibrated pump with frequent blood pressure recording. Typically, intra-arterial blood pressure recording is preferred owing to the need for rapid and frequent monitoring, particularly during the initial titration. An accurate noninvasive system may offer equal efficacy, however.

The major concern with sodium nitroprusside is the rare risk of cyanide, or thiocyanate, toxicity. Cyanide intoxication is manifested by alterations in mental status, gastrointestinal complaints, arrhythmias, seizures, or lactic acidosis. The last finding occurs in the setting of a reduced systemic oxygen uptake and a narrow arterial-venous oxygen gradient. Cyanide is liberated during the combination of nitroprusside with sulfhydryl groups in red blood cells and tissues. The circulating cyanide is converted rapidly in the liver to thiocyanate with subsequent excretion by the kidney. Cyanide toxicity from nitroprusside is uncommon and occurs primarily in patients receiving infusions for greater than 24 to 48 hours, in patients with underlying renal insufficiency, and in patients in whom the dose used exceeds the capacity of the body to detoxify cyanide (>2 µg/kg/min increases the risk of cyanide accumulation).

The treatment of cyanide intoxication involves the administration of sodium thiosulfate. Sodium thiosulfate donates its sulfane sulfur atom in a reaction catalyzed by the enzyme rhodanese to convert cyanide to the much less toxic thiocyanate ion, which is excreted in the urine. For severe cases, sodium nitrite also may be administered. The nitrites exert their effect by oxidizing hemoglobin to methemoglobin, with attraction of the cyanide molecule to the ferric ion; this results in displacement of the cyanide from the cytochrome aa_3 to form a ferricyanide complex. The onset of action of sodium nitrite is rapid, but the induction of methemoglobinemia decreases the oxygen-carrying capacity of blood and may be harmful in patients with anemia or significant carboxyhemoglobinemia.

Hydroxocobalamin (vitamin B_{12a}) is another safe and effective antidote for cyanide intoxication that does not effect oxygen-carrying capacity. This compound reacts with circulating cyanide to form cyanocobalamin, with subsequent urinary excretion. Hydroxocobalamin has been shown to minimize the risk of cyanide accumulation during nitroprusside use in surgery.[29]

Thiocyanate toxicity in association with nitroprusside infusion also is rare. Clinical manifestations include fatigue, gastrointestinal complaints, and mental status changes. The symptoms most typically appear with plasma thiocyanate levels that exceed 5 to 10 ng/dL and occur with higher dose nitroprusside infusion in renal impairment.

Intravenous fenoldopam is a postsynaptic dopamine-1 receptor antagonist with short-acting vasodilator properties. In contrast to sodium nitroprusside, fenoldopam administration is not associated with a risk of toxic metabolite accumulation. Similar to sodium nitroprusside, fenoldopam lowers blood pressure by decreasing peripheral vascular resistance. The medication causes slight elevation in heart rate and an increase in renal blood flow. The preservation of renal blood flow is attributed to the drug's mechanism as a dopamine-1 receptor agonist.

The hemodynamic effects of fenoldopam have been compared with nitroprusside in a multicenter investigation of patients with acute hypertension.[30] This prospective, randomized trial in 153 patients at 24 centers showed that fenoldopam was as effective as nitroprusside in controlling acute systemic hypertension. The average decreases in systolic and diastolic blood pressure at 6 hours of infusion were similar in the two study groups. The average maintenance infusion rate of fenoldopam was 0.41 µg/kg/min (range 0.1 to 1.62 µg/kg/min), and the average maintenance infusion rate of nitroprusside was 1.67 µg/kg/min (range 0.3

to 8 μg/kg/min) when target blood pressure control was achieved. The time required to reach the maintenance infusion rate also was similar in the two groups (85 minutes for patients who received fenoldopam and 94 minutes for patients who received nitroprusside). In a subset of the population studied, renal indices, including creatinine clearance, urinary output, and sodium excretion, were better in the group randomized to fenoldopam treatment. The study sample is too small to draw definitive conclusions, however. Both drugs were equally well tolerated.

The use of fenoldopam in patients with hypertensive emergencies was evaluated in 107 patients with a diastolic blood pressure greater than 120 mm Hg and clinical evidence of acute vasculopathy.[31] Infusion rates of 0.01 μg/kg/min, 0.03 μg/kg/min, 0.1 μg/kg/min, or 0.3 μg/kg/min for 24 hours were compared. The time required to reduce diastolic blood pressure by 20 mm Hg ranged from an average of 55 minutes among the patients given the highest dose to 133 minutes among the patients given the lowest dose. Within this range of doses, fenoldopam was safe and found to provide a flexible dose-titration regimen that is effective when the blood pressure must be reduced rapidly.

Labetalol is an oral and parenteral agent that acts as an alpha-adrenergic and nonselective beta-adrenergic blocker. The blood pressure–lowering effect is produced through a reduction in systemic vascular resistance without a compensatory increase in heart rate. The drug has been used effectively in patients with end-organ dysfunction and acute neurologic injury, pheochromocytoma, cocaine intoxication, dissecting aneurysm, and eclampsia. The primary contraindication to the use of labetalol relates to its nonselective beta-blocking properties. Labetalol is approximately one fifth as potent as propranolol as a nonselective beta blocker. Despite this knowledge, the drug should be used cautiously in patients with reactive airways disease, heart block, or decompensated left ventricular failure.

Nitroglycerin is a direct vasodilator that is known to promote coronary vascular dilation. When administered intravenously, the medication has a relatively short duration of action. Nitroglycerin has favorable effects for patients with acute coronary syndromes, including reducing myocardial oxygen demand via its effects on preload and afterload and augmenting myocardial oxygen delivery through its effects on the coronary circulation.

Nicardipine hydrochloride is a calcium channel blocker that acts primarily as a systemic and coronary artery vasodilator. The greater water solubility of this drug compared with other calcium channel blockers (e.g., nifedipine) allows intravenous administration with a short onset and duration of action and easy titration of therapeutic effect. The medication has no significant effect on cardiac inotropy and promotes afterload reduction. The medication has been reported most extensively in the preoperative and postoperative patient environments.

Comparative investigations of nicardipine and nitroprusside for postoperative hypertension have suggested the agents are equally effective.[32-34] Nicardipine offers the advantage of avoiding the issues related to cyanide and thiocyanate intoxication. Nicardipine is metabolized by the liver, and excretion can be impaired in these patients.

Enalapril is an intravenously administered ACE inhibitor. The medication reduces renin-dependent vasopressor activity and reduces aldosterone production. Similar to other ACE inhibitors, the medication is effective in patients with low-to-normal renin levels and hypertension.

Phentolamine is a rapid-acting, alpha-adrenergic blocker. Phentolamine is the drug of choice for hypertensive emergencies secondary to pheochromocytoma, monoamine oxidase–tyramine interactions, and clonidine rebound hypertension.

SUMMARY

The treatment of high systemic arterial blood pressure in the ICU must be incorporated into a comprehensive assessment of the patient. Clinical situations that are associated with progressive end-organ damage require urgent intervention, most frequently with a titratable medication and careful ongoing monitoring. In contrast, aggressive antihypertensive therapy in asymptomatic patients without immediate risk of organ dysfunction can be harmful. The intensivist is routinely challenged to recognize this distinction in a hypertensive patient.

Chapter 6
LOW SYSTEMIC ARTERIAL BLOOD PRESSURE

Kyle J. Gunnerson

When initially assessing a critically ill patient, it is essential to perform a rapid, focused physical examination (the ABCs of resuscitation). After ensuring that the patient has a patent airway (A) and is effectively breathing (B), the next step is to assess the adequacy of the circulation (C).

INITIAL EVALUATION

The initial evaluation should be a global assessment (Fig. 6–1). When walking into a patient's room, the clinician should think, "What do I see?" Quickly determine whether the patient is in distress or has problems related to the airway or breathing. Look for obvious evidence of external hemorrhage, and assess the adequacy of intravenous access. Look for evidence of hypoperfusion. Do not rely only on blood pressure readings, as there is no "normal" blood pressure applicable to every patient, and a blood pressure value in the normal range does not always equate with adequate tissue perfusion. A patient with a history of poorly controlled chronic hypertension may have signs of hypoperfusion even when the blood pressure is within the normal range (for nonhypertensive patients). Conversely, a patient with cirrhosis may be adequately perfused despite having a lower-than-normal blood pressure. A quick assessment of perfusion should include evaluation of mental status, urine output, and skin findings (temperature plus presence or absence of diaphoresis, mottling, and adequate capillary refill). If any of these parameters are abnormal, a more urgent approach to treatment must be taken.

A focused cardiac and pulmonary examination is essential. The examiner should seek evidence of jugular venous distention, presence of an S_3 or S_4 heart sound, new or worsening murmurs, or muffled heart sounds. The examiner should check for the presence of rales. It is also important to note whether there are absent breath sounds, a finding suggestive of pneumothorax.

During the initial evaluation, pay close attention to pulse pressure, diastolic pressure, and surrogates of systemic vascular resistance (SVR), such as capillary refill. These basic concepts of cardiac physiology will be useful in determining the cause and devising a treatment plan.

WHAT IS THE CAUSE?

To help focus the differential diagnosis of a hypotensive patient, it is important to review basic cardiovascular physiology. The first concept to remember is that *pressure = flow × resistance*, where flow is cardiac output and resistance is SVR. Because cardiac output is determined by stroke volume (SV) × heart rate, the presence of hypotension means that at least one of these parameters (i.e., SV, SVR, or heart rate) is abnormal.[1] Disturbances in heart rate are discussed in Chapter 7 and should be obvious by feeling the peripheral pulse or looking at the electrocardiogram monitor; the focus here is on conditions associated with decreased SV or SVR. By properly measuring pulse pressure and diastolic pressure, the clinician can determine whether the cause is a change in SVR or SV.

During systole, the SV is ejected into the proximal arterial conduits. Because more blood is being ejected than the peripheral circulation can accommodate in the arterioles, the arterial walls distend, increasing systolic blood pressure (SBP) in a way that is directly proportional to the SV and indirectly proportional to the capacitance (C) of the arterial wall. This relationship is represented by the formula $SBP = SV \div C$.[1] That is, for a fixed SV, if capacitance is higher, the SBP is lower.

During diastole, the portion of the SV that was "stored" by the distention of the arterial walls during systole fills the peripheral arterioles, leading to a progressive decrease in blood pressure until the next systolic phase. This is the diastolic pressure, a parameter that is directly related to the SVR and capacitance (i.e., low diastolic pressure = low SVR and/or capacitance).[1] When using these basic cardiovascular principles to understand the cause of hypotension, it is important to remember the following: (1) capacitance does not change from heartbeat to heartbeat, and (2) SV depends on preload, afterload, and contractility.

Numerous problems can be associated with low SVR, including sepsis (see Chapter 147), adrenal insufficiency (see Chapter 176), vasodilating medications (see Section XII), neurogenic shock (see Section III), and severe liver dysfunction (see Chapter 120). Decreased SVR is suggested by the presence of a widened pulse pressure and low diastolic pressure.[2,3]

Reduced SV can be due to decreased preload, decreased contractility, or increased afterload. The most common cause of inadequate preload is hypovolemia (see Chapter 229). Other causes of inadequate preload include increased intrathoracic pressure due to dynamic hyperinflation in mechanically ventilated patients (see Chapter 64)[4,5] or tension pneumothorax, pulmonary embolism,[6] mitral valve stenosis,[7,8] cardiac tamponade,[9] and right ventricular failure.[10] Decreased contractility can be caused by myocardial ischemia or infarction, cardiomyopathy, myocarditis, negative inotropic drugs, and direct myocyte toxins such as chemotherapeutic agents and inflammatory mediators (tumor necrosis factor and interleukin-1 beta).[11] A reduction in SV can be identified by decreased systolic blood pressure and normal or narrow pulse pressure.

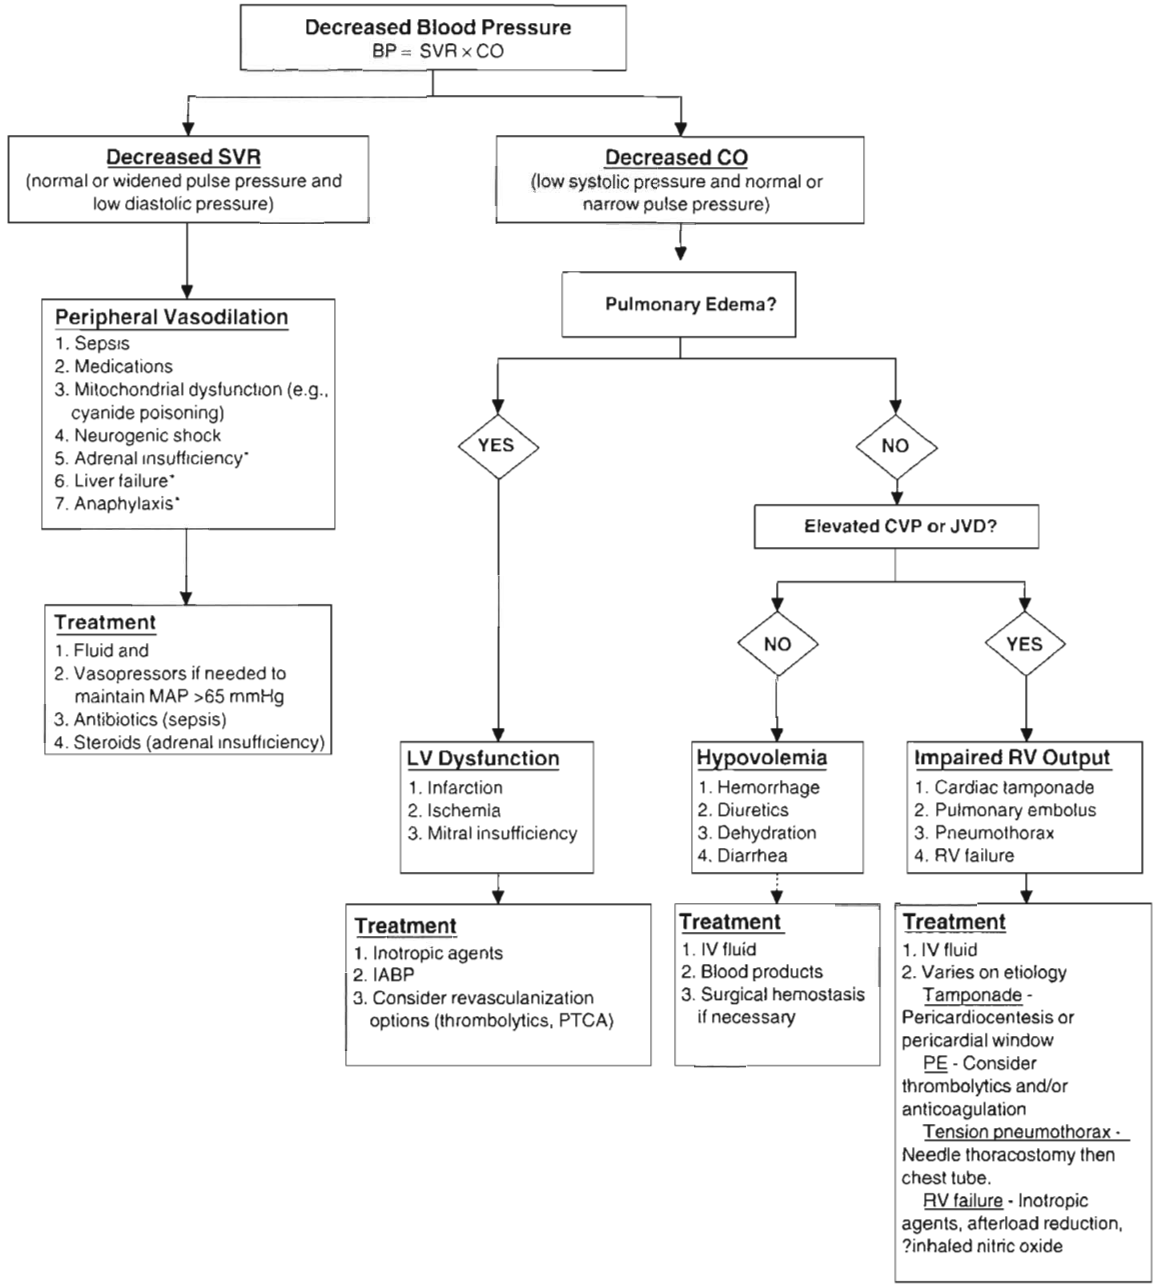

FIGURE 6–1. Initial approach to a patient with low systemic arterial blood pressure. *Adrenal insufficiency, liver failure, and anaphylaxis are sometimes listed as vasodilatory shock; however, data are inconclusive. BP, blood pressure; CO, cardiac output; CVP, central venous pressure; IABP, intra-aortic balloon pump; IV, intravenous; JVD, jugular venous distention; LV, left ventricle; MAP, mean arterial pressure; PE, pulmonary embolism; PTCA, percutaneous transluminal coronary angioplasty; RV, right ventricle; SVR, systemic vascular resistance.

TREATMENT

Until proved otherwise, hypotension should be considered synonymous with hypoperfusion and thus treated aggressively. This initial treatment includes monitoring *and* therapeutic measures. All patients should have adequate intravenous access, preferably two patent 18-gauge or larger catheters. The patient should be monitored using a standard electrocardiogram monitor and pulse oximetry, and a 12-lead electrocardiogram should be performed to look for evidence of myocardial ischemia. Supplemental oxygen should be given as needed to keep oxygen saturation greater than 92%. A 1-L fluid bolus of an isotonic crystalloid solution should be infused as rapidly as possible while data are being gathered. The history, focused examination, and assessment of pulse pressure and diastolic pressure will aid in the formulation of a more specific treatment strategy.

Chapter 7
TACHYCARDIA AND BRADYCARDIA

Arthur Boujoukos

Bradycardia (heart rate <60 beats/min) and tachycardia (heart rate >100 beats/min) are encountered frequently in the intensive care unit (ICU). Evaluation and management should proceed concurrently.

Bradycardia with or without hypotension should prompt a consideration of metabolic disturbances, drug effects, and myocardial ischemia. If bradycardia is of abrupt onset, hypoxemia or acidosis can be quickly excluded by obtaining an arterial blood gas measurement. If the patient is unresponsive, intubate him or her and institute mechanical ventilation. If the patient is already intubated, disconnect the ventilator and manually ventilate the patient (using an Ambu bag) to ensure adequate ventilation and oxygenation. Mucous plugging of the endotracheal tube or airways should be excluded in an acutely hypoxemic patient. Once these conditions are excluded, evaluate the electrocardiogram (ECG) for evidence of second- or third-degree heart block or ischemic changes. Aminophylline (100 mg i.v.) has been reported to correct ischemic heart block.[1] Insertion of a temporary transvenous pacemaker may be indicated in the setting of ischemic heart block, because further deterioration can occur unpredictably. Medications that can cause bradycardia include beta-adrenergic blockers, amiodarone, diltiazem, verapamil, digoxin, and propofol. Severe toxicity due to overdose with a beta-adrenergic antagonist leading to bradycardia, hypotension, and shock can be treated with glucagon (5 to 10 mg i.v., followed by an infusion of 1 to 10 mg/h diluted in D5W). Moderate drug-induced bradycardia (heart rate >40 beats/min) can be observed until the offending drug is metabolized, as long as peripheral perfusion appears to be adequate. Dopamine (starting at 3 μg/kg/min and titrated upward as needed) can be used to provide temporary support for bradycardic hypotensive patients. Atropine (1-mg i.v. bolus; repeat × 1 as necessary) is occasionally beneficial. Bradycardia in the setting of preexisting shock and refractory acidosis is an ominous sign, and transcutaneous or transvenous pacing is generally futile.

When acute-onset tachycardia occurs, the degree of resulting hemodynamic instability must be assessed. It is critical to differentiate hypotension leading to tachycardia (e.g., rapid atrial fibrillation due to increasing dopamine titration in sepsis or hypovolemic shock causing sinus tachycardia) from hypotension caused by tachycardia (e.g., ventricular tachycardia after myocardial infarction). In the former situation, intravascular volume loading or decreasing the dose of a beta-adrenergic agonist is indicated. In the latter circumstance, rapid conversion of the rhythm should bring about hemodynamic stability.

Sustained regular tachycardia (heart rate >160 beats/min) associated with a narrow QRS complex on the ECG is often reentrant. These dysrhythmias can often be converted with carotid sinus massage. Adenosine can be administered (6 mg i.v., followed by 12 mg i.v. if no response to the lower dose) if sequential carotid sinus massage fails or is contraindicated. Patients presenting with reentrant supraventricular tachycardia in the ICU often have a past history of this dysrhythmia. Beta-adrenergic blockers or calcium channel blockers are reasonable choices for both acute conversion and maintenance therapy. Specific beta blockers include metoprolol 5 mg i.v. every 5 minutes or an esmolol infusion of 500 μg/kg/min over 1 minute, then a 50 μg/kg/min infusion. Esmolol can be rebolused and the drip titrated to a maximum of 400 μg/kg/min. For diltiazem, use 5- to 10-mg boluses titrated upward if the patient's blood pressure tolerates the increase.

Sinus tachycardia is probably the most common dysrhythmia encountered in the ICU. Its meaning, importance, and management vary, depending on the clinical circumstances. In trauma and postsurgical patients, tachycardia can be a sign of bleeding and hypovolemia. It is usually reasonable to administer an intravascular volume challenge (e.g., 500 mL of colloid solution in adults) and check the hemoglobin concentration. Sinus tachycardia and hypertension can be manifestations of opioid withdrawal, failure of a ventilator weaning trial, or inadequate sedation. Most patients at high risk for coronary disease warrant prophylactic treatment with a beta-adrenergic blocker to prevent myocardial ischemia secondary to a high "rate-pressure product" and high myocardial oxygen demand.[2,3] In particular, perioperative patients with significant cardiac risk should have titrated therapy with a beta-adrenergic blocker to maintain the heart rate at less than 80 beats/min unless significant contraindications exist.[4]

Sustained tachycardia associated with hemodynamic instability (i.e., arterial hypotension) and a wide QRS complex on the ECG should be treated as ventricular tachycardia (Fig. 7–1). Unsynchronized cardioversion should proceed expeditiously. Sustained and nonsustained ventricular tachycardia without hemodynamic instability typically occurs in patients with cardiomyopathy or acute myocardial infarction. Initial interventions should include correction of hypokalemia or hypomagnesemia (if present), reduction in the dose of beta-adrenergic agonists (if being infused), and removal of physical stimuli such as pulmonary artery catheters. Amiodarone (150-mg i.v. bolus, then 1 mg/min infusion for 6 hours, then infusion at a rate of 0.5 mg/min) is the preferred therapy in this setting. Consider myocardial ischemia as the cause of monomorphic ventricular tachycardia, and perform the appropriate diagnostic workup. Polymorphic ventricular tachycardia should prompt a

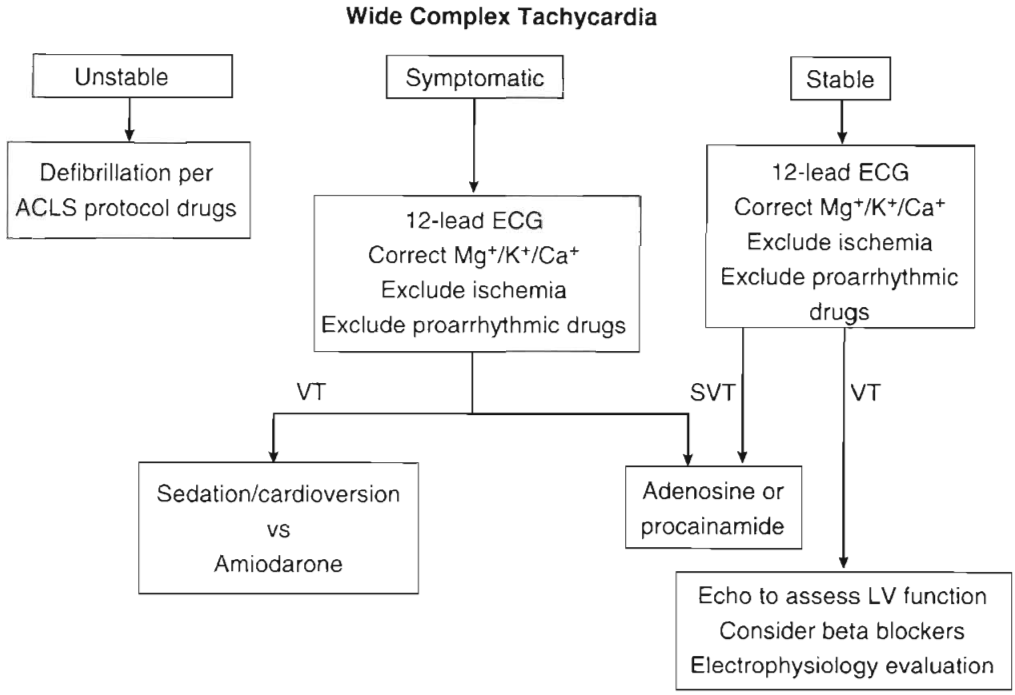

FIGURE 7–1. Algorithm for the diagnosis and testing of wide-complex tachycardia. ACLS, advanced cardiac life support; ECG, electrocardiogram; LV, left ventricle; SVT, supraventricular tachycardia; VT, ventricular tachycardia.

thorough evaluation of the medication list, searching for agents that prolong the QTc (Table 7–1).

Atrial fibrillation with rapid ventricular response can cause significant hemodynamic instability requiring emergent electrical cardioversion. The initial attempt should be synchronized, using 100 J of energy. If unsuccessful, subsequent cardioversion attempts should use escalating energy levels (i.e., 200, 300, 360 J). Atrial fibrillation with rapid ventricular response in the absence of hemodynamic instability can be managed initially by using drugs or other interventions to provide rate control. The goal should be to reduce heart rate to less than 120 beats/min. First, minimize adrenergic stimulation by instituting mechanical ventilation, if high work of breathing and respiratory failure appear to be contributing factors. Reduce the rate of catecholamine (epinephrine, dobutamine, dopamine) infusions, if possible. If the patient is not currently receiving treatment with inotropes or vasopressors, consider beta-adrenergic blockade as the first-line therapy. Metoprolol (5 mg i.v. every 5 minutes) or esmolol (500 μg/kg over 1 minute, then 50 μg/kg/min infusion) is a reasonable choice. If the patient requires treatment with inotropic agents to support cardiac output, a trial of diltiazem (5- to 10-mg i.v. bolus, followed by an infusion of 5 to 20 mg/h) is warranted. Amiodarone (see previous dosing recommendations) is a reasonable choice for both rate control and conversion therapy. There have been multiple reports about amiodarone lung toxicity, even with short-term therapy, so caution is warranted, particularly in critically ill patients with underlying lung pathology.[5] Digoxin is the least effective option acutely; it is relatively ineffective for controlling ventricular rate when endogenous or exogenous adrenergic tone is high.[6] With new-onset atrial fibrillation, conversion to sinus rhythm is desirable in patients who are poor candidates for anticoagulation. Conversion to sinus rhythm is also beneficial for patients with profound left ventricular dysfunction, because coordinated atrial contraction can contribute substantially to cardiac output under these conditions. In other patients, the primary goal should be to achieve rate control.[7,8] Conversion is significantly more likely to occur during rate control with beta blockers (e.g., esmolol) than diltiazem, but this may actually reflect a reduction in the spontaneous conversion rate when diltiazem is used.[9,10]

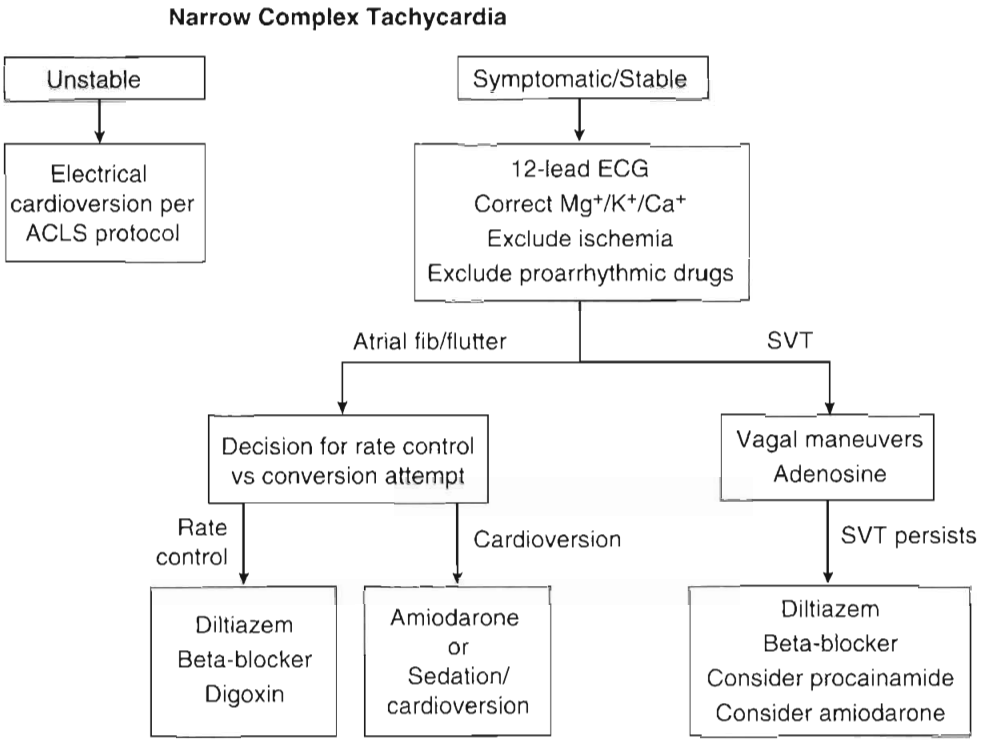

FIGURE 7–2. Algorithm for the diagnosis and testing of narrow-complex tachycardia. ACLS, advanced cardiac life support; ECG, electrocardiogram; fib, fibrillation; SVT, supraventricular tachycardia.

Amiodarone, particularly in patients with impaired ventricular function, is generally the drug of choice to achieve conversion.

Regular narrow-complex tachycardia with a heart rate between 145 and 155 beats/min is typically due to atrial flutter. Carotid sinus massage or adenosine can unmask this diagnosis, if it is in doubt from the 12-lead ECG (Fig. 7–2). Ventricular rate control is difficult to achieve pharmacologically when the dysrhythmia is atrial flutter; accordingly, conversion to sinus rhythm is the goal. Synchronized cardioversion should be tried starting at 50 J, using appropriate conscious sedation. If cardioversion converts the rhythm to atrial fibrillation, use synchronized electrical cardioversion again, starting with 100 J. If atrial fibrillation persists, treat with a rate-controlling agent and anticoagulation. If refractory or recurrent atrial flutter is the problem, attempt rate control with beta-adrenergic blockers or diltiazem, as for atrial fibrillation.

Chapter 8

RESPIRATORY DISTRESS WITH ARTERIAL HYPOXEMIA

Paul Rogers

Respiratory distress with hypoxemia is a common reason for patients to be admitted to the ICU. Because a patient's arterial oxygen saturation can be monitored easily using a continuous pulse oximeter, nurses and physicians are alerted immediately to changes in a patient's oxygen saturation. For these reasons, it is important for health care providers to understand the meaning of this measurement, recognize its limitations, and outline a plan for diagnosing and managing patients with hypoxemia.

Arterial hypoxemia is defined as a partial pressure of oxygen in arterial blood (PaO_2) less than 80 mm Hg while breathing room air. The PaO_2 represents the amount of oxygen in physical solution, whereas the oxygen saturation represents the fractional amount of oxyhemoglobin relative to total hemoglobin concentration. Oxygen saturation varies with the PaO_2 in a nonlinear relationship and is affected by temperature, partial pressure of carbon dioxide in arterial blood ($PaCO_2$), pH, and 2,3-diphosphoglycerate concentration (Fig. 8-1).

Falsely low saturations can be recorded if there is a poor waveform or if the light absorption is decreased by dark blue or black nail polish. Patients with methemoglobinemia may have a falsely low oxygen saturation, whereas patients with carboxyhemoglobinemia may have a falsely elevated oxygen saturation because the pulse oximeter cannot differentiate carboxyhemoglobin from oxyhemoglobin.[1] Finally, because the oxygen hemoglobin dissociation curve is affected by temperature, pH, partial pressure of carbon dioxide (PCO_2), and 2,3-diphosphoglycerate concentration, patients may have a higher or lower saturation for a given PaO_2.

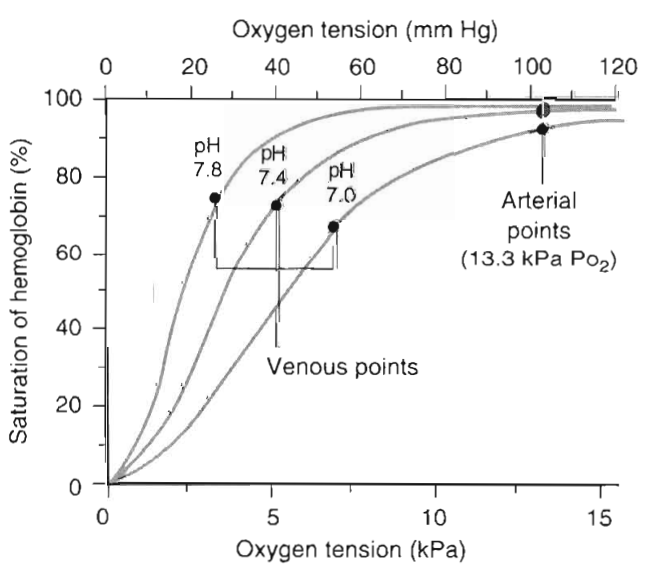

FIGURE 8–1. Oxygen saturation varies with the PaO_2 in a nonlinear relationship and is affected by temperature, $PaCO_2$, pH, and 2,3-diphosphoglycerate (2,3-DPG) concentration.

Patients who have significant decreases in oxygen saturation attempt to maintain oxygen delivery by increasing cardiac output. Although patients with normal left ventricular function and normal coronary vasculature can tolerate lower oxygen saturation, patients with coronary artery disease or decreased contractility may not be able to tolerate the compensatory tachycardia. The decision to begin mechanical or noninvasive ventilation should be based on the patient's cardiopulmonary physiology and not a specific oxygen saturation. A PaO_2 less than 40 mm Hg or an oxygen saturation less than 75% results in tissue hypoxemia, however, even if cardiac output increases. Generally, saturations in the low 90s on escalating levels of inspired oxygen concentration indicate impending respiratory failure, and invasive or noninvasive mechanical ventilation is necessary.

Etiologies for hypoxemia are best understood if approached from a physiologic point of view rather than by referring to a list of possible differential diagnoses. Simply stated, hypoxemia results from an imbalance between pulmonary ventilation and pulmonary capillary blood flow.[2] There is inadequate oxygen tension in the alveoli, the oxygen is unable to get to the alveoli because of reduced ventilation, or there is a diffusion abnormality preventing oxygen from entering the capillaries.

REDUCED ALVEOLAR OXYGENATION

Alveolar oxygenation is defined by the equation: $PalvO_2 = FiO_2 (BP - BP_{H_2O}) - PaCO_2/RQ$, where FiO_2 is the concentration of inspired oxygen, BP is the barometric pressure, BP_{H_2O} is the partial pressure of water, and RQ is the respiratory quotient. The respiratory quotient represents the amount of oxygen consumed relative to the amount of carbon dioxide produced when nutrients are metabolized and is generally assumed to be 0.8. The normal alveolar oxygenation is 100 mm Hg. According to the equation, factors that contribute to lower alveolar oxygenation are a reduction in barometric pressure or an increase in $PaCO_2$. Clinically, significant increases in $PaCO_2$ are explained by the relationship: $PaCO_2$ = carbon dioxide production/respiratory rate (tidal volume – dead space). Accordingly, the $PaCO_2$ increases with either an increase in production or a decrease in alveolar ventilation.

Alveolar ventilation represents that portion of the minute ventilation undergoing blood-gas exchange and is represented by the product of respiratory rate and tidal volume minus dead space.

Medications, such as narcotics and sedatives, and processes that reduce tidal volume, such as neuromotor weakness, are common causes of hypercarbia. If the alveolar oxygen tension is reduced, the arterial hypoxemia is due to factors that reduce the alveolar oxygen tension. If alveolar oxygen tension is normal, the hypoxemia is the result of either a ventilation/perfusion imbalance or a diffusion abnormality.

DIFFUSION ABNORMALITIES

Diffusion abnormalities are the least likely cause of hypoxemia in the ICU, but can occur as a result of an increase in the thickness of the capillary membrane, a reduction in total alveolar surface area, or a reduction in the capillary transit time. Increases in sympathetic tone because of fever, anemia, work of breathing, or sepsis can increase cardiac output and heart rate, resulting in faster transit times. With less opportunity for alveolar oxygen to diffuse into red blood cells, diffusing capacity is reduced. When capillary transit time is faster, the mean capillary arterial oxygen partial pressure decreases, and the diffusing capacity is reduced.

VENTILATION/DIFFUSION MISMATCH

The most common cause of hypoxemia is ventilation/perfusion mismatch. When perfusion is reduced as a result of a decrease in cardiac output or obstruction from pulmonary emboli, the percent of alveoli with adequate blood flow is reduced, increasing the dead space. If minute ventilation remains constant, the primary blood gas abnormality is an increase in carbon dioxide (PCO_2 = carbon dioxide production/respiratory rate × tidal volume – dead space).

When ventilation is reduced relative to perfusion, alveolar oxygenation decreases and results in arterial hypoxemia. This problem occasionally occurs with bronchospasm or bronchitis. Patients with ventilation/perfusion abnormalities generally respond to increasing the FIO_2. When there is no ventilation (as opposed to reduced ventilation), increasing the FIO_2 is not beneficial.

The portion of cardiac output that does not participate in gas exchange is called the *shunt fraction*. The normal shunt fraction is approximately 3% and is due to the bronchial arterial circulation. When alveoli are not ventilated, such as occurs with pulmonary edema, pneumonia, or atelectasis, the shunt fraction increases. As the shunt fraction increases, PaO_2 decreases (Fig. 8-2), and there is a blunted response to increasing the FIO_2, such that a patient with a shunt fraction greater than 50% has little response to increasing FIO_2 (Fig. 8-3).

Patients with refractory hypoxemia and a clear chest radiograph are often evaluated for a pulmonary embolus. In patients with otherwise previously normal lungs, pulmonary emboli are associated with modest decreases in arterial oxygenation; however, the major pathophysiology is an increase in dead space, which results in hypercarbia unless minute ventilation increases. The hypoxemia caused by pulmonary emboli is due to regional ventilation/perfusion abnormalities and responds to supplemental oxygen. If a patient with a pulmonary embolus has refractory hypoxemia unresponsive

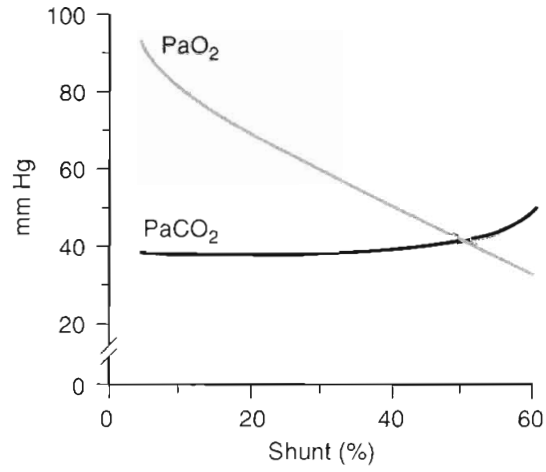

FIGURE 8–2. Decrease in PaO_2 with increasing shunt fraction.

to supplemental oxygenation, an echocardiogram should be performed to rule out a patent foramen ovale, which creates a right-to-left intracardiac shunt in response to the acute increase in pulmonary artery pressure.

Other causes of refractory hypoxemia with a clear chest radiograph are intracardiac shunts and intrapulmonary shunts resulting from either arterial-venous malformations or end-stage liver disease. Often the cause of refractory hypoxemia without radiographic findings on the plain chest film is atelectasis, which is not seen on the typical anteroposterior portable study obtained in the ICU.

It also is relatively common for patients to develop significant hypoxemia when they are started on an intravenous vasodilator, such as sodium nitroprusside. Infusion of sodium nitroprusside interferes with normal hypoxic vasoconstriction, leading to increased perfusion of poorly ventilated areas of the lung. As a result, shunt fraction increases.

Because calculating the shunt fraction, $QsCQ_t = CcO_2/C_{CO_2} - CV_{O_2}$, requires arterial and mixed venous blood gases for calculation of C_{CaO_2} (arterial) and C_{VO_2} (venous) oxygen contents, and because capillary oxygen cannot be directly measured, other indices have been used to estimate the extent of pulmonary gas exchange abnormality. These indices

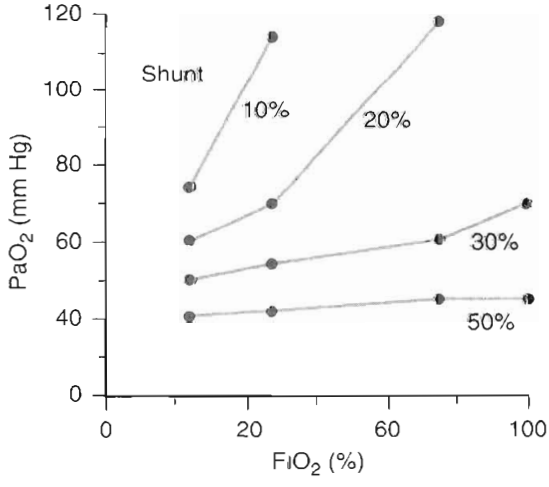

FIGURE 8–3. Blunted response to increasing the inspired oxygen concentration. A patient with a shunt greater than 50% has little response to increasing FIO_2.

include the alveolar-to-arterial (A-a) PO_2 gradient and the arterial/alveolar PO_2 ratio.

ALVEOLAR-ARTERIAL PARTIAL PRESSURE OF OXYGEN GRADIENT

The difference between the alveolar PO_2 and the arterial PO_2 (i.e., the A-a gradient) often is used to estimate the extent of pulmonary pathophysiology and to rule out hypoxemia due to low alveolar PO_2 as the cause of arterial hypoxemia.[3,4] A patient with a reduced alveolar PO_2 (e.g., secondary to breathing room air at high altitude) would have a normal A-a gradient, whereas a patient with ventilation/perfusion mismatching would have a widened A-a gradient. A patient with a PaO_2 of 48 mm Hg and a $PaCO_2$ of 80 mm Hg would have an alveolar PO_2 on room air of 50 mm Hg; the normal A-a gradient of 2 mm Hg is consistent with reduced alveolar PO_2, and causes of hypercarbia need to be ruled out and reversed.

The A-a gradient increases with age or increasing FiO_2, making it an unreliable predictor of the degree of pulmonary dysfunction.[4,5] The PaO_2/FiO_2 ratio also correlates with shunt fraction, but is influenced by increasing FiO_2.[3] The arterial/alveolar ratio is not influenced by FiO_2.[5]

These gradients and ratios are not a substitute for thorough bedside assessment. If a patient has low arterial oxygen saturation by pulse oximetry and is tolerating the reduced saturation without tachycardia or chest pain, adding supplemental oxygen and observing for an appropriate response is reasonable. If there is no increase in saturation, the patient has at least a 40% to 50% shunt and requires intubation or noninvasive ventilation to improve ventilation. Additional oxygen would not increase saturation. If the saturation responds to increasing the FiO_2, the patient has a shunt fraction less than 0.4 or ventilation/perfusion mismatching, and there is time to obtain a chest radiograph and arterial blood gas measurements. If the patient has low saturation and is unstable, immediate bag-and-mask ventilation and securing the airway take precedence over establishing a diagnosis.

REDUCED MIXED VENOUS OXYGEN

A final contribution to hypoxemia may be a reduced mixed venous oxygen content ($CmvO_2$) or saturation. In patients with normal lung function, reducing $CmvO_2$ has little influence on arterial oxygenation; however, in patients with a significant shunt fraction, reducing $CmvO_2$ contributes to arterial hypoxemia.[6] In patients with a widened A-a gradient and abnormally low $CmvO_2$, oxygenation can be improved by increasing venous saturation either by increasing oxygen delivery (increased hemoglobin concentration or cardiac output or both) or reducing oxygen consumption (e.g., induction of hypothermia or using neuromuscular blocking agents).

Chapter 9
ACUTE RESPIRATORY FAILURE

Lakshmipathi Chelluri

Acute respiratory failure is one of the leading causes of admission to an intensive care unit (ICU). In a recent study of cases in the United States, the reported incidence of acute respiratory failure requiring hospitalization was 137 in 100,000 population and the median age of the patients was 69 years.[1] Acute respiratory failure is secondary either to a failure of oxygenation (hypoxic respiratory failure) or to a failure of elimination of carbon dioxide (hypercarbic respiratory [ventilatory] failure). Chronic obstructive pulmonary disease (COPD) with acute exacerbation is the most common cause of ventilatory failure requiring ICU admission.

PATHOPHYSIOLOGY

Oxygenation and elimination of carbon dioxide are the primary gas exchange functions of the lung, and a failure of either one results in acute respiratory failure.[2]

CAUSES OF HYPOXIC RESPIRATORY FAILURE

HYPOVENTILATION

Arterial partial pressure of carbon dioxide ($PaCO_2$) increases with decrease in minute ventilation. An increase in $PaCO_2$ decreases alveolar partial pressure of oxygen (PAO_2) because the carbon dioxide displaces oxygen in the alveoli. Narcotics, anesthetics, and other medications that induce respiratory depression are the usual causes of primary hypoventilation.

VENTILATION-PERFUSION MISMATCH

Gas exchange is optimal when ventilation and perfusion in the lung are matched. A decrease in perfusion relative to ventilation (dead space) or a decrease in ventilation relative to perfusion (shunt) results in ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch. Hypoxia occurs as a result of $\dot{V}/\dot{Q}$ mismatch because of admixture of venous and arterial blood at the capillary level. $\dot{V}/\dot{Q}$ mismatch is the most common cause of hypoxia in hospitalized patients. In contrast to hypoxemia caused by an anatomic shunt, hypoxemia caused by $\dot{V}/\dot{Q}$ mismatching can be improved by administration of supplemental oxygen.

SHUNT

Hypoxia secondary to shunt occurs as a result of a direct mixture of venous and arterial blood in patients with a right-to-left shunt secondary to congenital cardiac disease or trauma. Oxygenation cannot be improved with supplemental oxygen in patients with an anatomic shunt.

DIFFUSION IMPAIRMENT

Thickening of the alveolar endothelial barrier or a decrease in transit time in the pulmonary capillary bed impairs diffusion of oxygen from the alveoli into the blood.

HIGH ALTITUDE

Barometric pressure decreases with increasing altitude, and, as a result, the partial pressure of oxygen in the ambient atmosphere decreases as well. Consequently, unless supplemental oxygen is provided, hypoxia is an inevitable consequence of respiration at high altitude.

IMPAIRED TISSUE PERFUSION

When tissue perfusion is impaired, the cells attempt to maintain normal oxygen consumption by extracting more oxygen from the available blood supply. As a consequence, venous oxygen tension decreases. Unless fractional pulmonary shunt flow is zero, decreased mixed venous oxygen tension inevitably decreases arterial oxygen tension. Although low tissue cardiac output or impaired blood flow to tissues can cause hypoxia, hypoperfusion is rarely a primary cause of clinically significant hypoxia. Nevertheless, hypoperfusion is a common factor exacerbating the degree of hypoxia caused by other problems.

If the circulating concentration of carboxyhemoglobin or methemoglobin increases, then the oxygen-carrying capacity of the blood decreases. Although arterial oxygen tension may be normal, arterial oxygen saturation is abnormally low because of the presence of hemoglobin derivatives that are incapable of transporting oxygen.

HYPERCARBIC RESPIRATORY FAILURE

Partial pressure of carbon dioxide in the arterial blood ($PaCO_2$) is inversely proportional to alveolar ventilation. $PaCO_2$ increases when the elimination of carbon dioxide is decreased because of a decrease in minute ventilation. $PaCO_2$ also increases if minute ventilation remains constant but carbon dioxide production increases. Primary pulmonary diseases are the most common cause of hypercarbia, although nonpulmonary causes contribute to hypoventilation, increased $PaCO_2$, and the need for mechanical ventilatory support.

Minute ventilation can be decreased due to pulmonary or nonpulmonary factors. Pulmonary causes of impaired minute ventilation include large airway obstruction (e.g., due to the presence of a foreign body or laryngeal spasm), small airway obstruction (e.g., bronchospasm), and destruction of lung parenchyma (e.g., emphysema). Extrapulmonary causes of hypercarbia include neurologic and muscular problems. Neurologic problems include depression of central respiratory drive due to the pharmacological effects of narcotics or sedatives; depression of respiratory drive as a consequence of stroke, intracranial hemorrhage, or head trauma (i.e., central alveolar hypoventilation); and impaired neuromuscular transmission to phrenic nerve injury or spinal cord injury (C5 or higher), Guillain-Barré syndrome, myasthenia gravis and the multifactorial syndrome, polyneuropathy of critical illness. Muscular weakness or skeletal abnormalities can cause a decrease in tidal volume and minute ventilation. The following are some causes of hypoventilation secondary to musculoskeletal abnormalities: prolonged use of neuromuscular blocking agents, malnutrition, hypomagnesemia, hypokalemia, hypophosphatemia, kyphoscoliosis, rib fractures, and flail chest.

Causes of hypercarbia secondary to increased carbon dioxide production and relative hypoventilation include overfeeding, since fat synthesis increases the ratio of carbon dioxide production relative to oxygen consumption (respiratory quotient), and fever and other hypercatabolic states.

CLINICAL PRESENTATION

Dyspnea is the most common symptom associated with acute respiratory failure. Dyspnea is usually associated with rapid shallow breathing and the use of accessory respiratory muscles.

The investigations to evaluate the causes of respiratory failure depend on the suspected mechanism of acute respiratory failure and the primary disease process. Pulse oximetry is a useful monitoring tool and should be carried out in virtually all cases. Other worthwhile diagnostic studies include the following:

Analysis of arterial blood gases will permit diagnosis of a widened alveolar-arterial P_{O_2} gradient and/or hypercarbia.

Examination of the chest radiograph is useful in almost all cases. If the chest film is clear, then the differential diagnosis should include pulmonary embolism, anatomic right-to-left shunt, pneumothorax, cirrhosis, and COPD. If the chest radiograph shows unilateral infiltrates or effusion, then the differential diagnosis should include pleural effusion, aspiration, lobar pneumonia, atelectasis, and infarction. If bilateral infiltrates are present, then the differential diagnosis should include pulmonary edema (cardiac and noncardiac causes), pneumonia, and pulmonary hemorrhage.[3]

Other more specialized tests, such as computed tomography and cultures, are needed based on the differential diagnosis for the suspected primary disease.

MANAGEMENT

The goal is to maintain adequate oxygenation and ventilation and treat the primary cause of respiratory failure. For hypoxic respiratory failure, the primary goal is to improve arterial oxygenation and maintain PaO_2 of 65 to 70 mm Hg and an arterial blood oxygen saturation (SaO_2) of greater than 93%. Administration of supplemental oxygen improves oxygenation in most clinical situations except for anatomic shunts. Low-flow oxygen can be delivered using a nasal canula or a face mask. The maximum fraction of inspired oxygen (FIO_2) that can be delivered using these approaches is about 0.4. This level of oxygen supplementation is not adequate when the alveolar-arterial (A-a) gradient is very wide. The FIO_2 delivered using a nasal canula or face mask also is dependent on minute ventilation. Accordingly, low-flow methods of providing supplemental oxygen should be used cautiously in patients who are dependent on hypoxic drive or have very high minute ventilation. A higher FIO_2 can be provided if a face mask is combined with a reservoir bag, because admixture of the supplemental oxygen with room air is minimized.

Noninvasive positive pressure ventilation and mechanical ventilation via an endotracheal tube are two approaches for providing supplemental oxygen and, at the same time, providing partial or total support for minute ventilation. In hemodynamically stable patients with mild or moderate respiratory failure, noninvasive positive pressure ventilation may decrease the need for intubation and mechanical ventilation and decrease the patient's length of stay in the ICU.[4,5] Noninvasive positive pressure ventilation should not be used in patients with altered mental status who are unable to protect the airway. Noninvasive positive pressure ventilation should not be used for patients who are unable to clear secretions adequately. For some patients, tolerance for noninvasive positive pressure ventilation can be improved by using a nasal mask and starting at a lower level of inspiratory pressure (5 cm H_2O).

In cases of hypercarbic respiratory failure, the primary goal of treatment is to maintain arterial pH at greater than 7.32 with a $PaCO_2$ appropriate for the pH.[6] Bronchodilators can be delivered as metered dose inhalers or nebulizers. Patients with tachypnea and respiratory distress may not be able to use metered dose inhalers. The bronchodilating effects of β-adrenergic agonists and anticholinergic drugs are synergistic. Long-acting β-adrenergic agonists should not be used to treat acute exacerbations of chronic bronchospasm. Corticosteroids are often used to treat acute exacerbations of diseases associated with airway inflammation and bronchospasm (e.g., asthma and COPD). The reported dosing range is wide. Intravenous methylprednisolone (40 mg i.v. every 12 h to 125 mg i.v. every 6 h) is often employed, if the response is inadequate to initial efforts using bronchodilator treatments with β-adrenergic agonists and anticholinergic agents. Aerosolized steroids may not improve bronchospasm during the acute episode but are useful for maintenance treatment. Although systemic absorption of aerosol steroids is not significant, they may cause adrenal suppression.

Patients who experience changes in the nature of the sputum and signs of infection may benefit from a short course (7-10 days) of antibiotic therapy.

The use of noninvasive positive pressure ventilation in hemodynamically stable patients with mild to moderate ventilatory failure may decrease the need for mechanical ventilatory support and length of stay. The precautions while using noninvasive positive pressure ventilation are the same as listed previously.

INTUBATION AND MECHANICAL VENTILATION

The need for mechanical ventilatory support is a clinical decision based on increased work of breathing (i.e., respiratory

rate >35), inability to clear secretions and maintain an adequate airway. The clinician has only two basic maneuvers for improving PaO_2 using mechanical ventilation. The first is to increase FIO_2. The second is to increase mean airway pressure. The latter goal can be achieved in two main ways: (1) application of positive end-expiratory pressure; or (2) changing the duty cycle so that the duration of inspiration is longer (in the extreme, this maneuver is called inverse ratio ventilation). In patients with acute lung injury, tidal volume should be limited to 6 mL/kg (ideal body weight). Prone positioning, inhaled nitric oxide, and transtracheal gas insufflation are some of the other methods used to improve oxygenation in patients with profound hypoxemia due to acute lung injury, but none of these approaches have been shown to improve survival.

Ventilation should be adjusted to maintain pH and $PaCO_2$ at levels that are appropriate for the patient, particularly in patients with COPD and chronic respiratory acidosis. Hyperventilation and excessive correction of $PaCO_2$ in patients with chronic respiratory acidosis results in secondary metabolic alkalosis and delay in weaning from mechanical ventilation. Alveolar air trapping (so-called auto-positive end-expiratory pressure) and hypotension (due to impaired venous return) may develop in patients with inadequate exhalation time, and caution should be used when increasing minute ventilation by increasing either ventilator-delivered respiratory rate or tidal volume in patients with severe airway obstruction.

PROGNOSIS

Mortality in patients with respiratory failure requiring positive pressure ventilatory support is dependent on the primary cause. The hospital mortality rate is 30% to 40% and the 1-year mortality rate is 50% to 70%. Functional status deteriorates immediately after the illness and improves to baseline by 6 to 12 months in survivors.[7]

Chapter 10
POLYURIA

Ramesh Venkataraman • John A. Kellum

Although polyuria in the critically ill is less common than oliguria, it is an important manifestation of a number of clinical conditions. Unless recognized and appropriately managed, polyuria can rapidly lead to the development of hypovolemia, severe hypernatremia, or both. Generally, urine flow varies, depending on the fluid intake, insensible losses (e.g., perspiration), and renal function. The average person excretes about 600 to 800 mOsm of solutes per day, and the average urine output is about 1.5 to 2.5 L/day.

Polyuria has been defined variably in the literature. The most commonly used definition is based entirely on absolute urine volume and arbitrarily defines polyuria as urine volume of greater than 3 L/day. However, some authors prefer to define polyuria as "inappropriately high urine volume in relation to the prevailing pathophysiologic state," regardless of the actual volume of urine.[1,2]

CLASSIFICATION

Polyuria is broadly classified into water diuresis or solute diuresis, depending on whether water or solute is the primary driving force for the increased urine output. However, some patients have a mixed water and solute diuresis.

WATER DIURESIS

DEFINITION AND PATHOPHYSIOLOGY

If the urine output is greater than 3 L/day and the urine is dilute (urine osmolality <250 mOsm/L), total solute excretion is relatively normal, and the polyuria is due to excessive excretion of water. In general, diuresis is marked, and urine osmolality is often less than 100 mOsm/L. Water diuresis is usually secondary to excess water intake, as in primary polydipsia, or to the inability of the renal tubules to reabsorb free water, as in central or nephrogenic diabetes insipidus. A good understanding of water homeostasis is critical in recognizing and managing water diuresis.

The normal plasma osmolality is 275 to 285 mOsm/L. To maintain this steady state, water intake must equal water excretion. The primary stimulus for water ingestion is thirst, mediated by either an increase in effective osmolality or a decrease in blood pressure or effective circulating volume. Under normal circumstances, water intake generally exceeds physiologic requirements.

Unlike water intake, water excretion is tightly regulated by multiple factors. The most dominant regulating factor affecting water secretion is arginine vasopressin, a polypeptide synthesized in the hypothalamus and secreted by the posterior pituitary gland. Once released, arginine vasopressin binds to vasopressin-2 receptors located on the basolateral membranes of renal epithelial cells lining the collecting ducts. Binding of arginine vasopressin to vasopressin-2 receptors initiates a sequence of cellular events, ultimately resulting in the insertion of water channels into the luminal cell membrane. The presence of these water channels permits passive diffusion of water (and hence its reabsorption) across the collecting duct. Any derangement in this process results in a lack of or inadequate water reabsorption by the collecting duct, resulting in water diuresis. The major stimulus for the release of arginine vasopressin is plasma hypertonicity. Its release is also affected by other nonosmotic factors such as effective circulating volume, hypoglycemia, and drugs. In summary, water diuresis occurs because of either excessive water intake sufficient to overwhelm the renal excretory capacity (primary polydipsia) or impairment of renal water reabsorption (central or nephrogenic diabetes insipidus). Impaired renal water reabsorptive capacity (leading to water diuresis) can occur due to failure of arginine vasopressin release in response to normal physiologic stimuli (central or neurogenic diabetes insipidus) or failure of the kidney to respond to arginine vasopressin (nephrogenic diabetes insipidus). In most patients, the degree of polyuria is determined primarily by the degree of arginine vasopressin lack or resistance.

PRIMARY POLYDIPSIA

Primary polydipsia can be recognized clinically based on the history of the patient. Usually, there is a history of psychiatric illness along with a history of excessive water intake. Many patients with chronic psychiatric illnesses have a moderate to marked increase in water intake (up to 40 L/day).[3,4] It is presumed that a central defect in thirst regulation plays an important role in the pathogenesis of polydipsia. In some cases, the osmotic threshold for thirst is reduced below the threshold for the release of arginine vasopressin. The mechanism responsible for abnormal thirst regulation in this setting is unclear. There is evidence that these patients have other defects in central neurohumoral control as well.[5] The diagnosis of primary polydipsia is usually evident from low urine and plasma osmolalities in the face of polyuria. Hyponatremia, when present, also points to the diagnosis of primary polydipsia. Hypothalamic diseases, such as sarcoidosis; trauma; and certain drugs, such as the phenothiazines, can lead to primary polydipsia (Table 10–1). There is no proven treatment for psychogenic polydipsia. Free water restriction is the mainstay of therapy.

TABLE 10–1. CAUSES OF POLYURIA

- Polyuria secondary to water diuresis
  - Excessive intake of water
    - Psychogenic polydipsia
    - Drugs—anticholinergic drugs, thioridazine
    - Hypothalamic diseases—surgery, sarcoidosis
  - Defective water reabsorption by the kidney
    - Central diabetes insipidus (vasopressin deficiency)
    - Renal tubular resistance to arginine vasopressin
      - Congenital nephrogenic diabetes insipidus
      - Acquired nephrogenic diabetes insipidus
        - Hypercalcemia
        - Hypokalemia
        - Drugs—lithium, demeclocycline
        - Chronic renal diseases—postobstructive diuresis, polyuric phase of acute tubular necrosis
        - Other systemic diseases—amyloidosis, sickle cell anemia
- Polyuria secondary to solute diuresis
  - Electrolyte-induced solute diuresis
    - Iatrogenic—excessive sodium chloride load, loop diuretic use
    - Salt-wasting nephropathy (rarely causes polyuria)
  - Nonelectrolyte-induced solute diuresis
    - Glucosuria—diabetic ketoacidosis, hyperosmolar coma
    - Urea diuresis—high-protein diet, acute tubular necrosis
    - Iatrogenic—mannitol

CENTRAL DIABETES INSIPIDUS

Lack of arginine vasopressin (central diabetes insipidus) can be caused by disorders that act at one or more of the sites involved in its secretion, interfering with the physiologic chain of events that lead to hormone release. The common causes of central diabetes insipidus, accounting for the vast majority of cases, include neurosurgery, head trauma, brain death, primary or secondary tumors of the hypothalamus, and infiltrative diseases (such as Langerhans cell histiocytosis).

NEPHROGENIC DIABETES INSIPIDUS

Nephrogenic diabetes insipidus refers to a decrease in urinary concentrating ability that results from renal resistance to the action of arginine vasopressin. The collecting duct cells may fail to respond to the actions of arginine vasopressin. Other factors that can cause renal resistance to arginine vasopressin involve interference with the countercurrent concentrating mechanism, such as medullary injury or decreased sodium chloride reabsorption in the medullary aspect of the thick ascending limb of the loop of Henle. In children, nephrogenic diabetes insipidus is usually hereditary. Congenital or hereditary nephrogenic diabetes insipidus is an X-linked recessive disorder resulting from mutations in the vasopressin-2 arginine vasopressin receptor gene.[6] The X-linked inheritance pattern means that males tend to have marked polyuria. Female carriers are usually asymptomatic but occasionally have severe polyuria. In addition, different mutations are associated with different degrees of arginine vasopressin resistance. Nephrogenic diabetes insipidus can also be inherited as an autosomal recessive disorder due to mutations in the acquaporin gene that result in absent or defective water channels, thereby causing resistance to the action of arginine vasopressin.[7]

The most common cause of nephrogenic diabetes insipidus in adults is chronic lithium ingestion. Polyuria occurs in about 20% to 30% of patients on chronic lithium therapy. The impairment in the nephron's concentrating ability is thought to be due to decreased density of vasopressin-2 receptors or to decreased expression of aquaporin-2, a water channel protein. Other secondary causes of nephrogenic diabetes insipidus include hypercalcemia, hypokalemia, sicke cell disease, and other drugs (see Table 10–1). A water diuresis also can follow relief of obstructive nephropathy. Hypercalcemia-induced nephrogenic diabetes insipidus occurs when the plasma calcium concentration is persistently above 11 mg/dL (2.75 mmol/L). This defect is generally reversible with correction of the hypercalcemia. The mechanisms responsible for hypercalcemia-induced nephrogenic diabetes insipidus are incompletely understood. Compared with hypercalcemia-induced diabetes insipidus, hypokalemia-induced nephrogenic diabetes insipidus is less severe and often asymptomatic. A rare form of nephrogenic diabetes insipidus can occur during the second half of pregnancy (gestational diabetes insipidus). This condition is thought to be caused by release of a vasopressinase from the placenta, leading to rapid degradation of endogenous or exogenous arginine vasopressin.[8]

DIAGNOSIS OF HYPOTONIC POLYURIA (WATER DIURESIS)

The correct diagnosis is often suggested by the plasma sodium concentration and the history. When the problem is primary polydipsia, the plasma sodium concentration is usually low (dilutional), whereas when the problem is central or nephrogenic diabetes insipidus, the plasma sodium concentration is typically normal or high (related to intravascular volume depletion). The rate of onset of polyuria sometimes provides a clue to the diagnosis; with central diabetes insipidus, the onset of polyuria is generally abrupt, whereas with nephrogenic diabetes insipidus or primary polydipsia, the onset of polyuria tends to be more gradual. Even if the history or plasma sodium concentration is helpful, the diagnosis of central versus nephrogenic diabetes insipidus should be confirmed by determining the urinary response to an acute increase in plasma osmolality induced by either water restriction or, less commonly, the administration of hypertonic saline (Fig. 10–1).

Comparing urine osmolality after dehydration with that after vasopressin administration can help differentiate diabetes insipidus due to vasopressin deficiency from other causes of water diuresis (see Fig. 10–1). In this test, fluids are withheld long enough to result in stable hourly urine osmolalities (<30 mmol/kg rise in urine osmolality for 3 consecutive hours). Plasma osmolality and urine osmolality are measured at this point; then the patient is given 5 units of aqueous vasopressin intravenously. The clinician measures the osmolality of a urine sample collected 30 to 60 minutes after the administration of vasopressin. In subjects with normal pituitary function, urine osmolality does not rise by more than 9% after vasopressin injection; however, in central diabetes insipidus, the increase in urine osmolality after vasopressin administration exceeds 9%. To ensure adequate dehydration, plasma osmolality before vasopressin administration should be greater than 288 mmol/kg. There is little or no increase in urine osmolality with dehydration in patients with nephrogenic diabetes insipidus, and there is no further change after vasopressin injection. In the future, a novel method to confirm the results of the water restriction test will be to measure the urinary excretion of aquaporin-2, the collecting tubule water channel that normally fuses with the

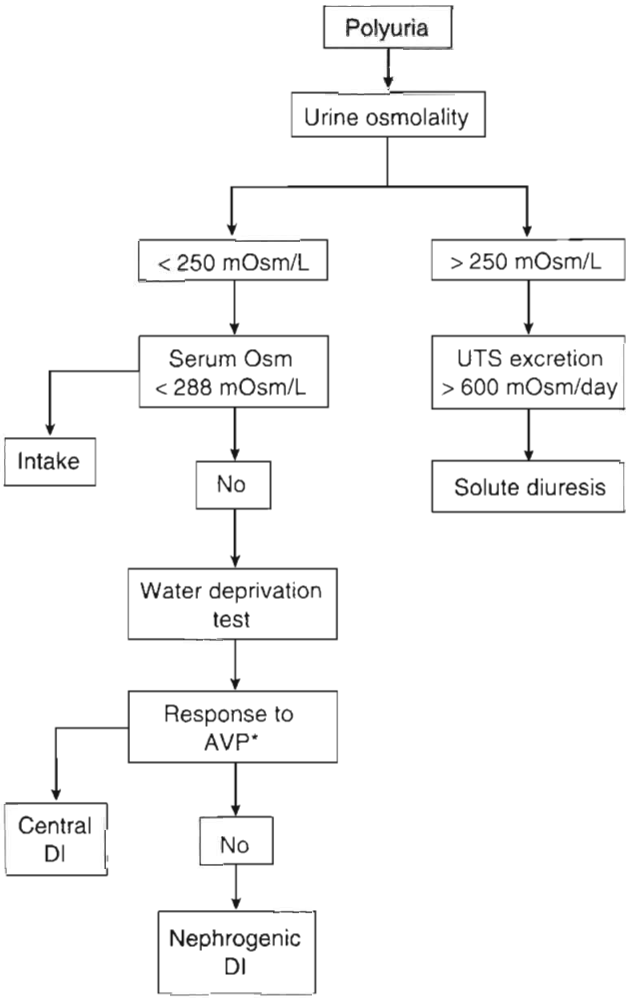

FIGURE 10–1. Approach to polyuria. *Response to arginine vasopressin (AVP) is defined as a greater than 9% increase in urine osmolality 30 to 60 minutes after vasopressin administration (see text for details). DI, diabetes insipidus; UTS, urine total solute concentration.

luminal membrane of the collecting tubule cells under the influence of arginine vasopressin. In one study, urinary aquaporin-2 excretion increased substantially and to a similar extent after the administration of vasopressin in normal subjects and in those with central diabetes insipidus.[9] However, in patients with hereditary nephrogenic diabetes insipidus, urinary aquaporin-2 excretion was unchanged after vasopressin administration.

TREATMENT OF WATER DIURESIS

Central diabetes insipidus can be treated by replacing arginine vasopressin. The agent of choice is desmopressin because it has prolonged antidiuretic activity and a minimal vasopressor effect. It is usually administered intranasally at doses of 10 to 20 μg once or twice per day. Patients with central diabetes insipidus with some residual releasable arginine vasopressin can be treated with drugs such as carbamazepine (100 to 300 mg twice daily), clofibrate (500 mg every 6 hours), or chlorpropamide (125 to 250 mg once or twice per day), which stimulate arginine vasopressin release.

Primary polydipsia can be treated only by eliminating the underlying problem. In patients with schizophrenia and polydipsia, clozapine has been shown to have a beneficial effect.

The mainstay of treatment of nephrogenic diabetes insipidus is solute restriction and diuretics. Thiazide diuretics in combination with a low-salt diet can diminish the degree of polyuria in patients with persistent and symptomatic nephrogenic diabetes insipidus. Thiazide diuretics (hydrochlorothiazide) act by inducing mild volume depletion. Hypovolemia induces an increase in proximal sodium and water reabsorption, thereby diminishing water delivery to the arginine vasopressin–sensitive sites in the collecting tubules and reducing the urine output. The potassium-sparing diuretic amiloride also may be helpful.[10]

SOLUTE DIURESIS

Solute diuresis causing polyuria is due to solute excretion in excess of the usual excretory rate.[11] Total urinary solute excretion varies widely among patients with different ethnicities, cultures, and dietary habits. The average urinary solute excretion in a healthy American adult is between 500 and 1000 mOsm/day. Solute diureses can be severe and can be caused by more than one solute concurrently. Solute diuresis is a relatively common clinical condition with important clinical implications. Unless there is adequate replacement of solute and water, a persistent solute diuresis contracts extracellular volume, leading to severe dehydration and hypernatremia. Although glucosuria is the major cause of an osmotic diuresis in outpatients, other conditions are often responsible when polyuria develops in the hospital. These conditions include administration of a high-protein diet, in which case urea acts as the osmotic agent, and volume expansion due to saline loading or the release of bilateral urinary tract obstruction. Multiplying urine osmolality by the 24-hour urine volume gives an estimate of total urinary solute concentration. If the total urinary solute concentration is abnormally large, a solute diuresis is present.

Solute diuresis can be due to either excessive electrolyte excretion or excessive nonelectrolyte solute excretion. If the total urinary electrolyte excretion exceeds 600 mOsm/day, an electrolyte diuresis is present. The total urinary electrolyte excretion (in mOsm/day) can be estimated as $2 \times (\text{urine } [Na^+] + \text{urine } [K^+]) \times \text{total urine volume}$.[1,12]

An electrolyte diuresis is usually driven by a sodium salt, usually sodium chloride (NaCl).[13] Common causes of NaCl-induced diuresis are iatrogenic administration of excessive normal saline solution, excessive salt ingestion, and repetitive administration of loop diuretics. Most often, NaCl-induced diuresis is accompanied by water diuresis, causing a mixed solute-water diuresis. Also, more than one electrolyte may be responsible for the diuresis.

A clearly excessive value for urine nonelectrolyte excretion (>600 mOsm/day) implies that nonelectrolytes are the predominant solutes contributing to the diuresis. The urinary nonelectrolyte excretion can be calculated by subtracting urine electrolyte excretion from the total urinary solute excretion. The urine osmolality in these disorders is usually above 300 mOsm/kg; the high osmolality contrasts with the dilute urine typically found with a water diuresis. Further, total solute excretion (calculated as the product of urine osmolality and the urine output over a 24-hour urine collection period) is normal with a water diuresis (600 to 900 mOsm/day) but markedly increased with an osmotic diuresis. The most common nonelectrolyte solute causing excessive diuresis is glucose. Conditions associated with glucose-induced diuresis include diabetic ketoacidosis and

hyperosmolar coma.[14] Excessive excretion of urea is another important cause of solute diuresis. This problem can occur with enteral nutrition using a high-protein tube feeding formula, following relief of urinary tract obstruction, or during recovery from acute tubular necrosis.[15] Mannitol administration (e.g., as a therapy for intracranial hypertension) also can lead to significant solute diuresis. This issue is pertinent because mannitol is often administered to patients with head trauma, who are at risk for the development of nephrogenic diabetes insipidus.

The correct diagnosis of solute diuresis depends on a clear systematic approach (see Fig. 10–1). Management usually involves treatment of the underlying disorder and repletion of extracellular volume by hydration. Because solute diuresis is often accompanied by hypernatremia, and because rapid correction of hypernatremia can have disastrous consequences (e.g., cerebral herniation), it is crucial to carefully monitor serum $[Na^+]$. The serum $[Na^+]$ should not be permitted to decrease more than 0.5 to 1 mEq/L per hour.

Chapter 11
OLIGURIA

Sanjay Subramanian • Ramesh Venkataraman • John A. Kellum

Oliguria is a common diagnostic challenge facing the critical care practitioner. This chapter provides a practical, physiology-based approach to diagnosing and treating oliguria.

DEFINITIONS AND EPIDEMIOLOGY

Many definitions for oliguria can be found in the literature. In general, *oliguria* is defined as urine output less than 200 to 500 mL/24 h. To standardize the use of the term across different studies and populations, the Acute Dialysis Quality Initiative (www.ADQI.net) adopted a definition of oliguria as urine output less than 0.3 mL/kg/h for at least 24 hours.

Given the lack of consensus over definitions until now, it is difficult to determine the incidence of oliguria. Some studies estimated that 18% of medical-surgical ICU patients with intact renal function exhibit episodes of oliguria.[1] Of ICU patients who develop acute renal failure, 69% are oliguric.[2] Overall, acute renal failure in the ICU has a poor prognosis; the mortality rates ranges from 30% to 70%. Oliguric acute renal failure compared with nonoliguric acute renal failure carries a higher risk of death. It is essential to understand the physiologic derangements leading to this exceedingly common problem.

PATHOPHYSIOLOGY

Urine output is a function of glomerular filtration rate and tubular secretion and reabsorption. Glomerular filtration rate is directly dependent on renal perfusion. Renal perfusion is a function of arterial pressure and renal vascular resistance. The intrarenal vasculature is capable of preserving glomerular filtration rate in the face of varying systemic pressure through important neurohumoral autoregulating mechanisms that affect tone in the afferent and efferent arterioles. Of these mechanisms, the renin-angiotensin-aldosterone system is perhaps the most important (Fig. 11-1). Oliguria indicates either a marked reduction in glomerular filtration rate or a mechanical obstruction to urine flow.

REDUCTION IN GLOMERULAR FILTRATION RATE

Oliguria secondary to a decrease in glomerular filtration rate usually is related to one of the following conditions:

1. Absolute decrease in intravascular volume. Causes include trauma, hemorrhage, burns, diarrhea, or sequestration of extravascular fluid, as in pancreatitis or after major abdominal surgery.

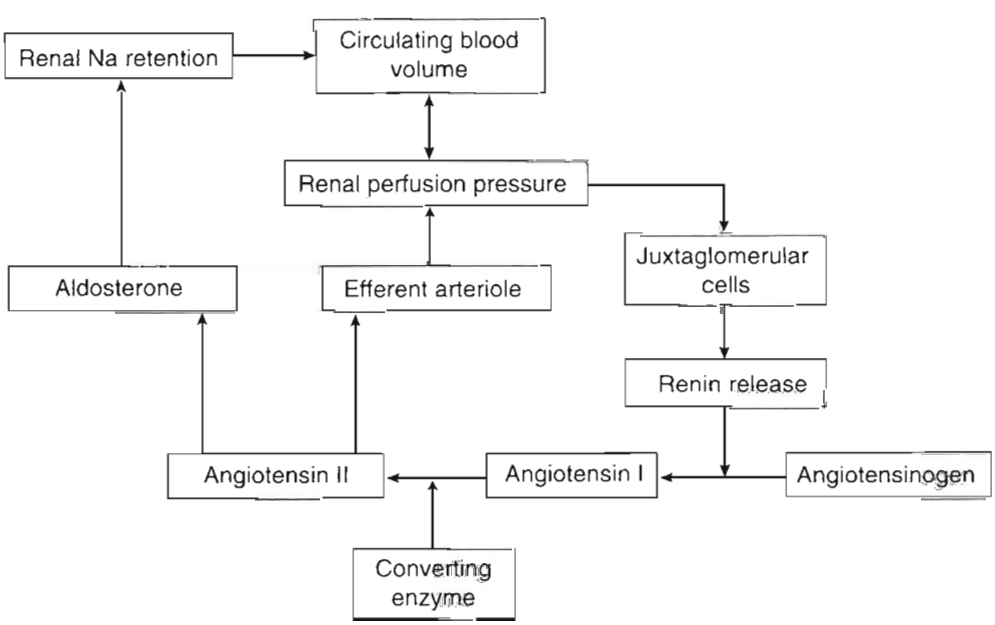

FIGURE 11-1. Network of effects and feedback loop for the renin-angiotensin-aldosterone system. As circulating blood volume or renal perfusion changes, renin secretion changes, resulting in downstream effects that ultimately influence renal resistance and sodium handling by the kidney. Changes in urine output are a direct result of these changes.

2. A relative decrease in blood volume. The primary disturbance is increased capacitance of the vasculature due to vasodilation. This abnormality is encountered commonly in patients with sepsis, hepatic failure, or nephrotic syndrome. Another cause of this abnormality is administration of vasodilating drugs, a category that includes many anesthetic agents.
3. Decreased renal perfusion. Factors that can reduce renal blood flow include structural causes, such as thromboembolism, atherosclerosis, dissection, and inflammation (vasculitis, especially scleroderma) affecting either the intrarenal or the extrarenal circulation. Although renal artery stenosis presents as subacute or chronic renal insufficiency, renal atheroembolic disease can present as acute renal failure with acute oliguria. Renal atheroembolization usually affects older patients with diffuse erosive atherosclerotic disease. Atheromatous embolization is seen most often after manipulation of the aorta or other large arteries during arteriography, angioplasty, or surgery.[3] This condition also may occur spontaneously or after treatment with heparin, warfarin, or thrombolytic agents. Certain drugs, such as cyclosporine, tacrolimus, and angiotensin-converting enzyme inhibitors, cause intrarenal vasoconstriction and reduce renal plasma flow, leading to oliguria. Rarely, decreased renal perfusion can be due to an outflow problem, such as renal vein thrombosis or abdominal compartment syndrome.
4. Acute tubular necrosis. Although acute tubular necrosis is often the result of the above-listed factors, it also can be due to direct nephrotoxic effects of agents such as antibiotics, heavy metals, solvents, contrast agents, or crystals (uric acid or oxalate).

MECHANICAL OBSTRUCTION

Oliguria secondary to mechanical obstruction can be subclassified further according to the anatomic site of the obstruction:

1. Tubular—ureteral obstruction, which can be caused by stones, papillary sloughing, crystals, or pigment.
2. Urethral or bladder neck obstruction—typically due to prostatic hypertrophy or malignancy.
3. A malpositioned or obstructed urinary catheter.

DIAGNOSTIC APPROACH TO OLIGURIA

Oliguria is associated with considerable morbidity and mortality. Merely reversing oliguria, particularly by administering diuretics, does not improve outcome. Rapidly determining the cause of oliguria is essential.

RULE OUT URINARY OBSTRUCTION

The initial step in diagnosis is to rule out urinary obstruction before embarking on a lengthy workup for prerenal or intrarenal causes of renal insufficiency. A prior history of prostatic hypertrophy may provide some clues to the presence of distal obstruction. In the ICU, distal obstruction presenting as oliguria is commonly due to obstruction of the urinary catheter (especially in male patients). In patients with new-onset oliguria, the urinary catheter must be flushed or changed to rule out obstruction. Although uncommon in the acute setting, complete or severe partial bilateral ureteral obstruction also can lead to acute, "acute-on-chronic," or chronic renal failure. Early diagnosis of urinary tract obstruction is important because many causes can be corrected, and a delay in therapy can lead to irreversible renal injury. Renal ultrasonography is usually the test of choice to exclude urinary tract obstruction.[4] It is noninvasive and can be performed at the bedside. Ultrasonography also obviates the potential allergic and toxic complications of radiocontrast media. In almost all cases, ultrasonography successfully diagnoses hydronephrosis and establishes its cause. Ultrasonography also can detect other causes of renal disease, such as polycystic kidney disease. Under some circumstances, however, renal ultrasound may not yield good results. In early obstruction or obstruction associated with severe dehydration, hydronephrosis may not be visualized at the time of the initial ultrasound examination, but may appear on a study done later in the course of the disease. Computed tomography should be performed if the ultrasound results are equivocal, if the kidneys are not well visualized, or if the cause of the obstruction cannot be identified.

LABORATORY INDICES

Some authorities advocate examining the urine sediment, whereas others do not. Although hyaline and fine granular casts are common in prerenal disease, acute tubular necrosis usually is associated with coarse granular casts and tubular epithelial casts. These findings lack discriminating power, however, and are of limited practical value. The main reason to examine the urinary sediment is to detect red blood cell casts, which indicate glomerular disease. The urinary sediment in post–renal failure is often bland, lacking casts or sediments. Occasionally a few red blood cells and white blood cells may be seen. Eosinophilia, eosinophiluria, and hypocomplementemia, if present, suggest that atheroembolization may be the cause of acute oliguria.[5]

Table 11-1 lists laboratory values useful in distinguishing prerenal from intrarenal causes of acute renal failure. A fractional excretion of sodium less than 1 traditionally has been used as evidence for a prerenal cause of oliguria. These indices are unreliable when the patient has received diuretic or natriuretic agents (including dopamine and mannitol)

TABLE 11–1. BIOCHEMICAL INDICES USED TO DISTINGUISH PRERENAL FROM INTRARENAL ACUTE RENAL FAILURE

	Prerenal	Renal
$Osmolality_U$ (mOsm/kg)*	>500	<400
$[Na^+]_U$ (mmol/L or mEq/L)	<20	>40
$[urea]_s/[creatinine]_S$	>0.1	<0.05
$[creatinine]_U/[creatinine]_S$	>40	<20
$Osmolality_U/osmolality_S$	>1.5	>1
FE_{Na} (%)	<1	>2
FE_{urea} (%)	<25	>25

$Osmolality_U$, urine osmolality; $[Na^+]_U$, urinary sodium ion concentration; $[urea]_s/[creatinine]_S$, ratio of serum urea to serum creatinine concentration; $[creatinine]_U/[creatinine]_S$, ratio of urine creatinine concentration to serum creatinine concentration; $osmolality_U/osmolality_S$, ratio of urine osmolality to serum osmolality; FE_{Na}, fractional excretion of filtered sodium; FE_{urea}, fractional excretion of filtered urea. $FE_{Na} = [Na^+]_U \times [creatinine]_S/[Na^+]_S \times [creatinine]_U \times 100$.

and may be confounded by endogenous osmolar substances (e.g., glucose or urea).

CLINICAL PARAMETERS

Traditional indicators of hydration status and tissue perfusion, such as systemic blood pressure, heart rate, body weight, presence or absence of jugular-venous pulsation, and presence or absence of peripheral edema, are of some utility. In the ICU, however, some of these indicators are less useful for a variety of reasons.

Presence or absence of jugular-venous pulsation is not an accurate way to assess right ventricular filling pressure when patients are receiving positive-pressure ventilation and positive end-expiratory pressure. Similarly, peripheral edema is often due to hypoalbuminemia and decreased oncotic pressure in critically ill patients. Patients may have a total body excess of salt and water and yet be intravascularly volume depleted. Blood pressure and heart rate are affected by numerous physiologic and treatment variables in the ICU and are unreliable measures of volume status.

In the ICU, it is common to assume that one can obtain a more accurate assessment of preload by measuring the central venous pressure or pulmonary artery occlusion pressure. These measurements provide unambiguous data, however, only when the pressures are low (<10 mm Hg). If central venous pressure or pulmonary artery occlusion pressure is increased, it does not ensure that filling pressures are adequate. Response to a single fluid challenge or even multiple fluid challenges may not detect hypovolemia depending on the degree of intravascular volume depletion. The presence of a cardiac index greater than 3 L/min/m^2 generally suggests *adequate* preload, but may not reflect *optimal* preload. The mixed venous oxygen saturation can serve as a surrogate for cardiac output, but does not define optimal filling. For patients receiving positive-pressure mechanical ventilation, the absence of arterial pulse-pressure variation provides robust evidence that intravascular volume is adequate. In other cases, echocardiography may provide the only reliable way to assess intravascular volume status.

ABDOMINAL COMPARTMENT SYNDROME

Another important and often overlooked reason for acute oliguria is abdominal compartment syndrome. *Abdominal compartment syndrome* is defined as symptomatic organ dysfunction that results from an increase in intra-abdominal pressure. Although this condition initially was described in trauma patients, abdominal compartment syndrome occurs in a wide variety of medical and surgical patients. Abdominal compartment syndrome is seen sometimes after major abdominal operations that are associated with massive resuscitation or tight abdominal wall closure. Abdominal compartment syndrome leads to acute renal failure and acute oliguria mainly by increasing renal outflow pressure and reducing renal perfusion. Other mechanisms include direct parenchymal compression and decreased venous return to the heart, leading to embarrassment of cardiac output and stimulation of the sympathetic nervous and renin-angiotensin systems on this basis. These factors lead to decreased renal and glomerular perfusion and manifest as acute oliguria. Intra-abdominal pressure greater than 15 mm Hg can lead to oliguria, and intra-abdominal pressure greater than 30 mm Hg can cause anuria.[6]

Abdominal compartment syndrome should be suspected in any patient with a tensely distended abdomen, progressive oliguria, and increased airway pressure (transmitted across the diaphragm). The mainstay of diagnosis is measurement of intra-abdominal pressure. The most common way to assess intra-abdominal pressure is to measure the pressure in the urinary bladder because it is easily performed. Bladder pressure has been shown to correlate well with intra-abdominal pressure over a wide range of pressures. Decompression of the abdomen with laparotomy, sometimes requiring that the abdomen be left open for a time, is the only definitive treatment for oliguria from abdominal compartment syndrome.

TREATMENT OF OLIGURIA

ENSURING ADEQUATE RENAL PERFUSION

The management of oliguria is based on identification and correction of precipitating factors. In addition, nephrotoxic drugs should be avoided, if possible, and doses of all renally excreted drugs should be adjusted appropriately. Efforts should be made to optimize renal perfusion by correcting hypotension and providing appropriate intravascular volume expansion. Correction of hypotension is especially crucial because in cases of acute renal failure secondary to sepsis and ischemia some of the important autoregulating mechanisms that help preserve glomerular filtration rate in the face of fluctuating blood pressure are disrupted. In these patients, renal blood flow is directly related to systemic arterial pressure. Vasoactive drugs may be necessary to increase the mean arterial pressures to more than usual values to maintain adequate renal perfusion urine output.[7] In patients with chronic hypertension and renal vascular disease, renal autoregulation curves (i.e., plots of renal perfusion as a function of blood pressure) are shifted to the right. A higher mean arterial pressure may be required to ensure adequate renal perfusion. Before starting treatment with a vasoactive drug, however, it is imperative to ensure that the patient is adequately volume resuscitated. The blood pressure target must be individualized based on numerous factors, such as the premorbid blood pressure and presence or absence of vascular disease. Hemodynamic monitoring devices may enable a more streamlined, "goal-directed" approach to therapy.

ROLE OF DIURETIC AGENTS

The use of diuretic agents in oliguric renal failure is widespread, despite a paucity of evidence supporting their efficacy. Traditionally, diuretics have been used in the early phases of oliguria to "jump start" the kidney and establish urine flow. Presumably the absence of oliguria makes it easier to regulate volume status, and given that nonoliguric renal failure generally has a better prognosis, clinicians frequently use diuretics in this setting.[8] A study by Anderson and coworkers[9] in 1977 claimed a reduction in mortality from 50% to 26% by using high doses of a loop diuretic to convert oliguric to nonoliguric renal failure. This study excluded patients with shock and perioperative renal failure. These results have not been reproduced in more recent trials. A study in 1997 by Shilliday and colleagues[10] examined the effect of treating acute renal failure patients with loop diuretics. Although administration of loop diuretics increased urine flow, there was no difference in the incidence of renal recovery, dialysis, or death among patients randomized to

diuretic therapy or placebo. Two other randomized controlled trials by Brown and coworkers[11] and Kleinknecht and associates[12] also failed to show any improvement in survival when loop diuretics were used in patients with oliguric renal failure. The PICARD study group reported the results of a large cohort study of critically ill patients with acute renal failure from 1989 through 1995.[13] The study showed that diuretic use was associated with an increased risk of death or nonrecovery of renal function. Accordingly, it is unlikely that the use of diuretics in patients with oliguric acute renal failure affords any benefit to the kidney. The use of diuretics in this setting should be restricted to the treatment of volume overload, and even then caution is advised.

VASOACTIVE AGENTS

Other agents have been used to "treat" oliguria, including dopamine and related compounds. Because urine output often increases with the addition of "low-dose" dopamine, many intensivists assume that it has a beneficial effect. Low-dose dopamine has been advocated since the 1970s as therapy for oliguria on the basis of its action on dopamine-1 receptors in doses less than 5 μg/kg/min. There is abundant evidence, however, that low-dose dopamine does not afford any renal protection in oliguria. Most evidence in favor of low-dose dopamine comes from uncontrolled trials or anecdotal studies. A comprehensive meta-analysis of dopamine in critically ill patients by Kellum and Decker[14] showed that dopamine did not prevent the onset of acute renal failure or decrease mortality or the need for dialysis.

There are important physiologic considerations that argue against a protective role for dopamine or any other dopamine receptor agonists, such as fenoldopam or dopexamine, in the oliguric state. First, the effect of dopamine agonists on urine output may be merely the natriuretic response mediated by inhibition of Na^+,K^+-ATPase in tubular epithelial cells.[15] Dopamine increases urine output because it is a diuretic. Second, treatment with dopaminergic antagonists, such as metoclopramide, has not been shown to affect renal function adversely. Third, the effect of dopamine may be counteracted by increased plasma renin activity in critically ill patients. A significant hysteresis effect has been shown for the action of dopamine on renal blood flow. Finally, although dopamine increases renal blood flow, it does not increase medullary oxygenation,[16] and by increasing solute delivery to the distal tubule, dopamine agonists actually worsen medullary oxygen balance.[17] Despite claims to the contrary, newer dopamine agonists, such as fenoldopam and dopexamine, not only have these limitations, but also can induce hypotension and further increase the risk of renal injury.

CONCLUSION

The presence of oliguria should alert the clinician to undertake a diligent search for any correctable underlying causes. The mainstay of treatment is to ensure adequate renal perfusion by optimizing blood pressure, cardiac output, and intravascular volume status. The use of diuretics and vasoactive agents, although still fairly common, is not supported by the evidence, and emerging data actually suggest harm.

Chapter 12
ACID-BASE DISORDERS

John A. Kellum

Conventional wisdom posits that acid-base disorders are more important for what they tell the clinician about the patient than for any harm that happens to the patient as a direct consequence of abnormal blood (or tissue) pH. This view is reasonable because most acid-base disorders are mild and well tolerated, but they allow the astute clinician to recognize underlying disorders that might be difficult to diagnose or even suspect otherwise. However, there are certain circumstances in which acid-base derangements are themselves dangerous, such as when the disorders are extreme (e.g., pH <7.0 or >7.7), especially when the acid-base derangement develops quickly. Such severe abnormalities can be the direct cause of organ dysfunction and can manifest as cerebral edema, seizures, decreased myocardial contractility, pulmonary vasoconstriction, and systemic vasodilation. Even less extreme derangements can produce harm because of the patient's response to the abnormality. For example, a spontaneously breathing patient with metabolic acidosis will attempt to compensate by increasing minute ventilation. The workload imposed by increasing minute ventilation can lead to respiratory muscle fatigue with respiratory failure or diversion of blood flow from vital organs to the respiratory muscles, resulting in organ injury. Acidemia can promote the development of cardiac dysrhythmias in critically ill patients or increase myocardial oxygen demand in patients with myocardial ischemia. In such cases, one must treat the underlying disorder and also provide treatment for the acid-base disorder itself. Finally, emerging evidence suggests that changes in acid-base status influence immune effector cell function. Thus, avoiding acid-base derangements could influence outcome by modulating systemic inflammation and/or host defenses against infection.

GENERAL PRINCIPLES

Three widely accepted methods are used to analyze and classify acid-base disorders, yielding mutually compatible results. The approaches differ only in assessment of the metabolic component (i.e., all three treat P_{CO_2} as an independent variable): (1) HCO_3^- concentration ($[HCO_3^-]$); (2) standard base-excess; (3) strong ion difference. All three yield virtually identical results when used to quantify the acid-base status of a given blood sample.[1-4] For the most part, the differences among these three approaches are conceptual; in other words, they differ in how they approach the understanding of mechanism.[5-7]

There are three mathematically independent determinants of blood pH:

1. The difference between the sum of the concentrations of strong cations (e.g., Na^+ and K^+) and the sum of the concentrations of strong anions (e.g., Cl^-, lactate); this difference is called the strong ion difference.
2. The total weak acid "buffers" concentration (A_{TOT}), which is mostly composed of the concentrations of albumin and phosphate.
3. P_{CO_2}.

Only these three variables (strong ion difference, A_{TOT}, and P_{CO_2}) can independently affect blood pH. $[H^+]$ and $[HCO_3^-]$ are dependent variables, being functions of strong ion difference, A_{TOT}, and P_{CO_2}. Changes in plasma $[H^+]$ occur as a result of changes in the dissociation of water and A_{TOT} brought about by the electrochemical forces produced by changes in strong ion difference and P_{CO_2}. The standard base-excess is mathematically equivalent to the change in strong ion difference required to restore pH to 7.4 given a P_{CO_2} of 40 mm Hg and the prevailing A_{TOT}. Thus, a standard base-excess of –10 mEq/L means that the strong ion difference is 10 mEq/L less than the strong ion difference that is associated with a pH of 7.4 when P_{CO_2} is 40 mm Hg.

ASSESSING ACID-BASE BALANCE

Acid-base homeostasis is defined by the pH of blood plasma and by the conditions of the acid-base pairs that determine it. Because blood plasma is an aqueous solution containing both volatile (carbon dioxide) and fixed acids, its pH will be determined by the net effects of all these components on the dissociation of water. The determinants of blood pH can be grouped into two broad categories, respiratory and metabolic. Respiratory acid-base disorders are disorders of carbon dioxide (CO_2) tension, and metabolic acid-base disorders comprise all other conditions affecting the pH. This latter category includes disorders of both weak acids (often referred to as "buffers," although the term is imprecise) and strong acids and bases (including both organic and inorganic acids). Acid-base disorders can be recognized by any of the following:

1. An alteration in the pH of the arterial blood (normally 7.35 to 7.45). If the pH is less than 7.35, then acidemia is said to be present; if the pH is greater than 7.45, then alkalemia is said to be present.
2. An arterial partial pressure of CO_2 (P_aCO_2) outside the normal range (35 to 45 mm Hg).
3. A plasma bicarbonate concentration outside the normal range (22-26 mEq/L).
4. An arterial standard base-excess of 3 or –3 mEq/L.

Although these criteria are useful in identifying an acid-base disorder, the absence of all four cannot exclude a mixed

acid-base disorder, alkalosis plus acidosis, which is completely matched. Fortunately, such conditions are quite rare.

METABOLIC ACID-BASE DISORDERS

Metabolic acid-base derangements are associated with a greater number of underlying conditions than are respiratory acid-base disorders and tend to be more difficult to treat. Metabolic acidosis is produced by a decrease in the strong ion difference, which, in turn, generates an electrochemical force that increases $[H^+]$. The strong ion difference decreases when the concentration of organic anions (e.g., lactate or β-hydroxybutyrate) increases. The strong ion difference also decreases when there is a loss of sodium bicarbonate (e.g., due to diarrhea or renal tubular acidosis) or there is a gain of exogenous anions (e.g., iatrogenic acidosis or poisonings). Metabolic alkaloses occur when the strong ion difference is inappropriately wide, although it need not be greater than the "normal" 40 to 42 mEq/L. Widening of the strong ion difference can be brought about by the loss of strong anions in excess of strong cations (e.g., vomiting, diuretics), or, rarely, by administration of strong cations in excess of strong anions (e.g., transfusion of large volumes of banked blood containing sodium citrate).

Similarly, the treatment of metabolic acid-base disorders requires a change in the strong ion difference. Metabolic acidoses are repaired by increasing plasma Na^+ concentration more than plasma Cl^- concentration (e.g., by infusing $NaHCO_3$) and metabolic alkaloses are repaired by replacing Cl^- either as NaCl (large volumes), KCl, or even HCl. Note that so-called "chloride-resistant" metabolic alkaloses are resistant to chloride only because of ongoing renal losses that increase in response to increased Cl^- replacement (e.g., hyperaldosteronism).

Pathophysiology of Metabolic Acid-Base Disorders

Disorders of metabolic acid-base balance occur as a result of

1. Dysfunction of the primary regulating organs.
2. Exogenous administration of drugs or fluids that alter the body's ability to maintain normal acid-base balance.
3. Abnormal metabolism that overwhelms the normal defense mechanisms.

The organs responsible for regulating the strong ion difference in both health and disease are the kidneys and, to a lesser extent, the gastrointestinal tract.

The Kidneys

Plasma flow to the kidneys is approximately 600 mL/min. The glomeruli filter the plasma to yield 120 mL/min of filtrate. Normally, more than 99% of the filtrate is reabsorbed and returned to the plasma. Thus, the kidney can only excrete a very small amount of strong ions into the urine each minute, and several minutes to hours are required to achieve a significant impact on the strong ion difference. The handling of strong ions by the kidney is extremely important, because every Cl^- ion that is filtered but not reabsorbed decreases the strong ion difference. Accordingly, "acid handling" by the kidney is generally mediated through Cl^- balance. The purpose of renal ammoniagenesis is to allow the excretion of Cl^- without Na^+ or K^+. Viewed this way, renal tubular acidosis can be regarded as an abnormality of Cl^- handling rather than of H^+ or HCO_3^- handling.[3]

Renal-Hepatic Interaction

Ammonium ion (NH_4^+) is important to systemic acid-base balance not because it stores H^+ or has a direct action in the plasma (normal plasma NH_4^+ concentration is <0.01 mEq/L). NH_4^+ is important because it is "co-excreted" with Cl^-. Of course, NH_4^+ is not only produced in the kidney. Hepatic ammoniagenesis (and, as we shall see, glutaminogenesis) is also important for systemic acid-base balance and is tightly controlled by mechanisms sensitive to plasma pH.[8] This reinterpretation of the role of NH_4^+ in acid-base balance is supported by the evidence that hepatic glutaminogenesis is stimulated by acidosis.[9] Glutamine is used by the kidney to generate NH_4^+ and thus facilitates the excretion of Cl^-. The production of glutamine therefore can be seen as having an alkalinizing effect on plasma pH because of the way the kidney utilizes it.

The Gastrointestinal Tract

Different parts of the gastrointestinal tract handle strong ions in distinct ways. In the stomach, Cl^- is pumped out of the plasma and into the lumen, thereby reducing the strong ion difference and pH of gastric juice. The pumping action of the gastric parietal cells increases the strong ion difference of the plasma by promoting the loss of Cl^-; this effect produces the so-called "alkaline tide" at the beginning of a meal when gastric acid secretion is maximal.[10] In the duodenum, Cl^- is reabsorbed and the plasma pH is restored. Normally, only slight changes in plasma pH are evident because Cl^- is returned to the circulation almost as soon as it is being removed. However, if gastric secretions are removed from the patient, either through a suction catheter or as a result of vomiting, Cl^- is lost and the strong ion difference increases. It is important to realize that it is the Cl^- loss, not the H^+ loss, that is the cause for widening of the strong ion difference and the development of metabolic alkalosis. Although H^+ is "lost" as HCl, it is also lost with every molecule of water removed from the body.

In contrast to the stomach, the pancreas secretes fluid into the small intestine that has a strong ion difference much greater than that of plasma; the $[Cl^-]$ of pancreatic secretions is quite low. Thus, the strong ion difference in the plasma perfusing the pancreas decreases, a phenomenon that peaks about an hour after a meal and helps counteract the alkaline tide. If large amounts of pancreatic fluid are lost, for example from surgical drainage, acidosis develops as a consequence of the decreased plasma strong ion difference. Fluid in the lumen of the large intestine has a wide strong ion difference because most of the Cl^- has been removed in the small intestine and the remaining electrolytes are mostly Na^+ and K^+ and HCO_3^-. The body normally reabsorbs much of the water and electrolytes from this fluid but when there is severe diarrhea, large amounts of this HCO_3^--rich and Cl^--poor fluid can be lost. If these losses are persistent, the plasma strong ion difference decreases and acidosis results.

In addition, the small intestine may contribute strong ions to the plasma. This effect is most apparent when mesenteric blood flow is compromised and lactate is produced, sometimes in large quantities, by the tissues of the small intestine.

METABOLIC ACIDOSIS

Traditionally, metabolic acidoses are categorized according to the presence or absence of unmeasured anions. The presence of unmeasured anions is routinely inferred by measuring the

TABLE 12–1. CAUSES OF AN INCREASED ANION GAP (AG)

Common Causes
Renal failure
Ketoacidosis
Diabetic
Alcoholic
Starvation
Metabolic errors
Lactic acidosis
Toxins
Methanol
Ethylene glycol
Salicylates
Paraldehyde
Toluene
Rare Causes
Dehydration
Sodium salts
Sodium lactate
Sodium citrate
Sodium acetate
Sodium PCN (>50 m units/day)
Carbenicillin (>30 g/day)
Decreased unmeasured cation
Hypomagnesemia
Hypokalemia
Hypocalcemia
Alkalemia

TABLE 12–2. POTENTIAL CLINICAL EFFECTS OF METABOLIC ACID-BASE DISORDERS

Metabolic Acidosis	Metabolic Alkalosis
Cardiovascular	***Cardiovascular***
Decreased inotropy	Decreased inotropy (Ca^{++} entry)
Conduction defects	Altered coronary blood flow*
Arterial vasodilatation	Digoxin toxicity
Venous vasoconstriction	
Oxygen Delivery	***Neuromuscular***
Decreased oxy-Hb binding	Neuromuscular excitability
Decreased 2,3-DPG (late)	Encephalopathy seizures
Neuromuscular	***Metabolic Effects***
Respiratory depression	Hypokalemia
Decreased sensorium	Hypocalcemia
	Hypophosphatemia
	Impaired enzyme function
Metabolism	***Oxygen Delivery***
Protein wasting	Increased oxy-Hb affinity
Bone demineralization	Increased 2,3-DPG (delayed)
Catecholamine, PTH, and aldosterone stimulation	
Insulin resistance	
Free radical formation	
Gastrointestinal

concentrations of electrolytes in plasma and calculating the anion gap, as described later. The differential diagnosis for a positive-anion gap acidosis is shown in Table 12-1. Non-anion gap acidoses can be divided into three types: renal, gastrointestinal, and iatrogenic (Fig. 12-1). In the intensive care unit (ICU), the most common types of metabolic acidosis include lactic acidosis, ketoacidosis, iatrogenic acidosis, and acidosis secondary to toxins.

The potential effects of metabolic acidosis and alkalosis on vital organ function are shown in Table 12-2. Metabolic and respiratory acidosis may have different implications with respect to survival, an observation that suggests that the underlying disorder is perhaps more important than the absolute degree of acidemia.[11]

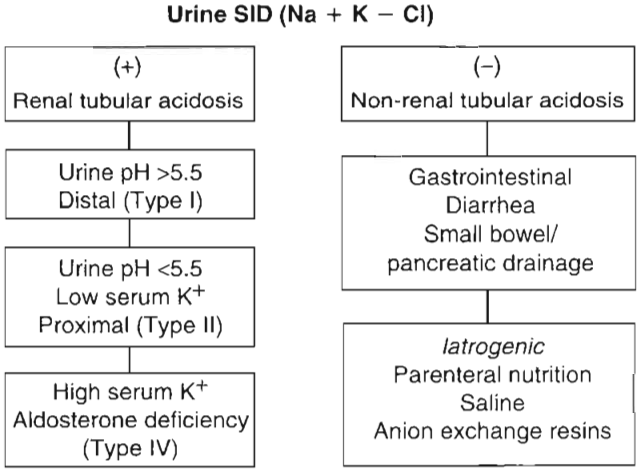

FIGURE 12–1. Differential diagnosis for a hyperchloremic metabolic acidosis. (SID, strong ion difference.)

If metabolic acidemia is to be treated, consideration should be given to the likely duration of the disorder. If it is expected to be short lived (e.g., diabetic ketoacidosis), maximizing respiratory compensation is usually the safest approach. Once the disorder resolves, ventilation can be quickly reduced to normal and there will be no lingering effects of therapy. However, if the disorder is likely to be more chronic (e.g., renal failure), therapy aimed at restoring the strong ion difference is indicated. In all cases, the therapeutic target can be quite accurately determined from the standard base-excess. As discussed, the standard base-excess corresponds to the amount the strong ion difference must change in order to restore the pH to 7.4, assuming a P_{CO_2} of 40 mm Hg. Thus, if the strong ion difference is 30 mEq/L and the standard base-excess is −10 mEq/L, the target strong ion difference would be 40 mEq/L. Accordingly, the plasma Na^+ concentration would have to increase by 10 mEq/L for $NaHCO_3$ administration to completely repair the acidosis. If increasing the plasma Na^+ concentration is inadvisable for other reasons (e.g., hypernatremia), then $NaHCO_3$ administration is also inadvisable. Importantly, $NaHCO_3$ administration has not been shown to improve outcome in patients with lactic acidosis.[12]

In addition, $NaHCO_3$ administration is associated with certain disadvantages. Large (hypertonic) doses given rapidly can lead to hypotension[13] and have the potential to cause a sudden, marked increase in P_{aCO_2}.[14] Accordingly, it is important to assess the patient's ventilatory status before $NaHCO_3$ is administered, particularly in the absence of mechanical ventilation. $NaHCO_3$ infusion also affects circulating $[K^+]$ and $[Ca^{++}]$ concentrations, which need to be monitored closely.

Tromethamine (Tris-buffer or Tham) is an organic buffer that readily penetrates cells.[15] It is a weak base (pK = 7.9) that does not alter the strong ion difference and does not affect plasma [Na^+]. Accordingly, it is often used when administration of $NaHCO_3$ is contraindicated because of hypernatremia. This agent has been available since the 1960s, but limited data are available on its use in humans with acid-base disorders. In small uncontrolled studies, tromethamine appears to be effective in reversing metabolic acidosis secondary to ketoacidosis or renal failure without obvious toxicity.[16] However, adverse reactions have been reported, including hypoglycemia, respiratory depression, and even fatal hepatic necrosis when concentrations exceeding 0.3 *M* are used. In Europe, a mixture of tromethamine, acetate, $NaHCO_3$, and disodium phosphate is available (Tribonate). This mixture seems to have fewer side effects than tromethamine alone, but experience with Tribonate is still quite limited.

The Anion Gap and the Strong Ion Gap

For more than 30 years, the anion gap has been used by clinicians and it has evolved into a major tool to evaluate acid-base disorders.[17] The anion gap is estimated from the differences between the routinely measured concentrations of serum cations (Na^+ and K^+) and anions (Cl^- and HCO_3). Normally, this difference, or "gap," is made up by albumin, and, to a lesser extent, by phosphate. Sulfate and lactate also contribute a small amount, normally less than 2 mEq/L. However, there are also unmeasured cations, such as Ca^{++} and Mg^{++}, and these tend to offset the effects of sulfate and lactate except when the concentration of sulfate or lactate is abnormally increased (Fig. 12-2). Plasma proteins other than albumin can be positively or negatively charged but in the aggregate tend to be neutral, except in rare cases of abnormal paraproteins such as in cases of multiple myeloma.[18] In practice, the anion gap (AG) is calculated as follows:

$$AG = ([Na^+] + [K^+]) - ([Cl^-] + [HCO_3^-])$$

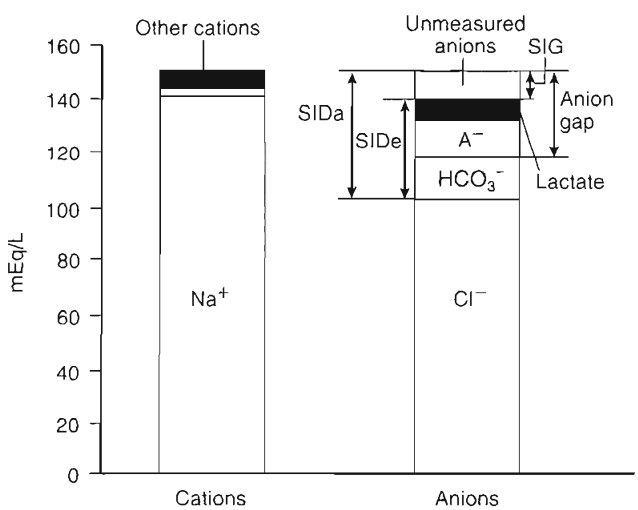

FIGURE 12–2. Charge balance in blood plasma. "Other cations" include Ca^{++} and Mg^{++}. The strong ion difference (SID) is always positive (in plasma) and SID – SIDe (effective) must equal zero. Any difference between SID apparent (SIDa) and SIDe is the strong ion gap (SIG) and must represent unmeasured anions.

Because of its low and narrow extracellular concentration range, K^+ is often omitted from the calculation. The normal value for anion gap is 12 ± 4 (if [K^+] is considered) or 8 ± 4 mEq/L (if [K^+] is not considered). The normal range has decreased in recent years following the introduction of more accurate methods for measuring Cl^- concentration.[19,20] However, the various measurement techniques available mandate that each institution reports its own expected "normal anion gap."

The anion gap is useful because this parameter can limit the differential diagnosis for patients with metabolic acidosis. If the anion gap is increased, the explanation almost invariably will be found among five disorders: ketosis, lactic acidosis, poisoning, renal failure, or sepsis.[21] However, several conditions can alter the accuracy of anion gap estimation, and these conditions are particularly prevalent among patients with critical illness.[22,23] Dehydration can widen the apparent anion gap by increasing the concentration of all the ions used for the calculation. Hypoalbuminemia decreases the anion gap and has been recommended to "correct" the anion gap for changes in albumin concentration, because for every 1 g/dL decrease in serum albumin concentration, the apparent anion gap narrows by 2.5 to 3 mEq/L.[24] Respiratory and metabolic alkaloses are associated with an increase of up to 3 to 10 mEq/L in the apparent anion gap. The basis for this effect is enhanced lactate production (from stimulated phosphofructokinase enzymatic activity), reduction in the concentration of ionized weak acids (A^-), and, possibly, the additional effect of dehydration.

Other factors that can increase the anion gap are low Mg^{++} concentration and administration of the sodium salts of poorly reabsorbable anions (such as beta-lactam antibiotics).[25] Certain parenteral nutrition formulations, such as those containing acetate, may increase the anion gap. Citrate-based anticoagulants rarely can have the same effect after administration of multiple blood transfusions.[26] None of these rare causes, however, increases the anion gap significantly,[27] and they are usually easily identified. In recent years, some additional causes of an increased anion gap have been reported. It is sometimes widened in patients in non-ketotic hyperosmolar states induced by diabetes mellitus; the biochemical basis for this effect remains unexplained.[28] In recent years, unmeasured anions have been reported in the blood of patients with sepsis[29,30] and liver disease[31,32] and in experimental animals injected with endotoxin.[33] These anions may be the source of much of the unexplained acidosis seen in patients with critical illness.[34]

Additional doubt has been cast on the diagnostic value of the anion gap in certain situations, however.[22,30] Salem and Mujais[22] found routine reliance on the anion gap to be "fraught with numerous pitfalls." The primary problem with the anion gap is its reliance on the use of a "normal" range that depends on normal circulating levels of albumin and to a lesser extent phosphate, as discussed earlier. Plasma concentrations of albumin or phosphate are often grossly abnormal in patients with critical illness, leading to change in the "normal" range for the anion gap. Moreover, because these anions are not strong anions, their charge is affected by pH. These considerations have prompted some authors to adjust the "normal range" for the anion gap according to the albumin concentration[24] or phosphate concentration.[6] Each g/dL of albumin has a charge of 2.8 mEq/L at pH 7.4 (2.3 mEq/L at pH 7.0 and 3.0 mEq/L at pH 7.6). Each mg/dL of phosphate has a charge of 0.59 mEq/L at pH 7.4

(0.55 mEq/L at pH 7.0 and 0.61 mEq/L at pH 7.6). Thus, the "normal" anion gap can be estimated using this formula[6]:

$$\text{"normal" anion gap} = 2 \times [\text{albumin}]\ (\text{g/dL}) + 0.5 \times [\text{phosphate}]\ (\text{mg/dL})$$

Or for international units:

$$\text{"normal" anion gap} = 0.2 \times [\text{albumin}]\ (\text{g/L}) + 1.5 \times [\text{phosphate}]\ (\text{mmol/L})$$

These formulas only should be used when the pH is less than 7.35, and even then they are only accurate within 5 mEq/L. When more accuracy is needed, a slightly more complicated method of estimating $[A^-]$ is required.[31,35]

Another alternative to using the traditional anion gap is to use the strong ion difference. By definition, the strong ion difference must be equal and opposite to the negative charges contributed by $[A^-]$ and total CO_2. The sum of the charges from $[A^-]$ and total CO_2 concentration has been termed *strong ion difference effective.*[18] The *apparent strong ion difference* is obtained by measurement of each individual ion. Both the apparent strong ion difference and the strong ion difference effective should equal the true strong ion difference. If the apparent strong ion difference and strong ion difference effective differ, unmeasured ions must exist. If the apparent strong ion difference is greater than strong ion difference effective, these ions are anions and if the apparent strong ion difference is less than strong ion difference effective, the unmeasured ions are cations. This difference has been termed the strong ion gap to distinguish it from the anion gap.[31] Unlike the anion gap, the strong ion gap is normally zero and does not change with changes in pH or albumin concentration.

Positive Anion Gap Acidoses

Lactic Acidosis

In many forms of critical illness, lactate is the most important cause of metabolic acidosis.[36] Blood lactate concentration has been shown to correlate with outcome in patients with hemorrhagic[37] and septic shock.[38] Lactic acid has been viewed as the predominant source of metabolic acidosis due to sepsis.[39] In this view, lactic acid is released primarily from the musculature and the gut as a consequence of tissue hypoxia. Moreover, the amount of lactate produced is believed to correlate with the total oxygen debt, the magnitude of the hypoperfusion, and the severity of shock.[36] In recent years, this view has been challenged by the observation that during sepsis, even with profound shock, resting muscle does not produce lactate. Indeed, studies by various investigators have shown that the musculature actually may consume lactate during endotoxemia.[40-42] Data concerning the gut are less clear. There is little question that underperfused gut can release lactate; however, it does not appear that the gut releases lactate during sepsis if mesenteric perfusion is maintained. Under such conditions, the mesentery circulation can even become a net consumer of lactate.[40,41] Perfusion is likely to be a major determinant of mesenteric lactate metabolism. In a canine model of sepsis, gut lactate production could not be shown when flow was maintained with dopexamine hydrochloride.[42]

Studies in animals as well as humans have shown that the lung may be a prominent source of lactate in the setting of acute lung injury.[40,43-45] While studies such as these do not address the underlying pathophysiologic mechanisms of hyperlactatemia in sepsis, they suggest that using blood lactate concentration as evidence for tissue dysoxia is an oversimplification at best. Indeed, many investigators have begun to offer alternative interpretations of hyperlactatemia in this setting.[44-48] Table 12-3 lists several alternative sources of hyperlactatemia. In particular, pyruvate dehydrogenase, the enzyme responsible for moving pyruvate into the Krebs cycle, is inhibited by endotoxin.[49] However, data from recent studies suggest that increased aerobic metabolism may be more important than metabolic defects or anaerobic metabolism.[50] Finally, administration of epinephrine promotes lactic acidosis, presumably by stimulating cellular metabolism (e.g., increased hepatic glycolysis).

Administration of epinephrine may be a common cause of lactic acidosis in patients with critical illness.[51,52] Interestingly, this phenomenon does not occur when dobutamine or norepinephrine is infused[53] and does not appear to be related to decreased tissue perfusion.

Although controversy exists as to the source and interpretation of lactic acidosis in critically ill patients, there is no question about the ability of lactate accumulation to produce acidemia. Lactate is a strong ion by virtue of the fact that at a pH within the physiologic range, it is almost completely dissociated; for instance, the pKa for lactic acid is 3.9. Thus, at pH 7.4, 3162 lactic acid molecules are dissociated for every one that is not. Because the body can produce and dispose of lactate rapidly, it functions as one of the most dynamic components of the strong ion difference.

Plasma lactate concentration may be increased without an increase in $[H^+]$. There are two possible explanations for this phenomenon. First, if lactate is added to the plasma, not as lactic acid but rather as the salt of a strong acid (e.g., sodium lactate), there will be little change in the strong ion difference. The strong ion difference does not change because a strong cation (Na^+) is being added along with a strong anion. However, only if a very large amount of lactate is infused rapidly will there be an appreciable increase in the plasma lactate concentration. For example, the use of lactate-based hemofiltration fluid can result in hyperlactatemia with an *increased* plasma HCO_3^- concentration and pH.

TABLE 12–3. MECHANISMS ASSOCIATED WITH INCREASED SERUM LACTATE CONCENTRATION

Tissue Hypoxia
Hypodynamic shock
Organ ischemia
Hypermetabolism
Increased aerobic glycolysis
Increased protein catabolism
Hematologic malignancies
Decreased Clearance of Lactate
Liver failure
Shock
Inhibition of Pyruvate Dehydrogenase
Thiamine deficiency
Endotoxin?
Activation of Inflammatory Cells?

A more important mechanism whereby hyperlactatemia exists without acidemia (or with less acidemia than expected) is when the strong ion difference is corrected by the elimination of another strong anion from the plasma.[54] In the setting of sustained lactic acidosis induced by lactic acid infusion, Cl^- moves out of the plasma space, thus normalizing pH. Under these conditions, hyperlactatemia may persist but base-excess may be normalized by compensatory mechanisms to restore the strong ion difference.

Traditionally, lactic acidosis is subdivided into type A, in which the mechanism is tissue hypoxia, and type B, in which there is no hypoxia.[55] However, this distinction may be artificial. Some disorders, such as sepsis, may be associated with lactic acidosis due to a variety of mechanisms (Table 12-3), some of the "A" type and some of the "B" type. A potentially useful method of distinguishing anaerobically produced lactate from other sources is to measure the blood pyruvate concentration. The normal lactate to pyruvate ratio is 10:1.[56] A lactate-to-pyruvate ratio greater than 25:1 is considered to be evidence of anaerobic metabolism.[48] This approach makes biochemical sense, because pyruvate is reduced to lactate during anaerobic metabolism, thereby increasing the lactate-to-pyruvate ratio. Unfortunately, pyruvate is very unstable in solution and therefore is difficult to measure accurately in the clinical setting, greatly reducing the clinical utility of lactate/pyruvate determinations.

Treatment of lactic acidosis remains controversial. The only noncontroversial approach is to treat the underlying cause. The use of sodium bicarbonate ($NaHCO_3$) is equally controversial and remains of unproven value.[12]

Ketoacidosis

Another common cause of a metabolic acidosis with a positive anion gap is ketoacidosis. Ketones are formed by beta-oxidation of fatty acids, a process that is inhibited by insulin. In insulin-deficient states, ketone formation increases substantially. The accumulation of ketone bodies (acetone, β-hydroxybutyrate, and acetoacetate) in the plasma is exacerbated because elevated blood glucose concentrations promote an osmotic diuresis, leading to intravascular volume contraction. This state is associated with elevated circulating cortisol and catecholamine levels, which further stimulates free fatty acid production.[57] In addition, increased glucagon levels, relative to insulin levels, decreases intracellular concentrations of malonyl co-enzyme A and increases the activity of carnitine palmityl acyl transferase, effects that promote ketogenesis.

Both acetoacetate and β-hydroxybutyrate are strong anions (pKa 3.8 and 4.8, respectively).[58] Thus, like lactate, the presence of these ions decreases the strong ion difference and increases the $[H^+]$. Ketoacidosis may result from diabetes (diabetic ketoacidosis) or excessive alcohol consumption (alcoholic ketoacidosis). The diagnosis is established by measuring serum ketone levels. However, it is important to understand that the nitroprusside reaction only measures acetone and acetoacetate, and not β-hydroxybutyrate. Thus, the state of measured ketosis is dependent on the ratio of acetoacetate to β-hydroxybutyrate. This ratio is low when lactic acidosis coexists with ketoacidosis because the reduced redox state of lactic acidosis favors production of β-hydroxybutyrate.[59] In this circumstance, the apparent level of ketosis is small relative to the amount of acidosis and the elevation of the anion gap. There is also a risk of confusion during treatment of ketoacidosis because ketones as measured by the nitroprusside reaction can increase despite resolving acidosis. This effect occurs as a result of rapid clearance of β-hydroxybutyrate, improving acid-base balance without changing the measured level of ketosis. Furthermore, circulating ketone levels can even appear to increase as β-hydroxybutyrate is converted to acetoacetate. Hence, it is better to monitor therapy by measuring blood pH and anion gap than by assaying levels of serum ketones.

Treatment of diabetic ketoacidosis includes infusing insulin and large amounts of fluid; 0.9% saline is usually recommended. Potassium replacement is often required as well. Fluid resuscitation reverses the hormonal stimuli for ketone body formation, as discussed earlier, and insulin promotes metabolism of ketones and glucose. Administration of $NaHCO_3$ may produce a more rapid rise in the pH by increasing the strong ion difference, but there is little evidence that this effect is desirable. Furthermore, because increasing the plasma Na^+ concentration increases the strong ion difference, the strong ion difference will be too high once the ketosis is cleared ("overshoot" alkalosis). In any case, administration of $NaHCO_3$ is rarely necessary and should be avoided except in extreme cases.[60]

A more common problem in the treatment of diabetic ketoacidosis is persistence of acidemia after resolution of ketosis. This hyperchloremic metabolic acidosis occurs as Cl^- replaces ketoacids, thus maintaining decreases in strong ion difference and pH. This effect appears to occur for two reasons. First, exogenous Cl^- is often provided in the form of 0.9% saline, which, if given in large enough quantities, results in a so-called dilutional acidosis (see later). Second, renal Cl^- reabsorption increases as ketones are excreted in the urine. Increases in the tubular Na^+ load produce electrical-chemical forces favoring Cl^- reabsorption.[61]

The acidosis seen in patients with alcoholic ketoacidosis is usually less severe. Treatment consists of intravenous fluid administration and infusion of glucose, instead of insulin, as would be the case with diabetic ketoacidosis.[62] Indeed, insulin is contraindicated, because it may cause precipitous hypoglycemia.[63] Thiamine also must be given to avoid precipitating Wernicke's encephalopathy.

Renal Failure

Renal failure, especially when chronic, leads to accumulation of sulfates and other acids, widening the anion gap, although this increase usually is not large.[64] Similarly, uncomplicated renal failure rarely produces severe acidosis, except when it is accompanied by a high rate of acid generation, such as occurs during hypermetabolism.[65] In all cases, the strong ion difference is decreased and remains so unless some therapy is provided. Hemodialysis removes sulfate and other ions and allows normal Na^+ and Cl^- balance to be restored, thus returning the strong ion difference to normal (or near normal). However, patients not yet requiring dialysis and those who are between treatments often require some other therapy to increase the strong ion difference. $NaHCO_3$ is used as long as the plasma Na^+ concentration is not already elevated.

Toxins

Metabolic acidosis with an increased anion gap is a major feature of various types of drug and substance intoxications (see Table 12-1).

Other and Unknown Causes

In the nonketotic hyperosmolar state associated with poorly controlled diabetes, the anion gap widens for unexplained

reasons.[28] Even when very careful methods are applied, using the strong ion gap or similar strategies, unmeasured anions have been detected in the blood of patients with sepsis[29,30] and liver disease[31] and in experimental animals given endotoxin.[32] Furthermore, unknown cations also appear in the blood of some critically ill patients.[30] The significance of these findings remains to be determined.

Non-Anion Gap (Hyperchloremic) Acidoses

Hyperchloremic metabolic acidosis occurs as a result of either the increase in $[Cl^-]$ relative to strong cations, especially Na^+, or the loss of cations with retention of Cl^-. As seen in Figure 12-1, these disorders can be separated by history and by measurement of urinary Cl^- concentration. When acidosis occurs, the normal response by the kidney is to increase Cl^- excretion. Failure to do so identifies the kidney as the problem. Extrarenal causes of hyperchloremic acidosis are exogenous Cl^- loads (iatrogenic acidosis) or loss of cations from the lower gastrointestinal tract without proportional losses of Cl^-.

Renal Tubular Acidosis

Examination of the urine and plasma electrolytes and pH and calculation of the urine apparent strong ion difference allow one to correctly diagnose most cases of renal tubular acidosis (see Fig. 12-1).[66] However, caution must be exercised when the plasma pH is greater than 7.35, because urinary Cl^- excretion is normally decreased when pH is this high. In such circumstances, it may be necessary to infuse sodium sulfate or furosemide. These agents stimulate Cl^- and K^+ excretion and can be used to unmask the defect and probe K^+ secretory capacity.

The defect in all types of renal tubular acidosis is an inability to excrete Cl^- in proportion to Na^+, although the reasons vary by type. Treatment largely depends on whether the kidney responds to mineralocorticoid replacement or whether there are losses of Na^+ that can be replaced as $NaHCO_3$.

Classic distal (type I) renal tubular acidosis responds to $NaHCO_3$ replacement; typically, only 50 to 100 mEq/day are required. Defects in K^+ reabsorption are also common in this type of renal tubular acidosis and K^+ replacement is also required. A variant of the classic distal renal tubular acidosis is a hyperkalemic form that actually is more common than the classic type. The central defect here appears to be impaired Na^+ transport in the cortical collecting duct. These patients also respond to $NaHCO_3$ replacement. Proximal (type II) renal tubular acidosis is characterized by both Na^+ and K^+ reabsorption defects. The disorder is uncommon and usually appears as a component of Fanconi's syndrome, which also is characterized by defects in the reabsorption of glucose, phosphate, urate, and amino acids.

Treatment of this disorder with $NaHCO_3$ is ineffective because increased ion delivery merely results in increased excretion. Thiazide diuretics have been used to treat this disorder, with varying success.

Type IV renal tubular acidosis is caused by aldosterone deficiency or resistance. These disorders are diagnosed by the presence of high serum $[K^+]$ concentration and low urine pH (<5.5). Treatment is usually most effective if the cause can be removed; most commonly, drugs, such as nonsteroidal anti-inflammatory agents, heparin, or potassium-sparing diuretics, are responsible. Occasionally, mineralocorticoid replacement is required.

Gastrointestinal Acidosis

Fluid secreted into the gut lumen contains higher amounts of Na^+ than Cl^-. Large losses of these fluids, particularly if volume is replaced with fluids containing equal amounts of Na^+ and Cl^-, results in a decrease in the plasma Na^+ concentration relative to the Cl^- concentration and a decrease in strong ion difference. Such a scenario can be avoided if formulations such as lactated Ringer's solution are used instead of normal saline to replace gastrointestinal losses.

Iatrogenic Acidosis

Two of the most common causes of a hyperchloremic metabolic acidosis are iatrogenic and both are due to administration of Cl^-. Modern parenteral nutrition formulas contain weak anions, such as acetate, in addition to Cl^-. The proportions of each anion can be adjusted depending on the acid-base status of the patient. If an insufficient amount of weak anions is provided, the plasma Cl^- concentration increases, decreasing the strong ion difference and resulting in acidosis. A similar condition can arise when normal saline is used for fluid resuscitation, resulting in the development of "dilutional acidosis." Dilutional acidosis was first described more than 40 years ago,[67,68] although some authors have argued that this problem is rarely clinically significant.[69] This view pertains because large doses of NaCl produce only minor degrees of hyperchloremic acidosis in healthy animals.[70] This line of reasoning cannot be applied to critically ill patients, who often require infusion of a very large volume of resuscitation fluid. Furthermore, acid-base balance is often already deranged in critically ill patients, and these patients may not be able to compensate normally by increasing ventilation or may have abnormal buffer capacity due to hypoalbuminemia. In intensive care unit and surgical patients[71-73] as well as in animals with experimental sepsis,[74] saline-induced acidosis clearly occurs.

Administration of normal saline causes acidosis because this solution contains equal amounts of Na^+ and Cl^-, whereas the normal Na^+ concentration in plasma is 35 to 45 mEq/L greater than the normal Cl^- concentration. Administration of 0.9% saline increases the Cl^- concentration relatively more than the Na^+ concentration. Many critically ill patients have a significantly lower strong ion difference than do healthy individuals, even when there is no evidence of a metabolic acid-base derangement.[75] The lower strong ion difference in critical illness is not surprising given that the positive charge of the strong ion difference is balanced by the negative charges of A^- and total CO_2. Since many critically ill patients are hypoalbuminemic, A^- tends to be reduced. Because the body defends P_{CO_2} for other reasons, a reduction in A^- leads to a reduction in strong ion difference to maintain normal pH. Thus, a typical intensive care unit patient might have a strong ion difference of 30 mEq/L rather than 40 to 42 mEq/L. If this same patient then develops a metabolic acidosis (e.g., lactic acidosis), the strong ion difference decreases further. If the patient is resuscitated with a large volume of 0.9% saline, metabolic acidosis is exacerbated. This relationship is illustrated in Figure 12-3, which shows that a patient with a lower baseline strong ion difference is more susceptible to a subsequent acid load.

One alternative to using normal saline to resuscitate patients is to use Ringer's lactate solution. This fluid contains a more physiologic difference between $[Na^+]$ and $[Cl^-]$ and thus its strong ion difference is closer to normal (28 mEq/L as compared to 0 mEq/L for normal saline). Morgan and

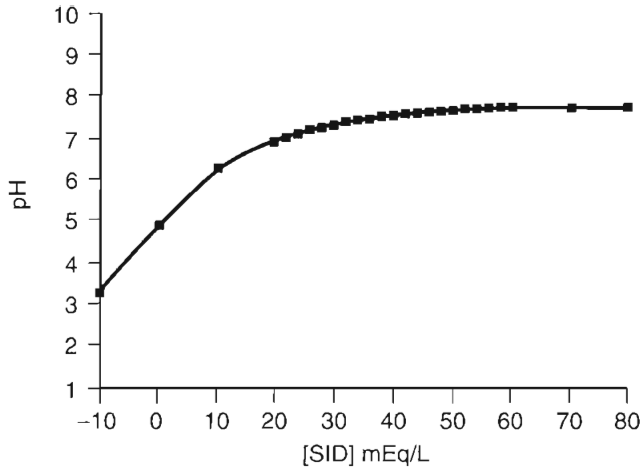

FIGURE 12–3. Plot of pH versus strong ion difference (SID). For this plot, A_{TOT} and Pco_2 were held constant at 18 mEq/L and 40 mm Hg, respectively. This plot assumes a water dissociation constant for blood of 4.4×10^{-14} (Eq/L). Note how steep the pH curve becomes at SID < 20 mEq/L.

colleagues recently showed that a solution with a strong ion difference of approximately 24 mEq/L results in a neutral effect on the pH as blood is progressively diluted.[76]

Unexplained Hyperchloremic Acidosis

Critically ill patients sometimes manifest hyperchloremic metabolic acidosis for unclear reasons. Often these patients have other coexisting types of metabolic acidosis, making the precise diagnosis difficult. Patients with sepsis and acidosis frequently have normal circulating lactate levels.[77] Often, unexplained anions are the cause,[29-31] but hyperchloremic acidosis also can be a contributing factor.

METABOLIC ALKALOSIS

Metabolic alkalosis occurs as a result of an increase in strong ion difference or a decrease in A_{TOT}. These changes can occur secondary to the loss of anions (e.g., Cl^- from the stomach, albumin from the plasma) or the retention of cations (rare). Sometimes the loss of Cl^- is temporary and can be treated effectively by replacing the anion; metabolic alkalosis in this category is said to be "chloride responsive." In other cases, hormonal mechanisms produce ongoing losses of Cl^-. Thus, at best, the Cl^- deficit can be offset only temporarily by Cl^- administration; this form of metabolic alkalosis is said to be "chloride resistant" (Table 12-4). Similar to hyperchloremic acidosis, these disorders can be distinguished by measurement of the urine Cl^- concentration.

Chloride-Responsive Disorders

The chloride-responsive disorders usually occur as a result of Cl^- losses from the stomach, such as from vomiting or gastric drainage. The treatment is to replace the Cl^-, which can be achieved slowly with NaCl or more rapidly with KCl or even HCl. Saline plus KCl is the treatment of choice because volume depletion and K^+ usually coexist with the acid-base disturbance in patients with chloride-responsive metabolic alkalosis. Dehydration in turn stimulates aldosterone secretion, leading to increased tubular Na^+ reabsorption and increased urinary losses of K^+. Administration of normal saline is effective because the administration of equal amounts of Na^+ and Cl^- result in larger relative increases in Cl^- concentration compared to Na^+ concentration. In rare circumstances, when neither K^+ nor intravascular volume depletion is a problem, it may be desirable to give back Cl^- as HCl.

Diuretics and other forms of volume contraction produce metabolic alkalosis predominantly by stimulating aldosterone secretion, as discussed earlier. However, diuretics also induce K^+ and Cl^- excretion directly, further complicating the problem and inducing metabolic alkalosis more rapidly.

TABLE 12–4. DIFFERENTIAL DIAGNOSIS OF A METABOLIC ALKALOSIS (INCREASED STRONG ION DIFFERENCE)

Chloride Loss < Sodium
Chloride-responsive (urine Cl^- concentration <10 mmol/L)
Gastrointestinal losses
Vomiting
Gastric drainage
Chloride wasting diarrhea (villous adenoma)
Post-diuretic use
Post-hypercapnea
Chloride-unresponsive (urine Cl^- concentration >20 mmol/L)
Mineralocorticoid excess
Primary hyperaldosteronism (Conn's syndrome)
Secondary hyperaldosteronism
Cushing's syndrome
Liddle's syndrome
Bartter's syndrome
Exogenous corticoids
Excessive licorice intake
Ongoing diuretic use
Exogenous Sodium Load (>Chloride)
Sodium salt administration (acetate, citrate)
Massive blood transfusions
Parenteral nutrition
Plasma volume expanders
Sodium lactate (Ringer's solution)
Other
Severe deficiency of intracellular cations
Magnesium, potassium

Chloride-Resistant Disorders

The chloride-resistant disorders (see Table 12-4) are characterized by an increased urine Cl^- concentration (>20 mEq/L) and are said to be "chloride resistant" because of ongoing Cl^- losses. Most commonly, excessive chloride occurs as a result of excessive mineralocorticoid activity. Treatment requires that the underlying disorder be addressed (Table 12-5).

Other Causes of Metabolic Alkalosis

Rarely, an increased strong ion difference and therefore metabolic alkalosis occurs secondary to cation administration rather than anion depletion. Examples of these disorders include milk-alkali syndrome and intravenous administration of strong cations without strong anions. The latter occurs with massive blood transfusion because Na^+ is given with citrate (a weak anion) instead of Cl^-. Similar results occur when parenteral nutrition formulations contain too much acetate and not enough Cl^- to balance the Na^+ load.

RESPIRATORY ACID-BASE DISORDERS

Respiratory disorders are far easier to diagnose and treat than metabolic disorders because the mechanism is always the same, although the underlying disease process may vary.

TABLE 12–5. TREATMENT OF METABOLIC ALKALOSIS

Condition	Treatment
Primary aldosteronism	Spironolactone or other agents that block distal tubular sodium reabsorption improve alkalosis, hyokalemia, and hypertension. Large doses may be necessary. Restriction of sodium intake and potassium supplementation may be necessary. When an adenoma can be identified, surgery is curative. When the cause is bilateral adrenal cortical hyperplasia, therapy is medical. Dexamethasone is effective in long-term therapy of familial dexamethasone-responsive aldosteronism.
Secondary aldosteronism	Angiotensin-converting enzyme inhibitors are usually effective. Repair of the underlying lesion, if feasible, may be required.
Cushing's syndrome	Due to pituitary oversecretion of ACTH: surgery or radiation Due to adrenal adenoma or carcinoma: adrenalectomy Due to secondary or ectopic ACTH production: address the underlying malignancy
Liddle's syndrome	Triamterene may be effective.
Bartter's syndrome	Treatment often unsatisfactory long-term. Potassium-sparing diuretics, potassium and magnesium supplementation, angiotensin-converting enzyme inhibitors, cyclooxygenase inhibitors are partially effective.
Exogenous corticoids	Discontinuation of the offending agent(s) and vigorous initial potassium replacement.
Severe K or Mg depletion	Replacement of these electrolytes (may require very large amounts).

CO_2 is produced by cellular metabolism or by the titration of HCO_3^- by metabolic acids. Normally, alveolar ventilation is adjusted to maintain the arterial $Paco_2$ between 35 and 45 mm Hg. When alveolar ventilation is increased or decreased out of proportion to $Paco_2$ production, a respiratory acid-base disorder exists.

Pathophysiology of Respiratory Acid-Base Disorders

Normal CO_2 production by the body (about 220 mL/min) is equivalent to 15,000 mM/day of carbonic acid.[78] This amount compares to less than 500 mM/day for all nonrespiratory acids that are handled by the kidney and gut. Pulmonary ventilation is adjusted by the respiratory center in response to changes in $Paco_2$, blood pH, and Pao_2 as well as other factors (e.g., exercise, anxiety, wakefulness). Normal $Paco_2$ (40 mm Hg) is maintained by precise matching of alveolar minute ventilation to metabolic CO_2 production. $Paco_2$ changes in compensation for alterations in arterial pH produced by metabolic acidosis or alkalosis in predictable ways (Table 12-6).

Respiratory Acidosis

When CO_2 elimination is inadequate relative to the rate of tissue production, $Paco_2$ increases to a new steady state determined by the new relationship between alveolar ventilation and CO_2 production. Acutely, the increase in $Paco_2$ increases both the $[H^+]$ and the $[HCO_3^-]$ in blood according to the carbonic acid equilibrium equation. Thus, the change in $[HCO_3^-]$ is mediated simply by the dissociation of H_2CO_3 into H^+ and HCO_3^-, not by an active physiologic adaptation response. Similarly, the increase in $[HCO_3^-]$ does not "buffer" the increase in $[H^+]$. There is no change in the strong ion difference and hence no change in standard base-excess. Cellular acidosis always occurs in respiratory acidosis, since CO_2 builds up in the tissues. If the $Paco_2$ remains increased, active compensatory mechanisms are activated and the strong ion difference increases to restore $[H^+]$ toward normal.

Primarily, compensation is accomplished by removal of Cl^- from the plasma space. Since movement of Cl^- into the tissues or red blood cells results in intracellular acidosis, Cl^- must be removed from the body to achieve a lasting effect on the strong ion difference. The kidney is the primary organ for Cl^- removal, although the adaptive capacity of the gastrointestinal tract for Cl^- elimination has not been fully explored. Accordingly, patients with renal disease have a difficult time adapting to chronic respiratory acidosis. When renal function is intact, Cl^- is eliminated in the urine and, after a few days, the strong ion difference increases to the level necessary to return blood pH to about 7.35. It is unclear whether this amount of time is required by the physiologic constraints of the system or to avoid being overly sensitive to transient changes in alveolar ventilation. In any case, this adaptation results in an increased pH for any degree of hypercarbia. According to the Henderson-Hasselbalch equation, the increased pH will result in an increased $[HCO_3^-]$

TABLE 12–6. OBSERVATIONAL ACID-BASE PATTERNS

Disorder	HCO_3^- (mEq/L)	Pco_2 (mm Hg)	SBE (mEq/L)
Metabolic acidosis	<22	$= (1.5 \times HCO_3^-) + 8$ $= 40 + SBE$	< −5
Metabolic alkalosis	>26	$= (0.7 \times HCO_3^-) + 21$ $= 40 + (0.6 \times SBE)$	> +5
Acute respiratory acidosis	$= [(Pco_2 - 40)/10] + 24$	>45	= 0
Chronic respiratory acidosis	$= [(Pco_2 - 40)/3] + 24$	>45	$= 0.4 \times (Pco_2 - 40)$
Acute respiratory alkalosis	$= [(40 - Pco_2)/5] + 24$	<35	= 0
Chronic respiratory alkalosis	$= [(40 - Pco_2)/2] + 24$	<35	$= 0.4 \times (Pco_2 - 40)$

From Kellum,[6] with permission.

for a given P_{CO_2}. Thus, the "adaptive" increase in $[HCO_3^-]$ *results from* the increase in pH and is not the *cause for* the increase in pH.

Although the change in HCO_3^- concentration is a convenient and reliable marker for the metabolic compensation, it is not the mechanism. This point is more than semantic because only changes in the independent variables of acid base balance (P_{CO_2}, A_{TOT}, strong ion difference) can affect the plasma $[H^+]$, and $[HCO_3^-]$ is not an independent variable.

Diseases of Ventilatory Impairment

As for virtually all acid-base disorders, treatment begins with addressing the underlying disorder. Acute respiratory acidosis can be caused by central nervous system suppression, neuromuscular disease or impairment (e.g., myasthenia gravis, hypophosphatemia, hypokalemia), or airway and parenchymal lung disease (e.g., asthma, acute respiratory distress syndrome). This last category of conditions also produces primary hypoxia, not just alveolar hypoventilation. The two can be distinguished by the alveolar gas equation:

$$P_{AO_2} = P_{IO_2} - Pa_{CO_2}/R$$

where R is the respiratory exchange coefficient (generally assumed to be 0.8) and P_{IO_2} is the inspired oxygen tension (room air is approximately 150). Thus, as Pa_{CO_2} increases, the P_{AO_2} will decrease in a predictable fashion. If the P_{AO_2} is reduced further, there is a defect in gas exchange.

Chronic respiratory acidosis is most often caused by chronic lung disease (e.g., chronic obstructive lung disease) or chest wall disease (e.g., kyphoscoliosis). Rarely, its cause is central hypoventilation or chronic neuromuscular disease.

When and How to Treat

The primary threat to life in cases of respiratory acidosis comes not from acidosis but from hypoxemia. If the patient is breathing room air, Pa_{CO_2} cannot exceed 80 mm Hg before life-threatening hypoxemia results. Accordingly, supplemental oxygen is always required, although, unfortunately, oxygen administration alone is almost never sufficient treatment, and the defect in ventilation must be addressed directly. When the underlying cause can be addressed quickly (e.g., reversal of narcotics with naloxone), it may be possible to avoid endotracheal intubation. More often, however, mechanical ventilation must be initiated. Mechanical support is indicated when the patient is unstable or at risk for instability or when central nervous system function deteriorates. Furthermore, in patients who are exhibiting signs of respiratory muscle fatigue, mechanical ventilation should be instituted before overt respiratory failure occurs. Thus, it is not the absolute Pa_{CO_2} value that is important but rather the clinical condition of the patient.

Chronic hypercapnia requires treatment when there is an acute deterioration. In this setting, it is important to recognize that the goal of therapy is not a normal value for Pa_{CO_2} (35-45 mm Hg) but rather restoration of the patient's baseline Pa_{CO_2} (if known). If the baseline Pa_{CO_2} is not known, a target Pa_{CO_2} of 60 mm Hg is reasonable. Overventilation has two undesirable consequences. First, life-threatening alkalemia can occur if the Pa_{CO_2} is rapidly normalized in a patient with chronic respiratory acidosis and an appropriately large strong ion difference. Second, even if the Pa_{CO_2} is corrected slowly, the patient will reduce the plasma strong ion difference over time, making it impossible to wean the patient from mechanical ventilation.

Noninvasive ventilation is another treatment option that is useful in selected patients, particularly those with normal sensorium.[79] Rapid infusion of $NaHCO_3$ in patients with respiratory acidosis can induce acute respiratory failure if alveolar ventilation is not increased to adjust for the increased CO_2 load. Thus, if $NaHCO_3$ is used, it must be administered slowly and alveolar ventilation adjusted appropriately. Furthermore, as discussed previously, $NaHCO_3$ works by increasing the plasma $[Na^+]$. If this is not possible or not desirable, $NaHCO_3$ should be avoided.

Occasionally, it is useful to reduce CO_2 production, which can be achieved by reducing the carbohydrate load in the nutritional support regimen, lowering the temperature in febrile patients, and providing adequate sedation for anxious or combative patients. Treatment of shivering in the postoperative period can reduce CO_2 production. However, it is unusual to control hypercarbia with these techniques alone.

Permissive Hypercapnia

In recent years, there has been increased recognition of ventilator-associated lung injury. Accordingly, a strategy designed to reduce minute ventilation and hence increase Pa_{CO_2}, so-called permissive hypercapnia or controlled hypoventilation, has been increasingly employed.[11] However, permissive hypercapnia is not without risks. Sedation is mandatory and the use of neuromuscular blocking agents is frequently required. Hypercapnia is associated with increased intracranial pressure and pulmonary hypertension, making this technique unusable in patients with brain injury or right ventricular dysfunction. Controversy exists as to how low to allow the pH to go. While some authors have reported good results with pH values less than 7.0,[11] most authors advocate more modest pH reductions (>7.25).

Respiratory Alkalosis

Respiratory alkalosis may be the most frequently encountered acid-base disorder. It occurs in a number of pathologic conditions, including salicylate intoxication, early sepsis, hepatic failure, and hypoxic respiratory disorders. Respiratory alkalosis also occurs with pregnancy and with pain or anxiety. Hypocapnia appears to be a particularly bad prognostic indicator in patients with critical illness.[80] As in acute respiratory acidosis, acute respiratory alkalosis results in a small change in $[HCO_3^-]$ as dictated by the Henderson-Hasselbalch equation. If hypocapnia persists, the strong ion difference will begin to decrease as a result of renal Cl^- reabsorption. After 2 to 3 days, the strong ion difference assumes a new, lower, steady state.[81] Severe alkalemia is unusual in patients with respiratory alkalosis, and management is therefore directed to the underlying cause. Typically, these mild acid-base changes are clinically more important for what they can alert the clinician to, in terms of underlying disease, than for any threat they pose to the patient. In rare cases, respiratory depression with narcotics is necessary.

Pseudorespiratory Alkalosis

The presence of arterial hypocapnia in patients with profound circulatory shock has been termed *pseudorespiratory alkalosis*.[82] This condition can be seen when alveolar ventilation is supported but the circulation is grossly inadequate. In such conditions, the mixed venous P_{CO_2} is significantly elevated but the arterial P_{CO_2} is normal or even decreased secondary to decreased CO_2 delivery to the lungs and increased pulmonary transit time. Overall CO_2 clearance is markedly decreased and there is marked tissue acidosis, usually involving both

metabolic and respiratory components. The metabolic component comes from tissue hypoperfusion and hyperlactatemia. Arterial oxygen saturation also may appear to be adequate despite tissue hypoxemia. This condition is rapidly fatal unless cardiac output is rapidly corrected.

UNIFIED APPROACH TO THE PATIENT WITH ACID-BASE IMBALANCE

CHARACTERIZING THE DISORDER

The first step in the approach to a patient with an acid-base imbalance is to characterize the disorder. Acid-base imbalances are usually recognized by abnormalities in the venous plasma electrolyte concentrations, so it is useful to start there. Measurement of venous $[HCO_3^-]$ is the easiest way to screen for acid-base disorders. However, a normal $[HCO_3^-]$ does not exclude the possibility of an acid-base derangement, even a serious one. Therefore, if the history and physical examination findings lead one to suspect a disease process that results in an acid-base imbalance, more investigation is required. The normal $[HCO_3^-]$ is 22 to 26 mEq/L. Increases in $[HCO_3^-]$ occur with primary and compensatory metabolic alkaloses and decreases occur with primary or compensatory metabolic acidoses. Unfortunately, in mixed disorders, $[HCO_3^-]$ may be misleading and the presence of any abnormality in $[HCO_3^-]$ requires further investigation. In addition to examining the $[HCO_3^-]$, venous blood can be used to calculate the anion gap: $([Na^+] + [K^+]) - ([Cl^-] - [HCO_3^-])$. If $[HCO_3^-]$ or the anion gap are abnormal or if there is clinical suspicion for a mixed disorder, arterial blood should be sampled for blood gas analysis. This test will provide information on the pH, $Paco_2$, and standard base-excess. Although simple disorders will conform to the equations presented in Table 12-6, "mixed" disorders are quite common.

In patients with acidemia, the next step is to examine the anion gap. The anion gap should also be examined when there is suspicion of an occult metabolic acidosis even in a patient with alkalemia. However, severe alkalemia will increase the anion gap by 2 to 4 mEq/L and hence wider "tolerance limits" should be used. If the anion gap is calculated from an alkalemic blood sample, only significant abnormalities (>8-10 mEq/L above normal) should be considered important. More often, however, it is not excessive sensitivity but rather insensitivity that plagues the anion gap calculation. The accuracy of the anion gap can be improved easily by using a patient-specific normal range, rather than a standard one. If unmeasured anions are detected, it is a good idea to compare their amounts to the abnormality in standard base-excess. For example, if the calculated anion gap is 5 mEq/L greater than expected and the standard base-excess is −15 mEq/L, a mixed metabolic acidosis is present. The unmeasured anions (e.g., ketones) are accounting for a standard base-excess of −5 mEq/L while some other process is responsible for another 10 mEq/L. This sort of abnormality can occur if very large amounts of 0.9% saline are used to treat a patient with diabetic ketoacidosis. As the ketosis resolves, the acidosis persists because the strong ion difference has been decreased due to excessive Cl^- administration.

DETERMINING THE CAUSE

Once the disorder has been characterized, the clinician must integrate the information obtained from the history and physical examination to arrive at an accurate diagnosis. Mixed disorders continue to be problematic, as any acid-base disorder that fails to fit into the classification scheme shown in Table 12-5 can be considered a mixed disorder, but some mixed disorders appear to be simple disorders when first encountered. For example, a patient with chronic respiratory acidosis and a $Paco_2$ of 60 mm Hg would be expected to have a standard base-excess of +8 mEq/L (see Table 12-6). If this patient develops a metabolic acidosis, the standard base-excess will decrease and may be 0 mEq/L. At this point, it may appear that the patient has a pure, acute respiratory acidosis rather that a mixed disorder. If the metabolic acidosis causes an increase in the anion gap, this abnormality may provide a clue. Another useful method is to obtain at least two blood gas analyses to examine for trends. In general, however, it is only by careful attention to history and physical examination that the true diagnosis can be made.

Chapter 13

HYPERNATREMIA AND HYPONATREMIA

John K. McIlwaine • Howard L. Corwin

Disorders of plasma sodium concentration—hyponatremia and hypernatremia—are among the most common clinical problems observed in the critically ill. These disorders are often asymptomatic; however, in some patients, they may result in symptoms ranging from minor to life threatening. The approach to treating these disorders in individual patients involves balancing the risk of treatment versus the risk of the disorder itself.

HYPERNATREMIA

Hypernatremia is a common clinical problem, being observed in up to 2% of the general hospital population and 15% of patients admitted to the intensive care unit.[1–4] In the outpatient setting, hypernatremia is most prevalent in the geriatric patient population; however, hypernatremia in hospitalized patients is observed in all age groups.[1,5] Mortality rates in patients with hypernatremia can range as high as 70%.[1–6] Although this high mortality rate no doubt reflects the severity of underlying disease in these patients, there is significant morbidity related to hypernatremia itself. Neurologic sequelae from hypernatremia are common, particularly in the pediatric population.[6]

The maintenance of a normal serum sodium concentration (135 to 145 mEq/L) is dependent on the balance between water intake and water excretion. Hypernatremia results from a deficit of free water that leads to an increase in serum tonicity. The usual mechanism underlying the development of hypernatremia is inadequate water intake and increased free water loss. However, hypernatremia also can result from the intake of hypertonic sodium solutions. Hypernatremia may be associated with volume depletion, euvolemia, or hypervolemia, depending on the balance of salt and water loss and intake. Sodium content is low, normal, or high, respectively, in each of these circumstances. Relative sodium and volume status has important implications for the treatment of patients with hypernatremia.

The brain is particularly susceptible to the effects of hypernatremia. The acute increase in extracellular tonicity as a result of the hypernatremia results in intracellular dehydration as water moves across the cell membrane to maintain osmotic equilibrium. The net result is a loss of brain volume, which in turn places mechanical stress on cerebral vessels. This mechanical stress can result in bleeding. With chronic hypernatremia, cellular adaptation occurs. So-called idiogenic osmoles accumulate in brain cells, which minimizes cellular dehydration. However, the presence of these idiogenic osmoles presents a risk for the development of cerebral edema during the treatment of hypernatremia.

The symptoms of hypernatremia are nonspecific and often difficult to separate from those of the underlying illness in hospitalized patients. Central nervous system abnormalities are most common. These symptoms can include confusion, weakness, and lethargy in the early stages and progress to seizures, coma, and death in the later stages. The symptoms result from the movement of water out of the brain cells rather than the hypernatremia per se. Neurologic deterioration can be seen during treatment as a result of the development of cerebral edema. Signs of volume depletion or volume overload may be present, depending on the cause of the hypernatremia.

The treatment of hypernatremia is water repletion (Table 13–1). The water deficit may be estimated as follows: Water deficit = [0.6 × Total body weight] × [(Serum sodium concentration/140) − 1]. Total body water is assumed to be 60% of body weight. However, the percentage of water relative to total body weight is closer to 50% in women and in the elderly of both genders. Treatment should be instituted at a rate that balances the risk of hypernatremia with the risk of too rapid correction, particularly in cases of chronic hypernatremia. Half the calculated deficit should be replaced within the first 12 to 24 hours at a rate of sodium concentration correction no greater than 2 mEq/L per hour. The remainder of the water deficit can be replaced over the next 48 hours. The rapidity of replacement should be determined by the acuteness of onset and the severity of symptoms. Neurologic status needs to be closely monitored during replacement for evidence of the development of cerebral edema. Ongoing fluid and electrolyte losses also need to be replaced during treatment. In patients with hypernatremia associated with volume depletion and hemodynamic instability, volume replacement with isotonic saline is indicated initially. Once hemodynamic stability is achieved, water replacement can be initiated. Hypotonic saline (e.g., 0.45 saline) may be preferable to water as the replacement fluid

TABLE 13–1. TREATMENT OF HYPERNATREMIA

Calculate water deficit
Replace half the deficit over 12–24 h
Do not correct more rapidly than 2 mEq/L/h
Replace the remaining deficit over 48 h
If hemodynamic instability is present, give isotonic saline until stable before replacing water deficit with hypotonic saline
If volume overload is present, treat with diuretic and 5% dextrose
Dialysis may be indicated if renal failure is present
Ongoing fluid and electrolyte losses should be replaced
Neurologic status should be closely monitored

for these patients. If hypernatremia is associated with hypervolemia (e.g., intake of hypertonic saline or sodium bicarbonate), treatment should be directed toward reducing sodium intake and inducing its loss. In these patients, diuretics can be used along with free water (5% dextrose) infusion. However, if renal failure is present, dialysis may be necessary.

HYPONATREMIA

Hyponatremia is one of the most common electrolyte abnormalities seen in hospitalized patients. It occurs in 2% to 4% of hospitalized patients and up to 30% of patients in intensive care units.[7–10] Mortality for patients with acute hyponatremia is reportedly as high as 50%, whereas mortality for those with chronic hyponatremia is 10% to 20%.[7–11]

Hyponatremia is a water problem, not a sodium problem; there is always an excess of water relative to sodium when hyponatremia is present. In hyponatremia, water excretion by the kidney is impaired. Patients who are hyponatremic may be volume depleted, or hypovolemic (water deficit and sodium deficit), euvolemic (water excess and normal sodium content), or hypervolemic (water excess and sodium excess). As with hypernatremia, the patient's volume status has implications for the treatment of hyponatremia.

In the presence of hyponatremia, there is a decrease in extracellular tonicity relative to the intracellular space. The osmolar gap causes movement of water from the extracellular space into the intracellular space and results in cell swelling. In the central nervous system, cellular swelling manifests as cerebral edema and results in the symptoms associated with hyponatremia. The degree of cerebral cell swelling correlates with the severity of symptoms observed. The central nervous system adapts to hyponatremia in two ways. First, cerebral edema causes an increase in interstitial hydrostatic pressure and results in the movement of fluid from the interstitial space into the cerebrospinal fluid, leading to some amelioration of cerebral edema. Second, solutes are lost from cells, resulting in a decrease in intracellular osmolarity and thus water movement out of cells. The solutes lost are initially sodium and potassium, followed by organic solutes over the next several days. Because of cerebral adaptation, the severity of neurologic symptoms is related to the acuteness and magnitude of the hyponatremia. If hyponatremia develops gradually, brain cells can compensate by decreasing intracellular osmolarity through the loss of osmolytes, thereby limiting the degree of cerebral edema and resultant neurologic dysfunction. However, with the correction of chronic hyponatremia, the regeneration of these osmolytes lags behind, and cerebral dehydration can occur with rapid correction.

In acute hyponatremia, nausea, vomiting, lethargy, and confusion can progress to coma, seizures, and eventual herniation and death.[11,12] The elderly and the young are more likely to be symptomatic from hyponatremia.[9] Menstruating women also tend to be more symptomatic and are at greater risk for neurologic complications from acute hyponatremia.[11] Early in the development of hyponatremia, the symptoms are difficult to separate from those related to the underlying disease process.

Treatment of hyponatremia is dependent on the acuteness of the hyponatremia and the presence and severity of symptoms (Table 13–2). Acute (<48 hours) or chronic (>48 hours) symptomatic hyponatremia (e.g., seizures) requires immediate therapy. However, the optimal approach for the treatment of these patients is controversial.[12–14] The controversy results from reports of the occurrence of a central demyelination syndrome associated with the correction of hyponatremia in some patients.[15–22] This syndrome appears to be more common with chronic hyponatremia (>48 hours), overcorrection of hyponatremia, large corrections (>12 to 25 mEq/L per 24 hours), and rapid correction (>1 to 2 mEq/L per hour).[19–22]

TABLE 13–2. TREATMENT OF HYPONATREMIA

Acute Symptomatic Hyponatremia
3% hypertonic saline with loop diuretic
Correct no more than 2 mEq/L/h
Correct no more than 12–15 mEq/L/h over first 24 h
Chronic Symptomatic Hyponatremia (>48 h, or unknown duration)
3% hypertonic saline with loop diuretic
Correct no more than 1.5 mEq/L/h initially
Correct to resolution of symptoms or 10% correction of serum sodium
Correct no more than 12 mEq/L/24 h
Close monitoring of electrolytes and neurologic status
Asymptomatic Hyponatremia
Euvolemia
Treat underlying cause
Water restriction
Occasionally loop diuretic or demeclocycline to lower urine osmolarity
Hypertonic saline rarely indicated
Hypovolemia
Treat underlying cause of fluid loss
Normal saline
Hypervolemia
Treat underlying cause of decreased effective circulating volume
Salt and water restriction
Loop diuretics for some patients

The approach to the treatment of acute symptomatic hyponatremia is infusion of hypertonic saline (3%). Therapy is targeted toward resolution of symptoms or a 10% to 15% increase in serum sodium concentration. In patients with a high urine osmolarity, the addition of a loop diuretic facilitates correction of the hyponatremia by decreasing urine osmolarity. The rate of correction should be less than 2 mEq/L per hour and less than 15 mEq/L total over 24 hours. The amount of hypertonic saline necessary to correct the serum sodium concentration to a safe level (e.g., 120 mEq/L) can be estimated by calculating the sodium deficit:

$$\text{Sodium deficit} = 0.5 \times \text{Lean body weight} \times (120 - \text{Observed serum sodium concentration})$$

The amount of hypertonic saline required to replace the deficit is then infused at a rate that permits correction within the parameters noted earlier. Frequent checking of electrolytes is necessary to ensure that correction is not too rapid.

In treating patients with chronic (>48 hours, or of unknown duration) symptomatic hyponatremia, the higher risk of neurologic complications related to therapy mandates a more cautious approach. As with acute hyponatemia, neurologic symptoms predominate in the clinical presentation of these patients. Initial treatment with 3% sodium chloride should be directed toward the resolution of symptoms or a 10% increase in serum sodium concentration. The increase in serum sodium concentration should be at a rate less than

1.5 mEq/L per hour initially, and the total correction should not exceed 12 mEq/L per 24 hours. Close monitoring of serum electrolytes and neurologic status is mandatory. The resolution of symptoms allows for a decrease in the rate of correction. Calculation of sodium deficit can be used to estimate the volume of hypertonic saline necessary for correction, as noted earlier.

Most patients with hyponatremia are asymptomatic. Aggressive correction of serum sodium in these patients is not indicated. Treatment in asymptomatic patients is based on the underlying cause of the hyponatremia and the patient's volume status: euvolemic, hypovolemic, or hypervolemic (edema).

The majority of hyponatremic patients are euvolemic. In this group, the syndrome of inappropriate antidiuretic hormone is the most common diagnosis. The inappropriate (nonosmotic) presence of antidiuretic hormone impairs free water excretion by the kidney; impaired water excretion coupled with water intake results in hyponatremia. Water restriction is the mainstay of therapy for these patients. The amount of water restriction must be sufficient to achieve negative water balance (i.e., the difference between the total intake and excretion of water), or correction of hyponatremia will not occur. Therefore, all water losses (insensible losses, urinary losses, and gastrointestinal losses) must be considered when deciding on the degree of water restriction. If urine osmolarity is high, it may be necessary to decrease it to achieve a negative water balance. This can be achieved by adding a loop diuretic; however, salt intake must be increased to correct for losses resulting from the increased natriuresis with diuresis. Less commonly, demeclocycline (300 to 600 mg twice a day), which interferes with the action of antidiuretic hormone, is used to decrease urine osmolarity. In patients with more pronounced hyponatremia, the combination of normal saline and a loop diuretic can be used to correct hyponatremia. The use of hypertonic saline is rarely, if ever, indicated in these asymptomatic patients.

Hyponatremia associated with volume depletion is a result of the loss of both sodium and water, combined with the simultaneous intake of water or hypotonic fluids. The release of antidiuretic hormone stimulated by hypovolemia inhibits the kidney's ability to excrete water. The net result is positive water balance and hyponatremia. The treatment of hyponatremia in this setting is infusion of normal saline to correct the volume depletion. As volume status is corrected, antidiuretic hormone excretion is switched off, and the kidney excretes the excess water, correcting the serum sodium concentration. The cause of the initial sodium and water loss should also be identified and treated.

Hyponatremia associated with hypervolemia is very common. Clinical conditions associated with hyponatremia and hypervolemia include heart failure, cirrhosis, and nephrotic syndrome. The hallmark of these conditions is the presence of edema. The mechanism for the development of hyponatremia in these settings is diminished effective circulating volume leading to sodium and water retention. The water retention is a result of nonosmotic antidiuretic hormone release impairing the kidney's ability to excrete water. In this respect, the mechanism is similar to that responsible for hyponatremia associated with volume depletion. Therapy is directed toward correcting the primary disease process responsible for the decrease in effective circulating volume. Specific treatment of the hyponatremia consists of sodium and water restriction. The use of loop diuretics may facilitate free water excretion and correction of the hyponatremia; however, thiazide diuretics may exacerbate hyponatremia and should be avoided.

This case-controlled and cohort study to determine the risk factors for hyponatremic encephalopathy and the clinical course of patients with encephalopathy found a correlation between poor neurologic outcomes and menstruant women in the setting of acute postoperative hyponatremia.

Karp BI, Laureno R: Pontine and extrapontine myelinolysis: A neurologic disorder following rapid correction of hyponatremia. Medicine 1993;72:359–373.

In this retrospective study of patients who developed neurologic dysfunction after correction of hyponatremia, there appeared to be a correlation between the rate of sodium correction and neurologic dysfunction.

Palevsky PM, Bhagrath R, Greenberg A: Hypernatremia in hospitalized patients. Ann Intern Med 1996;124:197–203.

This well-done prospective cohort study identifying the epidemiology and causes of hypernatremia in a hospitalized patient population found that hospitalized patients of any age may develop hypernatremia.

Snyder NA, Feigal DW, Arieff AI: Hypernatremia in elderly patients: A heterogeneous, morbid, and iatrogenic entity. Ann Intern Med 1987;107:309–319.

These investigators followed a prospective cohort of hospitalized elderly patients (older than 60 years) and determined that hospitalized patients often develop hypernatremia secondary to inappropriate fluid management. These patients had a longer length of stay and slightly increased mortality, although there was no control for severity of illness.

Sterns RH, Cappuccio JD, Silver SM, et al: Neurologic sequelae after treatment of severe hyponatremia: A multicenter perspective. J Am Soc Nephrol 1994;4:1522–1530.

This multicenter retrospective study evaluated the effect of correction rates of severe hyponatremia (<106 mEq/L) on outcome. Patients who were chronically hyponatremic and corrected to a normal serum sodium concentration at a rate of less than 12 mEq/day or 0.55 mEq/h did not develop postcorrection neurologic sequelae.

Chapter 14
HYPERKALEMIA AND HYPOKALEMIA

Sergio Zanotti-Cavazzoni • R. Phillip Dellinger

Hyperkalemia and hypokalemia are the most common electrolyte abnormalities found in hospitalized patients.[1] Data regarding their precise prevalence in intensive care unit (ICU) patients are not available. However, the high incidence of abnormalities in serum potassium concentration undoubtedly reflects both physiologic abnormalities that are common in ICU patients and the effects of therapeutic interventions that are commonly used in the care of critically ill patients. Because of comorbid conditions, critically ill patients are also at a higher risk of developing complications from altered serum potassium levels. Timely recognition and intervention are essential for minimizing morbidity and mortality due to abnormal serum potassium levels.

HYPERKALEMIA

Hyperkalemia is defined as a serum potassium concentration (serum $[K^+]$) greater than 5.0 mEq/L. Hyperkalemia is less frequent than hypokalemia but is more likely to cause serious complications in critically ill patients. Severe hyperkalemia requires rapid correction to prevent serious cardiovascular complications. The measured value for serum $[K^+]$ can be elevated as a result of in vitro phenomena, usually the release of K^+ from cells during the clotting process. Pseudohyperkalemia should be recognized and considered in patients with marked elevations of white blood cells or platelets.[2] Simultaneous measurements of plasma (unclotted) and serum (clotted) $[K^+]$ should identify this problem. A serum $[K^+]$ that is 0.2 to 0.3 mEq/L greater than plasma $[K^+]$ is indicative of pseudohyperkalemia. Pseudohyperkalemia may also result from hemolysis of a blood specimen after collection; this event is usually identified in the laboratory and reported.

True hyperkalemia occurs by two mechanisms: (1) impaired K^+ excretion, and (2) shifts in intracellular and extracellular K^+ (Table 14–1). Renal insufficiency is the most common cause of altered K^+ excretion. With acute oliguric renal failure, elevated potassium levels, if not treated, are life threatening. In most patients with nonoliguric chronic renal failure, mild hyperkalemia is evident.[3] With some causes of chronic renal failure, such as diabetes mellitus and tubulointerstitial diseases, hyperkalemia is more pronounced and is probably related to low circulating renin and aldosterone levels.[4] Decreased aldosterone production promotes the development of hyperkalemia. Patients with acquired adrenal insufficiency develop hyperkalemia despite normal renal function. Various drugs used in the ICU can produce hyperkalemia by impairing K^+ excretion. Patients with abnormal renal function are more susceptible to drug-induced hyperkalemia, and potassium supplements are the most common cause.[5] Potassium-sparing diuretics (spironolactone, amiloride, and triamterene) inhibit K^+ excretion and can produce severe hyperkalemia.[6,7] Spironolactone is the most dangerous of these drugs with respect to impaired K^+ excretion, and it has prolonged effects even after discontinuation. Its use has increased significantly after reports of improved mortality in patients with congestive heart failure.[8] Angiotensin-converting enzyme inhibitors reduce circulating aldosterone levels and are associated with hyperkalemia in patients with renal insufficiency.[9] Angiotensin receptor blockers have less impact on circulating aldosterone levels and are less likely to produce hyperkalemia.[9] Nonsteroidal anti-inflammatory drugs and cyclooxygenase-2 inhibitors block prostaglandin synthesis, causing indirect suppression of renin release and aldosterone secretion. Nonsteroidal anti-inflammatory drugs and cyclooxygenase-2 inhibitors also reduce renal blood flow and glomerular filtration rate, particularly in patients with prerenal azotemia (due to decreased intravascular volume or heart failure). These compounds may produce hyperkalemia by these mechanisms in patients with or without renal dysfunction.[10,11] Heparin inhibits aldosterone synthesis and can cause significant hyperkalemia in patients with altered renal function.[12–14] Other drugs that may cause hyperkalemia by decreasing glomerular filtration rate and aldosterone secretion include cyclosporine and tacrolimus.[15] Trimethoprim and pentamidine inhibit renal K^+ excretion and can cause hyperkalemia in patients with renal insufficiency.[15] Patients undergoing ureterojejunostomy may develop hyperkalemia in the immediate postoperative period, presumably from increased jejunal absorption of urinary K^+.[16]

TABLE 14–1. CAUSES OF HYPERKALEMIA

Impaired K^+ Excretion
Renal failure
Mineralocorticoid deficiency
Addison's disease
Renal tubular acidosis (type 4)
Heparin-induced inhibition of aldosterone synthesis
Hereditary enzyme deficiencies
Pseudohypoaldosteronism
Drugs: potassium-sparing diuretics, angiotensin-converting enzyme inhibitors, nonsteroidal anti-inflammatory drugs, trimethaphan, cyclosporine, tacrolimus, pentamidine
Shifts of K^+ out of Cells
Hypertonicity
Tissue breakdown: rhabdomyolysis, burns, trauma
Drugs: beta blockers, digoxin, succinylcholine, arginine, lysine
Familial hyperkalemic periodic paralysis
Insulin deficiency or resistance

Alterations in the relationship between intracellular and extracellular [K^+] may lead to severe hyperkalemia in critically ill patients, either by increased release of intracellular K^+ or by inhibition of extracellular-to-intracellular K^+ movement. The effects of acidosis on serum [K^+] are complicated and are not fully understood. The traditional teaching that acidosis produces a shift of K^+ from the intracellular to the extracellular space, thus causing hyperkalemia, was based on observations of hyperkalemia in patients with diabetic ketoacidosis and renal failure.[17] Based on these data, an inverse relationship with serum pH and serum [K^+] was described. This relationship has since been disproved, and changes in serum [K^+] in relation to acid-base disorders are more complex than initially thought. Most forms of acute acidosis do not present with hyperkalemia. The most common forms of acute metabolic acidosis in critically ill patients, diabetic ketoacidosis and lactic acidosis, are not associated with K^+ shifts out of cells.[18] Hyperkalemia seen with diabetic ketoacidosis is most likely caused by increased release of intracellular K^+ due to the breakdown of muscle cells.[16] Hypertonicity of the extracellular fluid causes water to exit cells, and K^+ follows. Unless renal function is adequate to eliminate the excess K^+, hyperkalemia develops. This situation may occur in patients with uncontrolled diabetes and can lead to severe hyperkalemia in the presence of renal failure and hypoaldosteronism.[19] Massive tissue breakdown can occur with trauma, burns, and rhabdomyolysis, leading to release of K^+ into the extracellular space. If renal mechanisms for K^+ excretion are impaired, severe hyperkalemia may develop. Drugs can affect the transmembrane balance of K^+. Beta-adrenergic blockers inhibit the entry of K^+ into cells and, in combination with renal failure, can promote the development of hyperkalemia.[20] Succinylcholine blocks normal reentry of K^+ into cells after depolarization and causes a transitory increase in serum [K^+]. In patients with severe burns or extensive trauma, the transient hyperkalemia induced by succinylcholine can be more prolonged and severe.[21,22] Digoxin impairs K^+ entry into cells by inhibiting the cell membrane Na^+, K^+-ATPase. It does not produce hyperkalemia in therapeutic doses but may cause hyperkalemia with toxic levels.[23,24] Familial hyperkalemic periodic paralysis is a rare congenital disease that causes a mutation in cell membrane Na^+ channels, producing transient episodes of severe hyperkalemia secondary to paroxysmal shifts in K^+ from cells to the extracellular compartment.[25]

CLINICAL EFFECTS

Most of the clinical consequences of potassium abnormalities are related to the effect on the transmembrane resting cell potential. Cardiac and neuromuscular cells are particularly sensitive to changes in serum [K^+]. Most often, hyperkalemia is asymptomatic. However, it affects the cardiac conduction system, as evidenced by characteristic changes in the electrocardiogram (ECG) that serve as indicators of potential life-threatening arrhythmias (Table 14–2). The first sign of increased serum [K^+] is tenting of the T wave. Changes associated with progressive increases in serum [K^+] include widening of the QRS complex, the progressive development of atrioventricular conduction blocks, a slow idioventricular rhythm, an ECG tracing that looks like a sine wave, ventricular fibrillation, and finally asystole.[26] There is no absolute level of serum [K^+] associated with a particular ECG abnormality, but rapid rises seem to be more dangerous, particularly in patients without a history of chronic renal insufficiency.[27,28] Hyperkalemia can cause paresthesias and weakness in the arms and legs, followed by a symmetrical flaccid paralysis of the extremities that ascends toward the trunk, finally involving the respiratory muscles. The cranial nerves are usually not affected by hyperkalemia.

TABLE 14–2. ELECTROCARDIOGRAM CHANGES CAUSED BY ABNORMAL [K^+]

Hyperkalemia	Hypokalemia
Peaked T waves	Broad, flat T waves
Loss of P waves	ST depression
Widening QRS complexes	U wave
Sine wave	QT interval prolongation
Ventricular arrhythmias	Ventricular arrhythmias
Asystole	

TREATMENT

The primary goal of treating hyperkalemia is to prevent adverse cardiac complications. Treatment modalities are aimed at one of three mechanisms to prevent or decrease these complications: (1) direct antagonism of hyperkalemic effect on the cell membrane polarization, (2) movement of extracellular K^+ into the intracellular compartment, and (3) removal of K^+ from the body. Patients with a serum [K^+] greater than 6.5 mEq/L or ECG signs suggestive of hyperkalemia should be treated emergently.

Direct Antagonism of Hyperkalemic Effect on Cell Membrane Polarization. The intravenous infusion of calcium gluconate antagonizes the effects of hyperkalemia on the heart. This effect occurs within minutes and lasts 30 to 60 minutes. If a salutary effect is noted, repeat doses may be used. The recommended dose is 10 mL of 10% calcium gluconate or chloride. Extreme caution must be used in patients with hyperkalemia and digitalis toxicity, because the administration of ionized calcium may potentiate the effects of digoxin on the conduction system.[15,29] Calcium should be avoided in the setting of digoxin toxicity.

Movement of Extracellular K^+ into the Intracellular Compartment. Administration of insulin shifts K^+ into cells; this effect occurs in 15 to 30 minutes and lasts approximately 2 to 4 hours.[30] The recommended dose is 10 units of regular insulin intravenously; dextrose (50 g) should be added to avoid hypoglycemia. This dose will decrease serum [K^+] by 0.5 to 1.5 mEq/L. Patients without intravenous access can be treated with inhaled $beta_2$-adrenergic agonists such as albuterol. Albuterol drives K^+ into cells by increasing Na^+, K^+-ATPase activity. Albuterol (10 to 20 mg in 4 mL of saline by nasal inhalation over 10 minutes) can lower the serum [K^+] by 0.5 to 1.5 mEq/L.[31] Sodium bicarbonate is much less effective than either insulin or albuterol but may produce shifting of [K^+] into cells.[32] The use of sodium bicarbonate should be limited to situations in which it is indicated for the treatment of concurrent acidosis.

Removal of K^+ from the Body. Finally, removal of K^+ is necessary to prevent a recurrence of hyperkalemia once the effects of the preceding measures have waned. Loop diuretics can be helpful in patients with sufficient renal function (dosing depends on medication and renal function); however,

TABLE 14–3. TREATMENT OF HYPERKALEMIA

Treatment	Mechanism	Dosage/Comment	Onset	Duration
Calcium	Cardiac cell stabilizer	10 mL of 10% solution (calcium gluconate or calcium chloride)	Seconds	30–60 min
Insulin (regular)	Shifts K^+ into cells	10 U i.v. + glucose (50 g)	15–30 min	2–4 h
Albuterol	Shifts K^+ into cells	10–20 mg by inhaler over 10 min	20–30 min	2–3 h
Sodium bicarbonate	Shifts K^+ into cells	In cases of acidosis	Delayed	—
Kayexalate with sorbitol	Removes K^+ from body	Oral: 15–30 g	4–6 h	—
		Retention enema: 30–50 g	1 h	—
Loop diuretics	Removes K^+ from body	Intravenous, varies by drug and renal function	1 h	—
Hemodialysis	Removes K^+ from body	Preferred over peritoneal dialysis in acute cases	15–30 min	—

most often, other measures are needed. Sodium polystyrene sulfonate (Kayexalate) binds to K^+ secreted in the colon. Each gram of resin removes 0.5 to 1 mEq of K^+. The usual dose of Kayexalate is 15 to 30 g orally. Because the resin causes constipation, sorbitol (15 mL of a 70% solution) should be administered to induce osmotic diarrhea. If oral administration is not feasible, Kayexalate can be given as a retention enema, consisting of 30 to 50 g of the resin in 70% sorbitol solution. It is important, however, that the enema be retained for at least 30 to 60 minutes to obtain the desired therapeutic effect. The effects of Kayexalate on serum $[K^+]$ occur in 4 to 6 hours when the agent is given orally and in 1 to 2 hours when it is given as an enema. Serious side effects of Kayexalate and sorbitol include bowel necrosis and perforation. These complications seem to be more likely in severely immunocompromised patients or shortly after operation; accordingly, Kayexalate should be avoided in these circumstances.[33–35] Both peritoneal dialysis and hemodialysis are very effective in removing K^+ from the body. In acute cases when serum $[K^+]$ needs to be corrected rapidly, hemodialysis is preferred. Hemodialysis can quickly remove 50 to 125 mEq of K^+ and should be used as definitive treatment when other treatments fail. Peritoneal dialysis is also effective in removing K^+ from the body, but its effects are slower than those achieved with hemodialysis or cation exchange resins. In addition to the implementation of rapid treatment, the causes of hyperkalemia should be sought and corrected, and offending drugs should be discontinued when possible. See Table 14–3 for a summary of the treatment for hyperkalemia.

HYPOKALEMIA

Hypokalemia is more common than hyperkalemia and is defined as serum $[K^+]$ less than 3.6 mEq/L. Severe hypokalemia can lead to significant complications; more important, understanding its causes and how to treat it may reduce complications from the treatment itself. Low serum $[K^+]$ reflects a disbalance of normal K^+ homeostasis, with one rare exception. In patients with leukemia and markedly elevated white cell counts, K^+ can be taken up by the abnormal cells in the test tube and produce pseudohypokalemia.[36] However, as noted earlier, in vitro changes in $[K^+]$ more commonly produce pseudohyperkalemia. Hypokalemia usually occurs as a consequence of K^+ depletion due to either increased excretion or inadequate intake. Shifts in extracellular and intracellular $[K^+]$ also can cause hypokalemia (Table 14–4).

In critically ill patients, increased losses are more commonly responsible for K^+ depletion than is inadequate ingestion. The use of diuretics is the most common cause of hypokalemia in hospitalized patients. Both loop and thiazide diuretics cause increased delivery of Na^+ and Cl^- to the collecting duct, promoting the secretion of K^+ and causing hypokalemia. Diuretics are often used in high doses or administered by continuous infusion in critically ill patients, increasing the risk of hypokalemia. K^+ losses can also occur from increased stool output. Because K^+ is secreted into the colon, patients with high outputs from ileal or jejunal ostomies do not develop hypokalemia. Upper gastrointestinal losses such as vomiting or nasogastric suctioning contain small amounts of K^+. However, these losses are associated with hypochloremia and metabolic alkalosis, both of which may cause increased renal K^+ excretion, exacerbating the resultant hypokalemia. Large doses of laxatives or repeated enemas lead to excessive K^+ losses and hypokalemia. Magnesium depletion and some forms of renal tubular acidosis (type 1 and some forms of type 2) can cause renal K^+ wasting. Other drugs also can lead to hypokalemia. For example, fludrocortisone and hydrocortisone increase K^+ excretion. Aminoglycosides, amphotericin B, cisplatin, and foscarnet

TABLE 14–4. CAUSES OF HYPOKALEMIA

Increased Excretion

- Diarrhea, laxative or enema abuse
- Renal losses
  - Diuretics (loop and thiazides)
  - Metabolic alkalosis
  - Osmotic diuresis (uncontrolled hyperglycemia)
  - Nonreabsorbable anions
  - Mineralocorticoid excess
    - Primary hyperaldosteronism
    - Congenital adrenal hyperplasia
    - Glucocorticoid-responsive aldosteronism
  - Other causes
    - Liddle's disease
    - Enzyme deficiencies
    - Bartter's syndrome
  - Magnesium depletion
  - High-dose glucocorticoids

Shifts of K^+ into Cells

- Drugs
  - Beta-adrenergic agonists
  - Insulin
  - Theophylline
  - Caffeine
- Delirium tremens
- Hyperthyroidism
- Familial hypokalemic periodic paralysis
- Barium poisoning

cause magnesium depletion and increased K^+ renal losses.[37] Penicillin and its synthetic derivatives, when given intravenously, cause increased Na^+ delivery to the distal nephron, promoting K^+ secretion and potentially causing hypokalemia.[37]

Alkalosis can cause movement of K^+ into cells. This effect is seen with both metabolic and respiratory alkalosis and occurs as a consequence of hydrogen ions leaving the cell to minimize changes in extracellular pH, and K^+ moving into the cells to maintain electroneutrality. The direct effects of alkalosis on serum [K^+] are small, and the hypokalemia seen with metabolic alkalosis is more often caused by chloride losses producing increased delivery of Na^+ to the distal nephron, which stimulates K^+ losses. A number of $beta_2$-adrenergic agonist drugs, including bronchodilators, decongestants, and tocolytics, can cause K^+ shifts into cells and transient hypokalemia.[37] Theophylline stimulates cell membrane Na^+, K^+-ATPase and promotes K^+ entry into cells; hypokalemia is commonly seen with theophylline toxicity.[38] Barium can block the exit of K^+ from cells and cause hypokalemia.[39] Thyroid hormone can stimulate Na^+, K^+-ATPase, and hypokalemia is sometimes seen with hyperthyroidism. Increased endogenous beta-adrenergic stimulation occurs with delirium tremens, producing intracellular movement of K^+ and hypokalemia.[40] Familial hypokalemic periodic paralysis, a rare hereditary disease, is associated with a mutation in cell membrane calcium channels and causes episodes of severe hypokalemia triggered by high sodium intake or exercise.[41] These patients can present with severe muscle weakness and respiratory failure from hypoventilation.

CLINICAL EFFECTS

It is estimated that approximately 20% of hospitalized patients have a serum [K^+] less than 3.6 mEq/L; most are asymptomatic. As discussed earlier, the consequences of changes in serum [K^+] occur as a result of alterations in the resting membrane potential, making cardiac and neuromuscular cells the most susceptible targets. The most serious and potentially fatal effects of hypokalemia are related to disturbances in cardiac electrical activity that can lead to cardiac arrest. However, cardiac arrest caused by hypokalemia occurs almost exclusively in patients with underlying cardiac disease or patients taking digitalis.[42] Hypokalemia is also associated with characteristic ECG changes (see Table 14–2). Progressive decreases in serum [K^+] produce broad, flat T waves; ST depression; and the appearance of U waves, QT interval prolongation, and finally ventricular arrhythmias, leading to cardiac arrest.[26] When serum [K^+] is less than 3.0 mEq/L, generalized weakness can develop. When serum [K^+] decreases to less than 2.5 mEq/L, muscle necrosis and rhabdomyolysis can occur. With progression of hypokalemia, an ascending muscle paralysis develops, leading to respiratory failure and arrest.

TREATMENT

The immediate goal of treatment in hypokalemia is to prevent or correct cardiac electrical disturbances and serious neuromuscular weakness. The long-term goal of treatment is to achieve repletion of total body potassium to normal levels. Supplementation of [K^+] is the principal treatment for hypokalemia and is achieved with the administration of potassium chloride or potassium phosphate. In general, plasma [K^+] decreases by approximately 0.3 mEq/L for each 100 mEq decrease in total body K^+. This relationship is more difficult to estimate when serum [K^+] is less than 2 mEq/L.[37] K^+ replacement should be given orally except when severe hypokalemia is associated with respiratory or cardiac instability, in which case the intravenous route is recommended. Intravenous administration of K^+ should not exceed 20 mEq/h, to minimize possible iatrogenic hyperkalemia. For infusion of K^+, an infusion pump and continuous cardiac monitoring are mandatory.[15] In the case of life-threatening arrhythmias due to severe hypokalemia, more rapid infusion into a central vein may be appropriate. In these rare circumstances, KCl should be diluted to 10 mEq per 100 mL of infusion fluid. In most cases, oral supplementation of K^+ is preferred, because this route is safer and produces a more gradual increase in serum [K^+]. Because supplementation of K^+ is usually not an emergency, it is best accomplished using moderate doses of KCl (20 to 40 mEq once or twice a day) over several days. Potassium phosphate is used when hypophosphatemia is also present (as in diabetic ketoacidosis); occasionally, potassium bicarbonate is used in the setting of metabolic acidosis and hypokalemia. However, for most cases of hypokalemia, KCl is the salt of choice for replacement of K^+. Serum [K^+] should be followed closely, especially when using intravenous or higher doses, to prevent the development of hyperkalemia. If magnesium levels are low, they should be corrected, because hypomagnesemia promotes renal loss of K^+, making correction of hypokalemia more difficult. Finally, prevention of further episodes should be addressed with proper K^+ intake and supplementation in patients with a continuous cause for hypokalemia. The use of potassium-sparing diuretics may be helpful in certain clinical situations, but caution must be exercised, because the development of hyperkalemia can have severe consequences.

Chapter 15
HYPOPHOSPHATEMIA AND HYPERPHOSPHATEMIA

Stephen Trzeciak • R. Phillip Dellinger

PHOSPHATE HOMEOSTASIS

Derangements in the metabolism of phosphate are common in the intensive care unit and can be clinically significant. One of the keys to understanding phosphate homeostasis is an appreciation of the fact that serum phosphate measurements may not reflect total body phosphorus stores because (1) the vast majority of total body phosphorus is found in the bones (in the form of hydroxyapatite); (2) the majority of phosphate is intracellular, and extracellular phosphate accounts for only a small fraction of total body phosphorus stores; and (3) shifts between the intracellular and extracellular compartments occur. There is no common laboratory test to accurately measure total body phosphate stores. Low serum phosphate concentration is referred to as *hypophosphatemia*, whereas a state of low total body phosphorus stores is referred to as *phosphate depletion*.

Phosphate serves a number of crucial functions. It is an essential component of the main energy "currency" of the cell: adenosine triphosphate. Phosphate is also a component of phospholipids in cell membranes and of hydroxyapatite, the structural matrix of bone. Phosphate also serves as a buffer against acid-base derangements.

Phosphate homeostasis is a function of bone metabolism, intestinal absorption, and kidney resorption. Bone metabolism is linked to calcium homeostasis. In the setting of hypocalcemia, increased parathyroid hormone levels cause phosphate and calcium to be released from the bone. Intestinal absorption of phosphate occurs in the small bowel, mostly in the jejunum. Vitamin D, produced by the kidney in increased amounts when serum phosphate levels are low, increases the intestinal absorption of both calcium and phosphate. Phosphate is excreted from the kidneys, but most of the excreted phosphate load undergoes resorption in the proximal tubule. Parathyroid hormone increases phosphate excretion by inhibiting phosphate resorption in the kidney. Resorption increases in the setting of phosphate deficiency.

HYPOPHOSPHATEMIA

Hypophosphatemia is typically classified as mild (serum phosphate concentration 2.5 to 3 mg/dL), moderate (1 to 2.5 mg/dL), or severe (<1 mg/dL). Although mild to moderate hypophosphatemia may be subclinical, severe hypophosphatemia may be associated with significant morbidity. The all-cause mortality rate in patients with serum phosphate concentrations less than 1 mg/dL has been reported to be as high as 30%.[1]

Common causes of hypophosphatemia are summarized in Table 15–1. Respiratory alkalosis (of any cause) may induce a transcellular shift of phosphate and cause hypophosphatemia. Other causes of hypophosphatemia include renal phosphate losses, inadequate intestinal absorption of phosphate, and extreme catabolic states. Renal losses of phosphate occur with osmotic diuresis or excessive diuretic therapy. Hyperparathyroidism (either primary or secondary) causes hypophosphatemia by decreasing urinary resorption of phosphate. Proximal renal tubular disorders also impair phosphate resorption and cause hypophosphatemia. Total body phosphate depletion also occurs in extreme catabolic states, such as burns or sepsis.

Hypophosphatemia should be anticipated when nutritional support is initiated in a chronically malnourished patient. When a carbohydrate load is administered in the setting of chronic malnutrition, there is a spike in insulin release that increases cellular phosphate uptake and can induce a precipitous decrease in serum phosphate concentration. This phenomenon has been termed the *refeeding syndrome*. A common example is the initiation of enteral or parenteral nutrition in an alcoholic patient who suffers from chronic hypophosphatemia due to malnutrition.[2] Profound hypophosphatemia in the refeeding syndrome can produce severe clinical manifestations, and death has been reported.[3] Concurrent hypokalemia and hypomagnesemia are common. In chronically malnourished patients, the refeeding syndrome can be avoided with a cautious introduction of nutritional

TABLE 15–1. COMMON CAUSES OF HYPOPHOSPHATEMIA

  - Nasogastric suctioning
  - Malabsorption syndromes
- Extreme catabolic states
  - Burns
  - Trauma
  - Sepsis

support (especially carbohydrates), careful monitoring of serum phosphorus levels, and appropriate phosphate supplementation when indicated.[3]

Patients with diabetic ketoacidosis typically have phosphate depletion because hyperglycemia induces increased urinary losses of phosphate via an osmotic diuresis. However, the serum phosphate concentration may be normal in the initial phase of therapy, because severe acidosis causes a shift of phosphate into the extracellular space from the intracellular compartment. As the acidosis is corrected, however, phosphate shifts back to the intracellular compartment, leading to a precipitous decrease in serum phosphate levels.[4] Although common, the clinical significance of moderate hypophosphatemia in diabetic ketoacidosis is unclear. Therapy for hypophosphatemia in diabetic ketoacidosis is typically warranted only if the serum phosphate level is less than 1.0 mg/dL or if hypophosphatemia is associated with severe clinical manifestations, such as central nervous system or left ventricular dysfunction.[5]

Clinical manifestations due to hypophosphatemia are rare unless the serum phosphate concentration is less than 1 mg/dL. The clinical findings are summarized in Table 15–2. Diffuse skeletal muscle weakness may be profound.[6] Respiratory failure secondary to diaphragmatic weakness may occur.[7,8] Respiratory failure may be primary, or it may manifest as an inability to wean from mechanical ventilation. Central nervous system dysfunction may include confusion, lethargy, and gait disturbance. Hematologic manifestations, including acute hemolytic anemia and leukocyte dysfunction (impaired phagocytosis and chemotaxis), have been reported. Cardiovascular manifestations may include acute left ventricular dysfunction and a reversible dilated cardiomyopathy that typically responds only to phosphate repletion. Rhabdomyolysis also may occur.[9]

Hypophosphatemia also may cause disorders of oxygen transport. Profound hypophosphatemia can impair oxygen delivery to the tissues because of decreased production of 2,3-diphosphoglycerate, a key molecule in erythrocytes that facilitates the release of oxygen from hemoglobin. Decreased intracellular levels of 2,3-diphosphoglycerate cause a leftward shift of the oxyhemoglobin dissociation curve.

Because phosphate serves as a buffer in acid-base derangements, hypophosphatemia may be clinically significant in the interpretation of acid-base status. Phosphate and proteins (albumin) are measured anions. Unmeasured anions are accounted for in acid-base interpretation by calculation of the anion gap. Although there is no true "normal" value for the anion gap, the value is typically lower for a patient with low measurable anions (i.e., either hypophosphatemia or hypoalbuminemia, or both). Therefore, a "normal" value for the calculated anion gap in the setting of profound hypophosphatemia may actually represent the presence of unmeasured anions. As a rule, the expected anion gap (in mEq/L) equals twice the serum albumin concentration (in g/dL) plus one half of the serum phosphate concentration (in mM/L). Thus, a patient with hypophosphatemia and hypoalbuminemia may have an elevated anion gap even if the measured anion gap is less than the commonly used threshold of 10 to 12.

Severe hypophosphatemia (phosphate concentration <1 mg/dL) mandates intravenous phosphate replacement. Phosphate should not be administered by the intravenous route to patients with renal failure; it should also be avoided in patients with hypercalcemia, because metastatic calcification can occur. For moderate hypophosphatemia (phosphate concentration 1 to 2.5 mg/dL), oral supplementation may be adequate for a patient who is able to take medications by mouth or nasogastric tube. The degree of true phosphate depletion is difficult to assess because most phosphate is intracellular; therefore, it is impossible to accurately predict the exact amount of phosphate supplementation required to replenish phosphate stores.

HYPERPHOSPHATEMIA

Hyperphosphatemia is defined as a serum phosphate level greater than 4.5 mg/dL; it may be clinically significant at levels greater than 5 mg/dL. The most common cause of hyperphosphatemia is renal failure. Renal insufficiency causes hyperphosphatemia because phosphate excretion by the kidneys is impaired. The serum phosphate level is usually normal until the creatinine clearance falls below 30 mL/min. Other causes of hyperphosphatemia include rhabdomyolysis, hemolysis, and tumor lysis syndrome[10]; any insult causing extensive cell damage releases phosphorus into the extracellular space. Hyperphosphatemia has also been reported in patients using bisphosphonate medications (decreased renal phosphate clearance) and patients abusing phosphate-containing laxatives. Causes of hyperphosphatemia are summarized in Table 15–3.

The most frequent clinical findings in acute hyperphosphatemia are signs and symptoms of hypocalcemia.

TABLE 15–3. COMMON CAUSES OF HYPERPHOSPHATEMIA

Abuse of phosphate-containing laxatives
Excessive (iatrogenic) phosphate administration
Bisphosphonate therapy

Hyperphosphatemia produces hypocalcemia by three mechanisms: (1) precipitating calcium (formation of calcium-phosphorus complexes), (2) interfering with parathyroid hormone–mediated resorption of bone, and (3) decreasing vitamin D levels.[11] Clinical signs and symptoms of hypocalcemia, such as muscle cramping, tetany, hyperreflexia, and seizures, as well as cardiovascular manifestations, may be evident.

Management of acute hyperphosphatemia includes limiting phosphate intake and enhancing urinary phosphate excretion. In the absence of end-stage renal disease, phosphate excretion can be optimized with saline infusion (volume diuresis) and diuretic administration. Diuretics that work on the proximal tubule, such as acetazolamide, are especially effective for enhancing phosphate excretion. Any patient with life-threatening hyperphosphatemia should be considered for dialysis.

Oral phosphate binders decrease the absorption of phosphate in the gut and are a mainstay for preventing and treating hyperphosphatemia in patients with chronic renal failure. Calcium and aluminum salts are widely used. However, calcium salts can produce hypercalcemia and metastatic calcification from a high calcium-phosphorus ($Ca \times PO_4$) product, and aluminum salts may be toxic. In dialysis patients, chronic management of hyperphosphatemia with calcium-free phosphate binders, such as sevelamer hydrochloride (Renagel), may reduce long-term mortality by preventing cardiovascular complications associated with a high calcium-phosphorus product.[12] Sevelamer is highly effective in increasing fecal elimination of phosphate without producing hypercalcemia or aluminum toxicity.[13] In the acute management of patients with hyperphosphatemia accompanied by hypocalcemia, the likelihood (and clinical significance) of metastatic calcification with acute calcium administration is unclear.

Chapter 16
HYPOMAGNESEMIA

D. Patrick Bryant • Robert N. Cooney

Magnesium (Mg^{++}) is an important ion that participates in more than 300 enzymatic reactions, especially those involving adenosine triphosphate (ATP) as a cofactor. Although the relationship between hypomagnesemia and intracellular magnesium deficiency remains unclear, hypomagnesemia is common in critically ill patients and is associated with increased mortality.[1,2]

CELLULAR PHYSIOLOGY AND METABOLISM OF MAGNESIUM

Magnesium is a divalent cation that is localized predominantly to the intracellular compartment. It is the second most abundant intracellular cation after potassium and plays an important role in cellular metabolism and homeostasis. At the cellular level, magnesium influences membrane function by regulating ion transport. Magnesium is required for Na^+, K^+-ATPase activity, which maintains transmembrane gradients for sodium (Na^+) and potassium (K^+).[3,4] Magnesium also regulates intracellular calcium (Ca^{++}) flux by competing for Ca^{++} binding sites and influencing intracellular Ca^{++} transport.[3,4] Magnesium is an essential cofactor for most processes that require ATP. It acts by neutralizing the negative charge on the phosphate anion of ATP to facilitate enzyme binding and hydrolysis of the phosphate moiety. Intracellular Mg^{++} is required for numerous critical biochemical processes, including DNA synthesis, activation of gene transcription, initiation of protein synthesis, and regulation of energy metabolism via glycolysis and the tricarboxylic acid cycle.[3–6]

Total body magnesium (21 to 28 g) is distributed in bone (53%), muscle (27%), soft tissue (19%), and blood (0.8%).[3] The normal concentration of total magnesium in serum is 1.5 to 2.3 mg/dL. Approximately 19% of circulating magnesium is bound to protein (predominantly albumin), whereas 14% is complexed to serum anions (citrate, phosphate, and bicarbonate). The majority of magnesium in serum exists as an ionized species (67%), which represents the physiologically active form.[3,7] Consequently, measurements of total serum Mg^{++} may not accurately reflect the relative abundance of circulating Mg^{++}.[1–3]

Magnesium homeostasis is maintained by the small intestine, kidney, and bone.[3,8] The average dietary intake of magnesium is approximately 300 mg/day. Normally, only one third of dietary Mg^{++} is absorbed.[8,9] However, intestinal Mg^{++} uptake increases to compensate for dietary or total body Mg^{++} deficiency.[3,8,9] Unlike calcium, there are no hormonal mechanisms for regulating Mg^{++}. Consequently, normal renal filtration and reabsorption of Mg^{++} are important regulatory mechanisms for Mg^{++} homeostasis.[3,8] Non–protein-bound Mg^{++} is filtered by the glomerulus. Under normal conditions, up to 95% of filtered Mg^{++} is reabsorbed in either the proximal tubule (35%) or the thick ascending loop of Henle (60%).[3,8] Magnesium reabsorption in the loop of Henle is linked to sodium chloride transport and is inversely related to flow. Consequently, diuretic use and other conditions associated with increased tubular flow result in decreased Mg^{++} reabsorption.[3,8] Under conditions of persistent Mg^{++} deficiency, mobilization of Mg^{++} from bone also represents a potential homeostatic mechanism.[3]

PREVALENCE AND CAUSE OF HYPOMAGNESEMIA

The reported prevalence of hypomagnesemia in adult patients admitted to the intensive care unit ranges from 15% to 60%, depending on whether total or ionized magnesium is measured.[1,2,10,11] A recent study found that severe ionized hypomagnesemia is most common after liver transplantation and in patients with severe sepsis.[2] Magnesium deficiency in critically ill patients may be caused by inadequate Mg^{++} intake, increased renal or gastrointestinal losses, acute intracellular shifts of Mg^{++}, and other medical conditions (e.g., burn injury, massive blood transfusion, cardiopulmonary bypass). Increased renal losses of Mg^{++} are associated with alcohol abuse, diabetes, acute tubular necrosis, diuretics, aminoglycosides, amphotericin, cyclosporine, cisplatin, digoxin, and other medications.[2,3,8,10,12] Vomiting, diarrhea, nasogastric tube losses, and pancreatitis are associated with increased gastrointestinal losses of Mg^{++}.[2,3,8,10,12] Acute extracellular-to-intracellular shifts of magnesium caused by refeeding with glucose or amino acids, insulin, catecholamines, or metabolic acidosis may also result in hypomagnesemia.[2,3,8,10,12] Hypoalbuminemia is associated with a reduction in total Mg^{++} in plasma, but the ionized fraction may remain normal. Critically ill patients are at increased risk for hypomagnesemia, and the development of hypomagnesemia is associated with an increased risk of mortality.[1,2]

CLINICAL SIGNS AND SYMPTOMS OF HYPOMAGNESEMIA

Hypomagnesemia is frequently asymptomatic in critically ill patients and is commonly identified through routine blood work or when hypomagnesemia is suspected clinically.[8,10–12] However, the relationship between systemic and cytoplasmic hypomagnesemia is unclear, and it has not been established whether changes in enzymatic function caused by cytoplasmic

Mg^{++} depletion can lead to clinically significant problems. Hypomagnesemia is most commonly seen in conjunction with hypokalemia, hypocalcemia, and other electrolyte abnormalities. Consequently, it is difficult to assess the clinical consequences of isolated hypomagnesemia. In most instances, symptoms are attributed to Mg^{++} deficiency only after other electrolyte abnormalities are corrected.[3,8,10–12] As summarized in Table 16–1, the clinical sequelae of magnesium deficiency most commonly affect the cardiovascular, metabolic, and neuromuscular systems.

CLINICAL USES OF MAGNESIUM

Hypomagnesemia is associated with electrocardiographic changes that are similar to those found in hypokalemia; these include flattened T waves, U waves, and prolonged QT interval. Magnesium is a cofactor for Na^+, K^+-ATPase in cardiac tissue.[3,8,11,12] Reductions in intracellular K^+ result in cell depolarization and can lower the threshold for generation of an action potential, as well as decrease the time for repolarization. Consequently, hypomagnesemia is associated with atrial (premature atrial contractions, atrial fibrillation, multifocal atrial tachycardia), digoxin-related, and ventricular (ventricular tachycardia, torsades de pointes) dysryhthmias.[8,11,12] Magnesium is currently recommended as the initial therapy for torsades de pointes and as an adjunct for refractory ventricular dysrhythmias.[3,8,11,12] Magnesium administration during acute myocardial infarction was associated with reduced mortality in the second Leicester Intravenous Magnesium Intervention Trial (LIMIT-2)[13] but not the fourth International Study of Infarct Survival (ISIS-4).[14] However, in the ISIS trial, magnesium replacement was performed following coronary reperfusion. So at present, there are no conclusive data to support routine magnesium administration in patients with acute myocardial infarction. However, based on the LIMIT-2 study, there is some evidence that magnesium may be beneficial if given before coronary reperfusion.[15]

Hypomagnesemia is commonly associated with both hypokalemia and hypocalcemia.[8] This association is related in part to the fact that medications and homeostatic changes that affect magnesium often affect potassium as well. In addition, renal losses of potassium are increased in hypomagnesemia and are refractory to supplementation unless the magnesium deficiency is corrected first.[3,8] A somewhat similar condition exists for hypocalcemia, in that hypomagnesemia suppresses parathyroid hormone release and activity.[16] Consequently, hypocalcemia is refractory to Ca^{++} replacement unless the magnesium deficiency is corrected as well.[3,8]

Magnesium can have a depressant effect on the nervous system due to its ability to cause presynaptic inhibition.[3,8,12] It depresses the seizure threshold by competitively inhibiting *N*-methyl-D-asparate receptors.[3,8,11,12] The neurologic and neuromuscular manifestations of hypomagnesemia include coma, seizures, weakness, and signs of muscular irritability.[3,8,11,12] Hypomagnesemic patients may have a positive Chvostek's sign even with normal ionized calcium and may develop nystagmus, tetany, or seizures followed by rhabdomyolysis.[3,8,11,12] Consequently, Mg^{++} replacement is indicated in this setting and is also commonly used in patients with preeclampsia (blood pressure >140/90 with proteinuria) or eclampsia (associated seizures) during late pregnancy.[11,12]

Magnesium replacement has been used to treat bronchospasm in patients with asthma.[11,12] The proposed mechanism of action for the therapeutic benefit of Mg^{++} in bronchospasm involves its relaxant effects on smooth muscle.[11,12] Several studies have shown improved FEV_1 following intravenous magnesium or improved peak flow rates with nebulized magnesium, while others have not.[11,12] Consequently, additional studies are needed to adequately define the role of magnesium in patients with asthma.

TREATMENT OF HYPOMAGNESEMIA

The initial step in managing hypomagnesemia is to identify and eliminate factors contributing to the development of magnesium deficiency. This may involve interventions to minimize gastrointestinal losses or reevaluating the need for medications that cause renal magnesium wasting (e.g., aminoglycosides, diuretics). The severity of hypomagnesemia, urgency of clinical symptoms (dysrhythmias, muscle cramps.), associated electrolyte abnormalities (K^+ and Ca^{++}), and renal function should be assessed before initiating Mg^{++} therapy.

In general, intravenous administration of Mg^{++} is preferred in symptomatic critically ill patients. However, caution must be used with Mg^{++} replacement when renal dysfunction is present, because severe hypermagnesemia may result. Current recommendations for magnesium replacement therapies are of limited value, owing to the lack of controlled studies examining time-matched controls and the use of total serum versus ionized magnesium concentration for monitoring. Magnesium can be administered intravenously as magnesium sulfate ($MgSO_4$; 1 g = 4 mmol) or magnesium chloride ($MgCl_2$; 1 g = 4.5 mmol) and orally as magnesium gluconate (500 mg = 1.2 mmol) or magnesium oxide (400 mg = 6 mmol). When intravenous magnesium replacement is used, a bolus followed by continuous infusion or infusion

alone is preferred, because renal filtration and excretion may limit Mg^{++} retention. For torsades de pointes, 1 to 2 g of intravenous $MgSO_4$ over 5 minutes is recommended. For urgent hypomagnesemia, an intravenous bolus of 8 to 12 mmol of Mg^{++} (2 to 3 g $MgSO_4$), followed by an infusion of 40 mmol Mg^{++} (10 g $MgSO_4$) over the next 5 hours, should be considered. For routine treatment of hypomagnesemia, an infusion of 40 mmol Mg^{++} should be given over a 24-hour period. For outpatients on diuretics with chronic magnesium losses, oral magnesium therapy with 2 to 3 g (12 to 24 mmol) per day is recommended. Orally, magnesium oxide is more easily absorbed than other formulations.

Chapter 17
HYPOCALCEMIA AND HYPERCALCEMIA

Richard J. King • Robert N. Cooney

Abnormal serum calcium is a common finding in critically ill patients. The prevalence of hypocalcemia in intensive care unit (ICU) patients ranges from 70% to 90% when total serum calcium is measured and from 15% to 50% when ionized calcium is measured.[1] Hypercalcemia occurs less frequently; the reported incidence is less than 15% in critically ill patients.[2] Hypocalcemia is associated with injury severity and mortality in critically ill patients.[1,3–6] However, it is not known whether a low serum calcium concentration is protective, harmful, or simply prognostic in critical illness. Therefore, in most instances, the management of hypocalcemia involves treating the underlying medical condition, except when patients are symptomatic or hemodynamically unstable. This chapter provides a brief overview of calcium physiology, the regulation of serum calcium concentration, potential causes and symptoms of hypocalcemia, conditions associated with hypocalcemia, and guidelines for treating hypo- and hypercalcemia in critically ill patients.

CALCIUM PHYSIOLOGY AND METABOLISM

Calcium is a divalent ion (Ca^{++}) involved in critical biologic processes such as muscle contraction, blood coagulation, neuronal conduction, hormone secretion, and the activity of various enzymes.[3,7] Therefore, it is not surprising that intra- and extracellular calcium concentrations are tightly regulated. A normal adult has approximately 1 to 2 kg of total body calcium, localized primarily in bone (99%) as hydroxyapatite.[1,3,4] Skeletal stores of calcium represent a virtually unlimited reservoir. Release of calcium from this reservoir is regulated predominantly by extracellular Ca^{++} concentration, parathyroid hormone (PTH), and calcitonin. Extracellular concentrations of Ca^{++} are typically 10,000 times greater than cytoplasmic Ca^{++} levels.[1,3] Similarly, the majority of intracellular calcium (>90%) is found in subcellular organelles (mitochondria, microsomes, endoplasmic or sarcoplasmic reticulum) as opposed to the cytoplasmic compartment. Ca^{++}-mediated cell signaling involves rapid changes in cytoplasmic Ca^{++} concentration secondary to movement of the ion from both internal and external stores.[8,9] Cytoplasmic Ca^{++} influx occurs through cell membranes by receptor-activated, G protein–linked channels. The release of internal Ca^{++} from endoplasmic or sarcoplasmic reticulum is stimulated by second messengers.[8] The efflux of cytoplasmic Ca^{++} involves transport of Ca^{++} across the cell membrane and into the endoplasmic or sarcoplasmic reticulum by specific transporters.[8–10] Alterations in Ca^{++}-dependent signaling have been identified in muscle, hepatocytes, neutrophils, and T lymphocytes during sepsis and may contribute to the development of organ dysfunction during catabolic illness (for review see reference 9).

Extracellular calcium homeostasis is maintained by the coordinated actions of the gastrointestinal tract, kidneys, and bone.[1,3] Levels of extracellular Ca^{++} are detected by calcium-sensing receptors on parathyroid cells.[10] In response to low serum Ca^{++} concentrations, the parathyroid glands secrete PTH. This hormone reduces renal reabsorption of phosphate, increases renal calcium reabsorption, and stimulates renal hydroxylation of vitamin D.[1,3] PTH and 1,25-dihydroxy-vitamin D (calcitriol) promote the release of calcium from bone by activating osteoclasts.[1,3] Calcitriol also stimulates intestinal absorption of dietary calcium and regulates PTH secretion by inhibiting PTH gene transcription. PTH secretion is also influenced by serum phosphate concentration. Increases in circulating phosphate concentration stimulate PTH secretion by lowering the extracellular Ca^{++} concentration. Magnesium is required for the release of PTH from parathyroid cells, which may explain why hypocalcemia is common in patients with magnesium deficiency. Calcitonin is a calcium-regulating hormone secreted by the parafollicular C cells of the parathyroid glands during hypercalcemia. Although calcitonin inhibits bone resorption and stimulates urinary excretion of calcium, its does not appear to play a major role in calcium homeostasis in humans.[1,3]

The normal concentration of Ca^{++} in the extracellular space (plasma and interstitium) is 1.2 mmol/L and represents 50% of the total extracellular calcium; of the remaining 50%, 40% is bound to plasma proteins and 10% is combined with citrate, phosphate, or other anions. Total serum calcium normally ranges from 9.4 to 10.0 mg/dL (2.4 mmol). The distribution of ionized and bound calcium may be altered in critically ill patients. Chelating substances such as citrate and phosphate can influence the abundance of ionized Ca^{++}. An increased free fatty acid concentration caused by lipolysis or parenteral nutrition results in increased binding of calcium to albumin.[11] Protein-bound calcium is also increased during alkalosis and reduced during acidosis.[1,3] Correcting total serum calcium for albumin and pH does not accurately estimate ionized Ca^{++}.[12,13] Therefore, most ICU laboratories measure ionized calcium. Hypocalcemia is defined as an ionized Ca^{++} level less than 1.0 mmol/L or a total level less than 8.5 mg/dL.[13]

HYPOCALCEMIA IN CRITICALLY ILL PATIENTS

Ionized hypocalcemia is frequently seen in critically ill patients with sepsis, pancreatitis, or severe traumatic injuries or following major surgery. The incidence ranges from 15% to 50%.[3] The degree of hypocalcemia correlates with illness severity as measured by the Acute Physiology and Chronic

Health Evaluation (APACHE) II score and is associated with increased mortality in critically ill patients.[6] In particular, the degree of systemic inflammation as assessed by circulating cytokine or procalcitonin levels appears to correlate with hypocalcemia in ICU patients.[14] Potential causes for the hypocalcemia of critical illness include impaired PTH secretion or action, vitamin D deficiency or resistance, calcium sequestration or chelation, or impaired mobilization of Ca^{++} from bone (Table 17–1).

Hypocalcemia in the ICU is rarely caused by primary hypoparathyroidism. However, sepsis and systemic inflammatory response syndrome are commonly associated with hypocalcemia, which is caused in part by impaired secretion and action of PTH and failure to synthesize calcitriol.[1,3,14] Hypomagnesemia can contribute to hypocalcemia during critical illness by inhibiting PTH secretion and target organ responsiveness.[1,3,7] However, hypomagnesemia correlates with hypocalcemia in ICU patients only weakly.[6] In many instances, the cause of hypocalcemia of critical illness is multifactorial. Elderly patients are at increased risk for vitamin D deficiency owing to malnutrition, poor absorption, and hepatic or renal dysfunction.[3] Renal failure can precipitate hypocalcemia by impairing the formation of calcitrol and promoting hyperphosphatemia; phosphate chelates ionized calcium.[1,3] Other potential causes of ionized hypocalcemia in critically ill patients include alkalosis (increased binding of Ca^{++} to albumin), medications (anticonvulsants, antibiotics, diphosphonates, radiocontrast agents), massive blood transfusion, sepsis, and pancreatitis.[1,3,6,7]

Patients receiving blood transfusions can develop hypocalcemia as a consequence of Ca^{++} chelation by citrate, which is used as an anticoagulant in banked blood.[15–17] The incidence of transfusion-related hypocalcemia is related to both the rate and the volume of blood transfusion.[15,16] When blood transfusions are administered at a rate of 30 mL/kg per hour (2 L/h in a 70-kg patient) and hemodynamic stability is maintained, ionized Ca^{++} levels are preserved by physiologic compensatory mechanisms.[17] Transient hypocalcemia can be observed during rapid transfusion and can be prolonged or exacerbated by hypothermia or renal or hepatic failure.[15–17] Consequently, ionized calcium should be monitored and calcium replaced when clinically indicated during massive transfusion.

HYPOCALCEMIA IN SEPSIS AND PANCREATITIS

Hypocalcemia is especially common in critically ill patients with systemic infection and pancreatitis.[1,3,6,9,14] Animal models of sepsis demonstrate reductions in serum calcium concentration following endotoxin infusion.[9,14,18,19] When septic patients with hypocalcemia were compared with nonseptic controls, increased tumor necrosis factor and interleukin-6 levels were inversely correlated with ionized Ca^{++}.[20] Septic patients with hypocalcemia can have increased or decreased PTH levels; however, urinary excretion of calcium and bone resorption are preserved when compared with controls.[14,20] Procalcitonin levels appear to be increased during sepsis-induced hypocalcemia, but mature calcitonin exerts only a weak and transient effect on calcium levels.[20,21] The collective results from studies of animal models and patients suggest that the cause of hypocalcemia during severe infection is multifactorial, but the effects of inflammatory cytokines, impaired activation of vitamin D, and elevated procalcitonin levels are all contributory.

It is unclear whether sepsis-induced hypocalcemia is pathologic or protective. Calcium administration in experimental sepsis has been shown to increase or have no effect on mortality.[18,19] Similarly, investigations of the effects of Ca^{++} channel blockade on septic mortality demonstrate conflicting results.[22,23] Therefore, although sepsis-induced hypocalcemia is common in critically ill patients, neither routine replacement of calcium nor the use of calcium channel blockers is supported by the existing literature. As with most situations, sepsis-induced hypocalcemia should be treated if patients are symptomatic.

Pancreatitis represents another inflammatory condition that is associated with hypocalcemia in critically ill patients.[1,3,23–25] Saponification of retroperitoneal fat contributes to the development of hypocalcemia in patients with pancreatitis.[3,23–25] In experimental pancreatitis, injection of free fatty acids into the peritoneum induces hypocalcemia in rats.[23] However, the amount of calcium chelated is relatively small compared with the amount available for exchange from calcium stores in the bone reservoir. Interestingly, elevated levels of PTH seen in pancreatitis, as in sepsis, do not result in normalized ionized calcium levels.[25] Although resistance of bone and kidney to PTH may be a factor, it is likely that inflammatory pathways identical to those in sepsis are responsible. In pancreatitis, as in sepsis, hypocalcemia is an indicator of disease severity. As with most clinical conditions, calcium replacement during pancreatitis should be reserved for symptomatic or hemodynamically unstable patients.

SIGNS AND SYMPTOMS OF HYPOCALCEMIA

Hypocalcemia is frequently asymptomatic, and attributable signs or symptoms may be difficult to elucidate in critically

ill patients. In general, the signs and symptoms of hypocalcemia correlate with both the magnitude of the condition and the rapidity of its onset. Neurologic (paresthesias, seizures, dementia) and cardiovascular (hypotension, impaired cardiac contractility, dysrhythmias) signs can be seen with ionized hypocalcemia when Ca^{++} is less than 1.0 mmol/L.[3,7] Neuromuscular symptoms of hypocalcemia include muscle spasms and tetany, when severe. Psychiatric disturbances (dementia, psychosis, depression) also may be attributable to hypocalcemia.[3,7]

Classic signs of hypocalcemia include Chvostek's and Trousseau's signs, which test for latent tetany. Chvostek's sign is an involuntary twitching of facial muscles in response to light tapping of the facial nerve. It is nonspecific and is present in 10% to 25% of normal adults, and it may be completely absent in chronic hypocalcemia. Trousseau's sign is carpopedal spasm induced by reduced blood flow to the hand when a blood pressure cuff is inflated to 20 mm Hg for 3 minutes. Trousseau's sign is also nonspecific and may be absent in a third of patients with hypocalcemia.

Cardiac dysrhythmias such as ventricular tachycardia, prolonged QT interval, and heart block are more serious complications of hypocalcemia.[3,7] In addition, decreased cardiac output and hypotension, especially when refractory to vasopressors and volume infusion, should prompt calcium replacement when hypocalcemia is present.[3,7]

TREATMENT OF HYPOCALCEMIA

Critical thresholds for calcium replacement vary, but severe ionized hypocalcemia (<0.8 mmol/L) and symptomatic hypocalcemia should be replaced in critically ill patients.[1,3,7,26] Calcium treatment of asymptomatic ionized hypocalcemia (>0.8 mmol/L) is usually unnecessary and may be potentially harmful in conditions such as sepsis and cellular hypoxia.[1,3,7,26]

Treatment of hypocalcemia requires intravenous calcium replacement. The two solutions most commonly used are 10% calcium chloride and 10% calcium gluconate. Each solution contains 100 mg/mL of calcium salt and is available in 10-mL ampules. Ten percent calcium chloride contains 27 mg/mL (1.36 mEq) of elemental calcium; 10% calcium gluconate contains 9 mg/mL (0.46 mEq). Typically, 10 mL of 10% calcium gluconate solution is infused over 10 minutes. A total of 200 mg of elemental calcium may be necessary to raise the total serum calcium by 1 mg/dL. Because the effect of calcium infusion is usually brief, a continuous infusion may be necessary. Calcium chloride should not be infused peripherally if calcium gluconate is available; the former can produce tissue necrosis and thrombophlebitis if extravasation occurs.

Hemodynamically unstable patients in the ICU who are hypocalcemic may show a transient increase in blood pressure or cardiac output with calcium administration. This is probably due to increased cardiac performance.[26] However, in the presence of tissue hypoxia, calcium administration may aggravate the cellular injury.[9,13,22] Nonetheless, calcium administration is probably warranted in hypocalcemic, hemodynamically unstable patients, especially those requiring adrenergic support.

HYPERCALCEMIA

Hypercalcemia is rare in critically ill patients, estimated to occur in 1% to 15% of ICU patients.[2] Defined as an increase in serum calcium above 10.4 mg/dL (2.60 mmol/L), hypercalcemia is usually caused by excessive bone resorption. Hyperparathyroidism and humoral hypercalcemia of malignancy are the most common causes of hypercalcemia in hospitalized patients.[2,7,27] Less common causes of hypercalcemia include sarcoidosis, prolonged immobilization, and medications such as thiazide diuretics.

Mild hypercalcemia is usually asymptomatic. However, patients with circulating Ca^{++} concentrations above 12 mg/dL may manifest symptoms of confusion, delirium, psychosis, and coma.[2,7,27] Patients with hypercalcemia may also experience nausea, vomiting, constipation, abdominal pain, and ileus. Cardiovascular effects of hypercalcemia include hypotension, hypovolemia, and shortened QT interval. Profound skeletal muscle weakness may result. Seizures, however, are rare.

Treatment of hypercalcemia should be directed at the underlying medical condition. Saline infusion and diuresis are indicated in symptomatic patients and when the serum calcium level rises above 14 mg/dL (3.5 mmol/L). For patients with underlying malignancy, treatment with salmon calcitonin, pamidronate, or plicamycin may be necessary. These agents act to inhibit bone resorption. Salmon calcitonin should be started at 4 IU/kg every 12 hours via subcutaneous or intramuscular injection. If the response is inadequate after 2 days, the dose may be increased to 8 IU/kg every 12 hours to a maximum of 8 IU/kg every 6 hours. Hydrocortisone can also be used in combination with calcitonin to treat hypercalcemia associated with multiple myeloma. Dosing of pamidronate depends on the severity of hypercalcemia. For a corrected serum calcium level of 12 to 13.5 mg/dL, pamidronate should be given as a single intravenous dose of 60 to 90 mg over 4 to 24 hours. For higher calcium levels, a single 90-mg dose should be given over 24 hours. Longer infusion times (i.e., >4 hours) may reduce renal toxicity. If necessary, retreatment should be initiated only after 7 days have elapsed, to allow time for a complete response to the initial dose. The dose and manner of treatment are the same as for initial therapy. The recommended dose of plicamycin for hypercalcemia is 25 μg/kg daily for 3 to 4 days. Additional treatments may be given at 1-week intervals. Usual maintenance regimens are two to three doses per week.

Chapter 18
HYPOGLYCEMIA

Greet Van den Berghe

DEFINITION AND DIAGNOSIS

Hypoglycemia is the most common endocrine emergency, the most frequent complication of insulin-requiring diabetes, and the principal factor limiting optimization of glycemic control. When unrecognized and not treated appropriately, significant morbidity, including permanent neurologic deficits and death, may ensue. Hypoglycemia is generally defined arbitrarily as a blood glucose concentration less than 50 mg/dL (2.8 mmol/L) with neuroglycopenic symptoms or less than 40 mg/dL (2.2 mmol/L) in the absence of symptoms. Clinically significant hypoglycemia is characterized by Whipple's triad: (1) symptoms of neuroglycopenia, (2) simultaneous blood glucose concentration less than 40 mg/dL (2.2 mmol/L), and (3) relief of symptoms with the administration of glucose. This blood glucose concentration cutoff corresponds to a plasma glucose concentration of 45 mg/dL (2.5 mmol/L). All three criteria should be met to establish a diagnosis of hypoglycemia, at least outside the intensive care unit (ICU), because a precipitous fall from hyperglycemia to euglycemia in a patient with diabetes can produce hypoglycemic symptoms,[1] and because asymptomatic hypoglycemia with glucose levels as low as 30 mg/dL (1.7 mmol/L) can occur during fasting in normal women and during pregnancy.[2] In the ICU, however, sedation can mask symptoms of neuroglycopenia and counterregulatory responses may be impaired, which complicates the diagnosis of hypoglycemia in this setting. Further, asymptomatic patients can have artifactual hypoglycemia due to in vitro consumption of glucose by blood cells (especially when the blood leukocyte count is very high).

A hypoglycemic disorder should be suspected whenever the blood glucose reading is low. However, most reflectance glucometers in home and hospital use have poor precision at low levels of blood glucose.[3] Caution should be exercised with alternative-site capillary blood glucose testing, which has been demonstrated to have a 30-minute lag time compared with finger-stick testing for the detection of hypoglycemia.[4] The recently developed continuous interstitial glucose monitoring system[5] and the noninvasive Glucowatch Biographer[6] are less effective at detecting low blood glucose levels and can have a delayed response to low blood glucose concentrations. Therefore, the laboratory measurement of a low plasma glucose concentration, in the presence of appropriate symptoms, remains the most reliable way to diagnose severe hypoglycemia. In the ICU, the measurement of arterial blood glucose concentration using modern blood gas analyzers approaches the accuracy of conventional laboratory methods.[7]

INCIDENCE OF SEVERE HYPOGLYCEMIA

Although the frequency of severe hypoglycemia in diabetes is well documented, there is little information on the incidence of serious hypoglycemia in nondiabetic subjects or in the general population. A retrospective study of adults requiring hospitalization indicated that 0.4% of acute medical admissions per year are hypoglycemia related.[8] In a prospective study of 130 hospital admissions due to adverse drug reactions, hypoglycemia was the fourth most common disorder.[9] A review of 54,850 autopsies in a large medical center revealed 123 deaths (0.2%) due to hypoglycemic coma.[10] Because of the difficulty of postmortem diagnosis and frequent associated comorbidities, severe hypoglycemia is often unrecognized, particularly in nondiabetic individuals.

Severe hypoglycemia occurs commonly in patients with diabetes, even if the stringent definition of the Diabetes Control and Complications Trial is employed (i.e., symptoms severe enough to require assistance for treatment). Hypoglycemia occurs at least once a year in up to 30% of patients with type 1 diabetes.[11] In type 2 diabetes, even with intensive therapy, the risk is probably 100-fold less. Over 6 years of observation in the United Kingdom Prospective Diabetes Study, severe hypoglycemia was reported in 2.4% of patients treated with metformin, 3.3% of those treated with a sulfonylurea, and 11.2% of those treated with insulin.[12] However, when matched for duration of insulin therapy and circulating levels of HbA_{1c}, the frequency of severe hypoglycemia was similar in type 1 and type 2 diabetes.[13] As insulin usage among patients with type 2 diabetes increases, it is inevitable that severe hypoglycemia will become more common in daily practice.

With the introduction of tight blood glucose control in the surgical ICU, the incidence of blood glucose values below 40 mg/dL (2.2 mmol/L) has been reported to range from 0.8% to 5.2% of patients, depending on the targeted level of blood glucose control.[7] With the use of algorithms advising frequent blood glucose measurements (i.e., every 1 to 4 hours), brief episodes of such low blood glucose levels do not impose a major risk of sequelae.

PATHOPHYSIOLOGY

The central nervous system relies primarily on glucose for the generation of cellular energy. Cells in the central nervous system have endogenous glucose reserves that are sufficient for only minutes if the supply of glucose from the bloodstream is inadequate. In addition, neurons are unable to synthesize glucose. Finally, the brain cannot use fuels other

than glucose during acute hypoglycemia.[14] Hence, when the brain is acutely deprived of glucose, serious neurologic dysfunction occurs. Therefore, the body has several mechanisms to maintain the plasma glucose concentration within the narrow range of 60 to 140 mg/dL (3.3 to 7.7 mmol/L) in both the fed and fasting states. When glucose use exceeds glucose production, the brain senses decreasing glucose levels and activates counterregulatory pathways. The glucose threshold for activation of these mechanisms is approximately 67 mg/dL (3.6 mmol/L), but this setpoint can be altered by recent hyperglycemia or antecedent hypoglycemia. The important components of the endocrine defense against hypoglycemia were identified in the 1980s.[15] As glucose levels decline, the first counterregulatory mechanism is the suppression of endogenous insulin secretion. Next in the hierarchy of responses is the release of two hormones, glucagon and epinephrine, that antagonize the action of insulin. These hormones activate glycogenolysis and gluconeogenesis and stimulate fatty acid oxidation and protein breakdown to provide substrates for gluconeogenesis. With more severe or prolonged hypoglycemia (>3 hours), increases in growth hormone and cortisol release raise the blood glucose level.

The physiologic responses to hypoglycemia and the glucose threshold at which they occur can be modulated in normal and diabetic humans. In type 1 diabetes, the glucagon response to hypoglycemia is lost within 3 years after diagnosis, rendering patients dependent on epinephrine-mediated counterregulation and making them more vulnerable to prolonged episodes of severe hypoglycemia. Exposure to antecedent hypoglycemia diminishes the counterregulatory response to a subsequent episode. The brain adapts to antecedent hypoglycemia by increasing glucose uptake so that a more profound hypoglycemic stimulus is required to trigger sympathoadrenal activation and autonomic symptoms.[16] Also, the level of glycemic control affects counterregulatory thresholds. With strict glycemic control, epinephrine release is not triggered until a lower glucose level is reached.[17,18] Conversely, diabetic patients with poor glycemic control can experience hypoglycemic symptoms when the blood glucose concentration decreases to lower values within the normal or even hyperglycemic range.[19]

There are four pathophysiologic mechanisms capable of exceeding the body's counterregulatory capacity and causing severe hypoglycemia: (1) excessive insulin effect, (2) diffuse hepatic dysfunction, (3) limited substrate for gluconeogenesis, and, rarely, (4) excessive glucose consumption. More than one mechanism can be operative in critically ill patients.

DIFFERENTIAL DIAGNOSIS

Hypoglycemia is commonly classified as (1) drug or toxin induced, (2) fasting induced, or (3) postprandial. An alternative clinical classification of hypoglycemic disorders separates patients who appear healthy (with or without coexistent disease) from those who appear ill (including those with a predisposing illness and those who are hospitalized). For otherwise healthy patients, the most important causes of fasting hypoglycemia are accidental or factitious drug ingestion and insulinoma. The differential diagnosis in ill or hospitalized patients includes predisposing illness, drug interactions, and other iatrogenic factors (Table 18–1).[20]

Insulin treatment of diabetes is the most common cause of hypoglycemia in adults. Risk factors for frequent severe hypoglycemia in type 1 diabetes include lower HbA_{1C} levels, higher daily insulin dose, longer duration of diabetes, absence of residual C peptide, and a prior history of severe hypoglycemia.[11] Hypoglycemia unawareness is the loss of autonomic warning symptoms of developing hypoglycemia. It affects approximately 25% of subjects with type 1 diabetes and is an important predictor of severe hypoglycemia. Insulin-treated type 2 diabetics are also vulnerable to severe hypoglycemia, especially if their disease is well controlled and they have been on insulin for many years.[13] Whether intensive insulin therapy increases the incidence of severe hypoglycemia is controversial.[21-23] Switching from animal to human insulin does not result in an increased incidence of severe hypoglycemia,[24] and newer insulin analogs, such as glargine and lispro, as well as continuous delivery systems, may lessen the risk of fasting or postprandial severe hypoglycemia.[25-27]

Sulfonylureas are a common cause of severe hypoglycemia.[28] The incidence is higher in the elderly and with the use of long-acting agents, such as chlorpropamide and glyburide (glibenclamide),[29] although the latter remains controversial.[19] Liver dysfunction prolongs the hypoglycemic

TABLE 18–1. DIFFERENTIAL DIAGNOSIS OF HYPOGLYCEMIA

	Increased Insulin Effect	Hepatic Dysfunction	Decreased Substrate	Increased Glucose Consumption
Drug/toxin	Insulin overdose Sulfonylureas Rodenticide Vacor Pentamidine Quinine Angiotensin-converting enzyme inhibitors	Ethanol Nonselective beta blockers	Chronic renal insufficiency	Exercise
Fasting	Insulinoma Autoimmune disease Insulin-like growth factor-II–secreting tumor	Congestive heart failure Septic shock Combined endocrine deficiencies	Uremia Severe wasting	Large tumors Prolonged exercise
Postprandial	Upper gastrointestinal surgery (e.g., Bilroth II) Ethanol Noninsulinoma Pancreatogenous hypoglycemia	Unripe akee fruit (*Blighia sapida*) (hypoglycin)		

activity of tolbutamide, acetohexamide, glyburide, and glipizide. Renal insufficiency especially prolongs the activity of chlorpropamide and glyburide. A crude rate of serious hypoglycemia of 1.23 per 100 person-years has been reported in elderly users of sulfonylureas.[30] Sulfonylurea-induced hypoglycemia can be prolonged (up to 27 days), with recurrences after initial normalization of glucose levels.[31] Discovery of inadvertent or factitious sulfonylurea overdose may avoid an exhaustive search for insulinoma in patients presenting with hyperinsulinemic hypoglycemia.[32]

The metabolism of ethanol depletes hepatocellular levels of nicotinamide-adenine dinucleotide, which is a cofactor critical for the entry of substrates into gluconeogenesis pathways.[33] Ethanol also inhibits cortisol and growth hormone responses and delays the epinephrine response to hypoglycemia.[34] However, ethanol does not inhibit glycogenolysis. Therefore, ethanol-induced hypoglycemia does not occur until hepatic glycogen stores have been depleted (after 8 to 12 hours of fasting).[35] There is no correlation between blood ethanol levels (although alcohol is usually detected) and the degree of hypoglycemia, and severe hypoglycemia can occur with ethanol levels as low as 45 mg/dL. The incidence of alcohol-induced hypoglycemia is generally less than 1% in adults, but hypoglycemic coma is commonly related to ethanol ingestion.[36]

In the absence of a drug or toxic cause, adults with severe fasting hypoglycemia should be evaluated for insulinoma, insulin-secreting tumor of the islets of Langerhans,[37] or unusual causes, such as excessive production of insulin-like growth factor II or rapid glucose consumption by tumors, diffuse hepatic dysfunction, septic shock, panhypopituitarism, polyglandular endocrine deficiency syndromes, and autoimmune hypoglycemia. The diagnosis of postprandial (reactive) hypoglycemia remains controversial.[38]

CLINICAL PRESENTATION

The symptoms of hypoglycemia can be divided into autonomic and neuroglycopenic. Autonomic symptoms such as sweating, palpitations, tremor, and hunger are due to the effects of increased activation of the sympathetic nervous system in response to blood glucose levels of approximately 55 mg/dL (3.7 mmol/L). Elderly patients report fewer autonomic symptoms.[39] Neuroglycopenic symptoms are due to impairment of cerebral functioning and include confusion, odd behavior, drowsiness, difficulty with speech, blurred vision, hemiplegia (Todd's palsy), seizure, and coma. Neuroglycopenic symptoms occur at blood glucose levels of approximately 45 mg/dL (2.5 mmol/L). Symptoms of hypoglycemia appear to be similar in type 1 and type 2 diabetes[13] and whether they are induced by sulfonylureas, insulin, or its analogs.[24,40,41]

Patients with hypoglycemia unawareness have a sevenfold increased risk of severe hypoglycemia, and episodes of hypoglycemia in these patients can be recurrent and unpredictable.[42] Likely pathogenic mechanisms for hypoglycemia unawareness include recurrent exposure to hypoglycemia, with subsequent increases in brain glucose uptake and possibly reduced beta-adrenergic sensitivity.[43,44] Fortunately, scrupulous avoidance of hypoglycemia for a period of weeks to months restores hypoglycemia awareness.[45,46] Surgical removal of an insulinoma also restores autonomic symptoms of hypoglycemia.[47]

EVALUATION

The first step in the evaluation of a patient with suspected hypoglycemia is documentation of low plasma glucose concentration in the presence of neuroglycopenic symptoms (Fig. 18–1). Unless there is an obvious medication-related cause for severe hypoglycemia, blood should be drawn for the measurement of glucose, insulin, and C peptide before the administration of glucose and, when indicated, for the diagnosis of thyroid hormone and cortisol deficiency or uremia. In cases of fasting hypoglycemia, intentional, accidental, or surreptitious ingestion of glucose-lowering medications should be investigated to avoid the lengthy workup for insulinoma.[37] Sulfonylurea ingestion causes elevated insulin and C peptide levels, which mimics the findings associated with an insulinoma. Confirmation of the diagnosis of sulfonylurea ingestion can be made using high-pressure liquid chromatography or radioimmunoassay to detect sulfonylureas in blood or urine. The results of these tests are extremely important for further management.

MANAGEMENT

In all cases of suspected severe hypoglycemia, a patent airway and hemodynamic stability should be secured while a rapid bedside estimation of blood glucose is performed. In cases of suspected overdose, emesis should not be induced in a hypoglycemic patient. When alcohol abuse is suspected, thiamine (100 mg i.v. or i.m. per day until the patient is consuming a complete diet) should be given to avoid acute Wernicke's encephalopathy. Administration of glucose is the fundamental remedy. In an awake patient with a protected airway, an initial dose of 20 g of glucose orally works. Examples of oral carbohydrates suitable for the correction of hypoglycemia are flavored glucose tablets and juices and sodas high in sugar content. A response should occur within 10 to 15 minutes and typically lasts 1 to 2 hours. Hence, a snack is advisable to avoid recurrent hypoglycemia.

When patients are unwilling or unable to take oral carbohydrates, intravenous dextrose (glucose) should be given. The recommended initial dose of 50 mL of 50% dextrose provides 25 g dextrose and, within 5 minutes, produces a mean rise in blood glucose to 220 mg/dL (12.5 mmol/L) from nadir values as low as 20 mg/dL (1.1 mmol/L).[48] In ICU patients receiving insulin by continuous intravenous infusion and also receiving a baseline enteral or intravenous glucose load, an additional 10-g glucose bolus is usually sufficient to correct hypoglycemia, and the smaller glucose load avoids the need to greatly modify the insulin dosing regimen.[7,49] For prolonged hypoglycemia (e.g., caused by sulfonylurea overdose), prolonged dextrose infusion plus octreotide may be required.[50]

Parenteral glucagon directly stimulates hepatic glycogenolysis. Glucagon is effective in restoring consciousness if given soon after the onset of hypoglycemic coma. Glucagon is particularly effective in pancreatectomized patients but is much less useful in type 2 diabetes because it stimulates insulin secretion as well as glycogenolysis. Patients with depleted glycogen stores, such as those with alcohol-induced hypoglycemia, may not respond to glucagon. Adverse reactions to glucagon administration include nausea and vomiting, delaying carbohydrate ingestion.

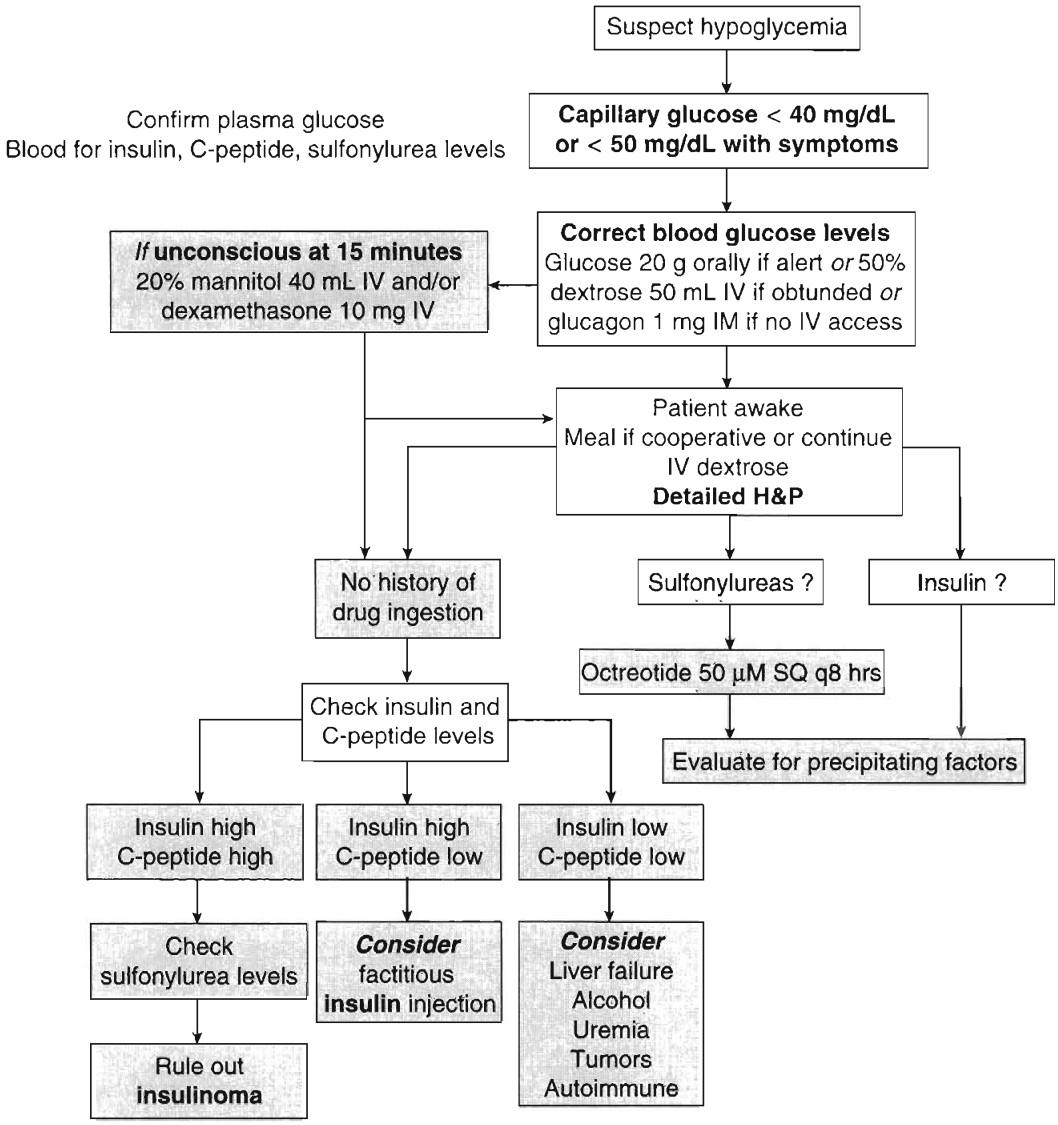

FIGURE 18–1. Approach to severe hypoglycemia in adults. H & P, history and physical examination

In cases of sulfonylurea overdose, octreotide is more effective than diazoxide for reversing hyperinsulinemia, reducing dextrose requirements, and preventing recurrent hypoglycemia.[50] The recommended dose of octreotide as an antidote for sulfonylurea overdose is 50 µg subcutaneously, repeated every 8 hours if necessary. Activated charcoal binds sulfonylureas and can be administered in cases of suspected overdose.

Cerebral edema can complicate severe hypoglycemia and should be suspected when unconsciousness lasts more than 30 minutes following normalization of blood glucose. Treatment with intravenous mannitol (40 mL of a 20% solution) and glucocorticoids (10 mg of dexamethasone) in addition to intravenous dextrose is advised.

SEQUELAE

Although severe hypoglycemia induces marked cognitive dysfunction,[51] most patients recover rapidly and completely.[52] The effect of repeated severe hypoglycemia on cognitive function in adults is controversial.[53,54] Although focal neurologic symptoms secondary to severe hypoglycemia occur occasionally, severe and permanent cognitive impairment is usually the result of protracted hypoglycemia, often in association with excess alcohol consumption.

The overall mortality from severe hypoglycemia is unknown. The mortality rate from alcohol-induced hypoglycemia may be as high as 10% in adults.[36] An estimated 2% to 4% of deaths in patients with type 1 diabetes have been attributed to hypoglycemia. Severe hypoglycemia is the cause of unexpected overnight death in young diabetic patients,[55] which is explained by the impairment of hormonal responses to hypoglycemia during sleep in normal and diabetic patients.[47,56]

Chapter 19
ANEMIA OF CRITICAL ILLNESS

Ali Hallal • Carl Schulman • Stephen Cohn

Anemia is a common clinical problem in the ICU. In the United States, 12.4 million units of blood were transfused into 4.5 million patients in 1999, with about 25% given to the critically ill.[1] Approximately 85% of patients spending more than 1 week in the ICU receive 1 or more units of packed red blood cells (RBCs) in their first week and continue to require 2 to 3 units of blood per week thereafter.[2] A recent multicenter European study showed that 37% of patients in the ICU are transfused.[3] Similarly, a multicenter observational study in the United States evaluated 4992 patients from 284 different ICUs and found that 44% of patients received at least one transfusion during their ICU stay.[4]

Blood is an increasingly scarce resource. The National Blood Data Resource Center suggests that the need for blood transfusion in the United States will exceed its availability in the near future. Patients have historically been transfused at a hemoglobin (Hb) threshold of 10 g/dL. Over the last decade, several studies have shown that packed RBC transfusion is independently associated with worse clinical outcomes, independent of the degree of anemia or the severity of illness. The scarcity of blood and the considerable economic impact of blood transfusion (about $500 per unit) have prompted new approaches for the management of anemia in the ICU.

There are three major classes of anemia: (1) hypoproliferative anemia secondary to marrow production defects, (2) ineffective erythropoiesis caused by red cell maturation defects, and (3) decreased survival of red cells secondary to blood loss, hemolysis, or both (Fig. 19-1). The majority of anemia cases (75%) are hypoproliferative. The pathogenesis of this type of anemia is explained by a form of marrow dysfunction characterized by inadequate erythropoiesis in response to the degree of anemia. Most cases of anemia encountered in critically ill patients are of the hypoproliferative type, although other causes may play a role.

BASIC LABORATORY PARAMETERS

The complete laboratory evaluation of anemia is beyond the scope of this chapter; only the pertinent iron studies that aid in understanding the pathogenesis of anemia of the critically ill are discussed. Of these, the most important laboratory tests are measurements of serum iron concentration, serum transferrin and transferrin receptor protein concentrations, total iron binding capacity, and serum ferritin concentration.

Iron absorbed from food or released from stores circulates in plasma bound to transferrin, the iron transport protein. The iron-transferrin complex interacts with a specific transferrin receptor protein on the surface of early erythroid cells. Subsequently, the complex is internalized, and iron is released intracellularly. Within erythroid cells, iron in excess of the amount needed for hemoglobin synthesis binds to the storage protein apoferritin, forming ferritin. Iron in the ferritin pool can be released and reused in the iron metabolism pathway. The serum ferritin level correlates with the total body iron stores and, therefore, is the most suitable laboratory estimate of iron stores.[5] During the maturation of reticulocytes to erythrocytes, the cells lose all activities of the components of the hemoglobin-synthesizing system, including transferrin receptor proteins, which are released into the circulation.[6] The level of transferrin receptor protein in the circulation provides a quantitative measure of total erythropoiesis and can be used to measure the expansion of the erythroid marrow in response to recombinant erythropoietin therapy. The serum iron level represents the amount of circulating iron bound to transferrin. The total iron binding capacity is an indirect measure of the circulating transferrin. Once the iron binding capacity of transferrin is exceeded, the expression of transferrin receptor protein decreases, limiting further access of iron into the cells. The normal range for serum iron is 50 to 150 μg/dL; the normal range for total iron binding capacity is 300 to 360 μg/dL, and transferrin saturation is normally 25% to 50%. Iron deficiency states are associated with a transferrin saturation of less than 18%. The normal values of ferritin vary with age and gender. Adult men have ferritin levels averaging approximately 100 μg/dL, whereas adult women have levels around 30 μg/dL. Normal values for transferrin receptor protein concentration are 4 to 9 μg/L.[5] Because the anemia of critical illness is caused by impaired iron release and a blunted response to erythropoietin, the laboratory findings in this syndrome are characterized by a low serum iron concentration, low total iron binding capacity and transferrin saturation, normal transferrin receptor protein level, and normal to high ferritin level.

CAUSE AND PATHOGENESIS

Anemia in critically ill patients is the result of multiple factors, including (1) blood loss secondary to phlebotomy, gastrointestinal bleeding, coagulation disorders, or surgical procedures; (2) bone marrow depression secondary to renal failure or chronic diseases; (3) nutritional deficiencies; and (4) immunologically mediated iron deficiency in combination with a blunted response to erythropoietin.

Blood loss due to phlebotomy is an often unrecognized yet significant cause of anemia in the ICU. A recent study

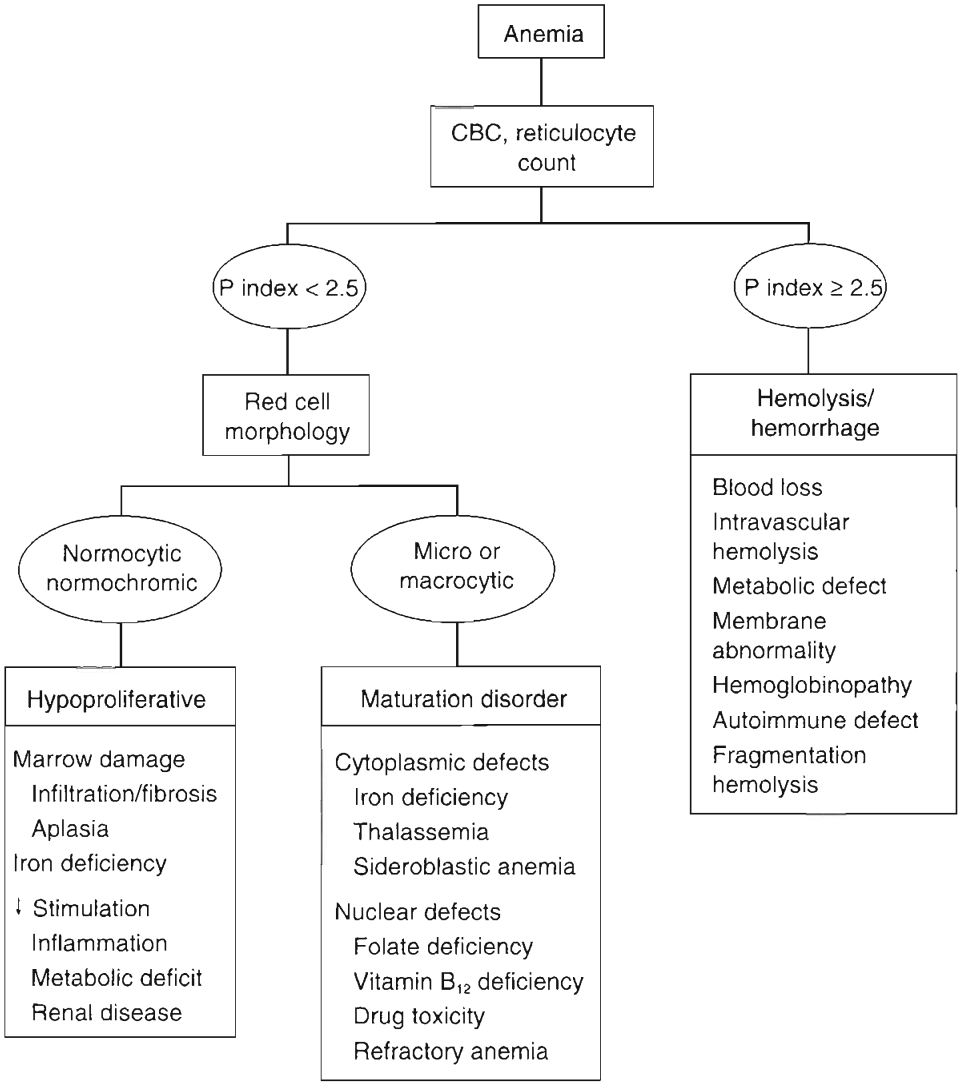

FIGURE 19–1. Physiologic classification of anemia. The reticulocyte production index (P index) is a correction of the reticulocyte count based on the level of anemia and the circulatory life span of a prematurely released reticulocyte. CBC, complete blood count. (From Adams JW, Longo DL: Anemia and polycythemia. In Braunwald E, Fauci AS, Kasper DL, et al: Harrison's Principles of Internal Medicine, 15th ed. New York, McGraw-Hill, 2001, p 352.)

showed that patients admitted to the ICU are phlebotomized an average of 4.6 times a day, for an average total volume of 41.1 mL.[3] Patients with arterial catheters have blood drawn four times a day, for a mean of 944 mL over the course of an ICU stay.[7] Approximately half of patients are transfused as a direct result of excessive phlebotomy.[2]

Although rare since the advent of effective gastrointestinal prophylaxis, gastrointestinal bleeding can be a serious problem in the ICU. The overwhelming majority of critically ill patients demonstrate evidence of mucosal damage within the first 24 hours of their admission to the ICU. Overt anemia occurs in 5% of patients with stress-related gastrointestinal bleeding. Clinically important bleeding necessitating transfusion is observed in only 1% to 4% of critically ill patients.[8] Stress gastritis occurs predominantly in critically ill patients on mechanical ventilation and those with coagulopathy.[9]

Anemia of critical illness is a distinct multifactorial entity, although it is similar in many respects to the anemia of chronic disease. Inflammation appears to be a major factor, causing an alteration in the metabolism of intracellular iron. In addition, these patients have a blunted response to erythropoietin, which leads to a decrease in RBC production.[10,11] In anemia related to critical illness, there is also a decrease in iron availability, secondary to a decrease in both iron reutilization and iron absorption.[12,13]

When iron availability is reduced, critically ill patients who are anemic fail to respond with an appropriate increase in circulating erythropoietin levels. In addition, their reticulocytes are unable to respond suitably to endogenous erythropoietin.[10] Erythropoietin is a glycoprotein with a molecular weight of approximately 34,000 daltons; it is produced mainly in the kidney and, to a lesser extent, in the liver. The primary role of erythropoietin is to regulate RBC production. It also is required for the survival and differentiation of erythroid progenitors in the bone marrow, but it is not responsible for the commitment of stem cells to the erythroid lineage.[14] Erythropoietin production is regulated by hypoxia, which leads to an increase in its gene transcription; it then exerts its action in the bone marrow by stimulating the expression of erythroid colony-forming units that become mature erythrocytes. As tissue oxygenation improves, receptors in the kidney act to down-regulate the production of erythropoietin through a negative feedback mechanism.

The erythropoietin response observed in critically ill patients appears to result from inhibition of the erythropoietin gene by inflammatory mediators. Interleukin-1 beta and

tumor necrosis factor are known to suppress gene expression and erythropoietin production in isolated, perfused rat kidneys and in human hepatoma cell cultures.[15] Interleukin-6 is also an inhibitor of erythropoietin production in the kidney.[15]

The clinical data demonstrate that critically ill patients fail to produce the appropriate amount of endogenous erythropoietin in response to anemia and also have a markedly blunted response to exogenously administered erythropoietin. Rogiers and coworkers compared erythropoietin concentrations in critically ill patients and in those with iron deficiency anemia.[16] Serum erythropoietin concentrations were serially determined by enzyme-linked immunosorbent assay in 36 critically ill, nonhypoxemic patients who stayed more than 7 days in the ICU. Eighteen ambulatory patients with iron deficiency anemia served as the control group. Although erythropoietin concentrations in the critically ill patients were somewhat greater than those in adults without anemia, they were significantly lower than those measured in the control group at similar hematocrits. Whether the critically ill patient is a trauma victim[17] or a surgical, medical,[18] or pediatric patient,[19] the anemia encountered in the ICU appears to be the result of both a blunted response to erythropoietin and abnormalities in iron metabolism (Fig. 19-2). The cascade of events contributing to anemia in the critically ill is summarized in Figure 19-3.

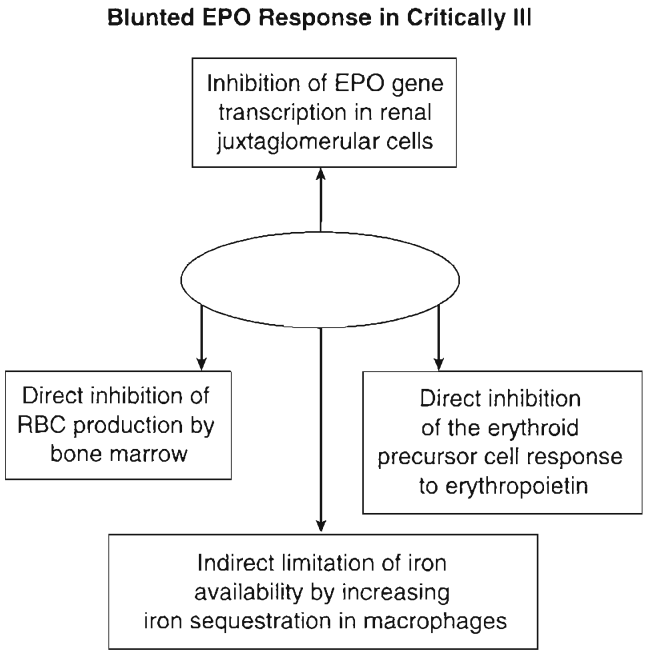

FIGURE 19–2. The inflammatory response that occurs early in injury is related to the release of proinflammatory mediators. This leads to the inhibition of erythropoietin (EPO) gene transcription in the renal juxtaglomerular cells. The inflammatory response has a direct inhibitory effect on red blood cell (RBC) production in the bone marrow and also inhibits the erythroid precursor cell response to erythropoietin. The availability of iron is limited due to decreased iron absorption and increased iron sequestration. IFN, interferon; IL, interleukin; TGF, transforming growth factor; TNF, tumor necrosis factor. MANAGEMENT

BLOOD TRANSFUSION

Blood transfusion is the standard management of anemia in the critically ill. Among the issues being reevaluated are the identification of patients who might benefit from conservative treatment of anemia and the threshold for transfusion at which the benefits outweigh the risks. These risks include infectious disease transmission, immune-mediated reactions (acute or delayed hemolytic reactions, febrile allergic reactions, anaphylaxis, and graft-versus-host disease), and non–immune-related complications (fluid overload, hypothermia, electrolyte toxicity, and iron overload).

Current estimates of the risk of infection per unit of blood are approximately 1 in 2 million for human immunodeficiency virus, 1 in 1 million for hepatitis C virus, and 1 in 100,000 for hepatitis B virus.[20] The most common transfusion-related infections are secondary to bacterial contamination, which occurs 12.6 times per 1 million units of allogeneic blood components transfused.[21] The risk of bacterial contamination is higher for packed cells than for whole blood. With RBC transfusion, gram-positive cocci (staphylococcal and streptococcal species) represent 58% of cases, gram-negative bacteria (*Yersinia enterocolitica*) represent 32%, and other bacteria represent 10%. In one study, 26.5% of cases of infection (49 of 185) were considered a serious threat, and 9.7% (18 of 185) had a fatal outcome. Overall, bacterial contamination accounted for 22% of all transfusion-related deaths.[21]

The incidence of major ABO mismatching is estimated at 1 in 138,673 RBC units.[21] Surprisingly, there is no significant difference in the incidence of major ABO mismatching between patients receiving allogeneic and autologous transfusion. The incidence of ABO mismatch-related death is around 1 per 2 million units transfused.[21] Despite advances in the understanding of red cell antigens, fatal acute hemolytic reactions still occur in 1 of every 250,000 to 1 million transfusions.[22]

Half of all deaths from acute hemolytic reactions are caused by ABO incompatibility. One in 1000 patients

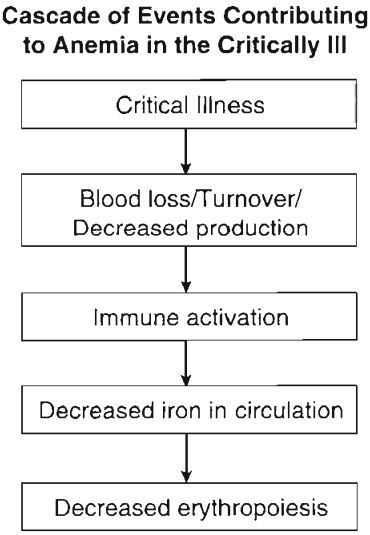

FIGURE 19–3. Summary of the cascade of events leading to anemia in the critically ill. (Adapted from Advancement in Critical Care Education (ACCE): Managing Anemia in the Surgical Patient. Princeton, NJ, DesignWrite, 2003, p 7, fig 1.)

demonstrates clinical manifestations of a delayed hemolytic transfusion reaction.[22] Hemolytic transfusion reaction occurs as a result of antigens that are not routinely detected by antibody assays before transfusion.

Transfusion-related acute lung injury is a serious complication with clinical symptoms similar to those of acute respiratory distress syndrome.[23] It is estimated that transfusion-related acute lung injury occurs in 1 of 5000 transfusions and has a mortality rate of 5% to 10%.[23] The pathogenesis of transfusion-related acute lung injury is still not well understood, but a two-hit hypothesis has been advanced to explain why some blood transfusion recipients develop the condition and others do not. The first hit is thought to be the priming of neutrophils, and the second hit is postulated to involve the transfusion of a lipid cytokine or an antibody that activates the primed neutrophils, leading to an inflammatory process.[23] Unfortunately, treatment is currently limited to supportive measures.

Transfused blood appears to be an immunosuppressive agent. Numerous clinical studies have examined the association of perioperative allogeneic blood transfusion with either cancer recurrence or postoperative bacterial infection,[24-32] as well as organ dysfunction. Clinical evidence of transfusion-associated immunomodulation was initially suggested by Opelz and colleagues in 1973, when improved renal allograft survival was demonstrated in patients transfused before transplantation.[25] Although several theories have been postulated to explain transfusion-associated immunomodulation, both animal and human data suggest that it is most likely secondary to the effect of transfused white blood cells (WBCs).

Seven randomized, controlled trials designed to investigate the impact of allogeneic blood transfusion on the incidence of postoperative infection have yielded contradictory findings.[26-32] Van de Watering and colleagues looked at the effect of leukocyte-depleted versus buffy coat–reduced blood transfusion in cardiac surgery patients.[29] Their study detected an association between WBC-containing allogeneic blood transfusion and postoperative mortality from causes other than postoperative infection. Multivariate regression analysis showed that the number of RBC units transfused was the most significant predictor of postoperative mortality. Patients who received leukocyte-depleted blood transfusion had a significantly reduced mortality. Jensen and colleagues, studying patients undergoing colorectal surgery, observed a 71% reduction in the incidence of postoperative infection in recipients of poststorage leukocyte-depleted transfusions.[28] Houbiers and colleagues, in a similar study, found no difference in the incidence of postoperative infection between the two groups.[31] The existing data from the various studies, although not compelling, justify a high degree of suspicion that an adverse transfusion-associated immunomodulation effect does exist. Because the evidence implicates allogeneic WBCs in the production of transfusion-associated immunomodulation, several western European countries and Canada have instituted the universal reduction of WBCs in all transfused blood components. Appropriately designed clinical studies are still needed to confirm the benefit of leukocyte-depleted blood transfusions.

Vamvakas and Carven reported that patients who received allogeneic transfusions perioperatively had significantly longer hospital stays.[33] These observations concur with the data collected by Taylor and coworkers, who reviewed the relationship between transfusion and infections in a medical-surgical-trauma ICU.[34] The nosocomial infection rate for the entire cohort was 6%. The nosocomial infection rates for the transfusion and nontransfusion groups were 15% and 3%, respectively ($P < 0.005$). The chance of infection increased 1.5-fold with each unit of packed RBCs transfused. After adjusting for age and the probability of survival, nosocomial infection still occurred at a consistently higher rate in patients who were transfused. Certainly, the fact that patients requiring transfusion are likely more ill remains a confounding factor in these studies.

TRANSFUSION OF THE CRITICALLY ILL

The overuse of transfusion is a significant problem. In 1995 Corwin and colleagues reported that 40% of transfusion events in the ICU had no clinical indication.[2] More recently, a large multicenter U.S. trial showed that patients who were transfused did not differ significantly with respect to their mean pretransfusion hemoglobin, admitting diagnosis, or indication for transfusion.[3] Thus, it appears that the hemoglobin value is still the major determinant in the decision to transfuse. Several questions need to be answered when we consider transfusing critically ill anemic patients: (1) Is a low hematocrit harmful to the critically ill patient? (2) What is the lowest tolerable hemoglobin concentration? (3) Will RBC transfusion benefit the anemic critically ill patient?[35]

A reasonable indication for the transfusion of RBCs is to augment the oxygen carrying capacity of the blood. Unfortunately, there is a lack of data defining the hemoglobin concentration in humans that hinders adequate oxygen delivery and initiates tissue hypoxia.[36] Studies in animals and humans show that the oxygen extraction ratio (O_2 consumption/O_2 delivery) progressively increases as a compensatory response to hemodilution. However, isovolemic hemodilution to a hemoglobin concentration of 5 g/dL in resting humans does not produce evidence of inadequate systemic oxygen delivery or adverse clinical effects.[36] This finding is consistent with data obtained by studying anemic patients who refuse transfusion.[37] Recently a Canadian trial demonstrated that a restrictive transfusion strategy (transfusion trigger: hemoglobin concentration of 7 to 9 g/dL) was at least equivalent if not superior to a liberal transfusion strategy (transfusion trigger: hemoglobin concentration of 10 to 12 g/dL).[38]

The optimal hemoglobin concentration in critical illness is unknown. Nelson and colleagues observed that postoperative anemia of less than 28% is associated with a significant increase in myocardial ischemia and morbid cardiac events among high-risk patients undergoing infrainguinal arterial bypass procedures.[39] Fang and colleagues reported that the lowest hematocrit during cardiopulmonary bypass (<14% for low-risk patients and <17% for high-risk patients) was an independent risk factor for mortality among patients undergoing coronary artery bypass grafting.[40] Similarly, Carson and colleagues studied the effect of anemia in Jehovah's Witnesses undergoing surgery.[41] They demonstrated that a low preoperative hemoglobin or a substantial operative blood loss was associated with an increase in the risk of death or serious morbidity only in patients with cardiovascular disease. Gould and colleagues investigated the impact of anemia on surgical mortality in a historical control group who refused blood for religious reasons.[42] Their study showed a rise in mortality in perioperative

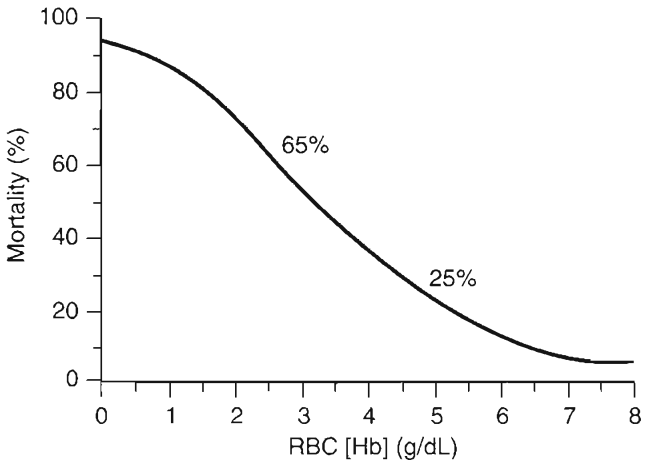

FIGURE 19–4. Mortality and hemoglobin levels in historical controls who refused blood for religious reasons. Note the sharp rise in mortality at hemoglobin levels less than 5 g/dL. RBC, red blood cell. (Adapted from Gould SA, Moore EE, Hoyt DB, et al: The life-sustaining capacity of human polymerized hemoglobin when red cells might be unavailable. J Am Coll Surg 2002;195:445-452, fig 4.)

patients as the hemoglobin level decreased below 5 g/dL (Fig. 19-4). The treatment of anemia in elderly patients (older than 65 years) is not as well defined as in other populations. Wu and colleagues demonstrated that blood transfusion is associated with a lower short-term mortality rate in elderly patients with acute myocardial infarction and a hematocrit less than 30.[43] Clearly, transfusion practices must be individualized to consider all disease processes and existing comorbidities.

Typically, blood is administered to improve oxygen delivery to the tissues. Although blood transfusion might acutely increase oxygen delivery, a matching improvement in tissue oxygen consumption is not necessarily seen, particularly in sepsis. For example, Dietrich and coworkers demonstrated that increasing oxygen carrying capacity with blood transfusion did not improve tissue oxygenation or decrease lactate levels in patients with shock.[44] The same conclusion was reached by Silverman and colleagues in a study evaluating the efficacy of dobutamine or packed RBC transfusion on splanchnic tissue oxygen utilization.[45] Indeed, blood transfusion may have an unfavorable impact on oxygen delivery in sepsis. Fitzgerald and coworkers concluded that storing rat RBCs for 28 days impairs their ability to improve tissue oxygenation when transfused into either control or septic rats.[46] This contrasted with an observation that transfusion of fresh blood acutely increases systemic oxygen uptake in this animal model. Marik and Sibbald showed that old blood (>15 days) transfused into septic patients was accompanied by splanchnic ischemia, as shown by gastric tonometry.[47] It is known that during storage, the concentration of 2,3-diphosphoglycerate (2,3-DPG) in RBCs progressively decreases. In addition, the adenosine triphosphate content of stored RBCs decreases, and the cells become less deformable. The microcirculation in septic patients is not normal, and old, poorly deformable RBCs may become entrapped in capillaries, promoting the development of tissue ischemia. Martin and colleagues observed a statistically significant association between the transfusion of old blood (>14 days) and increased duration of ICU stay.[48] The age of transfused RBCs was the only predictor of the length of ICU stay in patients who received transfusions. The implications of this association between adverse outcomes and the infusion of aged RBCs is worrisome, given that a typical unit of transfused blood in ICUs is between 16 (Europe) and 21 (U.S.) days old.[3,4] Finally, blood transfusion has been shown in several studies to be an independent predictor of multiorgan failure, even after correction for other indices of shock.[3,49]

To elucidate the possible advantages of transfusion in critically ill patients, Hebert and colleagues in Canada conducted a randomized, controlled clinical trial (the TRICC study) to determine whether a restrictive approach to red cell transfusion (transfusion trigger: hemoglobin concentration between 7 and 9 g/dL) was equivalent to a more liberal transfusion strategy (transfusion trigger: hemoglobin concentration between 10 and 12 g/dL) in critically ill patients.[38] The average number of transfusions was reduced by 54% when the lower threshold was used, and 33% of the patients in the restrictive group did not require transfusion. The 30-day mortality rate was similar in both groups. However, the death rate was significantly lower with the restrictive strategy among typical ICU patients (Acute Physiology and Chronic Health Evaluation [APACHE] II score = 20) and among patients younger than 55 years. A subsequent subgroup analysis of patients with cardiovascular disease found no significant mortality differences between the two transfusion strategies.[50] There was a trend, however, toward decreased survival with the restrictive strategy in patients with active or severe ischemic heart disease. Finally, there appears to be no difference in the duration of mechanical ventilation between the two transfusion policies.[51] Therefore, the TRICC study provides convincing evidence that restricting transfusion to critically ill patients with a hemoglobin concentration of 7 g/dL or less is safe and conserves this precious resource. Use of a restrictive transfusion approach at our busy trauma center reduced our yearly consumption of packed cells by about 25% (absent changes in the use of platelets or clotting factors), with no discernible impact on outcome.

Despite a restrictive strategy, 60% of ICU patients are still transfused. Based on the growing body of evidence suggesting the detrimental clinical effect of blood transfusion, new therapies that can increase hemoglobin levels in critically ill patients have emerged. Recombinant human erythropoietin may assist in augmenting red cell production in this population. Recently, Corwin and colleagues demonstrated a 19% reduction in blood transfusion among a group of critically ill patients who received high weekly doses of recombinant human erythropoietin compared with those receiving a placebo.[52] There were no significant differences in the frequency of adverse events or in mortality between the two groups. The effect of erythropoietin translated into only 0.6 unit per patient over 28 days.

ANNOTATED REFERENCES

To elucidate the possible advantages of transfusion in critically ill patients, these Canadian investigators conducted a randomized, controlled clinical trial that showed that a restrictive approach to red cell transfusion (transfusing at a hemoglobin of 7 to 9 g/dL) is equivalent to a more liberal transfusion strategy (transfusing at 10 to 12 g/dL).

Marik PE, Sibbald WJ: Effect of stored-blood transfusion on oxygen delivery in patients with sepsis. JAMA 1993;269:3024-3029.

Although blood transfusion might acutely increase oxygen delivery, a matching improvement in tissue oxygen consumption is not necessarily seen, especially in sepsis. These authors showed that transfusing old blood (>15 days) in septic patients is accompanied by splanchnic ischemia, as shown by gastric tonometry.

Rogiers P, Zhang H, Leeman M, et al: Erythropoietin response is blunted in critically ill patients. Intensive Care Med 1997;23:159-162.

This study used enzyme-linked immunosorbent aassay to measure erythropoietin levels in critically ill patients with no renal failure and compare them with levels in ambulatory patients with iron deficiency anemia. It showed that erythropoietin is inappropriately low in critically ill patients with sepsis.

Vincent JL, Baron JF, Reinhart K, et al: Anemia and blood transfusion in critically ill patients. JAMA 2002;288.

This trial, one of the largest prospective observational studies, showed that 37% of patients admitted to the ICU are transfused. In addition, it provided evidence of an association among transfusion, diminished organ function, and mortality.

Chapter 20
THROMBOCYTOPENIA

William C. Aird

INCIDENCE

Thrombocytopenia is often classified according to whether platelets are being consumed, sequestered, or underproduced in the bone marrow. However, a more practical classification takes into account the clinical setting (Table 20-1).[1] In the ICU, thrombocytopenia occurs in up to 20% of medical and 35% of surgical admissions.[2] Although there are many causes of thrombocytopenia in this setting, the two most important ones are sepsis and heparin. Sepsis is a major risk factor, being associated with thrombocytopenia in 35% to 59% of cases.[2] The incidence of heparin-induced thrombocytopenia is influenced by the dose and type of heparin preparation, as well as the patient population receiving it. It is estimated that 2% of cardiac medical patients and 15% of orthopedic patients develop heparin-induced thrombocytopenia antibodies following exposure to unfractionated heparin, and up to one half of patients who undergo cardiac bypass surgery develop such antibodies. Only a minority of patients who form heparin-induced thrombocytopenia antibodies develop thrombocytopenia, and an even smaller fraction develop the clinical complication of thrombosis (reviewed in reference 1).

PATHOPHYSIOLOGY

Patients with sepsis may develop de novo ethylenediaminetetraacetic acid (EDTA)–dependent antibodies that cause platelet clumping in the test tube, with resultant pseudothrombocytopenia.[3] Immune mechanisms rarely contribute to sepsis-induced thrombocytopenia.[4] Nonspecific platelet-associated antibodies can be detected in up to 30% of ICU patients.[4] In these cases, nonpathogenic immunoglobulin G (IgG) presumably binds to bacterial products on the surface of platelets, to an altered platelet surface, or as immune complexes. A subset of patients with platelet-associated antibodies has autoantibodies directed against the integrin glycoprotein IIb/IIIa.[4] These antibodies have been implicated in the pathogenesis of immune thrombocytopenic purpura and, although not proved, may play a role in mediating sepsis-induced thrombocytopenia. Nonimmune platelet destruction is the most important cause of thrombocytopenia in severe sepsis. There is increased binding of platelets to the activated endothelium, resulting in their sequestration, activation, and destruction. Less commonly, thrombocytopenia is associated with underlying disseminated intravascular coagulation. Bone marrow specimens have demonstrated a high incidence of hematophagocytosis in patients with sepsis and thrombocytopenia.[5] The degree to which this pathologic process is a cause or simply a marker of sepsis-related thrombocytopenia is not clear.

Heparin-induced thrombocytopenia is a clinicopathologic syndrome that is diagnosed by the detection of circulating antibodies, usually of the IgG1 subclass, and thrombocytopenia with or without thrombosis. Heparin-induced thrombocytopenia antibodies, which recognize a cryptic autoantigen composed of multimolecular complexes of the chemokine platelet factor 4 (PF4) and heparin, may be detected by antigen assays or activation assays. Seroconversion occurs 5 to 10 days following initiation of heparin therapy. An important exception to this rule is that patients who have been treated with heparin in the past 100 days are at risk for developing rapid-onset heparin-induced thrombocytopenia promptly on re-exposure to heparin.[6] Heparin-induced thrombocytopenia occurs when platelet-bound PF4-heparin-IgG complexes interact with the Fcγ receptor type IIa (FcγRIIA), leading to platelet activation and aggregation.

In addition to sepsis and heparin-related mechanisms, other causes of thrombocytopenia should be considered in

TABLE 20–1. DIFFERENTIAL DIAGNOSIS OF THROMBOCYTOPENIA

Outpatients
Pregnancy
Immune thrombocytopenic purpura
Myelodysplastic syndrome
Hypersplenism
Antiphospholipid antibody syndrome
Hereditary thrombocytopenia
Non–ICU and MICU Inpatients
Drugs, including heparin

Post-transfusion purpura
Folate deficiency
Coronary Care Unit Inpatients
Heparin
Glycoprotein IIb/IIIa antagonists
Adenosine diphosphate receptor antagonists
Coronary artery bypass surgery
Intra-aortic balloon pump
Emergency Room Patients
Acute alcohol toxicity
Thrombocytopenic thrombotic purpura/hemolytic uremic syndrome
Immune thrombocytopenic purpura
Drugs

critically ill patients, including other drugs, dilutional thrombocytopenia following trauma or complicated surgery and multiple transfusions, acute folate deficiency,[7] and preexisting underlying disease (e.g., cancer, hypersplenism, immune thrombocytopenic purpura).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients with thrombocytopenia may develop petechiae, purpura, bruising, or frank bleeding. The diagnosis of thrombocytopenia is made from the complete blood count. It is important to examine the peripheral blood smear to rule out platelet clumping. If such a phenomenon is observed, the platelet count should be repeated in blood drawn into a tube that contains an anticoagulant other than EDTA. If thrombocytopenia is associated with consumptive coagulopathy, any or all of the following laboratory tests may be abnormal: International Normalized Ratio, partial thromboplastin time, thrombin time, circulating concentration of D-dimer, plasma fibrinogen level, concentration of thrombin-antithrombin complexes, and plasma concentration of prothrombin fragment 1.2. The peripheral smear may show schistocytes. Although patients with sepsis may have increased platelet-associated IgG, this test is nonspecific and does not help in guiding therapy.

It is important to recognize that thrombocytopenia associated with sepsis, and particularly heparin-induced thrombocytopenia, can coexist with an underlying hypercoagulable state. Indeed, patients with heparin-induced thrombocytopenia are at far greater risk for thrombosis than for bleeding. These patients typically have mild to moderate reductions in platelet counts (median, 60,000/μL). Only 5% of cases are associated with platelet counts less than 15,000/μL.[8] It is important to recognize that thrombotic complications may occur with a "normal" platelet count (i.e., >150,000/μL). Findings suggestive of the diagnosis of heparin-induced thrombocytopenia in these patients is a 30% to 50% or greater fall in the platelet count within the normal range, or the presence of erythematous or necrotic skin lesions at subcutaneous heparin injection sites.

PROGNOSIS

Thrombocytopenia is a predictor of mortality in ICU patients and in patients with severe sepsis.[9,10] The degree and duration of thrombocytopenia, as well as the net change in the platelet count, are important determinants of survival.[10-12]

TREATMENT

Treatment of thrombocytopenia depends on the underlying mechanism. As a general rule, when thrombocytopenia is associated with an increased risk for bleeding and is not attributable to immune mechanisms, patients should be transfused with platelets to maintain a minimal platelet count. Although guidelines for prophylactic transfusions in patients with chemotherapy-induced thrombocytopenia have been established,[13] the threshold for transfusing in the ICU is not clear. This caveat notwithstanding (and in the absence of evidence-based guidelines), most patients are transfused to achieve a platelet count of 10,000/μL or greater. If the patient has concomitant coagulopathy (e.g., due to disseminated intravascular coagulation or liver disease), active bleeding, or platelet dysfunction (e.g., due to uremia), it may be prudent to employ a more liberal transfusion strategy with the goal of maintaining an even higher platelet count.

Patients with sepsis have an underlying shift in the hemostatic balance toward the procoagulant side. Indeed, platelets are activated in the setting of sepsis and likely contribute in important ways to the pathogenesis of the syndrome. Therefore, when considering the cost-effectiveness of platelet transfusion, it is important to consider the theoretic risk of accelerating the underlying pathophysiology (i.e., "adding fuel to the fire"). The best approach for treating sepsis-associated thrombocytopenia is to target the host response. Indeed, as long as the low platelet count is causally related to the host response, optimal therapy consists of some combination of low tidal volume ventilation,[14] activated protein C,[15] low-dose glucocorticoids,[16] intensive insulin therapy,[17] and early goal-directed therapy.[18]

The treatment of choice in heparin-induced thrombocytopenia is to discontinue all heparin, including heparin flushes, and to institute therapy with an alternative rapid-acting anticoagulant that either inhibits thrombin or reduces thrombin generation. Warfarin, low-molecular-weight heparin, ε-aminocaproic acid (ancrod), and, as a general rule, platelet transfusions should be avoided, because they may exacerbate the underlying prothrombotic state. Two direct thrombin inhibitors, lepirudin and argatroban, have been evaluated and approved by the Food and Drug Administration for the treatment of heparin-induced thrombocytopenia–related thrombosis.[19] Lepirudin may be given with or without a 0.4 mg/kg i.v. bolus, followed by 0.15 mg/kg/h adjusted to 1.5 to 2.5 times the patient's baseline activated partial thromboplastin time or the mean of the laboratory range. Argatroban is given at 2 μg/kg/min i.v. adjusted to 1.5 to 3 times the patient's baseline activated partial thromboplastin time or the mean of the laboratory range. The dose of lepirudin and argatroban should be reduced in renal insufficiency and hepatobiliary disease, respectively. Selected patients with life- or limb-threatening thrombosis may benefit from adjuvant therapies, including thrombolytic drugs, surgical thromboembolectomy, intravenous gammaglobulin, plasmapheresis and antiplatelet agents.

Chapter 21
COAGULOPATHY

William C. Aird

Hemostasis is typically divided into two components: primary and secondary. Primary hemostasis refers to the cellular (or platelet) response, whereas secondary hemostasis refers to the protein response (clotting cascade). In reality, both primary and secondary hemostasis are tightly interconnected, feed back on each other, and operate in unison. Nevertheless, from a conceptual standpoint, it is helpful to consider each limb of hemostasis separately. In this chapter, we review the clotting mechanism. The reader is referred to Chapter 20 for a discussion of the most common platelet disorder in the ICU: thrombocytopenia.

GENERAL PRINCIPLES

The blood clotting cascade is highly complex, consisting of a series of linked reactions in which a serine protease, once it is activated, is capable of activating its downstream substrate. For purposes of this chapter, the scheme can be simplified according to the following themes: (1) the final step in the clotting cascade is the conversion of fibrinogen to fibrin, a process that is mediated by a serine protease called thrombin; (2) fibrin is the "glue" that holds platelet plugs together and contributes to the host defense against pathogens; (3) there are two pathways—extrinsic and intrinsic—that converge to induce thrombin generation and fibrin formation; (4) blood coagulation is always initiated by the extrinsic pathway (via tissue factor) and is amplified through the intrinsic pathway; (5) the prothrombin time (PT) measures the integrity of the extrinsic (and common) pathways, and the activated partial thromboplastin time (aPTT) measures the integrity of the intrinsic (and common) pathways; and (6) every procoagulant step is balanced by a natural anticoagulant. Tissue factor pathway inhibitor neutralizes the extrinsic pathway; heparin is a cofactor for antithrombin III, which serves to inhibit serine proteases (most notably, factor Xa and thrombin) in the cascade; activated protein C functions with its cofactor protein S to inactivate the cofactors of the procoagulant response (factors Va and VIIIa); and the fibrinolytic pathway degrades preformed fibrin. In the final analysis, hemostasis represents a balance between anticoagulant and procoagulant forces.[1,2]

Disorders in hemostasis occur when the hemostatic balance shifts toward one side or the other, resulting in one of two clinical phenotypes: bleeding or thrombosis. The myriad causes, diagnostic workup, and treatment of coagulation disorders are beyond the scope of this chapter. In the sections that follow, we consider the coagulopathy that occurs in patients with sepsis. The reasons for choosing sepsis as the case study are several-fold: (1) sepsis is common in the ICU and accounts for the preponderance of coagulopathy; (2) a consideration of the mechanisms, diagnosis, and therapy of coagulopathy in this setting may be widely applicable to conditions in which the innate immune response is activated (e.g., sepsis, trauma, burns, postoperative systemic inflammatory response syndrome); and (3) recent therapeutic breakthroughs emphasize the importance of targeting the host response rather than the clotting cascade per se.

INCIDENCE

Previous studies demonstrated that the coagulation system is activated in the vast majority of patients with severe sepsis.[3] For example, circulating levels of D-dimers are elevated in virtually all patients with severe sepsis,[4] and protein C levels are decreased in up to 90% of such patients.[4,5] Acquired antithrombin III deficiency is also common in the setting of sepsis, with levels below 60% occurring in more than half of patients.[6,7] Although the operational definition varies among studies, disseminated intravascular coagulation (DIC) is estimated to occur in 15% to 30% of patients with severe sepsis, including those with septic shock.[8-13]

MECHANISMS

In sepsis, the clotting cascade is initiated through the up-regulation of tissue factor expression on circulating monocytes, tissue macrophages, and possibly subsets of endothelial cells.[14] At the same time, sepsis attenuates many of the natural anticoagulant mechanisms. For example, circulating levels of protein C and antithrombin III are reduced, and the fibrinolytic pathway is suppressed.[15,16] Moreover, sepsis-mediated down-regulation of thrombomodulin on the endothelial cell surface may impair the activation of protein C.[17] Together, these changes further tilt the balance toward the procoagulant side, resulting in thrombin generation, fibrin deposition, and clotting factor consumption. DIC represents the extreme in the pathophysiologic continuum. In addition to these systemic effects, sepsis results in local activation of the endothelium through the release of a number of inflammatory mediators. Once activated, the endothelium expresses a procoagulant phenotype. The nature and degree of this response vary among different sites of the vascular tree.[2,18,19] The systemic consumption of clotting factors may be accompanied by thrombocytopenia, and when sufficiently advanced, these processes may ultimately result in bleeding. Other factors that may contribute to sepsis-associated bleeding include trauma-related coagulopathy secondary to hypothermia, metabolic acidosis, or massive transfusions; vitamin K deficiency; liver dysfunction; and heparin treatment.[20]

Local activation of the coagulation system in sepsis is an integral component of the innate immune response and may

play a protective role in walling off infection.[21] However, in patients with severe sepsis, systemic activation of coagulation is harmful to the patient and is associated with increased mortality.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Severe sepsis is usually associated with a net procoagulant state, as evidenced by local or diffuse microvascular thrombi. These changes occasionally manifest as skin lesions, as occurs in purpura fulminans. More commonly, the coagulation cascade interacts with the inflammatory pathway to induce endothelial cell activation and secondary dysfunction of internal organs, including the liver, kidneys, lungs, and brain. Patients are at risk for bleeding when the consumption of clotting factors outstrips the production.[22,23] Bleeding is more common when the coagulopathy is exacerbated by concomitant thrombocytopenia, liver disease, heparin use, and invasive procedures. In large prospective studies, the incidence of serious bleeding in patients with severe sepsis varies between 2% and 6%.[7,24] The most sensitive laboratory markers of sepsis-associated coagulopathy include reduced circulating protein C levels and increased circulating D-dimer levels. However, protein C levels are not routinely measured, and elevated D-dimers are nonspecific. In general, coagulation factor levels are inversely correlated with the severity of sepsis.[7,6] One exception is factor VIII, an acute phase protein. Fibrinogen, another acute phase protein, may be elevated in the early stages of sepsis but is reduced in up to 50% of patients with severe sepsis.[3,5,25]

Marked activation of coagulation and secondary consumption of clotting factors may lead to DIC. No single test is sufficiently sensitive or specific to make the diagnosis of DIC. Recently, a scoring system was proposed that employs simple laboratory tests, including platelet count, elevated fibrin-related marker (e.g., soluble fibrin monomers, fibrin degradation products), prolonged PT (or International Normalized Ratio), and fibrinogen level.[26,27] Other markers of coagulation activation, such as thrombin-antithrombin complexes, fibrinopeptides and $F_{1,2}$, are considered investigational in this setting.

The PT or aPTT may be elevated for reasons other than sepsis-associated consumption of clotting factors (Table 21-1). As a general rule, increased clotting times are caused by inhibitors against one or more clotting factors or a congenital or acquired deficiency state. In the ICU, prolongation of the PT or aPTT is almost always related to an acquired deficiency state. An isolated increase in PT indicates factor VII (extrinsic pathway) deficiency and may be seen in early liver failure or during the initial stages of warfarin (Coumadin) therapy. An isolated increase in the aPTT points to a defect in the intrinsic pathway, namely, factor XII, XI, IX, or VIII. An increase in both PT and aPTT reflects an abnormality in the common pathway (factors X or V, prothrombin, or fibrinogen) or a combined deficiency in the extrinsic and intrinsic pathways. The latter occurs with heparin therapy, long-term warfarin treatment, vitamin K deficiency, advanced liver disease, DIC, or dilutional coagulopathy.

PROGNOSIS

Certain markers of coagulation activation have been correlated with negative outcome in patients with sepsis.[28] For example, low antithrombin III levels in patients with sepsis are predictive of poor survival.[25] Decreased protein C levels in severe sepsis have been shown to correlate with mortality, presence of shock, length of ICU stay, and ventilator dependence.[5] In clinical studies of multiple organ dysfunction, maximum PT and aPTT were shown to be longer in nonsurvivors than in survivors.[29] DIC is an independent predictor for mortality in patients with sepsis.[30]

TABLE 21-1. CAUSES OF INCREASED PROTHROMBIN TIME (PT) OR ACTIVATED PARTIAL THROMBOPLASTIN TIME (APTT)

Increased PT—Defect in Extrinsic Pathway
Deficiency or inhibitor of factor VII
Early warfarin (Coumadin) therapy
Early liver disease
Increased aPTT—Defect in Intrinsic Pathway
Deficiency or inhibitor of factor XII, XI, IX, or VIII
Heparin (though usually affects PT as well)
Liver disease (though usually affects PT as well)
Lupus anticoagulant (may affect PT as well)
Increased PT and aPTT—Defect in Common Pathway or Combined Defect in Extrinsic and Intrinsic Pathways
Heparin (all serine proteases affected, especially II and X)
Disseminated intravascular coagulation (all factors, including pro- and anticoagulants, affected)
Liver disease (all factors except VIII affected)
Warfarin (factors II, VII, IX, and X affected)
Vitamin K deficiency (factors II, VII, IX, and X affected)
Direct thrombin inhibitors
Lupus anticoagulant

TREATMENT

The consumption of clotting factors with or without secondary DIC is rarely associated with a bleeding diathesis in patients with sepsis. Rather, the underlying coagulopathy reflects a procoagulant state and is associated with increased fibrin deposition in the microvasculature. Thus, transfusion therapy with platelets, fresh frozen plasma, or plasma components is indicated only in patients with active bleeding or in those with a high risk for this complication (e.g., other types of coagulopathy, trauma, surgery, or other invasive procedures).[23,27]

Based on an understanding of the underlying pathophysiology, there has been a shift in emphasis from procoagulant replacement to anticoagulant therapy. Initial studies with thrombin inhibitors were disappointing. Although these drugs clearly inhibit thrombin generation and fibrin formation, they do not appear to have an impact on organ dysfunction and survival.[31] In contrast, preclinical and early-phase clinical studies employing recombinant human protein C, antithrombin III, and tissue factor pathway inhibitor resulted in not only decreased thrombin generation but also improved survival.[8,32-35] One possible explanation for these findings is that the natural anticoagulants have a dual function: inhibition of coagulation and suppression of inflammation. Activated protein C, antithrombin III, and tissue factor pathway inhibitor have each been shown to modulate the inflammatory response under in vitro and in vivo conditions.[36-38]

Unfortunately, in phase 3 studies, infusions with antithrombin III or tissue factor pathway inhibitor failed to

improve 28-day all-cause mortality in patients with severe sepsis.[7] In contrast, the Protein C Worldwide Evaluation in Severe Sepsis trial, a large phase 3 study, confirmed the anticoagulant and anti-inflammatory properties of recombinant human activated protein C (drotrecogin alfa [activated]).[4] Most important, these effects translated into a survival advantage for patients with high-risk severe sepsis. At present, we do not know whether the different outcomes in the phase 3 trials of antithrombin III, tissue factor pathway inhibitor, and activated protein C are explained by differences in study design or whether they reflect important differences at the mechanistic level.

CONCLUSIONS

Most patients in the ICU have activation of the clotting cascade. This would be more apparent if we routinely tested patients with a sensitive assay of clotting activation, for example, protein C levels, markers of thrombin activation, or D-dimers. In the face of unrelenting coagulation activation, the clotting factors may become sufficiently consumed to create a bleeding diathesis. Important challenges for the intensivist are to (1) delineate and track a patient's position on the hemostatic scale (prothrombotic versus hemorrhagic), (2) understand that both phenotypes may occur concomitantly (e.g., microthrombi within internal organs and mucosal bleeding), and (3) target each component separately—that is, replenish the clotting factors in the face of severe of bleeding (e.g., plasma products) while attenuating the underlying host response (e.g., low tidal volume ventilation, activated protein C, low-dose glucocorticoids, intensive insulin therapy, and early goal-directed therapy).

Aird WC: Vascular bed–specific hemostasis: Role of endothelium in sepsis pathogenesis. Crit Care Med 2001;29:S28-S35.

This review emphasizes the notion of hemostasis as a balance between procoagulants and anticoagulants and applies the principle to an understanding of hemostatic changes in sepsis.

Bernard GR, Vincent JL, Laterre PF, et al: Efficacy and safety of recombinant human activated protein C for severe sepsis. N Engl J Med 2001;344:699-709.

This landmark study was the first to demonstrate a survival benefit of a drug in patients with severe sepsis. Clinicians who are involved in the care of patients with severe sepsis should be familiar with the inclusion and exclusion criteria that were used in this phase 3 clinical trial.

Faust SN, Levin M, Harrison OB, et al: Dysfunction of endothelial protein C activation in severe meningococcal sepsis. N Engl J Med 2001;345:408-416.

For those interested in the role of the endothelium in sepsis and the potential for bridging bench to bedside, this article is a must-read. It was previously shown that activated endothelial cells express lower levels of the natural anticoagulant thrombomodulin. In this study, the investigators demonstrated that a similar phenomenon occurs in the intact vasculature in patients with sepsis.

Levi M, Ten Cate H: Disseminated intravascular coagulation. N Engl J Med 1999;341:586-592.

This is an excellent and still timely review of DIC.

Taylor FB Jr, Toh CH, Hoots WK, et al: Towards definition, clinical and laboratory criteria, and a scoring system for disseminated intravascular coagulation. Thromb Haemost 2001;86:1327-1330.

There has been little consensus on the definition or diagnostic criteria of DIC. This paper represents an important first attempt to establish a set of criteria that may be tested prospectively in clinical trials.

Chapter 22
HYPERBILIRUBINEMIA

Mitchell P. Fink

Bilirubin is a byproduct of heme metabolism. Heme, which is largely derived from the hemoglobin in senescent red blood cells, is oxidized in the spleen, liver, and other organs by two isoforms of the enzyme heme oxygenase, in the presence of nicotinamide adenine dinucleotide phosphate (NADPH) and molecular oxygen, to form biliverdin, carbon monoxide, and iron.[1] Subsequently, biliverdin is converted into bilirubin by the phosphoprotein biliverdin reductase, which also uses NADPH as a cofactor. Bilirubin is lipophilic molecule. To be excreted, bilirubin that is produced in extrahepatic organs is bound to albumin and transported to the liver. The liver takes up the bilirubin-albumin complex through an albumin receptor. Bilirubin, but not albumin, is transferred across the hepatocyte membrane and transported through the cytoplasm to the smooth endoplasmic reticulum bound primarily to ligandin or Y protein, a member of the glutathione S-transferase gene family of proteins. Within hepatocytes, bilirubin is converted to water-soluble derivatives, bilirubin monoglucuronide and bilirubin diglucuronide, by the enzyme uridine diphosphate-glucuronosyl transferase. These conjugated forms of bilirubin are secreted across the canalicular membrane into bile via an energy-dependent process. Conjugated bilirubin is excreted in the bile into the intestine, where it is broken down by gut flora to urobilinogen and stercobilin.

Total serum bilirubin consists of an unconjugated fraction and a conjugated fraction. The conjugated forms of bilirubin exist both free in the serum and bound covalently to albumin; the latter is known as delta-bilirubin.[2] Conjugated bilirubin is water soluble and reacts directly when certain dyes are added to the serum specimen. The unconjugated bilirubin does not react with the colorometric reagents until a solvent is added. Accordingly, the conjugated and unconjugated forms of bilirubin are often referred to as "direct" and "indirect" bilirubin. The sum of these two measurements is "total" bilirubin. The normal total bilirubin concentration in adults is less than 18 μmol/L (1.0 mg/dL). Although any total bilirubin concentration that is higher than the upper limit of normal constitutes hyperbilirubinemia, jaundice (i.e., yellow discoloration of the sclerae, mucous membranes, and skin) is usually not clinically apparent unless the serum total bilirubin level is greater than 50 μmol/L (2.8 mg/dL). Unconjugated or indirect hyperbilirubinemia is present when the total serum bilirubin concentration is above the upper limit of normal and less than 15% of the total is in the direct or conjugated form.

DIFFERENTIAL DIAGNOSIS

The long list of diagnoses depicted in Table 22-1 divides the causes of hyperbilirubinemia into two large groups, according to whether the predominant abnormality is an increase in the circulating concentration of unconjugated (indirect) bilirubin or an increase in the concentration of conjugated (direct) bilirubin. Although this classification scheme is useful under some circumstances, many of the diagnoses listed in Table 22-1 are extremely rare and very unlikely to be

TABLE 22–1. DIFFERENTIAL DIAGNOSIS OF HYPERBILIRUBINEMIA

A. Unconjugated hyperbilirubinemia
  1. Overproduction of bilirubin
    a. Hemolysis, intravascular: disseminated intravascular coagulation
    b. Hemolysis, extravascular
      (1) Hemoglobinopathies
      (2) Enzyme deficiencies such as glucose-6-phosphate dehydrogenase deficiency
      (3) Autoimmune hemolytic anemias
    c. Ineffective erythropoiesis
    d. Resorption of hematoma
    e. Massive transfusion
  2. Hereditary unconjugated hyperbilirubinemia
    a. Gilbert's syndrome (autosomal dominant)
    b. Crigler-Najjar syndrome type I (autosomal recessive)
    c. Crigler-Najjar syndrome type II (autosomal dominant)
  3. Drugs
    a. Chloramphenicol: neonatal hyperbilirubinemia
    b. Vitamin K: neonatal hyperbilirubinemia
    c. 5β-Pregnane-3α, 20α-diol: cause of breast milk jaundice

B. Conjugated hyperbilirubinemia
  1. Inherited disorders
    a. Dubin-Johnson syndrome (autosomal recessive)
    b. Rotor syndrome (autosomal recessive)
  2. Hepatocellular diseases and intrahepatic causes
    a. Viral hepatitis
    b. Alcoholic hepatitis
    c. Drug-induced hepatitis (e.g., due to isoniazid, nonsteroidal anti-inflammatory drugs, zidovudine)
    d. Cirrhosis
    e. Drug-induced cholestasis (e.g., due to prochlorperazine, haloperidol [Haldol], estrogens)
    f. Sepsis
    g. Postoperative jaundice
    h. Infiltrative liver disease: tumor, abscesses (pyogenic, amebic), tuberculosis, parasites (*Toxoplasma*), *Pneumocystis jirovecii* pneumonia, *Echinococcus*
    i. Primary biliary cirrhosis
    j. Primary sclerosing cholangitis
  3. Extrahepatic causes
    a. Gallstone disease
    b. Pancreatitis-related stricture
    c. Pancreatic head tumor
    d. Cholangiocarcinoma
    e. Primary sclerosing cholangitis

TABLE 22-2. CLASSIFICATION FOR ACUTE JAUNDICE ASSOCIATED WITH CRITICAL ILLNESS

I. Extrahepatic Bile Duct Obstruction
  A. Choledocholithiasis
  B. Common bile duct stricture
  C. Traumatic or iatrogenic common bile duct injury
  D. Acute pancreatitis
  E. Malignancy (e.g., ampullary carcinoma)
II. Increased Bilirubin Production
  A. Massive transfusion
  B. Resorption of blood collections (e.g., hematomas, hemoperitoneum)
  C. Acute hemolysis
    1. Disseminated intravascular coagulation
    2. Immune-mediated
III. Impaired Excretion due to Hepatocellular Dysfunction, Hepatitis, or Intrahepatic Cholestasis
  A. Drug- or alcohol-induced hepatitis
  B. Drug-induced intrahepatic cholestasis
  C. Drug-induced hepatocellular necrosis
  D. Gilbert's syndrome
  E. Sepsis and other causes of systemic inflammation
  F. Total parenteral nutrition
  G. Viral hepatitis

encountered by the intensivist caring for critically ill (adult) patients. A more useful classification scheme is depicted in Table 22-2. In this scheme, the causes of jaundice are lumped into three primary categories: extrahepatic obstruction to bile flow; increased bilirubin production; or impaired excretion secondary to hepatocellular necrosis and/or intrahepatic cholestasis and/or hepatitis. Often multiple mechanisms are involved at once.

The incidence of hyperbilirubinemia among critically ill patients is quite variable. Jaundice is present in more than 50% of patients with intra-abdominal sepsis, 33% of victims of severe polysystemic trauma, and from 3% to more than 20% of ICU patients recovering from cardiac surgery.[3–6] Determining the cause of hyperbilirubinemia of new onset is important when managing ICU patients, because some problems can be corrected. Exclusion of a mechanical cause for jaundice (e.g., obstruction of the common bile duct due to choledocholithiasis or stricture) assumes the highest priority because failure to correct this problem in a timely fashion can lead to serious morbidity or even mortality.

Iatrogenic injuries to the common bile duct are fortunately quite rare, although the incidence of this complication is greater after laparoscopic cholecystectomy than after open excision of the gallbladder.[7] Damage to the biliary tree, stricture of biliary anastomoses, or retained stones after cholecystectomy or common bile duct exploration present as hyperbilirubinemia and elevated circulating levels of alkaline phosphatase or gamma-glutamyl transpeptidase. Most often the diagnosis is made by detecting dilation of intrahepatic and extrahepatic bile ducts using ultrasonography.

By exceeding the capacity of the liver to conjugate and excrete bilirubin into the bile, hemolysis can produce jaundice. However, the liver can excrete about 300 mg/day of bilirubin,[8] so clinically significant hyperbilirubinemia is only apparent if the rate of hemolysis (i.e., number of red blood cells lysed per unit time) is fairly rapid. Approximately 10% of the erythrocytes in an appropriately crossmatched unit of packed red blood cells undergo rapid hemolysis, yielding about 250 mg of bilirubin.[9] Accordingly, transfusion of a single unit of packed red blood cells is not likely to increase serum total bilirubin concentration. However, transfusion of multiple units of blood over a short period almost inevitably leads to some degree of hyperbilirubinemia, particularly if hepatic function is already impaired. Other reasonably common causes of acute hemolysis in ICU patients include sickle cell disease and immune-mediated hemolytic anemia and disseminated intravascular coagulation.

Any condition that leads to extensive hepatocellular damage will increase circulating total bilirubin concentration. Conditions in this category that are commonly encountered in ICU patients include viral hepatitis, "shock liver," alcoholic hepatitis, and hepatocellular injury induced by drugs, especially acetaminophen.[10] In most forms of jaundice due to hepatic inflammation or hepatocellular damage, circulating levels of transaminases are elevated to a greater extent than is total bilirubin concentration. Making a diagnosis of acetaminophen overdose early is very important, because specific therapy using *N*-acetylcysteine can be lifesaving.[10]

Two other conditions that are commonly associated with jaundice in ICU patients are sepsis and total parenteral nutrition (TPN). Both are associated with the development of intrahepatic cholestasis. Hyperbilirubinemia is a common occurrence in patients with extrahepatic infections leading to the development of severe sepsis.[11,12] Persistent hyperbilirubinemia in septic patients is associated with a significantly increased risk of mortality.[12] Efforts to understand the pathophysiologic mechanisms responsible for cholestatic jaundice due to sepsis have largely focused on lipopolysaccharide (LPS)-induced alterations in the function and expression of various bile acid transporters.[13–16] Nevertheless, another factor that probably contributes to the development of intrahepatic cholestasis is back-leakage of bile from the canalicular spaces into the sinusoids.[17–19]

The basis for TPN-induced cholestasis is also probably multifactorial. Prolonged bowel rest and ileus may promote bacterial overgrowth and increased translocation of LPS into the portal vein on this basis. Phytosterols are present in the lipid emulsions used for TPN and have been associated with cholestasis, especially in premature infants.[20] Results from two retrospective studies suggest that administration of more than 1 g/kg/day of lipid emulsion is associated with increased incidence of hepatocellular dysfunction.[21,22] These data, however, were derived by studying patients receiving TPN at home for very prolonged periods and may not be applicable to ICU patients. In any case, TPN is associated with the development of jaundice and hepatocellular damage. Accordingly, except in rare cases, most ICU patients are better served by receiving enteral rather than parenteral nutrition.

Chapter 23

THE MANAGEMENT OF GASTROINTESTINAL BLEEDING

Omer Bajwa • Paul E. Marik

The cornerstone of management of gastrointestinal bleeding involves volume resuscitation, correction of coagulation disorders, and protection of the airway while initiating diagnostic procedures to determine the site of bleeding. Management is multidisciplinary, involving the emergency room physician, the gastroenterologist, the surgeon, and frequently the intensivist and interventional radiologist.

Upper gastrointestinal bleeding is twice as common in males as in females and its incidence increases with age.[1] The mortality rate for patients with upper gastrointestinal bleeding has remained relatively stable over the past 40 years, ranging from 6% to 10%.[2-4]

Significant improvements in the management of patients with gastrointestinal bleeding has been offset by the increasing number of cases in older patients, who frequently have significant comorbidities.[5-7] The risk of death depends on the patient's age, the presence of shock, comorbid medical conditions, the presence of major stigma of recent hemorrhage, and the underlying cause of the hemorrhage (Table 23-1). Scoring systems to predict mortality and risk of rebleeding are based on host factors, the patient clinical course, and endoscopic findings,[8] and the mortality rate is largely dependent on the cause. Variceal hemorrhage is associated with very high mortality rate: up to 30% of initial bleeding episodes are fatal, and as many as 70% of survivors have recurrent bleeding after a first variceal hemorrhage.[7,9] In contrast, bleeding peptic ulcer disease has a mortality rate of approximately 0.5% in patients younger than 60 years and 10.0% in patients older than 60 years.

CAUSES OF UPPER GASTROINTESTINAL BLEEDING

The source of upper gastrointestinal bleeding can be anywhere above the ligament of Treitz. Occasionally, it can arise outside the gastrointestinal tract. Significant bleeding from the nose, oropharynx, mouth, or lungs can be manifestation of upper gastrointestinal bleeding. Upper gastrointestinal bleeding can be classified into several broad categories based on anatomic and pathophysiologic factors:

1. Erosive or ulcerative
2. Portal hypertension
3. Arteriovenous malformation
4. Traumatic or post-surgical
5. Tumors

CAUSES OF LOWER GASTROINTESTINAL BLEEDING

Lower gastrointestinal bleeding refers to blood loss of recent onset originating from a site distal to the ligament of Treitz that results in hemodynamic instability, anemia, or the need for blood transfusion.[10] Causes can be grouped into several categories:

1. Anatomic
2. Vascular
3. Inflammatory
4. Neoplastic

In patients younger than 50 years of age, hemorrhoids are the most common cause of rectal bleeding.[11]

The reported incidence and differential diagnosis of lower gastrointestinal bleeding varies depending on a number of factors, including patient age and diagnostic method used. Although there are many reports on lower gastrointestinal bleeding, most are small studies from single institutions that may be biased by referral patterns and diagnostic methods used. Vernava and associates[12] analyzed the Department of Veterans Affairs databases over a 4-year period and reported that lower gastrointestinal bleeding was present in 17,941 patients or 0.7% of all discharges during that time period.

MAJOR CAUSES OF GASTROINTESTINAL BLEEDING

PEPTIC ULCER DISEASE

Peptic ulcer disease accounts for 50% of cases of upper gastrointestinal bleeding[10] and remains the most common cause of bleeding in patients with portal hypertension and varices.[13] Bleeding results from the development of a mucosal ulceration adjacent to a vessel, which can result from factors such as *Helicobacter pylori* infection, use of nonsteroidal anti-inflammatory drugs, and critical illness. Concurrent aspirin and oral anticoagulation use increases the risk of bleeding further.[14,15] Bleeding resulting from aspirin and nonsteroidal anti-inflammatory drug use is dependent on dose and duration of use.[16,17] The current practice of acid suppression with medical therapy (H_2-antagonists, proton-pump inhibitors) has not affected the predominance of peptic ulcer bleeding as the cause of acute hemorrhage.[18]

TABLE 23–1. RISK FACTORS FOR DEATH AFTER HOSPITAL ADMISSION FOR ACUTE UPPER GASTROINTESTINAL HEMORRHAGE

Advanced age
Shock on admission (pulse rate >100 beats/min; systolic blood pressure <100 mm Hg)
Comorbidity (particularly hepatic or renal failure and disseminated cancer)
Diagnosis (worst prognosis for advanced upper gastrointestinal malignancy)
Endoscopic findings (active, spurting hemorrhage from peptic ulcer; nonbleeding, visible blood vessel; large varices with red spots)
Rebleeding (increases mortality 10-fold)

STRESS ULCERS

Stress-related gastric ulcers were previously a common cause of acute upper gastrointestinal bleeding in patients who were hospitalized for life-threatening nonbleeding illnesses.[19] With more aggressive resuscitation and early enteral nutrition, bleeding from stress ulceration has become an uncommon problem.

ESOPHAGEAL VARICES

Gastroesophageal variceal hemorrhage is a major complication of portal hypertension resulting from cirrhosis and accounting for 10% to 30% of all cases of bleeding from the upper gastrointestinal tract.[20] The distal 2 to 5 cm of the esophagus contains superficial veins that lack support from surrounding tissues, and this is the most common site of varices (Fig. 23-1).[21] The dilation of distal esophageal varices depends on a threshold pressure gradient, which is most commonly measured by the hepatic venous pressure gradient, defined as the gradient between the wedged, or occluded, hepatic venous pressure and the free hepatic venous pressure (normal gradient <5 mm Hg). At a hepatic venous pressure gradient of less than 12 mm Hg, varices do not form.[22,23] Varices do not invariably develop in patients with gradients of 12 mm Hg or more; thus, this pressure gradient is necessary but not sufficient.[22,23] Gastroesophageal varices are present in 40% to 60% of patients with cirrhosis; their presence and size are related to the underlying cause, duration, and severity of cirrhosis.[24]

ESOPHAGITIS

Significant bleeding from esophagitis occurs in up to 8% of patients with upper gastrointestinal hemorrhage.[20,25-28] It more commonly causes occult blood loss rather than acute bleeding. Clinically obvious bleeding is most likely in patients with extensive ulcerative disease or with an underlying coagulopathy.

MALLORY-WEISS TEAR

Mallory-Weiss tears occur in gastric mucosa, although 10% to 20% can occur in esophageal mucosa. They account for approximately 5% to 10% of cases of upper gastrointestinal hemorrhage.[22,27-29] Although they are thought to be caused

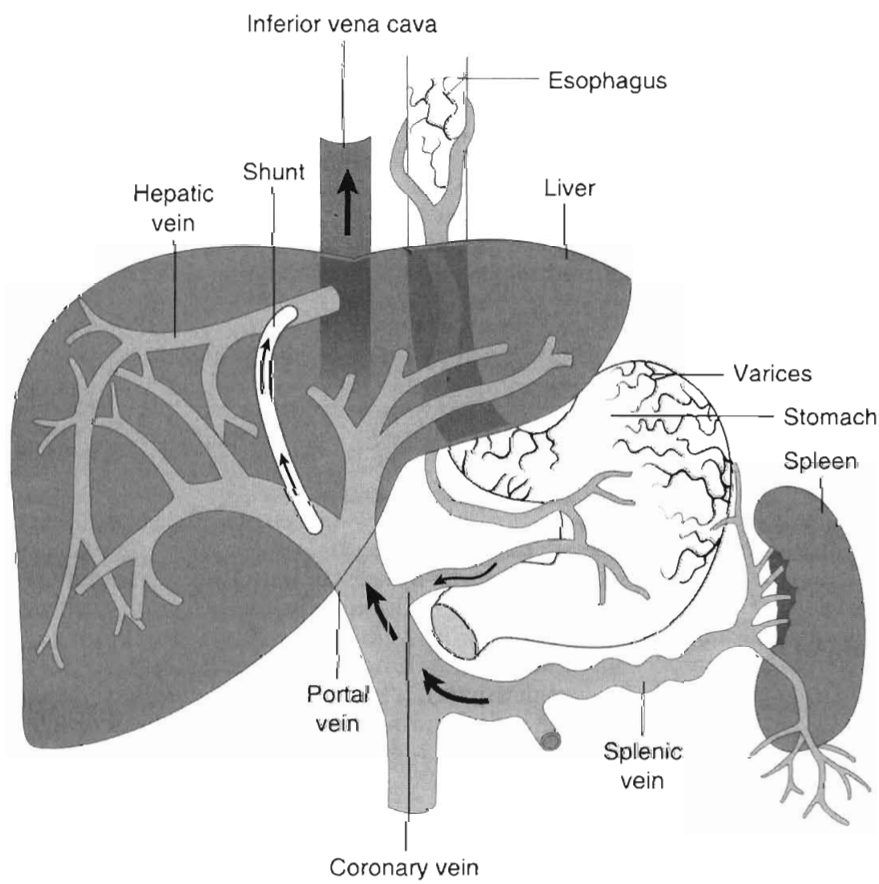

FIGURE 23–1. Transjugular intrahepatic portosystemic shunt (TIPS).

by retching, this history is obtained in less than one-third of patients.[27] Bleeding from Mallory-Weiss tears stops spontaneously in 80% to 90% of patients, and less than 5% of patients experience rebleeding, most often those with an underlying bleeding diathesis.[29,30]

ANGIODYSPLASIA

Angiodysplasia of the gastrointestinal tract is a common source of bleeding. The cause of these lesions is not clear. These lesions also occur in patients with Osler-Weber-Rendu syndrome. They are usually multiple and can occur anywhere from the stomach to the colon, although they are much more common in the colon.

DIVERTICULOSIS

The prevalence of diverticular disease is age-dependent, increasing from less than 5% at age 40, to 30% by age 60, to 65% by age 85. The high prevalence of the disease explains why diverticulosis is the most common cause of lower gastrointestinal bleeding even though less than 15% of patients with diverticulosis develop significant diverticular bleeding. Diverticular bleeding typically occurs in the absence of diverticulitis, and the risk of bleeding is not further increased if diverticulitis is present.[31] Risk factors for diverticular bleeding include[32]

1. Lack of dietary fiber
2. Aspirin and nonsteroidal anti-inflammatory drug use
3. Advanced age
4. Constipation

COLITIS

Infectious, ischemic, and idiopathic colitis (inflammatory bowel disease) can all manifest initially with hematochezia. Mucosal inflammation (colitis) is the common response to acute injury, resulting in activation of the immune system and inflammatory cascade. Establishing a specific diagnosis is paramount in the treatment of acute colitis, since therapy is dependent on the underlying disease process. The diagnosis requires an interpretation of the histologic and gross findings within its clinical context.

NEOPLASMS

Colon cancer is a relatively less common but serious cause of hematochezia. Neoplasm is responsible for approximately 10% of cases of rectal bleeding in patients older than 50 years of age but is rare in younger individuals.[33] Bleeding occurs as the result of overlying erosion or ulceration. The bleeding tends to be low grade and recurrent. Bright red blood suggests left-sided lesions; right-sided lesions can manifest with maroon blood or melena.

HEMORRHOIDS

Hemorrhoids are dilated submucosal veins in the anus located above (internal) or below (external) the dentate line. They are usually asymptomatic but can manifest with hematochezia, thrombosis, strangulation, or pruritus. Hematochezia results from rupture of internal hemorrhoids that are supplied by the superior and middle hemorrhoidal arteries. Hemorrhoidal bleeding is almost always painless. Bright red blood typically coats the stool at the end of defecation. Blood may also drip into the toilet or stain toilet paper. Occasionally, bleeding can be copious, causing great distress to the patient.

INITIAL MANAGEMENT OF GASTROINTESTINAL BLEEDING

Bleeding stops spontaneously in most patients, but aggressive management is required when bleeding does not quickly resolve or when patients are at high risk for rebleeding.[32] Priorities include achieving hemodynamic stability and the prevention of complications such as pulmonary aspiration.[34] The rate of bleeding dictates the urgency of management:

1. Patients with trace heme-positive stools and without severe anemia can be managed as outpatients.
2. Visible blood requires hospitalization and inpatient evaluation.
3. Persistent bleeding or rebleeding with hemodynamic instability necessitates admission to the intensive care unit (ICU).
4. Massive bleeding, defined as loss of 30% or more of estimated blood volume or bleeding requiring blood transfusion of 6 or more units in 24 hours, requires aggressive diagnostic and resuscitative methods in the ICU and the involvement of the intensivist, the gastroenterologist, and, frequently, the gastrointestinal surgeon.

In patients with upper gastrointestinal bleeding, the amount of blood loss can be estimated by measuring the return from a nasogastric tube. An approximate estimate of blood loss can be made by the hemodynamic response to a 2 L crystalloid fluid challenge:

1. If blood pressure returns to normal and stabilizes, blood loss of 15% to 30% has occurred.
2. If blood pressure rises but falls again, blood volume loss of 30% to 40% has occurred.
3. If blood pressure continues to fall, blood volume loss of greater than 40% has probably occurred.

The degree of blood loss can also be estimated clinically by an evaluation of the heart rate, blood pressure, respiratory rate, urine output, and mental status (Table 23-2). The clinical estimation of blood loss is somewhat more difficult in patients with cirrhosis who at baseline have a hyperdynamic circulation with a lower than normal systolic blood pressure and a widened pulse pressure.

History and Examination

A careful baseline cardiopulmonary evaluation is essential; this includes measurement of blood pressure and postural changes, heart rate, chest auscultation, and the ability of the patient to protect his or her airway. A digital rectal examination is always indicated to evaluate the quality of stool and look for the presence of blood, a mass, hemorrhoids, fissure, or fistula. Presence of significant comorbid disease must be determined.

The clinical features of the gastrointestinal bleeding provide clues to the probable source of bleeding within the gastrointestinal tract (Table 23-3). When small amounts of bright red blood are passed per rectum, the lower gastrointestinal tract

TABLE 23–2. CLINICAL INDICATORS AS TO DEGREE OF BLOOD LOSS

Blood loss (mL)	<750	750–1500	1500–2000	>2000
Blood loss (%bv)	<15%	15–30%	30–40%	>40%
Blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure*	Normal	Decreased	Decreased	Decreased
Pulse rate	<100	>100	>120	>140
Respiratory rate	14–20	20–30	>30	>35
Urine output (mL/hr)	>30	20–30	<20	<10
Mental status	Anxious	Anxious	Anxious and confused	Confused and lethargic
Fluid replacement	Crystalloid	Crystalloid	Crystalloid + blood	Crystalloid + blood

*Pulse pressure may be widened in patients with cirrhosis.

can be assumed to be the source. In patients with large-volume maroon stools, nasogastric tube aspiration should be performed to exclude upper gastrointestinal bleeding, although in approximately 15% of patients with upper gastrointestinal bleeding, nasogastric aspirate fails to reveals blood or "coffee ground" material. Concern that placement of a nasogastric tube may induce bleeding in patients with coagulopathies is outweighed by the benefits of the information obtained. A nasogastric tube should be inserted in *all* patients with upper gastrointestinal bleeding to monitor ongoing bleeding and to decompress the stomach. There are no data to suggest that nasogastric tube placement initiates or potentiates bleeding in patients with esophageal varices. Although there are no published reports of nasogastric tubes causing band dislodgment or variceal bleeding, cautious placement of a small nasogastric tube is recommended after variceal banding.

Iced-saline lavage does not prevent or decrease upper gastrointestinal bleeding.[35] Gastric lavage with lukewarm tap water is as safe as lavage with saline and considerably cheaper.[36] Coffee-ground material or a frankly bloody gastric aspirate confirms an upper gastrointestinal source of bleeding, while a non-bloody yellow-green nasogastric aspirate that contains duodenal secretions suggests the absence of bleeding proximal to the ligament of Treitz.[37] However, in up to 50% of patients with a bleeding duodenal ulcer, a nonbloody gastric aspirate is obtained,[35,36] possibly because of insufficient reflux of blood from the duodenum through the pylorus. Similarly, an intermittently bleeding upper gastrointestinal lesion may result in a nonbloody gastric aspirate. The color of the gastric aspirate is of prognostic significance. Patients with coffee-ground or black gastric aspirates and whose stool is melanotic have a reported mortality rate of 9%.[38] However, patients who have bright red blood per gastric aspirate and red blood per rectum have a 30% mortality rate.[38] Red blood per rectum from an upper gastrointestinal source usually signifies rapid bleeding.[39]

TABLE 23–3. CLINICAL INDICATORS OF GASTROINTESTINAL BLEEDING AND THE PROBABLE SOURCE LOCATION WITHIN THE GASTROINTESTINAL TRACT

Clinical Indicator	Probability of Upper Gastrointestinal Source	Probability of Lower Gastrointestinal Source
Hematemesis	Almost certain	Rare
Melena	Probable	Rare
Hematochezia	Possible	Probable
Blood-streaked stool	Rare	Almost certain
Occult blood in stool	Possible	Possible

After the gastric contents have been aspirated, the nasogastric tube should be left in place. The nasogastric tube allows monitoring of ongoing bleeding and is essential to prevent pulmonary aspiration. Once there is no longer any evidence of bleeding, the nasogastric tube can be removed. Maintaining this tube for a prolonged period, especially when the tube is attached to suction, may injure gastric mucosa and exacerbate the gastrointestinal hemorrhage.[40]

INITIAL RESUSCITATION

The first priority in the management of any patient with gastrointestinal bleeding is volume resuscitation. Two large-bore peripheral intravenous lines or a large-bore central line is essential. Volume resuscitation should be initiated with normal saline (a 2-L volume challenge) followed by lactated Ringer's solution. Large-volume resuscitation with normal saline alone will cause a hyperchloremic metabolic acidosis and is associated with coagulation abnormalities. Colloidal solutions have a limited role in patients with acute gastrointestinal bleeding. Patients with an estimated blood loss in excess of 15% to 30% (about 1 L) require blood transfusion (see Table 23-2). In addition, patients with a preexistent coagulopathy (due to liver disease or use of anticoagulants) require transfusion with fresh frozen plasma. Platelet transfusion is indicated if the platelet count is less than 50,000/mm^3. Therefore, a complete blood count including platelet count, blood typing, a prothrombin time and partial thromboplastin time, in addition to blood chemistries and liver function tests should be obtained at the time of line placement. In patients with massive ongoing bleeding, type O blood can be used until cross-matched blood is obtained.

The end-points of resuscitation include normalization of the patient's blood pressure and pulse and indices of end-organ perfusion (mentation, urine output, skin perfusion). Vasopressor agents should be avoided (at least initially) because pressor-mediated vasoconstriction in a hypovolemic patient can cause severe end-organ ischemia.[41] Patients with a history of congestive heart failure, renal failure, or cirrhosis require close monitoring during volume resuscitation; overly aggressive volume resuscitation may precipitate acute pulmonary edema and respiratory failure. A pulmonary artery catheter may help titrate volume expansion in these patients.[42]

Once venous access has been established, a nasogastric or orogastric tube should be placed. Gastric lavage should be performed in all patients with upper gastrointestinal bleeding to remove particulate matter, fresh blood, and clots to facilitate

endoscopy and to decrease the risk of massive aspiration. The risk of aspiration is especially high in patients with massive bleeding or those who have an altered mental status. Endotracheal intubation is recommended in these patients. In addition, endotracheal intubation facilitates endoscopy. In patients with severe upper gastrointestinal bleeding and clinical evidence or a history of advanced liver disease or a history of previous variceal bleeding, an octreotide infusion should be commenced prior to endoscopy (see treatment of variceal hemorrhage).

TRIAGE: WHO TO ADMIT TO THE INTENSIVE CARE UNIT?

At the time of presentation to hospital, patients should be stratified into a high risk (high risk of rebleeding, requiring surgery, and dying) or low risk group. Patients with one or more of the following criteria are stratified as high risk:

1. Systolic blood pressure of less than 100 mm Hg on presentation
2. Severe comorbid disease (e.g., cardiac, pulmonary, renal)
3. Evidence of active, ongoing gastrointestinal hemorrhage
4. Prothrombin time greater than 1.5 times normal

The rate of rebleeding is approximately 3% in the low-risk group and 25% in the high-risk group. Patients in the low-risk group therefore do not require admission to an ICU and can be adequately managed on a general medical floor. The decision regarding ICU admission should, however, be individualized based on the patient's risk stratification, age, comorbid diseases, clinical presentation, and endoscopic findings.[43] Patients with active bleeding and two or more comorbidities have a greater than 10% mortality rate and should be observed in the ICU.[44] Patients with coronary artery disease, regardless of the severity of the gastrointestinal bleeding, are best managed in the ICU because hypovolemia and hypoperfusion from gastrointestinal bleeding can precipitate myocardial ischemia.[45] Admission to the ICU should be considered when endoscopic stigmata of recent hemorrhage, particularly visible vessels, are noted.

FURTHER MANAGEMENT OF UPPER GASTROINTESTINAL BLEEDING

Over the past 20 years, endoscopy has developed as the modality of choice for determining diagnosis, prognosis, and therapy for upper gastrointestinal bleeding. Endoscopy should be performed only after the patient has received adequate volume resuscitation and has achieved a degree of hemodynamic stability but within 6 to 12 hours of presentation. In patients who have had relatively minor bleeding, endoscopy can be performed on a semi-elective basis.

Nonvariceal Bleeds. A meta-analysis of a large number of studies of nonvariceal bleeds demonstrated that endoscopic intervention decreased the mortality rate.[46] The main techniques are injection therapy and thermocoagulation. Employed as the sole therapy in the past, injection therapy is currently followed by thermocoagulation. Although sclerosing agents have been used, epinephrine-containing solutions are now preferred.[47]

Variceal Bleeding. Variceal bleeding stops spontaneously in more than 50% of patients; however, in those who continue to bleed, the mortality rate approaches 70% to 80%. Sclerotherapy is effective for controlling acute bleeding but is associated with a high complication rate, including the risk of ulceration and stricture formation.[48] The risk of secondary ulceration and rebleeding following endoscopic injection sclerotherapy of gastric varices has been reported to be much higher than for esophageal varices.[49] Therefore, treatment of gastric varices without active bleeding or adherent clots should be avoided.

Without treatment to obliterate the varices, there is a 60% to 70% risk of rebleeding. The risk for acute recurrent bleeding is highest within the first 24 to 72 hours of the initial bleed and decreases with time, similar to peptic ulcer hemorrhage.[50,51] Another option is variceal band ligation[51-53]; advantages over injection sclerotherapy include fewer local and systemic complications, lower rebleeding rates, fewer endoscopic treatment sessions to obliterate varices, and lower mortality rate.[54-58]

The diagnostic and therapeutic value of endoscopy in patients with upper gastrointestinal bleeding is often limited by the presence of residual blood or clots. Failure to identify the cause of bleeding at the initial endoscopy examination due to residual blood often necessitates a second endoscopy within several hours with a resultant delay in diagnosis that can increase morbidity and mortality.[59] To avoid this problem, gastric lavage is usually performed with a large-diameter nasogastric tube just before endoscopy.[60] Erythromycin induces rapid gastric emptying in healthy subjects and in patients with diabetic gastroparesis.[60-62] An infusion of 250 mg erythromycin prior to endoscopy improves esophagogastroduodenal cleansing and enhances the quality of the endoscopic findings.[61]

FURTHER MANAGEMENT OF BLEEDING PEPTIC ULCERS

PHARMACOLOGIC THERAPY

Gastric acid-suppressing agents such as histamine receptor-2 blockers (H_2 blockers) have long been available as treatment options for patients with peptic ulcer disease. In acutely bleeding patients, these agents have not been shown to reduce the number of transfusions, episodes of further bleeding or rebleeding, or the need for surgery.[63]

During the past 10 years, proton pump inhibitors have been widely used to suppress gastric acid secretion in patients with a variety of acid-related disorders.[64] Data from a number of studies[65-71] suggest that intravenous proton pump inhibitors reduce the risk of recurrent upper gastrointestinal bleeding; however, they may not affect other outcome variables. Somatostatin is effective for controlling hemorrhage from esophageal varices,[72,73] but its efficacy in the setting of nonvariceal upper gastrointestinal hemorrhage has not been demonstrated.[74]

ROLE OF SURGERY

Although surgical intervention for peptic ulcer bleeding has become less commonplace than in the past, the indications for operation remain unchanged, including severe hemorrhage unresponsive to initial resuscitative measures; unavailability or failure of endoscopic or other nonsurgical therapies to control persistent or recurrent bleeding; and a coexisting

second indication for operation, such as perforation, obstruction, or suspicion of malignancy.[75,76]

Patients in a trial randomized to endoscopic retreatment had significantly fewer complications and tended to have decreased transfusion requirements, 30-day mortality rate, and use of the ICU compared with patients randomized to surgery.[77] Nevertheless, 10% to 12% of patients with acute ulcer hemorrhage still require operative intervention for adequate hemostasis.[78]

FURTHER MANAGEMENT OF ESOPHAGEAL VARICES

PHARMACOLOGIC INTERVENTIONS

Vasopressin causes direct splanchnic and systemic vasoconstriction mediated via the V_1 receptor on vascular smooth muscle and thereby decreases portal venous flow and portal pressure.[79] Vasopressin may also compress esophageal submucosal vessels and decrease esophagogastric collateral blood flow by contracting esophageal smooth muscle and increasing lower esophageal sphincter tone.[79,80] Vasopressin can be administered either intravenously or directly into the superior mesenteric artery; the simpler route is preferred.[81] As with other potent vasoconstrictors, vasopressin must be administered via a central venous line. It is infused continuously, at an initial dose of 0.4 U/min, with gradual increments to a maximum of 1.0 U/min.[82] Higher doses are associated with increased toxicity without further benefit. Vasopressin achieves hemostasis in about 55% of patients.[83] Systemic side effects occur in 20% to 30% of patients. Ischemic side effects include myocardial ischemia, cerebral ischemia, and acrocyanosis.[82] Vasopressin is also associated with congestive heart failure, cardiac arrhythmias, hyponatremia, hypertension, and phlebitis at the venous infusion site. Vasopressin should be used extremely cautiously in patients with coronary artery disease or prior congestive heart failure. Concomitant administration of nitroglycerin, either intravenously or sublingually, improves vasopressin safety and efficacy.[84] The combination of vasopressin and nitroglycerin more effectively controls bleeding and reduces toxicity but does not reduce mortality as compared with vasopressin alone.[85] Vasopressin should not be administered for longer than 24 hours. Terlipressin, a synthetic vasopressin analog, has been used instead of vasopressin to attempt to reduce the toxicity.[86] Terlipressin is as effective as vasopressin in achieving hemostasis and may be associated with a lower incidence of adverse side effects.[82,87]

Somatostatin causes splanchnic vasoconstriction, reduces azygos blood flow, reduces portal collateral circulation, and decreases portal pressure.[88] Somatostatin has been successfully used as an alternative to vasopressin to control variceal bleeding.[89] Octreotide, a synthetic somatostatin analog, is more commonly used than somatostatin. Randomized, controlled trials have shown greater control of variceal bleeding with octreotide, as compared with control, but no improvement in survival.[90] Octreotide produces modest systemic hemodynamic effects and few cardiovascular complications.[89] Octreotide is administered as a 50-μg bolus, followed by infusion at 50 μg/h. If bleeding is controlled, the infusion is continued for 5 days, then discontinued without tapering. Several studies have shown that somatostatin and octreotide are as effective as endoscopic sclerotherapy.[89,91,92]

BALLOON TAMPONADE

Variceal hemorrhage that is unresponsive to combination therapy with octreotide and endoscopic therapy should be temporarily controlled by balloon tamponade. Balloon tamponade initially controls the hemorrhage in 60% to 90% of cases.[93,94] Rebleeding occurs in approximately 50% of cases after balloon deflation, when balloon tamponade is used alone.[95] Balloon tamponade should be only a temporizing measure, before more definitive therapy is instituted (transjugular intrahepatic portosystemic shunt or surgery). Endotracheal intubation and adequate sedation is essential before placement of the balloon.[96,97] Balloon tamponade is associated with significant morbidity, particularly when used by inexperienced clinicians. Relative contraindications to balloon tamponade include an esophageal stricture, recent caustic ingestion, recent esophageal surgery, large hiatal hernia, recent sclerotherapy, an unproven variceal source of bleeding, and an improperly trained support staff.[98,99] Esophageal rupture occurs in about 3% of cases. Other complications include pulmonary aspiration, alar necrosis, nasopharyngeal bleeding, and balloon impaction.[95,98,99]

TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT

Transjugular intrahepatic portosystemic shunt (TIPS) is an intrahepatic shunt between the hepatic and portal veins created by angiographic methods (see Fig. 23-1). The shunt is kept patent by a fenestrated metal stent. This low-resistance channel between the portal and hepatic (systemic) veins decompresses the portal vein, similar to a surgical side-to-side portacaval shunt, but avoids the need for general anesthesia and laparotomy.

Approximately 10% to 20% of patients fail to stop bleeding with endoscopic treatment combined with somatostatin infusion.[100-103] Others rebleed in the first few days after cessation of the index bleed. A second attempt at endoscopic hemostasis is sometimes effective and is generally recommended.[104] When two attempts at hemostasis fail, however, the risk of mortality rises exponentially.[105-107] Even though emergency surgery is highly effective in arresting hemorrhage

TABLE 23–4. COMPLICATIONS OF TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT (TIPS)

Technique-Related Complications	Complications Related to Portosystemic Shunting	Stent-Related Complications
Neck hematoma	Hepatic encephalopathy	TIPS-associated hemolysis
Cardiac arrhythmias	Increased risk of bacteremia	Infection of stent
Perihepatic hematoma	Liver failure	Stent stenosis or ruptured liver capsule malfunction
Extrahepatic puncture of portal vein		

and preventing rebleeding, it is associated with a mortality rate of approximately 50%.[108-112] A recent study enrolled patients who were actively bleeding and who were considered to be poor-risk candidates for surgery.[113] Patients were initially stabilized with balloon tamponade, and a TIPS was placed within 12 hours. The balloon was deflated within 12 to 24 hours after TIPS placement. TIPS was placed successfully in all but one patient. The 5-week survival rate among this extremely high risk group of patients was 60%, compared with 10% for historical control subjects. Patients without pulmonary aspiration had a 90% survival rate at 5 weeks. These data have been corroborated by smaller series and provide the basis for the use of TIPS for esophageal variceal hemorrhage refractory to emergency endoscopic treatment and pharmacologic treatment in patients who are poor surgical candidates.[114-117]

The role of TIPS in treating active hemorrhage uncontrolled by first-line therapy in patients who are good surgical candidates (i.e., with well-preserved liver function and absence of complications of bleeding) remains controversial. In the absence of well-defined clinical guidelines, the choice of therapy is often dictated by the available expertise.

NONSELECTIVE BETA-BLOCKERS

Nonselective beta blockers (propranolol, nadolol) have been used to prevent recurrent bleeding. Treatment with these agents can reduce the risk of recurrent bleeding and death from bleeding by about 40%. Sympathetic adrenergic activity regulates splanchnic arteriolar resistance.[118] Alpha-adrenergic agents, acting locally, cause vasoconstriction, whereas beta-adrenergic agents cause vasodilation. Blockade of beta-adrenergic receptors allows unrestricted alpha-adrenergic activity, producing splanchnic arteriolar vasoconstriction and decreasing portal venous inflow. Propranolol is the prototypic nonselective beta blocker.[119]

After an oral or intravenous dose of propranolol, portal pressure decreases by 9% to 31%,[120-127] as measured by the hepatic venous pressure gradient. This decrease is primarily due to a decrease in hepatic wedge pressures, with a small contribution from increased systemic venous pressures.[123,128] It has been suggested that a decrease in heart rate and cardiac output also contributes to the decrease in portal venous inflow.[121-124] Findings suggest that the portal decompressive effect of propranolol is a specific splanchnic effect rather than a consequence of its systemic effects.[129] In the long term, tachyphylaxis occurs in 50% to 70% of patients,[144] which is clinically important because only those with a sustained decrease in portal pressures can benefit from beta blockade.[130,131] Patients whose hepatic venous pressure gradient increases above 12 mm Hg lose the protective benefit of beta blockade and are at an increased risk of bleeding. The underlying reason for this problem, in large part, is a concomitant increase in portocolateral venous resistance. In principle, the latter could be prevented by adding a venodilator after starting beta-blocker therapy. Nitrates such as isosorbide mononitrate have been shown to act synergistically with beta blockers in reducing hepatic venous pressure gradient. The cumulative risk of hemorrhage was decreased from 29% in those receiving nadolol alone to 12% in those who received the combination of nadolol and isosorbide mononitrate.[132] Nitrates, however, may worsen the vasodilation of cirrhosis and may impair tissue oxygenation, presumably by dilation of arteriovenous channels in the peripheral circulation. Restriction of combination therapy to patients selected on the basis of a failure of beta blockers therefore seems prudent.

Several other nonselective beta blockers have also been used, including nadolol, sotalol, betaxolol, and mepindolol. Nadolol has a longer half-life of biologic activity[132,133] and can be administered once a day. It is more hydrophilic than propranolol; this hydrophilicity limits its intestinal absorption after oral administration as well as its ability to cross the blood-brain barrier.[134,135] Propranolol is administered orally twice a day. The dose should be increased slowly until the heart rate decreases by 25% from baseline but not below 55 beats/minute. Once a stable dose is achieved, propranolol can be changed to a once-a-day, sustained-release form[136] that is equally effective.[137-143]

SURGICAL MANAGEMENT

Surgery for bleeding esophagogastric varices continues to be the most reliable method to control acute hemorrhage and prevent its recurrence. Operative approaches generally consist of either decompression of the high-pressure portal venous system into the low-pressure systemic venous system by creation of a shunt or devascularization of the distal esophagus and proximal stomach with or without disconnection of the portal and azygous venous systems. In most instances, surgical procedures are used for prevention of recurrent hemorrhage rather than treatment of the initial bleeding episode. Because of the effectiveness of endoscopic therapies, emergency surgery for variceal hemorrhage in most centers is reserved for patients who have failed initial nonsurgical treatment and have reasonable hepatic function.[144]

ANTIBIOTICS IN VARICEAL BLEEDING

Bacterial infections are common in patients with cirrhosis. The overall incidence of bacterial infections in cirrhotic patients admitted with gastrointestinal hemorrhage is 44%. Spontaneous bacterial peritonitis is the most common manifestation of infection, which is usually caused by enteric Gram-negative bacteria (mainly *Escherichia coli*). Mortality has been shown to be higher in these patients than in noninfected patients.[145,146] It has also been shown that infections also predispose to recurrent variceal hemorrhage.[147] A meta-analysis of five trials of short-term antibiotic prophylaxis in patients with variceal bleeding showed both a decrease in the number of infections in treated patients and improved survival.[148] The current recommendation is oral administration of either levofloxacin (500 mg every day) or ciprofloxacin (500 mg q12h) for 7 days in all patients with cirrhosis admitted with an upper gastrointestinal bleed.

FURTHER MANAGEMENT OF LOWER INTESTINAL BLEEDING

The management of acute lower gastrointestinal hemorrhage is a challenging task that requires an efficient, disciplined, and orderly evaluation, choosing among several sophisticated diagnostic tools, while concurrently stabilizing the patient and planning definitive therapy. The source of the bleeding lesion can be extremely difficult to ascertain, as even massive hemorrhage can spontaneously stop, thereby thwarting even the most sophisticated and carefully planned efforts at localization. Eliciting a medical history and identifying pertinent

risk factors help in determining the cause of lower intestinal bleeding. Use of aspirin or nonsteroidal anti-inflammatory drugs use is strongly associated with diverticular bleeding. Bleeding associated with antecedent hypovolemia should raise the possibility of ischemic colitis, whereas prior radiation therapy for prostate or pelvic cancer suggests radiation proctitis, which can appear months or years after radiation. A history of severe constipation should raise the possibility of a stercoral ulcer, and a recent colonoscopic polypectomy suggests post-polypectomy bleeding.

A careful digital rectal examination and sigmoidoscopy should be done to exclude anorectal pathology and to confirm the patient's description of the symptoms. Of rectal carcinomas diagnosed by proctoscopy, 40% are palpable on digital rectal examination.[149]

COLONOSCOPY

The role of colonoscopy in the evaluation and management of lower gastrointestinal bleeding has evolved over the past two decades. The practice of early and rapid diagnosis and treatment of bleeding by colonoscopy has gained widespread support, in part because of evidence that total colonic preparation with an oral purge is safe, even in elderly patients.[150-152] Elderly patients generally prefer colonoscopy to double-contrast barium enemas, and the yield and value of colonoscopy are well justified.[153] Endoscopic therapy is applied to lower gastrointestinal bleeding in 12% to 27% of cases.[154,155] Modes of endoscopic therapy for acute lower intestinal bleeding, in particular for angiodysplasia and diverticular disease, include thermal contact probes, laser, monopolar electrocautery (hot biopsy forceps), injection sclerotherapy, and band ligation.

SCINTIGRAPHY AND ANGIOGRAPHY

If the source of bleeding is not detected on colonoscopy, a bleeding scan followed by angiography should be considered if bleeding is severe. Although not as precise in identifying the site of bleeding as angiography, scintigraphy is safe and more sensitive, detecting active bleeding reliably at rates less than 0.1 mL/min.[156,157] Angiographic extravasation of contrast material can be seen with bleeding rates as low as 0.5 mL/min. Angiographic demonstration of a tumor, neovascularization, or vascular lesions may identify a presumed source of bleeding in the absence of extravasation. The rate of localizing the site of lower intestinal bleeding ranges from 28% to 77%.[158] A major limitation of diagnostic and therapeutic angiography is the risk of renal failure from intravenous contrast material.

Angiography may permit transcatheter administration of vasoconstrictor therapy for lower gastrointestinal bleeding.[159] Rates of initial hemostasis range from 62% to 100% with this technique, although bleeding can recur in 16% to 50% of patients in the short term. Efficacy rates in controlling colonic bleeding are somewhat higher (83%) compared with small bowel bleeding (71%). In one series, 41% of patients had complications from intra-arterial vasopressin, including fluid retention, hyponatremia, transient hypertension, sinus bradycardia, and transient arrhythmias (premature contractions and atrial fibrillation). Major complications occurred in 9% to 21% of patients and included pulmonary edema, serious arrhythmias, myocardial ischemia, and hypertension requiring treatment.[160]

Transcatheter embolization with various embolic agents, including surgical gelatin sponges, microcoils, polyvinyl alcohol particle, and detachable balloons, has been used to control massive lower intestinal bleeding. This technique has been associated with abdominal pain, fever, and mesenteric infarction. Ischemic complications appear to be more common when embolization is performed for colonic than for upper gastrointestinal hemorrhage because of the relatively sparse colonic collateral circulation. Embolic therapy may have utility in patients with coronary artery disease or in other situations in which vasopressin is relatively contraindicated or has failed and may be an alternative to emergency surgery in high-risk patients.

SURGERY

Age, probably by association with increased comorbidity, is an important risk factor for postoperative mortality. The postoperative mortality rate in patients undergoing surgery for colorectal cancer is 3.7% in patients aged 70 to 79 years, 9.8% in those aged 80 to 89 years, and 12.9% in those older than 90.[161] Surgery is generally considered in patients with acute lower intestinal bleeding, when the blood transfusion requirement is greater than 4 U during 24 hours, or when bleeding recurs. Accurate preoperative localization of the bleeding site is essential for successful segmental colonic resection. Blind segmental resection of the colon or segmental resection based solely on tagged red blood cell scan localization is associated with substantial risk of rebleeding and morbidity.[162] High morbidity and mortality rates are associated with blind limited resection and emergency total abdominal colectomy. The rebleeding rate for blind limited resection is 33%.[162] The mortality rate for total abdominal colectomy ranges from 5% to 33%, whereas the mortality rate for blind limited resection can be 57%.[154,155]

This randomized placebo-controlled trial investigated the risk of recurrent bleeding after a variceal bleeding episode in patients treated with propranolol.

Chapter 24
ILEUS

Vishal Bansal • Juan B. Ochoa

DEFINITION

Ileus is defined as the absence of physiologic motility of the bowel leading to a disturbance in the progression of bowel contents through the gastrointestinal tract.

Ileus must be distinguished from mechanical bowel obstruction, which is defined as the presence of anatomic barriers, either extrinsic or intrinsic, that prevent the normal progression of bowel contents through the gastrointestinal tract.

PATHOPHYSIOLOGY

NORMAL GASTROINTESTINAL MOTILITY

During fasting states, the coordinated contractions of the gastrointestinal tract are called migrating motor complexes and are divided into three phases[1]:

1. Resting phase
2. Intermittent contractions of moderate amplitude
3. High-pressure waves

When a food bolus is introduced into the intestine, organized migrating motor complexes disappear and digested food (chyme) is propelled through the gastrointestinal tract by spikes in the contraction of smooth muscle in the wall of the gut. Longitudinal progression of intestinal contents (made up by food and secretions) occurs through the integration of several complex processes. Specifically, activation of the sympathetic nervous system decreases gastrointestinal motility. Activation of the parasympathetic nervous system increases gastrointestinal motility.[2] The interstitial cells of Cajal are distributed throughout the tunica muscularis and are electrically coupled with one another. These cells are responsible for the pacemaker activity of the gastrointestinal tract.[1] Myenteric and submucosal nerve plexi integrate with the autonomic nervous system. Nitric oxide produced by neuronal nitric oxide synthase produces smooth muscle relaxation and decreases gastrointestinal motility. Multiple endocrine substances affect gastrointestinal motility. Some of these substances, including motilin, gastrin, and cholecystokinin, increase gastrointestinal motility. Other hormones, notably somatostatin and glucagon, decrease gastrointestinal motility. Activation of the innate immune system can impair gastrointestinal motility in patients with sepsis or after surgical manipulation of the small bowel and colon. Inflammatory mediators, such as nitric oxide and prostaglandins, have direct inhibitory effects on normal contractile activity.[3]

CLINICAL CONSEQUENCES OF ILEUS

Ileus results in the inability to tolerate enteral feeding, nausea, vomiting, constipation, and obstipation. Accumulation of fluid and air in the bowel results in abdominal distention. Symptoms and consequences of ileus can range from minimal to life-threatening. Serious consequences of ileus include intestinal ischemia, intestinal perforation, and abdominal compartment syndrome. Intolerance of enteral feeding compromises the ability to provide adequate nutritional support to critically ill patients.

DIAGNOSIS

Tools to aid clinicians in identifying and diagnosing gastrointestinal dysfunction are poorly developed. Ileus is suggested by the presence of the following signs and symptoms: abdominal distention, nausea, vomiting, high output from a nasogastric (Salem sump) tube, high gastric residual volumes during enteral tube feeding, abdominal pain, absent bowel sounds, constipation, or obstipation. No clear guidelines exist to determine what is an abnormal degree of abdominal distention or an excessive amount of nasogastric output. The true incidence of ileus in cases of critical illness is unknown. Radiologic findings suggestive of ileus are increased air in the small intestine, bowel distention, and presence of air-fluid levels.

Ileus is often diagnosed by challenging the patient with an enteral diet. Gastric ileus (i.e., absence of normal gastric emptying) is observed in as many as one third of all critically ill patients and is more common in hemodynamically unstable patients. Thus, clinicians often attempt to place feeding tubes into the small bowel, where success in achieving nutritional goals is more common.

Three types of clinical ileus are observed:

1. Adynamic ileus
2. Spastic ileus observed rarely in diseases such as porphyria or lead poisoning
3. Ischemic ileus, identified in hemodynamically unstable patients with low flow states and classified as nonocclusive mesenteric ischemia

TREATMENT

1. *Adequate hemodynamic resuscitation* helps to ensure adequate organ blood flow. It is especially important to reduce infusion of exogenous catecholamines, if at all

possible, because these agents promote development of ileus.

2. *Judicious administration of intravenous fluids.* Excessive fluid resuscitation can promote bowel edema, decreasing intestinal blood flow and increasing intra-abdominal pressure.
3. *Maintaining or restoring normal circulating electrolyte levels is crucial.* Hypokalemia, in particular, inhibits normal muscle contraction and nerve depolarization.
4. *Avoiding narcotics.* Morphine and other opioids decrease coordinated contractions of the gut and decrease forward propulsion of chyme. These effects may be especially important in postoperative patients.
5. *Avoiding prolonged starvation.* Starvation is associated with mucosal atrophy. Early use of the gastrointestinal tract (within the first 24 to 48 hours of the onset of critical illness) is associated with achieving caloric goals earlier, earlier time to bowel movements, and overall shorter lengths of hospital stay. The initial goal of early enteral nutrition is to prevent development of intestinal mucosal atrophy, and thus a low rate (10-20 mL/h) of enteral feeding is all that is necessary.
6. *Do not assume that a patient has ileus and should not be fed enterally.* Passage of flatus and the presence of bowel sounds are not reliable indicators of normal gastrointestinal motility.[4] Virtually all hemodynamically stable postoperative patients should be fed enterally as soon as hemodynamic stability and resuscitation are achieved.
7. *Total parenteral nutrition (TPN) is not an adequate substitute for enteral nutrition.* TPN rarely achieves adequate nitrogen retention in patients with critical illness. There are no data to support indiscriminate use of TPN in patients with ileus.[5]
8. *Use of nonsteroidal anti-inflammatory agents.* In surgical patients, the use of systemic ketorolac is associated with early bowel movements, increased tolerance to oral diet, and a significant decrease in narcotic use. In animals subjected to surgical manipulation of the gastrointestinal tract, ketorolac is associated with faster gastric emptying and restoration of normal migrating motor complexes.[6]
9. *In the intensive care unit, the use of metoclopramide has not been shown to provide clinical benefit.* Erythromycin, used because of its molecular similarity to motilin, can be used in some cases, but its efficacy is disappointing.
10. *Newer agents are being tested for clinical use to aid in the prevention of or to hasten the resolution of ileus.* These agents include narcotic antagonists, nitric oxide synthase inhibitors, and protein tyrosine kinase inhibitors.

CONCLUSION

Ileus can lead to significant clinical adverse consequences and mortality, especially if the problem is not recognized and adequately treated. The criteria and tools for the diagnosis of ileus are poorly developed, and this fact hinders progress in this area. Inappropriately diagnosing ileus often leads to unnecessary, prolonged starvation of patients or inappropriate use of TPN. Significant progress in the understanding of the mechanisms that lead to the development of ileus will permit the implementation of logical treatments.

Chapter 25
DIARRHEA

Juan B. Ochoa • Vishal Bansal

Diarrhea is one of the most common abnormal manifestations of gastrointestinal dysfunction in the intensive care unit (ICU). The reported incidence ranges from 2% to 63% of cases.[1] Although many definitions exist in the literature, diarrhea is best defined as bowel movements that, because of increased frequency, abnormal consistency, or increased volume, are deleterious to the well-being of the patient.

CRITERIA

Several criteria are used to diagnose diarrhea[1]:

1. *Abnormal frequency.* Normal frequency is described as one or two bowel movements per day. Three or more bowel movements per day is abnormal.
2. *Abnormal consistency.* Stool that is either nonformed or contains excessive fluid content is abnormal. The normal water content of stool is 60% to 85% of total weight.
3. *Volume.* Stool volume varies according to the amount and type of food intake. Insoluble fiber adds bulk. Normal volume is approximately 200 g per bowel movement. Volumes greater than 500 g are abnormal.

PATHOPHYSIOLOGY

There are several classification systems for diarrhea, a situation that suggests that no classification system is ideal for helping clinicians care for patients. Perhaps the most useful approach is to classify diarrhea based on pathophysiology.

1. *Increased mucosal secretion that overwhelms mucosal absorption.* On average, up to 9 L of fluid is secreted into the gastrointestinal lumen. To this volume must be added the normal oral intake. Less than 1% of the total fluid volume is normally excreted as stool. Thus, the small and large intestine have an amazing capacity to absorb fluid. In the intestinal mucosa, passive and active transport of sodium determines the absorption of water. Increased formation of cyclic adenosine monophosphate within enterocytes inhibits absorption of sodium and promotes the active secretion of fluids into the lumen.[2] Thus, diarrhea caused by excessive secretion of fluids is called "secretory" diarrhea. Secretory diarrhea characteristically contains large amounts of fluid and is described as "watery." Secretory diarrhea is observed in patients with cholera or rotavirus infections and can also be observed in endocrine disorders, such as carcinoid syndrome or the syndrome associated with vasoactive intestinal peptide–secreting tumors.
2. *Increased mucus secretion from the large bowel.* Production of large amounts of mucus and other secretions from the large bowel characteristically leads to a different type of diarrhea. This form of diarrhea is observed in patients with colonic infections, such as *Clostridium difficile* colitis and amebiasis.[3]
3. *Diarrhea due to increased osmotic load.* Many substances that are taken orally and are not fully absorbed can exert a significant osmotic force overwhelming the physiologic absorptive capacity of the mucosa. Many patients with diarrhea in the ICU fall into this category. Subclassifications of osmotic diarrhea exist.
   a. *Osmotic diarrhea caused by medications.* Sorbitol, a poorly absorbed sugar alcohol, is used in the formulation of many orally administered drugs. Thus, sorbitol is frequently and inadvertently given to patients in the ICU when medications are administered via a feeding tube. Sorbitol often is overlooked as a causative factor leading to diarrhea.[4] Other osmotic agents include GoLYTELY solution and magnesium-containing medications.
   b. *Incomplete digestion and malabsorption.* The incidence of malabsorption among patients in the ICU is unknown. However, malabsorption may play an important role in ICU-acquired diarrhea in a variety of circumstances. Incomplete protein digestion (azotorrhea) is one cause of malabsorption leading to diarrhea. A key step in protein breakdown occurs in the stomach, catalyzed by the digestive enzyme pepsin. This enzyme is active only at low pH. In the ICU, virtually all patients receive medications (H_2 blockers and proton pump inhibitors) to increase gastric pH.[5] In addition, feeding tubes frequently bypass the stomach, delivering nutrients directly into the proximal small intestine. Poor digestion of carbohydrates can also contribute to diarrhea in the ICU. In addition to sorbitol, other enterally administered carbohydrates, including glucose, lactose, or fructose, can overwhelm the absorptive capacity of the small bowel causing an osmotic influx of fluid into the gut lumen. Inadequate digestion of fats is a third factor that promotes diarrhea on the basis of malabsorption. Steatorrhea (diarrhea caused by undigested fats) is characteristically observed in patients with pancreatic insufficiency. Inadvertent lack of mixing pancreatic enzymes with the food bolus can occur in patients with intestinal bypass or pancreatic fistulas or in patients that have undergone a pancreatectomy. Steatorrhea is also observed in patients with biliary diversion. Diarrhea due to an excessive load (overfeeding) of any of the above components (protein, carbohydrate, or fat) can be observed in the ICU.

Iatrogenic overfeeding occurs in up to 33% of patients in the ICU and is a result of inappropriate estimation of caloric and protein needs or inadequate metabolic surveillance.[6] Administration of an excessive load of any of these substances also can occur with specialized formulas that contain altered amounts of one or more of these components.

4. *Atrophy of the gastrointestinal tract.* Atrophy of the brush border is associated with decreased capacity for digestion and absorption. Atrophy is observed in malnourished patients; thus, diarrhea is often observed in patients with hypoalbuminemia. Mucosal atrophy also occurs when oral intake of food is discontinued for days or weeks. This cause of mucosal atrophy is a particular problem in surgical patients because prolonged periods of "bowel rest" are still frequently ordered.
5. *Abnormal motility.* Intestinal dysmotility (ileus) is a frequent problem in the ICU. The use of promotility agents (e.g., erythromycin) can inadvertently cause diarrhea in these patients.
6. *Abnormal gut flora.* The normal colonic flora is essential for the proper functioning of the large bowel. Systemic administration of antibiotics markedly alters the microbial ecology of the colonic lumen, possibly leading the development of diarrhea.

DIAGNOSIS

Careful and complete evaluation of diarrhea is necessary for good patient care. Unfortunately, diarrhea is often ignored or hastily treated. Diagnostic laboratory tests are inadequate, making it more difficult to properly diagnose and treat diarrhea. The following questions constitute a useful approach for managing patients with suspected diarrhea:

- Does the patient really have diarrhea? Clinicians rarely will question the diagnosis of diarrhea. Most often, the diagnosis is made by the nurse at the bedside.
  A concerted effort at defining diarrhea is essential:
- Can an iatrogenic cause explain the presence of diarrhea? Is the patient receiving a promotility agent or a stool softener? Is the patient receiving medications with a high concentration of sorbitol?
- Is the patient being fed excessively?
- Is the patient intolerant to any of the components of the diet?
- Is a specialized diet providing an excessive amount of a substance, such as fat, that the patient is having difficulty digesting?
- Is bypassing the stomach or inhibiting HCl secretion affecting the digestion of protein?
- Is the patient on any medications that can cause diarrhea?

Seek to determine whether diarrhea is caused by altered absorptive capacity:

- Could the patient have gut atrophy due to prolonged bowel rest?
- Is the patient malnourished?
- Does the patient have a condition (e.g., pancreatitis) that alters secretion of digestive enzymes?
- Does the patient have a chronic disease process (e.g., short gut syndrome) that alters absorption?

Seek to determine whether the patient might have an infectious cause of diarrhea:

- Is there any evidence of contamination of tube feeds?
- Are the tube feedings being administered via a closed system?
- Has the patient tested positive for *C. difficile* toxin?
- Has the patient been treated with multiple antibiotics, possibly leading to derangements in the colonic microbial ecology?

TREATMENT

Treatment depends on identification of the underlying cause or causes. Once identified, the causes of diarrhea should be eliminated, modified, or treated. This is particularly important when iatrogenic causes of diarrhea are identified. For example, antibiotics that are not needed (e.g., prophylactic antibiotics) should be discontinued.[7] Modification of the diet may be important, especially if the absorptive capacity is being overwhelmed by excessive quantities of a nutrient (often fat). Digestive aids, such as pancreatic enzymes or bile substitutes, should be administered to patients with a disease process (or treatment) that is associated with decreased production of these factors.

Agents that inhibit gastrointestinal motility, such as loperamide, should be used with caution. These agents are often ordered empirically but can worsen the underlying problem, especially when the problem causing diarrhea is an infection.

Bulk-forming agents are sometimes given to patients to improve the consistency of the fecal bolus. The proper amount of these agents must be prescribed, since bulk-forming therapeutics can also be a cause of diarrhea.[8]

Antibiotics to treat infectious diarrhea should be used with caution. If the diarrhea is causing minimal discomfort and is of no physiologic consequence, waiting for results from tests for *C. difficile* toxi may be prudent, rather than starting treatment for this infection empirically.[9]

Restoring normal colonic flora has become an increasingly frequent practice in the ICU. The administration of prebiotics and probiotics has been suggested by a number of different authors.[10,11] The side effects and complications associated with this new form of therapy are not clear at this point. The use of soluble fiber may have a role in restoring normal colonic function and flora.

When dealing with diarrhea, clinicians often stop administration of enteral nutrition or decrease the rate of enteral feeding. This strategy is reasonable only if the patient is being overfed or if the patient exhibits intolerance to the diet. Only very rarely is it appropriate to stop oral intake and start total parenteral nutrition as a treatment for diarrhea.

CONCLUSION

Diarrhea is a poorly studied clinical manifestation of gastrointestinal dysfunction in the ICU. The incidence of diarrhea is unknown due to lack of consistent definitions and a concerted effort to study the problem. We also have little understanding of the pathophysiology of diarrhea in the ICU. Despite these limitations, the cause of diarrhea often becomes obvious with a careful clinical evaluation of the patient.

Chapter 26
RASH AND FEVER

Burke A. Cunha

GENERAL CONCEPTS

The diagnostic approach to an ICU patient with a rash depends on whether the patient was admitted with the rash or acquired it in the hospital. Rashes are seldom the primary cause for an ICU admission. The best clinical approach to a patient ill enough to be admitted to the ICU with a rash acquired in the community is to analyze features of the rash. Its distribution and nature—maculopapular, vesicular, bullous, or petechial-purpuric—determine the range of diagnostic possibilities. Rashes are the dermatologic manifestation of an underlying infectious or noninfectious process, and patients admitted to the ICU with rash usually also have fever. Epidemiologic factors, patient age, and associated physical and laboratory findings all help narrow the diagnosis.[1-5]

Rashes acquired after hospitalization, either on the ward (requiring transfer to the ICU) or de novo in the ICU, represent a different set of diagnostic possibilities. The clinician must decide whether the rash is part of the basic underlying process that prompted the ICU admission or is the result of an unrelated process superimposed on the basic problem. For example, a patient in the ICU with an acute myocardial infarction may develop a rash on the basis of contact dermatitis or due to a hypersensitivity reaction to an antiarrhythmic medication.[6] Rash and fever in the ICU should always prompt an infectious disease consultation; in the absence of critical illness, patients with rash may also be referred for dermatologic consultation. As with community-acquired rashes, a patient who develops a rash in the ICU should be approached syndromically. In addition to the distribution of the rash, laboratory features and pulse-temperature relationships are of diagnostic importance. A history focusing on recent surgical procedures and medications is essential.[1,4]

COMMUNITY-ACQUIRED RASHES

Patients with rash who are ill enough to be hospitalized or transferred to the ICU are best approached diagnostically by analyzing the nature and distribution of the exanthem.

MACULOPAPULAR RASHES

Important causes of maculopapular rashes associated with serious illness include systemic lupus erythematosus (SLE), toxic shock syndrome (TSS), overwhelming staphylococcal bacteremia or sepsis, overwhelming pneumococcal bacteremia or sepsis, and drug reactions superimposed on an underlying disorder (e.g., myocardial infarction, pulmonary edema, acute pancreatitis, gastrointestinal hemorrhage, adrenal insufficiency, overzealous diuresis). SLE can be a particularly vexing problem, because acute exacerbations of SLE can produce symptoms and signs that clinically mimic bacteremia, community-acquired pneumonia, acute bacterial meningitis, or acute peritonitis. Blood cultures and radiology findings differentiate uninfected SLE flare from SLE flare with infection. TSS can occur in any patient colonized or infected with a TSS-1 producing strain of *Staphylococcus aureus*. TSS is an obvious component of the differential diagnosis in the presence of staphylococcal infection but may not come to mind when there are no signs of clinical infection (e.g., staphylococcal colonization of the nares).[5,7,8]

VESICULAR RASHES

Vesicular eruptions limit the diagnostic possibilities. A vesicular rash can represent chickenpox or reactivation of varicella-zoster virus manifesting as herpes zoster (shingles). Herpes zoster can be localized or disseminated. Disseminated shingles may resemble chickenpox, but patients with herpes zoster have a prior history of chickenpox. Before the appearance of the rash, localized herpes zoster can be a difficult diagnostic problem, presenting with acute thoracic or abdominal pain, depending on the dermatomal distribution. The appearance of vesicles in the same dermatomal distribution as the preceding pain confirms the diagnosis.[7,8]

BULLOUS RASHES

Bullous lesions can be caused by *Vibrio vulnificus* or gas gangrene (clostridial myonecrosis). Patients with either of these bullous disorders are critically ill. Bullous lesions are painful and tense, and the lesions are accompanied by diarrhea. Establishing their cause depends on obtaining a proper history. Patients with *V. vulnificus* have ingested undercooked shellfish, usually originating from the Gulf of Mexico. Clostridial myonecrosis occasionally presents after a crush injury or trauma to an extremity, when previously embedded clostridial spores become activated.[1,5,7]

PETECHIAL-PURPURIC RASHES

Petechial-purpuric rashes are associated with some of the most virulent and lethal infectious diseases. Petechiae can also accompany benign viral infections (e.g., enteroviral infections) and noninfectious disorders (e.g., drug fever). The presence of a petechial or purpuric rash requires evaluation by an experienced infectious disease consultant. Meningococcemia with or without meningitis,

Rocky Mountain spotted fever, dengue fever, dengue hemorrhagic fever, dengue shock syndrome, and arbovirally transmitted hemorrhagic fevers are all potentially lethal infections. Dengue fever can have hemorrhagic manifestations, but such findings are not synonymous with dengue hemorrhagic fever or dengue shock syndrome. Dengue fever should be considered in the differential diagnosis if the patient has lived in or visited an area where the disease is endemic. A history of recent travel to Latin America, Asia, or Africa should prompt the clinician to consider arboviral hemorrhagic fevers.

The two potentially fatal infectious diseases that are most likely to be confused are meningococcemia and Rocky Mountain spotted fever (Table 26-1).[1,7,9-12] Rocky Mountain spotted fever is diagnosed on the basis of the rash distribution and a history of recent tick exposure. Meningococcemia is suggested by rapid onset of disease, asymmetrical distribution of lesions, and irregularly shaped petechial-purpuric lesions. Overwhelming pneumococcal sepsis can also resemble meningococcemia. The former does not occur in normal hosts, however, and is invariably related to impaired splenic function. Therefore, in a patient with fever, rash, hypotension, and an obvious splenectomy scar, diagnosis is not a problem. Making the correct diagnosis in a timely fashion can be more challenging in patients with diminished splenic function or with congenital asplenia. Clinicians should be familiar with the disorders associated with diminished splenic function, which predispose to pneumococcal bacteremia or sepsis (Table 26-2).[5,7,8]

TABLE 26–1. DIFFERENTIAL DIAGNOSIS OF MENINGOCOCCEMIA AND ROCKY MOUNTAIN SPOTTED FEVER

Key Diagnostic Findings	Meningococcemia	Rocky Mountain Spotted Fever
Clinical Features		
Onset of rash ≤12 h into illness	+	–*
Nontender macular/petechial rash	–	+
Tender petechial rash	+	–
Relative bradycardia	–	+
Hypotension on admission	–†	–‡
Severe headache	–	+§
Conjunctival suffusion	–	+
Periorbital edema	–	+
Deafness	–	+
Abdominal pain	–	+
Splenomegaly	–	+
Edema of dorsum of hands/feet	–	+
Leg/muscle tenderness	–	+
Laboratory Features		
Thrombocytopenia	+	+
Leukopenia	–	+¶
Leukocytosis	–	+
↑ Erythrocyte sedimentation rate	–	+
↑ SGOT/SGPT	–	+

* Usually day 3 to 5.
† Only with Waterhouse-Friderichsen syndrome.
‡ Later, following excessive fluids or myocarditis.
§ Frontal or retro-orbital.
¶ Generalized.
SGOT/SGPT, aspartate transaminase/alanine transaminase.

TABLE 26–2. DISORDERS ASSOCIATED WITH DECREASED SPLENIC FUNCTION

Chronic alcoholism	Congenital asplenia
Chronic active hepatitis	Sickle cell trait/disease
Myeloproliferative disorders	Splenic infarct
Waldenström's macroglobulinemia	Systemic mastocytosis
Non-Hodgkin's lymphoma	Rheumatoid arthritis
Sézary syndrome	Necrotizing vasculitis
Celiac disease	Thyroiditis
Regional enteritis	Steroid therapy
Ulcerative colitis	Gammaglobulin therapy
Immunoglobulin A deficiency	Amyloidosis
Intestinal lymphangiectasia	Splenectomy
	Hyposplenism of the elderly
	Disorders that decrease splenic artery flow

Adapted from Cunha BA: Severe community-acquired pneumonia. J Crit Illness 1997;12:711-721.

Table 26-3 presents the differential diagnostic features of community-acquired rashes that accompany conditions warranting ICU admission. It is important to remember that arthropod-borne hemorrhagic fevers may resemble meningococcemia.[13-15]

HOSPITAL-ACQUIRED RASHES

Two types of rashes are commonly seen in the ICU: vesicular-bullous and maculopapular.

VESICULAR-BULLOUS RASHES

Vesicular-bullous eruptions can be drug related, but gas gangrene is a diagnosis that should not be overlooked. Patients with severe drug reactions have multiple bullous lesions or can develop Stevens-Johnson syndrome; in either case, the rash is not rapidly progressive. In contrast, in patients with gas gangrene, the vesicular or bullous eruptions spread rapidly (over hours). Gas gangrene in the ICU is likely to be a complication of gastrointestinal surgery performed during the past few days. Skin near the bullous lesions is extremely tender; patients with gas gangrene have little fever but often experience watery diarrhea. Rapidly progressive hemolytic anemia due to lysis of red blood cells by clostridial lethicinases completes the clinical syndrome of gas gangrene. Despite the terminology, gas in tissues is not a prominent feature of gas gangrene. There is no gross crepitus or gas visible on radiographs. Small gas bubbles present in the muscle fascicles usually are not clinically obvious. Copious amounts of gas in the soft tissues or on radiographs should suggest a mixed aerobic-anaerobic infection by gas-producing organisms (e.g., necrotizing fasciitis)—an entity that is clinically distinct from gas gangrene. Mixed aerobic-anaerobic soft tissue infections occur most often in diabetes; although these infections are serious, they are not as rapidly progressive as gas gangrene. Mixed aerobic-anaerobic soft tissue infections do not involve primarily the muscle, as does clostridial myonecrosis.[1,4,5,7,8]

MACULOPAPULAR RASHES

Maculopapular rash as a result of surgical TSS is uncommon but occasionally occurs in the ICU setting. The typical surgical TSS patient develops a wound infection days after an operation.

TABLE 26–3. COMMUNITY-ACQUIRED RASHES IN THE ICU

Type of Rash	Central > Peripheral	Peripheral > Central	Palms and Soles	Appearance of Rash after Fever	Clinical Features	Comments
Petechial-Purpuric Rash						
Meningococcemia	+	+	–	1-2 h	Irregular distribution of painful, irregular petechial lesions Early, spares palms and soles Generalized headache Hypotension (if Waterhouse-Friderichsen syndrome) Leukocytosis Thrombocytopenia	History of recent mild upper respiratory tract infection common in late winter–early spring May present alone or with meningococcal meningitis
Rocky Mountain spotted fever	–	+	+	3-5 days	Painless macular-petechial rash begins in wrists, ankles Conjunctival suffusion Severe frontal headache Periorbital edema Bilateral relative bradycardia Edema of dorsum of hands, feet Splenomegaly in some Hypotension late (due to excessive i.v. fluids, myocarditis) Leukocytosis Thrombocytopenia	Late spring–early fall Recent history of tick exposure No lung involvement unless CHF (late)
Hemorrhagic/toxic smallpox	+	–	–	1-3 days	Fever, headache, and vomiting precede the appearance of petechial hemorrhage in a "swimming trunk" distribution	Hemorrhagic smallpox presents with petechial lesions and profound toxemia Patients may expire before vesicular lesions develop
Overwhelming pneumococcal bacteremia	–	+	+	1-2 days	Diffuse asymmetrical purpuric lesions Hypotension, shock early Leukopenia Thrombocytopenia Howell-Jolly bodies on peripheral smear	Occurs in asplenic patients (e.g., trauma, staging procedures for lymphoma, sickle cell anemia) Source of pneumococcal pneumonia may not be clinically apparent
Dengue hemorrhagic fever, dengue shock syndrome	+	–	+	3-4 days	Rash begins on thorax Palpable pinpoint petechiae on trunk Pain on eye movement Severe headache, myalgias Generalized adenopathy may be present "Camel-back" fever curve Leukopenia Thrombocytopenia	Recent travel history to Caribbean, Latin America, Asia
Arboviral hemorrhagic fevers	+	–	+	3-4 days	Acute onset with prominent hemorrhagic manifestations Severe headache, myalgias "Camel-back" fever curve Possibly abdominal pain, generalized adenopathy Encephalopathy, lethargy common Sore throat, cough Conjunctivitis Nausea, vomiting, diarrhea Abdominal pain ↑ SGOT/SGPT Leukopenia Thrombocytopenia Generalized adenopathy may be present	History of recent travel to Africa, Latin America, or Asia Rapidly fatal
Overwhelming staphylococcal bacteremia	–	+	+	3-5 days	Asymmetrical hemorrhagic lesions or infarcts in distal extremities	Usually obvious staphylococcal focus or *S. aureus* ABE

Continued

TABLE 26–3. COMMUNITY-ACQUIRED RASHES IN THE ICU—CONT'D

Type of Rash	Central > Peripheral	Peripheral > Central	Palms and Soles	Appearance of Rash after Fever	Clinical Features	Comments
					Leukopenia Thrombocytopenia No relative bradycardia Heart murmur if source is ABE	
Maculopapular Rashes						
Toxic shock syndrome (TSS)	+	–	+	1-2 days	Conjunctivitis Scarlatiniform maculopapular rash Bilateral periorbital edema Edema of the dorsum of hands, feet Oral, vaginal erythema Leukocytosis Thrombocytopenia ↑ SGOT/SGPT ↑ BUN/creatinine	Recent or current history of tampon use, menses May have only streptococcal colonization with TSS-1 strain Severe cases may have persistent hypotension despite fluid replacement
Systemic lupus erythematosus (SLE)	+	+	–	With flare	Rash usually facial, but may involve extremities Possibly severe abdominal pain On SPEP, α_2-globulins ↑ in SLE flare, but not in infection LFTs normal in SLE flare; if SGOT/SGPT elevated, test for CMV Leukopenia, lymphopenia, thrombocytopenia suggest SLE flare Microscopic hematuria, ↑ serum creatinine also indicative of SLE flare	Flare usually occurs when steroids tapered CMV may induce SLE flare Associated signs of cerebritis, pneumonitis, peritonitis, or serositis with SLE flare Migratory pulmonary infiltrates with effusion characteristic of SLE pneumonitis Rule out infection to diagnose SLE flare Infections common in SLE, but not during SLE flare
Cutaneous anthrax	–	+	±		Circular, raised lesions may initially be pruritic before ulcerating Painless lesions may be accompanied by painful regional adenopathy	Well-developed anthrax lesion is surrounded by a raised "gelatinous halo" Initial painless ulcer has central necrosis and evolves into an eschar
Drug rash	+	–	+	Days to weeks	Erythema multiforme, Stevens-Johnson syndrome in severe cases ↑ ESR Eosinophils usually present; eosinophilia less uncommon Mildly ↑ SGOT/SGPT ↑ WBC (with left shift) Relative bradycardia Negative blood cultures (excluding contaminants)	"Sensitizing" medication, usually not an antibiotic
Measles	+	–	–	2-3 days	Toxic appearance Intense red or purple confluent rash begins on face (3 days head to feet) Cough prominent Conjunctivitis (Giant cell) pneumonia Leukopenia ± Thrombocytopenia ± ↑ SGOT/SGPT Pseudoappendicitis	Occurs in spring Koplik's spots present before rash
Vesicular Rashes						
Chickenpox	+	+	+	2-3 days	Lesions appear in crops for first 3 days, then stop Vesicles are in different stages of development Vesicles lying on skin surface have "dew drop on rose petal" appearance	Critically ill adults usually have varicella pneumonia

TABLE 26–3. COMMUNITY-ACQUIRED RASHES IN THE ICU—CONT'D

Type of Rash	Central > Peripheral	Peripheral > Central	Palms and Soles	Appearance of Rash after Fever	Clinical Features	Comments
					Vesicles surrounded by "red halo" are pruritic ↑ Basophils No leukopenia No thrombocytopenia ± ↑ SGOT/SGPT	
Typical smallpox	–	+	+	5-7 days	Macular lesions start at hairline, followed by papules, vesicles, and pustules that rapidly cover the face and spread to the extremities Relative sparing of the trunk	Pustules in each anatomic region are in same stage of development, but stage differs from region to region Pustule of smallpox is umbilicated and deep in the dermis
Herpes zoster (shingles)				3-4 days		Before the appearance of the rash, the pain of dermatomal zoster may mimic an acute abdomen, pneumonia, pulmonary edema, or myocardial infection Acutely ill adults usually have disseminated varicella-zoster virus
Bullous Lesions						
Vibrio vulnificus	+	–	–	1-3 h	Painful hemorrhagic, bullous rash on trunk, buttocks Watery, profuse diarrhea Abdominal pain No muscle involvement No anemia	Primary septicemia from ingestion in patients with liver disease or severe wound infection from water containing "halophilic vibrios"

ABE, acute bacterial endocarditis; BUN, blood urea nitrogen; CHF, congestive heart failure; CMV, cytomegalovirus; ESR, erythrocyte sedimentation rate; LFT, liver function test; SGOT/SGPT, aspartate transaminase/alanine transaminase; SPEP, serum protein electrophoresis; WBC, white blood cell.
Adapted from Cunha BA: Approach to the patient with fever. In Samiy AH, Douglas RG Jr, Barondess JA (eds): Textbook of Diagnostic Medicine. Philadelphia, Lea & Febiger, 1987, pp 132-141.

Drainage from the wound is serosanguineous rather than purulent.

Staphylococcal sepsis is usually related to an intravascular device or source. Staphylococcal acute bacterial endocarditis may present initially with maculopapular lesions that become hemorrhagic or gangrenous. The diagnosis should be suggested by a peripheral location of lesions with an irregular outline in the setting of staphylococcal bacteremia.

Cholesterol emboli can be released into the systemic circulation during cardiopulmonary bypass. Thus, after open-heart surgery a patient may develop cholesterol emboli syndrome, which presents as a maculopapular rash with a livedo reticularis–like appearance. The rash occurs on the extremities and can be accompanied by myocardial infarction, acute pancreatitis, acute renal failure, or stroke due to organ ischemia caused by cholesterol emboli. Excluding drug rashes, cholesterol emboli syndrome is the only rash in the ICU associated with peripheral eosinophilia.

Drug rash is a drug hypersensitivity reaction associated with a skin rash. Most patients who develop drug rash do so after receiving new medications in the hospital. Drug-induced rashes are usually maculopapular, generalized, and pruritic and can involve the palms and soles; fever is almost always present. Mild transaminasemia and peripheral eosinophilia complete the clinical presentation. The clinical problem is that drug rash is often superimposed on one or more underlying medical disorders that brought the patient to the ICU in the first place. Even after discontinuing therapy with the offending drug, the rash and fever can take days to weeks to resolve.[16]

Many patients develop contact dermatitis while in the ICU. This condition is very common and must be differentiated from a drug rash. Patients with contact dermatitis do not have fever; in addition, the rash of contact dermatitis is limited to a localized area (e.g., the back), whereas a drug rash is never asymmetrical or limited to only one extremity or anatomic region. Contact dermatitis is not accompanied by eosinophilia or increased serum transaminase levels.

The types of hospital-acquired rashes and their differential diagnoses are presented in Tables 26-4 and 26-5.

TABLE 26–4. HOSPITAL-ACQUIRED RASHES IN THE ICU

Type of Rash	Central > Peripheral	Peripheral > Central	Palms and Soles	Appearance of Rash after Fever	Clinical Features	Comments
Maculopapular Rashes						
Overwhelming staphylococcal sepsis	–	+	+	3-5 days	Asymmetrical hemorrhagic lesions or infarcts in distal extremities Positive blood cultures Leukopenia ± thrombocytopenia	Usually obvious staphylococcal focus or *S. aureus* acute bacterial endocarditis
Surgical toxic shock syndrome	+	–	+	1-2 days	Surgical wound nonpurulent with serosanguineous discharge Scarlatiniform, maculopapular rash Extremity edema Oral, vaginal erythema Watery diarrhea Liver, renal dysfunction Negative blood cultures, leukocytosis ± thrombocytopenia	Recent history of surgical wound infection Severe cases may have persistent hypotension despite fluid replacement
Cholesterol emboli syndrome	–	+	–	Hours-days	"Livedo reticularis" rash on extremities Multisystem organ dysfunction: myocardial infarction, pancreatitis, CVA, intestinal ischemia Eosinophilia a key diagnostic clue Negative blood cultures Leukocytosis No thrombocytopenia	Recent cardiothoracic or carotid surgical procedure
"Surgical" scarlet fever	+	–	–	1-2 days	Diffuse sunburn-like rash "Sandpaper" skin Rash subsides in 6-9 days "Strawberry" tongue Leukocytosis ± thrombocytopenia Eosinophilia Group A streptococci in wound cultures ↑ ASO/anti-DNAse titers	Group A streptococcal wound infection due to erythrotoxin-producing strains
Drug rash	+	–	+	Days to weeks	↓ Platelets common Relative bradycardia Erythema multiforme, Stevens-Johnson syndrome in severe cases Mildly ↑ serum transaminases ↑ ESR Eosinophils usually present; eosinophilia less uncommon, may be pruritic Thrombocytopenia common Negative blood cultures (excluding skin contaminants)	"Sensitizing" medication, usually not an antibiotic ↑ WBC with left shift common, mimicking infection
Bullous Lesions						
Gas gangrene (clostridial myonecrosis)	–	–	–	Hours to days	Low-grade or no fever Patients very apprehensive Intense local pain Relative tachycardia Little or no gas on auscultation Bullous, hemorrhagic rash Leukocytosis No thrombocytopenia Rapidly progressive hemolytic anemia Watery diarrhea Radiograph shows small bubbles in muscle	Related to recently fecally contaminated wound Gross gas on auscultation or radiograph argues against diagnosis of clostridial myonecrosis

ASO, antistreptolysin O; CVA, cerebrovascular accident; ESR, erythrocyte sedimentation rate; WBC, white blood cell.

Chapter 27
CHEST PAIN

David T. Huang

Chest pain in the ICU is a common complaint that demands urgent evaluation. It is also a somewhat different entity from chest pain seen in the office, ward, or emergency department (ED). Although ICU patients typically are sicker and their problems more complex, management is expedited. ICU patients have already been identified as being critically ill, and they are already in the most resource-rich area of the hospital. The keys to proper management of chest pain in the ICU are a rapid and focused assessment of immediate problems, a careful consideration of the differential diagnosis, a logical evaluation plan, and empirical treatment while awaiting a definitive diagnosis.

INITIAL APPROACH

An ICU patient with chest pain should be seen as soon as possible. When performing the initial evaluation (Fig. 27-1), a good policy is to obtain a fresh set of vital signs and determine whether anything else has changed. First, ensure the adequacy of the basic ABCs: airway, breathing, and circulation. Ensure that the patient has intravenous access and is on a cardiac monitor. Next, take a moment to note the patient's cardiac rhythm and arterial oxygen saturation (pulse oximetry). Check the ventilator settings and, if an arterial catheter or pulmonary artery catheter is in place, the systemic arterial or pulmonary arterial pressure waveforms, respectively. Determine whether the patient appears obtunded, dyspneic, mottled, cool, or diaphoretic. Auscultate the chest and precordium, listening for heart murmurs, friction rubs, and the presence and quality of breath sounds. Seek to identify immediate life-threatening problems, such as tension pneumothorax, ventricular arrhythmias, or arterial hypoxemia, before moving on to perform a more detailed assessment. If life-threatening problems are suspected, evaluation and treatment must be performed almost concurrently. Other chapters in this textbook discuss these time-urgent conditions in greater detail.

HISTORY

If the patient is stable after the initial evaluation, obtain a more detailed history. If the patient can communicate, start with an open-ended question, such as "What's going on, Mr. Jones?" Physicians typically interrupt their patients after about 23 seconds,[1] so force yourself to simply listen for at least 1 minute before saying anything else. The most pertinent information will usually come out during those 60 seconds. Next, fully characterize the chest pain. In one study, only 42% of patients with confirmed thoracic aortic dissections were asked even basic questions about their pain.[2] Omitting one or more of these basic questions during the initial evaluation was associated with a delayed diagnosis. The mnemonic OLDCAAR can help clinicians avoid this mistake (Table 27-1).

The patient's bedside nurse should also be queried about recent changes in the patient's status (e.g., mental status, respiratory pattern, cardiac rate and rhythm). Last, a quick "chart dissection" should be performed, focusing on the initial history and physical examination, past medical history (paying special attention to cardiac risk factors and prior surgical procedures), reason for ICU admission, and the last few progress notes. Do not waste time asking the patient or nurse questions that can be answered by reading the medical record.

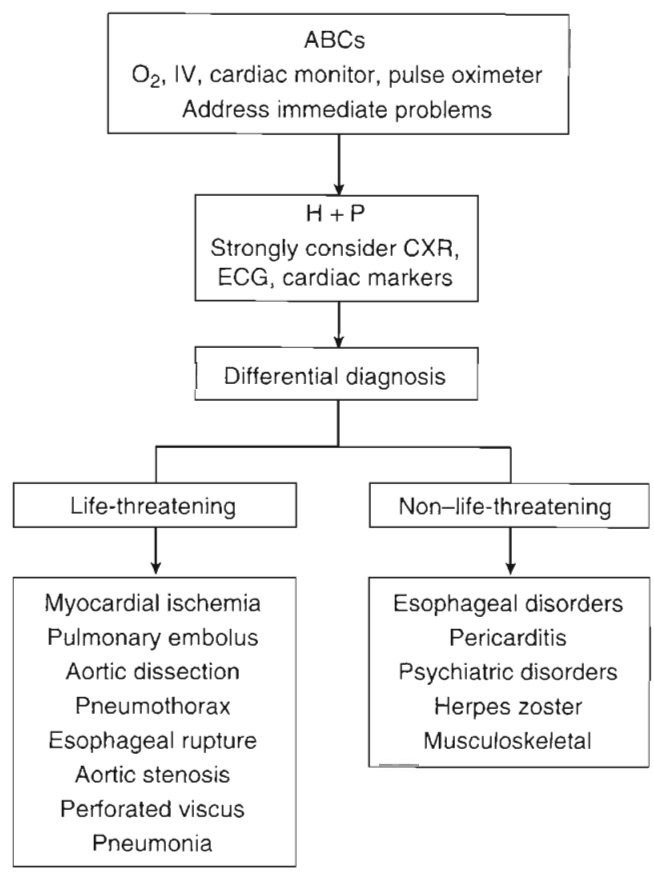

FIGURE 27–1. Approach to chest pain in the ICU. ABC, airway, breathing, circulation; CXR, chest x-ray; ECG, electrocardiogram; H + P, history and physical examination; IV, intravenous access.

TABLE 27–1. OLDCAAR MNEMONIC FOR EVALUATING PAIN

Domain	Suggested Questions
Onset	Sudden vs gradual? Maximal pain at onset?
Location	Generalized or localized? Can you point with one finger to where it hurts?
Duration	When did it start? Just now, or did the pain occur earlier, but you didn't want to bother anyone? Is it constant or intermittent? If intermittent, is there a trigger, or is it random?
Character	Sharp? Dull? Ache? Indigestion? Pressure? Tearing? Ripping?
Associated symptoms	"Dizzy"—vertiginous or presyncopal? Diaphoresis? Palpitations? Dyspnea? Nausea or vomiting?
Alleviating/ **A**ggravating	Position? Belching? Exertion? Deep breathing? Coughing?
Radiation	To the back? Jaw? Throat? Arm? Neck? Abdomen?

PHYSICAL EXAMINATION

Disrobe the patient to ensure optimal visualization, looking particularly for obvious chest wall asymmetry or deformities. Seek to identify areas of point tenderness or crepitus. Next, focus on the cardiac, pulmonary, and abdominal examinations. Check the blood pressure in both arms as you talk to the patient. Assess for asymmetry in pulse quality of the carotid, femoral, and radial pulses. There is a difference in the blood pressure recorded from the right and left upper extremities in about one third of patients with aortic dissection.[3] Check for pulsus paradoxus and jugular venous distention. Listen for asymmetry and quality of breath sounds in conjunction with a review of ventilator settings, if applicable. Evaluate the heart for diminished heart sounds, new murmurs, friction rubs, or gallops. Examine the abdomen for tenderness, pulsatile masses, and absent or abnormal (i.e., high-pitched) bowel sounds. Last, palpate and inspect the lower extremities for tenderness or size differential. Unfortunately, the physical examination is relatively insensitive, and supplemental tests are frequently necessary.[3]

DIAGNOSTIC ADJUNCTS

Unless the cause of new chest pain is obvious (e.g., tension pneumothorax, herpes zoster with visible lesions), a portable chest x-ray (CXR) and 12-lead electrocardiogram (ECG) and rhythm strip should almost always be obtained. In addition, serial measurements of circulating levels of creatinine phosphokinase MB or, preferably, troponin T or troponin I should be strongly considered to exclude a myocardial infarction (MI).

The CXR should be examined for pneumothorax; a widened mediastinum; new infiltrates; effusions; free subdiaphragmatic air; rib fractures; subcutaneous emphysema; malpositioned endotracheal, nasogastric, orogastric, or chest tube; and aortic silhouette abnormalities. Both the ECG and the CXR should be compared with the most recent study before the onset of chest pain.

The ECG and rhythm strip should be evaluated principally for arrhythmias and signs of ischemia, such as inverted T waves, ST segment depression or elevation, and new Q waves. More subtle ECG findings relevant to specific causes of chest pain are discussed in the next section.

An intravenous contrast–enhanced spiral computed tomography (CT) scan is helpful for excluding the diagnosis of pulmonary embolism and may detect other pathologic findings as well. In many centers, it is the diagnostic test of choice for pulmonary embolism. The ventilation-perfusion ($\dot{V}/\dot{Q}$) radionuclide lung scan is an alternative method of diagnosing pulmonary embolism. The $\dot{V}/\dot{Q}$ scan can be a useful alternative to spiral CT in patients with a history of allergic reaction to intravenous contrast material or those at high risk for contrast-induced nephropathy. Pulmonary angiography remains the gold standard for detecting pulmonary embolism, but it is an invasive procedure with a low but real risk of iatrogenic complications.

Echocardiography can be useful for assessing not only left and right ventricular function but also regional wall motion abnormalities, pulmonary hypertension, valvular disease, pericardial effusion, cardiac tamponade, and aortic dissection. Transthoracic echocardiography is usually the first step, followed by transesophageal echocardiography, if necessary. However, transthoracic echocardiography does not visualize the aorta well and can be limited by obesity, emphysema, and chest deformity. For patients in urgent need of aortic visualization, transesophageal echocardiography may be indicated as the initial choice.

DIFFERENTIAL DIAGNOSES

There are three rules to live by:

1. Do not assume that the admission diagnosis is necessarily correct or inclusive. MI can present as gastrointestinal complaints, especially among African Americans.[4] Conversely, the actual diagnosis among patients admitted with presumed (but unconfirmed) MI includes pneumonia, perforated duodenal ulcer, or acute cholecystitis, among myriad other possibilities.
2. Do not be biased by the type of ICU the patient happens to be in. For example, aortic dissection can present as a stroke, prompting admission to a neurologic ICU. Acute serious abdominal problems can occur in medical ICU patients. Indeed, a recent retrospective review of abdominal catastrophes in a medical ICU concluded, "delays in surgical evaluation and intervention are critical contributors to mortality rate in patients who develop acute abdominal complications in a medical ICU."[5]
3. Do not close your mind to alternative diagnoses, even if the diagnosis seems obvious.

ACUTE LIFE-THREATENING PROBLEMS

Myocardial Ischemia

The spectrum of myocardial ischemia ranges from angina to frank MI. Because coronary artery disease is highly prevalent in ICU patients, whether previously diagnosed or occult, a high index of suspicion for ischemia is mandatory. Enumeration of the patient's risk factors (hypercholesterolemia, hypertension, smoking history, family history, age, diabetes mellitus) is useful. The classic signs of myocardial ischemia include chest pain, diaphoresis, palpitations, nausea, syncope or near syncope, vomiting, and dyspnea. Pain often radiates to the neck, arm, or jaw. Unfortunately, myocardial ischemia can also present in much more subtle ways. The type of chest pain is variable and has been described as sharp, dull, tearing, or crushing. Many patients do not even report pain but describe only pressure or simply

an odd feeling. Importantly, MI can often present as gastrointestinal symptoms alone, such as "gas," "heartburn," or simply nausea. A retrospective review of 434,877 patients with confirmed MI found that 33% did not have chest pain.[6] Further, patients without chest pain had higher in-hospital mortality rates, possibly due to delays in care. These atypical presentations are more common in patients with heart failure, a previous stroke, or diabetes and in the elderly, women, and minorities.[4,6]

An ECG should be obtained, and supplemental oxygen and pain relief should be provided, if myocardial ischemia is deemed possible. Unless contraindicated, antiplatelet therapy in the form of aspirin 162 to 325 mg p.o or clopidogrel 75 mg p.o. (if aspirin allergy is present) should also be administered. The ECG should be compared with the most recent previous one and examined for ST segment elevation or depression, new Q waves, and T wave inversion. Unfortunately, many MIs are associated with equivocal ECG findings,[7] in which case serial cardiac enzymes and serial ECGs are necessary for diagnosis. Nitroglycerin and morphine should be used to relieve pain, checking the blood pressure before and after each dose. If pain is not relieved with these measures, alternative diagnoses such as aortic dissection should be considered. However, if the diagnosis of MI is strongly suspected, an interventional cardiology consultation should be obtained because persistent chest pain is an indication for urgent cardiac catheterization.[8]

Pulmonary Embolus

Most ICU patients have at least one risk factor for pulmonary embolus (prolonged bed rest, postoperative state, hypercoagulable state, trauma, burns, heart failure); therefore, pulmonary embolus, like MI, should be strongly considered in this population. Pulmonary embolus can present in multiple ways, but most frequently as pleuritic chest pain and dyspnea or tachypnea. Other presentations include syncope, hemoptysis, diaphoresis, cough, and hypoxia. Although pulmonary embolus is often associated with a widened alveolar-arterial (A-a) gradient, this finding is not very useful among ICU patients because it is neither specific (ICU patients often have many other reasons for hypoxia) nor sensitive (the A-a gradient is normal in approximately 25% of patients with pulmonary embolus).[9] Large pulmonary emboli that significantly occlude the pulmonary circulation present with obstructive cardiogenic shock, hypotension, and a sudden rise in central venous, right ventricular, and pulmonary arterial pressures. Echocardiography can be useful in this setting to confirm the diagnosis by demonstrating right heart failure and right ventricular dilatation with septal shift and subsequent left ventricular outflow obstruction.

The CXR is insensitive for diagnosing pulmonary embolus, so more advanced studies are typically required (CT, V/Q scan, pulmonary angiography). For each test, the risks of iatrogenic complications and complications during transport must be taken into account.

Aortic Dissection

The risk factors for aortic dissection overlap considerably with those for myocardial ischemia; therefore, this entity should always be considered among "rule out MI" patients (Table 27-2). Persistent chest pain without ECG changes is a potential clue that aortic dissection may be present.

The basic pathophysiology involves a tear of the aortic intima, leading to a false lumen between the intima and adventitia. A recent systematic review noted that the vast majority of patients complain of severe chest pain (90%) of sudden onset (84%).[3] The review also noted that 28% have a diastolic murmur (due to aortic regurgitation), 31% have a pulse deficit or blood pressure differential (>20 mm Hg), and 17% have focal neurologic deficits. The physical examination should search for these findings.

TABLE 27–2. AORTIC DISSECTION RISK FACTORS

Atherosclerosis risk factors (hypertension, diabetes, smoking, age, hypercholesterolemia)
Connective tissue disorders (Marfan's syndrome, Ehlers-Danlos syndrome)
Cocaine
Bicuspid aortic valve
Coarctation of the aorta
Trauma
Previous cardiac surgery (especially aortic valve replacement)
Intra-aortic catheterization
Giant cell arteritis

Patients with aortic dissection were once thought to experience a tearing or ripping sensation. However, the International Registry of Acute Aortic Dissection reported in its series of 464 patients that pain was most commonly described as "sharp."[10] Further, only about half the patients described back pain. Therefore, the absence of tearing or ripping pain radiating to the back should not exclude the diagnosis of aortic dissection.

Although a normal CXR does not rule out aortic dissection, the presence of certain findings can be helpful. These findings include a wide mediastinum, separation of intimal calcification from the outer border of the aortic knob by 1 cm or greater, deviation of the trachea to the right, and blurring of the aortic margin. Comparison to the most recent CXR is key. Contrast-enhanced spiral CT is usually the best confirmatory test, but if the risk of transport is too high, bedside transesophageal echocardiography should be performed. Immediate management should focus on blood pressure control, ideally using beta-adrenergic blockade with or without a vasodilator, such as sodium nitroprusside.

Pneumothorax

ICU patients are at high risk for pneumothorax due to iatrogenic complications from central venous catheterization and thoracentesis; preexisting and acquired pulmonary disease, particularly emphysema, asthma, and acute respiratory distress syndrome; and barotrauma secondary to mechanical ventilation. It is absolutely critical to diagnose pneumothorax in patients receiving positive pressure mechanical ventilation, because positive airway pressure can transform a simple pneumothorax into a tension pneumothorax. The cardinal signs of tension pneumothorax are hypotension, jugular venous distention, absence of breath sounds and hyperresonance to percussion on the affected side, and tracheal deviation (away from the affected side). Treatment is immediate needle (14 gauge) decompression, followed by chest tube placement. Needle decompression is quickly accomplished by inserting a large-bore (16 or 18 gauge) needle through the second or third anterior interspace in the midclavicular line of the involved hemithorax.

Simple pneumothorax presents similarly but less dramatically with hypoxia, dyspnea or tachypnea, pleuritic chest pain, decreased breath sounds with hyperresonance, and increased

peak airway pressure. An upright, expiratory CXR should be obtained in cases of suspected pneumothorax. If only a supine film is possible, the deep sulcus sign (hyperlucent, lowered hemidiaphragm with an unusually sharp cardiac border) can help make the diagnosis. Loculated pneumothoraces due to underlying pulmonary adhesions can be difficult to visualize on a CXR. In such cases, chest CT should be obtained promptly; left undiagnosed and untreated, simple pneumothorax can lead to tension pneumothorax. Communication with the radiologist is essential. If the diagnosis of a loculated pneumothorax is confirmed, CT-guided placement of a chest tube or pigtail catheter should be undertaken.

Esophageal Rupture

Prompt recognition is required, because esophageal rupture can lead to potentially lethal mediastinitis. Although usually suggested by a clear history of caustic substance ingestion, forceful vomiting, or iatrogenic trauma (secondary to orogastric lavage, esophageal stricture dilatation, nasogastric tube placement, esophageal intubation, endoscopy), less obvious causes can lead to a delay in diagnosis. Any sudden increase in intra-abdominal pressure can lead to esophageal rupture, and seizures and blunt abdominal trauma have been reported as inciting events. Patients with esophageal disease such as cancer, Barrett's esophagus, and varices are especially vulnerable to rupture.

Physical examination may reveal subcutaneous emphysema or the classic finding of mediastinal crackling on auscultation (Hamman's crunch). CXR may show pneumothorax, pneumomediastinum or pneumoperitoneum, pleural effusion, or subcutaneous emphysema. In victims of blunt abdominal trauma, several findings should increase the suspicion of esophageal rupture: left pneumothorax without associated rib fractures, pain or shock out of proportion to the injury, and particulate matter in the chest tube.[11] A water-soluble contrast study or esophagoscopy confirms the diagnosis.

Aortic Stenosis

The main physiologic effect of aortic stenosis is to impede left ventricular ejection, leading ultimately to left ventricular hypertrophy. Critical aortic stenosis results when this compensatory mechanism can no longer overcome the valvular stenosis or when the hypertrophy itself causes diastolic failure or excessive myocardial oxygen demand. The classic symptoms of angina, syncope, and dyspnea result. Clues suggesting critical aortic stenosis on physical examination include narrow pulse pressure, systolic murmur radiating to the carotid, S_4 gallop, and an aortic ejection click. CXR and ECG may show signs of left ventricular hypertrophy, but the definitive test is a Doppler echocardiogram. If positive, cardiac catheterization should be performed to look for concomitant coronary artery disease and to confirm the echo results. The urgency of these tests is determined by the severity of symptoms; once angina, heart failure, or syncope occurs, a prompt workup is required. Aortic valve replacement is the definitive therapy. Temporizing medical management focuses on cautiously decreasing afterload and treating angina with the careful administration of nitrates, angiotensin-converting enzyme inhibitors, and diuretics. Close hemodynamic monitoring is essential if these drugs are given, because decreases in diastolic pressure can worsen myocardial ischemia.

Miscellaneous

A perforated viscus sometimes presents as chest pain, but fortunately, this is usually easily picked up as free subdiaphragmatic air on an upright CXR. However, retroperitoneal perforations do not show up as free air under the diaphragm on CXR.

Pneumonia is often accompanied by pleuritic chest pain. Referred shoulder pain can result from diaphragmatic irritation by lower lobe pneumonia.

NON–LIFE-THREATENING PROBLEMS

All the following entities should be considered diagnoses of exclusion and should be considered only after life-threatening causes have been ruled out.

Esophageal Disorders

Owing to the shared innervation of the heart and esophagus, visceral pain originating from these two organs can be similar in character. Thus, it can be difficult to differentiate between myocardial ischemia and relatively benign esophageal disorders such as gastroesophageal reflux disease and esophageal dysmotility syndromes. The diagnosis of esophageal disease is supported by a history of pain precipitated by lying flat or the ingestion of hot or cold liquids or food. The diagnosis of an esophageal disorder is also supported if the pain is relieved by antacids. Nitroglycerin can relieve pain due to myocardial ischemia or esophageal spasm, so response to this drug it is not useful as a diagnostic tool. Confirmatory tests include esophageal manometry and esophageal pH monitoring. Alternatively, an empirical trial of a proton pump inhibitor can be tried first. Last, sometimes a nasogastric tube with the distal tip in the esophagus can produce pain, especially when left on suction.

Musculoskeletal Disorders

Chest wall pain is diagnosed with direct palpation or by asking the patient to press with his or her arms against resistance. Usually these maneuvers elicit pain from the affected area. Costochondritis and myofascial syndromes often have specific trigger points that can stimulate pain. Occult rib fractures should be sought carefully by examining the CXR. According to some reports, up to 15% of patients with MI also have chest wall pain, so unless a very specific, localized, and reproducible area of pain can be found, a cardiac workup should be performed.[12] The insertion points for each chest tube and central line should also be inspected. If chest pain is elicited on physical examination, the clinician should specifically ask the patient whether the pain is the same as the spontaneously occurring pain. A negative reply demands further workup.

Pericarditis

Although pericarditis itself is rarely life-threatening, other entities in the differential diagnosis, such as MI and cardiac tamponade, can be. Pain due to pericarditis is typically pleuritic, sharp or stabbing, and retrosternal or precordial, with radiation to the back, neck, shoulders, or arms. Pain is often relieved by leaning forward and worsened by lying flat. More useful in differentiating pericarditis from ischemia is the presence of a pathognomonic but often transitory triphasic (systole, early diastole, and presystole) friction rub. A pericardial rub sounds similar to hair being rubbed together and has been described as high-pitched. It is best heard with the

diaphragm of the stethoscope at the cardiac apex, with the patient seated and leaning forward.

Characteristic ECG findings also help differentiate pericarditis from MI. Both entities demonstrate ST segment elevation, but with pericarditis, ST segment depression is absent in the reciprocal leads, except occasionally in aV_R and V_1. Absence of Q waves, concave (instead of convex) ST segment elevation, PR depression, and upright T waves also strongly favor pericarditis.[13] Careful ECG review, auscultation, and history are the key to distinguishing between these two disorders and avoiding potentially fatal complications of contraindicated therapy (administration of a thrombolytic agent to patients with pericarditis can precipitate hemotamponade) or missing a diagnosis of life-threatening MI.

Pericarditis can lead to pericardial effusion. If it is large or acute, pericardial effusion can lead to cardiac tamponade. Pericardial effusion can present similarly to pulmonary embolus with dyspnea or tachypnea, tachycardia, and chest pain or pressure. ECG findings of electrical alternans and low voltage, coupled with cardiomegaly on CXR, strongly favor pericardial effusion. Pulsus paradoxus may also be present. Beck's triad (jugular venous distention, hypotension, muffled heart tones) points to a more emergent condition. Note that cardiac tamponade and tension pneumothorax share the first two components of Beck's triad, but the latter condition is characterized by normal heart tones, decreased breath sounds, and hyperresonance of the involved hemithorax. Beck's triad is not always present in patients with tamponade. For instance, if the patient is hypovolemic, jugular venous distention may not be apparent. Tamponade should be suspected when the clinical condition looks like congestive heart failure but breath sounds are clear. The ECG and CXR findings discussed for pericardial effusion are useful, but urgent echocardiography should be ordered to confirm the diagnosis. If the patient is in extremis and the clinical picture strongly suggests tamponade, pericardiocentesis should be performed. Volume loading should be done concurrently, because it can partially overcome the hemodynamic effects of tamponade.

Last, it is important to determine the underlying cause of the pericarditis. Possibilities include infection, malignancy, trauma, autoimmune disorders, and connective tissue disorders; it can also be idiopathic.

Psychiatric Disorders

Anxiety disorders, somatization, and panic attacks can all present with chest pain. Panic attacks, in particular, can be associated with symptoms that closely mimic those of MI. Both conditions are commonly associated with diaphoresis, tachypnea, dyspnea, palpitations, presyncope, and a sense of impending doom. Many patients with panic attacks have had extensive cardiac and gastrointestinal workups in the past, and obtaining these reports is helpful. Nonetheless, the dictum that "psychiatric patients get sick too" should be remembered. Psychiatric patients with real cardiac or pulmonary disease can be especially challenging to diagnose, and a thorough, empathic history is essential. Depression is often a comorbid psychiatric condition and should be appropriately treated.

Herpes Zoster

Inspection of the patient's thorax usually makes the diagnosis of herpes zoster, although pain precedes skin manifestations by 1 to 3 days. The lesions are limited to a single dermatome and start as a maculopapular rash that quickly changes to the characteristic vesicular lesions. Acyclovir is the treatment.

CONCLUSION

Attention to immediate problems, a thorough history and physical examination, and consideration of each life-threatening possibility are the key steps to managing chest pain in the ICU. The test battery of a CXR, ECG, and serial cardiac enzymes should be used liberally but intelligently. A high index of suspicion for occult disease is necessary for complex ICU patients.

ANNOTATED REFERENCES

Canto JG, Shlipak MG, Rogers WJ, et al: Prevalence, clinical characteristics, and mortality among patients with myocardial infarction presenting without chest pain. JAMA 2000;283:3223-3229.

This study of 434,877 patients with confirmed MIs found that fully one third of MI patients do not complain of chest pain at presentation. These atypical patients tended to be older, female, and diabetic and to have prior heart failure. Most important, the in-hospital mortality for these patients was more than double that of patients who presented with chest pain.

Gajic O, Urrutia LE, Sewani H, et al: Acute abdomen in the medical intensive care unit. Crit Care Med 2002;30:1187-1190.

This retrospective cohort study found that delays in surgical evaluation and intervention were independent, statistically significant correlates of mortality. Interestingly, it also found that risk factors for surgical delay included opioid use, mechanical ventilation, no peritoneal signs, antibiotics, and altered mental state. This suggests that a heightened index of suspicion for an acute abdomen may be necessary in ICU patients with these risk factors.

Hagan PG, Nienaber CA, Isselbacher EM, et al: The International Registry of Acute Aortic Dissection (IRAAD): New insights into an old disease. JAMA 2000;283:897-903.

The IRAAD is composed of 12 international referral centers, from which 3 years of data and 464 patients were analyzed. A key finding was that classic presentations such as tearing or ripping chest pain (50.6%), aortic regurgitation (31.6%), and pulse deficit (15.1%) were frequently absent, leading the authors to urge clinicians to maintain a high index of suspicion.

Klinger D, Green-Weir R, Nerenz D, et al: Perceptions of chest pain differ by race. Am Heart J 2002;144:51–59.

In this study of 215 patients with confirmed MI, African-American patients attributed their initial symptoms to a gastrointestinal cause 61% of the time, versus 26% in white patients.

Marvel MK, Epstein RM, Flowers K, Beckman HB: Soliciting the patient's agenda: Have we improved? JAMA 1999;281:283-287.

Although this study was conducted in primary care offices and not in an ICU, it emphasizes the importance of the basic history-taking process and listening to patients. It found that physicians interrupted their patients after a mean of only 23.1 seconds and that late-arising patient concerns were more common when physicians did not solicit questions during the interview.

Section II

BASIC SCIENCE

Chapter 28
REGULATION OF GENE EXPRESSION

Edward Abraham

KEY POINTS

1. Effective transcription requires assembly of a transcriptional apparatus that consists of RNA polymerase (Pol II), the enzyme that translates DNA sequences into RNA, with activator and coactivator proteins.
2. The stability of messenger RNA (mRNA) plays an important role in determining the final levels of gene products.
3. Cellular activation results in a sequence of signaling events, in which the initially activated kinases become capable of phosphorylating serine or tyrosine residues in downstream kinases or regulatory proteins. As a result of such kinase activity, transcriptional factors, nuclear coactivator proteins, and other regulatory molecules become phosphorylated, inducing enhanced transcriptional activity.
4. Dephosphorylation of regulatory proteins is an important negative regulatory event, resulting in down-regulation of transcriptional events, leading to a return to baseline levels of transcriptional activity.
5. The transcriptional regulatory factor nuclear factor-κB (NF-κB) is a central participant in modulating the expression of many of the immunoregulatory mediators involved in sepsis, acute lung injury, acute renal failure, and other organ system dysfunctions associated with critical illness and other inflammatory conditions, such as rheumatoid arthritis and inflammatory bowel disease.
6. The regulation of gene transcription is modulated positively by transcriptional activators and negatively by transcriptional repressors.
7. Interactions between transcriptional factors and chromatin structure determine that genes are transcribed at appropriate times and levels in response to cellular activation.

The expression of gene products is regulated at multiple steps. The initial events involve activation of intracellular kinases that phosphorylate transcriptional factors, regulatory cytoplasmic and nuclear proteins, resulting in enhanced gene transcription and messenger RNA (mRNA) production. Examples of such cascades are the phosphorylation of the p65 subunit of the transcriptional factor nuclear factor-κB (NF-κB), which increases transcriptional activity,[1,2] or of the inhibitory protein IκB-α,[3,4] which facilitates the degradation of IκB-α and nuclear translocation of NF-κB. Similarly, phosphorylation of the transcriptional factor cyclic adenosine monophosphate (cAMP) responsive element binding (CREB) protein on serine 133 by phosphokinase A, calmodulin kinases, or extracellular regulated kinases or through other kinase-mediated events enhances its transcriptional activity.[5,6] In the case of NF-κB, liberation from IκB-α allows NF-κB dimers to translocate to the nucleus, where they can interact with specific sequences in the promoter regions of genes and help initiate transcription.[7,8] CREB is normally bound to promoter sequences, but is not transcriptionally active unless phosphorylated on serine 133.[5,6]

Although availability in the nucleus of specific transcriptional factors is necessary for their interaction with binding sequences of the promoters and subsequent gene transcription, it is not sufficient. Evidence indicates that the presence of transcriptional factors in different locations in the nucleus is associated with different transcriptional activity.[9] Such information shows that it is not enough for a transcriptional factor simply to reach the nucleus to initiate transcription, but rather that there are differences between nuclear locations and that the transcriptional factor must find its way to the correct site before it can participate in gene expression.

Effective transcription requires assembly of a transcriptional apparatus that consists of RNA polymerase (Pol II), the enzyme that translates DNA sequences into RNA, with activator and coactivator proteins (Fig. 28-1). Pol II, when in the appropriate configuration with additional scaffolding, activator, and coactivator proteins, is required for transcription of genes from the 5′ end of their coding sequence. The transcriptional machinery cannot gain access to relevant promoter sites and initiate transcription unless chromatin surrounding the DNA is modified through acetylation, methylation, and association with many proteins, of which one of the most important seems to be ubiquitin.[10] Ubiquitin is a highly conserved 76-amino acid protein that is linked covalently to lysine residues in other proteins, including histones associated with DNA. Modifications in histones accomplished by addition of methyl and acetyl groups and of ubiquitin are required to expose DNA and allow access of the transcriptional apparatus to relevant promoter sequences, where it can initiate transcription.[11-13]

When mRNA is produced, its stability plays an important role in determining the final levels of gene products.[14-16] mRNA that remains available for translation for longer periods generally is associated with greater amounts of translated proteins. Post-translational events, including modification of protein length and structure, also are involved, in

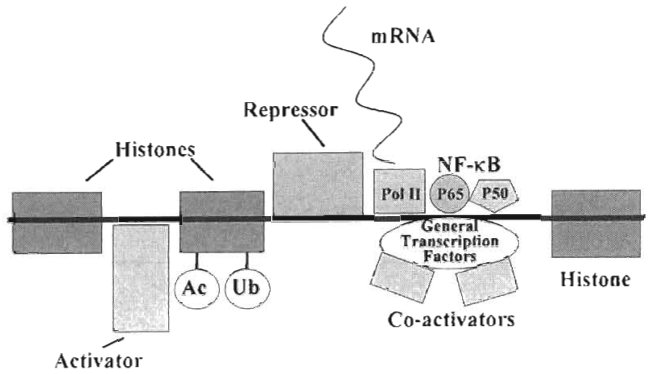

FIGURE 28–1. Regulation of gene transcription involves an interplay of histones, DNA, activators, repressors, and transcriptional machinery, primarily to allow RNA polymerase (Pol II) to produce mRNA. For transcription to occur, histones are acetylated and ubiquitylated, and a transcriptional apparatus, consisting of RNA polymerase, transcriptional factors (e.g., NF-κB), activators, and coactivators is assembled. The modifications of histones allow RNA polymerase to have access to relevant sequences in the promoter regions of genes and to initiate transcription from the 5′ end of the gene's coding sequence.

modifying intracellular and extracellular protein levels. An example of such post-translational regulation concerns the activity of caspase-1 in cleaving pro-interleukin (IL)-1β or pro-IL-18 to the mature extracellularly secreted forms of IL-1β and IL-18.[17-19]

KINASE-INDUCED PHOSPHORYLATION EVENTS AND GENE ACTIVATION

Phosphorylation of proteins by kinases often leads to their participation in signaling events that result in modified cellular activity. Kinase cascades become activated through receptor occupancy with their specific ligands, such as the interaction of lipopolysaccharide with the type 4 Toll-like receptor (TLR4) (Fig. 28-2).[17,20-22] Alterations in the intracellular milieu, including changes in oxidation state induced by increased concentrations of reactive oxygen intermediates in or around cells, also can result in the activation of kinases. Exposure of cell populations to hydrogen peroxide can produce increased activity of the inhibitor of NF-κB kinase (IKK) complex, resulting in enhanced nuclear concentrations of the NF-κB transcriptional factor.[23]

Cellular activation results in a sequence of signaling events, where the initially activated kinases become capable of phosphorylating serine or tyrosine residues in downstream kinases or regulatory proteins. As a result of such kinase activity, transcriptional factors, nuclear coactivator proteins, and other regulatory molecules become phosphorylated, inducing enhanced transcriptional activity. An example of such a cascade is the phosphorylation of the transcriptional coactivator TATA Box binding protein (TBP), a nuclear coactivator that participates in the transcriptional apparatus. Phosphorylation of TBP through activation of p38-related kinases allows enhanced association with NF-κB and increased transcription of NF-κB-dependent genes.[24]

In the same way that phosphorylation of regulatory proteins leads to increased transcriptional activity, dephosphorylation is an important negative regulatory event, resulting in down-regulation of transcriptional events, leading to a return to baseline levels of transcriptional activity. An example of the importance of dephosphorylation in modulating transcription is provided by data showing that the serine/threonine protein phosphatase 2A (PP2A) participates in regulating the activity of the activating protein 1 (AP-1) transcriptional complex.[25] In particular, AP-1 is formed and becomes transcriptionally active when phosphorylated c-Jun associates with c-Fos. Phosphorylation of c-Jun is under the regulatory control of the c-Jun N-terminal kinase (JNK). PP2A is a key regulator of JNK through its ability to dephosphorylate JNK, decreasing JNK's activity and ability to phosphorylate c-Jun. Activation of PP2A can also down-regulate AP-1-dependent transcription through its effects in dephosphorylating c-Jun.

Kinase-mediated phosphorylation is involved in enhancing nuclear accumulation of transcriptional factors, a necessary event for the initiation and enhancement of transcription. Nuclear translocation of the transcriptional factor NF-κB depends on IKK-mediated phosphorylation of inhibitory IκB cytoplasmic molecules, which leads to their destruction in the 26S proteosome and liberation of NF-κB to move into the nucleus.[4,26,27] This issue is discussed in more detail in the next section of this chapter.

NUCLEAR FACTOR κB

NF-κB is a prototypical transcription factor involved in acute inflammatory responses associated with critical illness. The transcriptional regulatory factor NF-κB is a central participant in modulating the expression of many of the immunoregulatory mediators involved in sepsis, acute lung injury, acute renal failure, and other organ system dysfunctions associated with critical illness and other inflammatory conditions, such as rheumatoid arthritis and inflammatory

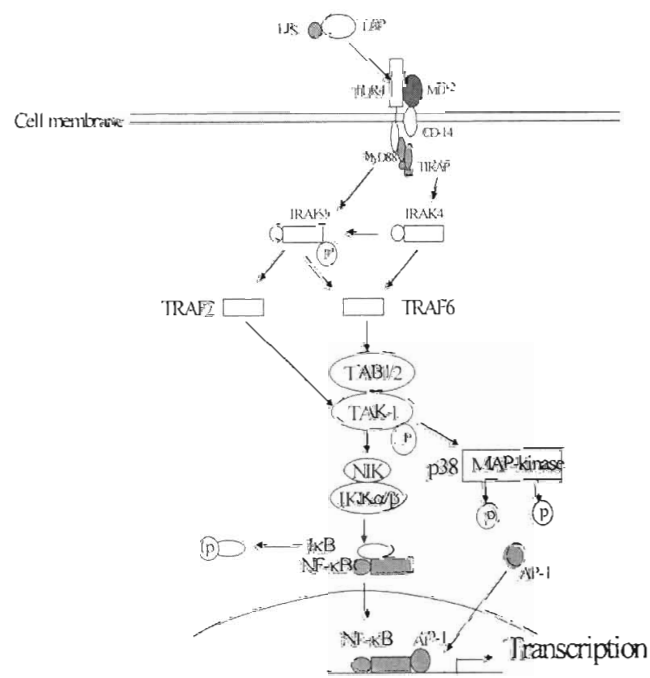

FIGURE 28–2. Interaction of lipopolysaccharide (LPS) and the LPS binding protein (LBP) with the type 4 Toll-like receptor (TLR 4) initiates a sequence of intracellular signaling events, involving activation of kinases that associate with scaffolding proteins, which ultimately leads to gene transcription through the activation of transcriptional regulatory factors, such as NF-κB and AP-1.

bowel disease. Signaling pathways initiated by engagement of TLRs, such as TLR 2 and TLR 4, by bacterial products or of cytokine receptors, including those for tumor necrosis factor (TNF)-α and IL-1, lead to nuclear accumulation of NF-κB and enhanced transcription of genes responsible for the expression of cytokines, chemokines, adhesion molecules, apoptotic factors, and other mediators of the acute inflammatory response associated with multiple organ system dysfunction in sepsis, acute lung injury, pancreatitis, burns, and other ICU conditions.[7,8,26,28,29]

In the active DNA binding form present in the nucleus and involved in transcriptional events, NF-κB is a dimer composed of members of the Rel family. Five mammalian members of this family have been identified: NF-κB1 (p50 and its precursor p105), NF-κB2 (p52 and its precursor p100), c-Rel, Rel A (p65), and Rel B. All of these proteins share a highly conserved Rel homology domain of approximately 300 amino acids composed of two immunoglobulin-like sequences. The Rel homology domain is responsible for dimerization of the NF-κB subunits, interaction with inhibitory IκB molecules, and DNA binding.

Various combinations of NF-κB have different transcriptional efficiency. The p50:p65 heterodimer promotes transcription, whereas p50:p50 homodimers suppress gene activation through preventing access to gene promoters by the transcriptionally active p50:p65 heterodimers.[30] Additionally, there is evidence that phosphorylation of the NF-κB subunits, particularly of p65, is important in optimizing transcriptional potential.[1]

NF-κB dimers normally are retained in the cytoplasm through interaction with inhibitors of the IκB family. Seven IκB molecules have been identified: IκB-α, IκB-β, IκB-γ, IκB-ε, Bcl-3, p100, and p105. Through their association with NF-κB cytoplasmic heterodimers and homodimers, IκB molecules mask the nuclear localization sequence of NF-κB and prevent its movement to the nucleus. Although IκB molecules initially were thought to reside only in the cytoplasm, more recent evidence shows that they shuttle in and out of the nucleus and have important roles in regulating the presence and activity of NF-κB dimers in the nucleus and the cytoplasm (Fig. 28-3).[31]

Cellular activation that leads to nuclear translocation of NF-κB and enhanced transcription of NF-κB-dependent genes can be induced by multiple stimuli, including LPS, peptidoglycans, and lipotechoic acid (from gram-positive bacteria); cytokines (e.g., TNF-α, IL-8, and IL-1β); T-cell and B-cell mitogens; complement fragments (e.g., C5a); reactive oxygen species; G-protein coupled receptor agonists; and other mediators associated with infection, ischemia, and stress responses. In a critically ill patient, in whom such proinflammatory stimuli are present at increased levels, the degree of NF-κB activation has been shown to correlate with patient outcome. In particular, nuclear concentrations of NF-κB in peripheral blood mononuclear cells from septic patients are higher in patients who subsequently die than in survivors.[32,33] Similar patterns of NF-κB activation, with greater nuclear accumulation being associated with a worse clinical outcome, specifically mortality or prolonged time on the ventilator, have been shown to be present among neutrophils from patients with acute lung injury.[34] These associations between enhanced nuclear levels of NF-κB and worse clinical outcome are not surprising because increased levels of many of the proinflammatory mediators under the regulatory control of NF-κB, such as TNF-α or IL-8, have

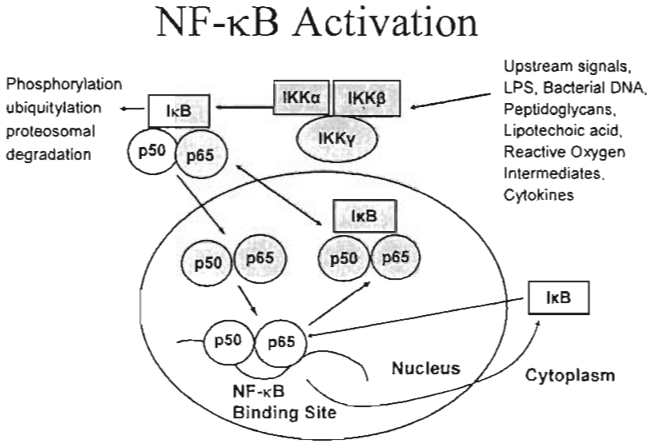

FIGURE 28–3. Multiple mediators associated with critical illness lead to activation of the IKK complex, which then phosphorylates IκBs, such as IκB-α, resulting in degradation of IκB and liberation of NF-κB dimers to move into the nucleus. The IKK complex consists of the kinases IKKα and IKKβ and the scaffolding protein IKKγ. In the nucleus, NF-κB binds to specific sites in promoter regions, where it can initiate transcription, including that of IκB-α. IκBs are primarily present in the cytoplasm, but are able to enter the nucleus, where they can facilitate the disassociation of NF-κB from binding to promoter sites and facilitate movement of NF-κB to the cytoplasm.

been shown to participate in acute inflammatory responses and organ dysfunction in sepsis, acute lung injury, and many other critical illnesses.

After cellular activation by appropriate stimuli, IκB molecules associated with NF-κB in the cytoplasm (particularly IκB-α) are phosphorylated, linked to the protein ubiquitin (i.e., ubiquitylated), and degraded by the 26S proteosome. Degradation of IκB molecules permits nuclear translocation of NF-κB, where it binds to specific sequences in the promoter regions of genes, participates in the formation of a transcriptional apparatus consisting of activator and coactivator proteins (including CREB binding protein (CBP) and RNA polymerase), and initiates transcription (see Fig. 28-3).

Phosphorylation of IκB occurs through activation of IKK.[4,26,29] Three components of IKK have been identified: the serine/threonine kinases IKKα and IKKβ and a regulatory subunit called IKKγ or NEMO. Many different protein kinases activate IKK, including Akt, PKCζ, MEKK1, MEKK2, MEKK3, NIK, COT/TPL-2, and TAK1. Although p38 has been shown to increase NF-κB-dependent transcription, it is unclear if this kinase has a role in enhancing nuclear translocation of NF-κB or whether its activity is primarily due to phosphorylation of NF-κB-associated coactivator proteins, such as TBP, or to enhancing phosphorylation of NF-κB subunits, such as p65. TAB1, an adapter protein that associates with p38α, is able to activate the kinase TAK1, leading to downstream phosphorylation and enhancement of activity of the IKK complex.[21,24,35,36]

Many of the genes regulated by NF-κB participate in inflammatory reactions leading to organ dysfunction and death in critically ill patients with conditions such as sepsis, acute lung injury, hemorrhage, burns, and pancreatitis.[7,8,26,28,37-40] A partial list of NF-κB inducible genes is provided in Table 28-1. Several of the cytokines under the regulatory control of NF-κB, such as IL-1 and TNF-α, also are able to induce further activation of this transcriptional factor, leading to potentiation of inflammatory responses

TABLE 28–1. NF-κB INDUCIBLE GENES INVOLVED IN CRITICAL ILLNESS

Class	NF-κB-Dependent Genes
Cytokines	IL-1α and IL-1β
	TNF-α
	G-CSF
	GM-CSF
	IL-6
	IFN-β
Chemokines	MIP-1α
	MIP-2
	IL-8
Adhesion molecules	ICAM-1
	VCAM-1
	E-selectin
	ELAM-1
Coagulation factors	Tissue factor
	Tissue factor pathway inhibitor
Others	Inducible nitric oxide synthase
	Cyclooxygenase-2
	IκB-α
	C3 complement
	Complement factor B

in the critically ill patient and further enhancement of NF-κB-dependent gene expression.

ROLES OF UBIQUITIN AND CHROMATIN IN MODULATING TRANSCRIPTION

The regulation of gene transcription is modulated positively by transcriptional activators and negatively by transcriptional repressors. Transcriptional activators function through facilitating direct contact of components of the general transcriptional apparatus, such as TBP, with histone-modifying moieties, such as histone acetyl transferases, and activator and coactivator proteins, such as CBP. These interactions result in modifications of chromatin structure, allowing direct access of the transcriptional complex, which includes RNA polymerase, to DNA, where the gene then can be transcribed (see Fig. 28-1). Transcriptional repressors antagonize many of these steps by deacetylating histones, blocking the recruitment or assembly of the transcriptional apparatus, or interacting with transcriptional co-repressors.

Interactions between transcriptional factors and chromatin structure determine that genes are transcribed at appropriate times and levels in response to cellular activation. The ubiquitin system is composed of a family of proteins that are capable of linking covalently to target proteins.[10,21,41] *Ubiquitylation* is the process by which ubiquitin is conjugated to a substrate protein and is essential for regulating transcription and facilitating access of transcriptional factors to relevant promoter sites. After phosphorylation on serines 32 and 36, IκB-α is ubiquitylated, an essential step that facilitates its recognition and breakdown in the 26S proteosome, allowing NF-κB to move to the nucleus and initiate transcription.[20,21,41] Modification of chromatin through covalent association with ubiquitin influences other chromatin modifications, such as acetylation and methylation, involved in transcriptional control.

Ubiquitylated forms of histones H1, H2A, and H2B are associated specifically with actively transcribed genes, providing a marker of transcriptionally active chromatin. Ubiquitylation of H2B is required for methylation of the histone H3 at lysine residues 4 and 79, which is required for telomeric gene silencing, the transcriptional down-regulation of the expression of genes proximal to the telomere.[10] It also is likely that histone ubiquitylation is involved in the activation of genes. Ubiquitylation of the linker histone H1 seems to be involved in enhancing activity of the general transcription factor TFIID complex.[10]

COORDINATION OF STEPS INVOLVED IN GENE EXPRESSION

The final step in the transcriptional regulatory process is initiation of transcription at the 5′ end of a gene by RNA polymerase II (Pol II), resulting in production of mRNA, which, after migrating to the cytoplasm, is translated to protein.[42,43] As described earlier, access of RNA polymerase to relevant gene sequences is a highly regulated event, involving a balance between stimulatory events initiated by cellular activation through receptor-ligand interaction, kinase activation, phosphorylation of regulatory proteins, modification of histones, and down-regulatory processes that occur through phosphatases and other kinases able to modulate the phosphorylation, acetylation, and ubiquitylation that lead to gene expression. Exquisite control of gene expression is achieved through the interplay of these multiple regulatory processes. Additional fine-tuning of protein production is accomplished through post-transcriptional events, involving control of mRNA stability, translational rates, and post-translocation modification of proteins.

Despite the regulatory processes that are available to modulate gene expression, critical illness often is associated with altered and pathologic production of immunoregulatory and other molecules that induce the development of organ dysfunction. Gene polymorphisms that lead to overexpression of regulatory molecules, such as plasminogen activator inhibitor-1 (PAI-1), which is involved in coagulation cascades, or of proinflammatory or anti-inflammatory mediators, such as TNF-α or IL-1ra, are associated with outcome from severe infections.[44-48] Similarly, increased activation of kinases, such as Akt, or of transcriptional factors, such as NF-κB, in neutrophils or other cell populations correlates with worse outcome from acute lung injury.[34] Future use of gene expression arrays and proteomics, which would permit identification of genes and proteins whose expression is altered in cell populations from patients at risk for or with a critical illness, are likely to help not only in early diagnosis, but, more importantly, also should permit therapies to be tailored to correct the alterations in gene and protein expression that contribute to organ system dysfunction and death in critically ill patients.

THE NEUTROPHIL: BALANCING ANTIMICROBIAL EFFECTIVENESS AND THE POTENTIAL FOR DAMAGE TO THE HOST

Theo J. Morales • Tomoko Suzuki • Gregory P. Downey

KEY POINTS

1. Neutrophils are key cells in the innate immune system serving in host defense.
2. The importance of each step in neutrophil functioning is demonstrated by a variety of disease states that result from deficiencies in these specific functions.
3. "Excessive" or unregulated neutrophil activation may contribute to the host cell damage seen in a variety of inflammatory based diseases such as acute respiratory disease syndrome (ARDS).
4. Proteases, reactive oxygen and nitrogen species, and lipid metabolites from activated neutrophils may all contribute to the host damage seen in ARDS.
5. Signal transduction pathways involving the enzyme PI3 kinase, various mitogen-activated protein kinases, especially the p38 pathway, and ultimately the transcription factor NF-κB have been implicated in contributing to the increased neutrophil activity seen in ARDS.
6. Modification of neutrophil function to achieve the optimal balance between adequate host defense and minimal host damage remains on the horizon.

Neutrophils contribute to host defense primarily through the recognition and destruction of pathogenic microorganisms, a functional role that is achieved through a series of rapid and coordinated responses, including chemotaxis, phagocytosis, and release of cytotoxic products. These responses are initiated by the interaction of cell surface receptors with specific ligands found on microbial targets or in the inflammatory milieu and the consequent induction of intracellular signaling pathways that couple such activating stimuli to physiologic antimicrobial responses. Paradoxically, these cellular and biochemical events may also result in damage to host tissues in inflammatory conditions, including ischemia-reperfusion injury, sepsis, acute lung injury (ALI), and the acute respiratory distress syndrome (ARDS). Therefore, to maximize host defense capabilities while minimizing damage to host tissues ("collateral damage"), neutrophil microbicidal responses must be tightly regulated. Notwithstanding the potential role of the neutrophil in inflammatory injury, it is important that the primary function of this "professional phagocyte" in host defense and in resolution of inflammation and tissue remodeling by clearance of debris is not eclipsed. In this chapter we briefly focus on the functions of neutrophils and then discuss the evidence implicating neutrophils in ARDS and ALI with ramifications for potential treatment options on the horizon.

NEUTROPHIL PRODUCTION

Neutrophils, so named because they stain in a neutral manner with Wright's stain, are crucial players in inflammation and the innate immune response. Formed in the bone marrow, the neutrophil progresses through defined stages of development from the myeloblast, promyelocyte, myelocyte, metamyelocyte, and band cell eventually to the mature polymorphonuclear neutrophil (PMN) (Fig. 29-1). This progression takes about 9 days. It is generally accepted that only the myeloblast, promyelocyte, and myelocyte are capable of cell division. Studies suggest approximately 100 billion neutrophils are produced in an adult per day. This can increase 1000-fold in times of need through the action of cytokines such as granulocyte-macrophage colony-stimulating factor. Once in the bloodstream neutrophils have a half life of approximately 7 hours.[1] A large group of mature neutrophils remain in the bone marrow for up to 2 days and outnumber circulating neutrophils 20 to 1. In addition, a portion of mature neutrophils marginate preferentially in the pulmonary vasculature. The reasons for this include the relatively large size of neutrophils compared with pulmonary capillaries, the organization of the pulmonary capillary bed, the lower pressure and shear stress of the pulmonary as compared with the systemic circulation, the less deformable nature of neutrophils as compared with red blood cells, and the fact that the pulmonary vasculature receives the entire cardiac output.[3]

The importance of the neutrophil in immune function is emphasized by various congenital and acquired conditions that result in neutropenia.[4] These patients are at risk for severe skin, lung, and other invasive bacterial and fungal infections.

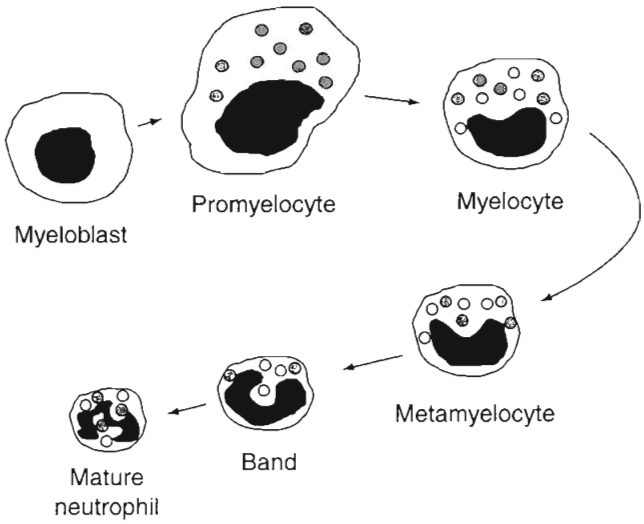

FIGURE 29–1. Progression from myeloblast to myelocyte takes 4 to 6 days. Promyelocytes develop azurophilic granules and myelocytes develop specific granules. Maturation from myelocyte to mature neutrophil takes 5 to 7 days. (Adapted from Skubitz KM: Neutrophilic leukocytes. In Lee FJ et al [eds]: Wintrobe's Clinical Hematology. New York, Raven, 1991, pp 553-563.)

BASIC NEUTROPHIL FUNCTION

The physiologic functions of neutrophils that are involved in their antimicrobial role are described individually.

ADHESION

To eradicate microorganisms, circulating neutrophils must move out of the vasculature into the infected tissues. Adhesion of neutrophils to vascular endothelium is the first step in this process.[1,5] Neutrophils and endothelial cells express a variety of cognate adhesion molecules on their respective surfaces (Table 29-1), the expression of which is regulated by various stimuli present in an inflammatory milieu. Selectins mediate the initial rolling and tethering of a circulating neutrophil to the vascular endothelium. L-selectin is expressed on neutrophils whereas P- and E-selectin are found on endothelial cells. The interaction between selectins and their cognate ligands serves to tether neutrophils, slowing them in their journey through the microvasculature, where they sense chemoattractants and other inflammatory agonists, leading to firm adhesion mediated by integrins interacting with endothelial ligands. The major integrins expressed by neutrophils are β_2 integrins (CD11/CD18), although recent studies have indicated that activated neutrophils also express $\alpha_4\beta_1$ integrins.[6] Endothelial cells express intercellular adhesion molecules (ICAMs), which are members of the IgG superfamily and are ligands for β_2 integrins and mediate firm adhesion. After adhering to the endothelium, neutrophils spread and then move between or through endothelial cells and migrate along chemoattractant gradients toward the invading pathogens. Gap junctions form between neutrophils and endothelial cells and serve to facilitate cell communication to assist in transmigration.[7]

The importance of adhesion molecules in innate immunity is illustrated by the propensity to infections in congenital diseases where these molecules are deficient or absent. Leukocyte adhesion deficiency (LAD) type I is the result of a deficiency of β_2 integrins.[4,8] As a consequence, neutrophils cannot adhere and migrate to sites of infection, resulting in a predisposition to recurrent, severe infections, despite a high neutrophil count, and delayed umbilical stump separation in the newborn. LAD type II, secondary to defective selectins,[4] is an autosomal recessive condition with characteristic physical features, short stature, and a predisposition to recurrent infections as well.

TABLE 29–1. SELECTED NEUTROPHIL AND ENDOTHELIAL ADHESION MOLECULES

	Other Names		Ligands
Neutrophil Integrins			
$\alpha_2\beta_1$			Collagen, laminin
$\alpha_3\beta_1$			Collagen, laminin, fibronectin, tenascin
$\alpha_4\beta_1$	VLA-4	CD49d/CD29	VCAM-1, fibronectin
$\alpha_5\beta_1$	VLA-5	CD49e/CD29	Fibronectin
$\alpha_6\beta_1$	VLA-6	CD49f/CD29	Laminin
$\alpha_9\beta_1$			VCAM-1, tenascin
$\alpha_L\beta_2$	LFA-1	CD11a/CD18	ICAM-1 to 3
$\alpha_M\beta_2$	Mac-1	CD11b/CD18	ICAM-1, C3bi, fibrinogen, factor x
$\alpha_X\beta_2$	P150,95	CD11c/CD18	Fibrinogen, C3bi

CHEMOTAXIS

Once out of the vasculature, neutrophils must be able to find their way rapidly to areas of inflammation and infection. This process of directional motility along a chemoattractant gradient is known as chemotaxis. Many chemoattractants bind to G-protein–coupled 7 transmembrane spanning domain receptors (e.g., receptors for fMLP, C5a, platelet-activating factor, leukotriene B_4, interleukin [IL]-8), leading to dissociation of the G-protein complex and activation of signal transduction cascades.[9] Ultimately, polymerization and reorganization of the actin cytoskeleton occurs, driving extension of a pseudopodia or lamellipodia, which are sheet-like protrusions of membrane rich in actin filaments.[10] Adenosine triphosphate–dependent contraction mediated by myosin then contracts the cytoskeleton toward the leading pseudopodium.[1] Cycles of protrusion, adhesion, contraction, and de-adhesion are repeated, allowing the neutrophil to move through the extracellular membrane. Defective actin polymerization is one cause of a primary chemotactic disorder manifest clinically as recurrent infections, typically of fungal origin.[8]

PHAGOCYTOSIS

The process of phagocytosis, or engulfment of particles greater than 3 μm, is important both for removal of dead cells and for microbial killing.[11] Importantly, most microbial killing occurs inside the neutrophil. Phagocytosis occurs when the neutrophil internalizes microscopic particles through extensions of the plasma membrane that surround the particle and fuse around it, isolating the particle in a nascent phagosome (Fig. 29-2).[12,13] This serves to compartmentalize both the pathogen and the leukocyte-derived cytotoxic products that are destined to kill and digest the pathogen.

Neutrophils can recognize invading microbial pathogens by virtue of specific membrane receptors that recognize highly conserved motifs on pathogens not normally present on higher-order eukaryotic cells (e.g., specific carbohydrates, glycolipids such as lipopolysaccharide, glycoproteins, and proteins).[11] Collectively, these receptors are termed *pathogen-associated molecular pattern (PAMP) receptors.*[14] Phagocytes also express receptors that recognize specific host proteins such as antibodies or complement that coat ("opsonize") the pathogen. These "phagocytic receptors" include receptors for the Fc fragment of antibodies (Fc receptors) and complement receptors such as CR3 that recognize pathogens coated with antibodies or complement, respectively. Importantly, opsonization improves phagocytic efficiency dramatically.[12] There is no known specific inherited disorder resulting in a primary phagocytic defect.[8]

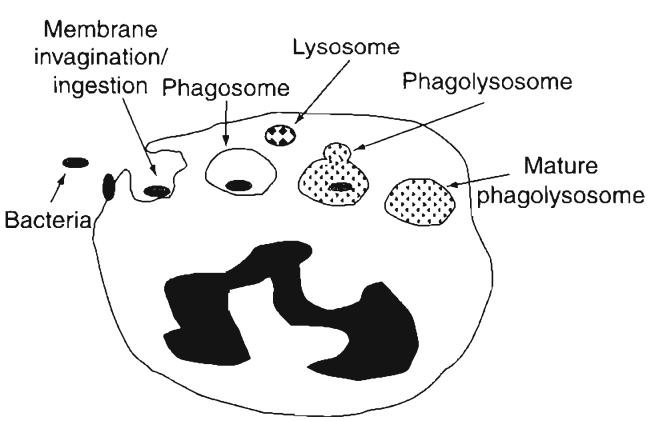

FIGURE 29–2. Process of phagocytosis.

MICROBIAL KILLING

As previously stated, most microbial killing occurs inside the neutrophil in specialized compartments (phagosome, phagolysosome). In this way, potentially damaging effects of neutrophil products on host cells are minimized. The neutrophil can effectively kill microbes by releasing various molecules and compounds into the phagosome. Stimulated neutrophils, through the action of NAPDH oxidase, produce potent oxidants, including superoxide (O_2^-) and hydrogen peroxide (H_2O_2). These reactive oxygen species can be converted by myeloperoxidase to generate the hypohalous acids such as HOCl (bleach) that are extremely potent antimicrobial products. Nonoxidative killing mechanisms include acidification of the phagosome (pH 3.5 to 6), lysozyme (hydrolyses cell walls), lactoferrin (binds iron), various proteases (including elastase, collagenase, gelatinase, cathepsin G, and proteinase-3), and defensins (small microbicidal cationic peptides).[1,15]

Neutrophils contain four types of intracellular granules: azurophilic (primary), specific (secondary), and gelatinase (tertiary) granules and secretory vesicles.[1] The compounds contained in these granules aid in microbial killing and facilitate cell adhesion and locomotion by delivery of granule-associated proteins to the phagosome or to the cell surface (Table 29-2).

The Chédiak-Higashi syndrome is an autosomal recessive disorder of dysfunctional granules. Its molecular basis is not completely understood, but giant primary granules are seen in neutrophils, and those affected suffer recurrent skin and pulmonary infections, typified by delayed *Staphylococcus* killing. Rarely, specific granule deficiencies are seen in which neutrophils are missing secondary granules, resulting in a poor inflammatory response and recurrent infections.[4,8] MPO deficiency, especially in combination with diabetes, leads to a predisposition to *Candida* infections. Chronic granulomatous disease, caused by defects in the phagocyte NADPH oxidase, results in recurrent infections with catalase-positive organisms such as *Staphylococcus aureus* and granuloma formation.[4,8]

SECRETION OF INFLAMMATORY MEDIATORS

Although for many years the primary function of neutrophils was viewed as responding to signals derived from other host cells and invading pathogens, it is now appreciated that these cells also play an active role in regulating inflammation though production and release of the cytokines IL-1, IL-6, IL-8, and tumor necrosis factor-alpha (TNF-α).[1,16] In addition, leukocyte-derived proteases participate in substrate processing that can result in the formation and release of chemotactic peptides from surface- or matrix-bound precursors.

APOPTOSIS

Although not classically considered a neutrophil antimicrobial function, apoptosis serves an important purpose. Once the

threat of microbial invasion or tissue injury is over, inflammation must be rapidly down-regulated and neutrophils eventually disposed of in a manner that will not result in release of cytotoxic products with consequent host cell injury. One noninflammatory way of disposal of effete (spent) neutrophils is through apoptosis, also known as programmed cell death.[17] There are many signals for this process involving a variety of signal transduction pathways, and this subject is beyond the scope of this chapter, but interested readers are referred to recent reviews of this important subject.[17]

NEUTROPHILS AND INFLAMMATORY TISSUE INJURY

Although neutrophils primarily serve a protective role in the body, it is apparent that as part of the exuberant inflammatory response, neutrophils and their products can contribute to the tissue injury and dysfunction seen in sepsis and ALI and ARDS. Normally, unstimulated neutrophils pass through the pulmonary vasculature and are retained in the pulmonary capillary for seconds to minutes. This transit time can be affected by hemodynamic and soluble factors but no damage to the lungs typically occurs under physiologic circumstances. However, under pathologic conditions such as in ALI and ARDS, large numbers of neutrophils are sequestered in the microvasculature of the lung and other organs. In these strategic locations, the neutrophils become activated and may release cytotoxic products outside the cell that are capable of damaging host tissues. Under such circumstances, neutrophils are no longer innocuous. In experimental models of lung injury, there is evidence that direct activation of neutrophils, for example by preincubation with agonists such as lipopolysaccharide, can cause lung injury when reinjected into animals[18] and, conversely, that depletion of neutrophils can attenuate lung injury.[16,19,20] Despite this apparent propensity for host damage, neutrophil depletion is not a practical strategy for the treatment of ARDS for two reasons. First, there is evidence that ARDS can occur in neutropenic patients,[21,22] implying that neutrophil-independent mechanisms of lung injury may still be sufficient to engender acute lung injury. Second, and perhaps most importantly, is that neutrophil depletion undoubtedly predisposes the patient to infection, which is the most common cause of death in patients with ARDS.

MICROVASCULAR SEQUESTRATION AND ADHESION OF LEUKOCYTES

One of the earliest changes in ALI is increased neutrophil sequestration in the pulmonary capillaries that is reflected clinically by a transient leukopenia preceding respiratory deterioration.[23] The reasons for this remain incompletely understood but are likely related in part to an alteration in cellular biophysical properties (cell stiffening) as a consequence of polymerization and redistribution of the actin cytoskeleton.[24] This makes the 8-μm neutrophil less deformable and more likely to be unable to negotiate the 5.5-μm-wide pulmonary capillaries. Various signals, including IL-1, IL-6, IL-8, and TNF-α, mainly from alveolar macrophages and leukocytes, and bacterial products such as formyl peptides and lipopolysaccharide, can stimulate neutrophils and contribute to microvascular sequestration.[25] Alternatively, increased sequestration may be related to marrow release of neutrophils; in a rabbit model, therapy with granulocyte colony-stimulating factor (G-CSF) caused the bone marrow to release increased numbers of neutrophils that preferentially sequestered in the lungs.[26] It is noteworthy that production of G-CSF, a potent cytokine that mobilizes bone marrow neutrophils, is stimulated by bacterial products as well as host-derived cytokines such as TNF-α and IL-1.

Stimulation of neutrophils will induce the up-regulation of the number and function of cell surface adhesion molecules, leading to enhanced adhesivity.[24,27] In addition, mechanical deformation of the neutrophil, especially once activated, as occurs with passage through the pulmonary vasculature, leads to increased integrin/ICAM-1 binding.[28] Adhesion not only prolongs neutrophil sequestration and allows for transmigration but also activates various signaling cascades and thus impacts on many aspects of neutrophil function, including phagocytosis and the respiratory burst.[29]

Strategies to reduce leukocyte microvascular sequestration and adhesion with the goal of diminishing tissue injury are not always successful. In sheep, for example, blockage of P-selectin did not protect against lung injury in a burn model.[30] By contrast, in a murine "two-hit" model of endotoxemia combined with hemorrhagic shock, aggressive fluid resuscitation combined with reduced neutrophil endothelial adherence ameliorated the subsequent development of ALI.[31]

Once the neutrophil has adhered to the endothelial cell, it can then transmigrate across the endothelial barrier and into the interstitium after a chemotactic gradient.[32] In this extravascular location, neutrophil activation can lead to tissue damage. However, it is important to bear in mind that the process of transmigration from the vascular space into the alveolus per se does not necessarily lead to alterations in endothelial or epithelial permeability or injury.[33,34] Rather, damage may be mediated by extracellular release of proteases and other cytotoxic compounds during transmigration if the neutrophil is also subject to unregulated activation.[35]

ROS AND PROTEASES

There is a substantial body of evidence implicating neutrophil proteases in the pathogenesis of ALI.[36-41] Indeed, mice that are genetically deficient in both granulocyte elastase and cathepsin G are protected from LPS-induced lung injury.[42] Elastase, cathepsin G, proteinase 3, and various matrix metalloproteinases may injure the lung directly through proteolytic action on cells. Alternatively, proteases can enhance the inflammatory response by stimulating production of cytokines[43,44] and contribute to pathology through enhanced transcription of mucin genes.[45,46] In addition, proteases can cleave proteins in the airway and lead to the production of chemotactic peptides.[43,47] Evidence for benefit of protease inhibitors is limited to controlled animal studies[48] and a few small clinical trials. However, despite the purported role of proteases in ALI, the inflammatory milieu is sufficiently complex that simply delivering antiproteases to the lung may not ameliorate lung injury (hence the failure of the body's own natural antiproteases to prevent lung injury). Antiproteases can be inactivated by oxidation or by direct proteolytic cleavage rendering them ineffective. An additional consideration is the "protected space" between the neutrophil and the adjacent target cell in which a localized area of high protease concentration can exist that is isolated from high-molecular-weight antiproteases such as α_1-antitrypsin.[49]

Oxygen and nitrogen reactive species generated by neutrophils can contribute to pulmonary cell damage and the pathology of ALI.[50] Free radical formation can be secondary to the action of NADPH oxidase resulting in the formation of superoxide. Superoxide can then reduce iron, form hydrogen peroxide, and, through the action of myeloperoxidase, form oxidized halogens, such as hypochlorous acid. Alternatively, free radicals can be generated through inducible nitric oxide synthase (iNOS), leading to the formation of peroxynitrite ($ONOO^-$). Inhibition of either of these enzymes, in specific animal models, results in attenuation of ALI.[51-53]

PHOSPHOLIPASE A_2 METABOLITES

Although still uncertain, the neutrophil is believed to be a key cellular source of phospholipase A_2 (PLA_2) in the setting of ALI. This enzyme results in the formation of arachidonic acid from plasma membrane phospholipids and has been implicated in the pathogenesis of ALI. Bronchoalveolar lavage fluid PLA_2 activity is increased in humans with ARDS.[54] In animal models, delivery of PLA_2 intravenously[55] or by direct intratracheal instillation[56] can result in lung injury. Additionally, pharmacologic inhibition of PLA_2 attenuated ALI associated with intestinal ischemia reperfusion in rats[57] and targeted gene disruption of PLA_2 can attenuate ALI associated with sepsis and acid aspiration in mice.[58] PLA_2 may influence lung injury through the production of various arachidonic acid metabolites, including platelet-activating factor, lysophosphatidylcholine, and prostaglandins.[25] Inhibition of PLA_2 has not been attempted in humans with ALI/ARDS, but selective inhibition of specific PLA_2 isoforms may represent a therapeutic approach to ALI/ARDS, especially as more specific inhibitors are developed.

APOPTOSIS

Evidence exists that neutrophil apoptosis is delayed early in the course of ARDS by the presence of various proinflammatory cytokines such as GM-CSF.[17] This may result in a prolonged inflammatory process and contribute to further lung injury. In addition, delayed clearance of apoptotic neutrophils by alveolar macrophages may result in greater inflammatory injury. Mice deficient in caspase-1, a deficiency

that resulted in delayed apoptosis, demonstrated prolonged pulmonary inflammation in response to intratracheal LPS administration.[59] However, the precise relationship between prolonged neutrophil survival in ALI remains to be defined, and given the potential untoward effects on the innate immune system of reducing neutrophil survival, further study is needed before this can be a suggested therapeutic approach.[17]

SIGNAL TRANSDUCTION PATHWAYS AS POTENTIAL THERAPEUTIC TARGETS

Research is uncovering the basic mechanisms regulating neutrophil function, and it is clear that specific cell signaling molecules fulfill important actions that allow the neutrophil to assume its role in inflammation and ALI. As our understanding of these processes increases, these molecules will become potential targets for pharmacologic modification in hopes of attenuating ALI and ARDS.

NF-κB

The transcription factor NF-κB binds to specific sequences in the promoter region of the genes for inflammatory cytokines such as IL-1β, IL-6, TNF-α, IL-8, and macrophage inflammatory protein as well as in other immunoregulatory molecules such as the endothelial adhesion molecules ICAM-1 and E-selectin that relate to the development and progression of lung injury.[60,61] NF-κB is normally composed of three components that bind to and form a complex (heterotrimer) that is retained in the cytoplasm through its association with the inhibitory molecule IκB. Phosphorylation, ubiquination, and proteolysis of IκB allows NF-κB to translocate to the nucleus and induce gene transcription.

The active form of NF-κB is a dimer composed of members of the Rel family in the active DNA-binding form. Five mammalian members of this family have been described: p50, p52, p65, c-Rel, and Rel B.[62,63] Various combinations of NF-κB have different transactivation abilities; for example, p50/p65 heterodimers are able to strongly promote transcription whereas p50/p50 homodimers produce important suppressive activities on gene activation.[60]

Hemorrhage or endotoxemia induces activation of NF-κB in lungs.[16,64] In this study, induced neutropenia significantly reduced the amount of NF-κB that accumulated in the nuclei of lung cell populations.[16] These observations indicate that neutrophils are important in modulating NF-κB activation in the lungs. Inhibition of NF-κB activation with antioxidants decreased edema, diminished neutrophil infiltration, and suppressed proinflammatory cytokine expression in the lungs.[64,65] As mentioned in the preceding section on apoptosis, apoptosis is thought to be a major mechanism for the clearance of effete neutrophils and especially important in the clearance of neutrophils from the injured lung.[66] NF-κB is considered to have both antiapoptotic and proapoptotic effects. Activation of the PI3-kinase/Akt pathway has potent antiapoptotic effects and NF-κB is a target of Akt. Activation of NF-κB results in enhanced transcription of antiapoptotic genes.[67-69] On the other hand, NF-κB may also have a proapoptotic role in p53-induced cell death.[70] Thus, NF-κB activation in the setting of acute lung injury may regulate not only the expression of proinflammatory mediators but also the numbers of activated neutrophils within the lung. Therefore, regulation of NF-κB is a logical target for potential therapeutic intervention for the prevention or minimization of ALI.

PHOSPHATIDYLINOSITOL-3-KINASE

Phosphatidylinositol-3-kinases (PI3K), a group of heterodimeric enzymes, catalyze the conversion of membrane phosphatidylinositol-3,4-biphosphate (PIP_2) to PIP_3 in response to various growth factors, hormones, chemokines, and chemoattractants.[71,72] PIP_3 can then lead to the activation of other cellular signaling pathways and thus impact on many aspects of neutrophil functioning, including chemotaxis, adhesion, and apoptosis. There are four isoforms of the catalytic subunit of PI3K, with PI3K-γ found exclusively in leukocytes. PI3K-α and PI3K-β knockout mice are not viable; however, PI3K-γ –/– mice, when exposed to LPS, have reduced lung edema, neutrophil accumulation, and pulmonary cytokine levels when compared with wild-type mice.[73] Although the precise mechanism by which PI3K inhibition modulates neutrophil-mediated lung injury is not clear, PI3K may contribute to ALI through its effects on NF-κB translocation, chemotaxis, or apoptosis.[60] There are currently no pharmacologic inhibitors specific to the γ isoform of PI3K, but with time PI3K-γ inhibition may be possible. Caution must be exercised, however, given the wide-ranging effects of PI3K.

MITOGEN-ACTIVATED PROTEIN KINASE

Three distinct mitogen-activated protein kinase (MAPK) pathways have been described in neutrophils: p38, extracellular signal-regulated kinase (ERK), and c-Jun NH_2-terminal kinase (JNK). These signaling pathways, composed of a cascade of kinases that are activated by phosphorylation, function to transmit signals from the cell surface to the cytoplasm and nucleus.

The p38 pathway is important in neutrophil adhesion, chemotaxis, respiratory burst, and apoptosis.[74-76] Selective p38 inhibition, even up to 4 hours after aerosolized administration of lipopolysaccharide to mice, resulted in reduced neutrophil accumulation in the alveolar airspaces as compared with the findings in control animals.[74] Although promising, this result contrasts with observations in endotoxemia and hemorrhage-induced ALI in which p38 inhibition had no effect on neutrophil accumulation or other markers of ALI.[77] It may be that p38 activity is specific to neutrophil migration to the airspaces or in response to airway LPS.[60]

The ERK pathway has important roles in cytokine production and chemotaxis to fMLP, LTB4, C5a, and IL-8, but because ERK inhibitors are toxic, little information exists pertaining to inhibition of this pathway in modulation of lung injury.

The JNK pathway is important in cell proliferation and apoptosis and is activated in response to cellular stress. JNK-1 knockout mice have increased susceptibility to hyperoxia-induced ALI.[78] Interestingly, BAL neutrophil counts were lower in knockout compared with wild-type mice. The reason for this is not clear but may be due to decreased adhesion and migration or to increased neutrophil apoptosis. In this model it is difficult to determine the specific effects of neutrophil JNK inhibition because all cells were affected and

increased epithelial cell apoptosis contributed significantly to the overall pathology. Inhibition of MAPK pathways in cell culture and controlled animal models may help distinguish the relative importance of these pathways in different cell types. However as a potential tool in humans, unless cell specific inhibitors are developed, generalized MAPK inhibition may prove to be an unrealistic therapeutic approach.

CONCLUSION

In this chapter, we have focused initially on the essential role of neutrophils in the innate immune response to invading microbial pathogens. The importance of this function is underscored by disease states resulting from the absence (neutropenia) or dysfunction (leukocyte adhesion deficiency and chronic granulomatous disease) where affected individuals have an enhanced susceptibility to infection. It remains a paradox that these essential antimicrobial processes can apparently turn against the host and result in tissue and organ injury. It must be emphasized that inflammation is an inherently beneficial process and that only when it becomes excessive or otherwise unregulated does host damage occur. Throughout this chapter we have indicated potential therapeutic targets that might be selected in an attempt to mitigate inflammatory injury while preserving the host defense functions of these essential phagocytes. It is clear, however, that given the complexities and redundancies of this system, successful therapeutic intervention will not be an easy task.

Chapter 30
MACROPHAGE FUNCTION

Donna M. Paulnock • Stefanie N. Vogel

KEY POINTS

1. **Macrophages are present in blood (monocytes) and all tissues of the body.** At these sites they provide a critical first line of host defense, through recognition and elimination of entering pathogens.
2. **Macrophages throughout the body express a wide range of functional activities,** including phagocytosis, secretory activity, and microbial killing. Macrophages in individual tissues express a unique spectrum of these properties that is regulated at and characteristic of that tissue site.
3. **Macrophages are the central cells in the process of inflammation,** the classic innate immune response to microbial infection. Macrophages at the site of inflammation are activated by host and microbial factors to express enhanced functional activities.
4. In addition to their roles in innate immunity, **macrophages and dendritic cells serve a critical function in the initiation of adaptive immune responses,** through their ability to serve as antigen-presenting cells (APCs) for the activation of T lymphocytes.

MACROPHAGE DEVELOPMENT AND IDENTIFICATION

Cells of the mononuclear phagocyte system are ubiquitously distributed throughout the body, present in essentially all tissues, in peripheral blood and bone marrow, and in body cavities.[1] Immature progenitor populations begin the developmental process in the bone marrow, ultimately giving rise to monocytes that enter the circulation. Blood monocytes then migrate into the peripheral tissues, where they differentiate further into resident tissue macrophages.[1,2] The network of fixed tissue macrophage populations present throughout the body thus is ideally positioned to serve as a first line of defense at the major portals of microbial entry in the body. In addition, this system of cells serves critical roles in maintaining tissue homeostasis and regeneration.[3]

Cytokines present in the bone marrow stromal milieu, including in particular granulocyte-macrophage colony-stimulating factor (GM-CSF) and colony-stimulating factor-1 (originally termed macrophage-colony-stimulating factor), control early macrophage progenitor cell commitment and differentiation.[4,5] Additional stimuli provided in each tissue, including both endogenous factors from other cells within the tissue and microbial factors resulting from the presence of circulating or commensal organisms, subsequently shape the functional and phenotypic attributes of resident macrophages present at that site, giving rise to cells adapted to perform specific functions within this local environment.[6-8] For example, in the liver, the fixed macrophage population, the Kupffer cells, provides key detoxification functions whereas microglia, specialized brain macrophages, are believed to provide cytokines and other growth and differentiation factors essential for other brain cells. Thus, a given macrophage population will have phenotypic and functional characteristics both in common with and distinct from macrophages found at other defined locations.

These aspects of macrophage development and anatomic location have made it difficult to identify markers that unequivocally define macrophages at various developmental stages or in various tissue sites. Few, if any, of the available monoclonal antibodies against macrophage surface antigens are either fully macrophage specific or identify all macrophage subpopulations. Nonetheless, recent characterizations have provided information on some molecules expressed solely by cells within the mononuclear phagocyte lineage. The antibody F4/80, although still functionally ambiguous, detects a cell surface glycoprotein that is expressed by mature mouse macrophages and often is used to identify these cells in tissue samples and preparations of isolated cells.[9] Similarly, the MAC-1 antibody detects the C3bi receptor, a critical member of the array of surface proteins expressed by macrophages, but also is expressed by granulocytic cells in the myeloid lineage.[10] The receptor for the differentiation factor CSF-1 serves as an alternative macrophage-specific marker, reflecting the critical role of CSF-1 in macrophage differentiation, and can aid in the identification of earlier developmental stages.[11]

A number of additional functionally associated surface molecules have been used to identify these cells in tissue and blood samples, although these clearly are not macrophage specific. Such molecules include cell surface receptors for the Fc portion of immunoglobulin G, for complement-coated particles, and for acute phase response proteins normally produced during the early stages of infection.[12-14] More recently, receptors for "pathogen-associated molecular patterns" (PAMPs) have been recognized as critical components of macrophage functional activities and thus useful as markers of these and other innate immune system cells. These include the Toll-like receptors (TLR) that play a major

role in pathogen recognition and initiation of inflammatory responses and other endocytic receptors, such as type A scavenger receptors and C-type lectin family molecules.[15] However, this category of molecules again is not strictly confined to macrophages. Thus, unlike the situation for T and B lymphocytes, it has not been possible to define phenotypically distinct markers for various stages of macrophage differentiation. However, the presence of subsets of cells that belong to the mononuclear phagocyte system in mice and humans can be assessed using combinations of antibodies against sets of cell surface proteins and such reagents can be used effectively to isolate/characterize these cells.

One final issue regarding macrophage identification is the recent recognition that differentiation into mature, tissue-specific macrophages is not the only developmental option for a cell within the myeloid lineage. These cells also may give rise to dendritic cell (DC) populations. DCs and macrophages share a number of functional attributes, including internalization of pathogenic microorganisms, secretion of cytokines, and antigen presentation to T cells, although DCs clearly are recognized as the most potent professional APC for naive T cells.[16] DCs are now recognized to be descended from both lymphoid and myeloid progenitor cells, deriving from hematopoietic progenitors of those lineages as well as from blood monocytes.[17,18] The re-direction of less-mature macrophages toward DC development is driven by a variety of diverse stimuli, including multiple cytokine mediators produced during the development of immune response.[19] These observations support the idea that early in their differentiation process, macrophages retain some degree of developmental plasticity. This may contribute to the enrichment of DC populations, and therefore antigen presentation and lymphocyte activation, during immune responses but also may pose some challenges for the process of macrophage versus DC identification.

MACROPHAGE FUNCTIONAL ACTIVITIES

Functionally, macrophages are the quintessential "multitasking" cells of the immune response. Although a full review of macrophage functional activities is beyond the scope of this brief discussion, macrophages generally do express a variety of shared functional characteristics, including phagocytic capability, cytokine production, processing and presentation of antigens to lymphocytes, and killing of microbes and tumor cells.[20] These activities reflect the participation of macrophages in the process of pathogen elimination at all levels, including microbial detection, microbial engulfment and cellular destruction, and the activation of downstream immune response cellular elements. Through these activities, macrophages both act directly as antimicrobial effector cells and bridge the early innate immune response with the more antigen-specific adaptive immune response.

The ability of macrophages to phagocytose particles represents the first step in a series of events that ultimately lead to the elimination of intruding microorganisms, tumor cells, and cellular debris. Internalization of different substances is mediated through multiple distinct surface receptors. These include complement receptors, vitronectin, and other specialized receptors that recognize apoptotic cells and altered self molecules.[21] Phagocytosis can be dramatically enhanced through the use of receptors for the Fc region of immunoglobulins bound to target cells such as tumor cells and parasites.[22] Finally, as noted in the preceding section on macrophage development, a large family of pattern recognition receptors (PRR) recognize various conserved motifs (mannans, lipopolysaccharides, polyanionic molecules, formylated peptides, and others) expressed by microbes but absent in their vertebrate hosts.[23] These evolutionarily conserved receptors are critical recognition receptors for initiation of multiple innate immune functions, and aspects of their structure and function are receiving considerable attention. Although phagocytosis is not a prerequisite for PRR-mediated signaling, the uptake of organisms after sensing through PRRs couples phagocytosis and intracellular signaling in many cases.[24,25] The specific molecular events that follow PRR engagement remain to be fully characterized for each receptor; however, activation of the NF-κB pathway of signal transduction and expression of genes transcribed after activation of this transcription factor family have emerged as prominent outcomes of innate recognition.[26]

Phagocytosis of microorganisms generally is followed by two outcomes in a macrophage population: the production of biologically active secreted products and the elimination of the phagocytosed target organisms. Two independent biochemical pathways principally contribute to the ability of macrophages to eliminate intracellular pathogens and extracellular targets. Synthesis of nitric oxide (NO) appears to be responsible for much of the antimicrobial activity of macrophages against certain pathogens.[27] This simple but strikingly effective molecule, along with additional reactive nitrogen intermediates, plays an essential role in the immune response to a number of intracellular pathogens, including *Mycobacterium tuberculosis*, the protozoan parasite *Toxoplasma gondii*, and the fungus *Cryptococcus neoformans*.[28-30] Reactive oxygen metabolites also are associated with the potent antimicrobial and antitumor activity of macrophages, including, most importantly, hydrogen peroxide and superoxide anion, which are directly toxic to microorganisms.[27] Toxic oxygen-derived products are produced as a result of the action of lysosomal enzymes, including NADPH oxidases, which on fusion of the phagosome and lysosome following organism internalization act to destroy the pathogen directly.[31,32] Additional microbicidal molecules derived from macrophages, including a large class of secreted antimicrobial peptides called defensins, various enzymes such as lysozyme, and diverse competitors for essential nutrients, such as lactoferrin, provide antimicrobial action for both intracellular and extracellular microbes.[33]

A second important outcome of the interaction between pathogens and macrophages is activation of these cells to release cytokines and other soluble mediators. Macrophages produce a vast array of secreted products after antigen interaction.[34] Many of these products result from induction of new gene expression as an outcome of PRR (and other receptor) engagement and the ensuing downstream signal transduction events. Recent studies using functional genomic analyses to dissect macrophage and DC innate responses have identified three broad classes of secreted products produced by macrophages after activation: (1) cytokines and chemokines, responsible for proinflammatory and anti-inflammatory effects, cell recruitment, and cell growth; (2) non–cytokine-secretory products, including enzymes that contribute to the inflammatory response (e.g., cyclooxygenase-2), hormones, and other molecules involved in basic cellular processes; and (3) products of inducible metabolic pathways, for example, NO and H_2O_2, the downstream products of inducible enzymes.[35-37] Some molecules

within this spectrum of responses are likely to represent pathogen-specific responses, whereas others can be induced by multiple organisms or nonmicrobial activating ligands. This is, in part, regulated by the particular PRR engaged. For example, it is clear that the differential gene expression observed in response to engagement of distinct TLRs is related to differential utilization of adapter proteins on extracellular activation by microbial agonists.[38] Thus, while the ability to produce immunoregulatory factors is a defining function of activated macrophages, the diversity of cytokines or other products induced will, again, be influenced by the nature of the inducing stimulus and the local microenvironment of the cells.

CURRENT PARADIGMS OF MACROPHAGE ACTIVATION

Although newly arrived tissue macrophages constitutively display some of their characteristic functions, such as phagocytosis, essentially all macrophage functions are induced or enhanced by cellular activation. The notion of an "activated macrophage" was originally proposed by Mackaness, and extended by Russell, Hibbs, and others, to describe a cell that had developed increased microbicidal or tumoricidal capacities as a function of stepwise signaling.[39-42] This definition still is valuable in emphasizing that there are substantial changes in macrophage activity and function during the evolution of an immune response that have beneficial outcomes for the host. Within the context of modern immunology, the concept of an activated macrophage can be expanded to define a cell that has responded to cell-derived and/or environmental factors with specific molecular changes that allow an enhanced functional response specific for the inciting stimulus.

Multiple studies have confirmed that the underlying basis of the activation process is the induction of new gene expression in response to host and microbial ligands. These ligands are almost limitless in their number and include such diverse mediators as the cytokines interferon-gamma (a potent macrophage activating agent) and interleukin (IL)-12; arachidonic acid metabolites; and microbial products such as bacterial lipopolysaccharide, lipoteichoic acid, and CpG oligonucleotides, to name a few. Studies of the response of isolated mouse macrophage populations have demonstrated that each agonist has distinct effects and induces a unique pattern of induced genes.[35-37] In addition, the activation response of any macrophage will be influenced by the nature of the microenvironment of that particular population of macrophages and whether multiple stimuli are used, such as is commonly the case in the stepwise activation treatments used in in-vitro studies of macrophage function.[42] The genetic background of the mouse strain (and presumably of human cells) and the source of macrophage progenitors also influence the level of activation achieved.[43] These considerations suggest that, again, there is no single characteristic, metabolic or genetic, that can be used universally to define an activated macrophage. Instead, the nature of the activation response will be linked to the nature of the inducing stimulus/stimuli and environment.

Recent studies have proposed that two subsets of activated macrophages can be identified that preferentially promote or dampen inflammatory and antimicrobial responses, labeled classically activated versus alternatively activated macrophages, respectively. These populations are defined largely on the basis of the immunopotentiating (e.g., IL-12, IL-18) versus immunosuppressive (e.g., IL-10, transforming growth factor-beta) cytokines produced.[44,45] Given the nature of macrophage heterogeneity discussed earlier, it seems likely that these functionally based distinctions represent examples of macrophages at different points along the continuum of the activation process or as a function of specific types or combinations of stimuli. Nonetheless, the importance of identifying macrophages that display functional polarization during infection or tumor development may be important for understanding how these situations modulate innate and acquired immune responses.

CENTRAL ROLE OF MACROPHAGES IN INFLAMMATION

The inflammatory response serves as perhaps the best showcase of the array of macrophage functional activities. Innate immune recognition underlies most inflammatory responses, and this is set in motion by pathogen recognition. As noted previously, macrophages located in peripheral tissues serve as an effective surveillance system for pathogen entry or other alterations in the cellular environment, and the decision to respond or not respond to a particular ligand is largely made by phagocytic cells at these sites.

The presence of changes in the tissue environment both stimulates the macrophages already present in the tissue and induces the rapid recruitment of additional macrophages to that site. Macrophage influx into a site of injury or infection is part of the process of inflammation and is recognized as a central component of the innate immune response.[46] Macrophages active during the early stages of inflammatory responses and at the initiation of wound healing produce the soluble inflammatory mediators such as IL-1, tumor necrosis factor-alpha, and IL-6 that stimulate a systemic response to infection.[47] Similarly, production of chemokines, including IL-8 (CXCL8), is an important outcome of microbial recognition. These chemotactic mediators enhance the recruitment and entry of phagocytes and lymphocytes to the inflammatory site and mediate changes in the local expression of adhesion molecules on endothelial cells, promoting the migration of circulating cells to the inflammatory site.[48] Finally, as discussed more fully later, the APC functions of macrophages and DCs require the increased expression of co-stimulatory molecules, as well as production of cytokines such as IL-12 and IL-18, for effective T-cell activation to proceed. The exact profile of cytokines induced by microbial recognition and produced by macrophages is determined by the nature of the stimulatory agonist and the cell surface receptor(s) engaged. In turn, these molecules both promote the functional activities of neighboring phagocytic cells and influence the character of the adaptive immune response that develops in their presence.

In the final analysis, it is somewhat difficult to separate the concept of inflammation from the process of macrophage activation, because the cells participating in the initiation of an inflammatory response clearly become activated during the development of this response. Analysis of the global response of these cells to microorganisms has suggested that a large portion of the activation-specific gene products induced in macrophages following ligand recognition are involved in regulating the subsequent inflammatory process.[35,36] In many cases, the inflammatory response, and the activities of macrophages activated during that process, are

sufficient to limit and even to clear an infection, occasionally without significant systemic effects in the infected host. Thus, this early macrophage response to infection is an effective host defense mechanism.

ROLE OF MACROPHAGES IN BRIDGING INNATE AND ADAPTIVE IMMUNE RESPONSES

If the innate immune response is not sufficient to contain infection, the ability of macrophages and DC to activate CD4+ T lymphocytes provides a critical bridge to the development of the adaptive response.[49] Much information is available concerning the events of T-cell stimulation by these professional APCs, and only a brief overview of this process is presented here. The stimulation of naive CD4+ T cells, or T helper cells, is the prototypical example of APC function, because activation of these cells is the cornerstone event in the development of adaptive immune responses.

The first stage of APC function is broadly referred to as antigen presentation and consists of antigen uptake, degradation, and loading onto major histocompatibility complex (MHC) molecules.[50,51] As noted previously, the ability of macrophages to phagocytose particles via both nonspecific and receptor-mediated uptake is a critical aspect of their presentation capacity. Antigen uptake, or in the case of intracellular pathogens the accessibility of microbial antigens within the cell, leads to the processing of these antigens into proteolytic peptides and their loading onto MHC class I or class II molecules.

Once effective peptide:MHC complexes are displayed by the APC, T-cell stimulation can follow. The process of T-cell priming (or the activation of naive cells) involves physical interaction with those cells in the T-cell zones of secondary lymphoid organs.[52] Cytokines and chemokines expressed by the macrophage after antigen uptake play a critical role in attracting and retaining naive T cells that are capable of responding to specific antigens, as noted in the previous section. T cells recognizing their cognate antigen on macrophages at these peripheral sites respond by binding the antigen:MHC complex via the T-cell receptor and binding co-stimulatory molecules such as B7.1 and B7.2 (CD80, 86) via the CD28 molecule. Increased expression of such co-stimulatory molecules is one consequence of macrophage-pathogen interaction, thus creating a reciprocal relationship between microbial recognition and T-cell stimulation. Additional engagement of adhesion molecules promotes formation of the T-cell synapse, thought to be critical for effective T-cell activation.[53] T-lymphocyte signaling through the T-cell receptor and co-stimulatory molecules then leads to T-cell activation, broadly defined as the induction of the new gene expression required for T-cell proliferation and differentiation. Effective activation requires that both the antigen:MHC complex and the co-stimulatory molecule(s) be expressed on the same APC and both must be recognized within a specific time span to lead to effective activation in the T cell.[54]

The final stage of T-cell activation by APC is the polarization of the CD4+ T-cell response toward a specific functional pathway, termed *type 1 or type 2 differentiation pathways.* Differential maturation of these responses is regulated by the nature of the cytokines produced by the APC and is thought to be influenced both by the nature of the microbial pathogen or altered cell initially recognized as well as aspects of antigen processing and presentation.[55] In this way, the APC helps to shape the character of the adaptive response, through modulation of the initial T-cell response.

CONCLUSION

Since their initial description as "big eaters" more than 100 years ago, macrophages have been recognized as scavenger cells in both invertebrates and higher organisms.[56] It is now recognized that this ubiquitously distributed population of fixed and circulating mononuclear phagocytes can express tremendous functional, morphologic, and metabolic diversity that is shaped by both the anatomic location and the differentiation or activation stage of each cell. By providing both a first line of host defense against microorganisms and altered host cells and the capacity to stimulate an adaptive immune response, the macrophage plays a central role in the regulation of host immunity.

This paper is a classic in the field of macrophage biology. It provides the first description of an activated or "angry" macrophage, a concept that remains central to our understanding of the host defense aspects of macrophage functions.

Chapter 31
ENDOTHELIAL FUNCTION

Larry W. Kraiss • Mark L. Martinez • Stephen M. Prescott • Guy A. Zimmerman

KEY POINTS

1. **Endothelial cells,** once thought to be inert vascular lining cells, **respond to signals from the environment with functional and phenotypic changes in physiologic conditions and in critical illness.** This process is termed *endothelial activation.*
2. **Endothelial activation** is induced by a variety of agonists that act via receptors of diverse classes. Endothelial receptors are linked to intracellular signaling cascades that regulate functional responses. Endothelial responses to hemodynamic and other mechanical forces and in injury also trigger intracellular signaling pathways.
3. **Endothelial responses triggered by activation or injury** influence vasoregulation, vascular permeability, hemostasis, acute and chronic inflammation, wound surveillance and repair, and other critical events, and they affect every organ.
4. **Endothelial function is dysregulated or becomes unregulated in human diseases,** including sepsis, ischemia-reperfusion syndromes, injury by oxidants or toxins, and other conditions. Endothelial cell dysfunction is a key pathophysiologic mechanism in **organ-specific syndromes** and in **systemic responses to injury.**
5. **Endothelial cell activation responses** provide molecular targets that may ultimately be useful for **therapeutic intervention** in syndromes of critical illness and other diseases. **Endothelial cell markers** may be useful in establishing the natural history of disease states and for following the course of specific syndromes.

INTRODUCTION

The vascular system of an adult human has a surface area of several square meters and is lined by 1×10^{13} or more endothelial cells,[1] which influence the function of every organ. Endothelial cells were once thought to be passive structural units with little or no capacity to respond to activating signals with changes in phenotype and function. Electron microscopic observations documenting that endothelial cells contain secretory granules and physiologic experiments suggesting that they are not passive in interactions with leukocytes, both of which were accomplished in the 1950s, indicated otherwise.[1] The studies of leukocyte–endothelial cell interactions built on earlier observations that the endothelium has particular roles in the response to injury[2] and in inflammation.[3] Multiple subsequent studies clearly demonstrated that endothelial cells respond to signals from the environment with diverse *activation* responses that are critical for vasoregulation, hemostasis, inflammation, wound repair, and organ-specific activities.[4,5] This is perhaps the most important conceptual advance in vascular biology in recent history. A corollary is that endothelial dysfunction contributes to a variety of human diseases and syndromes,[1,4] including critical illnesses.

The endothelium itself is now considered by many investigators and physicians to be an extended and complex organ with the capacity for local, regional, and systemic activation, depending on the physiologic or pathologic stimulus and concurrent modifying features.[1,6,7] In sepsis, trauma, ischemia-reperfusion, and other conditions that are common in critical illness, multiple biochemical and physical signals are generated that can be transmitted to intracellular transduction cascades in endothelial cells, mediating acute or more protracted functional changes. These activation events,[4,5] which are triggered by physical injury, microbial products, toxins, and other stimuli, were apparently conserved after a continuous endothelium appeared as part of a closed vascular system when vertebrate species emerged,[8] and they evolved to establish and preserve vascular integrity, maintain intravascular volume and oxygen and nutrient delivery, and recruit leukocytes and platelets for local defense and repair. Critical phenotypic changes of activated endothelium include rapid transformation to a vasoconstrictive, procoagulant, and proinflammatory state that can then be further modified in a time-dependent fashion.[1] Although these responses are required for homeostasis and defense, they can contribute to tissue damage if dysregulated (Fig. 31–1). In critically ill patients, endothelial cell activity varies, depending on the nature of the illness or injury. Endothelial responses have a critical influence on the complications of organ-specific or systemic illnesses such as acute respiratory distress syndrome (ARDS) and multiple organ failure (see Fig. 31–1).[9,10]

Vasculogenesis and *angiogenesis* are not reviewed in detail here but are fundamental processes with intricate molecular regulation that are important in neoplasia, chronic inflammation, responses of hypoxic tissues, and other pathologic processes, in addition to vascular and organ development.[1,11–16] Recent observations demonstrate novel mechanisms that regulate vascular guidance in developing tissues.[16,17] In critically ill patients, pro- and antiangiogenic signaling molecules are released by platelets and myeloid

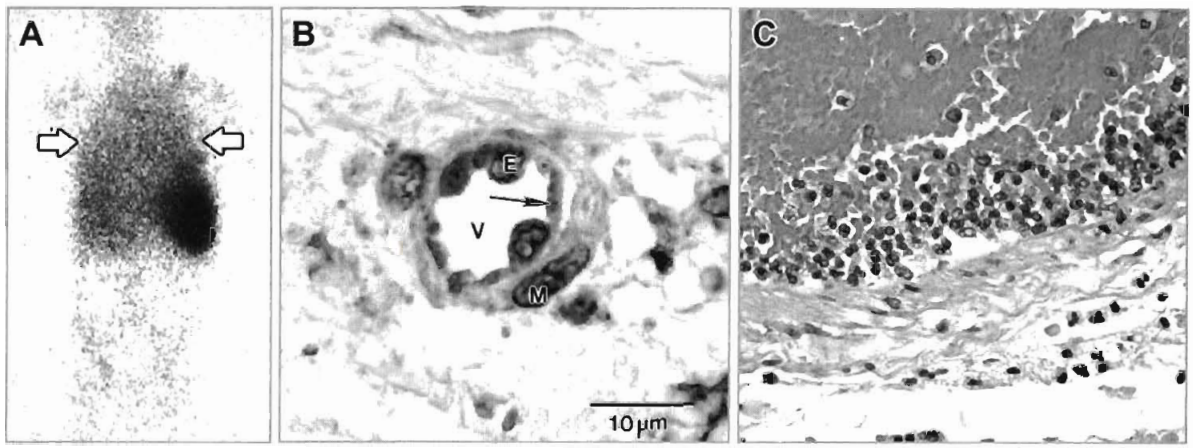

FIGURE 31–1. Endothelial cells are activated in human diseases and critical illness. *A*, Autologous radiolabeled leukocyte scanning in a patient early after the onset of acute respiratory distress syndrome secondary to Gram-negative sepsis demonstrates diffuse accumulation of polymorphonuclear leukocytes and monocytes in the lungs *(arrows)*, an event mediated in part by endothelial cell activation. There is also significant uptake of radiolabeled leukocytes in the liver and spleen. (See text for details; also reference 74.) *B*, Endothelial cells in a systemic venule in tissue removed during surgical exploration for an abdominal aortic aneurysm stain intensely for the CXC chemokine epithelial neutrophil-activating peptide-78 (ENA-78). ENA-78 is not expressed by unactivated endothelial cells at baseline. A variety of other new gene products are also expressed by activated endothelial cells. (See text for details; also references 4 and 62.) *C*, Autopsy sample from a subject dying of Gram-positive sepsis demonstrates dramatic accumulation of neutrophils, monocytes, and platelets in a systemic venule. A variety of clinical and experimental observations indicate that systemic endothelial cells are activated in septic syndromes caused by Gram-positive as well as Gram-negative bacteria, contributing to the accumulation and activation of leukocytes and platelets. V, venule; E, endothelial cell; M, macrophage. (*A*, From Zimmerman GA, Albertine KH, McIntyre TM: Pathogenesis of sepsis and septic-induced injury. In Matthay MA [ed]: Lung Biology in Health and Disease, vol 179. New York, Marcel Dekker, 2003, pp 245-287. *B*, From Imaizumi T, Albertine KH, Jicha DL, et al: Human endothelial cells synthesize ENA-78: Relationship to IL-8 and to signaling of PMN adhesion. Am J Respir Cell Mol Biol 1997;17:181-192.)

leukocytes and are generated by other mechanisms.[10,11] Certain of these mediators, such as the vascular endothelial growth factor family of polypeptides and sphingosine-1-phosphate, influence vascular permeability and other functions in addition to angiogenesis.[18–22] Angiogenic responses of endothelial cells may influence organ dysfunction and repair in specific syndromes of critical illness, but these issues are largely unexplored.

Endothelial cells at different sites in the vasculature may be more similar than dissimilar.[23] However, there is evidence of endothelial cell *heterogeneity* both between and within specific tissues and organs and between macrovascular and microvascular sources.[1,24] The genetic determinants of endothelial cell subtypes and the developmental and signaling pathways that influence their phenotypic fates after initial vasculogenic and angiogenic cues remain to be completely characterized.[1] These variables are critical to approaches that involve therapeutic delivery of stem or vascular progenitor cells to injured or terminally diseased tissues,[25] where microenvironments and selective cell-cell and cell-matrix interactions may differentially influence cell fates.[1] Endothelial cell heterogeneity and local microenvironments also are determinants of these cells' participation in gene therapy protocols and approaches.[1]

A pivotal advance in the study of endothelial cell phenotype and function occurred when methodology was developed that allows the cultivation and analysis of isolated endothelial cells from humans and experimental animals in culture and, in some models, in coculture conditions with other vascular cells.[21,26,27] Although isolated and cultured endothelial cells are not perfect replicas of the in vivo state, they have been remarkably informative (Fig. 31–2). For example, virtually all the adhesion and signaling molecules involved in endothelial interactions with leukocytes (see later) were identified using human endothelial cells in primary or early passage culture, and many additional activation events have been identified

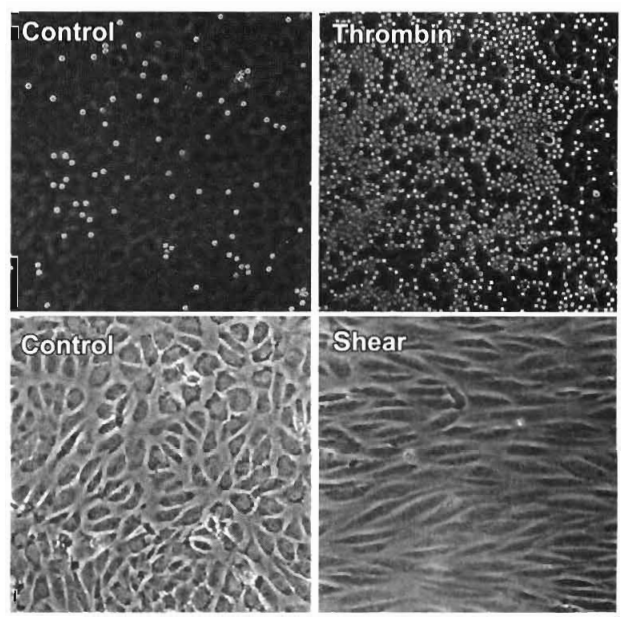

FIGURE 31–2. Cultured human endothelial cells are activated by diverse signals from the environment. *Top panels*, Human neutrophils (refractile white spheres) adhere dramatically to a monolayer of cultured human endothelial cells pretreated with nanomolar concentrations of thrombin for 5 minutes (right), compared with a control monolayer (left). Thrombin triggers endothelial cell activation, leading to neutrophil adhesion. The molecular mechanism for endothelial cell–dependent leukocyte adhesion under these conditions is shown in Figure 31–3*A*, and other relevant events are illustrated in Figure 31–4. (See text for details; also references 38, 40, and 41.) *Bottom panels*, A primary culture of human endothelial cells developed elongate morphology when subjected to shear (right), compared with a control monolayer incubated under static conditions (left) (L. W. Kraiss, unpublished experiment). As outlined in the text, cultured human endothelial cells undergo multiple additional activation events and phenotypic changes in response to clinically relevant signals from the environment. (*Top*, From Zimmerman GA, McIntyre TM, Prescott SM: Thrombin stimulates the adherence of neutrophils to human endothelial cells in vitro. J Clin Invest 1985;76:2235-2246.)

using this approach and validated in vivo (see Fig. 31–2). Strategies using isolated endothelial cells continue to be useful in defining characteristics relevant to critical illness. In addition, "in vivo cell biologic" approaches[10] are evolving and are likely to be informative in experimental models of critical illness and in clinical research involving human subjects in the intensive care unit. In animal models, endothelial-specific knockout and transgenic approaches now provide unique surrogate systems[28–30] that complement observations in in vitro and in vivo human systems and will expand our concepts of endothelial function and dysfunction.

The following sections outline specific aspects of endothelial cell function and pathobiology. Each topic is the subject of detailed discussions in vascular biology monographs and, because of space limitations, cannot be comprehensively discussed here. Therefore, the references include substantive reviews as well as illustrative archival reports.

ENDOTHELIAL RECEPTORS, INTRACELLULAR TRANSDUCTION CASCADES, AND ACTIVATION RESPONSES

Human endothelial cells display multiple surface receptors that transmit outside-in signals to intracellular transduction cascades, which then alter their functions and phenotypic characteristics. Certain endothelial adhesion molecules can also transmit outside-in signals. The diversity of endothelial signaling systems is evidence of the complexity of this cell type and its ability to mediate both physiologic responses and vascular alterations in critical illness and other pathologic conditions.

G protein–coupled pathways are major transduction mechanisms linked to surface *heptahelical receptors* and are ubiquitous in human cell signaling paradigms.[31] Human endothelial cells display heptahelical receptors (also called seven-membrane-spanning G protein–coupled receptors or serpentine receptors) that recognize thrombin, histamine, bradykinin, sphingosine-1-phosphate, and other hemostatic and inflammatory agonists. These surface receptors are differentially coupled to intracellular adapter proteins and enzymes that trigger phospholipase activation, calcium (Ca^{++}) transients, mitogen-activated protein kinase pathways, cyclic nucleotide turnover, and other intermediary events.[32] The resulting phenotypic changes and effector responses include surface translocation (degranulation) of intracellular storage granules (Weibel-Palade bodies), with von Willebrand factor release and P-selectin display on the cell surface; rapid platelet-activating factor (PAF) and prostacyclin (PGI_2) synthesis; cytoskeletal reorganization; altered permeability; altered gene expression; and others.

Human and murine endothelial cells constitutively express surface protease-activated receptors (PARs), a family of heptahelical G protein–coupled receptors that recognize thrombin and certain other proteases and transmit outside-in signals via a unique mechanism involving proteolytic release of a cryptic internal ligand.[29,33] Human endothelial cells also display PAR2, which recognizes mast cell tryptase, trypsin, and coagulation factors VIIa and Xa and is up-regulated by cytokines and lipopolysaccharide (LPS).[33–35] There is also evidence that PAR3 and PAR4 are expressed by endothelial cells and that expression of PAR4, like PAR2, is altered by inflammatory agonists.[36,37] Signaling via PARs provides regulated mechanisms by which endothelial cells respond to local thrombin generation and mast cell degranulation—two acute responses that are central in tissue injury and physiologic host defense.[33,38,39] Thrombin-induced signaling and PAR activation are also pathways for dysregulated vascular responses in syndromes of critical illness.[32,38,40] Stimulation of endothelial cell monolayers with thrombin provided the first evidence of endothelial cell–dependent adhesion of neutrophils (Figs. 31–2 and 31–3; also see later).[38,41,42] These and a variety of other studies demonstrated that thrombin induces endothelial cell activation by receptor-mediated mechanisms.[32,33,38,41] In more recent experiments, thrombin activation of cultured macro- and microvascular endothelial cells influenced intercellular gap formation by a mechanism dependent on intracellular Ca^{++} transients and a subtype of adenyl cyclase.[43] It was also reported that PAR1 and PAR2 differentially trigger exocytosis and alter permeability in human endothelial cell monolayers by influencing Rho–guanosine triphosphatase activity.[44] These and a variety of other observations document multiple thrombin-activated functional changes in endothelial cells that are relevant to endothelial behavior in critical illness. There is also evidence for thrombin signaling in vascular development and angiogenesis.[45] These findings, together with earlier observations of degranulation, endothelial cell–dependent leukocyte adhesion, and mitogenesis,[33,34,38,40,41] illustrate the diverse changes in endothelial cell phenotype triggered by PAR-mediated pathways.

Human endothelial cells display histamine H1 and bradykinin B2 receptors that mediate vasoactive and inflammatory signaling when engaged.[46,47] Histamine induces many of the same activation responses as thrombin does, including degranulation, translocation of P-selectin to the surface, rapid synthesis of PGI_2 and PAF, and endothelial cell–dependent neutrophil adhesion, and it can trigger the release of preformed chemokines in models of chronic inflammation.[46,48,49] Many of these events, which were first identified in cultured human endothelial cell systems, have been documented in vivo.[50] By using H1 and PAR2 receptors, endothelial cells respond to histamine and tryptase, which are key inflammatory agonists that are released locally in response to tissue trauma.[39] When PAR1 or other PARs that recognize thrombin are engaged in parallel with histamine stimulation, as frequently occurs in tissue injury in vivo, complex intracellular signaling responses result.[47,51,52] Although receptors for thrombin and histamine trigger many parallel and convergent signaling cascades and functional activities in endothelial cells, they also have distinct effects on gene regulation pathways in this cell type (D. Schmid, L. W. Kraiss, unpublished observations).

Receptor tyrosine kinases are expressed by human and murine endothelial cells and play critical roles in the maintenance of vascular structure and the adaptation to tissue injury and remodeling. In addition, they have developmental roles in vasculogenesis and angiogenesis. Endothelial-specific receptor tyrosine kinases include three members of the vascular endothelial growth factor receptor family and two structurally related receptors with immunoglobulin and epidermal growth factor homology domains, Tie1 and Tie2, which recognize members of the angiopoietin family and other ligands.[1,20] In development, these receptors and their ligands act in concert with other angiogenic and guidance receptors and pathways.[1,13,16,17] In addition to mediating angiogenesis and lymphangiogenesis, engagement of vascular endothelial growth factor and Tie receptors on endothelial cells transmits signals to endothelial nitric oxide synthase (eNOS), vasopermeability regulatory mechanisms, and inflammatory

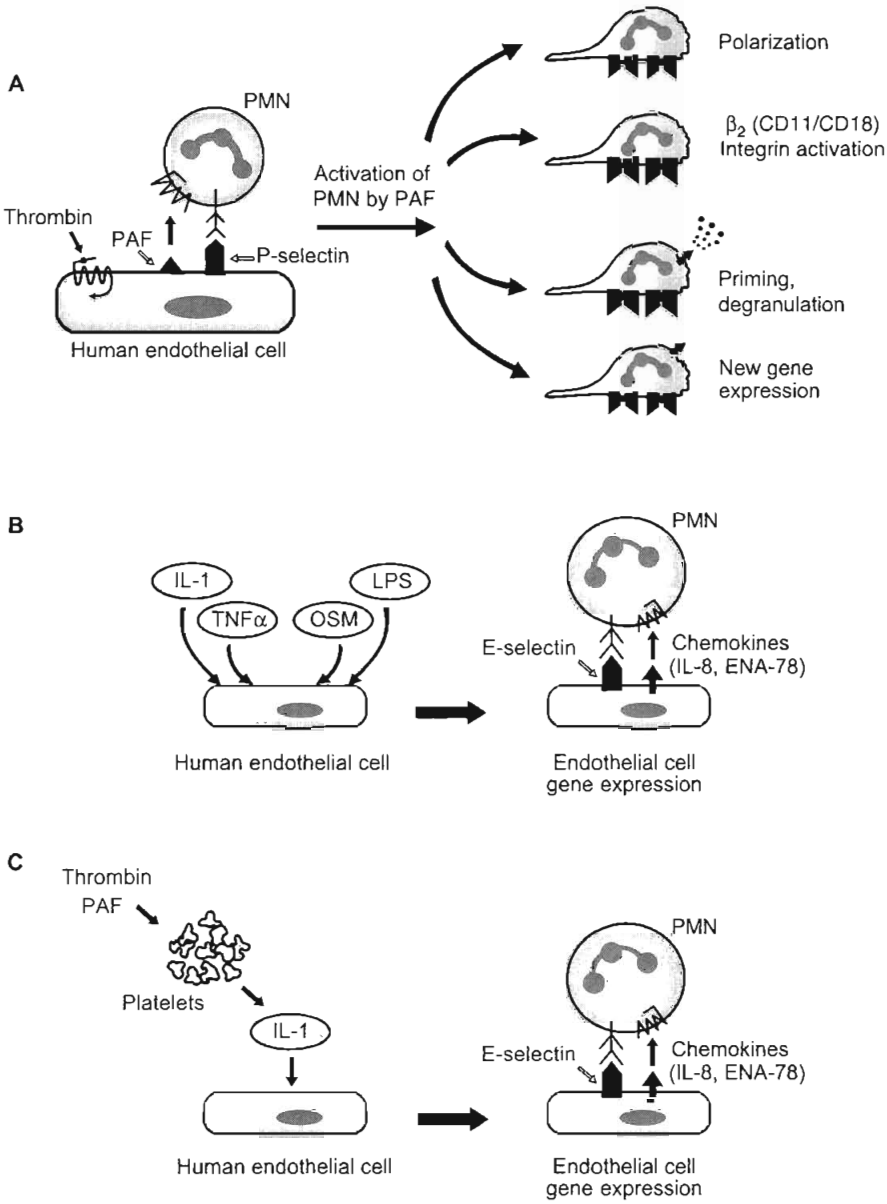

FIGURE 31–3. Human endothelial cells are activated by outside-in signals delivered by diverse inflammatory and thrombotic agonists and mechanisms. *A*, Human endothelial cells activated by thrombin via heptahelical protease-activated receptors (PARs) acutely translocate P-selectin from storage granules, rapidly synthesize platelet-activating factor (PAF), and use these factors as a juxtacrine adhesion and signaling system for neutrophils. (See text for details; also references 38, 40, and 41.) Human endothelial cells activated by thrombin via PAR pathways undergo additional changes that mediate inflammatory and thrombotic responses. *B*, Cytokines released by macrophages and other extravascular cells are recognized by receptors on endothelial cells, inducing multiple activation responses. Bacterial products, including lipopolysaccharide (LPS) and other endotoxins, bind to specific members of the Toll-like receptor family expressed by endothelial cells, also triggering activation events. *C*, Interleukin (IL)-1ß synthesized and released by stimulated platelets activates human endothelial cells, resulting in endothelial cell–dependent neutrophil adhesion. This illustrates a mechanism by which intravascular blood cells can initiate or amplify endothelial cell activation. ENA, epithelial neutrophil-activating peptide; OSM, oncostatin M; PMN, polymorphonuclear leukocyte; TNF, tumor necrosis factor. *(See also Color Figure 31–1.)* (*C*, Modified from Zimmerman GA, Albertine KH, McIntyre TM: Pathogenesis of sepsis and septic-induced injury. In Matthay MA [ed]: Lung Biology in Health and Disease, vol 179. New York, Marcel Dekker, 2003, pp 245-287.)

pathways.[20–22] Recent observations indicate that Tie2 expression is regulated by hypoxia and inflammatory cytokines in human endothelial cells.[15]

Cytokine receptors are regulators of endothelial cell phenotype and function in innate immune and acute inflammatory responses, hemostasis and thrombosis, acquired immunity and chronic inflammation, vascular remodeling, and other functions relevant to human disease (see Fig. 31–3). Endothelial cells constitutively express receptors for more than a dozen cytokines[53–55] and use them to transmit outside-in signals to mitogen-activated protein kinase cascades, ceramide turnover mechanisms, nuclear signaling pathways that involve nuclear factor kappa-B (NF-κB) and JAK/STAT activation, and other intracellular transduction circuits.[53–57] Endothelial responses to newly identified cytokines, such as high mobility group protein B1 (HMGB1), continue to be reported.[58,59] The most extensively characterized cytokine signaling events in human endothelial cells involve activation by tumor necrosis factor (TNF), interleukin-1alpha (IL-1α), and interleukin-1beta (IL-1β), which induce expression of genes that code for E-selectin and other adhesion molecules, interleukin-8 (IL-8), epithelial neutrophil-activating peptide-78 (ENA-78) and other chemokines, the inducible form of cyclooxygenase (COX-2), endothelial degranulating factors for neutrophils, and a variety of other inflammatory and thrombotic proteins and peptides.[53–56,60–64] The IL-1 signaling system, including recently identified IL-1 receptor-associated proteins, is conserved across evolutionary lines, is central to the responses of a variety of cells to infection and injury, and has both homologous features and molecular interfaces with Toll receptor signaling (see later).[65] Endothelial cells express the type I but not the type II ("decoy") IL-1 receptor—an unusual feature, because most cells display both.[53]

IL-1, TNF, IL-6, and other cytokines recognized by endothelial cell receptors are produced by macrophages and other extravascular cells in response to thrombotic or inflammatory stimuli (see Fig. 31–3).[53,54] In addition, some cytokines—for example, IL-1 and IL-6—are *endogenously*

produced by inflamed endothelial cells themselves, providing the basis for autocrine signaling loops.[53,54] Alternatively, cytokine agonists for endothelial cells can be produced by intravascular platelets or leukocytes, providing mechanisms that link thrombosis and inflammation and amplify inflammatory responses.[5,54,66,67] For example, human platelets synthesize IL-1β from constitutive messenger RNA (mRNA) transcripts in response to thrombin, PAF, and other agonists and release it in sufficient concentrations to trigger endothelial cell–dependent polymorphonuclear leukocyte (PMN) adhesion in in vitro assays (see Fig. 31–3).[67] Signal-dependent translation of IL-1β is one of many inflammatory activities of stimulated platelets[68] and provides a novel mechanism that explains earlier observations that platelets release IL-1 activity.[54,67] Activated platelets can also signal endothelium locally by releasing or displaying ligands recognized by heptahelical, growth factor, and other receptor classes, triggering key functional changes.[18,19,66] In a second example of endothelial signaling by blood cells, human neutrophils were recently found to release the alpha subunit of the IL-6 receptor (IL-6Rα), which can then associate with homodimers of glycoprotein 130 that are basally present on human endothelial cells.[54,69,70] In contrast, IL-6Rα is not constitutively expressed by endothelium.[54,69,70] The association of soluble IL-6Rα with transmembrane glycoprotein 130 homodimers constitutes a competent heterotrimeric receptor that confers to endothelial cells a new responsiveness to endogenously or exogenously synthesized IL-6, inducing the expression of inflammatory and thrombotic genes.[69,70] One consequence of new gene expression is a "switch" from neutrophil to mononuclear leukocyte accumulation, an event that is required for the resolution of acute inflammatory responses but is also a central mechanism in the transition to chronic inflammation if it is pathologically dysregulated.[71,72] This novel mechanism of retrograde or *trans*-signaling of endothelial cells by PMNs[69,70,72] may mediate a variety of pathologic activities of IL-6, together with other complex regulatory features of the system.[73]

Endothelial cells respond to local or systemic microbial invasion and to activation by LPS and other bacterial products with complex changes in inflammatory phenotype and, in some cases, by triggering apoptotic programs.[74–78] Recent characterization of the *Toll-like family of transmembrane receptors* (TLRs), which are conserved, innate immune sensors, provides insights into endothelial and leukocyte signaling by LPS and other endotoxins and microbial products.[74,79,80] The TLR system is composed of specific receptors that recognize pathogen-associated molecular patterns with ligand-dependent specificity.[79] TLRs act together with cell surface–associated modifying proteins (CD14, MD-2) and use a cytoplasmic transduction system linked to gene regulatory pathways and other effector mechanisms.[79,80] As previously noted, conserved IL-1 receptor-associated kinases are central intermediaries.[65,80,81] Human macrovascular and microvascular endothelial cells express TLR2 and TLR4 and use them to differentially recognize and respond to LPS and to bacterial endotoxic lipoproteins, including the Braun lipoprotein of *Escherichia coli* and other microbes.[82–85] Expression of TLR2 and TLR4 on cultured endothelial cells and endothelial cell lines can be modulated by LPS, interferon gamma, and reactive oxygen species.[83,85] Experimental studies in murine models demonstrate important differences in leukocyte-endothelial interactions, depending on the specific bacterial product injected, systemic versus local challenge, and the TLR and CD14 phenotype.[86,87] Previous studies in an in vitro model involving cultured human endothelial cells and whole blood demonstrated an indirect pathway of LPS-induced activation of endothelium that is mediated by monocytes and that dramatically amplifies endothelial sensitivity and response to this microbial product.[88] These and other studies indicate that in clinical sepsis and other vascular responses to pathogens, changes in endothelial phenotype and function likely involve both direct TLR signaling and indirect activation mediated by leukocyte and platelet products.[74]

Nuclear receptors recognize cell-permeant hormones, lipids, and therapeutic drugs.[89] A major nuclear hormone receptor in diverse cell types recognizes endogenous and synthetic glucocorticoids and mediates their regulatory effects on transcriptional programs.[89] The glucocorticoid receptor is present in nuclei of in situ human arterial endothelial cells, and its nuclear localization is influenced by shear stress in cultured bovine endothelial cells,[90] suggesting that nuclear receptor pathways may respond to endothelial activation or injury in a variety of conditions. Estrogen receptors, a second class of nuclear hormone receptors, are present in bovine and human endothelial cells.[91] Human endothelial cells also respond to activators of the peroxisome proliferators–activated receptor family under some conditions.[92]

In syndromes of critical illness, multiple endothelial cell surface and nuclear receptors are likely engaged in parallel and in sequence, generating complex phenotypic changes and functional responses. Sepsis is a sentinel example in which endothelial activation via several receptor pathways may be key to essential vascular and tissue responses,[74,77,78] as illustrated in this section.

ENDOTHELIAL RESPONSES TO HEMODYNAMIC FORCES

In vivo, endothelial cells are continuously subjected to hemodynamic forces. These forces include vascular wall distention induced by cyclic changes in transmural pressure and shear, which is the frictional force applied by blood flow.[93,94] Acute changes in shear induce phenotypic modulation and altered gene expression in cultured endothelial cells (see Fig. 31–2) and cellular remodeling in vessels and vascular grafts; both acute *increases* and *decreases* in shear induce phenotypic responses.[93–95] Alterations induced by shear and other hemodynamic forces are often similar to those triggered by inflammatory agonists.

Abrupt changes in shear induce rapid cytoskeletal remodeling and activation of intracellular signaling pathways in endothelial cells, including modulation of potassium channels, induction of calcium transients, alterations in inositol phosphates and diacylglycerol, generation of reactive oxygen intermediates, activation of mitogen-activated protein kinases, activation of Rho– and Rac–guanosine triphosphatases, and nuclear signaling and altered gene expression.[90,93–101] Functional consequences of shear-induced changes in endothelial cell phenotype include acute generation of nitric oxide (NO) and PGI_2, cytoskeletal and microtubular reorganization, changes in synthesis of inflammatory and thrombotic gene products, and altered DNA synthesis.[93,94,102–104] Endothelial cells also adapt to chronic changes in shear with structural alterations.[93] The mechanosensors that transmit hemodynamic outside-in signals to endothelial cells remain incompletely characterized.[93,105,106]

ENDOTHELIAL JUNCTIONS, PERMEABILITY, AND SELECTIVE BARRIER FUNCTIONS

Highly specialized junctional structures that link adjacent cells in interconnected monolayers of endothelial cells that line vascular channels regulate paracellular permeability and macromolecular transport and influence the transmigration of leukocytes from the intravascular space to the extravascular milieu.[107,108] Endothelial cell–matrix interactions mediated by basolateral integrins also influence permeability,[1,105] providing both cellular attachment and outside-in signals that modify specialized intercellular junctions. Junctional transfer of small molecules between adjacent endothelial cells occurs, potentially resulting in an additional mechanism of intercellular signaling.[109] As many as four types of junctions may mediate interactions between endothelial cells.[107] Adherens junctions and tight junctions are critical in regulating permeability and cell polarity and are modified by inflammatory and thrombotic signals,[107,110] including thrombin, sphingosine-1-phosphate, and other receptor-mediated agonists.[18,19,32,43] Thus, these multimolecular junctional structures and their interacting cytoskeletal elements are likely key sites of dysregulation in increased systemic and pulmonary vascular permeability in syndromes of critical illness.

Endothelial-specific cadherin 5, or vascular endothelial cadherin, is a central component of endothelial cell adherens junctions, contributes to the barrier function of endothelial cell monolayers, and is modified by receptor-mediated signals and leukocyte-endothelial interactions.[107,108,111] Vascular endothelial cadherin may signal through β-catenin, which influences vascular pattern and fragility in murine models,[30] and there is evidence for additional cadherin-catenin interactions.[112] Additional endothelial cell junctional molecules are involved in interactions between endothelial cells.[107] Recent observations indicate that S-ENDO 1–associated antigen (CD146), a transmembrane glycoprotein constitutively expressed by endothelial cells regardless of anatomic site or vessel size, is localized to intercellular boundaries and is coupled to a tyrosine kinase–mediated pathway that triggers intracellular Ca^{++} transients.[110,113] Cytoplasmic Ca^{++} levels regulate the activity of adenyl cyclase isoenzymes and interendothelial gap formation in cultured endothelial cell models,[43] suggesting that CD146 may have important influences on permeability via these mechanisms. These examples illustrate the concept that endothelial cell junctional molecules perform both adhesive and signaling functions and can be dysregulated in vascular injury.

The intricate mechanisms by which endothelial cell junctions are altered in leukocyte transmigration (Fig. 31–4) remain incompletely characterized and involve both adherens and tight junctions.[103,111] Vascular endothelial cadherin distribution is rapidly and dynamically modified during transmigration of PMNs and monocytes, providing a potential mechanism for interendothelial gap opening, leukocyte passage, and rapid gap closure.[111] Additional endothelial cell junctional molecules play specific roles in targeting leukocyte subclasses to intercellular sites of transmigration and stepwise emigration (see Fig. 31–4).[5] Platelet leukocyte adhesion molecule-1 is the best known of these.[5,114] Junctional adhesion molecule-1, also an immunoglobulin superfamily protein, was recently reported to be a binding partner for $\alpha_L\beta_2$ integrin on PMNs, monocytes, and T lymphocytes that is expressed predominantly at tight junctions of resting endothelial and epithelial cells.[115] CD99, a recently characterized O-glycosylated protein, is localized to endothelial cell junctions and mediates the transmigration of monocytes across cultured endothelial cell monolayers.[116] These findings indicate that endothelial cell junctional complexes and specific proteins localized to endothelial cell–endothelial cell contact domains regulate selective barrier functions involving both macromolecules and emigrating leukocytes, key functions that can be disrupted in

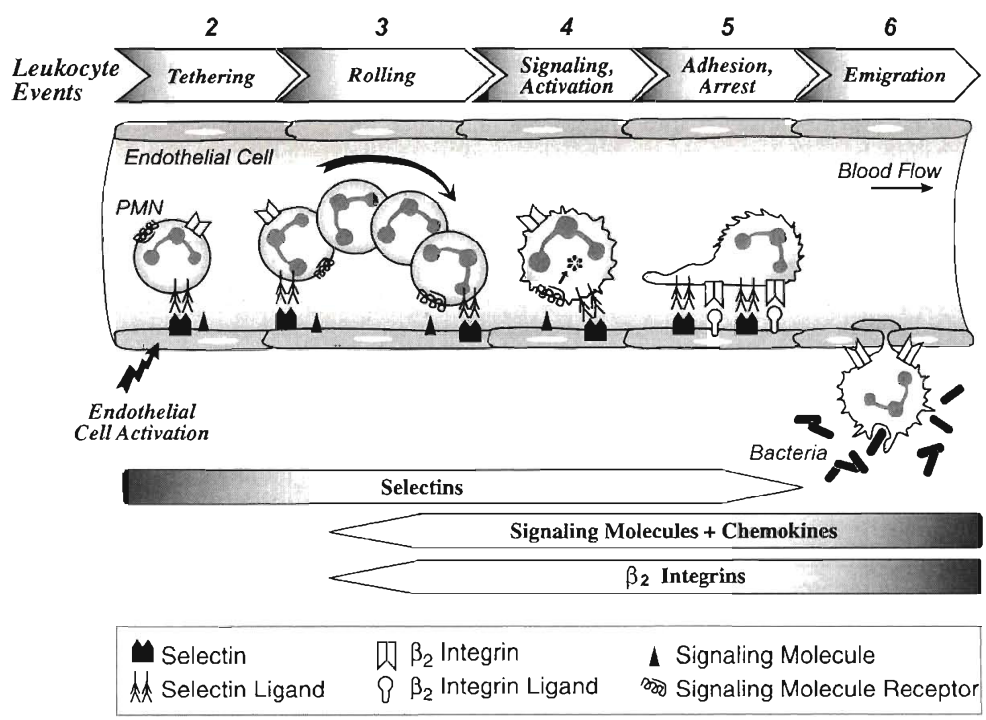

FIGURE 31–4. Activation of endothelial cells and multistep interactions control leukocyte targeting and function in inflammation. This multistep paradigm details key events in neutrophil (PMN) adhesion, localized activation, and transmigration in a postcapillary venule under conditions of flow. Each step (see text for details) is critical for PMN adhesion and emigration in dysregulated vascular injury. Initial activation of endothelial cells is key in this sequence of events. (From McIntyre TM, Prescott SM, Weyrich AS, Zimmerman GA: Cell-cell interactions: Leukocyte-endothelial interactions. Curr Opin Hematol 2003;10:150-158.)

inflammatory vascular injury involving dysregulated neutrophil accumulation and activation.[117–119]

ENDOTHELIAL CONTRIBUTIONS TO VASOREGULATION

Blood flow is partially regulated by the generation of vasoactive signaling factors by endothelium that act locally to modify vascular tone, caliber, responses to other stimuli, and hemodynamic variables.[1] NO and PGI_2 are key endothelial-derived vasodilators that also modify platelet responses and in some cases alter leukocyte-endothelial interactions.[1] Thus, they have both direct and indirect vasoactive features. In addition, endothelial cells synthesize vasoconstrictor substances, including endothelins and a number of other vasoactive factors, in response to signals delivered by surface receptors and hemodynamic forces.[1,120]

Endothelial cells generate NO in an enzymatic process catalyzed by nitric oxide synthase (NOS) in which L-arginine is converted to L-citrulline in the presence of oxygen and nicotinamide adenine dinucleotide phosphate (reduced form).[1] NO, a cell-permeant gas with a half-life of approximately 6 seconds, mediates intercellular interactions in a paracrine fashion and binds to the heme prosthetic group of guanyl cyclase in vascular smooth muscle cells, maintaining basal vascular tone and inducing vasorelaxation.[1] A parallel mechanism inhibits platelet activation responses and also leukocyte activities and smooth muscle migration and proliferation in some studies.[6,120] NO production is catalyzed by a family of NOS, including constitutive and inducible isoforms.[120] One isoform, eNOS (or NOS3), is basally active in endothelial cells, but its activity can be further increased by receptor-mediated agonists.[1] The effect of cytokines on eNOS activity and expression has species-specific characteristics, and these features may vary in individual vascular beds within a species.[1,6,54] Expression and activity of eNOS are increased in response to shear, in part secondary to transcriptional activation and a cis-acting shear response sequence in the promoter region of the gene,[1] and there is evidence for regulation by hypoxia.[121] eNOS activity can also be increased by Akt-dependent phosphorylation.[21,122] Additional features of the regulation of eNOS and inducible NOS isoforms have recently been reviewed.[120]

Activation of NOS in endothelial and other cell types influences hemodynamic events in sepsis and other syndromes of critical illness, although precise measures to modify these enzymes are not yet in general clinical practice.[123] Myeloperoxidase, a key PMN enzyme that is released by degranulation,[64] consumed NO and impaired endothelial-dependent vasodilatation in a rodent model of endotoxemia,[124] pointing to mechanisms that may contribute to pathologic hemodynamic responses in inflammatory vascular injury.

PGI_2, the first endothelial cell–derived relaxing factor to be identified, is also a major inhibitor of platelet activation and aggregation.[1,6,120] PGI_2 is synthesized by the microsomal enzyme cyclooxygenase (prostaglandin H synthase) acting on substrate arachidonic acid released from membrane phospholipids in response to cellular stimulation. The COX-1 isoform is constitutively expressed in endothelial cells, and PGI_2 generated by this enzyme is important in physiologic vasoregulation and as a local antithrombotic signal.[6,125,126] The inducible isoform, COX-2, is expressed in endothelial cells in response to stimulation with IL-1, TNF, LPS, and other inflammatory and thrombotic agonists and contributes PGI_2 and prostaglandin E_2 to the local inflammatory milieu.[6,60,61,125,126] The factors that regulate COX-2 expression in stimulated and inflamed endothelial cells are complex and continue to be dissected.[6,120,127,128]

ENDOTHELIAL REGULATION OF HEMOSTASIS

In the basal state, endothelial cells present an antithrombotic and anticoagulant surface, a critical phenotypic feature required for blood flow that acts in concert with mechanical forces and soluble factors.[1,6] In response to injury, the endothelium becomes prothrombotic and antifibrinolytic, providing a mechanism that facilitates hemostasis and wound repair and generates molecular links that couple endothelial activation to local myeloid leukocyte accumulation and other defensive inflammatory responses.[1,5,6,68,74] Endothelial procoagulant mechanisms that interface with inflammatory networks are part of an evolutionarily conserved innate defense system.[68,129,130] When dysregulated, however, this remarkable switch in endothelial phenotype initiates or amplifies pathologic thrombosis, a central mechanism of disease in critical illness.[5,74,77,129,130]

Anticoagulant and antithrombotic features of resting endothelial cells include pericellular heparin sulfate, glycosaminoglycans, and dermatan sulfate, which facilitate the activity of antithrombin III and heparin cofactor II, the expression of thrombomodulin and tissue factor pathway inhibitor (see later), and the release of PGI_2 and NO (see earlier). Each of these is dysregulated in specific syndromes of vascular injury and disease.[1,7,130]

The expression and activity of tissue factor are critical in hemostasis and in pathologic thrombosis. Tissue factor is a primary initiator of the coagulation cascade, a process that has been extensively reviewed.[130–134] Tissue factor potently accelerates factor VIIa–dependent activation of factors IX and X.[1] Thrombin generated by sequential protease-dependent steps in the tissue factor pathway subsequently cleaves fibrinogen to fibrin, the central component of the platelet-fibrin mesh that constitutes clots.[131–134] When endothelial cells that express tissue factor are exposed to plasma, thrombin is generated and fibrin is deposited on the endothelial cell surface.[1] Expression of tissue factor activity on endothelial cells is induced by a variety of pathophysiologically relevant stimuli in vitro, but factors that trigger its regional expression by endothelium in vivo remain in question.[1,6] Tissue factor is also synthesized by human monocytes and macrophages in response to LPS and other stimuli and is deposited on cell surfaces and shed into the blood in microparticles released by monocytes or neutrophils.[74,131,135] Tissue factor pathway inhibitor, a 42-kDa serine protease inhibitor with three tandem kunitz domains, is associated with endothelial granules and surfaces and is found to a lesser extent in association with platelets and in soluble form.[6,129,130,136] Tissue factor pathway inhibitor has anticoagulant effects by direct inhibition of factor Xa and by an indirect mechanism involving factor Xa–dependent inhibition of the tissue factor–factor VIIa complex.[130,137] In vivo, tissue factor pathway inhibitor expression is restricted to microvessels.[6] LPS and cytokines have only a slight effect on tissue factor pathway inhibitor expression by cultured endothelial cells in

vitro, but during infusion of LPS in rodents, its expression on pulmonary capillaries is reduced by a mechanism yet to be defined.[6]

Thrombomodulin, an integral membrane protein, is basally expressed by macro- and microvascular endothelial cells in vitro and in vivo and has profound effects on the regulation of hemostasis.[133,134] When thrombin is locally generated, it is recognized by thrombomodulin and binds to it, inhibiting the procoagulant activities of thrombin while facilitating its ability to cleave circulating protein C to activated protein C.[6,74,133,134] Activated protein C interacts with a cofactor that is synthesized by endothelial and other cell types—protein S—and this complex then inactivates factors Va and VIIa, inhibiting further thrombin generation and providing an endogenous "brake" on the procoagulant cascade that is proportional to the magnitude of the hemostatic stimulus under regulated physiologic conditions.[1,133,134] Thus, endothelial cells express key molecules that regulate coagulation. There is also evidence that activated protein C inhibits proinflammatory as well as prothrombotic cascades.[74,130,134,138] Activation of protein C by the thrombin-thrombomodulin complex is further enhanced by its high-affinity binding to an additional endothelial cell plasma membrane factor, the endothelial cell protein C receptor.[133,134,139,140] Thrombomodulin has additional regulatory effects, including enhancement of inactivation of thrombin by antithrombin III and protein C inhibitor and activation of thrombin-activatable fibrinolysis inhibitor (procarboxypeptidase B).[6]

Factors that regulate endothelial expression of thrombomodulin and endothelial cell protein C receptor continue to be defined and have regional features that may reflect endothelial cell specialization.[6,133,134] Thrombomodulin is differentially expressed by endothelial cells in specific vascular beds and is absent from brain endothelium.[6,133] It is reduced on the plasma membranes of endothelial cells in response to LPS challenge in in vitro models and in histologic analysis of biopsies from patients with meningococcemia.[74] Endothelial cell protein C receptor expression is highly specific for macrovascular endothelial cells, with the exception of hepatic sinusoids, a property influenced in part by sequence information in the promoter region of its gene.[6,140,141] LPS infusion in rodents is accompanied by an increase in endothelial cell protein C receptor mRNA but not protein,[140] indicating post-transcriptional regulation. The increased plasma levels of soluble thrombomodulin and endothelial cell protein C receptor that are reported in sepsis and other conditions appear to result from shedding of the surface proteins.[6,74]

Endothelial cells also have a major role in the regulation of fibrinolysis and synthesize a complex group of plasminogen activators, plasminogen activator inhibitors, and receptors for fibrinolytic factors.[1,6] There is evidence for differential expression of tissue plasminogen activator and other fibrinolytic regulatory molecules in specific vascular beds and for dysregulation of this system in response to pathologic stimuli.[1,6]

The balance between anticoagulant and prothrombotic features of endothelium is altered in many, and perhaps all, syndromes of critical illness. Sepsis is an intensely studied example.[74,77,129,130,137,146] Dysregulation of endothelial control of hemostasis contributed extensively to the preclinical and clinical rationales for recent trials of recombinant activated protein C and tissue factor pathway inhibitor in patients with septic syndromes.[129,130,137]

ENDOTHELIAL INTERACTIONS WITH LEUKOCYTES AND OTHER BLOOD CELLS

Endothelial cells were previously thought to be passive in interactions with leukocytes, but observations in the last 2 decades have clearly demonstrated *endothelial cell–dependent mechanisms of leukocyte adhesion and signaling* (see Figs. 31–2 to 31–4).[4,5,38,40,41] This facet of endothelial biology has been extensively reviewed.[1,4–6,53,54,64,72,142–144] Leukocyte-endothelial interactions are early and critical events in defense against infection and in wound surveillance and repair, but dysregulated adhesion and signaling of leukocytes is a central pathogenetic mechanism in vascular injury and a variety of human inflammatory diseases.[5,38,39] Similarly, dysregulated interactions between the vessel wall and circulating platelets or erythrocytes contribute to specific vascular pathologies.[1,5]

A multistep paradigm involving the tethering of leukocytes to stimulated endothelial cells, followed by rolling, localized signaling, consequent tight adhesion, arrest of activated leukocytes, and subsequent emigration between endothelial junctions (see previous section), characterizes the targeting of myeloid cells and lymphocytes in inflammation (see Fig. 31–4).[5] Fundamental aspects of this sequence of events were initially worked out in human cell models and from clinical observations of patients with leukocyte adhesion deficiency syndromes, and they have been validated and refined using animal models and further clinical observations.[5,143]

The central paradigm can be illustrated using interactions of inflamed endothelial cells and neutrophils (PMNs), although it is important to emphasize that there are cell- and context-specific variations, depending on the leukocyte subtype being considered and whether the situation involves acute or chronic inflammation or injury.[5] An overview of the multistep paradigm[5,143,144] is illustrated in Figure 31–4 and summarized here. Under basal conditions, endothelial cells and circulating PMNs are not adhesive to each other. Stimulation of endothelial cells with inflammatory agonists induces their activation and differential expression of specific selectins on their plasma membranes, which then mediates the capture, tethering, and rolling of quiescent unactivated PMNs. In the first step, endothelial cell activation by thrombin, histamine, and certain other rapidly acting agonists induces translocation of P-selectin, which is constitutively present in Weibel-Palade storage granules, to the endothelial cell plasma membrane. In contrast, LPS, IL-1, TNF, and additional cytokines signal transcriptionally regulated synthesis of a different selectin, E-selectin, which is not basally present in most endothelial cells. After synthesis, E-selectin is also displayed on the endothelial cell surface and, like P-selectin, captures and tethers PMNs (step 2). In this step, selectin ligands on the PMN are engaged by P-selectin or E-selectin displayed on the inflamed endothelial cell surface. P-selectin glycoprotein ligand-1 is the dominant selectin ligand on human and murine PMNs and has been shown in in vitro and in vivo experiments to mediate both tethering and rolling (step 3). L-selectin on the PMN surface also mediates tethering and rolling by interacting with ligands on inflamed endothelial cells and acts as an adhesion molecule for cell-cell interactions with other PMNs that accumulate locally. After tethering and rolling, endothelial cell–dependent signaling of PMNs triggers their activation (step 4). When endothelial cells are stimulated by thrombin or histamine, PAF is rapidly synthesized and is translocated

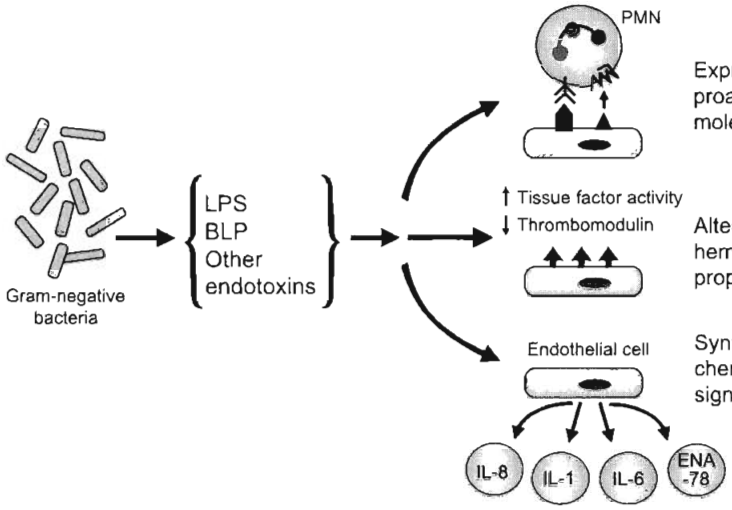

FIGURE 31–5. Endothelial cell activation and functional responses contribute to inflammatory vascular injury and thrombosis in septic syndromes. Lipopolysaccharide (LPS) and other endotoxins, such as Braun lipoprotein (BLP), activate human endothelial cells via Toll-like receptors and induce multiple phenotypic changes in experimental sepsis and clinical septic syndromes. ENA, epithelial neutrophil-activating peptide; IL, interleukin; PMN, polymorphonuclear leukocyte. (From Zimmerman GA, Albertine KH, McIntyre TM: Pathogenesis of sepsis and septic-induced injury. In Matthay MA [ed]: Lung Biology in Health and Disease, vol 179. New York, Marcel Dekker, 2003, pp 245-287.)

to the cell surface, where it acts as a signaling molecule that triggers PMN activation of PMNs tethered by P-selectin. Alternatively, in endothelial cells stimulated with LPS, IL-1, or TNF, IL-8 and ENA-78 are synthesized under transcriptional control and mediate the activation of PMNs in concert with tethering by E-selectin. Activation of PMNs by signaling molecules (e.g., PAF, IL-8, ENA-78) displayed in a juxtacrine fashion at the endothelial cell surface or when locally released induces stimulation-dependent changes in affinity and avidity of β_2 integrins on the leukocyte surface. Activated β_2 integrins then recognize intercellular adhesion molecule-1 and other ligands on the endothelial cell plasma membrane (step 5). Engagement of P-selectin glycoprotein ligand-1 enhances the activation of β_2 integrins on human PMNs signaled by PAF or IL-8. Binding of β_2 integrins to endothelial cells counterligands and then mediates tight adhesion and arrest of the PMNs (step 5), events that are essential to prevent the dislodgment of leukocytes by shear forces and for their subsequent emigration across endothelial cell junctions (step 6).

Activation of endothelial cells resulting in the display of selectins and the synthesis of PAF, IL-8, and other signaling molecules for neutrophils is critical for the sequence of events outlined in Figure 31–4 in host defense.[4,5,38,143] Similarly, constitutive and regulated expression of endothelial ligands for neutrophil β_2 integrins and expression of junctional proteins that participate in PMN emigration are essential determinants for orderly neutrophil targeting in physiologic inflammation.[5,111,115,116,143,144] Activation of endothelial cells is also central to targeting and spatially localized signaling of other classes of leukocytes in host defense.[5] In syndromes of inflammatory vascular injury, one or more of these critical steps can become disordered or unregulated, leading to pathologic accumulation and activation of leukocytes and consequent vessel and tissue damage (see Figs. 31–1 and 31–5).[5] Similarly, dysregulated accumulation and activation of platelets resulting from disruption at one or more molecular control points are central mechanisms in acute and subacute vascular injury.[5,144] These pathologic mechanisms are features of sepsis,[74] ischemia-reperfusion injury,[145,146] and other syndromes of vascular damage.

GENE EXPRESSION BY ACTIVATED ENDOTHELIAL CELLS: MECHANISTIC DIVERSITY

When appropriately stimulated, endothelial cells express or alter the expression of multiple genes. As with other responses outlined in this chapter, this was not predicted by earlier interpretations of endothelial cells as passive lining cells.[1] Patterns of transcript expression by endothelial cells may be markers of particular phenotypes in disease, such as neoplasia.[147]

Mechanisms of gene regulation in endothelial cells illustrate considerable diversity. Depending on the stimulus and time after activation, phenotypes of activated endothelial cells reflect transcriptional induction of new gene programs,[4,148–151] including genes controlled by transcription factors of the NF-κB and AP-1 families.[53,152–156] *Transcriptional regulation* is critical for new expression of E-selectin and certain other adhesion molecules by activated endothelial cells[153] and for altered expression of COX-2, chemokines, degranulating factors, and a variety of other endothelial cell gene products that are synthesized in response to injury or infection and in repair.[4,53,54,60–64,76,84,150]

In addition to transcriptional regulation, there is emerging evidence that endothelial cells have diverse *post-transcriptional mechanisms*, although these are largely uncharacterized. Individual examples that together indicate that post-transcriptional control is a key fact of gene expression in endothelial cells include shear-induced stabilization of granulocyte-macrophage colony-stimulating factor and COX-2 mRNAs,[97,128] differential expression of endothelial cell protein C receptor mRNA and protein in response to LPS,[140] and attenuation of the amount of E-selectin mRNA present in the actively translated polyribosome-associated fraction of transcripts when shear is applied to TNF-stimulated monolayers.[157] Post-transcriptional regulation provides important biologic advantages in gene regulation, including precise modulation of levels of specific proteins when acting in concert with transcriptional control.[158,159] Thus, cells with the complex functions subserved by endothelial cells would be expected to use these mechanisms.

Translational control, including signal-dependent translation of constitutive mRNAs,[5,68] is an important facet of

post-transcriptional regulation.[160] Rapid synthesis of the corresponding protein without a requirement for transcription or nuclear export of the message is one advantage of signal-dependent translation of specific transcripts that are present in the basal state.[5,68] Translational control mechanisms in stimulated endothelial cells and their phenotypic consequences are now being characterized.[102,157,161–165] Human endothelial cells have p70S6 kinase and other key components of the mammalian target of rapamycin specialized translation control pathway[163,164] and use this mechanism to regulate expression of the NF-κB family member Bcl-3 in endothelial cell monolayers subjected to shear.[164] Rapamycin, an immunosuppressant and antiangiogenic agent, inhibits Bcl-3 translation under these conditions.[164] Tumstatin, an endothelial cell–specific inhibitor of protein synthesis, inhibits mammalian target of rapamycin and angiogenesis by an integrin signaling mechanism.[165] In addition, preliminary analysis of the "translational state" of multiple mRNA transcripts in activated endothelial cells indicates differential effects by specific inflammatory and thrombotic agonists and that multiple translational control mechanisms may be used.[166] Our preliminary studies also indicate that human endothelial cells have a portfolio of RNA binding proteins and other key regulatory components in post-transcriptional regulatory and translational control pathways (M. Martinez, A. S. Weyrich, G. A. Zimmerman, unpublished studies).

ENDOTHELIAL RESPONSES IN DISEASE

As outlined throughout this chapter, changes in endothelial phenotype and function are central mechanisms in acute and subacute responses to disease, including syndromes of critical illness that are considered in detail elsewhere in this text. Endothelial cell responses in sepsis (see Figs. 31–1 and 31–5) are particularly profound and illustrative examples. Endothelial alterations in septic syndromes have recently been reviewed.[74,77,78,130,137,140] Dysregulated endothelial mechanisms are also central to systemic manifestations in ARDS, to multiple organ failure, and to localized and systemic ischemia-reperfusion syndromes, including traumatic and hemorrhagic shock and resuscitation.[10,145,146,167,168] There is evidence for quantitative and qualitative differences in endothelial responses in trauma and hemorrhagic shock compared with sepsis.[169–174] Patterns of endothelial phenotype that result from the superimposition of sepsis, trauma, ARDS, or other acute critical illnesses on the substrate of chronic endothelial dysfunction in atherosclerosis, diabetes, and other diseases of vascular dysfunction or chronic inflammation[1,175] remain to be precisely described and mechanistically characterized.

ACKNOWLEDGMENTS

We thank our colleagues and collaborators at the University of Utah and elsewhere for contributions to work cited. Mary Madsen and Michele Czerwinski prepared the manuscript, and Diana Lim drafted the figures. This contribution was supported in part by National Heart, Lung, and Blood Institute (NHLBI) awards HLO4151 (LWK) and HL44525 (GAZ), an NHLBI SCOR in ARDS (SMP, GAZ), a Lifeline Foundation Faculty Award (LWK), and the University of Utah Fellowship-to-Faculty transition program (LWK), which is funded by a Biomedical Support Grant to Medical Schools from the Howard Hughes Medical Institute.

The concept of endothelial cell activation and its relationship to endothelial injury are discussed, particularly with respect to acute lung injury syndromes. Endothelial gene expression and rapid responses that do not require changes in gene expression are outlined.

Chapter 32
LUNG EPITHELIAL FUNCTION

Michael A. Matthay

KEY POINTS

1. The **pulmonary epithelium is morphologically diverse** from the airway epithelium to the alveolar epithelium to subserve the specific functions required at each level of the lung epithelium.
2. The **alveolar epithelium provides a tight barrier** to the passive movement of solutes and protein to keep the airspaces dry so that they can carry out the main function of the lung: to excrete carbon dioxide and absorb oxygen.
3. The **alveolar epithelium contains sodium and chloride ion channels** that are responsible for the vectorial transport of alveolar fluid from the airspaces to the lung interstitium.
4. The **active ion transporting capacity of the alveolar epithelium** is responsible for the resolution of alveolar edema.
5. The **process of alveolar fluid reabsorption** can be up-regulated by cyclic adenosine monophosphate agonists.

This chapter first considers the morphologic characteristics of the proximal, distal, and alveolar epithelium, with particular reference to the pathophysiology of acute critical illnesses. The next section considers the abnormalities of the airway epithelium in acute and chronic obstructive lung diseases and how these may contribute to acute respiratory failure in critically ill patients. The final section focuses on the role of the alveolar epithelium in lung fluid balance in patients with pulmonary edema.

MORPHOLOGY OF THE PULMONARY EPITHELIUM

There are major differences in the morphologic features of the pulmonary epithelium from the proximal airway epithelium to the alveolar epithelium. Some of these differences and their relationship to the regional function of the lung epithelium are considered here.

AIRWAY EPITHELIUM

Overall, the conducting airways form the connection between the outside world and the terminal respiratory units where gas exchange occurs. There are three major groups of intrapulmonary airways: bronchi, membranous bronchioles and respiratory bronchioles, and gas exchange ducts. Bronchi, by definition, have cartilage in their walls. Respiratory bronchi serve a dual function—as conducting airways and as part of the alveolar volume for gas exchange.[1] Overall, the conducting airways occupy the first 16 generations of airways, but ultimately they end blindly in the alveoli. Gas exchange occurs primarily in the branches that make up the last seven generations, including the respiratory bronchioles, alveolar ducts, alveolar sacs, and alveoli (Fig. 32–1). The distal airway epithelium is composed of terminal respiratory bronchial units with polarized epithelial cells that have the capacity to transport sodium and chloride, including ciliated Clara cells and nonciliated cuboidal cells.

In reference to the pathophysiology of acute and chronic obstructive airway disease, it should be emphasized that most airway resistance resides in the upper airways in the bronchi. There are glands in the submucosa in the bronchi that secrete water, electrolytes, and mucins into the lumen. Studies of the regulation of secretion in vivo and by explant cultural systems in vitro have demonstrated that release can be modulated by neurotransmitters, including cholinergic, adrenergic, and inflammatory mediators. Goblet cells, which are mucin-secreting epithelial cells, are present at most airway levels (Fig. 32–2). Several other cells are associated with the airways, including basal cells, lymphocytes, smooth muscle cells, and mast cells. Lymphocytes are frequently found between airway epithelial cells. There are also circular bands of smooth muscle around the airway epithelium as far peripherally as the respiratory bronchioles. The tone in the smooth muscles is altered by the autonomic nervous system and by local mediators released from a variety of cells. Abnormalities of several of these structural and cellular components contribute to the pathophysiology of acute and chronic obstructive lung disease.[1]

ALVEOLAR EPITHELIUM

The alveoli are composed of a thin alveolar epithelium (0.1 to 0.2 μm) that covers 99% of the airspace surface area in the lung and contains thin, squamous type I cells and cuboidal type II cells (Fig. 32–3). Alveolar type I cells cover 95% of the alveolar surface.[1,2] The close apposition between the alveolar epithelium and the vascular endothelium facilitates the efficient exchange of gases, but it also forms a tight barrier to the movement of liquids and proteins from the interstitial and vascular spaces, thus assisting in maintaining relatively dry alveoli.

At the alveolar level, the tight junctions that bind the alveolar epithelium are critical for maintaining apical and

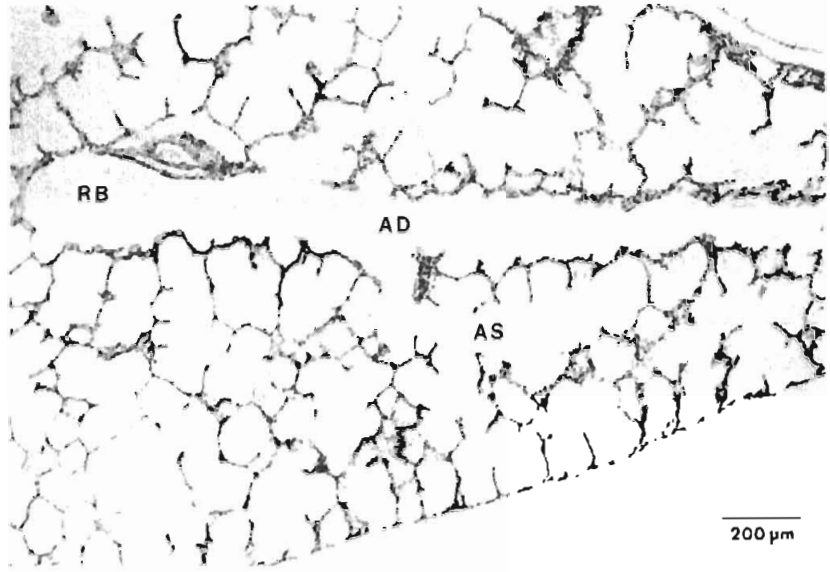

FIGURE 32–1. Longitudinal section of a gas exchange duct showing that its diameter remains relatively constant along the respiratory bronchiole (RB) and alveolar duct (AD). Alveolar sacs (AS) communicate with the gas exchange duct. (Human surgical specimen, 10-µm-thick paraffin section, light microscopy.) (From Albertine KH, Williams MC, Hyde DM: Anatomy of the lungs. In Murray JF, Nadel JA [eds]: Textbook of Respiratory Medicine, vol 1 Philadelphia, WB Saunders, 2000, pp 3-33.)

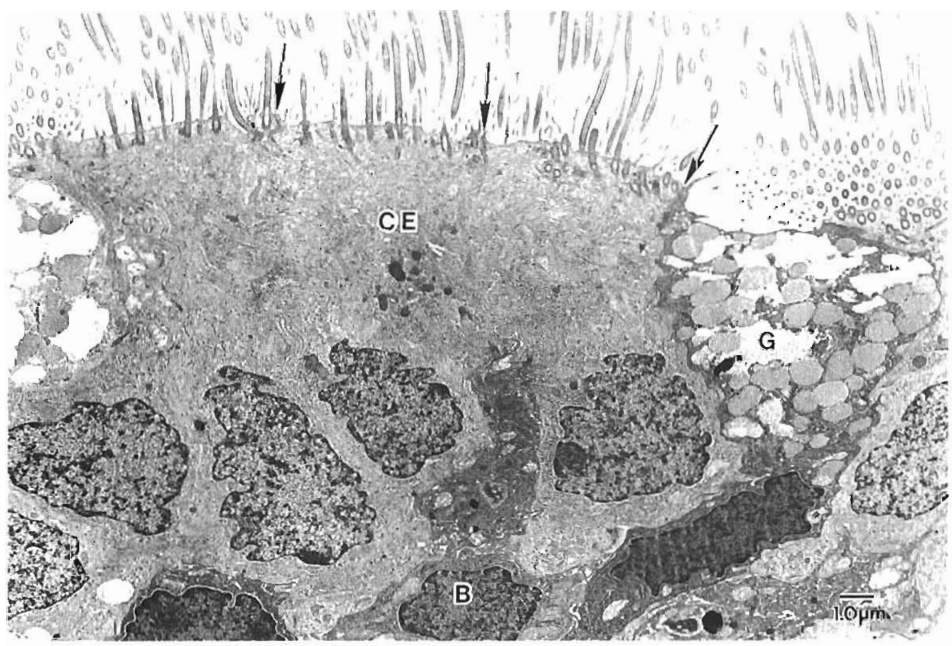

FIGURE 32–2. Cells comprising the bronchial epithelium are ciliated epithelial cells (CE), goblet cells (G), and basal cells (B). Goblet cells have abundant mucous granules in the cytoplasm, and their apical surface is devoid of cilia. Basal cells, as their name indicates, are located along the abluminal portion of the lining epithelium, adjacent to the basal lamina. The arrows at the apical surface of the airway cells indicate the location of junctional complexes between contiguous epithelial cells. (Human lung surgical specimen, transmission electron microscopy.) (From Albertine KH, Williams MC, Hyde DM: Anatomy of the lungs. In Murray JF, Nadel JA [eds]: Textbook of Respiratory Medicine, vol 1. Philadelphia, WB Saunders, 2000, pp 3-33.)

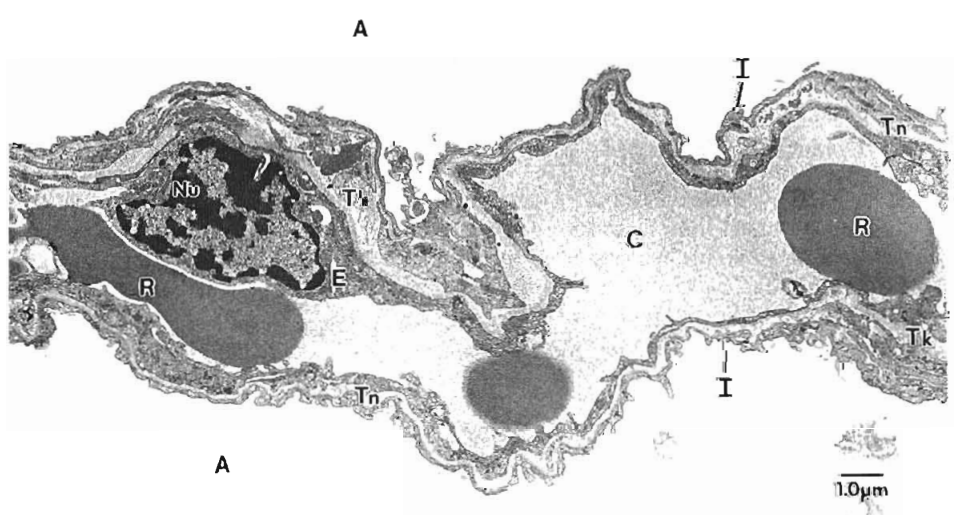

FIGURE 32–3. The thick (Tk) and thin (Tn) sides of an alveolar capillary (C) change as the capillary courses between alveoli (A). The basal laminae of the capillary endothelium and alveolar epithelium fuse in the thin regions. The nucleus (Nu) of an endothelial cell (E) is visible above a red blood cell (R). I, type I pneumonocyte. (Human lung surgical specimen, transmission electron microscopy.) (From Albertine KH, Williams MC, Hyde DM: Anatomy of the lungs. In Murray JF, Nadel JA [eds]: Textbook of Respiratory Medicine, vol 1. Philadelphia, WB Saunders, 2000, pp 3-33.)

basolateral polarity. Ion transporters and other membrane proteins are asymmetrically distributed on opposing cell surfaces, conferring vectorial transport properties to the alveolar epithelium. Based on a variety of physiologic studies, the distal alveolar epithelium is much tighter than the capillary endothelium, with an effective pore radius of 0.5 to 0.9 nm, versus 6.5 to 7.5 nm.[2]

The most extensively studied cell in the distal pulmonary epithelium is the alveolar type II cell (Fig. 32–4*A*), partly because it can be readily isolated from the lung and studied in vitro.[2-4] The alveolar type II cell is responsible for the secretion of surfactant, as well as for the vectorial transport of sodium and chloride from the apical to the basolateral surface. When the lung is injured, type II cells proliferate to provide a new alveolar epithelial barrier (see Fig. 32–4*B*). After the repair process is complete, the alveolar epithelium returns to its more normal appearance (see Fig. 32–4*C*). The active vectorial transport of ions by alveolar epithelial type II cells provides a major driving force for the removal of fluid from the alveolar space. Sodium uptake occurs on the apical surface, partly through amiloride-sensitive and amiloride-insensitive channels. Subsequently, Na^+, K^+-ATPase pumps sodium actively from the basolateral surface into the lung interstitium.[4] The epithelial sodium channel (ENaC), cloned in 1994, participates in sodium movement across the membrane. There is new evidence that cystic fibrosis transmembrane conductance regulator (CFTR), the product of the cystic fibrosis gene, plays an important role in cyclic adenosine monophosphate (cAMP) up-regulated fluid transport across alveolar type II cells and the alveolar epithelium in vivo.[5] The role of the alveolar type I cell and vectorial fluid transport in the lung is less certain, although some investigators recently found that type I cells express sodium channels.[6,7] Type I cells also express aquaporin-5 on the apical surface, although vectorial fluid transport does not seem to depend on the function of this water channel.[3]

AIRWAY EPITHELIUM IN ACUTE AND CHRONIC LUNG DISEASE

The contribution of abnormalities in the proximal and distal airway epithelium to several acute and chronic lung diseases has been explored in depth in recent years. This section focuses on abnormalities of pulmonary epithelium that occur in asthma, chronic obstructive pulmonary disease (COPD), and cystic fibrosis.

ASTHMA

Asthma is a disease of the airways characterized by airway narrowing with spontaneous and pharmacologic reversibility.[1] In patients who die of acute asthma, it is recognized that the airways are edematous and the blood vessels congested, and there are usually cellular infiltrates, including neutrophils and eosinophils. Mucous plugs frequently fill the peripheral airways, and there is desquamation of epithelial cells. In patients with asthma, there is evidence of abnormalities in airway cell growth and differentiation that are similar to those of chronic inflammatory diseases such as chronic bronchitis and cystic fibrosis. These abnormalities include metaplasia of the lining epithelium from ciliated cells to squamous and goblet cells. The basement membrane is often thickened. Anatomic studies of surviving patients with asthma also demonstrate some inflammatory changes, including epithelial cell desquamation, squamous cell transformation, and neutrophil infiltration, as well as an increase in goblet cells.[1] It has generally been assumed that the airway epithelium exists as an interface between the body and the external environment; therefore, the airway epithelium must

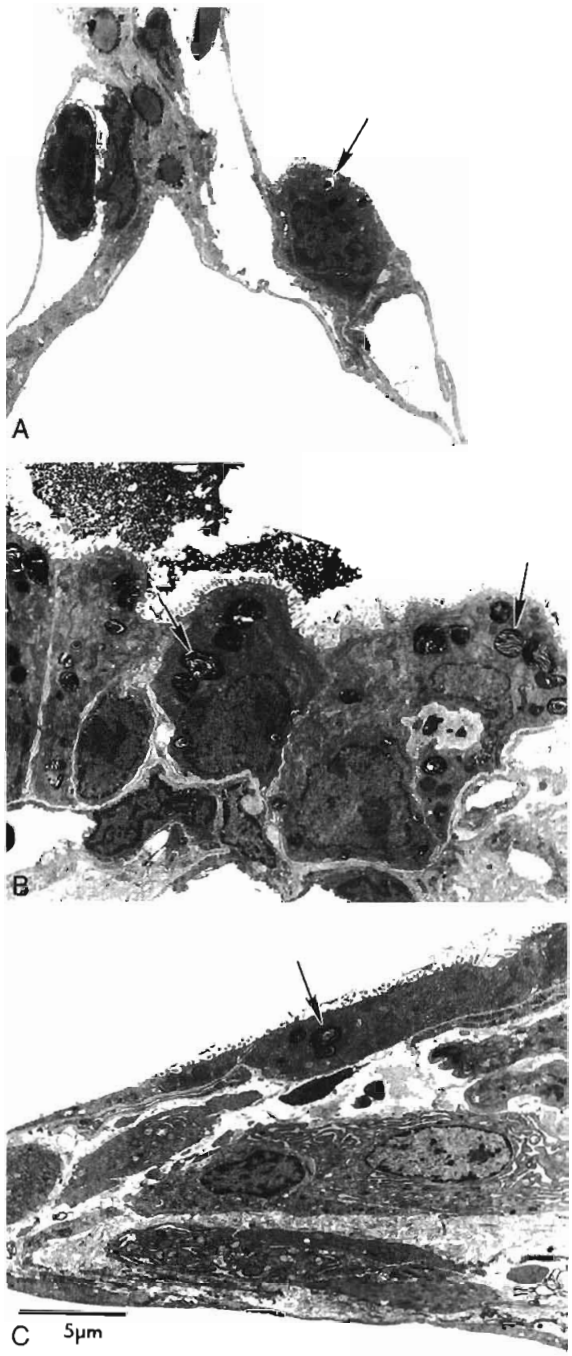

FIGURE 32–4. Ultrastructural appearance of normal rat lungs and rat lungs after the intratracheal instillation of bleomycin. *A*, Control lung (saline instilled). *B*, Ten days after instillation of bleomycin. *C*, Sixty days after instillation of bleomycin. Compared with the appearance of normal alveolar epithelial type II cells *(A, arrow)*, bleomycin-exposed alveolar type II cells *(B, arrow)* have more microvilli and larger lamellar bodies; these type II cells are hyperplastic and hypertrophied, apparently as a response to the bleomycin injury. Type II cell proliferation is the first stage of repair after injury has caused the death of type I cells, the thin cells that line most of the alveolar surface (see *A*). *C* shows recovery toward a more normal alveolar epithelial type II cell, which is flatter. (From Folkesson HG, et al: Upregulation of alveolar epithelial fluid transport after subacute lung injury in rats from bleomycin. Am J Physiol Lung Cell Mol Physiol 1998;275:L478-L490.)

have mechanisms to protect the internal environment from damaging organisms and irritants. The response of these cells has been studied in more detail recently, and their contribution to clinical asthma is still being worked out, but clearly there are specific abnormalities in the airway epithelium in patients with asthma. There is considerable evidence regarding the role of inflammation and coagulation-dependent mechanisms in the pathogenesis of asthma.[8,9]

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

The primary etiologic factor in the development of COPD is cigarette smoking. There is, however, individual variation in susceptibility. The mechanisms by which cigarette smoke causes emphysema, chronic bronchitis, and COPD are incompletely understood. In chronic bronchitis, there are inflammatory changes in airway epithelium. Ciliated epithelial cells undergo squamous metaplasia, and there is goblet cell proliferation, along with an increase in the volume of smooth muscle and glands. In emphysema, there is a loss of alveoli, resulting in what is commonly known as panlobular emphysema. Loss of alveoli and distal airspaces is a characteristic feature of emphysema resulting in ventilation and perfusion mismatch.[1] Recent evidence indicates that progression of COPD is associated with the accumulation of inflammatory mucous exudates in the lumen of small airways and infiltration of the airway walls with innate and adaptive immune cells that form lymphoid follicles.[10]

CYSTIC FIBROSIS

Cystic fibrosis is a genetic disorder transmitted as an autosomal recessive trait. In brief, the airway epithelium shows progressive evidence of inflammation, gland and goblet cell hypertrophy, and obstruction by secretions. The relationship between the genetic defect in cystic fibrosis and the actual clinical disease is not well understood. The abnormality in cystic fibrosis involves a failure to correctly encode CFTR, the integral protein of epithelial cells. This protein is a chloride channel that must have several other important effects, because abnormalities in transport do not explain all the abnormalities in patients with cystic fibrosis. CFTR is expressed in airway epithelium, although recent work indicates that it is also expressed highly in alveolar epithelium and has an important role in vectorial fluid transport (see next section). The mechanism by which pulmonary epithelium and airways are damaged in cystic fibrosis has been the subject of intense study. Abnormalities in ion transport, the airway surface liquid, and various innate immune responses to infection have all been implicated.[11]

ALVEOLAR EPITHELIUM

This section considers the role of the alveolar epithelial barrier in preventing alveolar flooding, as well as the role of the alveolar epithelium in resolving alveolar edema. On balance, considerable progress has been made in the last 2 decades in understanding the role of the alveolar epithelium in regulating lung fluid balance under normal and pathologic conditions.

FORMATION OF ALVEOLAR EDEMA

As described earlier, the alveolar epithelial barrier is a typical tight epithelium that resists the passive movement of macromolecules and even small solutes. This tight barrier facilitates the primary function of the alveolar epithelium—mainly, to maintain dry airspaces that can facilitate gas exchange. The epithelial barrier is also responsible for the secretion of surface-active material by alveolar epithelial type II cells.

Under normal conditions, the tight epithelial barrier prevents alveolar flooding, even in the presence of mild or moderate interstitial pulmonary edema. Several studies have demonstrated that the interstitial space of the lung can accommodate up to 500 mL of edema fluid before alveolar flooding occurs.[1] Therefore, patients may develop hydrostatic or increased permeability edema with interstitial pulmonary edema without flooding of the airspaces. From a radiographic perspective, this can be appreciated with radiographic signs of interstitial pulmonary edema and Kerley's B lines. In the presence of interstitial edema in the lung, gas exchange is minimally impaired. Once alveolar flooding occurs, pulmonary edema is associated with progressive arterial hypoxemia. The mechanisms of alveolar flooding are related primarily to a progressive rise in interstitial pressure that results in a breakdown of the epithelial barrier. The exact site of airspace flooding may be proximal to the alveolus under conditions of hydrostatic edema. In patients with acute lung injury, there may be injury to alveolar epithelial cells that facilitates the translocation of interstitial edema fluid into the distal airspaces of the lung. The active ion transport properties of the alveolar epithelium—specifically, the ability to transport fluid from the apical to the basal surface of distal lung epithelium—also helps prevent or minimize alveolar flooding. Once alveolar flooding does occur, active vectorial ion transport mechanisms are responsible for the removal of edema fluid from the distal airspaces of the lung (see next section).

RESOLUTION OF ALVEOLAR EDEMA

The distal airway and alveolar epithelium have ion transporters with the capacity to actively transport sodium and chloride, resulting in a mini-osmotic gradient that reabsorbs the water fraction of the edema fluid (Fig. 32–5). The first in vivo evidence that active ion transport in the mature lung accounted for the removal of alveolar edema fluid was obtained in studies of anesthetized, ventilated sheep.[12] In those studies, the critical discovery was that isosmolar fluid clearance of salt and water occurred in the face of a rising concentration of protein in the distal airspaces of the lung. The initial protein concentration of the instilled protein solution was the same as that of the circulating plasma. After 4 hours, the concentration of the protein increased from 6.5 to 8.4 g/100 mL, while the plasma protein concentration was unchanged. In longer-term studies in anesthetized, spontaneously breathing sheep, alveolar protein concentrations increased to even higher levels. After 12 and 24 hours, the alveolar protein concentration increased to 10.2 and 12.9 g/100 mL, respectively.[13] These data provided evidence that active ion transport must be responsible for the fluid clearance in the mature lung, especially in the face of a rising alveolar protein osmotic pressure. Additional studies in the intact lung supported the hypothesis that removal of alveolar

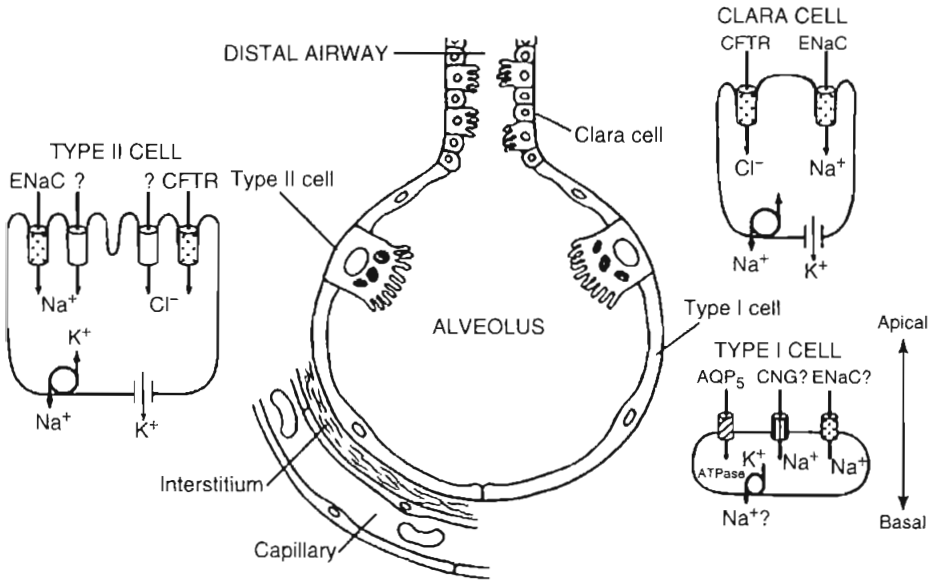

FIGURE 32–5. Schematic diagram of the distal pulmonary epithelium that is relevant for salt and water transport. AQP, aquaporin; CFTR, cystic fibrosis transmembrane conductance regulator; ENaC, epithelial sodium channel. (From Matthay MA: Lung epithelial fluid transport and the resolution of pulmonary edema. Physiol Rev 2002;82:569-600.)

fluid requires active transport processes. For example, elimination of ventilation to one lung did not alter the rate of fluid clearance in sheep, thus ruling out changes in transpulmonary airway pressure as a major determinant of fluid clearance, at least in the uninjured lung. Further, if active ion transport were responsible for fluid clearance, then fluid clearance should be temperature dependent. Studies in an in situ perfused goat lung preparation showed that the rate of fluid clearance progressively declined as temperature was lowered from 37° C to 18° C.[3] Additional evidence for active ion transport was obtained in intact animals with the use of amiloride, an inhibitor of sodium uptake by the apical membrane of alveolar epithelium and distal airway epithelium. Amiloride inhibited 40% to 70% of basal fluid clearance in most species, including the human lung. Studies were also done that used ouabain to inhibit Na^+, K^+-ATPase. The results showed that ouabain inhibited 90% of fluid clearance in isolated lung preparations.[2]

Interestingly, an early discovery from intact adult animal studies, as well as from earlier studies of fetal sheep, demonstrated that the rate of alveolar fluid clearance could be up-regulated by cAMP agonists.[3] Some species do not increase their fluid clearance with cAMP agonist therapy, but the majority of species double the rate of alveolar fluid clearance with beta-adrenergics, including the human lung.[2,3]

Several catecholamine-dependent mechanisms have the capacity to up-regulate alveolar fluid transport.[3] Both exogenous and endogenous catecholamine release can substantially up-regulate fluid clearance. For example, in the presence of hypovolemic or septic shock, the rapid rise in plasma catecholamines is sufficient to enhance alveolar epithelial fluid transport, thus preventing or limiting the formation of alveolar edema. In addition, several studies have demonstrated that aerosolized adrenergic therapy can increase the rate of fluid clearance in hydrostatic or increased permeability edema in a variety of experimental preparations.[2,3] From a clinical perspective, it is possible that administration of an aerosolized $beta_2$ agonist might be effective in up-regulating alveolar fluid transport and enhancing the resolution of pulmonary edema in patients. Clinical trials are needed to test this possibility.

There are several catecholamine-independent factors that can regulate fluid clearance as well. For example, hormonal factors, such as glucocorticoids, can up-regulate transport by transcriptional mechanisms, and thyroid hormone may work by a post-translational mechanism. Some growth factors can work by either transcriptional or direct membrane effects, or by enhancing the number of alveolar epithelial type II cells. There is also evidence that a proinflammatory cytokine, tumor necrosis factor, can up-regulate sodium uptake and fluid transport by novel mechanisms.[3]

Recent research has identified mechanisms that can impair vectorial alveolar fluid transport under pathologic conditions. For example, the halogenated anesthetics can decrease fluid clearance by inhibition of the amiloride-sensitive component. The effect is rapidly reversible after exposure to the inhaled anesthetic; the effect can also be overcome through the administration of a $beta_2$ agonist.[2] Lidocaine has been recognized as another anesthetic that can decrease alveolar fluid clearance, whether instilled directly into the lung or given intravenously in clinically relevant concentrations.[3] There is a growing body of literature demonstrating that alveolar hypoxia decreases alveolar fluid clearance by approximately 50% in the normal lung. The effect of hypoxia appears to be primarily at the membrane level, resulting in a decreased availability of ion transporters at both the apical and the basolateral membranes. Interestingly, $beta_2$ agonists can also overcome the depressant effects of hypoxia.[14]

Overall, several new insights have been obtained regarding the role of alveolar epithelium in regulating lung fluid balance. The resolution of alveolar edema depends on an intact alveolar epithelium that can transport sodium and chloride, creating an osmotic gradient for the reabsorption of water from the distal airspaces of the lung. In clinical studies, the resolution of alveolar edema is rapid in patients with resolving hydrostatic edema. In the presence of acute lung injury, there is considerable heterogeneity in the capacity of the alveolar epithelium to reabsorb pulmonary edema fluid. Patients with impaired alveolar fluid transport have a worse clinical course and a higher mortality, suggesting that alveolar epithelial injury is a major determinant of outcome

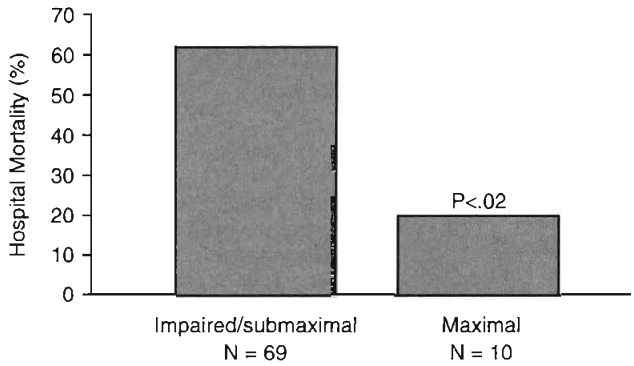

FIGURE 32–6. Hospital mortality (*y*-axis) plotted against two groups of patients with acute lung injury or acute respiratory distress syndrome—those with maximal fluid clearance (>14%/h), and those with impaired or submaximal fluid clearance (<14%/h). The columns represent present hospital mortality in each group (N = number of patients). Hospital mortality of patients with maximal fluid clearance was significantly less ($P < 0.02$). (From Ware LB, Matthay MA: Alveolar fluid clearance is impaired in the majority of patients with acute lung injury and the acute respiratory distress syndrome. Am J Respir Crit Care Med 2001;163:1376-1383.)

in patients with acute lung injury (Fig. 32–6).[15] Conceivably, the rate of alveolar fluid transport could be up-regulated in patients with acute lung injury by the administration of aerosolized beta$_2$-adrenergic agonists, but this hypothesis requires a clinical trial to test its efficacy.

This clinical study found that alveolar fluid clearance is impaired in most patients with acute lung injury and that impaired fluid clearance is associated with a higher mortality.

Chapter 33

LYMPHOCYTE FUNCTION AFTER INJURY

John A. Mannick • James A. Lederer

KEY POINTS

1. The initial immune response to serious injury is one of inflammation.
2. Multiple organ dysfunction syndrome is clearly recognized as a major cause of mortality after serious injury and is associated with perturbations of both innate and adaptive immunity.
3. The pivotal cell in the adaptive immune system is the T-helper lymphocyte, which through cytokine production and cognate interaction sets in motion both antigen-specific cell-mediated immune responses and antibody formation.
4. Serious injury in humans and in experimental animals results in impairment of immune functions mediated by T cells. Impairments include delayed hypersensitivity responses, rejection of skin allografts, and tumor immunity.
5. A variety of agents that increase T-helper-1 function have been shown to be effective in reducing mortality from a septic challenge in various animal models of injury. These agents include IFN-γ, GM-CSF, anti-IL-6 monoclonal antibody, anti-IL-10 antibody, IL-18, and IL-12. Treatments other than cytokines and their inhibitory antibodies have also proven effective, including prolactin, melatonin, cyclooxygenase II inhibitors, and hypertonic saline.
6. Proestrus female animals are less affected immunologically than males after serious injury and a testosterone receptor antagonist can improve T-helper-1 function and resistance to sepsis in injured male animals.

Most investigators now agree that the initial immune response to serious injury is one of inflammation, usually termed the *systemic inflammatory response syndrome* (SIRS).[1-3] In patients or experimental animals with major traumatic or thermal injury, SIRS is evident shortly after initial resuscitation; and in a significant minority of patients (25% to 35%) SIRS persists without respite and may lead directly to the multiple organ dysfunction syndrome (MODS), particularly if infection supervenes.[4] MODS is clearly recognized as a major cause of mortality after serious injury and infection.[1-3] Because cells of the innate immune system are the chief source of inflammatory mediators after injury, and cellular and molecular components of innate immunity are major effectors in the early defense against invading microorganisms, it is not surprising that the majority of research on the immune consequences of injury has focused on the innate immune system.[5-9]

The T and B lymphocytes of the adaptive immune system by contrast ordinarily respond only when activated by antigen-presenting cells of the innate immune system; and although T-cell receptors and antibodies produced by B cells demonstrate remarkable diversity and exquisite precision for individual antigenic epitopes, several days of clonal expansion after initial activation are ordinarily required for a significant adaptive response to become evident.[3] Thus, at first glance, the adaptive immune system appears to be ill suited to play a role in host defense early after injury, although later participation might be anticipated. And, in fact, in the majority of injured patients the SIRS response remits after several days without progression to early MODS[4] but the patient is often left with an increased susceptibility to nosocomial infection, which is associated with production of anti-inflammatory mediators by the adaptive immune system, referred to as the compensatory anti-inflammatory response syndrome (CARS).[4,10,11] Invasive infection occurring during this period of adaptive immune depression may again induce systemic inflammation, which in turn may lead to late MODS.[4]

DECREASED T-LYMPHOCYTE FUNCTION AFTER INJURY—HISTORICAL EVIDENCE

The pivotal cell in the adaptive immune system is the T-helper lymphocyte, which through cytokine production and cognate interaction sets in motion both antigen-specific cell-mediated immune responses and antibody formation.[3] For more than 3 decades it has been evident that serious injury in humans and in experimental animals resulted in impairment of immune functions mediated by T cells. These include delayed hypersensitivity responses, rejection of skin allografts, and tumor immunity.[12-16] Moreover, a number of reports indicated that the proliferative response to T-cell mitogens by peripheral blood mononuclear cells (PBMCs) was significantly impaired in patients after traumatic or thermal injury.[17,18] These early reports were followed by studies demonstrating that diminished T-cell mitogen–induced proliferation by PBMCs was associated with decreased production of interleukin (IL)-2 and interferon-gamma (IFN-γ) by the same cells.[19,20] Decreased production of these cytokines appeared to be associated with subsequent infectious complications although a causal relationship was not established.[19,20]

T-LYMPHOCYTE PHENOTYPE CHANGES IN INJURED PATIENTS

Following the report by Mosmann and coworkers[21] that mature T-helper cells expressed at least two phenotypes, it became clear that serious injury induced decreased production of cytokines typical of T-helper-1 (Th1) cells (e.g., IL-2 and IFN-γ). It was not certain whether this represented a generalized depression of T-helper cell function or whether the synthesis of T-helper-2 (Th2) cytokines was maintained or even increased after injury. Several groups including our own studied this question in injured patients and found that the production of the Th2 cytokine IL-4 was increased several days after injury, as revealed by mitogen stimulation of circulating T cells and by direct measurement of plasma cytokines.[22,23] Our laboratory and Sherry and colleagues[24,25] reported similar findings for IL-10, although there is at least one clinical study reporting no increase in IL-10 production after injury.[26] From these studies it appeared likely that Th1 cytokine production was inhibited after injury whereas Th2 cytokine production was maintained or perhaps increased. The vigorous IL-4 production noted several days after injury offered an explanation for the previously puzzling observation that injured patients frequently had elevated levels of immunoglobulin E (IgE) in their plasma,[27] because IL-4 is the principal inducer of this immunoglobulin isotype.

ANIMAL MODELS RELEVANT TO INJURED PATIENTS

To study these and other aspects of the immune response to injury more systematically, many investigators have turned to animal models of injury and sepsis. The clinical relevance of this animal research obviously depends on how closely the animal model(s) resemble populations of injured patients. Models that appear to mimic clinical injury include full-thickness burn models (of 25% to 60% body surface area) in mice and rats, models of hemorrhage and soft tissue trauma, and models of hemorrhage and skeletal trauma in the same species. Appropriate septic challenges used in these models include direct burn wound contamination with pathogenic bacteria, intratracheal administration of pathogenic organisms, and cecal ligation and puncture (CLP), which induces a localized peritonitis with mixed gut flora. These models have allowed a number of groups of investigators to confirm and expand observations made in seriously injured patients. Rodents, especially mice, are also available with multiple genetic modifications, which allow clear-cut answers to questions concerning the importance of specific cell types or mediators in the phenomena observed.

EVIDENCE THAT NORMAL RESISTANCE TO INFECTION REQUIRES A FUNCTIONAL ADAPTIVE IMMUNE SYSTEM

For example, by using the recombinase activating gene (Rag)–deficient mouse (which lacks an adaptive immune system) Hotchkiss and coworkers[28] were able to demonstrate convincingly that adaptive immunity, more specifically adaptively transferred, syngeneic T cells are essential for survival after CLP. In these experiments the T cells were genetically altered to overexpress the antiapoptotic protein Bcl-2, thus ensuring their protracted survival in the Rag hosts. Similar experiments in our own laboratory have shown that the administration of wild-type splenocytes to the Rag animals will reconstitute T cells and B cells in the spleen and lymph nodes and will restore normal resistance to CLP.[29] Reconstitution of adaptive immune cells also reduces the excessive production of proinflammatory cytokines noted after burn injury in unmodified Rag animals.[29] The cell type responsible for the latter effect appears to be the $CD4^+$ T-helper cell and, more specifically, the $CD25^+$ $CD4^+$ T-helper cell now known to have immunoregulatory properties in a variety of experimental systems.[30]

By using animal models it was also possible, beginning nearly 15 years ago, to confirm the clinical impression that serious injury induces lowered resistance to infection at predictable time points. For example, Moss and associates[31] from our laboratory showed that in a mouse burn model mortality versus sham burn animals after CLP was similar early after injury (15% to 20%) but that there was a nearly 80% mortality at 10 days in the burn mice, which then gradually returned to control (sham burn) levels over the ensuing 10 to 15 days. Similar time dependent susceptibility to infectious challenge has also been noted in animal models of hemorrhage and trauma by Ayala and Chaudry and their coworkers[32] and by Strong and coworkers.[33]

In several animal models the loss of resistance to an infectious challenge after serious injury was coincident with decreased production of T-helper-1 cytokines and increased production of Th2 cytokines by T cells undergoing polyclonal activation in vitro.[31,32,34-38] On the other hand, in some instances, loss of resistance to infection occurred at a time when cells of the innate immune system were shown to respond with greater than normal production of inflammatory mediators on exposure to molecules associated with pathogenic organisms (e.g., endotoxin or peptidoglycan).[33,39,40] Considered together these results suggest that after serious injury, when adaptive immunity manifests a maximal anti-inflammatory response associated with decreased resistance to infection, the innate immune system is capable of supranormal and possibly destructive proinflammatory mediator production when it encounters products of the microorganisms that might be expected to be present in a supervening infection. In other words, sepsis that follows CARS in seriously injured patients may induce an exaggerated and destructive SIRS response; thus, SIRS and CARS may coexist. These findings also may begin to provide a cellular and molecular explanation for the "second hit" phenomenon,[1,4,41] which has been defined by several investigators as an exaggerated inflammatory response to a second stressful event occurring several hours to several days after an initial injury (first hit). The second-hit phenomenon is believed by many clinicians to play a significant role in the induction of MODS in a sizeable number of patients.[1,4,41]

ALTERED T-HELPER CELL PHENOTYPE AFTER INJURY, IN VIVO EFFECTS, AND POSSIBLE MECHANISMS

Thus, animal studies in the aggregate demonstrate that serious injury, both thermal and traumatic, is followed in several days by loss of Th1 function and production of cytokines stimulatory of host defenses (i.e., IL-2 and IFN-γ), whereas there is normal or increased production of Th2 cytokines, which can be inhibitory of innate and adaptive immune responses.

Using the mouse burn model, we[42] also explored the question of whether loss of Th1 cytokine production in vitro by lymphocytes from injured animals was accompanied by a loss of Th1 function in vivo as indicated by production of Th1-dependent antibody isotypes. These studies showed that when mice were immunized with a conventional antigen at the time of injury, Th1-dependent IgG2a production by B cells was markedly inhibited at 10 days while production of the Th2-dependent isotypes IgG1 and IgE was unaffected. At the same time burn but not sham-burn animals demonstrated loss of antigen specific T-cell proliferation and marked diminution in antigen specific IL-2 and IFN-γ production.

To define some of the molecular mechanisms involved in the diminished Th1 cytokine production after injury we first determined that IL-2 and IFN-γ messenger RNA (mRNA) expression in Th cells were diminished after burn as compared with sham-burn injury in the mouse whereas IL-4 mRNA was increased.[43] We further showed that decreased IL-2 mRNA expression was associated with markedly lower expression of the transcription factors activator protein-1 (AP-1) and nuclear factor-kappa B (NF-κB) heterodimer, but not nuclear factor of activated T cells (NFAT), in the nuclei of Th cells from burn versus sham-burn animals.[44] AP-1 and NF-κB are known to be essential for IL-2 gene transcription. Similar, but not identical findings have been reported by Choudhry and colleagues[45] in a rat burn model.

An important question remaining is whether the diminished production of protective Th1 cytokines several days after injury is a compensatory reaction to stimulation of Th cells early after injury or whether it simply represents a response to down-regulatory signals from the innate immune system. Monocytes/macrophages of the innate immune system are known to express lower levels of antigen-presenting major histocompatibility complex class II molecules by several days after injury[46] and to be primed for increased production of potentially inhibitory mediators, including prostaglandin E_2 (PGE_2),[6,47-49] transforming growth factor-beta (TGF-β),[50] and perhaps IL-10.[51] At the same time these cells have diminished capacity to produce IL-12, the cytokine ordinarily required for induction of the Th1 phenotype.[49,51]

To shed further light on this issue, we have explored the possibility that T cells early after injury may be activated to make a vigorous Th1-type response. We[52] initially used two strains of T-cell–receptor transgenic mice for this purpose. Seventy-five percent of the Th cells in these animals respond only to a specific peptide antigen, which they would not be expected to encounter at the time of injury. In these animals it was found that the Th cells responded to the cognate antigen in vitro with increased rather than decreased IFN-γ production for as long as 7 days after injury when compared with sham-burn controls. The injection of the relevant antigen in vivo at the time of injury produced death in 100% of the burn animals and in none of the sham animals. These studies suggested that burn injury initially induced a state of increased and potentially harmful Th1 activity in these two transgenic strains.

To confirm these findings in wild-type animals, we turned to a bacterial superantigen, staphylococcal enterotoxin B (SEB), which activates approximately 20% of the Th cell population expressing the Vβ chain of the T-cell receptor to which the superantigen binds.[53] Thus, immediate evidence of T-cell reactivity could be obtained at the time of injury without the necessity for clonal expansion, which is a prerequisite for a detectable response to a conventional antigen. These studies again showed that superantigen administration at the time of burn injury caused death of burn, but not sham-burn, animals in a dose-dependent manner and that mortality could be prevented by anti–IFN-γ antibody and soluble TNF-α receptor (thus confirming the importance of these cytokines in the fatal response) and by blockade of T-cell co-stimulation through the use of cytotoxic lymphocyte–associated protein-4 bound to immunoglobulin (CTLA4-Ig), which binds to co-stimulatory molecules on antigen presenting cells. Abrogation of mortality by CTLA4-Ig further established that death by superantigen administration at the time of injury was, indeed, a T cell–mediated phenomenon.

The two experiments just described strongly suggested that the loss of Th1 function and cytokine production with the dominance of Th2-type cytokine production, noted at about a week after injury in several human and animal studies described earlier, represented a regulatory response to activation of T cells at the time of serious injury.

This proposition could be tested most easily in the T cell–receptor transgenic mouse model. As noted previously, when burn, but not sham-burn, animals were immunized with cognate antigen at the time of injury, 100% mortality ensued. However, we found that the administration of small amounts of the same cognate antigen at the time of injury permitted survival of the majority of the immunized T cell–transgenic animals. Splenic and lymph node T cells harvested from un-immunized burn animals 7 days after injury produced large quantities of IFN-γ in comparison with sham-burn controls when cultured with the cognate antigen. In contrast, the same cell population harvested at day 7 after injury from immunized burn, but not sham-burn, animals produced large quantities of IL-4 and IL-10 on antigen stimulation in vitro.[54] In wild-type animals there is an early spontaneous proliferation of Th cells but not T cytotoxic or B cells in vivo within the first 12 hours after burn, but not sham-burn, injury. The proliferative response ceases by 24 hours. There is evidence of selective Vβ chain expression by the proliferating T-helper cell population, thus suggesting, but certainly not proving, that endogenous superantigen may be involved in this process.[55]

THERAPEUTIC RESTORATION OF T-HELPER CELL FUNCTION AFTER INJURY

Can restoration of Th1 function restore normal resistance to infection after serious injury? A variety of agents have been shown to be effective in reducing mortality from a septic challenge in various animal models of injury. These include IFN-γ,[56] GM-CSF,[57] anti–IL-6 monoclonal antibody,[58] anti–IL-10 antibody,[59] IL-18,[60] and IL-12.[43,51] Agents other than cytokines and their inhibitory antibodies have also proven effective. These include prolactin,[61] melatonin,[62] cyclooxygenase II inhibitors,[6,33] and hypertonic saline.[63] Of considerable interest recently has been the demonstration that sex differences play a role in the loss of Th1 function after injury.[64-66] Female proestrus mice are far less affected than male mice, and the use of the testosterone receptor antagonist, flutamide, after hemorrhage or trauma/hemorrhage restored Th1 cytokine production and proliferative capacity in injured as compared with sham-injured male mice and also increased survival after CLP.

Among the therapeutic agents mentioned earlier, one which is known to affect Th1 function directly is IL-12, which induces the Th1 phenotype. The administration of low doses of recombinant IL-12 beginning shortly after injury in the mouse model of burn injury in our laboratory reduced mortality from subsequent CLP to that of sham-injured controls.[51] Whereas the effect of IL-12 was dependent on IFN-γ production, the results obtained with IL-12 were superior to those achieved with IFN-γ itself in the same model.[43] IL-12 therapy was similarly shown to be protective against death from infection in burn mice by Kobayashi and colleagues.[36] IL-12 therapy was further shown to restore production of Th1-dependent antibody isotypes.[42] However, the clinical use of IL-12 to attempt to reduce the incidence of infection and septic death after serious injury is not particularly attractive because of IL-12 toxicity as demonstrated in clinical cancer trials.[67]

In summary, it appears likely that T-helper cells are programmed for a proinflammatory Th1-like response early after serious injury, which is followed in several days by the emergence of a Th2-like regulatory phenotype. The appearance of the latter phenotype is associated with diminished resistance to infection in a number of animal models and some clinical studies. B cells of the adaptive immune system are deficient in production of certain complement fixing antibodies, notably those of the IgG2 family, which appears to result from loss of effective Th1 function. Increased production of the Th2-dependent antibody IgE has been commonly observed in both injured humans and in animal models.

The fact that restoration of Th1 function by a variety of interventions is associated with improved resistance to infection in the postinjury period in animal models suggests that one or more of these approaches could prove useful clinically in preventing the onset of nosocomial infection with its attendant risk of death from MODS in seriously injured patients.

The data presented in this manuscript indicate that major injury can lead to depression of the T cell responses, which correlates with the subsequent development of infectious complications. Inhibition of cyclooxygenase pathways was able to reverse or decrease this immunologic defect.

Goebel A, Kavanagh EG, Lyons A, et al: Injury induces deficient interleukin-12 (IL-12) production while IL-12 therapy after injury restores resistance to infection. Ann Surg 2000;231:253-261.

Serious injury is associated with loss of function of the Th1 lymphocyte phenotype and decreased IL-12 production. In this manuscript, IL-12 production was shown to be reduced in peripheral blood mononuclear cells from severely injured patients. In humans, there is a reciprocal relation between diminished IL-12 production and increased IL-10 production at approximately 1 week after injury. Low-dose IL-12 therapy in the mouse burn model markedly increased survival after a septic challenge, even when treatment was carried beyond the onset of sepsis. Low-dose IL-12 treatment in the mouse increased production of proinflammatory mediators important in host defense and at the same time maintained or increased production of IL-10, an important antiinflammatory cytokine.

Hotchkiss RS, Chang KC, Swanson PE, et al: Caspase inhibitors improve survival in sepsis: A crucial role of the lymphocyte. Nat Immunol 2000;1:496-501.

Sepsis induces lymphocyte apoptosis, and prevention of lymphocyte death may improve the chances of surviving this disorder. This study demonstrated that inhibition of caspase 3 in mice resulted in decreased lymphocyte apoptosis and improved resistance to infection. Such results indicate that caspase inhibitors enhance immunity by preventing lymphocyte apoptosis and also that lymphocyte apoptosis is involved in the control of infection during sepsis.

O'Sullivan ST, Lederer JA, Horgan AF, et al: Major injury leads to predominance of the T-helper-2 lymphocyte phenotype and diminished interleukin-12 production associated with decreased resistance to infection. Ann Surg 1995;222:482-492.

This paper shows that major burn and traumatic injury led to increased Th2 cell responses, and decreased IL-12 production. Such changes in T lymphocyte functions were associated with decreased resistance to infection.

Wichmann MW, Zellweger R, DeMaso CM, et al: Mechanism of immunosuppression in males following trauma-hemorrhage: Critical role of testosterone. Arch Surg 1996;131:1186-1192.

Male sex hormones appear to be associated with worsened outcome from sepsis and hemorrhage. In these experiments, castration of male mice before soft tissue trauma and hemorrhagic shock maintains normal immune function, whereas sham-castrated male mice show significant immunodepression. The maintenance of immune function by androgen deficiency was not related to changes in the release of corticosterone. Such results suggest that the use of testosterone-blocking agents after trauma/hemorrhage could prevent the depression of immune functions and decrease the susceptibility to sepsis under those conditions.

Chapter 34
COAGULATION

Charles T. Esmon

KEY POINTS

1. Inflammation promotes blood coagulation.
2. Blood clotting enzymes promote inflammation.
3. Proteolytic products of clotting factors (fragment 1-2) can be used to assess intravascular coagulation and fibrin formation or degradation (D-dimer).
4. Natural anticoagulants inhibit coagulation and dampen inflammation.
5. Natural anticoagulant mechanisms are impaired by inflammatory mediators.
6. Microparticles released from cells by potent agonists contribute to thrombosis.
7. Platelet activation promotes inflammation.

OVERVIEW OF BLOOD COAGULATION

Thrombosis and disseminated intravascular coagulation are relatively common complications in critically ill patients. Recent studies have shown that inflammation is a major driving force in initiating and amplifying the blood clotting process. Under normal circumstances, blood clotting is limited to the site of injury. This regulation is due in large part to natural anticoagulant pathways. Inflammation can down-regulate these pathways, leading to a tilt in the hemostatic balance favoring clot formation. Further, the blood clotting enzymes can amplify the inflammatory response, and several of the natural anticoagulant pathways exhibit anti-inflammatory activity. Thus, the change in the hemostatic balance impacts inflammation as well as favoring clot formation. Finally, normal circulation of the blood is important in preventing thrombosis. In large part, this is due to the presence of potent anticoagulant mechanisms that are concentrated in the microcirculation. Thus, when blood has little or no flow in the large blood vessels, the clotting process proceeds in the absence of adequate negative regulatory mechanisms.

The goal of this chapter is to provide a framework for understanding the regulation of the blood coagulation process. Biochemical details are presented only when they are deemed to be important for understanding the process. For a more complete biochemical description of the blood clotting process, see reference 1.

Triggering the innate immune system has long been recognized to result in potential stimulation of the blood coagulation system. More recently, the highly integrated interactions of these two systems have become apparent. Inflammation triggered by the innate immune system initiates not only the blood clotting process but also the natural anticoagulant pathways, components of which are consumed or down-regulated by the inflammatory mediators. The anticoagulant components play an important role in limiting the inflammatory response. This chapter summarizes current information on the linkage between the regulation of the coagulation and inflammatory responses to infection.

BLOOD COAGULATION PATHWAYS

The main pathways of blood coagulation are shown in Figure 34-1. All the reactions involved in generating thrombin, the enzyme responsible for blood clotting, require negatively charged phospholipid membranes to proceed at physiologically relevant rates. Functional membrane phospholipid expression (phosphatidylserine, phosphatidylethanolamine) requires exposure of the cells to potent activators such as collagen together with thrombin (for platelets) or the membrane attack complex (C5b9) of the complement system to achieve full activity.[2]

Tissue factor triggers the blood clotting process. Under normal circumstances, tissue factor is found primarily on cells lining the outside of the blood vessel,[3] where it is strategically placed to trigger hemostasis when the blood vessels are injured or severed. Once an inflammatory challenge occurs, tissue factor expression is induced on macrophage-monocytes.[4,5] Recently, it has been shown that circulating tissue factor is present in blood, albeit at low levels, where it appears to augment hemostasis and the growth of thrombi.[6] When tissue factor is exposed to blood, it binds factor VII. Factor VII is converted to the active serine protease, factor VIIa, by thrombin, factor Xa, or factor VIIa, processes that are accelerated by factor VII and factor VIIa binding to tissue factor.[7] The tissue factor–factor VIIa complex can convert either factor IX or factor X to their proteolytically active forms, factors IXa and Xa.[8] Factors V and VIII circulate as inactive high-molecular-weight proteins. They must be proteolytically activated by thrombin or factor Xa to participate effectively in the coagulation cascade. In the case of factor VIII, it circulates in complex with another very high molecular weight protein, von Willebrand's factor, a protein involved in platelet adherence to the vessel wall at wound sites. The von Willebrand's factor–factor VIII interaction helps stabilize factor VIII, a protein that is normally relatively unstable. Upon activation of factor VIII, von Willebrand's factor dissociates, leaving a relatively unstable factor VIIIa molecule. Factors Va and VIIIa are not proteases

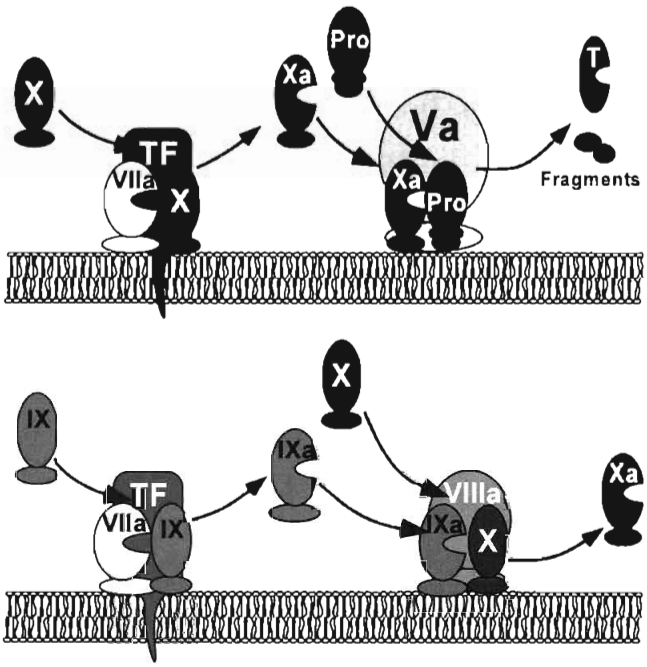

FIGURE 34–1. Initiation of the coagulation cascade. Tissue factor (TF) on extravascular cells is exposed to blood at a wound site. Factor VII (not shown) is activated by thrombin (T), factor Xa, or factor VIIa (when bound to tissue factor). The tissue factor–factor VIIa complex then cleaves factor X to generate the serine protease factor Xa. This binds to factor Va, and the complex converts prothrombin (Pro) to thrombin. Roughly half of the prothrombin molecule is released as activation fragment 1-2 (Fragments). Circulating levels of this fragment are used to determine the degree of intravascular coagulation. Alternatively, the tissue factor–factor VIIa complex can activate factor IX. Factor IXa binds to factor VIIIa to activate factor X. At this point, the different pathways converge. Factors VII, IX, and X and prothrombin need vitamin K for their synthesis. The vitamin generates γ-carboxyglutamic acid from glutamic acid residues located toward the amino terminus. These residues are required for calcium-dependent binding to negatively charged phospholipids.

but serve as cofactors that bind to both the substrates and the enzymes to accelerate the coagulation process. Factor IXa binds to factor VIIIa, and this complex also converts factor X to factor Xa. Factor Xa in complex with factor Va converts prothrombin to thrombin.[9] Nearly half the prothrombin, including the domain responsible for binding to negatively charged phospholipids, is released during activation. This activation fragment (fragment 1-2) can be detected in the circulation using immunoassays and is a monitor of intravascular coagulation (Table 34-1).

In addition to clotting blood, thrombin activates many cells, altering their phenotype by leading to tissue factor, leukocyte adhesion molecule, and cytokine expression.[10] Therefore, thrombin generation has the potential to amplify the inflammatory pathways.

TABLE 34–1. ASSAYS USED TO DETECT INTRAVASCULAR COAGULATION

Assay	Activity Measured
Fibrinopeptide A	Fibrin formation
Thrombin-antithrombin complex	Thrombin formation
D-dimer	Fibrin degradation
Prothrombin fragment 1-2	Prothrombin activation

Traditionally, blood coagulation was thought to occur via one of two pathways: the extrinsic pathway (described earlier), and the intrinsic pathway triggered by the activation of factor XII. Factor XII is activated on surfaces such as glass or collagen. Factor XIIa activates factor XI in vitro, and factor XIa in turn activates factor IX. From that point on, the pathways converge. The physiologic importance of the intrinsic pathway to coagulation is questionable, however, because patients with factor XII deficiency do not have bleeding problems. In contrast, patients with factor IX deficiency exhibit a variable and usually mild bleeding diathesis. Why factor XI deficiency, but not factor XII deficiency, is associated with increased bleeding risk remained unclear until it was shown that thrombin could feed back to activate factor XI, thereby bypassing the factor XII requirement.[11,12] Subsequently, it was shown that binding of factor XI to activated platelet receptors further enhanced this thrombin activation of factor XI.[13] This pathway is involved in bradykinin formation and has weak profibrinolytic activity (Fig. 34-2).

Once thrombin is formed, it clots fibrinogen, a process that requires the release of small peptides from fibrinogen, allowing the newly revealed N-termini to participate in fibrin formation. Fibrinogen is a complex molecule with two copies of three independently coded chains: α, β, and γ. These small fragments, referred to as fibrinopeptides A and B, are derived from the N-termini of the α and β chains (Fig. 34-3). Immunoassays designed to detect fibrinopeptides have been used to monitor intravascular coagulation (see Table 34-1).

The fibrin formed initially is somewhat fragile. Very rapidly during clot formation, factor XIII is activated by thrombin and crosslinks the clot (Fig. 34-3). Six transamidation reactions occur between the fibrin chains, each involving crosslinking between glutamine and lysine residues. The new amide bond is very stable. The resultant clot is more resistant to clot lysis and mechanical forces.[1,14]

FIBRINOLYSIS

Once the thrombus forms, it can be removed by the fibrinolytic system. The primary mechanism is initiated when tissue plasminogen activator (t-PA) binds to fibrin. The fibrin–t-PA complex rapidly converts plasminogen into the fibrinolytic enzyme plasmin. The process is facilitated by plasminogen binding to the fibrin clot and concentrating the enzyme and substrate in close proximity.[14] Fibrin is then degraded into fibrin degradation products, including D-dimer (see Fig. 34-3). D-dimer levels in the circulation are often used as a measure of intravascular coagulation (see Table 34-1). This is somewhat indirect, however, because it is a simultaneous measure of clot formation and lysis. If the fibrinolytic system is severely impaired, intravascular clot formation could be occurring without a concomitant increase in fibrinolysis and a subsequent increase in D-dimer levels.

Plasmin and t-PA are rapidly inactivated by α_2-antiplasmin and plasminogen activator inhibitor-1 (PAI-1). PAI-1 levels are elevated in inflammatory diseases and can result in impaired fibrinolysis.[15]

A weaker fibrinolytic system is initiated by another protease, urokinase. Urokinase can activate plasminogen without strong requirements for binding to fibrin. It is generally believed that the primary function of urokinase involves binding to a urokinase receptor, at which time it is involved

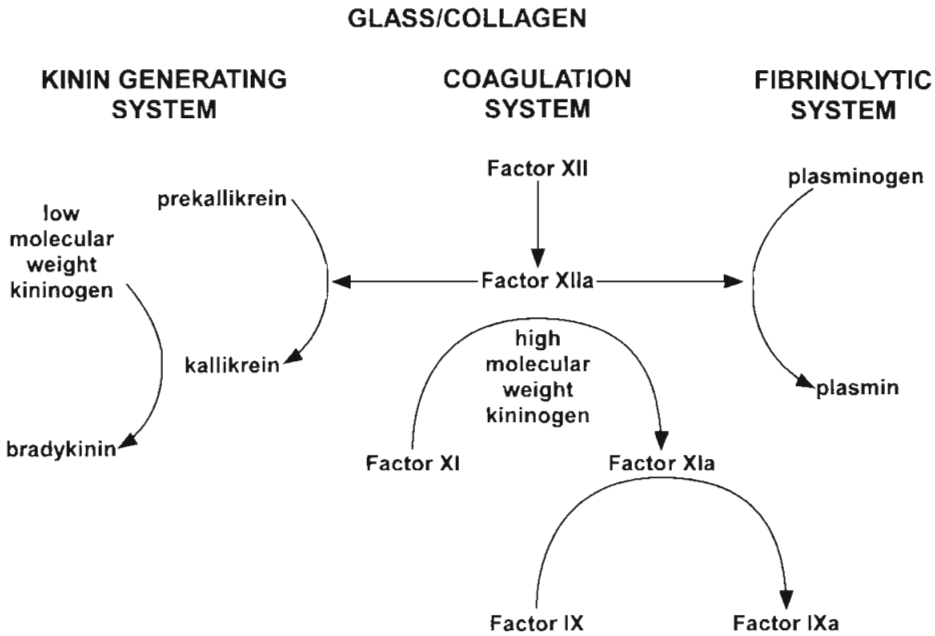

FIGURE 34–2. Intrinsic coagulation system. When blood contacts foreign surfaces such as glass, certain soils, or collagen, factor XII is activated. In the presence of high-molecular-weight kininogen, factor XIIa activates factor XI, which in turn activates factor IX. The pathway can also generate bradykinin. Factor XIIa activation of prekallikrein leads to the formation of bradykinin. Alternatively, factor XIIa can activate plasminogen, stimulating fibrinolysis.

in cellular migration, tumor growth, and development, in part mediated through cell surface activation of plasminogen.[14,16]

An obvious question is why there is so much complexity. In part, this seems to be due to the vast array of insults to which the coagulation system must respond—everything from minor nicks to severe trauma. A simple system could easily seal the wound, regardless of magnitude, but it would most likely lack the control mechanisms required to generate a hemostatic response without occlusive thrombosis. The potential thrombin that can be generated from prothrombin is more than 100 times enough to clot blood. Unchecked, these pathways would make more than enough thrombin to clot all the blood within seconds, making it essential to have potent negative regulatory mechanisms in place. This is the function of the natural anticoagulant pathways described later in this chapter.

NATURAL ANTICOAGULANT PATHWAYS

INHIBITION OF TISSUE FACTOR–FACTOR VIIa COMPLEX

Two major mechanisms regulate tissue factor–factor VIIa activity: tissue factor pathway inhibitor (TFPI) and antithrombin-heparin. Both function by inhibiting the protease factor VIIa bound to tissue factor. TFPI has an unusual

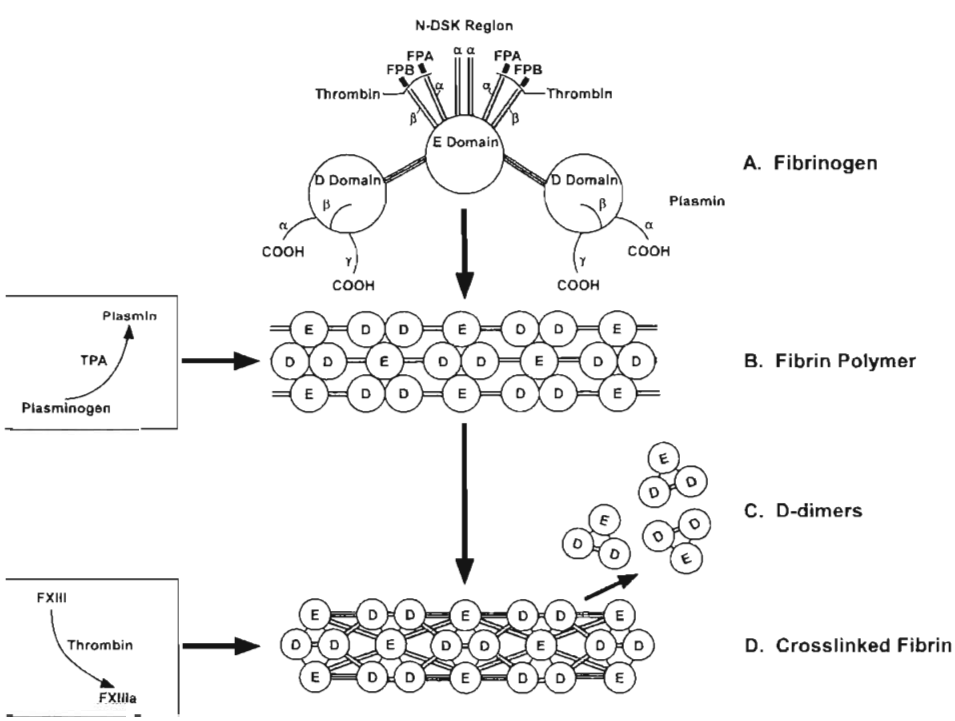

FIGURE 34–3. Formation and lysis of fibrin. Fibrinogen *(A)* has three globular domains. When thrombin releases small peptides from fibrinogen, a polymer forms *(B)*. Plasmin cleaves the polymer to release fibrin degradation products, including D-dimers *(C)*. Thrombin also activates factor XIII to cause fibrin crosslinking *(D)*. This helps stabilize the clot. FPA, fibrinopeptide A; FPB, fibrinopeptide B; N-DSK, amino-terminal disulfide knot; TPA, tissue plasminogen activator.

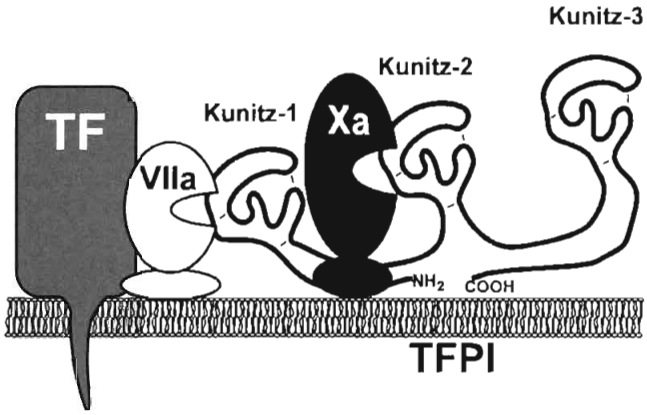

FIGURE 34–4. Proposed mechanism for tissue factor pathway inhibitor (TFPI) inhibition of the factor VIIa–tissue factor (TF) complex. Factor Xa first binds to the second Kunitz domain of the inhibitor. The complex then binds to the membrane surface. This concentrates the first Kunitz domain near factor VIIa and leads to factor VIIa inhibition. The process is reversed by removing calcium.

mechanism of action (Fig. 34-4).[17] Structurally, TFPI is composed of three Kunitz inhibitory domains. TFPI binds to factor Xa through the Kunitz 2 protease inhibitory domain. The factor Xa–TFPI complex then binds to negatively charged membrane surfaces in the presence of calcium, increasing the local concentration and favoring relatively stable, reversible inhibition of factor VIIa bound to tissue factor by the Kunitz 1 domain of TFPI.[17] Gene deletion of TFPI in mice results in an embryonic consumptive coagulopathy leading to embryonic lethality.[18] It is difficult to assess the impact of inflammation on TFPI function because the majority of TFPI is vessel associated,[17] and much of this is stored in agonist releasable endothelial cell granules.[19] Heparin also causes the release of TFPI from the vessel.[17]

Antithrombin can also inhibit the tissue factor–factor VIIa complex (see later). Although the relative importance of antithrombin versus TFPI inhibition of tissue factor–factor VIIa is uncertain, it is clear that antithrombin activity decreases markedly during severe sepsis, often dropping below 50%.[20] This decreased level of antithrombin is associated with thrombosis in thrombophilic patients.[21] Because the rate of inhibition is strongly dependent on the inhibitor concentration, a decrease in antithrombin would contribute to increased stability of the tissue factor–factor VIIa complex and hence favor intravascular coagulation.

ANTITHROMBIN REGULATION OF AMPLIFICATION REACTIONS

Antithrombin inhibition of the factor VIIa–tissue factor complex, factor IXa, factor Xa, and thrombin are all thought to be accelerated by vascular heparin-like proteoglycans. Antithrombin forms a tight, apparently covalent 1:1 complex with these enzymes (Fig. 34-5). Heparin is a highly sulfated sugar polymer that varies in size, sugar composition, and degree of sulfation. There is a relatively specific sugar sequence that determines high-affinity interaction with antithrombin.[22] Low-molecular-weight heparins are often used therapeutically. These have reduced activity toward thrombin because they cannot effectively form the bridge that is shown in Figure 34-5, but they retain a high activity toward factor Xa. Once the enzyme complex forms, heparin dissociates

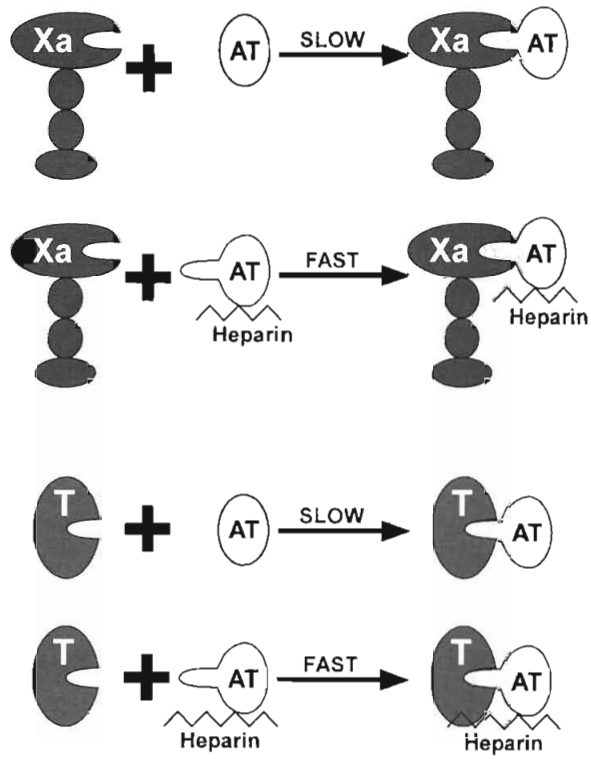

FIGURE 34–5. Heparin involvement in antithrombin function. Antithrombin (AT) undergoes a conformational change when bound to heparin, making the "bait" site more accessible. In the case of factor Xa, this is sufficient to stimulate inactivation. In the case of thrombin (T), longer heparin molecules are needed. This is the basis for some of the differences between low- and high-molecular-weight (unfractionated) heparin.

due to major conformational changes in both the enzyme and the antithrombin or related inhibitors.[23] The vascular heparin-like molecules may be inactivated during severe sepsis,[24] further reducing the effectiveness of the natural anticoagulants. This is likely to be even more important when the antithrombin level has been reduced by consumption.

PROTEIN Z–PROTEIN Z PROTEASE INHIBITOR COMPLEX REGULATION OF FACTOR Xa

Protein Z, a vitamin K–dependent anticoagulant protein, plays a significant role in the inhibition of factor Xa. Protein Z binds tightly to protein Z protease inhibitor. The protein Z protease inhibitor–protein Z complex binds to negatively charged membrane surfaces due to direct protein Z interaction with the membrane. This complex then inactivates factor Xa.[25] Deletion of the protein Z gene in mice exacerbates the thrombotic response caused by other coagulation abnormalities,[26] but alone, it is not sufficient to cause thrombosis. Low protein Z levels in humans appear to be associated with an increased risk of stroke.[27] Because protein Z appears to be a negative acute-phase reactant,[28] inflammation may reduce the effectiveness of this system also.

INHIBITION OF FACTOR Va AND VIIIa BY ACTIVATED PROTEIN C: THE PROTEIN C ANTICOAGULANT PATHWAY

The protein C anticoagulant pathway is the most complex of the natural anticoagulant mechanisms and is also the most sensitive to down-regulation by acute inflammatory responses.

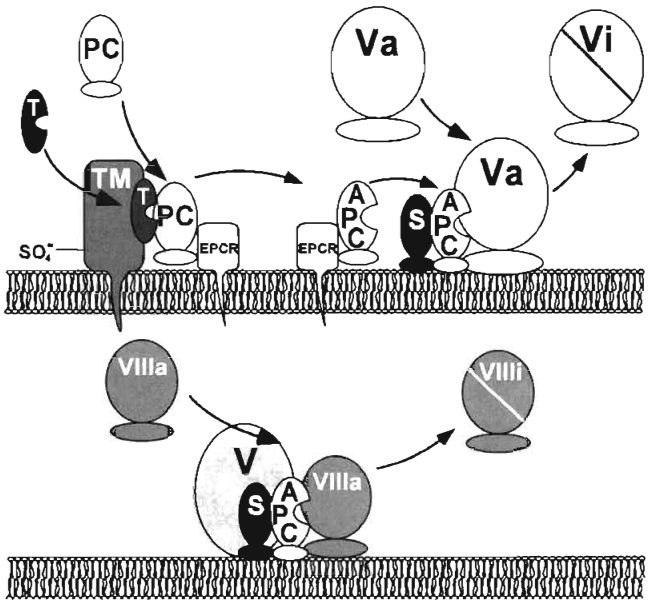

FIGURE 34–6. Protein C anticoagulant pathway. Thrombin (T) binds to thrombomodulin (TM) and activates protein C (PC). The activation is augmented by protein C binding to the endothelial cell protein C receptor (EPCR). Both protein C and activated protein C (APC) bind reversibly to EPCR. When APC dissociates from EPCR, it binds to protein S (S), and this complex inactivates factors Va (Va and Vi) and VIIIa (VIIIa and VIIIi). In the case of factor VIIIa, factor V (V) also increases the inactivation rate.

The pathway is illustrated in Figure 34-6. Protein C circulates as an inactive vitamin K–dependent zymogen at about 4 μg/mL in plasma. It is activated proteolytically on the surface of the endothelium by a complex between thrombin and thrombomodulin. Protein C activation rates are increased when protein C is bound to the endothelial cell protein C receptor (EPCR).[29] EPCR may be particularly important in preventing large vessel thrombosis[30] because it is most abundant on large blood vessels. Protein C and activated protein C (APC) bind to EPCR with comparable affinity (30 nM). The APC-EPCR complex does not appear to inactivate factor Va.[31] It is likely that this complex cleaves an alternative substrate or receptor.[32,33] This would be consistent with in vivo observations that APC infusion dampens cellular responses to inflammatory agents and decreases the generation of inflammatory cytokines.[34,35] When APC dissociates from EPCR, it can bind to protein S and catalyze the selective proteolytic inactivation of factors Va and VIIIa.[36] A common dimorphism exists in factor V in which the Arg residue at residue 506 is replaced by Gln, resulting in a factor Va that is more resistant to inactivation by APC. This condition, referred to as factor V Leiden or APC resistance, is associated with an increased risk of thrombosis.[21,37] It is found in approximately 5% of whites but is rare in other races.

APC also enhances fibrinolysis by forming a tight 1:1 complex with PAI-1 and thereby inactivating this major inhibitor of fibrinolysis. APC normally reacts slowly with PAI-1, but recently it has been shown that the reaction becomes quite rapid in the presence of vitronectin,[38] suggesting a dominant role for this reaction around platelets that release vitronectin.

Compared with other serine proteases or clotting factors, APC has a relatively long half-life in the blood of about 15 minutes before it becomes inactivated by α_1-antitrypsin (sometimes called α_1-proteinase inhibitor), protein C inhibitor or α_2-macroglobulin.[39] The APC-inhibitor complex is then cleared relatively rapidly from the circulation. Because of the relatively slow inactivation of APC, it is possible to detect circulating levels of it. This allows direct evaluation of APC levels in patients,[40,41] which in turn allows evaluation of the functionality of the protein C activation complex in vivo.

Thrombin binding to thrombomodulin not only augments protein C activation but also results in inhibition of fibrinogen clotting, platelet and endothelial cell activation, and factor V activation.[36] In addition, thrombin bound to thrombomodulin is inactivated much more rapidly than free thrombin is. Antithrombin and protein C inhibitor contribute similarly to the rapid inactivation of thrombin bound to thrombomodulin, resulting in an estimated half-life of 1 to 2 seconds for thrombomodulin bound to thrombin.[42] In severe sepsis, down-regulation of thrombomodulin would result in both decreased protein C activation and decreased thrombin clearance. It is apparent from studies of APC levels in septic patients that protein C activation can be severely impaired in a subset of patients with severe sepsis.[41,43] The modulation of thrombin functions, and the regulation resulting from thrombin-thrombomodulin interaction, allows thrombomodulin to serve as a molecular switch in the control of hemostasis and thrombosis.

IMPACT OF INFLAMMATION ON COAGULATION

Some of the changes in the vessel wall and the hemostatic balance that are caused by inflammation are illustrated in Figure 34-7. Bacteria and other pathogens can lead to the formation of inflammatory cytokines such as tumor necrosis factor (TNF) and interleukin-1 beta (IL-1β). These mediators, or endotoxin itself, induce synthesis and expression of tissue factor, primarily on monocytes and macrophages.[4,5] Because the monocytes and macrophages are in contact with the blood, they initiate intravascular coagulation when stimulated by these inflammatory mediators.

Complement activation as a result of inflammation can also augment the coagulant response. As mentioned previously, complement C5b9 (the membrane attack complex of complement) is a very effective cell agonist, leading to expression of negatively charged phospholipids on the surface of cells that can propagate the coagulation reaction.[44] During bacterial infections, complement activation occurs not only due to recognition of the infectious agent but also due to the increase in the acute-phase protein, C-reactive protein, which appears to augment complement activation during sepsis.[45] Cell surface expression of negatively charged lipids is a major regulatory event controlling physiologic and pathologic clotting. For instance, infusion of factor Xa at relatively high concentrations has little thrombotic effect unless coinfused with negatively charged phospholipids. These lipids are a surrogate for the activated cell surface or cellular microparticles released following treatment with potent cell agonists.[46] Further, when only an inflammatory cytokine such as TNF is infused into experimental animals, there is little fibrin formation unless appropriate lipids are also infused (and blood flow is impaired).[47] Thus, available evidence suggests that inflammation can contribute directly to two critical events in intravascular coagulation: the synthesis and expression of intravascular tissue factor and the generation

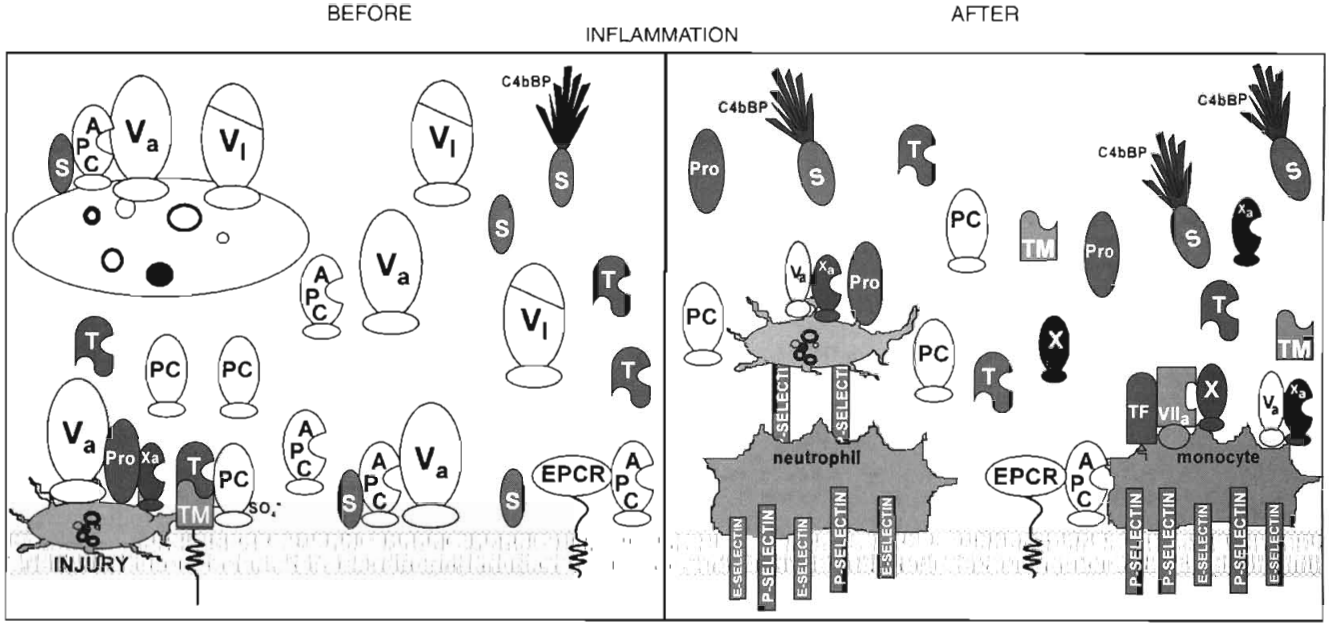

FIGURE 34–7. Impact of inflammation on the regulation of coagulation. Under normal circumstances, strong anticoagulant properties are associated with the endothelium. Inflammation causes leukocytes to adhere, thrombomodulin (TM) to be shed, and the endothelial cell protein C receptor (EPCR) to be down-regulated. Tissue factor (TF) is induced on leukocytes. Protein C (PC) is consumed, and free (active) protein S (S) decreases. Active lipid surface becomes exposed, propagating the coagulant response. APC, activated protein C; Pro, prothrombin; T, thrombin.

of membrane surfaces capable of augmenting the initiation and propagation of the coagulant response.

Thrombin impacts both its own generation and the inflammatory response. In addition to clotting fibrinogen and activating platelets, thrombin plays a major role in leukocyte activation by causing the expression of the leukocyte adhesion molecule P-selectin on platelets and endothelial cells.[48] Thrombin is a potent agonist for endothelial cell platelet-activating factor formation, a potent neutrophil agonist.[49] Neutrophil activation is potentiated by adhesion to P-selectin, further augmenting the inflammatory response. P-selectin appears to play an important role in thrombus formation. Blocking P-selectin binding to its ligand, the P-selectin glycoprotein ligand-1, decreases thrombus formation under both flow[50] and stasis conditions.[51]

Inflammatory mediators can also impact platelet function. For instance, interleukin-6 (IL-6) not only increases platelet production but also creates a population of platelets that are more thrombogenic. IL-6–induced platelets are more readily activated by platelet agonists such as thrombin.[52] Activated platelets are a rich source of the proinflammatory mediator CD40 ligand. CD40 ligand induces tissue factor formation[53,54] and increases inflammatory cytokines such as IL-6 and interleukin-8 (IL-8).[55,56]

IMPACT OF INFLAMMATION ON NATURAL ANTICOAGULANT PATHWAYS

Natural anticoagulant pathways play key roles in preventing excessive inflammation induced by augmentation of the coagulation response. In addition to preventing excess clotting, these pathways feed back to dampen the inflammatory response. However, in severe acute inflammatory diseases, some of the key negative regulatory pathways are down-regulated.

Both thrombomodulin and EPCR are down-regulated by inflammatory cytokines such as TNF at the transcriptional level.[57,58] In cell culture, about half the activity disappears in 8 hours. A single exposure of the endothelium to the cytokine reduces the protein and messenger RNA levels more than 90%, and these low levels are maintained for at least 24 hours. Neutrophil adhesion and activation on the endothelium can reduce thrombomodulin activity further, both through oxidation of a sensitive methionine residue[59] and by elastase-mediated release of soluble thrombomodulin,[60] a form with reduced activity. Decreased protein C activation is particularly important, because factors Xa and IXa are resistant to inactivation by antithrombin when they are complexed with factors Va and VIIIa, respectively.[61,62]

The protein C pathway seems to be particularly important in the prevention of microvascular thrombosis, as demonstrated by the purpura fulminans that develops in neonates with protein C deficiency.[63] Down-regulation of thrombomodulin, with the loss of thrombin clearance and decreased protein C activation, would therefore be expected to have a major effect on clotting in the microcirculation, a major site of thrombotic complications in sepsis.

ANTI-INFLAMMATORY ACTIVITIES OF NATURAL ANTICOAGULANT PATHWAYS

Natural anticoagulants have anti-inflammatory activities as well as anticoagulant functions. Antithrombin, TFPI, and APC have all been shown to protect baboons from *Escherichia coli* sepsis when given before the challenge.[64] In the baboon and several rodent models,[65] neither synthetic factor Xa inhibitors[65] nor active site-blocked factor Xa, an effective, high-affinity, competitive inhibitor of prothrombin activation in vivo,[66] protected the animals from death or

organ failure and failed to diminish cytokine elaboration. In contrast to ineffective synthetic coagulation inhibitors, the ability of natural anticoagulants to both protect from sepsis and minimize inflammation-mediated injury suggests that cellular and anti-inflammatory activities of the natural anticoagulants may be important aspects of their physiologic functions.

ANTITHROMBIN

Antithrombin can protect experimental animals from endotoxin-mediated septic shock.[67] Heparin prevents this protection, despite increasing the antithrombotic activity. A negative effect of heparin and antithrombin coadministration was observed in clinical trials.[68] High levels of antithrombin in vitro have been shown to inhibit endotoxin-induced IL-6 formation by mononuclear cells and endothelium.[67,69] Antithrombin stimulates prostacyclin release from endothelial cells in culture,[70] a process that appears to be protective in lung injury models.[71] Antithrombin-mediated signaling probably occurs through syndecan-4.[69] Antithrombin binding to cell surface receptors has also been shown to block nuclear factor kappa-B (NF-κB) translocation.[72] This prevents the subsequent release of cytokines and the induction of adhesion molecules.

TISSUE FACTOR PATHWAY INHIBITOR

TFPI infusion can reduce leukocyte activation and decrease TNF in vivo.[65] Although inhibition of cytokine elaboration appears to be independent of blood coagulation, the mechanism responsible for TFPI-mediated cellular effects remains unknown.

PROTEIN C PATHWAY

APC has been shown to protect nonhuman primates from *E. coli*–induced sepsis whether given before or after the *E. coli* challenge.[73] Recently, this observation was confirmed and extended in clinical studies demonstrating that APC infusion can reduce the relative risk of all-cause 28-day mortality from severe sepsis by 19.4%.[74] One feature of critically ill patients is the relatively high frequency of antiphospholipid antibodies.[75] Some antiphospholipid antibodies inhibit APC anticoagulant activity extremely effectively,[36] but whether this is the case in critical care patients remains to be examined.

The protective effects of APC appear to be receptor mediated. APC binding to monocytic cells can block agonist-induced calcium transients[76] and inhibit NF-κB–mediated signaling.[34,77-79] In cultured endothelium, APC reduces NF-κB messenger RNA levels, reduces the expression of cell surface adhesion molecules and cytokine formation, and elevates molecules involved in preventing apoptosis.[35] On the monocytic cell line U937, APC has been shown to dampen both basal levels and the phorbol-induced expression of tissue factor in an EPCR-dependent fashion.[32] Under appropriate conditions, APC can also cleave protease-activated receptors,[33] which are normally cleaved by coagulation enzymes, particularly thrombin.[10] The role of cleavage of the protease-activated receptors in APC function remains to be fully elucidated. Most of the downstream events following activation of these receptors enhance inflammation.[80] It is possible that activation of the protease-activated receptors is a negative side reaction occurring under in vitro conditions.

Conway and coworkers[81] recently revealed a novel anti-inflammatory activity of thrombomodulin. The N-terminal lectin-like domain[82,83] dampened activation of the mitogen-activated protein kinase and NF-κB signaling systems in endothelium. This anti-inflammatory activity was imparted by either cellular thrombomodulin or the soluble lectin-like domain. Infusion of the lectin-like domain, which does not participate in protein C activation, resulted in decreased leukocyte adhesion to the endothelium. These observations have important implications. Thrombomodulin is down-regulated on endothelium overlying atherosclerotic plaques, on vein bypass grafts, in diabetes, and by acute inflammatory insults such as bacterial infection.[84] Loss of thrombomodulin would not only reduce protein C activation but also increase the endothelium's sensitivity to leukocyte-mediated injury. Important roles for thrombomodulin in vascular protection were demonstrated earlier when its overexpression was found to reduce thrombosis, restenosis, and leukocyte infiltration in rabbits with deep arterial injury.[85,86]

Thrombomodulin also accelerates thrombin activation of a plasma procarboxypeptidase B called thrombin-activatable fibrinolysis inhibitor (TAFI).[87] TAFI removes terminal lysine residues in fibrin. Lysine residues facilitate binding of plasminogen or plasmin and t-PA. Removal of these lysine residues decreases the rate of clot lysis about fourfold.[87] Initially, TAFI was considered a prothrombotic molecule. More recently, it was found that TAFI can remove terminal Arg residues very effectively from vasoactive substances such as the anaphylotoxin C5a, generated during complement activation; this inactivates C5a. Recent studies found that TAFI is the major enzyme responsible for the inactivation of C5a.[88,89] Activation of TAFI by the thrombin-thrombomodulin complex appears to be important in preventing vascular toxicity due to C5a in conditions in which complement activation is intense. Thus, thrombomodulin may play multiple roles in the regulation of clotting, inflammation, and complement-mediated cell injury.

EPCR was recently found to be important in controlling the inflammatory response to bacterial infusion. Specifically, when protein C binding to EPCR was blocked and the animals were challenged with a low dose of *E. coli*, both the coagulant and cytokine responses were elevated dramatically, and more leukocytes migrated into the tissues compared with controls.[90] A possible mechanism involved in diminishing leukocyte migration was suggested by the recent finding that soluble EPCR, released by a metalloproteinase in endothelium,[91] binds to activated neutrophils. Soluble EPCR binds to proteinase 3, a cytosolic protein of the neutrophil that is released upon activation. Proteinase 3 binds to neutrophil integrins, particularly Mac-1 (CD11b/CD18),[92] whether or not it is bound to EPCR. In vivo data suggest that this interaction reduces tight binding of neutrophils to activated endothelium.

EPCR is also a candidate for immune modulatory functions. The crystal structure of EPCR[93] reveals that it is closely related to the major histocompatibility complex (MHC) class 1/CD1 family of proteins, most of which are involved in inflammation. The crystal structure demonstrated that EPCR has a tightly bound phospholipid in the "antigen presenting groove."[93] CD1 family members serve as glycolipid antigen-presenting molecules. For instance, CD1c seems to present a lipid antigen derived from tuberculosis.[94] The CD1

family of proteins then instructs T cells to modulate the cellular and humoral response to inflammation.[95] Further, these proteins appear likely candidates for involvement in autoimmunity.[95] Whether EPCR plays similar roles should become clear through the analysis of genetically modified mice.[96]

STRUCTURES LINKING THE COAGULATION PATHWAY AND INFLAMMATION

Coagulation and inflammatory pathways share many conserved structures, suggesting parallel evolution. In addition to the EPCR–MHC class 1 similarities, tissue factor and the cytokine receptors share structural similarities,[97] and the selectins involved in leukocyte adhesion and the lectin domain of thrombomodulin are homologous.[98] The complement and coagulation systems also have functional interactions. Protein S and a complement regulatory protein, C4 binding protein, bind tightly. When binding occurs, protein S anticoagulant activity is lost, but this allows C4 binding protein to interact with membrane surfaces, probably protecting mammalian cells from complement activation–mediated damage.[99] These findings suggest that the coagulation and inflammatory pathways evolved in parallel.

SUMMARY

It is clear that coagulation and inflammation are involved in mutual regulation. Considering these interactions, it is apparent that inflammation can contribute to a hypercoagulable state by many discrete mechanisms. Likewise, natural anticoagulants can decrease the inflammatory process. The ability of natural anticoagulants to down-regulate the inflammatory process may provide new therapeutic strategies for the treatment of acute inflammatory disease.

KEY POINTS

PATHWAYS OF ACTIVATION

1. The **complement system can be activated** by one of three separate pathways: the classic, lectin, and alternative pathways.
2. Typically, the **classic pathway is activated by immunoglobulin G immune complexes or C-reactive protein.** The lectin pathway is activated by mannose residues on surfaces of bacteria. The alternative pathway is activated by lipopolysaccharide from Gram-negative bacteria.
3. Regardless of the activation pathway, **the most important products of activation are the anaphylatoxins C3a and C5a and the membrane attack complex C5b-9,** which cause lysis of Gram-negative bacteria. C3a induces histamine release from mast cells and causes smooth muscle contraction. C5a reacts with receptors (C5aR) on neutrophils and macrophages to cause cell signaling, chemotactic movement, enzyme release, and generation of superoxide anion ($O_2^{\bullet}$) and H_2O_2, which are involved in the myeloperoxidase-dependent killing of bacteria.

COMPLEMENT RECEPTORS AND THEIR FUNCTIONS

1. **Complement receptors exist on a variety** of myeloid and nonmyeloid cells and induce signaling responses in the presence of the ligand (complement activation product).
2. **Receptors of C1q (C1qR)** exist on a variety of cell types and often work synergistically with Fc receptors to enhance the inflammatory response.
3. **Receptors for C3a (C3aR) and C5a (C5aR)** are abundant on myeloid cells. In mast cells, the presence of C3a induces granule secretion and histamine release. Engagement of C3aR on smooth muscle cells results in smooth muscle contraction, especially in the airways. Engagement of C5aR on phagocytic cells causes mitogen-activated protein kinase signaling cascades, resulting in chemotaxis, enzyme release, and generation of superoxide anion ($O_2^{\bullet}$) and H_2O_2. Engagement of C5aR on endothelial cells causes P-selectin and tissue factor expression on the endothelium and release of von Willebrand's factor, a procoagulant protein.

GENETICALLY BASED COMPLEMENT DEFICIENCIES

1. **Deficiencies of early complement components (C1q, C1r, C1s, C2, C4)** are associated with manifestations of systemic lupus erythematosus (SLE), glomerulonephritis, and susceptibility to streptococcal pneumonia. Deficiencies of C3 are often life-threatening owing to loss of innate immune defenses to bacteria. Deficiencies of C5, C6, C7, C8, or C9 cause increased susceptibility to infection by *Neisseria* species.
2. **Deficiency of C1 inhibitor** causes hereditary angioedema, and **deficiency of a glycoprotein I–anchored protein** prevents the functioning of complement regulatory proteins, resulting in paroxysmal nocturnal hemoglobinuria.

IN VIVO BIOLOGIC FUNCTIONS OF COMPLEMENT

1. **Ischemia-reperfusion injury in animals** undergoing gut or myocardial ischemia has been shown to be complement and neutrophil dependent.[1] Infusion of C1 inhibitor can ameliorate the injury. Complement activation products also play an important role in hyperacute rejection following organ transplantation.
2. **In the setting of sepsis in animals and humans,** there is clear evidence of complement activation. In animals with sepsis, blockade of C5a or its receptor (C5aR) is protective. There are also suggestions that complement activation occurs in acute respiratory distress syndrome and that C5a can also be generated by activated phagocytic cells.[2]
3. **In SLE, rheumatoid arthritis (RA), and many cases of glomerulonephritis,** there is evidence of complement activation in synovial tissues and in the kidney, as demonstrated by deposition of C3 or its activation products in these locations.
4. **In acute thermal injury and acute trauma,** including cases of closed head injury, there is evidence that complement activation has occurred.

COMPLEMENT INHIBITORS

Several mechanisms exist to prevent uncontrolled activation of the complement system (Fig. 35-1). Such inhibitors of complement activation either exist in plasma or are bound to the cell membrane. As explained later, genetic deficiency of such inhibitors is often associated with human disease.

The natural fluid phase inhibitors occur accordingly: C1 inhibitor inhibits activation of C1s and C1r and, thereby, the classic pathway, but it has also been shown to inhibit activation of the mannose-binding lectin (MBL) pathway. Heterozygous deficiency of C1 inhibitor manifests clinically as life-threatening angioedema. Factor H and C4 binding protein are large plasma proteins that inhibit C3 and C4 activation (in part, as cofactors for other inhibitors), thus inhibiting all pathways of complement activation. Factor I is a serum protease that inactivates C3b and C4b and, therefore, C3 and C5 convertases. It needs cofactors to elicit its effect. Carboxypeptidase N is another serum protein that greatly reduces the biologic activities of C3a and C5a. S protein, fibronectin, and clusterin are present in the plasma and disable the insertion of C5b-9 into the cell membrane.

The membrane-bound inhibitors elicit their effects at different points of the complement system as well. CD59 is a glycoprotein I (GPI)–linked protein that blocks the insertion of C9 into the membrane-bound C5b-9 and also prevents the polymerization of C9, which effectively inhibits the ability of C5b-9 to cause cell lysis.[3] Membrane cofactor protein and

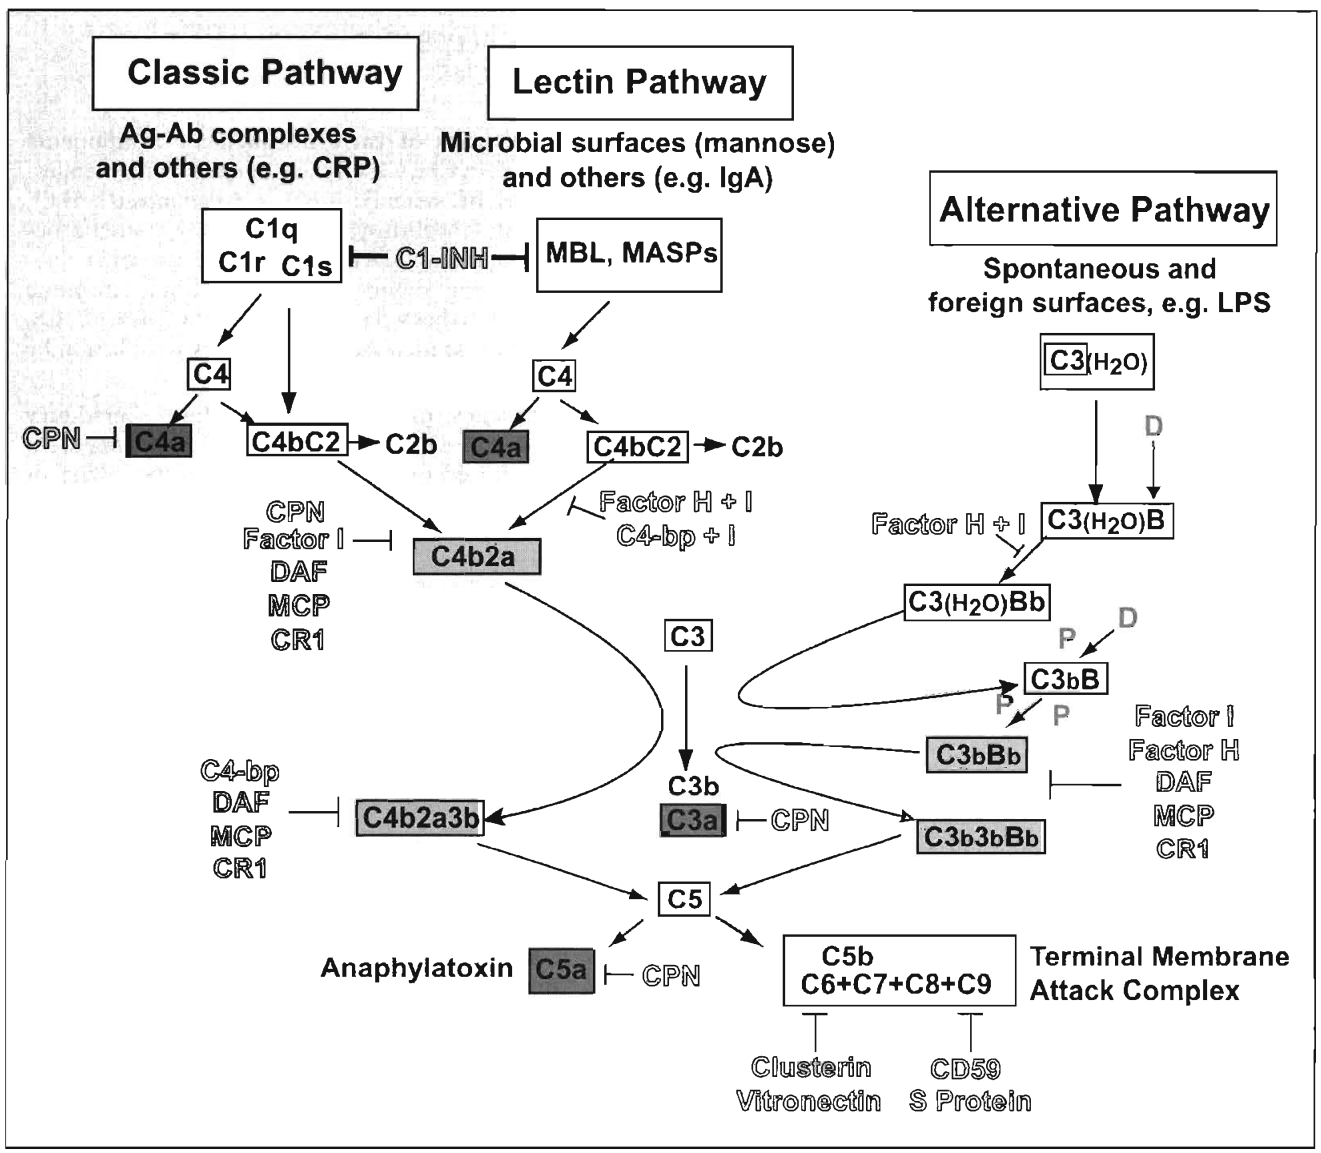

FIGURE 35–1. Activation pathways of the complement system. Complement components C1 to C9 are depicted in square boxes, as well as mannose-binding lectin (MBL) and the MBL-associated serine proteases (MASP). C3 and C5 convertases (classic and alternative) are depicted. The complement split products and anaphylatoxins C3a, C4a, and C5a are depicted. Cofactors of activation are factor D (D) and properdin (P). Inhibitor function is depicted with the symbol (⊥). Membrane-bound inhibitors are CD59, decay-accelerating factor (DAF), complement receptor 1 (CR1), and membrane cofactor protein (MCP). Fluid phase inhibitors are C1 esterase inhibitor (C1-INH), factor H, factor I, clusterin, vitronectin, S protein, and carboxypeptidase N (CPN). IgA, immunoglobulin A; LPS, lipopolysaccharide.

decay-accelerating factor act, either directly or as cofactors for factor I, to deactivate C3 and C5 convertases of all pathways, as well as to cleave C3b and C4b.

COMPLEMENT RECEPTORS

Many of the effects associated with complement activation are achieved by the binding of activated complement products (the anaphylatoxins and opsonic factors such as C3b) to specific receptors. A broad variety of complement receptors exists, although the function of some of them is not yet well established. Often, complement receptors bind various complement activation products with different affinities and thereby elicit a wide range of effects on different cell types (Table 35-1). In general, complement receptors may function as signaling units (transmembrane receptors) for various cell types or as inhibitors of complement activation, especially in their soluble form.

The C1q receptor is present on myeloid cells, endothelial cells, and platelets and can bind C1q as well as MBL. C1qR enhances the phagocytic activity of neutrophils, especially when initiated by Fc receptor activation (binding of immunoglobulin G [IgG] to the cell surface) or by complement receptor 1 (CR1) activation (see later). C1qR may be involved in the up-regulation of cell adhesion molecules on endothelial cells (see Table 35-1). CR1 exists on most blood cell types, as well as on dendritic cells, podocytes in renal glomeruli, and liver Kupffer cells, and also exists in a soluble form. CR1 binds C3b (and the derivative iC3b), as well as C4b and C1q, with high affinity. Many functions have been assigned to CR1.[4] CR1 elicits complement regulatory functions by facilitating, in concert with cofactor I (similar to decay-accelerating factor or membrane cofactor protein), cleavage of C3b and C4b, thereby inactivating C3 and C5 convertases. CR1 is believed to be involved in the clearance of C3b-bound immune complexes in the serum to promote phagocytosis activity and to activate T cells (see Table 35-1).

Complement receptor 2 (CR2) binds iC3b and C3d (cleavage products of C3b) and interacts less effectively with C3b. CR2 is also the receptor that binds Epstein-Barr virus. CR2 is present on B cells, some subtypes of T cells, thymocytes, and a variety of epithelial cells. CR2 is believed to be responsible for a variety of effects, especially activation of B cells and T cells and their adherence when bound to immune complexes.[5]

Complement receptors 3 and 4 (CR3, CR4) are members of the integrin family and are expressed on most myeloid cells. Both receptors bind iC3b and C3b but have affinities to many other ligands (e.g., fibrinogen, intercellular adhesion molecule-1). Besides many other effects elicited by these receptors, they are believed to enhance the phagocytic activity of neutrophils and macrophages.[6]

Whereas some complement receptors interact with a variety of C3 and C3b cleavage products (CR1–4), as well as with C1q (C1qR), other complement receptors specifically recognize the cleavage products C3a (C3aR) and C5a (C5aR). Both receptors are widely expressed on almost all cell types and operate through G-protein activation, leading to phosphorylation of various intracellular signaling pathways, such as the mitogen-activated protein kinase pathways. Most of the known biologic effects of complement ligation are associated with activation of C3aR or C5aR. Recent work suggests that C5aR plays a role in the onset of experimental sepsis and the development of multiorgan failure[7] and that it may be induced in various organs during sepsis by interleukin-6 (IL-6).[8] Similarly, it has been suggested that C3aR plays an important role in the lung during endotoxic shock.[9,10] Blockade of C5aR in experimental sepsis greatly improves survival.[7,11]

BIOLOGIC FUNCTIONS OF THE COMPLEMENT SYSTEM

Obviously, an important and already mentioned biologic effect of the complement system is its opsonic function (C3b), which marks invading microorganisms as "foreign," leading to a targeted host defense response. Ultimately, the formation of C5b-9 leads to the lysis of Gram-negative bacteria, another important defense mechanism of innate immunity. But besides these prominent functions, there are numerous other biologic effects elicited by activation of the complement system (Table 35-2). An important function with broad implications is the regulation of immune complex processing and solubility. Immune complexes often activate complement and bind C3b, resulting in clearance from the circulation via binding with CR1.[12] In addition, complement factors (especially C3b) are responsible for inducing the solubility of immune complexes, and thereby their size.[13] Similarly, the clearance of circulating necrotic or apoptotic

TABLE 35–1. COMPLEMENT RECEPTORS

Receptor	Molecular Weight	Biologic Functions
C1qR	126,000	Enhances Fc-receptor and CR1-mediated phagocytosis, induces adhesion molecule expression on endothelial cells
C5aR (CD88)	50,000	Induces C5a-dependent chemotactic responses of neutrophils, release of granular enzymes and production of superoxide anions in phagocytic cells, vasodilatation, increases in vascular permeability, increases in adhesion molecule expression on endothelial cells, procoagulatory and antifibrinolytic effects, increased expression of various cytokines in different cell types
C3aR	60,000	Similar to C5aR
CR1 (CD35)	190,000-250,000	Binds C3b (and iC3b), C4b, and C1q and facilitates, together with factor I, cleavage of C3 and C5 convertases, clearance of C3b-bound immune complexes in serum; promotes phagocytosis, activation of T cells
CR2 (CD21)	145,000	Binds iC3b and C3d and stimulates B cells (antibody production), Epstein-Barr virus receptor, maintenance of self-tolerance
CR3 (CD11b/CD18)	170,000	Binds iC3b and C3b as well as other molecules (e.g., fibrinogen, intercellular adhesion molecule), integrin-adhesion function, enhances phagocytosis activity of neutrophils, facilitates antibody-mediated phagocytosis
CR4 (CD11c/CD18)	150,000	Similar to CR3

TABLE 35–2. BIOLOGIC ACTIVITIES OF COMPLEMENT ACTIVATION PRODUCTS

Product	Biologic Functions
C1q	Clearance of immune complexes, enhancement of antibody-dependent cellular cytotoxicity, enhancement of phagocytosis in monocytic cells, increase in reactive oxygen species production in neutrophils, adhesive function in fibroblasts
C5a > C3a (>C4a) Anaphylatoxins	Chemotaxis of neutrophils, release of granular enzymes and superoxide anion production in phagocytic cells, increased vascular permeability and vascular dilatation, regulation of cytokine and chemokine production during sepsis, procoagulative and antifibrinolytic effects, pro- and antiapoptotic effects dependent on cell type
C3b	Opsonizing function for bacteria and other invading microorganisms leading to targeted phagocytosis, clearance of immune complexes and circulating apoptotic cells or cell debris, enhancement of antibody production by B cells, regulation of immune tolerance
C5b-9 (MAC)	Permeation of membranes and lysis of bacteria and other invading microorganisms, enhancement of cytokine and adhesion molecule production in various cell types, mediation of tissue injury during ischemia-reperfusion, regulation of cell apoptosis and cell cycle activity, increase in prothrombinase activity on platelets

MAC, membrane attack complex.

cells is believed to be strongly dependent on complement activation and interaction with C1q.[14,15] If, in the presence of complement deficiencies, such clearance becomes inefficient, circulating debris (including immune complexes and dead cells) could act as an autoantigen and possibly initiate the development of autoantibodies, resulting in autoimmune disease.[16] This may explain why most of the deficiencies in the classic complement pathway are associated with the development of SLE.

C5b-9 (membrane attack complex) in sublytic concentrations is involved in the regulation of apoptosis and cell cycle activity.[17] Besides this, membrane attack complex plays a role in the activation of various immune cells via signaling-induced gene transcription, leading to the generation of proinflammatory mediators in nucleated cells and to the generation of reactive oxygen species.[18] C5b-9 has also been demonstrated to make a major contribution to complement-mediated tissue injury after ischemia-reperfusion,[19,20] and it causes relaxation of coronary arteries.[21]

More recently, the biologic effects elicited by the anaphylatoxins C5a and C3a have generated a lot of attention because of their numerous, mostly proinflammatory effects. C5a facilitates a strong chemotactic effect on neutrophils,[22] the release of granular enzymes from phagocytic cells,[23] the production of superoxide anion in neutrophils,[24] and vasodilatation and increases in vascular permeability,[25] as well as expression of adhesion molecules, in endothelial cells.

Recent studies provide evidence of "cross-talk" between the complement system and the coagulation system, suggesting that C5a may be involved in procoagulant effects and antifibrinolytic effects during the onset of sepsis.[26] C5a and C5b-9 have been shown to increase the expression of tissue factor on endothelial cells and monocytes, and C5b-9 has been demonstrated to increase prothrombinase activity on endothelial cells. These observations provide a possible explanation for the described cross-talk.

Even though the complement system is regarded as one of the most powerful defense functions of innate immunity, it also plays an important role in the activation of the adaptive immune system in terms of antigen presentation and antibody production.[27,28] Complement activation (especially C3b deposition) is believed to enhance the antibody production of B cells[29] and to increase the survival time of B cells in various settings of inflammatory disease.

In addition to its affiliation with inflammatory responses, recent studies provide evidence that the complement system plays a role in modulating cellular responses and cell-cell interactions that are crucial to early development and cell differentiation.[30]

GENETIC DEFICIENCIES IN THE COMPLEMENT SYSTEM

Genetically based deficiencies in complement proteins or cofactors of complement activation are rare and, in many cases, are compatible with human life only in the heterozygous state,[31] because most of these defects are inherited in an autosomal recessive manner. Clinically, most patients with deficiencies in complement proteins or cofactors of complement activation have an increased risk of infection (Table 35-3), with meningococcus being the predominant bacterial infection in the case of complete deficiency of C5.[32,33] Generally, there is a distinction among deficiencies of the classic and MBL pathways (C1q, C1r, C1s, C2, C4, MBL), deficiencies of the alternative pathway (factors D and B, properdin), deficiencies of factor C3 together with factors H and I (all resulting in low C3 concentrations), and deficiencies of late-acting complement components (C5, C6, C7, C8, C9). Each of these groups of deficiencies presents with a distinctive pattern of bacterial infection, as described in detail elsewhere.[34] Deficiencies in the classic pathway group are all associated with an increased occurrence of SLE. Infections that occur in the presence of deficiencies involving classic pathway proteins, as well as in deficiencies in C3 and in alternative pathway proteins, are often severe and life threatening (see Table 35-3). Deficiencies in the terminal, late-acting complement components are associated with meningococcal meningitis, but individuals with one of the distal pathway deficiencies are often asymptomatic during their lifetimes. In general, the treatment for complement deficiencies is linked to prophylactic immunization, especially with tetravalent meningococcal vaccine and *Haemophilus influenzae* vaccine. Assessment for complement deficiencies usually is not done during routine screenings.

Deficiencies for the receptors CR1 and CR2 have not been reported, but defective CR3 or CR4 (heterodimeric β_2 integrins) due to mutations in the CD18 β chain results in so-called leukocyte adhesion deficiency, which is linked to frequent and severe bacterial infections.

In contrast to the rarity of deficiencies in complement components, deficiencies in inhibitory proteins of the

TABLE 35–3. GENETICALLY DETERMINED DEFICIENCIES IN THE COMPLEMENT SYSTEM AND RELATED CLINICAL SYMPTOMS

Deficient Component	Clinical Manifestations
Classic pathway (C1q, C1r, C1s, C2, C4)	SLE, glomerulonephritis, recurrent severe infections starting in early childhood (streptococcal pneumonia predominant)
Alternative pathway (factors B, D, P)	Reduced complement activation ability; infection (predominantly meningococcal) starting in adolescence—for factor D especially, often life-threatening
C3, factors H and I	Life-threatening recurrent bacterial infections (especially oropharynx, pulmonary, meninges), often leading to sepsis starting in early childhood; reduced clearance of immune complexes
C5-C9	Predominantly meningococcal infections or gonococcal sepsis, usually in adolescence; approximately 50% recurrent infections; rarely life-threatening. SLE associated in some cases
CR4, CR3 (integrins)	Leukocyte adhesion deficiency syndrome, bacterial infections rarely recurrent
C1-INH	Hereditary or acquired angioedema; also associated with SLE and autoimmune glomerulonephritis
GPI-anchoring protein (affecting CD59 and DAF function)	Paroxysmal nocturnal hemoglobinuria accompanied by thrombosis, iron deficiency anemia (manifestation in young adulthood)

DAF, decay-accelerating factor; GPI, glycoprotein I; INH, inhibitor; SLE, systemic lupus erythematosus.

complement system are more common. C1-esterase inhibitor deficiency can be either inherited (by autosomal dominant mutations) or acquired (formation of autoantibodies).[35] Both forms lead to the clinical picture of angioedema, which is associated with recurrent episodes of edema of the subcutaneous tissue and gastrointestinal tract and often life-threatening edema of the upper airways.[34] Experimental evidence suggests that both complement activation and kallikrein activation (generating bradykinin) are linked to edema in patients with hereditary or acquired angioedema.[36]

Another well-known clinical symptom associated with defects in the inhibitory part of the complement system is paroxysmal nocturnal hemoglobinuria.[37,38] Patients with this disorder develop recurrent hemolytic episodes involving all types of bone marrow–derived blood cells. The defect is a genetic deficiency in a GPI anchoring protein, which is necessary for the proper function of the GPI-linked membrane-bound complement inhibitors CD59 and decay-accelerating factor.[39] This defect results in a high rate of membrane buildup of C5b-9, which is usually controlled by CD59 and decay-accelerating factor. This results in a high rate of lysis of red blood cells especially, as well as other cell types such as granulocytes, lymphocytes, and monocytes. Patients with paroxysmal nocturnal hemoglobinuria often experience an increased incidence of thrombosis and related complications.

SEPSIS

The complement system has been demonstrated to play a key and harmful role in the onset of sepsis in rodents. Microorganisms in the bloodstream or their products, such as lipopolysaccharide, can cause complement activation. Given the well-known variety of proinflammatory effects of complement activation, it is not surprising that sudden "overactivation" of this powerful system can result in serious, harmful consequences in the host. Conversely, experimental data involving C3 and C4 knockout animals suggest that an intact complement system (at least involving C3 and C4) may be required to a certain extent to clear endotoxin and bacteria.[40,41] The harmful effects of complement activation in the context of sepsis have been ascribed to excessive generation of the potent anaphylatoxin C5a. Various clinical studies indicate that complement activation occurs during human sepsis, as exemplified by elevated serum levels of C3a and C5a. In some studies, these levels were significantly higher in nonsurviving septic patients and in those with multiorgan failure than in those with less severe sepsis and survivors.[42–44] Experimental studies in primates suggested some time ago that blockade of C5a by antibodies could significantly attenuate *Escherichia coli*–induced septic shock and acute respiratory distress syndrome (ARDS) in monkeys.[45,46] Studies in rats suggested that lipopolysaccharide-induced shock could be mimicked by the injection of C5a, whereas blockade of C5a with antibody attenuated lipopolysaccharide-induced responses.[47] Blockade of C5a during experimental sepsis was found to be protective in rats,[48] and in another study, the protective effects of C5a blockade during sepsis were associated with the prevention of multiorgan failure.[49] In these studies, C5a generation had to be inhibited early in the course of sepsis to protect against multiorgan failure and death. The exact role of C5a at the onset of sepsis has yet to be determined, but experimental evidence suggests that when C5a is generated in excessive amounts, it may be involved in the shutdown of crucial innate immune functions of neutrophils (generation of reactive oxygen species, release of granular enzymes, phagocytosis, chemotaxis), increasing the susceptibility for infection in the later stages of sepsis. Production of IL-6 and adhesion molecules is also linked to C5a. C5a can interact directly with endothelial cells and myeloid cells. C5aR has been shown to be up-regulated in an IL-6–dependent manner on various cell types (endothelial, epithelial) during experimental sepsis, potentially intensifying the effects of circulating C5a.[7] It remains to be determined whether such findings can be extrapolated to humans with sepsis and whether potential therapeutic targets can be derived from such findings.

The naturally occurring inhibitor of the classic complement and lectin pathways, C1-esterase inhibitor, also inhibits clotting factor XIIa–mediated contact activation of the coagulation system. It has been shown to be decreased in humans with sepsis.[50] Initial pilot clinical trials involved the infusion of C1 inhibitor into septic patients, with some suggestion of benefit in these patients.[51,52] A randomized, double-blind trial suggested that the administration of C1 inhibitor attenuated renal impairment in patients with severe sepsis or septic shock.[53] Larger phase II and III clinical trials will have to be conducted to confirm such findings.

ACUTE RESPIRATORY DISTRESS SYNDROME

A role for the complement system in ARDS has been suggested, based on elevated plasma levels of C3a and C5a in patients with ARDS. These levels were correlated with neutrophil aggregation and lung dysfunction.[54,55] Treatment with anti-C5a antibodies in an animal (primate) model of ARDS resulted in improved oxygenation and circulatory parameters.[45] Serum levels of C5a and C3a in humans with ARDS may reflect the severity of lung injury and might be useful for predicting clinical outcome.[56] Based on these and other findings, a phase I clinical trial used recombinant soluble CR1 in patients with ARDS,[57] but phase II trials will be necessary to determine the potential benefits of such treatment.

ISCHEMIA-REPERFUSION AND ORGAN TRANSPLANTATION

Clinical settings of ischemia-reperfusion, such as myocardial infarction, artery stenosis, thrombosis, and dissecting aortic aneurysm, as well as solid organ transplantation and heart surgery, are accompanied by rapid changes in cell homeostasis, leading to perturbations in signaling pathways and surface molecule expression. Depending on the time and severity of ischemia-reperfusion, toxic products accumulate intracellularly, leading to apoptosis and necrosis, causing loss of organ function. Depending on the duration and severity of ischemia-reperfusion, the injury may be completely or partially reversible. After the reestablishment of blood flow to the organ, oxygenation occurs, and repair mechanisms may be set into motion. During reperfusion, activation of the complement system and incoming neutrophils contribute to further cell injury; such injury appears to be dependent on the amount of complement and neutrophil activation. Experimental data suggest that complement products of the classic pathway are associated with ischemia-reperfusion cardiac injury in rats,[58] rabbits,[59] and humans,[60] and that complement depletion reduces infarct size.[61] Different strategies to block complement activation in experimental settings of ischemia-reperfusion have been successful in terms of reducing organ damage and impairing function. In experimental models of acute myocardial ischemia-reperfusion, successful strategies include the application of soluble CR1 (sCR1),[62] C1 inhibitor,[63-65] blocking antibodies to C5[66] or C5a,[67,68] a small molecular inhibitor of C1s,[69] and antibodies to MBL.[70] These and other findings led to the first successful use of C1 inhibitors in patients receiving emergency surgery for failed percutaneous transluminal coronary angioplasty in 1998. In another study, C1 inhibitor was administered to neonates undergoing transposition of the large arteries, with the beneficial effect of less inflammatory response in the treated group.[71] These preliminary data have not been confirmed in larger clinical trials. Another promising strategy is the use of monoclonal antibodies to C5, which may benefit patients undergoing cardiopulmonary bypass procedures.[72] In these studies, patients treated with anti-C5 showed significantly reduced postoperative myocardial injury, fewer cognitive defects, and less blood loss, suggesting a range of benefits. These findings need to be replicated in large phase II clinical trials.

It has also been suggested that complement activation is a major mediator of hyperacute organ rejection after transplantation. In an experimental model of lung allotransplantation, the administration of sCR1 significantly limited the amount of acute and subacute rejection.[73] No clinical data exist demonstrating the potential benefits of such a strategy in organ transplantation in humans, however. It is not clear to what extent the different complement pathways contribute to ischemia-reperfusion–related injury (reviewed in reference 74).

AUTOIMMUNE DISEASES

Various autoimmune diseases are associated with circulating immune complexes and evidence of complement activation. A possible role of complement activation in the development and progression of autoimmune diseases has been suggested. C1q, C4, C3, and C5b-9 have been found in association with tissue damage in SLE, RA, Sjögren's syndrome, Behçet's syndrome, bullous pemphigoid, dermatomyositis, myasthenia gravis, Alzheimer's disease, multiple sclerosis, and other neurologic diseases. Tissues often affected by complement activation in these autoimmune diseases are skin, kidney, choroid plexus, blood vessels (endothelial cells), and skeletal muscle. A strategy to target complement activation in these diseases in a clinical setting has not yet been developed. A few prominent examples are discussed here.

SYSTEMIC LUPUS ERYTHEMATOSUS

As mentioned earlier, complement deficiencies, especially in the classic pathway, are often associated with SLE. Indeed, C4 serum levels in SLE patients are often reduced (consumptive hypocomplementemia) and may be a useful monitor of disease progression.[34] About one third of SLE patients also have autoantibodies to C1q. In addition, in SLE nephritis, C3 deposition often occurs in kidney glomerular mesangial cells and is strongly associated with the severity of the nephritis. Blockade of C5 in a rodent model of SLE resulted in improved survival and reduced proteinuria and glomerular damage.[75] SLE mice that were deficient in factor B (alternative complement pathway) also showed less renal disease progression.[76]

RHEUMATOID ARTHRITIS

In the synovial fluid of RA patients, elevated levels of C5b-9 are frequent.[77,78] Interaction of C5b-9 with synovial fibroblasts in RA has been demonstrated.[79] In an experimental model of RA in rodents, blockade of the late complement components with monoclonal antibodies to C5 resulted in amelioration of disease activity and partial reversal of joint destruction.[80] Similar results were found in rodents treated with recombinant sCR1.[81] Genetic deficiency of C3, C5, or factor B significantly decreased joint destruction in RA models in rodents.[82-84] Accordingly, it has been suggested that the alternative complement pathway plays a critical role, in contrast to the classic pathway.[84] Recent studies demonstrated that C5a and its receptor, C5aR, are important mediators in experimental RA settings; blockade of C5aR with an oral antagonist or C5aR gene knockout resulted in greatly reduced joint destruction in such studies.[85,86] The complement system, therefore, appears to play a major role in the induction and progression of RA. The occurrence of C-reactive

protein may be important for complement activation in RA in humans.[87]

IMMUNE COMPLEX GLOMERULONEPHRITIS

Circulating immune complex (deposited in a subepithelial location) and locally formed immune complex (deposited subendothelially or mesangially) are the cause of various types of glomerular diseases (reviewed in detail elsewhere).[34] A pathogenetic role for complement activation in immune complex–induced glomerulonephritis can be assumed from experimental Heymann glomerulonephritis models in which inhibition of complement activation resulted in attenuated acute and chronic renal injury. Genetic knockout of C3 as well as C4 in mice also resulted in beneficial effects in a glomerulonephritis model.[88,89] Similar results were obtained when various C3 inhibitors were overexpressed.[90,91]

ALZHEIMER'S DISEASE

This degenerative disease is characterized by "senile plaques," consisting of neurofibrillary tangles and interstitial deposition of β-amyloid in the brain tissue and cerebral blood vessels. In Alzheimer's disease, the presence of C1q, C3, C4, and C5b-9 has been demonstrated in senile plaques, suggesting a pathogenetic role for the complement system.[92,93] Other studies demonstrated that β-amyloid (peptides 39-43) effectively activates the classic complement pathway via C1q.[94] In addition, it was demonstrated that the production of C1 inhibitor in brain cells is reduced in senile plaques from Alzheimer's patients.[95] A recent study suggested a prominent role for C5aR in Alzheimer's disease progression,[96] and activation of the complement system may also be a key factor.[97] Recent studies provide evidence of the potential beneficial role of the complement product C3 in a mouse model of Alzheimer's disease; overexpression of a soluble complement receptor-related protein y (sCrry), which initiates C3 activation, caused increased deposition of β-amyloid, suggesting a possible regulatory role for C3.[98] Even though the complement system appears to be involved in the progression of Alzheimer's disease, it is not clear to what extent therapeutic strategies targeting activation of the complement system might be beneficial.

ACUTE BURN INJURY

Evidence of activation of the complement system in patients with acute burn injuries was found in the 1970s.[99] Subsequent studies demonstrated early consumptive depletion of C1q, C3, C4, and C5 after burn injury[100,101] and the generation of C3a.[102] Neutrophil activation is related to increased expression of CR1 and CR3 on neutrophils in burn patients.[103] In rodent models of burn injury, complement activation and deposition at the site of tissue injury were also noted,[104,105] and the generation of hydroxyl radicals was suggested as an initiating mechanism.[106] Additional activation of the alternative complement pathway in a murine model of burn injury worsened the outcome.[107] The vascular injury in the lungs of mice following thermal skin injury revealed a strict dependency on the generation of C5a, suggesting that this anaphylatoxin is a major player in burn-associated tissue injury.[108] In subsequent studies, complement inhibition with sCR1 in a rodent model of thermal injury demonstrated significant reduction in associated lung injury (reduced vascular lack of albumin and reduced hemorrhage).[109] In a thermal injury model in pigs, complement inhibition with C1 inhibitor was also reported to be beneficial,[110] perhaps related to reduced bacterial translocation in the gut barrier after skin burn injury[111] and significant reduction in vascular leak.[112] Clinical trials to confirm these findings have yet to be done.

ACUTE TRAUMA

Trauma patients often show elevated levels of inflammatory mediators in the blood. Tissue injury is believed to trigger an acute inflammatory response, especially by activation of the complement system. Although the exact mechanisms of such activation are not yet understood, it has been reported that patients with traumatic brain injury show elevated levels of the complement components C3 and factor B in cerebrospinal fluid.[113] An important role of the complement system has also been suggested in patients with multiple trauma, in whom elevated levels of complement activation products have been found. Elevated C3a levels reportedly correlate with outcome.[114,115] The complement system's role in organ dysfunction has been suggested in animal models of closed head injury.[116] One study reported that C5aR was induced on neurons after closed head injury in mice, mediated by tumor necrosis factor and lymphotoxin-α.[117] Recent studies suggest that in patients with head injury, elevated levels of C3b and C5b-9 are present,[113,118] the latter correlating with blood-brain barrier dysfunction.[119] Despite the strong evidence for the role of complement activation in trauma-related tissue injury, only one study exists demonstrating the beneficial effects of complement inhibition (using C1 inhibitor) in a murine model of acute trauma.[120] Whether therapeutic intervention (complement inhibition) in patients with acute trauma would be beneficial remains speculative. If so, the timing of drug administration would be crucial for achieving maximal clinical success.

CONCLUSION

Activation of the complement system appears to be a double-edged sword. Although complement activation is a crucial defensive function of the innate immune system in combating invading microorganisms, it also appears to be responsible for a variety of harmful effects. A broad spectrum of stimuli can activate the complement system, leading to the production of powerful proinflammatory and potentially harmful mediators such as the anaphylatoxin C5a and C5b-9. The complement system is clearly involved in the progression of autoimmune diseases and plays a role in acute inflammatory conditions such as sepsis, burn injury, trauma, and ischemia-reperfusion–related injury (e.g., myocardial ischemia and organ transplantation). In all these disorders, inhibition of complement activation has been demonstrated to have beneficial effects in experimental settings. Only preliminary data from clinical studies of complement inhibition in acute inflammatory disorders are available. In these studies, C1 inhibitor (in sepsis trials) and sCR1 and monoclonal antibodies against C5 (in trials of cardiopulmonary bypass) have been used and suggest potential benefits. However, larger clinical trials employing these interventions are needed.

Because the complement system is involved in so many different physiologic systems and defense mechanisms, each acute inflammatory disorder likely requires a specific target in the complement system for optimal beneficial effects. More research is needed to understand the precise contribution of the various complement activation pathways and the specific complement activation products involved in clinical disorders. General problems of drug discovery (half-life, side effects, safety, costs) and the potential problem of increased susceptibility to infection are important considerations if complement activation is to be inhibited (discussed in detail in reference 121).

Recent experimental data suggest the benefits of inhibiting C5a or C5aR with antibodies or with small molecular chemical inhibitors (especially for ischemia-reperfusion injury, sepsis, and RA). Because this approach does not target complement activation in general (as does C1 inhibitor or sCR1) but rather targets a more specific activation product downstream, this strategy appears to be promising and needs to be evaluated in a clinical setting.

Given the impressive experimental evidence of the beneficial effects of complement inhibition in various acute inflammatory (and other) disorders, it seems likely that successful therapeutic strategies will be developed in clinical settings in humans in the near future.

Chapter 36

CYTOPATHIC HYPOXIA: MITOCHONDRIAL DYSFUNCTION IN SEPSIS

Mitchell P. Fink

KEY POINTS

1. Adenosine triphosphate (ATP) is the **energy currency of the cell.**
2. **Aerobic generation of ATP** by a process termed oxidative phosphorylation is carried out in cells by specialized organelles, the mitochondria.
3. Data from studies using animal models of sepsis or biopsies of human skeletal muscle support the view that **severe sepsis is associated with derangements in cellular respiration and mitochondrial dysfunction**; this phenomenon has been termed cytopathic hypoxia.
4. Although it is now well established that mitochondrial function is impaired in sepsis, **it remains to be determined whether cytopathic hypoxia is an epiphenomenon or one that actually contributes to organ dysfunction and mortality.**

According to the first law of thermodynamics, the total amount of energy in a system remains constant before and after any sort of transforming event. The second law of thermodynamics holds that even though the total amount of energy does not change after a transforming event, the total amount of usable energy—the Gibbs free energy (G)—always decreases. In accordance with the second law, all reversible chemical reactions proceed in a direction that results in a net decrease in the Gibbs free energy for the system; in other words, the change in G (ΔG) is always less than zero. When cells in living systems need to carry out a reaction for which ΔG is positive, they couple the reaction to another reaction that is energetically favorable (i.e., characterized by $\Delta G < 0$). If the algebraic sum of the ΔGs for the two coupled reactions is negative, formation of the desired product can proceed. Within cells, the exergonic reaction that drives the formation of the desired product is almost always the hydrolysis of the terminal pyrophosphate ester linkage of adenosine triphosphate (ATP) to yield adenosine diphosphate (ADP) and inorganic phosphate anion (Pi). The hydrolysis of ATP also drives other energy-requiring processes in cells, such as the active pumping of solutes against a concentration gradient across a membrane barrier. Thus, for proper functioning, all cells need a steady supply of ATP. Stated another way, ATP is the energy currency of the cell.

ATP can be generated in cells as a result of both aerobic and anaerobic processes. Anaerobic generation of ATP, or of the energetically equivalent compound guanosine triphosphate (GTP), occurs in both the cytosol and the mitochondria as a result of the phosphorylation reactions that are catalyzed by the enzymes phosphoglycerate kinase, pyruvate kinase, and succinyl coenzyme A synthase. Aerobic generation of ATP occurs in the mitochondria as a result of a carefully orchestrated series of reactions that effectively couple the oxidation of substrates by molecular oxygen (O_2) to the phosphorylation of ADP to form ATP.

Good "reducing agents" are elements or compounds that have a strong propensity to donate electrons to another element or compound. Conversely, good "oxidizing agents" are elements or compounds that avidly accept electrons. Molecular oxygen is a very potent oxidizing agent. Two strong reducing agents—the reduced forms of nicotinamide adenine dinucleotide (NADH) and flavin adenine dinucleotide ($FADH_2$)—are produced in cells during certain enzymatic reactions that occur during glycolysis and the citric acid cycle. In mitochondria, these two reducing agents are oxidized by O_2, and the energy released during this process is used to drive the formation of ATP.

The reaction of a strong reducing agent, such as NADH, with a powerful oxidizing agent, such as O_2, releases a large amount of energy (i.e., ΔG is very negative). To take optimal advantage of this highly exergonic redox reaction and capture as much of the energy released as possible in a usable form (i.e., the high-energy terminal pyrophosphate bond of ATP), mitochondria "step down" the reducing potential of NADH (and $FADH_2$) in stages. Thus, the electrons are not transferred from NADH to O_2 all at once; rather, they are transferred through a series of intermediate compounds, called electron carriers, that have progressively lower reducing potentials. Several of the electron carriers involved in the mitochondrial respiratory chain are organized as complexes (called complexes I to IV) located within the inner mitochondrial membrane (Fig. 36-1). These complexes use the energy released during electron transfer to actively pump hydrogen ions from the mitochondrial matrix into the intermembrane space, thereby generating an electrochemical gradient across the inner mitochondrial membrane. The presence of this gradient drives hydrogen ions through a mitochondrial enzyme, F_oF_1-ATPase, that catalyzes the formation of ATP from ADP and Pi.

For each mole of glucose metabolized to carbon dioxide and water, the net yield of ATP from substrate-level (anaerobic) phosphorylation reactions is 4 moles of ATP, whereas

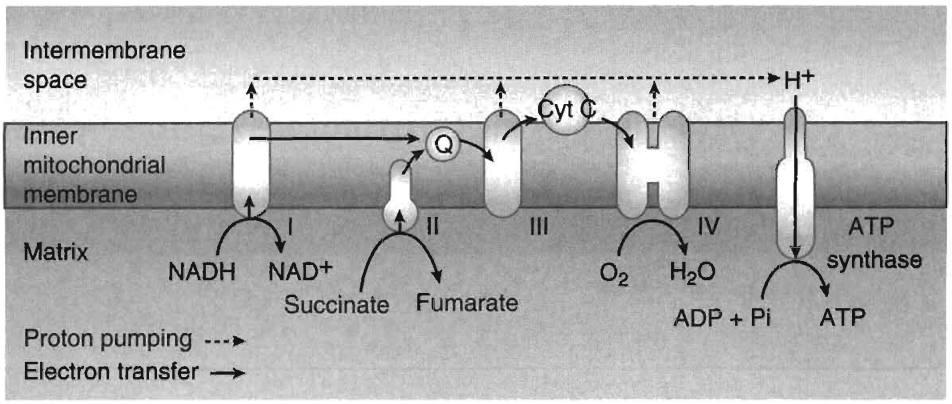

FIGURE 36–1. Diagrammatic representation of mitochondrial electron transport and proton pumping across the inner mitochondrial membrane. Oxidation or conversion of succinate to fumarate requires reducing equivalents supplied by flavin adenine dinucleotide ($FADH_2$). ADP, adenosine diphosphate; ATP, adenosine triphosphate; Cyt C, cytochrome *c*; NAD, nicotinamide adenine dinucleotide; NADH, reduced form of NAD; Pi, inorganic phosphate; Q, ubiquinone. (Adapted from Brealey D, Singer M: Mitochondrial dysfunction in sepsis. Curr Inf Dis Rpt 2003;5:365-371.)

the net yield of ATP from oxidative phosphorylation reactions is 32 moles of ATP. Thus, oxidative metabolism in normally functioning mitochondria is far more efficient at producing ATP than is anaerobic metabolism, and many cell types, such as hepatocytes, neurons, and cardiac myocytes, are dependent on a steady supply of O_2.

EVIDENCE FOR IMPAIRED MITOCHONDRIAL RESPIRATION IN SEPSIS

Convincing data support the view that early, aggressive efforts to improve systemic O_2 delivery by administering intravenous fluids, packed red blood cells, and inotropic agents can improve outcome for patients with septic shock.[1] By the same token, however, efforts to improve systemic O_2 delivery later in the course of sepsis are at best ineffective[2,3] and at worst deleterious.[4] If improving perfusion and O_2 delivery in patients with established sepsis fails to improve survival or prevent organ system dysfunction, one might wonder whether alterations in energy metabolism are important at all in the pathogenesis of the syndrome.[5] Alternatively, one could hypothesize that cellular energetics are deranged in sepsis not just because O_2 delivery is impaired but also because the cells' ability to use available O_2 is compromised. The term *cytopathic hypoxia* has been used to describe such an acquired intrinsic derangement in cellular respiration.[6,7] Although the clinical significance of this phenomenon has not been established with certainty, accumulated evidence supports the notion that cytopathic hypoxia occurs when certain cell types are exposed to proinflammatory cytokines or sera from septic patients in vitro.[8-10] Further, it is fairly clear that mitochondrial function is impaired in experimental animals with sepsis or endotoxemia.[11-15]

Measurements of Tissue Oxygen Partial Pressure and Cytochrome a,a_3 Redox State. Tissue hypoxia is an expected correlate of any of the three classic causes of impaired cellular aerobic metabolism identified by Barcroft more than 80 years ago.[16] Thus, when the delivery of O_2 decreases on the basis of low arterial oxygen tension (PO_2), anemia, or hypoperfusion, cells extract a greater fraction of the available O_2 in an effort to defend aerobic ATP production. As a consequence, the distribution of tissue PO_2 values shifts to the left (i.e., closer to 0). In contrast, when ATP production is impaired as a result of an intrinsic derangement in cellular respiration, cells extract less O_2 per unit time from the available supply. The expected consequence of this change in O_2 extraction is a rightward shift in the tissue PO_2 distribution (i.e., toward higher values).

One line of evidence that supports the concept of cytopathic hypoxia comes from studies measuring tissue PO_2 in patients or experimental animals. If tissue hypoperfusion is a major factor contributing to cellular dysfunction in sepsis, septic shock, or endotoxemia, one would predict the detection of abnormally low tissue PO_2 values in these conditions. However, if classic tissue hypoxia is not important, or if the main problem is an intrinsic derangement in cellular O_2 use, one would predict normal or even supranormal tissue PO_2 values in animals or patients with sepsis. Indeed, observations of this sort have been reported.

Astiz and colleagues used cecal ligation and puncture (CLP) in a rat model of sepsis and showed that mean skeletal muscle PO_2 was similar in septic animals and normal controls, provided that the rats with peritonitis were infused with albumin solution to expand intravascular volume.[17] In a conceptually similar study, Hotchkiss and coworkers used a novel approach to determine whether tissue hypoxia occurs after the induction of sepsis in rats.[18] Tissue PO_2 was not measured directly but was estimated by measuring the retention of [^{18}F]-fluoroisonidazole, a lipophilic 2-nitroimidazole derivative that is irreversibly bound to intracellular macromolecules under hypoxic, but not normoxic, conditions. Retention of [^{18}F]-fluoroisonidazole in a variety of tissues, such as skeletal muscle and liver, was similar in septic rats and nonseptic controls. These data provide very strong evidence that sepsis in rats is not associated with tissue hypoxia.

Some data support the even more remarkable conclusion that tissue PO_2 actually increases in sepsis relative to normal values. For example, VanderMeer and colleagues used a porcine model to investigate the effects of endotoxemia on intestinal mucosal PO_2.[19] When anesthetized pigs were infused with lipopolysaccharide (LPS) and simultaneously resuscitated to maintain normal cardiac output, mean mucosal PO_2 increased significantly. Similarly, Rosser and coworkers reported that bladder mucosal PO_2 increased in rats challenged with LPS.[12] The same pattern has been observed in humans. Boekstegers and colleagues showed that the distribution of PO_2 values in skeletal muscle was shifted to the left in patients with cardiogenic shock, as expected, but was shifted to the right (i.e., to supranormal values) in patients with septic shock.[20] Similar findings were reported by Sair and associates.[21] These data are consistent with the view that cellular utilization of O_2 is impaired in patients with sepsis and septic shock.

This same idea is supported by another related study. Simonsen and colleagues used near-infrared spectroscopy to monitor the redox state of the terminal element of the mitochondrial respiratory chain, cytochrome oxidase, in skeletal

muscle cells of baboons rendered septic by an infusion of viable *Escherichia coli*.[22] The functional status of cytochrome oxidase was monitored by periodically causing temporary skeletal muscle ischemia using a proximally placed tourniquet. Inflating the tourniquet caused a decrease in the spectroscopic signal from oxidized cytochrome oxidase, whereas deflating the tourniquet resulted in an increase in the signal from the oxidized enzyme. Early in the sepsis protocol (i.e., at 6 hours), the rate of cytochrome oxidase reduction following tourniquet ischemia was the same as at baseline, although the rate of reoxidation following the release of ischemia was slowed. These data are consistent with the notion that delivery of O_2 to the tissue is decreased early in sepsis. Later in the sepsis protocol (e.g., at 18 hours), the rate of cytochrome oxidase reduction during tourniquet ischemia was markedly slowed, a finding that was thought to be consistent with either a defect in the enzyme's ability to accept electrons from O_2 or a limitation in the availability of reducing equivalents (i.e., NADH, $FADH_2$, or both). These data are particularly interesting because they suggest that cytopathic hypoxia is not present early in sepsis but develops after the septic process has evolved for many hours. These temporal considerations might explain the positive results obtained in a clinical trial of early, goal-directed hemodynamic support by Rivers and associates[1] and the negative results obtained in similar trials that included patients with more established critical illnesses.[3,4]

Not all studies of sepsis have obtained data showing that tissue PO_2 values are normal or increased. Indeed, contrary findings have been reported by a number of investigators. For example, two studies showed that intestinal mucosal PO_2 decreased when experimental animals were infused with LPS to a sepsis-like state.[23,24] Similarly, Sair and colleagues reported that skeletal muscle PO_2 decreased markedly in a rat model of endotoxemia.[25] Differences in the timing of the measurements (i.e., early versus late sepsis) or in the adequacy of resuscitation might explain the discordant findings regarding tissue PO_2 levels in different studies.

Measurements of Mitochondrial Respiration. The colorless compound 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) is reduced by functioning mitochondria to a blue dye (MTT-formazan). Concentration of the blue product can be determined spectrophotometrically. Thus, reduction of MTT is a convenient, albeit indirect, way to assess mitochondrial function. In 1974, Bankey and coworkers used this approach to assess mitochondrial function in cocultures of rat hepatoctyes and rat liver macrophages.[26] Sequential stimulation of the cultures with a proinflammatory cytokine, interleukin-6 (IL-6), and then LPS decreased MTT reduction by about 50%. Similar results were reported more recently by Zingarelli and colleagues, who showed that MTT reduction is decreased in cultured macrophages and vascular smooth muscle cells after incubation with a proinflammatory cytokine, interferon gamma (IFN-γ), plus LPS.[27]

Unno and coworkers used the reduction of MTT to MTT-formazan to assess mitochondrial function in vivo.[28] In this study, rats were injected with saline or a low dose of LPS that caused neither hypotension nor mortality. Twenty-four hours later, the lumen of the intestine was loaded with a solution of MTT. After a 30-minute incubation period, the epithelial layer was scraped off the intestine, and the concentration of MTT-formazan in enterocytes was determined spectrophotometrically. MTT reduction was significantly lower in enterocytes from endotoxemic rats than in those from normal controls. When the endotoxemic rats were treated with aminoguanidine, a drug that blocks inducible nitric oxide synthase (iNOS), MTT reduction was restored to normal levels. This latter finding suggests that impaired mitochondrial respiration in sepsis is mediated, at least in part, by a mechanism that depends on increased production of the mediator, nitric oxide (NO), due to up-regulated expression of the enzyme, iNOS.

The MTT assay reflects the activity of a number of different dehydrogenases, particularly succinate dehydrogenase,[29] and is not a direct measure of mitochondrial O_2 consumption per se. Several studies have obtained more direct evidence that cellular or mitochondrial respiration is impaired in animals with sepsis or endotoxemia. For example, Kantrow and associates showed that hepatocytes isolated from septic rats consumed significantly less O_2 than did hepatocytes from nonseptic control rats.[30] Later, King and colleagues showed that ileal mucosal O_2 consumption is impaired in endotoxemic rats.[11] In these studies, rats were injected with either LPS or a similar volume of the saline vehicle. Eight hours later, a strip of ileal mucosa was obtained from the animals and mounted in a polarographic chamber to determine the rate of O_2 consumption (Fig. 36-2). The decrease in the rate of ileal mucosal O_2 consumption induced by LPS injection was not due to decreased delivery, because the measurements were made ex vivo with the tissue suspended in a well-oxygenated buffer. If the endotoxemic rats were treated with aminoguanidine to block iNOS activity, normal ileal mucosal O_2 consumption was preserved. Thus, these findings support the notion that the development of cytopathic hypoxia in LPS-challenged rats requires iNOS-dependent NO production.

Chen and coworkers evaluated cardiac muscle mitochondrial function in rats with sepsis induced by CLP.[31] As in some previous studies, these investigators evaluated mitochondrial function both early after the onset of sepsis (9 hours after CLP) and later (18 hours after CLP). Rather than measuring cellular or mitochondrial O_2 consumption, these investigators used standard enzymatic assays to determine the activities of

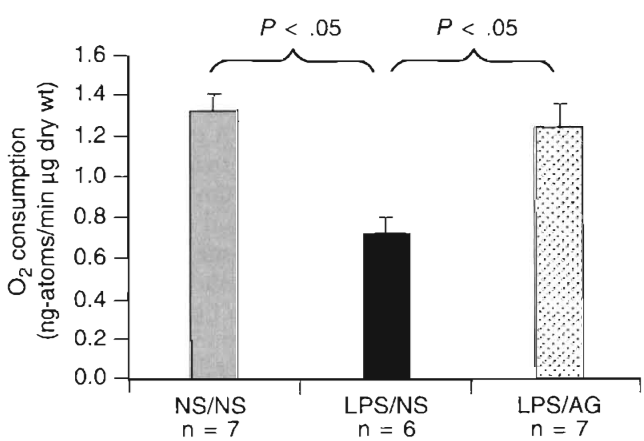

FIGURE 36–2. Effect of lipopolysaccharide (LPS) on ileal mucosal oxygen (O_2) consumption. Rats in the NS/NS group were injected at 0 hours with normal saline (NS) and treated with NS. Rats in the LPS/NS group were injected with LPS (5 mg/kg) at 0 hours and treated with NS. Rats in the LPS/AG group were challenged with the same dose of LPS and treated with aminoguanidine (AG; 30 mg/kg per dose at 1, 3, and 6 hours). Ex vivo O_2 consumption was measured at 8 hours. (Adapted from King CJ, Tytgat S, Delude RL, Fink MP: Ileal mucosal oxygen consumption is decreased in endotoxemic rats but is restored toward normal by treatment with aminoguanidine. Crit Care Med 1999;27:2518-2524.)

key mitochondrial enzymes (NADH cytochrome *c* reductase, succinate cytochrome *c* reductase, cytochrome *c* oxidase). Early after the induction of sepsis, these enzymatic activities were normal, as was expression of the four mitochondrial enzyme complexes involved in electron transport and respiration (complexes I to IV), as assessed by Western blotting. In contrast, in samples of cardiac tissue obtained 18 hours after the onset of sepsis, the function of all three mitochondrial enzymes was significantly decreased, as was the expression of complexes II and IV.

In addition to the results from animal studies, there are now data from clinical studies that support the idea that mitochondrial function is impaired in human sepsis as well. Brealey and coworkers assessed mitochondrial function in skeletal muscle biopsies obtained from 28 critically ill septic patients within 24 hours of admission to an ICU, as well as in biopsies obtained from 9 control patients undergoing elective hip surgery.[32] Using standard polarographic methods, these investigators assessed the activity of the four mitochondrial enzyme complexes responsible for electron transport and respiration (complexes I to IV). The biopsy specimens were also analyzed with respect to several other relevant biochemical parameters, including ATP concentration and nitrite-nitrate concentration (an index of NO production). Of the 28 patients with sepsis, 16 survived and 12 died. Complex I activity was significantly lower in septic nonsurvivors than controls. Skeletal muscle ATP concentrations were significantly lower in the 12 patients with sepsis who died than in the 16 septic patients who survived ($P = 0.0003$) and in controls ($P = 0.05$). Complex I activity was inversely correlated with tissue nitrite-nitrate concentration ($P = 0.0004$), suggesting that increased NO production and sepsis-induced cytopathic hypoxia are linked phenomena.

POTENTIAL MECHANISMS OF CYTOPATHIC HYPOXIA IN SEPSIS

INHIBITION OF PYRUVATE DEHYDROGENASE

The end product of glycolysis is pyruvic acid, a three-carbon alpha-keto acid. Pyruvic acid can either be reduced to lactic acid or enter the tricarboxylic acid (TCA) cycle, ultimately to be oxidized to water and carbon dioxide. The rate-limiting step for entry of pyruvate into the TCA cycle is the reaction catalyzed by the enzyme complex pyruvate dehydrogenase (PDH). In the presence of NAD^+ (the oxidized form of nicotinamide adenine dinucleotide) and coenzyme A, PDH converts pyruvate into acetyl coenzyme A. Because of its pivotal role in the regulation of intermediary metabolism, the activity of PDH is tightly regulated by both end-product inhibition and reversible phosphorylation. A group of isoenzymes, the PDH kinase family, catalyzes the phosphorylation of PDH to its inactive form (PDH_i). A PDH phosphatase catalyzes the dephosphorylation of PDH_i to the active form of the enzyme complex (PDH_a). Vary and coworkers showed that the PDH_i/PDH_a ratio in skeletal muscle tissue increases during chronic sepsis in rats.[33,34] The mechanism responsible for this effect is increased PDH kinase activity rather than decreased PDH phosphatase activity.[35,36] Because inactivation of PDH limits the flux of substrate through the TCA cycle, excess pyruvate accumulates in cells, leading to increased production of lactate. Thus, according to the data obtained by Vary and coworkers, hyperlactatemia in sepsis is not necessarily evidence of impaired O_2 delivery but may be the result of the combined effects of PDH inhibition and accelerated glucose transport into cells.[34] Some clinical data support this notion.[37]

NITRIC OXIDE–MEDIATED INHIBITION OF CYTOCHROME OXIDASE

Sepsis is associated with iNOS induction and increased production of the pluripotent signaling and effector molecule NO.[38] At physiologically relevant concentrations (~1 μM), NO rapidly, but reversibly, inhibits the activity of cytochrome oxidase, the terminal enzyme complex of the mitochondrial electron transport chain.[39-42] NO-mediated inhibition of mitochondrial O_2 consumption is the result of competition by the two gases (O_2 and NO) for the same binding site on the enzyme complex.[43,44] Accordingly, the inhibitory effect of NO tends to be more pronounced when PO_2 is relatively low.[40-42] Although much of the work related to this mechanism has been done using NO derived from an exogenous source (i.e., authentic NO gas or a chemical compound that releases NO in solution), it is clear that endogenously produced NO is also capable of causing reversible inhibition of cytochrome oxidase, leading to reduced cellular respiration.[45]

PEROXYNITRITE-MEDIATED INHIBITION OF MITOCHONDRIAL ENZYMES

Under the right conditions, NO reacts rapidly with a partially reduced form of O_2, superoxide radical anion (O_2^-), to form peroxynitrite ($ONOO^-$), a molecular species that is a potent oxidizing, nitrosating, and nitrating agent.[46-49] Appropriate conditions for the production of $ONOO^-$, namely, biosynthesis of approximately equimolar levels of NO and O_2^- in close proximity, are present in many cell types during sepsis. In addition, small quantities of O_2^- are continually being produced by mitochondria. Under certain conditions, such as when O_2 availability is limited[50] or cytochrome oxidase is inhibited by NO,[51] mitochondria generate increased quantities of O_2^- by this mechanism. Moreover, a calcium-dependent NOS isoform that is either identical or very similar to neuronal NOS is present in mitochondria.[52-56] Thus, within the confines of the organelle itself, mitochondria are capable of generating both NO and O_2^- and, under appropriate conditions, large quantities of the potentially toxic moiety $ONOO^-$.[54,57]

Incubating mitochondria with authentic $ONOO^-$ causes irreversible inhibition of mitochondrial respiration. The deleterious effects of $ONOO^-$ on mitochondrial function are potentiated by increases in the concentration of ionized calcium (Ca^{++}).[58,59] The synergistic effects of $ONOO^-$ and Ca^{++} are likely important in a number of pathophysiologic conditions relevant to critical care medicine (e.g., inflammation, tissue ischemia followed by reperfusion), because these conditions are known to increase intramitochondrial concentrations of both species.

Several mechanisms have been implicated as being important in this phenomenon. Specifically, $ONOO^-$ has been shown to inhibit the mitochondrial F_oF_1-ATPase that phosphorylates ADP to form ATP.[60] In addition, $ONOO^-$ inhibits two of the mitochondrial enzyme complexes (I and II) that are involved in electron transport.[60] Finally, $ONOO^-$ inhibits the activity of aconitase, the TCA cycle enzyme that converts citrate into isocitrate.[61] Endogenous production of

$ONOO^-$ secondary to iNOS induction plus O_2^- generation has been implicated as the major factor in impaired mitochondrial respiration in some tissues, such as rat diaphragm, following in vivo challenge with LPS.[15] Data obtained by Brealey and colleagues support the view that complex I activity is impaired in skeletal muscle biopsy samples from patients with lethal septic shock, probably as a result of increased production of NO or a related compound, such as $ONOO^-$.[32]

THE PARP HYPOTHESIS

PARP-1 is a nuclear enzyme that participates in a variety of cellular functions, including the repair of single-strand breaks in nuclear DNA,[62,63] DNA replication,[64] and apoptosis.[64] PARP-1 is activated by single-strand breaks in nuclear DNA and then catalyzes the cleavage of NAD^+ into ADP-ribose and nicotinamide and the polymerization of the resultant ADP-ribose units into branching poly(ADP-ribose) homopolymers.[65,66] The poly(ADP ribose) generated by this process is degraded by various nuclear enzymes, most notably poly(ADP-ribose) glycohydrolase.[66,67] The concurrent actions of PARP-1 and poly(ADP-ribose) glycohydrolase constitute the functional equivalent of an NADase. In states of acute inflammation, reactive oxygen species, including $ONOO^-$ (and related oxidants), cause single-strand breaks in nuclear DNA and thereby activate PARP-1. Activation of PARP-1 has also been identified within mitochondria following oxidant stress,[68] suggesting that damage to mitochondrial DNA induced by reactive oxygen species might be another mechanism leading to activation of the PARP pathway. Activation of PARP-1 leads to intracellular depletion of NAD^+ and its reduced form, NADH. Because NADH is the main reducing equivalent used to support oxidative phosphorylation, activation of PARP-1 can lead to a marked impairment in the cells' ability to use O_2 to support ATP synthesis—in other words, cytopathic hypoxia.

The notion that redox stress can lead to PARP-1 activation and hence metabolic inhibition was first proposed by Schraufstatter and associates.[69,70] More recently, Szabó and coworkers showed that exposure of cultured cells to physiologically relevant concentrations of $ONOO^-$ activates PARP-1 and thereby impairs mitochondrial respiration.[71] They further showed that endogenously generated $ONOO^-$ was capable of activating PARP-1 and thereby inhibiting mitochondrial respiration in cultured immunostimulated macrophages[72] and vascular smooth muscle cells.[73]

Recent in vitro studies by Khan and colleagues support the importance of PARP-1–dependent NAD^+/NADH depletion as a mechanism for cytopathic hypoxia caused by inflammatory mediators.[8] The consumption of O_2 by human Caco-2 enterocyte-like cells was measured using an O_2-sensitive optode. Incubation of the cells with cytomix—a cocktail of three proinflammatory cytokines (tumor necrosis factor, IL-1β, and IFN-γ)—decreased cellular O_2 consumption by more than 50%. This phenomenon was entirely reversible; if the cells were washed free of the cytokine cocktail and then incubated for a short period in normal culture medium, the normal rate of O_2 consumption was restored. Thus, the cytokine-induced decrease in O_2 consumption was caused not by cell death but by a sublethal process that impaired normal cellular respiration. The decrease in O_2 consumption induced by incubation with cytomix was significantly ameliorated by pharmacologically blocking NO or $ONOO^-$ production, providing further support for the role of NO and related compounds in the pathogenesis of cytopathic hypoxia. Moreover, pharmacologic inhibition of PARP-1 also ameliorated the development of cytopathic hypoxia, providing support for the PARP hypothesis. The decrease in O_2 uptake induced by cytomix was associated with significantly decreased cellular levels of NAD^+/NADH. Interestingly, incubating the cytomix-stimulated Caco-2 cells with NAD^+ encapsulated in liposomes partially restored cellular NAD^+/NADH levels and prevented the development of cytopathic hypoxia.

In addition to the findings just described, other data support the view that PARP-1 activation is a major factor in the pathogenesis of sepsis. For example, using pharmacologic agents to block PARP-1 activity can prevent LPS-induced vascular contractile dysfunction in rodents.[74,75] Moreover, in comparison to wild-type controls, mice with a genetic defect in the PARP-1 enzyme (i.e., PARP-1 knockout mice) are relatively resistant to the lethal effects of LPS.[76,77] Treatment with a potent PARP-1 inhibitor, PJ34, significantly improves survival in a porcine model of lethal bacterial peritonitis.[78]

The notion that NO-dependent activation of PARP-1 contributes to the pathogenesis of cytopathic hypoxia is also supported by clinical data. Specifically, Boulos and colleagues showed that serum samples from patients with septic shock inhibited the reduction of MTT by cultured human umbilical vein endothelial cells, whereas sera from control subjects did not have this effect. When the endothelial cells were treated with a PARP-1 inhibitor, 3-aminobenzamide, or with an NOS inhibitor, *N*-methyl-L-arginine, the impairment in mitochondrial respiration (as assessed by MTT assay) induced by sera from septic patients was significantly ameliorated.[9]

Despite the findings cited here, the PARP-1 story is more complicated than originally envisioned. It is now recognized that PARP-1 participates in activation of the proinflammatory transcription factor nuclear factor kappa-B (NF-κB). PARP-1 participates in NF-κB–dependent signaling by binding directly to the transcription factor,[79,80] binding to another coactivating molecule (the protein p300),[81] or poly(ADP-ribosyl)ating NF-κB.[82] These effects are not dependent on PARP-1–induced alterations in intracellular energy metabolism but can nonetheless explain why a genetic deficiency in PARP-1 or treatment with a PARP-1 inhibitor can alter responses to a proinflammatory stimulus such as LPS (see earlier). To further complicate matters, activation of PARP-1 conceivably can alter energy metabolism independent of any direct effects on mitochondrial function; recent data indicate that activation of PARP-1 can promote poly(ADP-ribosyl)ation of glyceraldehyde phosphate-3-dehydrogenase, a key enzyme in the glycolytic pathway.[83]

CYTOPATHIC HYPOXIA AS A CAUSE OF ORGAN DYSFUNCTION DUE TO SEPSIS

A decade ago, the notion that sepsis is associated with mitochondrial dysfunction was controversial. Indeed, a number of studies suggested that acute sepsis or endotoxemia in animal models caused an *increase* in mitochondrial function.[84,85] Today, few dispute that sepsis is associated with an acquired intrinsic derangement in cellular respiration (cytopathic hypoxia). It remains unclear, however, whether cytopathic hypoxia is an epiphenomenon or a pathophysiologic mechanism that actually contributes to organ dysfunction and, ultimately, mortality in patients with sepsis or septic shock.

For cytopathic hypoxia to impact the function or viability of cells (and hence the function of organs), the impairment in mitochondrial function has to be severe enough to cause a decrease in the cellular phosphorylation potential, the rate of ATP turnover, or both. The phosphorylation potential is determined by the relative concentrations of ATP, ADP, and Pi: phosphorylation potential = [ATP]/[ADP][Pi]. In many in vitro studies, the function or viability of cells is not markedly altered unless the ATP concentration or phosphorylation potential is substantially reduced (≤70% of normal).[86-89]

In animal models, the effects of sepsis on cellular ATP content are variable, depending on myriad factors, including the method of inducing sepsis (or systemic inflammation), the timing of the ATP measurements with respect to the onset of the inflammatory process, the tissue or organ studied, and the assay used to assess ATP concentration. When rodents are injected with LPS, ATP levels in a variety of organs typically decrease significantly,[90,91] although ATP levels in skeletal muscle are typically unchanged.[91-93] If skeletal muscle is stimulated to induce repetitive contraction, however, it is possible to detect impaired synthesis of ATP.[93] It is unclear whether LPS-induced depletion of cellular ATP concentration in rodent models of septic shock is due to impaired perfusion, mitochondrial dysfunction, or some combination of the two.

Despite the findings just cited, it is important to recognize that acute endotoxemia in rodents is probably not a good animal model for sepsis-induced multiple organ dysfunction in humans. Accordingly, it is pertinent that several studies have failed to detect evidence of cellular ATP depletion in animal models of sepsis characterized by the presence of a true focus of infection (e.g., CLP in rats).[94-97] Contrary results have been reported, however, possibly because of differences between early and late sepsis.[98] Further, in the clinical study by Brealey and colleagues cited previously, ATP levels were significantly lower in skeletal muscle biopsy samples from patients with lethal sepsis than in samples from sepsis survivors or control subjects.[32] Thus, the question of whether sepsis leads to ATP depletion must be regarded as open and worthy of further study.

Steady-state levels of ATP (or even phosphorylation potential) may not be the most important parameter. The rate at which ATP is consumed and synthesized (i.e., the ATP turnover rate) may be more important, because it is conceivable that cells could defend ATP concentration in the setting of either classic hypoxia or cytopathic hypoxia by decreasing the rate at which ATP is used; this phenomenon has been termed metabolic suppression.[99,100]

To investigate this issue, Berg and coworkers used an in vitro "reductionist" model of sepsis to test the hypothesis that ATP turnover rate is modulated by the presence of a proinflammatory milieu. Nontransformed rat enterocytes were studied under control conditions or following incubation for 24 or 48 hours with cytomix, a mixture of the proinflammatory cytokines tumor necrosis factor, IL-1β, and IFN-γ. To measure ATP turnover rate, ATP synthesis was acutely blocked by adding to the cells a mixture containing 2-deoxyglucose (to block glycolysis), potassium cyanide, and antimycin A (to inhibit oxidative phosphorylation). ATP content was measured at baseline (before metabolic inhibition) and 0.5, 1, 2, 5, and 10 minutes later. Log-linear ATP decay curves were generated, and the kinetics of ATP utilization were calculated. Remarkably, the ATP consumption rate was higher in cytomix-stimulated cells than in control cells. In contrast, the rate of ATP disappearance was similar in cytokine-naïve and immunostimulated IEC-6 cells when protein and nucleic acid synthesis was inhibited, suggesting that the increased rate of ATP synthesis following incubation with cytomix was used to support increased protein synthesis. The rates of glucose consumption and lactate production were significantly greater in cytomix-stimulated cells, suggesting that the increased rate of ATP turnover was supported by enhanced (aerobic) glycolysis. Other investigators have shown that experimental sepsis is associated with accelerated aerobic glycolysis,[101] and clinical data are available to support this view as well.[102] It is noteworthy, therefore, that Scharte and coworkers showed that proinflammatory cytokines increase the expression of glycolytic genes in cultured epithelial cells, even in the absence of hypoxia.[103]

CONCLUSION

Several lines of evidence support the notion that cellular respiration is deranged in established sepsis, not just on the basis of inadequate tissue perfusion but also on the basis of impaired mitochondrial function. If this concept is correct, a promising approach will be to develop pharmacologic strategies—for example, administration of potent and selective PARP-1 inhibitors—to restore normal mitochondrial function. Further research is needed to determine whether altered cellular respiration during sepsis truly contributes to cellular and organ dysfunction or is simply an epiphenomenon.

This study showed that ileal mucosal oxygen consumption (assessed ex vivo) is impaired in rats injected 8 hours earlier with lipopolysaccharide, but this effect is abrogated if the animals are treated with a drug that blocks the enzymatic activity of inducible nitric oxide synthase.

Chapter 37
OXIDATIVE LUNG INJURY

Todd L. Astor • David Weill

KEY POINTS

1. In pulmonary tissue, smooth muscle cells, endothelial cells, alveolar cells, and leukocytes have all been shown to **produce free radicals.**
2. **Superoxide** may have the most central role in oxidative lung injury because of its dual ability to directly alter cellular proteins and to form other highly reactive radical species.
3. The **most significant sources of free radicals** in lung tissue cells are the mitochondria and endoplasmic reticulum.
4. **Nitric oxide** is highly radical as a result of an odd number of electrons and through a variety of reactions produces reactive nitrogen species.
5. The **most rapid formation of reactive nitrogen species** occurs as a result of a radical-radical reaction between nitric oxide and various free radicals.
6. **Three enzyme systems** are primarily responsible for the enzymatic component of the antioxidant defenses: (1) superoxide dismutase (SOD); (2) catalase; and (3) the glutathione system.
7. **Several nonenzymatic antioxidants contribute to the cellular defenses** by acting as scavengers of toxic radicals.
8. **Reactive oxygen and nitrogen pulmonary cytotoxicity** is primarily mediated by two mechanisms: (1) lipid peroxidation and (2) damage to DNA.
9. **A variety of pulmonary cell types are susceptible to oxidant toxicity.**
10. **Reactive oxygen and nitrogen species** can affect pulmonary artery smooth muscle contractility and endothelial cell proliferation.
11. A **combination of necrosis and apoptosis** is likely involved in **oxidant-induced lung injury.**
12. **Animal and human studies demonstrate mixed results** concerning the sensitivity of healthy lungs to hyperoxic exposure.
13. **Results of animal studies** show that oxidative lung injury plays a major role in hyperoxia-induced lung injury.
14. The antioxidant response to hyperoxia-induced free radical formation is a complex process that is dependent on changes in expression of a variety of enzymes and nonenzymatic scavenger compounds.
15. There is now substantial evidence that generation of oxidative and nitrosative species is a major contributor to inflammatory lung injury in ARDS.
16. Certain antioxidants that function well under normal physiologic conditions may become overwhelmed in ARDS, whereas others demonstrate increased expression and activity.
17. Ischemia-reperfusion lung injury continues to be a significant cause of early morbidity after lung transplantation.
18. Generation of reactive oxygen species occurs as a direct result of both anoxia-reoxygenation and ischemia-reperfusion that occurs during the procurement-storage-transplantation period.
19. Elevated levels of free iron, calcium, and activated leukocytes increase the generation of free radicals during ischemia-reperfusion of the allograft.
20. Paraquat, bleomycin, and nitrofurantoin are examples of agents with the potential for inducing oxidative lung injury.
21. Hyperoxic therapy has been implicated as the principal inciting factor in the development of bronchopulmonary dysplasia in infants.
22. Oxidative lung injury in bronchopulmonary dysplasia is primarily a result of the oxidation of surfactants, lipids, and proteins.
23. The antioxidant response in newborns with bronchopulmonary dysplasia is variable and is in large part dependent on the stage of development of the infant (i.e., preterm vs. term).
24. Limited data on the use of oxygen therapy suggest minimizing the length of exposure to an F_IO_2 higher than 0.6, utilizing oxygen-sparing interventions, and avoiding oxygen therapy in patients with lung injury secondary to specific toxins.
25. Mechanical ventilation with a low tidal volume strategy (6 mL/kg) should be utilized in patients with possible oxidant lung injury.
26. Although several studies demonstrate a potential benefit for exogenous antioxidant administration, there are not yet enough conclusive data to support its routine use in the clinical setting.

Since the discovery of oxygen in 1775 we have marveled at the life-sustaining power that it possesses. However, we have also realized that oxygen holds the potential for the spoliation of life. Early scientists such as Priestley, Scheele, Lavoisier, Laplace, and Bert all recognized this "two-faced" nature of oxygen and conducted studies to better understand its destructive nature.[1-4] These studies were the preface to the understanding that we now have of the toxic effects of oxygen and its reactive metabolites, collectively known as oxidant injury. Oxidant injury can occur throughout the body, but the lung is the most susceptible organ, and lung injury induced by reactive oxygen species is often devastating and irreversible.

GENERATION OF REACTIVE OXYGEN SPECIES

In pulmonary tissue, smooth muscle cells, endothelial cells, alveolar cells, and leukocytes have all been shown to produce free radicals.[5-8] Superoxide may have the most central role in oxidative lung injury because of its dual ability to directly alter cellular proteins and to form other highly reactive radical species. Superoxide radicals are produced by both cellular enzymatic and nonenzymatic (auto-oxidation) reactions. Enzymes capable of forming superoxide include xanthine oxidase (by the oxidation of purines and of NADH), arachidonic acid peroxidases, nitric oxide synthase, NADPH oxidase, and NADH oxidase.[9-12] Phagocytic cells in the lung can form large amounts of superoxide during bursts of respiratory activity.[13]

The most significant sources of free radicals in lung tissue cells are the mitochondria and endoplasmic reticulum.[14-16] Formation of free radicals requires the presence of molecular oxygen and is a constant process occurring in normal cellular metabolism. Molecular oxygen is reduced by the sequential addition of electrons to form the highly reactive free radicals superoxide radical (O_2^-), hydrogen peroxide (H_2O_2), and hydroxyl radical (OH•):

$$O_2 \rightarrow O_2^- \rightarrow H_2O_2 \rightarrow OH\bullet \rightarrow H_2O$$

Two molecules of water are produced in the reduction of molecular oxygen in a reaction catalyzed by cytochrome oxidase in the electron transport chain in the mitochondria. Cytochrome oxidase, which contains cytochrome a and cytochrome a3, acts as the terminal electron receptor. Under normal conditions there exists a small loss of electron flow (1% to 2%) along the proximal portion of the electron transport chain. Electron loss first occurs during the reduction of NADH dehydrogenase to form a flavin semiquinone free radical, which then reacts with O_2 to form O_2^- (auto-oxidation). Ubiquinone is the second site of electron loss, and the reduction of ubiquinone forms the ubisemiquinone free radical by auto-oxidation. Another important source of O_2^- is the electron transport chain of the endoplasmic reticulum.[16] In the endoplasmic reticulum O_2^- is most likely produced from the auto-oxidation of reduced NADPH cytochrome P_{450} reductase and the reduced cytochrome P_{450}.

Regardless of its source of production, O_2^- is relatively unstable. It can react with proteins that contain transition metal groups (e.g., heme, iron-sulfur), resulting in alteration of cellular function.[17-19] The majority of O_2^- produced, however, is converted to H_2O_2 in a reaction catalyzed by superoxide dismutase[20]:

$$O_2^- + O_2^- + 2H^+ \rightarrow H_2O_2 + O_2^-$$

H_2O_2 is a more stable, nonradical compound. Most of the cellular damage by H_2O_2 results from its further reduction to form hydroxyl radicals by a series of iron catalyzed reactions. Iron is first reduced by O_2^- in the Haber-Weiss reaction, and the reduced form of iron in turn reduces H_2O_2 to form OH• in the Fenton reaction.[21] OH• is also produced directly from O_2^- in a reaction involving hypohalous acids.[22,23] Hypohalous acids are potent oxidants formed when H_2O_2 is oxidized by eosinophil-specific peroxidase and neutrophil-specific peroxidase in the presence of a halide.

GENERATION OF REACTIVE NITROGEN SPECIES

Nitric oxide (NO) is a cytotoxic agent present in many types of environmental pollutants, including cigarette smoke.[24] NO has also been shown to be produced endogenously throughout the body and serves a variety of significant regulatory functions. Nitric oxide synthase (NOS) catalyzes the formation of NO from L-arginine.[25,26] There are constitutive (NOS I, NOS III) and inducible (NOS II) forms of NOS. The constitutive forms are Ca^{++} and calmodulin dependent and synthesize small amounts of NO for brief periods. The inducible form produces large amounts of NO for extended periods.[27,28]

Nitric oxide is highly radical as a result of an odd number of electrons and through a variety of reactions produces reactive nitrogen species. In the presence of molecular oxygen, NO can be oxidized to nitrite (NO_2^-). The formation of NO_2^- leads to the oxidation of various biologic substrates in a reaction catalyzed by heme peroxidases such as MPO and EPO.[29-31] NO_2^- itself is oxidized to nitrogen dioxide radical ($NO_2\bullet$), as well as to nitrate (NO_3^-). Oxidation of NO by oxyhemoglobin (HbO_2) may lead to the formation of methemoglobin (Hb^{3+}) and NO_3^-.[32]

Potentially the most rapid formation of reactive nitrogen species occurs as a result of a radical-radical reaction between NO and various free radicals. For example, $ONOO^-$ is formed by the reaction on NO with O_2^-. $ONOO^-$ can be protonated to form peroxynitrous acid (ONOOH), a highly unstable and reactive compound capable of both oxidizing and nitrating reactions involving a variety of biochemical substrates (e.g., lipids, amino acids).[33]

ANTIOXIDANT MECHANISMS

During normal aerobic metabolism in lung cells, reactive oxygen and nitrogen species are produced that, at low levels, serve a variety of important biologic functions. However, these reactive metabolites are potentially very damaging to biologic substrates such as lipids, proteins, and carbohydrates. A system of enzymatic and nonenzymatic antioxidants exists in the lung to prevent the formation and facilitate the removal of these reactive species.

Three enzyme systems are primarily responsible for the enzymatic component of the antioxidant defenses: (1) superoxide dismutase (SOD); (2) catalase; and (3) the glutathione system. SOD is both an intracellular and extracellular enzyme,

located in the cytosol, in the mitochondria, and on the outside of the plasma membrane.[34-36] The cytosolic form of SOD contains copper and zinc and is associated with pulmonary and endothelial vascular smooth muscle cells. The mitochondrial form contains manganese and is abundant in pulmonary artery smooth muscle and endothelium.[35] During times of oxidative stress, SOD has a significant role in protecting lung cells by catalyzing the dismutation of O_2^- to H_2O_2.[37]

Catalase and the glutathione system are the central mechanisms for the reduction of H_2O_2. Catalase is a hemoprotein found in peroxisomes. It has an iron-heme active site that undergoes divalent oxidation and reduction in catalyzing the reduction of H_2O_2.[38] The glutathione system is likely more important than catalase in the reduction of H_2O_2 and is also responsible for the elimination of lipid peroxidases formed from the free radical altered lipid membranes.[39] The glutathione system is actually a redox cycle in which the key enzyme is glutathione peroxidase. Glutathione peroxidase catalyzes the reduction of H_2O_2 and lipid peroxidases by using reduced glutathione as a cosubstrate. This reaction forms glutathione disulfide, which is subsequently reduced back to glutathione by glutathione reductase.[40] Glutathione reductase activity is dependent on NADPH generated from the hexose monophosphate shunt.[41]

Several nonenzymatic antioxidants contribute to the cellular defenses by acting as scavengers of toxic radicals. Vitamin E, the most important of these compounds, protects against oxidant-induced membrane injury by scavenging lipid peroxide radicals.[42] Thioredoxins, a newly described family of proteins located in the inner mitochondrial membrane of airway epithelial cells, respond to oxidative stress by scavenging reactive species and activating other antioxidant systems such as Mn-SOD.[43] Metallothionein, a metalloprotein expressed in pulmonary endothelial cells, is thought to have an important function in intracellular iron homeostasis and as a free radical scavenger of superoxide radicals.[44] Other free radical scavengers include vitamin C, uric acid, beta carotene, taurine, albumin, and bilirubin.

PATHOPHYSIOLOGY OF OXIDATIVE LUNG INJURY

Reactive oxygen and nitrogen species are cytotoxic to virtually all types of pulmonary cells. This toxicity is primarily mediated by two mechanisms: (1) lipid peroxidation and (2) damage to DNA.

All cell membranes are made up of polyunsaturated fatty acids. The hydroxyl free radical is particularly destructive to these fatty acids by removing a hydrogen atom from the fatty acid, resulting in the formation of peroxides and peroxyradicals. These radical intermediates may then remove another hydrogen atom from a different fatty acid, leading to a chain reaction resulting in the rapid destruction of the cellular membrane.[45] In addition, membrane phospholipase A_2 may be activated during lipid peroxidation, potentially contributing to the breakdown of the lipid bilayer.[46]

Cellular DNA is also a susceptible target for reactive oxygen species. The hydroxyl radical has been shown to directly hydroxylate guanine.[47] Reactive lipid species formed during lipid peroxidation are able to cross-link DNA proteins and cause strand breaks.[48] It has been suggested that this results in the activation of poly (adenosine diphosphate-ribosyl) polymerase (PARP), resulting in excessive consumption of adenosine triphosphate (ATP) and cell death.[49] Some environmental toxins and drugs cause DNA damage through the formation of active complexes with DNA in the presence of oxygen (see section on bleomycin-induced lung injury).[50] Reactive oxygen species have also been implicated in the modulation of gene transcription. Schreck and coworkers have proposed a role for superoxide in the activation of nuclear factor-kappa B (NF-κB), a potent regulator of gene transcription.[51] Demple and associates demonstrated a superoxide effect on gene transcription that may protect the host in which superoxide activates a system (soxRS system) of transcription/translation that leads to the expression of superoxide dismutase.[52]

Oxygen free radicals also have a profound effect on pulmonary artery smooth muscle contractility and can cause vasoconstriction through several mechanisms. Superoxide radical destroys the NO that is produced in the vascular endothelium, thus blocking the vasodilatatory effect induced by NO.[53] Superoxide, in the presence of xanthine oxidase, can also directly stimulate the contraction of pulmonary artery rings, most likely through a mechanism involving protein kinase C.[54] Superoxide is also capable of stimulating the release of calcium from the sarcoplasmic reticulum, as well as increasing the microsomal ATP-dependent calcium uptake in pulmonary vascular smooth muscle cells.[55]

All pulmonary cell types are susceptible to oxidant toxicity. Pulmonary artery endothelial cells initially proliferate in response to superoxide exposure and are stimulated to release higher concentrations of superoxide than quiescent cells. Continued superoxide exposure results in DNA strand breakage resulting in the depletion of ATP and also causes membrane lipid peroxidation. Both mechanisms contribute to an inhibition of endothelial cell proliferation.[56] Bronchial and type I alveolar epithelial cell death occurs in the early stages of oxidant injury and is likely due to a pattern of necrosis rather than apoptosis.[57] Type I alveolar cells are then replaced by hyperplasia of type II alveolar epithelial cells, resulting in a thicker alveolar epithelium.[58] Clara cells, nonciliated epithelial cells distributed throughout the respiratory tree, are extremely rich in cytochrome P_{450} and thus are very sensitive to oxidant stress.[59] Naphthalene exerts its toxic effects primarily through selective damage to Clara cells.[60] Finally, although oxidant lung injury may indeed stimulate inflammatory cells to proliferate and further generate reactive oxygen species, there is some evidence that oxidants may impair the antibacterial function of these inflammatory cells. For example, O'Reilly and colleagues demonstrated impaired phagocytic function due to actin polymerization in mouse alveolar macrophages during hyperoxic exposure.[61] This process appears to be due to NO and the nitration of actin and does not occur in the absence of inducible NOS.

The mode of cell death in oxidant-induced lung cell injury and death is controversial and has been attributed to both necrosis and apoptosis. Animal studies have suggested that although apoptosis may play a key role in programmed lung cell death, necrosis is the predominant mode of death occurring in oxidant lung injury.[49] However, it has been postulated that apoptosis may play a role in limiting the extent of oxidative lung injury and in the remodeling of lung tissue during the repair phase.[62]

OXIDATIVE LUNG INJURY IN THE ICU

The specific pathology and natural history of oxidative lung injury varies with specific disease states. The cascade of events usually involves an acute phase in which cell injury results from the initial generation of reactive oxygen species. This is followed by an inflammatory phase, in which cell death occurs from the response of mononuclear cells and alveoli become obliterated with exudate and hyaline membrane formation. Finally, in extensive disease a proliferative phase usually occurs, leading to proliferation of type II alveolar cells and fibroblasts. Ultimately, fibrosis in the lung interstitium may occur.[63]

We will examine the specific mechanisms of oxidative lung injury in five specific pathologic lung conditions frequently encountered in the ICU: (1) hyperoxia-induced lung injury; (2) ARDS; (3) ischemia/reperfusion injury; (4) lung injury from exposure to toxins; and (5) bronchopulmonary dysplasia. Oxidant lung injury has been implicated in many other lung diseases, including asthma, sarcoidosis, idiopathic pulmonary fibrosis, and radiation pneumonitis. Discussion of these pulmonary disorders is beyond the scope of this chapter.

HYPEROXIA

Treatment with high concentrations of oxygen is often necessary to treat acute and chronic hypoxemia in patients with lung disease. Hyperoxia has been shown to damage alveolar epithelial cells and pulmonary vascular endothelial cells in several animal models. However, studies in humans have demonstrated mixed results concerning the ability of hyperoxic exposure to cause significant lung injury in the absence of underlying lung disease.

Results of early studies analyzing changes in vital capacity with hyperoxic exposure suggested that the safe threshold of P_IO_2 is close to 0.6 atm.[64] This estimation was supported later by data from the U.S. Navy's shallow habitat air diving (SHAD) program studying long-term survival in a compressed air environment.[65,66] During several stages of this study men underwent shallow habitat dives with a P_IO_2 of 0.51 atm and 0.57 atm for a period of 29.5 days and 28 days, respectively. All men tolerated the protocol well and there was no evidence of decreased pulmonary function. In the final arm of this study men were exposed to cycles of 0.51 atm and 0.81 atm, with a mean of 0.61 atm. These subjects demonstrated chest discomfort as well as decreases in the vital capacity that correlated with the exposure to the P_IO_2 of 0.81 atm.

Determining the threshold for oxygen toxicity in actual patients is even more difficult. Patients requiring acute oxygen therapy usually have severe parenchymal lung injury, and therefore interpretation of worsening lung injury while receiving oxygen therapy can be obscured. However, there are several reports in the literature examining the effects of hyperoxic therapy on patients receiving mechanical ventilation for reasons other than primary lung disease. Singer and associates reported that post–cardiac surgical patients exposed to 100% F_IO_2 for a mean of 24 hours demonstrated no adverse effects when compared with a similar group receiving a mean F_IO_2 of 0.32.[67] Smith and coworkers analyzed pulmonary function, radiographs, and pathology in 41 patients treated with high-frequency jet ventilation using a mean F_IO_2 of 0.92 for a mean of 4.1 days and did not find any evidence of oxygen toxicity.[68] Kobayashi described a 32-year old patient with myasthenia gravis who, because of technical limitations of a ventilator, was ventilated with an F_IO_2 of 0.80 for 150 days.[69] Despite developing blindness secondary to systemic oxygen toxicity, this patient developed no evidence of pulmonary oxygen toxicity.

In contrast to these reports demonstrating an absence of pulmonary oxygen toxicity in patients receiving hyperoxic therapy, Barber and colleagues reported adverse pulmonary effects of hyperoxic ventilation in patients with cerebral trauma.[70] Patients ventilated with an F_IO_2 of 100% for a mean of 2 days had a lower mean PaO_2, increased deadspace, and worsening of chest radiographs when compared with a similar group ventilated with room air. However, at autopsy there were no histopathologic differences discovered between the two groups, suggesting that hyperoxia-induced atelectasis may have played a greater role than direct parenchymal lung injury in explaining the clinical differences.

Therefore, the degree of sensitivity of healthy lungs to hyperoxia remains unclear. In addition, the specific underlying pathophysiologic phenomena causing the observed clinical sequelae are not known. For example, a decrease in vital capacity may result from an acute tracheobronchitis and hypoxemia could be a manifestation of absorption atelectasis. Also, as previously mentioned, patients receiving hyperoxic therapy usually have underlying lung disease and distinguishing the etiology of their lung physiology and histopathology is impossible.

Because of these difficulties in studying a human lung model of hyperoxia, there has been a strong reliance on animal studies to help elucidate the mechanisms of hyperoxic lung injury. There is now significant evidence that oxidant injury plays a principal role in hyperoxia-induced lung injury. Gerschman and colleagues first suggested that hyperoxia-induced tissue injury results from the generation of oxygen-derived free radicals.[71] Freeman and associates[14] demonstrated that hyperoxia increases oxygen free radical production in rat lungs. The cellular enzymatic and nonenzymatic (auto-oxidation) reactions generating free radicals during normoxia were previously discussed. Production from each of these sources is increased during hyperoxia, but the nonenzymatic formation of free radicals (auto-oxidation) appears to play a much more significant role.[14]

As previously described, several enzymes play important roles in the generation of O_2^- and other reactive species. These enzymes demonstrate low Michaelis-Menten kinetics. They are saturated with molecular oxygen during normoxia, and therefore their rates of reaction are not increased with higher concentrations of oxygen.[14] In addition, there appear to be negative feedback mechanisms that may lower enzyme activity during hyperoxia. For example, Elsayed and coworkers showed that hyperoxia decreases the activity of xanthine oxidase both in rat lungs and in cultured lung endothelial cells.[72] The decreased activity was reproduced with purified enzyme in the presence of oxygen free radicals, supporting the theory of a feedback mechanism.

The most important source of increased free radical production during hyperoxia is the auto-oxidation of flavins and quinones in the electron transport chains of the mitochondria and endoplasmic reticulum.[73] These reactions demonstrate first-order kinetics, and therefore the rate of formation of free radicals is proportional to the concentrations of molecular oxygen and the oxidizable substrate.[14] Grisham and coworkers estimated that during hyperoxia with 100% oxygen, 85% of the free radicals produced by

lung cells are produced in the electron transport system of the endoplasmic reticulum and the remaining 15% are generated in the mitochondria.[74]

The antioxidant response to hyperoxia-induced free radical formation is a complex process that is dependent on changes in expression of a variety of enzymes and nonenzymatic scavenger compounds. Studies of gene expression in wild-type and knockout mice have better elucidated antioxidant expression during hyperoxia.[75] Perkowski and associates demonstrated no change in the gene expression of the antioxidant enzymes catalase, manganese SOD, and copper-zinc SOD in mice exposed to greater than 95% oxygen. However, there was a moderate increase in the expression of glutathione peroxidase and heme oxygenase-1, as well as a 7-fold increase in the expression of the heavy metal binding protein metallothionein.

ACUTE RESPIRATORY DISTRESS SYNDROME

ARDS is a lung disease characterized by a diffuse, patchy pattern of inflammation in the lung parenchyma. The pathogenesis of ARDS involves a complicated cascade of humoral and cellular responses.[76] After an initial insult (i.e., infection, sepsis, trauma, severe burns) there is a massive release of inflammatory cytokines such as tumor necrosis factor-alpha, IL-1, and IL-6, leading to the activation of lung epithelial, endothelial, and mononuclear cells. There is an increase in the expression of various adhesion molecules, selectins, and integrins that induces the extravasation and adhesion of neutrophils and eosinophils to lung tissue. The ensuing lung injury results from the inflammatory response by these activated cells. Until recently the mechanisms by which lung injury occurs have not been well understood.

There is now substantial evidence that generation of oxidative and nitrosative species is a major contributor to inflammatory lung injury in ARDS.[77] Oxidant free radicals are produced by activated neutrophils and macrophages, as well as by lung endothelial, epithelial, and alveolar cells. Similarly, synthesis of NO and other reactive nitrogen species is increased in lung inflammation.[78]

Cochrane and colleagues were the first to demonstrate evidence of oxidant activity in ARDS.[77] $Alpha_1$-proteinase inhibitor (PI), an inhibitor of elastase found in the lung, was found to be inactivated in the bronchoalveolar lavage (BAL) fluid, but not the plasma, from patients with ARDS. In addition, the activity of the inactivated $alpha_1$-PI was restored with a reducing agent. Later studies showed an increased level of H_2O_2 in the expired breath condensates from patients with acute lung injury/ARDS as compared with patients with healthy lungs.[79] Weiland and Laurent found increased superoxide levels in leukocytes isolated from the blood from patients with ARDS.[80] Evidence of accelerated superoxide generation in ARDS has been demonstrated in several recent human and experimental animal studies. Quinlan and coworkers demonstrated increased levels of hypoxanthine and xanthine, substrates for xanthine oxidase, in the plasma from patients with ARDS.[81] In an experimental in-situ lung model of endotoxin-induced ARDS in rats, increased levels of superoxide were observed by use of chemiluminescence.[82]

Nitric oxide has also been shown to possess a significant role in ARDS. NO can be produced by airway epithelial cells, endothelial cells, and type II alveolar cells, as well as by activated neutrophils and macrophages.[83,84] There is evidence that synthesis of NO and other reactive nitrogen species is increased during lung inflammation in ARDS. Sittipunt and colleagues measured increased levels of nitrate and nitrite, breakdown products of NO, in the BAL fluid from patients with or at risk for ARDS.[85] The levels of nitrate and nitrite decreased to near-normal levels several weeks after the onset of ARDS. These results were supported in a similar study by Zhu and coworkers demonstrating significantly higher levels of nitrate in pulmonary edema fluid collected with a wedged suction catheter from patients with ARDS.[86] Other studies have addressed the toxic effects of these reactive intermediates by measuring the byproducts of nitration reactions involving a variety of functionally important lung proteins. Nitrotyrosine, the end product of the nitration of the tyrosine residues of many proteins, has been found in tissues during acute inflammation.[85] Increased levels of nitrotyrosine have been shown both in pulmonary edema and BAL fluid from patients with ARDS.[85,86] Nitrated ceruloplasmin, transferrin, $alpha_1$-PI, and $alpha_1$-antichymotrypsin have all been detected in the plasma from patients with ARDS.[87] Nitrated surfactant protein A has been discovered in the edema fluid from patients with ARDS.[86] Because it has been previously suggested that surfactant protein A may play a role in the removal of infectious pathogens from the alveolar space, it has been hypothesized that the nitration of this protein may alter its function and render the patient with ARDS more susceptible to secondary infections.[88]

Together these results support a significant role for oxidant-mediated lung injury in ARDS. Therefore, antioxidant expression and activity would seem to be a principal factor in moderating damage to lung tissue. Several studies have demonstrated a decrease in the level of several antioxidants in patients with ARDS. For example; levels of glutathione, an antioxidant with the significant role of reducing H_2O_2, were found to be decreased in the BAL fluid of patients with ARDS.[89] However, levels of catalase, another antioxidant responsible for the reduction of H_2O_2, were actually increased.[90] Other studies have demonstrated an increase in the response of some antioxidants and a decrease in others in both plasma and BAL fluid from patients with acute lung injury. These results suggest that whereas certain antioxidants that function well under normal physiologic conditions may become overwhelmed in ARDS, others demonstrate increased expression and activity.

ISCHEMIA-REPERFUSION LUNG INJURY

Since 1983 lung transplantation has become the definitive therapy for patients with end-stage lung disease. However, despite improvements in the selection of donors, preservation of donor lungs, surgical techniques, and perioperative care, ischemia-reperfusion lung injury continues to be a significant cause of early morbidity after lung transplantation. Ischemia-reperfusion lung injury is characterized by a pattern of alveolar damage, pulmonary edema, and hypoxemia that occurs within the first 72 hours after transplantation.[91] Several factors likely contribute to the extent of injury, including donor lung injury, hypothermic storage, and increased organ ischemia time. Although several mechanisms for ischemia-reperfusion injury have been proposed, generation of reactive oxidative species appears to play a principal role. Oxidative stress occurs as a direct result of both anoxia-reoxygenation and ischemia-reperfusion that occurs during the procurement-storage-transplantation period.[91]

During the period in which the donor lung is not ventilated, hypoxia/anoxia results in a significant decrease in the level of ATP and a subsequent increase in the degradation product hypoxanthine.[92] Hypoxanthine is oxidized to form superoxide radicals in a reaction catalyzed by xanthine oxidase, an enzyme found in abundance in the pulmonary vascular endothelium.[9,27,97] This reaction cannot occur in the absence of oxygen, and therefore a buildup of hypoxanthine takes place during the anoxic period. On ventilation/reoxygenation with transplantation, the hypoxanthine generates high concentrations of superoxide. Zhao and colleagues demonstrated that this process is disrupted with allopurinol, an inhibitor of xanthine oxidase.[93]

Storage of the donor lung is characterized by a period of ischemia in which there is no blood flow into the lung. Oxidant generation from ischemia occurs primarily in the endothelial cells and is not dependent on hypoxia.[96] In response to the absence of the mechanical component of blood flow during ischemia, the endothelial cell membrane is depolarized, activating NADPH oxidase, nitric oxide synthase, and NF-κB.[97,98] As previously discussed, these enzymes catalyze the reactions generating reactive oxygen and nitrogen species.

Free radical–induced lung damage is influenced by other processes occurring during ischemia-reperfusion injury. Levels of free iron are increased during ischemia as a result of its release from ferritin and cytochrome P_{450}.[99,100] Iron undergoes reduction and oxidation and is responsible for catalyzing the production of hydroxyl radical from superoxide and hydrogen peroxide in the Haber-Weiss and Fenton reactions. Iron may also contribute to oxidant stress by enhancing the oxidation of glutathione and the peroxidation of lipids.[101] Iron chelators such as deferoxamine have been shown to be effective in moderating ischemia-reperfusion injury in animal models.[102] Other factors that may influence or contribute to oxidant injury include elevated levels of cytosolic calcium (increases conversion of xanthine dehydrogenase to xanthine oxidase) and leukocyte activation (increases free radical production through membrane bound NADPH oxidase system).[103,104]

TOXIN-INDUCED OXIDANT LUNG DAMAGE

Many environmental and pharmacologic compounds can cause significant lung injury. These compounds can inflict toxic effects through a variety of mechanisms and are associated with a spectrum of disease patterns.

Paraquat can cause toxic effects in the kidney, liver, and thymus, but the lung is the most common site of toxicity.[105] Animal studies have demonstrated that paraquat lung toxicity is characterized by a morphologic pattern of inflammatory cell infiltration, necrosis of type I and II alveolar cells, fibroblast infiltration and proliferation, and, finally, synthesis of large quantities of collagen. This cascade of events results in severe pulmonary fibrosis and can follow exposure by both parenteral and inhalational routes.[105-109]

The mechanisms of paraquat-induced lung injury have been well studied. Paraquat is a basic amine that, when taken up by the lung, results in significant increases in oxygen uptake and subsequent NADPH oxidation.[110] This is the first step of a redox cycle occurring in the endoplasmic reticulum of alveolar epithelial cells. Paraquat is reduced to a free radical in this reaction catalyzed by NADPH cytochrome c reductase. This free radical then immediately transfers its electron to molecular oxygen to form superoxide radical, and in the process it regenerates the original paraquat cation. The superoxide radical can then exert its direct toxicity or continue to react to form the equally dangerous hydrogen peroxide and/or hydroxyl radical. The regenerated paraquat cation is then free to restart the redox cycle, resulting in the generation of tremendous quantities of superoxide radicals.[110,111] Paraquat-induced lung injury has also been associated with increased NO synthesis, demonstrated by a decrease in injury with administration of inhibitors of NOS.[112]

With an understanding of these mechanisms of paraquat lung toxicity, one can predict the exogenous and endogenous factors that may influence the extent of lung damage. For example, Smith and Rose demonstrated that hyperoxia increases paraquat toxicity but hypoxia decreases it.[113] The host antioxidant response to paraquat toxicity is directed at the overwhelming production of superoxide. Animal studies have specifically identified important functions for glutathione, SOD, catalase, α-tocopherol, vitamin E, and selenium in counteracting paraquat-induced oxidant toxicity.[111]

Bleomycin is an antineoplastic drug used to treat various types of squamous cell cancers and lymphomas. Despite being a very effective cancer drug, its use is often limited by lung toxicity, initially manifesting as a pneumonitis and later progressing to pulmonary fibrosis.[114] The morphologic pattern of bleomycin-induced lung injury has been well studied in mice.[115] The initial stage of injury occurs within the first 4 weeks and is characterized first by vascular endothelial cell injury, followed by necrosis of type I alveolar epithelial cells, and finally by deposition of fibrin in the alveolar spaces. The second stage, typically occurring within 8 to 12 weeks, is characterized by metaplasia of type II alveolar epithelial cells, fibroblast organization and collagen deposition, and subsequent interstitial fibrosis.

The mechanisms of bleomycin-induced lung injury are not completely understood, but evidence strongly supports a role for reactive oxygen species. Scheulen and coworkers showed that cell destruction is a result of cleavage of both single- and double-stranded DNA and that this cleavage was dependent on oxygen, iron, and NADPH cytochrome P450 reductase.[116] In addition, bleomycin was found to significantly increase NADPH oxidation.[116] In response to these results, an active complex of bleomycin, iron, and oxygen has been implicated in the DNA damage associated with bleomycin lung injury, and three-dimensional models for this complex have been proposed.[117] Extracellular superoxide dismutase has been shown to play an important role in the antioxidant response to bleomycin-induced oxidative stress.[118]

Many other pharmaceutical and nonpharmaceutical agents are associated with oxidant-induced lung injury. Nitrofurantoin, an antibiotic used to treat urinary tract infections, causes lung toxicity by generation of superoxide, hydrogen peroxide, and hydroxyl radical by a mechanism similar to that of paraquat.[119] Naphthalene exposure can result in selective necrosis of pulmonary Clara cells and is likely mediated by reactive metabolites dependent on cytochrome P_{450}.[120] Vinylidine chloride (used in the plastics industry), malathion (insecticide), and 4-ipomeanol (produced by fungus in sweet potatoes) are all thought to induce oxidant-mediated lung injury through a variety of mechanisms.[121,122] Certain trace metals such as vanadium have been shown to cause lung injury through the induction of inflammation and apoptosis by reactive oxygen species.[123] Chronic exposure

to ethanol renders the lung susceptible to acute lung injury by decreasing glutathione levels and therefore indirectly increasing levels of oxygen free radicals.[124] Reactive intermediates have even been implicated in certain types of lung malignancies resulting from exposures to carcinogens, as in the case of many polycyclic aromatic hydrocarbons.[125]

BRONCHOPULMONARY DYSPLASIA

Bronchopulmonary dysplasia (BPD) is a lung disease in preterm infants that occurs usually as a complication of the respiratory distress syndrome. It is characterized by a histologic pattern of obliterative changes in the bronchioles with the formation of cysts.[126] Hyperoxic therapy has been implicated as the principal inciting factor, and in the past it has been suggested that the generation of reactive oxygen and nitrogen species is the major contributor to lung injury in BPD.[127,128] In fact, preterm infants are at particular risk for oxidative lung injury for several reasons: (1) deficiency in pulmonary surfactant; (2) decreased levels and function of antioxidant enzymes; (3) increased exposure to infections with subsequent inflammatory cytokine release; and (4) increased levels of free iron in the plasma.[129]

Recent evidence has strongly supported a role for oxidative lung damage in BPD. Oxidative lung injury in BPD is primarily a result of the oxidation of surfactants, lipids, and proteins. Several studies have demonstrated increased levels of oxidized ascorbic acid, uric acid, and *o*-tyrosine, all markers of peroxidation, in tracheal lavage fluid from preterm infants who later developed BPD.[130,131] Nogee and associates showed that superoxide, hydrogen peroxide, nitric oxide, and peroxynitrite all inactivate surfactant protein.[132] The oxidation of surfactant protein A results in a loss in its surfactant function and possibly its ability to augment the alveolar immune response to infection.[133] Pitkanen and colleagues measured an increased level of pentane and ethane, products of lipid peroxidation, in exhaled gas from preterm infants who later developed BPD.[134] Varsila and coworkers detected higher concentrations of carbonyl groups, side chains formed during the oxidation of proteins, in tracheal aspirates from newborns with BPD.[135]

The antioxidant response in newborns with BPD is variable and is in large part dependent on the stage of development of the infant (i.e., preterm vs. term). Animal studies of preterm newborns have demonstrated a lower level of intracellular enzymatic antioxidants such as glutathione when compared with term newborns.[136,137] In addition, in preterm newborns expression of antioxidant enzymes is not increased during times of oxidative stress.[138] The diminished antioxidant defenses in the newborn coupled with the increased oxidant production associated with early infection, inflammation, and oxygen therapy contribute to the lung injury associated with BPD.

EFFECTS OF ICU THERAPEUTIC INTERVENTIONS ON OXIDANT LUNG INJURY

OXYGEN THERAPY

Oxygen is the most common "drug" administered in the intensive care setting. The detrimental effects of oxygen and its reactive metabolites have been presented in detail. Oxygen toxicity can be viewed in a dose-response curve manner, with the dose equal to the product of the P_IO_2 and the duration of exposure. Therefore, as with all drugs, the minimum dose should be used that is necessary to induce the anticipated therapeutic benefit. As previously discussed, the determination of that threshold dose has been very difficult because of a number of confounding variables inherent in any human study of hyperoxic lung injury. However, from the data available the following recommendations can be made:

- Minimizing the length of exposure to elevated F_IO_2
- Utilizing oxygen-sparing interventions such as the application of positive end-expiratory pressure during mechanical ventilation and ensuring adequate oxygen delivery to organ tissues through the maintenance of cardiac output
- Avoiding oxygen therapy in patients with lung injury secondary to specific toxins (i.e., bleomycin, paraquat, and nitrofurantoin)

MECHANICAL VENTILATION

Ventilator management has been recognized as one of the most significant factors in determining clinical outcome in acute lung injury. Mechanical ventilation itself has been shown to induce a pattern of lung injury characterized by neutrophil infiltration of the interstitium and alveolar space and subsequent diffuse epithelial and endothelial cell injury.[139] These pathophysiologic effects are similar to those observed in ARDS and likely result from mechanical stress of alveolar overdistention and high transpulmonary pressures.[140] The ARDS Network published a landmark study in 2000 demonstrating that mechanical ventilation with low tidal volumes decreases mortality in patients with ARDS.[141] Several studies have suggested that a reduction in cytokine release is in part responsible for the protective effect of low tidal volume ventilation.[142] Hammerschmidt and associates demonstrated that mechanical ventilation with a low tidal volume (6 mL/kg) strategy attenuates increases in vascular permeability in a rabbit model of hypochlorite-induced oxidant lung injury. It has been further postulated that because mechanical ventilation may influence cellular metabolism, intrinsic antioxidant enzyme expression and function may be affected by ventilation strategy.[143] This limited evidence together with the results of the ARDS Network study support a recommendation of mechanical ventilation with a low tidal volume strategy (6 mL/kg) in patients with possible oxidant lung injury. In addition, adequate extrinsic positive end-expiratory pressure should be implemented in an attempt to reduce the F_IO_2 and minimize the potential for hyperoxia-induced oxidant injury.

ANTIOXIDANTS

A better understanding of the endogenous antioxidant response to oxidant stress has generated interest in the therapeutic potential for exogenous antioxidant administration. Studies of antioxidant therapy have focused on administration of both enzymatic and nonenzymatic antioxidants in a variety of lung diseases. Robbins and coworkers demonstrated a reduction in hyperoxia-induced lung injury with the use of recombinant human superoxide dismutase.[144] Gadek and associates administered enteral nutrition supplemented with

a variety of enzymatic and nonenzymatic antioxidants to patients with ARDS and observed a decrease in oxidant production and neutrophil count in BAL fluid.[145] Overexpression of extracellular superoxide dismutase has been shown to attenuate bleomycin-induced lung pulmonary fibrosis in mice.[118] Addition of reduced glutathione to preservation solutions for transplanted organs has been shown to reduce subsequent ischemia-reperfusion injury.[146] However, although these studies demonstrate a potential benefit for exogenous antioxidant administration, there are not yet enough conclusive data to support its routine use in the clinical setting.

FUTURE THERAPY

A variety of potential strategies to prevent and treat oxidative lung injury are being studied. The results of several animal studies have suggested that sublethal endotoxin injection may confer a protective effect against oxidative lung injury.[147] Studies of exogenous antioxidants targeted at specific oxidant mechanisms continue to demonstrate potential therapeutic benefit. A good example is the potential use of heme oxygenase-1 in protecting against oxidant-induced ischemia-reperfusion injury.[148,149] Attempts at improving delivery of antioxidants to lung tissue have yielded successful results. For example, Nakamura and coworkers used intratracheal administration of copper-zinc superoxide dismutase to prevent hyperoxia and ventilator-induced lung injury in newborn piglets.[150] Gene therapy techniques are also being studied in various animal models. Danel and colleagues showed that intratracheal administration of an adenovirus vector encoding copper-zinc superoxide dismutase improves survival of rats exposed to prolonged hyperoxia.[151]

ANNOTATED REFERENCES

Gram TE: Chemically reactive intermediates and pulmonary xenobiotic toxicity. Pharm Rev 1997;49:297-342.

This is a comprehensive review of pulmonary xenobiotic toxicity. The microscopic and ultrastructural effects of hyperoxic lung injury are first reviewed, followed by a summary of the enzymatic processes involved in oxygen toxicity. The author next reviews the mechanisms and pathologic changes associated with a variety of xenobiotic agents.

Nanavaty UB, et al: Oxidant-induced cell death in respiratory epithelial cells is due to DNA damage and loss of ATP. Exp Lung Res 2002;28:591-607.

In this study, Dr. Nanavaty and colleagues address the question of whether DNA damage or apoptosis is responsible for oxidant-induced lung injury. Using a model of hydrogen peroxide induced cytotoxicity in BEAS-2B and A549 cells, they demonstrate a decrease in cellular ATP and an absence of markers of apoptosis in response to injury. These results suggest that DNA damage is one of the primary reasons for oxidant-induced cell death.

Perkowski S, et al: Gene expression profiling of the early pulmonary response to hyperoxia in mice. Am J Respir Cell Mol Biol 2003;28:682-696.

The authors measure changes in total lung gene expression in C57BL/6 mice during hyperoxic exposure. Although no changes were noted in the expression of catalase, MnSOD, and Cu-Zn SOD in response to hyperoxia, glutathione peroxidase, glutathione-S-transferase, heme oxygenase-1, and metallothionein showed moderate increases. The expression of a variety of other lung genes in response to hyperoxia is also examined.

Perrot MD, Liu M, Waddell T, Keshavjee S: Ischemia-reperfusion-induced lung injury. Am J Respir Crit Care Med 2003;167:490-511.

The authors review the current evidence concerning the development of ischemia-reperfusion-induced injury in the lung allograft. The review first examines the role of donor lung assessment and management, including the effects of cold storage. The authors then look at the technique of lung preservation and review the current strategies for the prevention and treatment of ischemia-reperfusion-induced lung injury.

Saugstad OD: Bronchopulmonary dysplasia—oxidative stress and antioxidants. Semin Neonatol 2003;8:39-49.

In this review of BPD, Saugstad summarizes the role of oxidative stress in cellular and mitochondrial processes, leading to the inflammation and fibrosis observed in BPD. He also examines the host antioxidant responses in BPD and reviews the current and future therapeutic approaches to prevent oxidative injury in BPD.

KEY POINTS

1. **Apoptotic cell death** results from one of three major pathways: cell death receptor driven (extrinsic), the mitochondrial pathway (intrinsic), or an endoplasmic reticular stress-induced process.
2. **Blood neutrophil (polymorphonuclear leukocyte [PMN]) constitutive apoptosis** is dysregulated in patients with systemic inflammatory response syndrome, acute respiratory distress syndrome (ARDS), sepsis, trauma, and severe burns. A similar response has been reported in patients with ARDS with respect to PMNs in bronchoalveolar lavage fluids.
3. **Circulating lymphocytes from patients suffering from severe burns, blunt trauma, and sepsis,** as well as from patients who have had major elective surgery (nonseptic), exhibit significantly more apoptosis (approximately 20% to 60% apoptotic) than do peripheral lymphocytes from healthy donors. Similarly, increased lymphocyte apoptosis has been detected in the spleen and gut of patients with sepsis and multiple organ dysfunction syndrome, as well as in trauma and shock patients.
4. Although alterations in apoptosis are most evident in the critically ill, and most experimental models are most obvious in tissues of immune system origin, **a variety of epithelial cells, as well as select parenchymal cells and possibly endothelial cells, may be affected by changes in this pathway.**
5. **The mediators of the apoptotic changes in critically ill patients are as different as the cell type examined.** Nonetheless, data from several experimental models suggest that selective targeting of apoptotic proteins such as caspases and death receptors may provide novel therapeutic avenues in the future.

One of the central components in the control of inflammation is the ability to sustain or to shut down or eliminate cells by regulating their cellular suicide program (apoptosis). Apoptosis is a method by which cells are eliminated from the body in a controlled manner, resulting in clearance of cells without damage to the surrounding environment. The process by which a cell undergoes apoptosis has been reviewed extensively.[1-3] Initially, apoptosis was thought to be a process by which selected cell populations could be actively deleted from specific tissues during morphogenesis and tissue remodeling[4]; it has since been extended to include a variety of roles in immune response resolution and clonal deletion.

Apoptotic cell death results from one of three major pathways: cell death receptor driven (extrinsic), the mitochondrial pathway (intrinsic), or an endoplasmic reticular stress-induced process.[1,5-7] A description of some of the more salient features of these processes is provided as an orientation to the studies discussed here (Fig. 38-1).

The extrinsic death receptor pathway is mediated by the interaction of a trimeric tumor necrosis factor (TNF) receptor (TNF-R)–like family of membrane receptors and their associated ligands, including Fas ligand (FasL), TNF, and TNF-related apoptosis-inducing ligand (see Fig. 38-1). The most studied and the best understood are the TNF–TNF-R and FasL-Fas systems. In this respect, recent studies suggest that Fas-driven apoptosis appears to go through one of two nonexclusive processes, depending on whether it takes place in a type I or type II cell.[8] Type I cells appear to use signaling via Fas-associated death domain–mediated death-inducing signaling complex formation through the activation of caspase-8, driving primarily caspase-3 activation and culminating in the activation of downstream proteases that induce nuclear apoptosis. Alternatively, in type II cells, FasL-Fas–induced cell death appears to be mediated through the subsequent activation of Bid, a cytoplasmic proapoptotic protein. Once Bid is cleaved by caspase-8, it translocates to the mitochondrial membrane, where it interacts with proapoptotic agents such as Bax protein, which in turn deactivates antiapoptotic agents such as Bcl-2, leading to mitochondrial release of cytochrome *c* and Apaf-1/caspase-9, as well as decreased mitochondrial membrane potential (organelle dysfunction). These events lead to the intrinsic apoptotic pathway, also known as the mitochondrial-driven cell death pathway.

Although much is understood about the components of the mitochondrial apoptotic transition and the consequences of activating this intrinsic pathway (protein release leading to apoptosome formation), its initiation and regulation are less clearly and less directly defined. In this respect, a wide variety of exogenous stressors, such as steroids, reactive oxygen intermediates, nitric oxide, peroxynitrite, and chemokines and cytokines (via activation or inhibition of signaling through phosphatidylinositol-3-kinase-AKT (PI3K-AKT), protein kinase (PKC), mitogen-activated protein kinase (MAPK), and other kinases), as well as the loss of essential growth factors such as interleukin (IL)-2, IL-4, and granulocyte-macrophage colony-stimulating factor (GM-CSF), can result in the induction of apoptosis through this intrinsic pathway (see Fig. 38-1). Finally, endoplasmic

reticular stress-driven apoptosis is the least well understood. This pathway is mediated by the release and activation of caspase-12. However, little is known beyond the potential role of oxidant stress and Ca^{++} as an activator of this process.

As alluded to earlier, the very process of macrophage or lymphocyte activation required to mount a competent inflammatory or adaptive immune response to a foreign pathogen sets in motion, for most cells, processes involved in mediating their own demise.[9,10] In this respect, the process by which a mature T cell is activated, via concordant T-cell receptor complex stimulation and costimulatory molecule engagement, simultaneously induces the up-regulation of death receptors (such as Fas) that make the activated T cells more susceptible to ligands that induce apoptosis.[10-12] With respect to the resolution of inflammation or local tissue injury, lymphocyte Fas-FasL–mediated fratricide is also a potentially important process, with numerous examples of lymphocyte-lymphocyte induction of cell death being documented.[13,14] Macrophages and monocytes may also use such a mechanism, with granulocytes encountered at sites of inflammation.[15]

POLYMORPHONUCLEAR LEUKOCYTE APOPTOSIS

SUPPRESSION

Polymorphonuclear leukocytes (PMNs, neutrophils) play a crucial role in the primary immunologic defense against infectious agents, and they use the apoptotic program not only for resolution but also as a means of natural cell turnover. Although the primary role for PMNs is to eliminate pathogens, they can also be detrimental, being major contributors to organ damage induced by ischemia-reperfusion, trauma, and sepsis. The importance of PMNs in organ damage and mortality has been demonstrated using anti-PMN therapies to block lung and liver damage after sepsis induced by cecal ligation and puncture (CLP),[16] anti–IL-8 therapy to block PMN infiltration into the lung after lipopolysaccharide (LPS) treatment,[17] and anti-macrophage inflammatory protein-2 (anti-MIP2) treatment to block PMN infiltration into the peritoneum after the induction

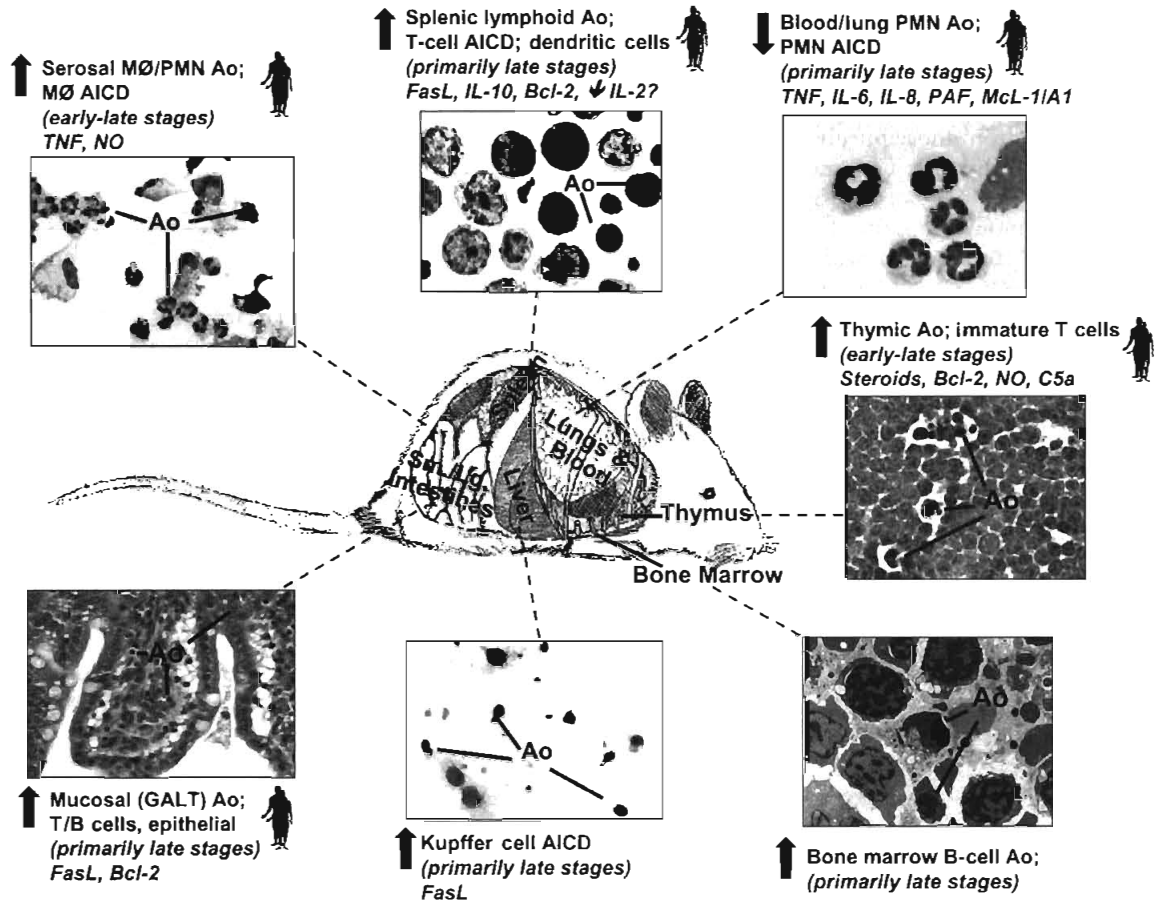

FIGURE 38–2. The frequency of apoptosis (A_o), the immune cell populations affected, the onset or expression of apoptotic changes, and the agents that mediate these cell death effects vary in mice subject to experimental sepsis and in patients (↕) with multiple organ failure due to trauma or sepsis. General increases (↑) or decreases (↓) in apoptosis in the septic mouse model are indicated either for in vivo or ex vivo cells or tissues or for activation-induced cell death (AICD) seen in vitro for a given cell population. (↕) indicates that a comparable observation has been made in humans. The stage (time period) during experimental sepsis when such apoptotic changes typically become evident is italicized in parentheses, and the mediators reported to affect apoptosis are listed last in italics. GALT, gut-associated lymphoid tissue; IL, interleukin; MØ, macrophage; NO, nitric oxide; PAF, platelet-activating factor; PMN, polymorphonuclear leukocyte; TNF, tumor necrosis factor.

of sepsis.[18] In each situation, tissue or organ damage was significantly reduced, and survival was improved.

It has been established that once PMNs are released into circulation, their apoptotic program has already been activated, and the typical half-life of an unstimulated PMN is 6 to 12 hours.[19] Because clearance of PMNs would limit the damage they could induce, it is not unexpected that peripheral blood as well as bronchoalveolar lavage PMN apoptosis is dysregulated in patients with systemic inflammatory response syndrome, acute respiratory distress syndrome, sepsis, trauma, and severe burns (Fig. 38-2).[20-25] It is also of interest to note that PMN apoptosis can be suppressed by surgery alone (elective, non–trauma related) at time points (<24 hours) that preclude the possible development of the clinical situations listed.[26]

REGULATION BY INFLAMMATORY MEDIATORS

PMNs recruited to sites of inflammation are exposed to factors that can influence apoptosis, such as bacterial products, lipids, cytokines, and changes in oxygen tension.[27] Elevated levels of cytokines such as granulocyte colony-stimulating factor (G-CSF), GM-CSF, IL-1, IL-6, IL-8, and TNF are often found in peritoneal fluid, bronchoalveolar lavage, and serum of trauma patients or experimental animals,[17,18,25,26,28-31] and each has been found, in vitro, to suppress apoptosis of PMNs from healthy volunteers.[19,25,32-34] Additionally, transmigration, bacterial products (e.g., LPS), and hypoxia have been found to suppress PMN apoptosis in vitro.[32,35,36] Similarly, when PMNs from healthy volunteers are incubated in bronchoalveloar lavage or serum from patients with burns,[23] acute respiratory distress syndrome,[29,37] or sepsis,[24] a significant reduction in apoptosis is observed. Although endothelial cells or macrophages are thought to produce a majority of these cytokines, PMNs have the ability to suppress their own apoptosis in an autocrine or paracrine manner through the production and secretion of antiapoptotic factors.[23,33,38-41]

EXTRACELLULAR MILIEU

Although the studies mentioned earlier demonstrate that inhibition of PMNs or their recruitment significantly improves the outcome of a septic insult, PMN apoptosis was not examined. In vitro experiments indicate that blood PMNs that were stimulated with various inflammatory stimuli, were subjected to in vitro migration, were exposed to various adhesins, or ingested microbes exhibit differences in

the rate at which they undergo apoptosis.[32,35,42] Therefore, PMNs in inflammatory sites would be expected to differ from those seen in the blood. This was observed in patient studies in which the PMNs isolated from the lung had different characteristics from those purified from the blood of the same patient.[43,44] Using the CLP model of sepsis, Ayala and colleagues assessed the extent of apoptosis in phagocytes expressing Gr1 (the mouse granulocyte marker) from three separate tissue sites.[45] In agreement with findings in patients, decreased apoptosis was seen in CLP mouse blood PMNs, while no change in the percentage of apoptosis was detected in the myelopoietic compartment of the bone marrow.[46] However, an increase in the percentage of $Gr1^+$ cells undergoing apoptosis was evident in cells taken from the peritoneum of the CLP mice, and the extent of apoptosis in these cells appears to be regulated by TNF.[45] Whether other death receptor or non–death receptor pathways are also involved in regulating apoptosis at this or other sites of PMN accumulation in traumatized or septic animals is unknown.

ROLE OF Bcl-2 FAMILY MEMBERS

The mechanism by which inflammatory agents suppress PMN apoptosis remains an active area of study, but numerous agents have been found that regulate members of the Bcl-2 family, which can inhibit spontaneous (mitochondrial-driven) and induced (Fas- or TNF-R–driven) apoptosis (Table 38-1). PMNs, unlike lymphoid cells, do not express Bcl-2 but do express other members of this family, such as Bcl-w, Mcl-1, Bak, Bcl-X_L, and A1,[42,44,47-51] and changes in their expression in response to stimulation are specific for the agent used. Studies by Leuenroth and associates indicate that in the hypoxic environments (mimicked in vitro) encountered in hemorrhaged animals or trauma patients, the suppression of apoptosis, at least in human PMNs, is regulated by the induction of Mcl-1.[42] Mcl-1 is also up-regulated upon stimulation with G-CSF, GM-CSF, IL-1ß, TNF, and LPS,[48,49] while these same agents have no effect on Bcl-X expression.[48] Chuang and coworkers demonstrated that messenger RNA for A1 was increased in response to G-CSF, GM-CSF, and LPS, but not IL-1ß or TNF.[49] And finally, Bax expression was down-regulated by G-CSF and GM-CSF, but not IL-8, LPS, or TNF.[44,51] Although patient data are limited, Dibbert and colleagues reported that PMNs isolated from patients with inflammatory diseases express reduced amounts of Bax, suggesting that changes observed in vitro mimic those that occur in vivo.[44] The majority of studies have concentrated on the Bcl-2 family members; changes in other pro- or antiapoptotic proteins, such as the inhibitor of apoptosis proteins (IAPs), that affect granulocyte cell death remain an area of active research.[52]

TABLE 38–1. POLYMORPHONUCLEAR LEUKOCYTE APOPTOSIS—MEDIATORS AND THE Bcl-2 FAMILY OF PROTEINS

Mediator	Mcl-1	A1	Bcl-X	Bax
G-CSF	↑	↑	↔	↓
GM-CSF	↑	↑	↔	↓
IL-1β	↑	↔	↔	nd
IL-8	↑	nd	nd	↔
TNF	↑	↔	↔	↔
LPS	↑	↑	↔	↔
Hypoxia	↑	nd	nd	nd

Arrows indicate the ability of each mediator to alter the expression of the Bcl-2 family members listed: ↑, increased expression; ↓, decreased expression; ↔, no effect.
G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IL, interleukin; LPS, lipopolysaccharide; nd, no data (the proteins were not examined); TNF, tumor necrosis factor.

LYMPHOCYTE APOPTOSIS

IMMUNOSUPPRESSION

Although PMNs make up a large part of the innate immune system, lymphocytes (B and T cells) are the primary players in the adaptive immune response to an inflammatory challenge. This adaptive immune response involves the rapid expansion of these cells in response to cytokine and antigen stimulation. Apoptosis was initially proposed as a mechanism whereby autoreactive lymphocytes could be removed (deselected) or as a process by which the extent of immune cell activation could be contained (resolved).[1,53] However, it is apparent that this same process can contribute to the pathophysiology of disease states such as human immunodeficiency virus (HIV) immune depression, cancer, autoimmune disorders, neurodegenerative diseases, inflammatory bowel disease, and ischemic injury.[1,5,53]

Lymphocyte apoptosis is a major concern in the ICU, because many critically ill patients exhibit immunosuppression as a result of lymphocyte apoptosis from several compartments (see Fig. 38-2). Circulating lymphocytes from patients suffering from severe burns,[54,55] blunt trauma,[55] and sepsis,[56] as well as from those who have undergone major elective surgery (nonseptic),[56,57] exhibit significantly more apoptosis (approximately 20% to 60% apoptotic) than do peripheral lymphocytes from healthy donors. Hotchkiss and colleagues detected lymphocyte apoptosis in the spleen and gut of trauma and shock patients,[58-60] and Middleton and associates found a significant amount of thymocyte apoptosis in patients who died more than 3 hours after an initial trauma.[61] The loss of lymphocytes from all three compartments is thought to be directly associated with the decreased number of lymphocytes in the circulation. Unfortunately, this immunosuppression leaves patients vulnerable to infection or unable to fight existing sepsis and may result in organ failure. Until recently, the contribution of the process of apoptosis to the pathophysiology of multiple organ dysfunction in critically ill patients had not been examined.[19] As with human lymphocytes, lymphocytes from rodents subjected to burn injury[62] and sepsis (CLP)[63,64] also exhibit pronounced immunosuppression, accompanied by increased lymphocyte apoptosis. This is the model of sepsis that has provided most of our current knowledge about the role of apoptosis in the critically ill (see Fig. 38-2).

THYMOCYTE APOPTOSIS

The initial experimental studies of trauma- and sepsis-induced changes in lymphoid apoptosis focused on the thymus because it is readily accessible and highly susceptible to stress-induced apoptosis. Studies involving various trauma, burn, sepsis, and shock models all consistently reported that thymic apoptosis increases in these settings (see Fig. 38-2).[46,65-68] In the CLP model of sepsis and in burn injury, it was observed that a rise in thymic apoptosis could be detected as early as 4 hours after injury and increased through 24 hours.[46,66] This increased apoptosis in the mouse

TABLE 38–2. AGENTS INVOLVED IN LYMPHOCYTE APOPTOSIS

GALT—mediators	Fas/FasL (+), endotoxin (↔)

+, ability to promote lymphocyte apoptosis; –, ability to suppress lymphocyte apoptosis; ↔, no effect on lymphocyte apoptosis; ↓, decreased protein expression.
GALT, gut-associated lymphoid tissue; IL, interleukin; NO, nitric oxide; TGF, transforming growth factor; TNF, tumor necrosis factor.

thymus appears to be primarily a response to glucocorticoids, and possibly nitric oxide (NO), rather than to endotoxin or death receptors such as Fas and TNF-R. Treatment with mifepristone, a glucocorticoid receptor antagonist, but not the neutralizing Fas-fusion protein, blocked thymic apoptosis (Table 38-2).[46,66] Support for a putative role of NO in thymic apoptosis comes from in vitro data in which thymocytes cultured with LPS-activated endothelial cells, which produce NO, or with NO donors exhibited increased apoptosis.[69] Another putative mediator of thymocyte apoptosis, either directly or indirectly, is the complement anaphylatoxin C5a; blocking its activity with anti-C5a therapy inhibited thymic apoptosis after CLP in rats.[67] Additionally, because cytokines play a prominent role in lymphocyte activation and apoptosis, Oberholzer and coworkers were able to inhibit thymocyte apoptosis during sepsis by using targeted expression of IL-10, resulting in reduced blood bacteremia and improved mortality.[70] This is of interest because IL-10 is generally regarded as an anti-inflammatory cytokine, and it has been found to have a proapoptotic effect on the circulating lymphocytes of trauma patients.[57]

SPLENOCYTE APOPTOSIS

In addition to thymic apoptosis, apoptosis in the spleen has been documented after burn injury and trauma and in cases of sepsis (see Fig. 38-2).[58,65,71-73] Just as the degree of lymphocyte apoptosis correlates with disease severity in patients, splenic apoptosis is correlated with the severity of burns; no apoptosis could be detected in the spleens of mice subjected to burns covering 18% of their total body surface area,[68] but it could be detected in mice subjected to burns covering 25% and 40%, with the level of apoptosis higher in the 40% group.[71] Similarly, Guan and associates demonstrated that in rats subjected to multitrauma events (hemorrhage ± multiple fractures), apoptosis rates were directly correlated with trauma severity.[65] Studies by Hiramatsu and Hotchkiss and their colleagues showed evidence of increased splenic lymphocyte apoptosis in septic mice, associated with increased mortality.[72,73] Histologic analysis of spleens from septic human patients, but not from nonseptic patients, demonstrated that apoptosis in the spleen involves primarily B cells and $CD4^+$ T cells.[58] Interestingly, in Rag-1 mice, which are deficient in B and T cells, apoptosis was still detected in thymic and splenic cell populations.[73] In vitro experiments to determine whether the increased lymphoid apoptosis in these tissues is associated with immune hyporesponsiveness indicated that mitogenic stimulation of splenocytes isolated from mice 24 hours after CLP causes a significant increase in the rate of activation-induced cell death (AICD).[64] This increase in AICD also appears to be restricted to T cells of the helper ($CD4^+$) lineage.[64]

APOPTOSIS IN THE GUT

A number of other lymphoid tissues also appear to actively undergo increased apoptosis following the onset of sepsis or shock (see Fig. 38-2). However, unlike in the thymus, where apoptosis is evident as early as 4 hours after CLP, apoptosis in other tissues typically does not appear until later (>12 hours). Mixed bone marrow cells showed an increase in apoptosis at 24 hours, but not at 4 hours, following CLP.[46] Although phenotypic and morphologic assessment indicated that most of the increase in apoptosis in the thymus was in the immature T-cell population ($CD4^+CD8^+$ and $CD8^-D4^-$ cells), the increase in bone marrow cell apoptosis was associated with only the B-lymphocyte population. Gut-associated lymphoid tissues, such as Peyer's patches, also exhibit increased apoptosis in response to polymicrobial sepsis.[72,74] As with the bone marrow, these changes were restricted to the B-cell population, which exhibited an increase of Fas antigen expression; this therefore appears to be an example of AICD in sepsis.[1] Chung and coworkers reported similar findings following traumatic shock.[46] The functional aspect of this increased in vivo apoptosis appears to be related to the endogenous stimulation of immunoglobulin A production by B lymphocytes and increased nuclear c-Rel expression.[75]

These findings are not restricted to the Peyer's patches; similar findings have been observed in the B-lymphocyte subset of the lamina propria (see Fig. 38-2).[46] Assessment of lamina propria mononuclear cell (LPMC) preparations from septic mice indicates that there are increases in the percentage of apoptosis in $CD4^+$ and $CD8^+$ cells, as well as macrophages, at both 4 hours (except for $CD4^+$) and 24 hours.[46] This is associated with a significant increase in the mixed LPMC IL-2, -10, and -15 gene expression observed at 24 hours, but not at 4 hours, after CLP. These findings correlate well with the in situ observations by Hiramatsu and colleagues, who reported evidence of increased apoptosis in Peyer's patches and in lymphoid cells lining the small and large intestines in mice 24 hours after CLP.[72] Hotchkiss and coworkers also documented that increased intestinal lymphoid apoptosis is a common finding in patients undergoing surgery after major trauma.[59] Intriguingly, it has been reported that the phenotypically distinct intestinal intraepithelial lymphocyte population also exhibits changes associated with increased apoptosis.[46] This appears to be a FasL-Fas antigen-mediated process independent of endotoxin sensitivity and may be a reflection of localized immune cell activation in response to sepsis (see Table 38-2).

CYTOKINES

One of the common effects of burn, trauma, and sepsis in both patients and animal models is a significant change in the expression of a number of pro- and anti-inflammatory cytokines, including TNF, IL-1, IL-4, IL-6, IL-10, IL-12, and IFN-γ.[76-79] The plasma concentration of several of these cytokines has been correlated with disease severity and levels of lymphocyte apoptosis in both patients and experimental animals.[57,76,77,80] Two cytokines that are prominent in burn

injury, trauma, and sepsis are TNF and IL-1β, and modulation of their activity in animal models led to several clinical trials, but without success.

One cytokine that has been shown to have a direct effect on lymphocyte apoptosis is transforming growth factor beta, which induces lymphocyte apoptosis and is expressed at high levels that correlate with increased splenic lymphocyte apoptosis after burn injury.[71] In contrast, the roles of the other cytokines in lymphocyte apoptosis are vague but nevertheless important to survival. Because the balance between pro- and anti-inflammatory cytokines is crucial to survival, the importance of IL-10 and IL-13 as regulatory molecules has been demonstrated. Through the use of neutralizing antibodies, IL-13 has been shown to have a protective effect on organ damage (i.e., liver, lung, kidney) and ultimately on survival, primarily by limiting the expression of cytokines such as TNF, MIP-2, and keratinocyte-derived cytokine (KC).[81] Similarly, Hasko and associates showed that mice deficient in IL-10 (IL10–/–) had higher levels of TNF, IL-1β, IL-2, IL-6, IL-12, and IFN-γ than did wild-type controls during sepsis, and that this deficiency resulted in increased apoptosis in the thymus.[82] In support of this, Ayala and coworkers demonstrated that splenocytes isolated from septic IL10–/– mice or wild-type splenocytes cultured with antibodies to IL-10 had reduced AICD.[64] The proapoptotic effect of IL-10 on increased AICD in the circulating lymphocytes of surgical trauma patients has also been reported.[57] Finally, O'Sullivan and colleagues found that patients and mice with trauma or burn injuries had suppressed IL-12 levels, and mice receiving IL-12 had decreased mortality after CLP.[78] Taken together, these data implicate several pro- and anti-inflammatory cytokines present in the critically ill that can directly or indirectly affect the apoptotic changes in immune cells.

MONOCYTE-MACROPHAGE AND DENDRITIC CELL APOPTOSIS

Regarding macrophages, the majority of work has assessed the in vitro response to stimuli such as LPS, TNF, IL-1, IL-10, IFN-γ, FasL, and NO.[83,84] As with the other immune cells mentioned earlier, the response of macrophages to apoptotic stimuli also appears to be time dependent.[84] Although most of the components of the FasL-Fas and TNF pathways are evident, it is less clear whether a comparable series of anti-apoptotic gene products is present. The macrophage response to polymicrobial sepsis appears to be tissue specific. Evidence of ex vivo apoptosis can be seen in peritoneal (serosal) macrophages isolated as early as 4 hours after CLP, and it increases over time; however, a small but significant decrease in the basal apoptosis frequency is evident in liver macrophages.[85] Interestingly, if they are subsequently challenged in vitro with an inflammatory stimulus such as LPS, both these macrophage populations become considerably more apoptotic than do comparative sham-CLP animal cells.[85,86] This is associated with a functional disability in their capacity to release proinflammatory cytokines, such as IL-1 and IL-6, and with decreased caspase-1 but increased caspase-3, -8, and -9 activity.[84] The role of FasL-Fas signaling in these changes also appears to be tissue specific. In peritoneal macrophages, apoptosis and cytokine release do not appear to be affected by FasL-Fas activation, but in liver macrophages, changes are seen.[87] To the extent that such changes in macrophage apoptosis and function may be just an aberration seen in mice, it is worth noting that Williams and coworkers reported similar observations in circulating monocytes derived from the blood of septic patients.[88] Finally, Hotchkiss and associates found that dendritic cells in patients who succumbed to sepsis also appear to exhibit increased evidence of apoptosis[89]; however, the mechanisms responsible for this are not clear. Studies examining dendritic cell apoptosis suggest that although they contribute to the fratricide of other cells, they may not be affected by FasL-Fas signaling themselves.[90] This remains to be determined in sepsis.

EFFECTS OF APOPTOTIC CELLS

Although we have discussed the potential direct pathologic effects of the apoptotic process on various cell lineages of the immune system, it is important to appreciate that the interaction with and clearance of apoptotic cells can have a significant effect on the host's immune response. The process of apoptotic cell clearance is primarily, but not exclusively, regulated by macrophages.[91] This process is mediated by the recognition of a variety of ligands expressed on apoptotic cells by receptors, primarily on macrophages, used to mediate the apoptotic cells' removal (Fig. 38-3). Through a pinocytotic mechanism, fibroblasts and epithelial cells may also contribute to apoptotic cell clearance.[92] The interaction of macrophages with apoptotic cells induces the expression of an anti-inflammatory phenotype in the macrophages. Until recently, there were few supportive data, but one could speculate that this might contribute to the anergy seen in macrophages isolated from septic mice or patients.[93] In this respect, Hotchkiss and colleagues recently showed that the administration or adoptive transfer of apoptotic lymphocytes derived from septic mice could suppress T helper 1 cytokine responsiveness while preserving the T helper 2 anti-inflammatory response associated with the immune-suppressive phenotype seen in experimental sepsis.[94]

Alternatively, the documented inability of monocytes or macrophages from septic, shocked, or traumatized animals to phagocytize materials at normal levels may contribute to the inadvertent accumulation of apoptotic cells in various hematopoietic, lymphatic, and immune tissues (see Fig. 38-3). In turn, the inability to appropriately clear these dying cells may allow them to progress to a state of secondary necrosis, producing localized bystander injury in the tissue. Such a scenario has been suggested by Vandivier and coworkers as a possible mechanism for tissue inflammation and the enhanced susceptibility to infection seen in cystic fibrosis patients.[95,96] It remains to be determined whether such defects in the macrophage-mediated clearance of apoptotic cells contribute to the changes seen in septic mice.

ANTIAPOPTOSIS THERAPIES

The importance of lymphocyte apoptosis in the development of multiple organ failure and subsequent death has been clearly demonstrated by the use of therapies to block the process at several steps in the apoptosis pathway. Starting at the cell surface, Chung and associates demonstrated that the use of Fas-fusion protein, which blocks FasL binding to cell surface Fas, preserves organ function and blood flow in mice subjected to CLP and reduces septic mortality (Fig. 38-4).[97] Hotchkiss and colleagues used several methodologies to inhibit apoptosis after CLP to assess its importance

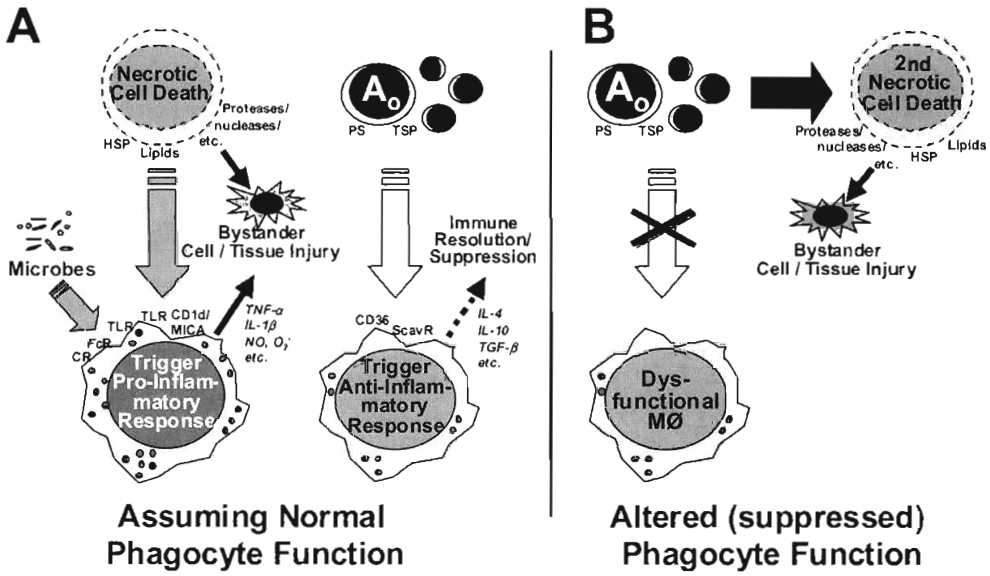

FIGURE 38–3. *A*, Depiction of the clearance of necrotic and apoptotic cell materials, as well as the effect of this process on the macrophage phenotype (proinflammatory versus anti-inflammatory), when phagocytic function is normal. *B*, The scheme in which phagocytic function is compromised, blocking apoptotic cell clearance and subsequently allowing apoptotic cells to move into secondary necrosis; this, in turn, produces bystander tissue injury. CD1d/MICA, nonvariant major histocompatibility class 1–like antigen family; CD36, cell differentiation antigen 36; CR, complement receptor; FcR, immunoglobulin constant region receptor; HSP, heat shock protein; IL, interleukin; MØ, macrophage; NO, nitric oxide; PS, phosphatidylserine; ScavR, scavenger receptor that binds PS; TGF, transforming growth factor; TLR, Toll-like receptor; TNF, tumor necrosis factor; TSP, thrombospondin.

in the pathology of sepsis (see Fig. 38-4).[98,99] Because caspase activity, particularly caspase-3, is crucial to all forms of apoptosis, they were able to use several pharmacologic caspase inhibitors to block lymphocyte apoptosis, which resulted in decreased apoptosis and increased survival. Similarly, sepsis did not induce lymphocyte apoptosis in caspase-3 –/– mice when compared with their background controls.[98] Finally, similar to the regulation of apoptosis in PMNs, expression of members of the Bcl-2 family of proteins has been found to be altered in lymphocytes either stimulated in vitro or isolated from animals subjected to trauma or sepsis (see Table 38-2). Lee and coworkers demonstrated that CD40 can inhibit Fas-mediated apoptosis in a B-cell lymphoma cell line through the induction of Bcl-X and A1.[100] Thymocytes isolated from protein kinase B transgenic mice were found to have resistance to a variety of apoptotic stimuli, and this correlated with elevated levels of Bcl-X_L.[101] Bcl-X_L was found to be significantly reduced in thymocytes after CLP,[67,102] and thymic apoptosis in response to sepsis was associated with decreased Bcl-2[102]; therapies that blocked apoptosis and improved survival either restored or increased Bcl-2 expression.[70,102] In light of this, it is no surprise that mice overexpressing Bcl-2 in T cells had improved survival in sepsis, which correlated with a lack of lymphocyte apoptosis in both the thymus and the spleen (see Fig. 38-4).[103]

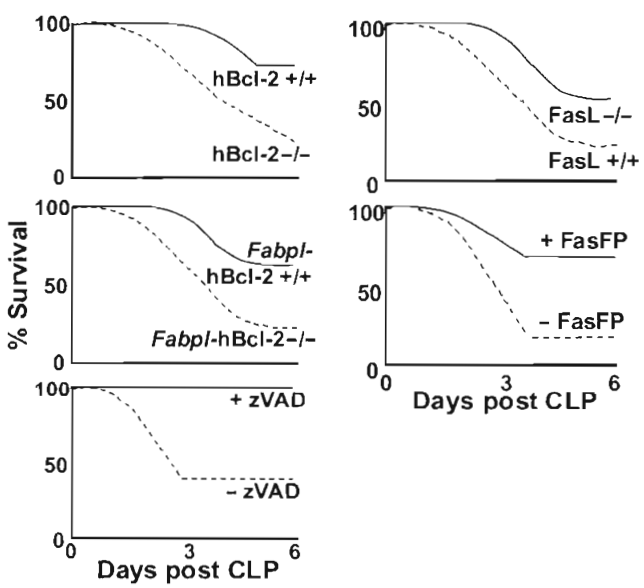

FIGURE 38–4. Results of survival studies illustrating the efficacy of directly inhibiting aspects of apoptosis in sepsis using the transgenic overexpression of the human Bcl-2 gene (under either a lymphoid restricted promoter [hBcl-2] or an intestinal epithelial cell restricted promoter [fabpl-hBcl-2]), pan-specific caspase inhibition (zVAD),[98] and death receptor inhibition in animals deficient in FasL (FasL–/–)[46] or administered Fas-fusion protein (FasFP) 12 hours after cecal ligation and puncture (CLP).

NON–IMMUNE CELL APOPTOSIS

At this point, it should be clear that a significant amount of experimental as well as clinical evidence exists for the presence of marked apoptotic changes and potential pathologic sequelae in both animals and patients with sepsis and multiple organ failure syndrome. Surprisingly, demonstration of apoptosis in nonimmune tissues and cells has been substantially more difficult in the clinical setting.

For example, although apoptosis in the vascular endothelium has been proffered as an explanation for the frequently observed loss of hemodynamic responsiveness in critically ill patients and certain septic animal models, there is a paucity of direct evidence for such an event.[104] This is due in large part to the difficulty of assessing this process directly in experimental animals, let alone patients. Nonetheless, some indirect evidence of apoptosis-induced shedding of $CD34^+$ cells into the bloodstream of critically ill patients has been

observed by Mutunga and Miniagar and their respective colleagues.[105,106]

Another potentially interesting apoptotic target is the surface of epithelial and mucosal cells. These cells, being at the mucosal interface, turn over via apoptotic processes on a regular basis. However, because mucosal sloughing and gut barrier dysfunction are common aspects of sepsis, trauma, and critical illness, it has been hypothesized that increased apoptotic cell death may contribute in a pathologic fashion to organ dysfunction in the gut[107,108] and in the lungs.[109] Experimental support for a pathologic role of gut epithelial cell apoptosis has been provided by Coopersmith and associates, who showed that septic mortality could be reduced in mice expressing the epithelial cell restricted overexpression of the human Bcl-2 gene (see Fig. 38-4).[107,110] Hotchkiss and colleagues also documented that, along with the predominance of lymphoid apoptosis seen in septic patients succumbing to their illness, there was consistent evidence of intestinal epithelial cell apoptosis; a similar but more transient observation was made in trauma patients undergoing bowel resection.[60] Epithelial cell injury in the lung has also been observed experimentally,[109,111,112] but its clinical contribution to chronic or acute lung injury remains to be clearly established. Further, the degree of interaction between immune cell subpopulations undergoing apoptosis and the extent of changes in epithelial cell apoptosis is unknown at present.

Beyond these observations and the substantial data provided by various experimental situations in vitro or in vivo,[113-120] there is little evidence of changes in the apoptotic process in the liver parenchyma, heart, kidney, or brain in the clinical setting of sepsis or multiple organ failure. This does not mean that apoptosis is not playing a role, but merely that it is not overt, or that the form of cell death induced in these organs, tissues, and cells is not solely apoptotic.

CONCLUSION

Our understanding of the mechanisms by which multicellular organisms regulate cell life and death via apoptosis has grown tremendously over the past few years. It is now clear that septic or traumatized animals and patients exhibit alterations in the apoptosis of cells in both the innate (PMNs) and the adaptive (lymphocytes) arms of the immune system. Even though PMN apoptosis is suppressed under similar conditions in which lymphocytes undergo increased apoptosis, the consequence of each appears to contribute to significant pathologic alterations in host cell function, which is associated with an increase in organ damage and mortality. However, we are just beginning to understand the mechanisms and mediators (e.g., FasL, TNF, IL-8, Bcl-2, Mcl-1, NO, steroids) that regulate these changes. The data clearly show the complexity of the apoptotic response, thus justifying the need to increase our understanding of apoptosis in the critically ill. This will require the use of complex and clinically comparable models of shock, trauma, burn, and sepsis in which the cells of each lineage can be assessed at various sites and times after insult. Such information will provide us with new insight into the pathobiology of the critically ill and may offer better therapeutic targets for the management of these devastating conditions.

This is one of several studies from this laboratory that illustrates the capacity of nitric oxide, like several other inflammatory agents present in critically ill patients, to be either antiapoptotic or proapoptotic.

Chapter 39
CELLULAR SIGNALING

Michael B. Fessler • Jerry A. Nick

KEY POINTS

1. **Intracellular signal transduction** describes mechanisms that allow an individual cell to coordinate responses to extracellular stimuli.
2. Intracellular signaling occurs primarily through **sequential phosphorylation of proteins.**
3. Although highly conserved, **signaling mechanisms are often adapted** for different uses by different cell types.
4. **Central signaling pathways** participate in multiple responses to a variety of receptors and stimuli.
5. Signaling pathways represent **potential targets to modify specific cellular responses.**

Signal transduction refers to sequential molecular interactions triggered within the cell in response to external conditions (e.g., ultraviolet radiation, heat, osmotic stress) or ligands (e.g., bacterial lipopolysaccharides, cytokines) that lead, in turn, to induction of specific cellular responses (e.g., transcription/translation, adhesion, chemotaxis). Intracellular signaling involves precisely timed, compartmentalized, specific, and reversible interactions between proteins and underlies biologic phenomena of health and disease alike, ranging from cellular proliferation to immunity to sepsis. Increasingly, the potential of cellular signaling molecules as diagnostic markers and therapeutic targets is being realized. A basic understanding of the principles of signal transduction and of the important cellular signaling cascades is necessary to evaluate current research in critical care medicine and may be of increasing use to the clinician.

BASIC PRINCIPLES OF SIGNAL TRANSDUCTION

PHOSPHORYLATION CASCADES AND ACTIVATION OF KINASES

Virtually all cellular signaling pathways described to date are regulated by protein phosphorylation. The phosphorylation of a target protein by a protein *kinase*—an enzyme that covalently attaches phosphate to the side chain of either serine, threonine, or tyrosine—can have multiple effects on the protein, including modulation of its enzymatic activity, stability, subcellular localization, and interaction with other proteins. Many signaling pathways involve *cascades* of two or more kinases in series in which an "upstream" kinase is phosphorylated, resulting in activation of the enzyme, with subsequent phosphorylation of a "downstream" kinase, which in turn is activated and able to phosphorylate specific substrates or additional kinases. Rare examples exist of inactivation of a target enzyme by phosphorylation (e.g., phosphorylation of glycogen synthase kinase 3 by protein kinase B).[1]

SIGNAL AMPLIFICATION AND REDUNDANCY

Fundamental principles determining the sensitivity of a signaling pathway to a stimulus are signal *amplification* and *redundancy.* Whereas a single-step phosphorylation pathway would yield an inefficient 1:1 molecular communication between external cellular ligand and cellular effector, multiple-step phosphorylation cascades utilizing kinases of increasing abundance in series permit multiplicative *signal amplification.* In a related fashion, an arrangement involving isolated, parallel signaling pathways with completely distinct stimuli and downstream functions would permit neither flexibility nor responsiveness to combinations of stimuli. This is avoided by the common phenomenon of *signal redundancy:* stimuli may activate more than one cascade, cascades may be activated by multiple different stimuli, and effector kinases may have overlapping substrate specificities.

REGULATION AND SPECIFICITY OF SIGNAL TRANSDUCTION

Many signaling molecules ubiquitous to human cells are co-localized in the cytoplasm and have overlapping or redundant downstream effects. Several sophisticated strategies have been identified that result in the pathway regulation and specificity necessary for effective, stimulus-appropriate signal transduction to occur. Considerable specificity may occur simply through maintenance in the cell of low "copy numbers" of particular kinases and their respective substrates. Because of this, research strategies that use transfection to investigate the functional role of signaling molecules (e.g., overexpression at nonphysiologic levels in cell lines) may unfortunately induce artifactual protein interactions. Larger-scale pathway regulation is made possible by counter-regulatory *phosphatases* and by interpathway signaling *crosstalk.* In addition to the specificity of receptor-ligand docking interactions, specific signaling protein-protein interactions are made possible by *scaffolding/anchoring/adaptor proteins* and by *protein interaction domains.*

PROTEIN INTERACTION DOMAINS

Virtually all signaling proteins described to date are constructed in a modular fashion from a combination of catalytic and interaction domains. Paired interaction domains in different proteins couple them into multi-protein complexes, thereby orchestrating complex signaling events. The extensive list of protein interaction domains described to date can be grouped into separate families characterized by their ligand specificity (Table 39-1). Prototypical examples include SH2 and PTB domains (recognizing phosphotyrosine motifs); 14-3-3, FHA, and WD40 domains (recognizing phosphoserine/threonine motifs); and PH and FYVE domains (recognizing specific phospholipids to allow for membrane targeting). Further layers of complexity are imparted by the preference of certain interaction domains for particular flanking amino acids in the ligand, thereby permitting differential localization of protein isoforms within the cell. The inclusion of multiple interaction domains of varying ligand specificity in a single protein results in extensive combinatorial possibilities, as well as intraprotein interactions through folding.

SCAFFOLD, ANCHORING, AND ADAPTOR PROTEINS

In addition to specific motif recognition of ligands by kinases, specific kinase-substrate interactions are facilitated by co-localization of proteins on scaffold, anchoring, or adaptor proteins at specific subcellular sites. In this manner, efficient kinase-kinase information flow may be facilitated or, alternatively, signaling molecules may be sequestered in a latent state in proximity to their upstream activating receptor. A prototypical example of such a scaffolding protein is that of the JIP proteins, which regulate JNK activation via possessing separate binding sites for both JNK and its upstream kinases, MKK7, MLK3, and HPK1.[2] Furthermore, JIP1/2 can form large cytoplasmic protein complexes through their ability to homo- and hetero-oligomerize and have SH3 and PTB domains, presumably facilitating complex regulatory protein-protein interactions. A second prototypical example of a scaffolding protein is that of the A kinase anchoring proteins (AKAPs), which are thought to co-localize protein kinase A (PKA) in an inactive form with its substrates and regulators at specific subcellular sites, presumably poising PKA to respond to local fluxes in cyclic adenosine monophosphate concentration.[3]

KINASE INACTIVATION BY PHOSPHATASES

The regulatory counterpart to phosphorylation by kinases is dephosphorylation by phosphatases. In addition to signal transduction, numerous cellular processes ranging from metabolism to RNA splicing are regulated by phosphatases.[4]

TABLE 39–1. COMMON PROTEIN INTERACTION DOMAINS AND THEIR ASSOCIATED RECOGNITION MOTIFS

Protein Interaction Domain	Binding Specificity
SH2, PTB	Phosphotyrosine
14-3-3, FHA	Phosphoserine/threonine
PH, FERM, FYVE, C1, C2	Phospholipid
WW, GYF, SH3, EVH1	Proline-rich sequences
EF-hand	Calcium binding

Although it is estimated that greater than 1000 phosphatase genes exist in the human genome, the complex variety of these mediators can be simplified down into three functional families: (1) those targeting phosphoserine and/or threonine residues, (2) those targeting phosphotyrosine residues, and (3) dual-specificity phosphatases targeting phosphotyrosine and/or threonine residues. While some degree of substrate specificity is intrinsic to all phosphatases, an additional layer of specificity is imparted by the combinatorial effects of regulatory molecules included in larger functional phosphatase complexes.

CROSSTALK

Although most signaling pathways were initially conceptualized as completely independent and parallel, it is now evident that signaling often involves a network of more than one pathway. For example, the three MAPK subfamilies can regulate one another both at upstream and downstream levels. Tumor necrosis factor-alpha (TNF-α) activates the guanosine triphosphatase p21rac, in turn activating the MKKK p65PAK, which activates MKK3, 4, 6, and 7, and thereby both the p38 and JNK pathways. Downstream, in the TNF-α–stimulated human neutrophil, p38 regulates the JNK pathway via protein phosphatase-2A.[5] Examples also exist of crosstalk between MAPK and non-MAPK pathways; for example, ERK has been reported to inhibit transforming growth factor-beta (TGF-β) signaling via phosphorylation of Smad2/3, which inhibits its nuclear retention.[6]

PROTOTYPICAL INTRACELLULAR SIGNALING CASCADES

MITOGEN-ACTIVATED PROTEIN KINASES

The MAPK superfamily, which includes the extracellular-regulated kinase 1 and 2 (ERK1/2 or p42/p44), p38, and c-jun NH_2-terminal kinase (JNK) families, is a highly conserved signaling system that regulates biologic functions ranging from embryogenesis to acute hormonal responses. MAPKs are serine/threonine kinases regulating an array of specific substrates (e.g., transcription factors, cytoskeletal proteins, other kinases) and are the final kinase in a three-kinase cascade (Fig. 39-1). Specifically, MAPK activation requires phosphorylation of both a threonine and tyrosine residue by a specific MAPK kinase (MKK), which requires activation by a serine/threonine MAPK kinase kinase (MKKK). This canonical understanding of a three-kinase pathway for the MAPKs has been challenged by reports that p38α can be activated by TAB1, which is not an MKK but rather an adaptor protein.[7] Moreover, new members continue to be added to the MAPK superfamily (e.g., ERK3, ERK5, ERK7), with over 20 MAPK isoforms described to date. For the sake of brevity, only the three classic, well-described MAPK families are discussed. MAPKs are examples of signaling molecules that can phosphorylate substrates within the cytosol but can also enter the nucleus to regulate transcription via activation of transcription factors. MAPKs are of particular interest in defining mechanisms of cellular response in the context of critical care medicine.

p42/44 (ERK 1/2) MAPK

The ERK subfamily has two MAPK isoforms, ERK 1 and 2, and follows the characteristic three-tiered design of the

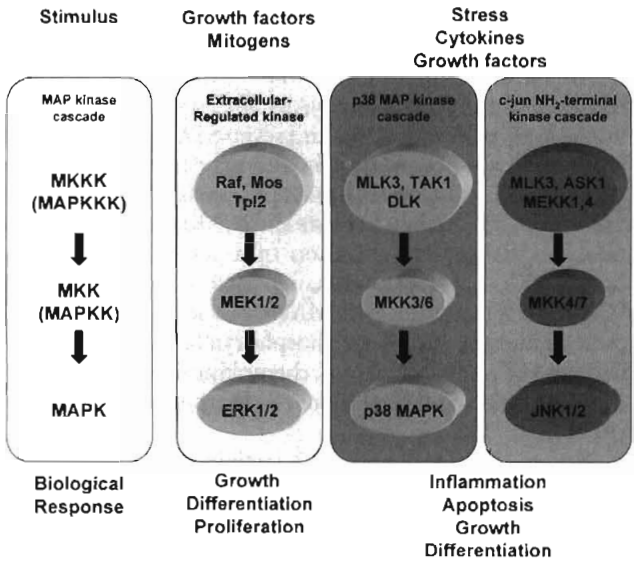

FIGURE 39–1. Mitogen-activated protein kinase (MAPK) cascades. The three major MAPK pathways are parallel signaling cascades, which include a MAPK kinase kinase (MKKK), a MAPK kinase (MKK), and a MAPK. After exposure of the cell to external stimuli, a variety of signaling mechanisms ultimately result in the phosphorylation (and activation) of serine/threonine kinases serving as MKKKs. The activated MKKK, in turn, phosphorylates one or more MKK-family members, which are then capable of phosphorylating both a threonine and tyrosine residue on one or more MAPKs. Once activated, the MAPKs serve as serine/threonine kinases, which phosphorylate an array of specific substrates within the cytosol (e.g., cytoskeletal proteins and other kinases) and nucleus (i.e., transcription factors).

MAPK superfamily, proceeding from raf kinase (MKKK) to MEK1/2 (MKK) to ERK1/2 (MAPK) (see Fig. 39-1). Raf, itself a proto-oncogene, is, in turn, activated at the plasma membrane by the proto-oncogenic G-protein ras. The ERK pathway is activated by several mitogens, including platelet-derived growth factor, epidermal growth factor, angiotensin II, TGF, insulin, and thromboxane A_2, and is generally considered to be a proliferation, transformation, and differentiation pathway. Nevertheless, the ERK1/2 pathway also plays a role in inflammation, because it may be activated in monocytes by both lipopolysaccharide and cellular adherence and is involved in monocytic production of proinflammatory cytokines (e.g., TNF-α).[8] Downstream substrates of ERK1/2 include MNK-1, Elk-1, and SAP-1.

p38 MAPK

The p38 subfamily has five known isoforms: p38α (also known as stress-activated protein kinase 2, or SAPK2), p38β, p38β2, p38δ (SAPK3), and p38γ. Each p38 isoform is characterized to varying extent by differences in tissue localization, preferred upstream activator, and potential substrates. The two major upstream activators of p38 are MKK3 and MKK6, although MKK6 is less abundant in leukocytes. In the neutrophil, MKK3 activates p38α.[9] Several diverse proteins appear capable of acting as MKKKs for the p38 pathway, including TAK1 and ASK-1. The p38 pathway is a major regulator of the inflammatory response, because it is activated by a broad range of proinflammatory stimuli (e.g., tumor necrosis factor, interleukin-1, platelet-activating factor, heat shock) and microbial stimuli (e.g., lipopolysaccharide, peptidoglycan) and plays a central role in many proinflammatory cellular responses[9] (e.g., production of TNF, interleukin [IL]-1, IL-6, and IL-8 by monocytes and neutrophils; oxidative burst, degranulation, chemotaxis, and adhesion in neutrophils; and E-selectin expression in endothelium). Other roles include regulation of T-helper-1 (Th1) differentiation and cytokine production by lymphocytes. Important p38 substrates include the serine kinases MAPK-activated protein kinase-2 (MAPKAP-K2) and MAPKAP-K3, pro-inflammatory transcription factors (e.g., ATF-2, NFκB),[9] phospholipase A_2, MAPK-interacting kinase-1 (MNK-1), myocyte enhancer factor 2, CHOP, SAP-1, and Elk-1. Studies suggest a selective role for p38 MAPK in cellular regulation at both the transcriptional and translational levels.[10]

C-jun NH_2-Terminal Kinase (JNK)

JNK is encoded by three different genes, yielding 10 isoforms with differing tissue expression (e.g., *JNK1* and *JNK2* are ubiquitous, whereas *JNK3* is limited to brain, heart, and testis). JNK is activated by two MKKs—MKK4 and MKK7, which, in turn, can be activated by at least 13 different MKKKs. Most proximally, it is thought that the JNK pathway can also be activated by the rho family small G-protein axis of cdc42/rac/p21-activated kinase. Like p38 MAPK, JNK can be activated by a number of stress-related stimuli (e.g., TNF, IL-1, ultraviolet radiation). Because of only very recent development of a chemical inhibitor for JNK, its role in the inflammatory response remains less clear than that of p38. Nevertheless, studies in a variety of cell types indicate a role in apoptosis,[11] TNF expression,[12] T-cell proliferation and differentiation,[13] and endothelial E-selectin expression.[14] JNK substrates include transcription factors such as ATF-2, Elk-1, and C-jun (a component of the proinflammatory AP-1 transcription complex regulating multiple cytokine genes).

PROTEIN TYROSINE KINASES

Protein tyrosine kinases (PTKs) are classified into two distinct categories: receptor tyrosine kinases and cytoplasmic kinases. The former, typified by such mitogen receptors as the insulin receptor and epidermal growth factor receptor, have autophosphorylating activity, thereby creating recognition motifs on the cytoplasmic domain of the receptor for SH2-containing proteins, such as the adaptor protein GRB2. By contrast, cytoplasmic PTKs, typified by the SRC, JAK, SYK, and ABL families, play an important upstream role in multiple signaling cascades by either phosphorylating receptor endodomains or activating other signaling proteins. For example, SRC has been reported to play a role upstream of raf activation in the ERK1/2 pathway whereas SYK and LYN have been reported in B-cell receptor signaling.

JAK-STAT CASCADES

Chemokines and cytokines are two distinct classes of small (i.e., 8 to 30 kDa) mediators that play a wide spectrum of roles in the activation, maturation, and homing of leukocytes to sites of inflammation. The Janus kinase (JAK)-signal transducer and activator of transcription (STAT) pathway represents one of the initial signaling pathways that mediates the response of cells to cytokines and chemokines (Fig. 39-2). In this pathway, ligand-induced receptor subunit dimerization allows recruitment and activation of tyrosine kinase JAKs, which phosphorylate tyrosine residues on the cytoplasmic domain of the receptor. The phosphorylated receptor subunits

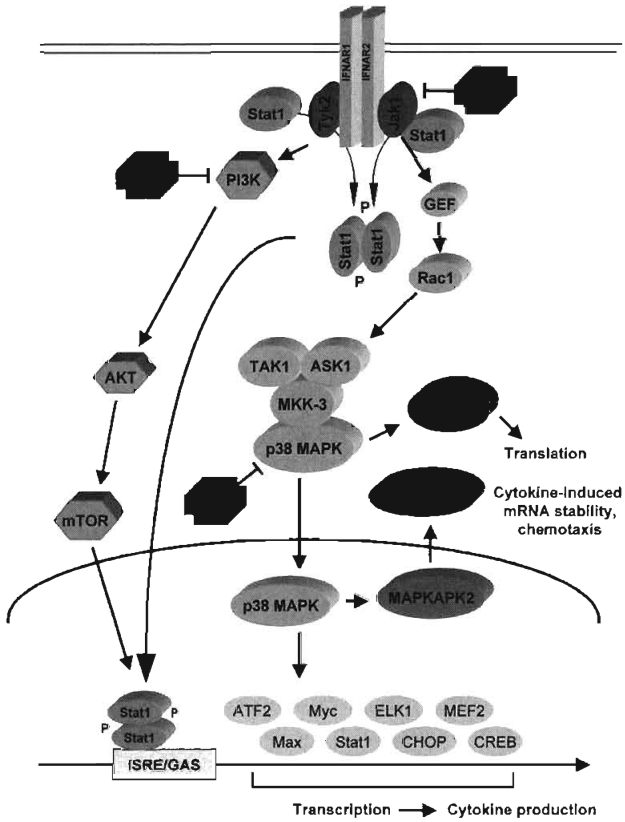

FIGURE 39–2. Potential relationship of major signaling pathways. Signal transduction by interferon-alfa (IFN-α) represents one of the best defined pathways to date and serves well as a backdrop to illustrate the potential regulatory interactions that exist between distinct signaling pathways (e.g., JAK/STAT, MAPK, PI3K, phosphatases) in coordinating the cellular response to an external stimulus. Signaling relationships depicted in this diagram are compiled from studies in a variety of cell types under a broad range of conditions and may well not be applicable to every human cell. Janus-family tyrosine kinase/signal transducer and activator of transcription (JAK/STAT) signaling: IFN-α binds to a type I IFN receptor (composed of subunits IFNAR1 and IFNAR2), which is associated with JAK-family members Tyk-2 and Jak-1. The receptor subunits provide docking sites for specific STATs, which are phosphorylated by JAKs, dissociate from the receptor, form dimers, and then translocate into the nucleus where they modulate transcription by binding to the promoters of cytokine-regulated genes. MAPK signaling: Crosstalk with the MAPK pathways may also occur as JAKs can regulate activation of small G-proteins such as rac1 via activation of guanine exchange factors (GEFs), and rac1, in turn, can activate the p38 MAPK cascade. p38 MAPK phosphorylates cytosolic proteins such as MAPK interacting kinase (MNK1/2) and also translocates to the nucleus, where it enhances cytokine transcription via activation of a broad array of transcription factors, and regulates stability of cytokine mRNAs via phosphorylation of the kinase MAPK activated protein kinase-2 (MAPKAPK-2). Phosphoinositol 3-kinase (PI3K) signaling: Activation of JAKs has also been linked to PI3K activation, which can then serve to activate AKT (protein kinase B). AKT is central to a wide range of signaling pathways, including activation of STATs via mammalian target of rapamycin (mTOR). Regulation by phosphatases: An important mechanism for limiting signal transduction is dephosphorylation (resulting in deactivation) of kinases by phosphatases. Protein tyrosine phosphatases (PTPs) such as SH2-containing phosphatase 1 (SHP1) dephosphorylate JAKs and MAPKs. JAK activates SHP2, which, in turn, dephosphorylates Tyk-2 and Jak-1. Protein serine/threonine phosphatases such as phosphoprotein phosphatase 2A and 2C (PP2A and PP2C) serve to dephosphorylate AKT and p38 MAPK, respectively.

then provide docking sites for specific members of a family of latent cytoplasmic transcription factors termed the *signal transducers and activators of transcription* (STATs) via their SH2 domains. Recruited STATs are activated via tyrosine phosphorylation by JAKs and form homodimers or heterodimers that translocate to the nucleus where they modulate transcription by binding to the promoters of cytokine-regulated genes. Specificity of JAK-STAT signaling is generated by the existence of four JAK and seven STAT isoforms. STAT4 and STAT6 have been described to play an important regulatory role in a murine model of sepsis.[15] Crosstalk with other signaling pathways exists since JAKs can regulate Rac1 phosphorylation via activation of a substrate-protein that functions as a guanine exchange factor for Rac1. In turn, Rac1 can activate the p38 MAPk cascade and the ERK1/2 cascade and the ERKs can phosphorylate and enhance activation of STAT.[16] In addition, chemokine-induced activation of JAKs results in activation of phosphoinositol-3-kinase (PI3K).

Negative regulation of JAK activity occurs in part by dephosphorylation of a critical tyrosine residue by protein tyrosine phosphatases (PTPs) such as SHP-1 and -2, which also bind to receptors via their SH2 domains, or by binding JAKs directly.

CLINICAL SIGNIFICANCE OF SIGNAL TRANSDUCTION

SIGNALING MOLECULES AS POTENTIAL DIAGNOSTIC MARKERS

The number of reports of signaling molecule modification in human disease continues to grow and, with it, the potential for harvesting new diagnostic and prognostic information from patient specimens. For example, in one clinical study, the quantity of p38 MAPK activation in alveolar macrophages proved to be a superior predictor of patients at risk for acute respiratory distress syndrome and for multiple organ dysfunction syndrome compared with a panel of standardized clinical parameters.[17] In inflammatory bowel disease, p38α expression is increased in intestinal lamina propria macrophages and neutrophils.[18] In acute respiratory distress syndrome, increased activation of the downstream proinflammatory transcription factor nuclear factor-kappa B (NF-κB) is detected in alveolar macrophages,[19] whereas decreased NF-κB or Akt activation in peripheral leukocytes predicts improved survival.[20]

SIGNALING PATHWAYS AS THERAPEUTIC TARGETS

Because of the ubiquitous expression of signaling molecules, and the differing role of particular molecules in various tissue types, systemic inhibition of signaling events carries with it the potential for uncertain side effects and even antagonism. For example, whereas endothelial p38 MAPK activation inhibits platelet aggregation by inducing prostacyclin production,[21] platelet p38 activation promotes platelet aggregation.[22] Moreover, specific signaling molecules may function in widely different roles in different cell types (e.g., ERKs regulate proliferation in many cell types but play a role in adhesion in neutrophils). Nevertheless, under certain conditions, specific cell types may be targeted. For example, the IC_{50} of p38-regulated TNF-α release by murine alveolar macrophages is 3 logs greater than that by murine neutrophils.[23]

Despite the aforementioned challenges, multiple chemical inhibitors of different MAPK family members have been

developed in recent years. A MEK1/2 inhibitor has shown promise in pancreatic carcinoma. Inhibitors of p38 MAPK have shown promise in multiple animal models of arthritis, endotoxic shock, pancreatitis, ischemia-reperfusion injury, and acute pulmonary inflammation,[23,24] and clinical trials are underway for the treatment of rheumatoid arthritis and psoriasis. A recently developed JNK inhibitor appeared beneficial in a rat model of arthritis,[25] whereas a dual p38/JNK inhibitor has shown promise in Crohn's disease.[26] Furthermore, recent studies suggest that even *post-injury* treatment with a p38 MAPK inhibitor, as would occur in patient care, is effective in inhibiting ongoing inflammation.[24]

CONCLUSION

Significant progress has been made over the past decade in our understanding of the intracellular events that couple receptor-ligand binding to subsequent inflammatory and immune responses of the cell. Because proinflammatory events regulated by the MAPK, JAK-STAT, and other signaling cascades have been implicated in the pathogenesis of both acute respiratory distress syndrome and multiple organ dysfunction syndrome, it is probable that in upcoming years such signaling mediators will enter common parlance in the intensive care unit as both diagnostic biomarkers and therapeutic targets.

Chapter 40
RECEPTOR PHYSIOLOGY

Frederick J. Ehlert

KEY POINTS

1. Physiologic receptors can be divided into four families, based on structural and functional properties: nuclear receptors (ligand-activated gene regulatory proteins), ligand-regulated enzymes, ligand-gated ion channels, and G protein–linked receptors.
2. There are five classes within the ligand-regulated enzyme family: receptor tyrosine kinases, which phosphorylate signaling proteins on tyrosine residues; tyrosine kinase–associated receptors, which associate with enzymes having tyrosine kinase activity; receptor tyrosine phosphatases, which cleave phosphotyrosine ester groups on signaling proteins; receptor serine-threonine kinases, which phosphorylate signaling proteins containing serine and threonine residues; and receptor guanylyl cyclases, which catalyze the formation of cyclic guanosine-3′,5′-monophosphate within the cytosol.
3. Hydropathy analysis of the primary sequences reveals at least three families of ligand-gated ion channels: the four transmembrane receptors, which include nicotinic acetylcholine receptors, 5-HT_3 receptors, glycine receptors, and $GABA_A$ receptors; the excitatory amino acid receptors; and the P2X purinergic receptors.
4. The GTPase cycle is set in motion when an agonist activates a G protein–linked receptor.

The idea of a "receptor" was first introduced by Ehrlich and Langley around the turn of the 20th century in an attempt to explain the remarkably selective and potent effects that some natural and synthetic chemicals had on biologic tissues. They argued that pharmacologic agents must interact specifically with macromolecular components in tissue to produce physiologic effects. This idea, of course, is now a readily demonstrable fact. Researchers have identified hundreds of receptors and determined the primary sequence of many of these proteins through gene cloning. The precision of our knowledge about receptors is perhaps most spectacularly illustrated by the nicotinic acetylcholine receptor. Electron micrographic analysis of crystallized nicotinic acetylcholine receptors from *Torpedo* has produced high-resolution pictures showing a channel-like structure with a central pore, presumably representing the microscopic tunnel through which positive cations flow when the receptor binds its neurotransmitter, acetylcholine.[1]

The identification of receptors as the target for many drugs has an important corollary. It implies that drugs do not create new responses in tissues; rather, they start, stop, or modulate natural physiologic functions. For example, synthetic muscarinic agonists are able to elicit contractions of intestinal smooth muscle because they bind with muscarinic receptors and trigger a signaling cascade that results in the mobilization of calcium and the activation of contractile proteins in the muscle. Obviously, this signaling pathway evolved to respond not to synthetic drugs but to the neurotransmitter acetylcholine. The idea that drugs use physiologic mechanisms also applies to responses that are somewhat more complex than the readily quantifiable responses in peripheral tissues. For instance, the sensation of euphoria and well-being produced by opiate drugs, such as morphine and heroin, implies the existence of reward pathways in the brain whose natural function is to provide positive reinforcement to the organism under appropriate conditions.[2]

Within this general context, one can define many classes or types of receptors. There are the so-called physiologic receptors, which mediate the effects of a variety of neurotransmitters, peptide and steroid hormones, biogenic amines, and eicosanoids. In addition, enzymes, transport proteins, and ion channels are important receptors for a variety of drugs that usually, but not always, block the function of these proteins. Finally, the cytoskeleton and DNA itself may constitute the "receptor" for some agents.

This chapter reviews some of the quantitative aspects of drug-receptor interactions and provides a brief survey of the major families of physiologic receptors and their signaling mechanisms.

RELATIONSHIP BETWEEN RECEPTOR OCCUPANCY AND RESPONSE

RECEPTOR THEORY

The binding of a reversible drug to a receptor usually obeys the following scheme:

$$D + R \leftrightarrow DR \qquad \text{[Equation 1]}$$

in which D denotes the drug concentration, R denotes the receptor concentration, and DR denotes the drug-receptor complex. At equilibrium, the relationship between the drug-receptor complex and the drug concentration is:

$$[DR] = \frac{[D] \cdot R_T}{[D] - K_D} \qquad \text{[Equation 2]}$$

in which R_T denotes the total concentration of receptors and K_D denotes the equilibrium dissociation constant of the

drug-receptor complex. The K_D has units of concentration (e.g., molar) and is equivalent to the concentration of drug required for half-maximal receptor occupancy. The K_D is a measure of the observed affinity of a drug for a receptor. The lower the K_D, the higher the affinity. This scheme is usually called the law of mass action. Its consequences adequately reflect the manner in which a variety of drugs bind with receptors under physiologic conditions.

The size of the response elicited by a drug depends on its intrinsic efficacy and the percentage of receptors that it occupies. It is easier to understand the property of intrinsic efficacy if we consider how the drug-receptor complex behaves in the absence of other ligands or endogenous neurotransmitters. In the absence of drugs, most native receptors are silent. An agonist is a drug that binds to the receptor, turns it on, and triggers a response. The property that enables the agonist to turn on the receptor is called *intrinsic efficacy*. An antagonist is a drug that lacks intrinsic efficacy but is capable of binding to the receptor. Such agents have no effect by themselves but are capable of antagonizing the action of an agonist, whether it is an exogenous drug or an endogenous neurotransmitter. The amount of intrinsic efficacy can vary widely among different drugs, and drugs with small or intermediate levels of intrinsic efficacy are called *partial agonists*.

INVERSE AGONISTS

This general framework may not be sufficient to account for the behavior of all receptor systems. For example, the guanosine triphosphatase (GTPase) activity elicited by opiate receptors is already active in the absence of agonists when this function is measured in brain homogenate in a hypotonic buffer.[3] Under these conditions, the addition of agonists causes a further increase in the GTPase activity, whereas antagonists either have no effect or inhibit the ongoing basal GTPase activity. In other words, if the receptor is already turned on in the absence of agonists, some antagonists can actually turn off the receptor. Most of the few native receptors that behave in this fashion have been shown to do so under nonphysiologic conditions. However, some mutated forms of receptors have been shown to be constitutively active.[4]

SPARE RECEPTORS CONCEPT

Figure 40-1 shows the relationship between occupancy and response for a highly efficacious agonist (Fig. 40-1*A*), a less efficacious agonist (Fig. 40-1*B*), and a partial agonist (Fig. 40-1*C*). In Figure 40-1*A*, the concentration-response curve for the agonist lies to the left of the occupancy curve, indicating that it requires only a low level of receptor occupancy to produce a maximal response. This behavior is typical for a highly efficacious agonist. In Figure 40-1*B*, there is closer agreement between the two curves, so that the response is proportional to receptor occupancy. Although this less efficacious agonist is capable of eliciting a maximal response, it can do so only at a much higher level of receptor occupancy compared with the more efficacious agonist shown in Figure 40-1*A*. In Figure 40-1*C*, the agonist has little intrinsic efficacy, so it is incapable of eliciting a maximal response even when the receptors are fully occupied. Consequently, the agonist is designated a partial agonist.

When an agonist is capable of eliciting a maximal response at a submaximal level of receptor occupancy (e.g., Fig. 40-1*A*), the situation is referred to as *spare receptors*. Unfortunately, this term has created considerable confusion in the pharmacologic literature. The term does not imply that some of the receptors are extra or unnecessary; rather, it means that only a small fraction of the total functional receptor population needs to be occupied by the agonist to elicit a maximal response. The presence of spare receptors enhances the potency of the agonist because lower concentrations of the agonist can produce effective responses. The functional activity of the total receptor population can be appreciated by considering what happens when some of the receptors are inactivated. After partial receptor inactivation, the concentration-response curve of a highly efficacious agonist shifts to the right without a decrease in the maximal response. The loss in potency associated with inactivation of some of the receptors illustrates that spare receptors are functional and maintain the sensitivity of the receptor system. Another important point is

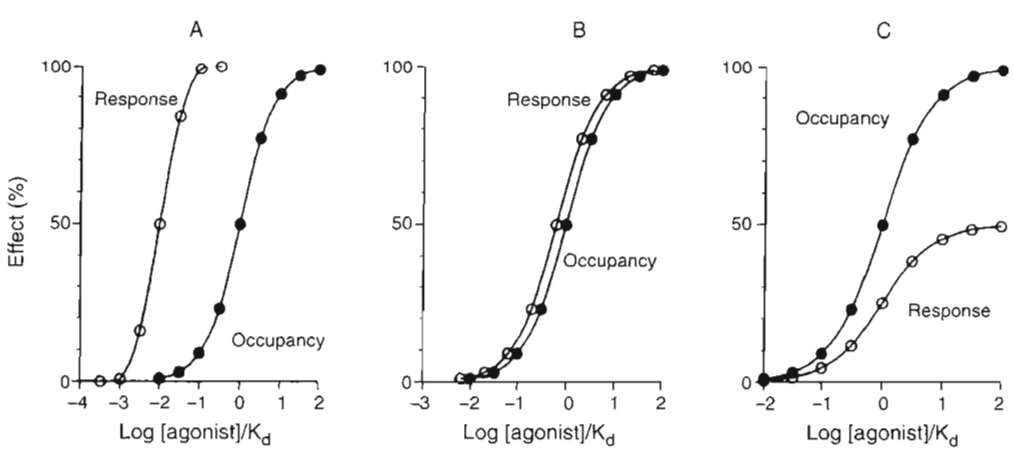

FIGURE 40–1. Relationship between receptor occupancy (●) and response (○) for a highly efficacious agonist *(A)*, a less efficacious agonist *(B)*, and a partial agonist *(C)*. Both occupancy and response are expressed as percentages of their maximum values and are plotted on the ordinate scale. The concentration of the agonist is expressed on the abscissa as a log of the ratio of the agonist concentration divided by the equilibrium dissociation constant of the drug-receptor complex (K_d).

that the presence of spare receptors does not imply that there are excess receptors relative to effectors. In fact, the converse is usually the case. In many signaling cascades, there is divergence along every step in the pathway. That is, one receptor may interact with several effector molecules, and each effector generates several second messenger molecules, and so forth. This divergence leads to amplification and thereby enables a relatively small number of agonist-receptor complexes to generate a significant physiologic response.

ANTAGONIST DISSOCIATION CONSTANT

Because antagonists lack intrinsic efficacy, all that is necessary to describe their interaction with a receptor at equilibrium is the K_D. This parameter can be estimated by measuring an agonist concentration-response curve in the absence and presence of the competitive antagonist. A competitive antagonist will shift the log concentration-response curve of an agonist to the right in a parallel fashion without causing a decrease in the maximal response. The K_D of the antagonist can be estimated from the shift in the dose-response curve using the following equation:

$$CR - 1 = [A]/K_D \qquad \text{[Equation 3]}$$

in which CR (concentration ratio) denotes the EC_{50} value of the agonist (concentration of agonist causing a half-maximal response) in the presence of the antagonist divided by that measured in its absence, and $[A]$ denotes the concentration of the antagonist.

SECONDARY ALLOSTERIC SITES

The relationships described earlier are adequate to account for the interactions of agonists and antagonists with the primary recognition site of a receptor. Some receptors have secondary allosteric sites where drugs can also bind and modify the ability of primary ligands to activate the receptor. One such example is the gamma-aminobutyric acid-A ($GABA_A$) receptor.[5] This receptor is a chloride channel that is regulated by the neurotransmitter GABA. When GABA binds to its site on the $GABA_A$ receptor, it causes the chloride channel to open. In addition to the GABA recognition site, there are other allosteric sites, including one for benzodiazepine-like drugs. A tranquilizing benzodiazepine, such as diazepam, binds to the allosteric site and increases the affinity of GABA for its site on the channel, thereby enhancing the effects of GABA. This allosteric effect can account for the pharmacologic properties of benzodiazepines, which include relief from anxiety, sedation, and protection against seizures. In contrast, some β-carboline derivatives bind to the allosteric site and inhibit the binding of GABA. These compounds have been called *inverse agonists* because they elicit responses that are opposite to those of benzodiazepines (i.e., anxiety, convulsions). However, they are more appropriately referred to as allosteric GABA antagonists because they produce their effects by antagonizing GABA. In addition, there are some compounds that bind to the allosteric site and have no effect on the binding of GABA. These compounds (e.g., Ro 151788) are called benzodiazepine antagonists, and although they have no effects by themselves, they antagonize both the tranquilizing effects of benzodiazepines and the convulsant effects of β-carbolines.

RECEPTOR FAMILIES

Physiologic receptors can be divided into four families, based on structural and functional properties[6]:

1. Nuclear receptors (ligand-activated gene regulatory proteins)
2. Ligand-regulated enzymes
3. Ligand-gated ion channels
4. G protein–linked receptors

Each family has a distinct overall structure and general function that are shared by all its members. Within each family, there is usually, but not always, a considerable amount of sequence homology. Previously, regions of high homology within a given family enabled molecular biologists to use low-stringency hybridization techniques to identify additional members of the same family; today, genome databases can be queried to identify potentially new members. In some instances, the endogenous ligands for the cloned receptor protein have not been identified, leading to their designation as *orphan receptors*. A cursory survey of the four receptor families follows.

NUCLEAR RECEPTORS

The nuclear receptors function as ligand-activated gene regulatory proteins that bind to DNA and regulate the activity of specific genes in a ligand-dependent manner.[7] This family includes receptors for thyroid hormone, retinoids, vitamin D, and the various steroid hormones, including glucocorticoids, mineralocorticoids, androgens, progesterone, and estrogen. Most of these receptors are located in the nucleus. Not surprisingly, the ligands for these receptors can readily penetrate the plasma membrane, and their access to the receptor is controlled by hormone binding proteins and by enzymatic processing of the ligand itself.

Receptors belonging to the nuclear receptor superfamily all share a similar structure having three major domains.[7] Near the center of the sequence is a highly conserved domain of 66 to 68 amino acids that constitutes the DNA binding region of the receptor. In this domain, the sequence forms two loops that are held in place by a zinc atom that interacts with cysteine residues on opposite sides of the loop. Each of the two loops is called a *zinc finger*, and many proteins that bind with DNA have a zinc finger–like structure. The second major domain of this family of receptors is the carboxy-terminal region, which functions as the ligand binding domain. This region of the receptor also shows considerable sequence homology, particularly among the androgen, glucocorticoid, mineralocorticoid, and progesterone receptors, which have structurally similar ligands (i.e., steroids). The third major domain is the amino-terminal region, which shows the greatest variation in size and the least conservation in sequence. This domain of the receptor is thought to mediate transcriptional activation.

A variety of evidence supports the existence of these distinct functional domains on steroid receptors. Perhaps the most dramatic evidence comes from studies of chimeric receptors in which a domain from one receptor is replaced with the corresponding domain from another. For example, when the 66–amino acid DNA binding region of the estrogen receptor is replaced with that of the glucocorticoid receptor, a chimeric receptor is formed that turns on a

glucocorticoid-inducible gene in the presence of estradiol.[8] Truncated receptors have also yielded clues about functional domains, as well as the mechanism of ligand-induced activation. For example, glucocorticoid receptor mutants lacking most of the ligand binding domain demonstrate constitutive activity.[9] That is, the truncated receptor binds to DNA and causes transcriptional activation in the absence of hormone. Apparently, the ligand binding domain of the glucocorticoid receptor normally prevents DNA binding and transcriptional activation, whereas the binding of the hormone relieves this tonic inhibition. Finally, several cases of hormonal resistance have been attributed to point mutations in the ligand binding domain resulting in diminished hormone binding.[7]

Although the details are unclear, the binding of hormone to its receptor triggers the formation of receptor dimers that subsequently bind to DNA.[7] The site on DNA where binding occurs is called the *hormone response element.* These sites are located in the regulatory regions of steroid-induced genes, and several have been identified. The consensus sequences of hormone response elements exhibit dyad symmetry, which is consistent with the idea that a receptor dimer interacts with the hormone response element.

LIGAND-REGULATED ENZYMES

The ligand-regulated enzymes represent a huge family of cell surface receptors. The unifying structural feature of these receptors is the presence of an extracellular ligand binding domain that regulates an intracellular domain that either has intrinsic enzymatic activity or associates with an enzyme. In most instances, the two domains of the receptor are connected by a single transmembrane-spanning region. There are five classes within the ligand-regulated enzyme family:

1. Receptor tyrosine kinases (RTKs), which phosphorylate signaling proteins on tyrosine residues
2. Tyrosine kinase–associated receptors, which associate with enzymes having tyrosine kinase activity
3. Receptor tyrosine phosphatases, which cleave phosphotyrosine ester groups on signaling proteins
4. Receptor serine-threonine kinases, which phosphorylate signaling proteins containing serine and threonine residues
5. Receptor guanylyl cyclases, which catalyze the formation of cyclic guanosine-3′,5′-monophosphate (GMP) within the cytosol

Receptor Tyrosine Kinases

The RTK family includes receptors for numerous growth factors, including insulin, fibroblast growth factor, epidermal growth factor, and platelet-derived growth factor. The structural and functional properties of these receptors have been reviewed.[10,11] As mentioned earlier, members of this family have an extracellular ligand binding domain, an intracellular tyrosine kinase domain, and a transmembrane-spanning domain (Fig. 40-2). Most growth factor receptors are formed from a single polypeptide chain; however, the class II RTKs, which include receptors for insulin and insulin-like growth factor, are heterotetrameric, consisting of two α and two β subunits connected by disulfide bonds (see Fig. 40-2). The two α subunits contribute to the ligand binding domain, whereas the two β subunits traverse the membrane and possess the tyrosine kinase activity. The class I and II RTKs, which include the epidermal growth factor receptor and the insulin receptor, have cysteine-rich regions in their extracellular ligand binding domains. Another class, which includes the fibroblast growth factor receptor, has three immunoglobulin-like domains in the extracellular ligand binding portion of the receptor. The tyrosine kinase domain is the most highly conserved domain among the different classes of RTKs. This domain contains an adenosine triphosphate binding site and a tyrosine acceptor site. In the class III RTKs, these two functional regions of the kinase domain are separated by a hydrophilic, proline-rich sequence of 77 to 107 amino acids. The results of studies of chimeric receptors constructed from heterologous ligand binding and kinase domains provide further support for the existence of autonomous functional domains. In each case, the hybrid receptors displayed the appropriate ligand specificity and kinase activity.

Ligand binding to monomeric RTKs results in dimerization, which is a prerequisite for growth factor–dependent

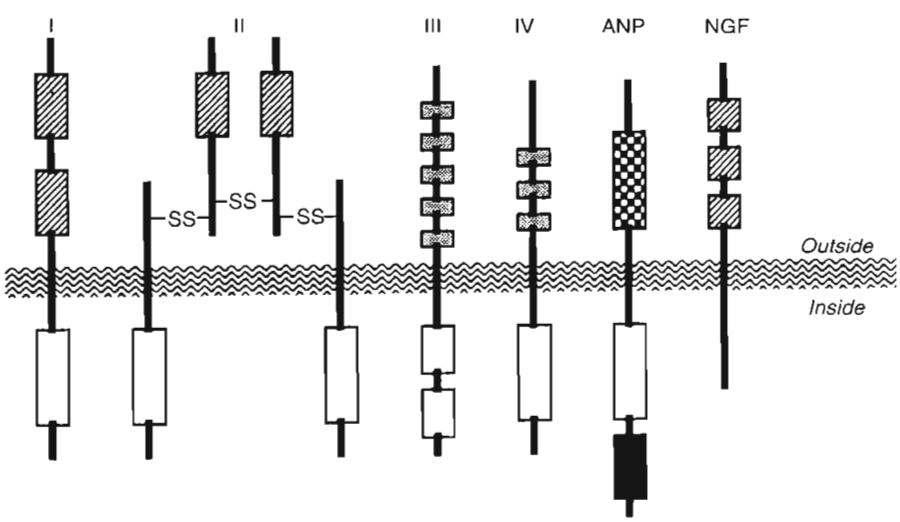

FIGURE 40–2. Structure of different members of the ligand-regulated enzyme superfamily of receptors. The figure shows the transmembrane topography of the primary sequences of the receptor tyrosine kinases (I, II, III, and IV), the receptor for atrial natriuretic peptide (ANP), and the receptor for nerve growth factor (NGF). The boxes indicate the various functional domains of the receptor, which are shaded according to the following scheme: diagonal lines, cysteine-rich domain; shaded, immunoglobulin domain; checkered, ANP binding domain; open, tyrosine kinase domain; and black, guanylyl cyclase domain.

kinase activation. Interestingly, the kinase activity of the tetrameric insulin receptor, which is analogous to an epidermal growth factor receptor dimer, is much greater than that of the dimeric αβ form of the insulin receptor. The results of ligand binding studies have demonstrated that growth factors bind to dimeric receptors with a higher affinity compared with monomers, suggesting that the tighter binding of the growth factor to the dimer provides the drive for receptor aggregation. Once made active by their respective ligands, all growth factor receptors autophosphorylate on several tyrosine residues. This autophosphorylation triggers a complex signaling pathway that is characterized by a series of protein-protein interactions and the phosphorylation of signaling proteins on tyrosine residues. The details of the signaling pathway can vary, depending on the receptor and the cell type.

When a growth factor triggers the autophosphorylation of its receptor, various signaling proteins bind to the receptor and become activated. These signaling proteins typically contain SH-2 domains that have high affinity for specific phosphotyrosine residues on the receptor. Myriad intracellular signaling proteins contain SH-2 domains, and these proteins are thought to mediate the effects of growth factors by binding to specific phosphotyrosine residues on the receptor.[12] These target proteins include the phosphoinositide-specific phospholipase Cγ (PLCγ), GTPase-activating protein, and members of the Src family of tyrosine kinases. In addition, several adapter proteins have been identified that lack enzymatic activity but contain both SH-2 and SH-3 domains. These adapter proteins are thought to bind to phosphotyrosine on the receptor via their SH-2 domains and to other signaling proteins via their SH-3 domains. Examples of adapter proteins are Grb2 and SHC, which enable mSOS to associate with the growth factor–receptor complex. The docking of mSOS to the receptor via adapter proteins enables mSOS to interact with the intracellular guanosine triphosphate (GTP) binding protein, Ras, and cause it to give up its bound guanosine diphosphate (GDP) and take up GTP. Once bound with GTP, Ras initiates a protein kinase signaling cascade that results in the activation of mitogen-activated protein kinase. This kinase triggers a variety of events associated with cellular growth and differentiation. The activity of Ras is inhibited by GTPase activating protein, which increases the intrinsic GTPase activity of Ras, thereby converting it from the active GTP bound form to the inactive GDP bound form.

Receptor Guanylyl Cyclases

Another member of the ligand-regulated enzyme superfamily is the receptor for atrial natriuretic peptide (ANP).[13,14] This receptor contains an extracellular ligand binding domain for ANP, a single transmembrane-spanning domain, and an intracellular domain that has guanylyl cyclase activity (see Fig. 40-2). The binding of ANP to this receptor causes an increase in the concentration of cyclic GMP inside the cell. This second messenger activates a cyclic GMP-dependent protein kinase, which ultimately triggers a variety of responses, including diuresis, natriuresis, and vasorelaxation. Interestingly, the extracellular domain of the ANP receptor is homologous with an ANP binding protein that is thought to have a role in the clearance of ANP from the circulation. The proximal portion of the intracellular domain is homologous to the kinase domain of RTKs, although no ANP-induced kinase activity has been detected. The most distal portion of the intracellular domain represents the catalytic domain, and it is homologous to the soluble form of guanylyl cyclase.

LIGAND-GATED ION CHANNELS

The ligand-gated ion channels represent a large superfamily that includes receptors for acetylcholine (nicotinic acetylcholine receptor), GABA ($GABA_A$ receptor), glycine, and various excitatory amino acids (e.g., glutamate, aspartate).[6] As the name implies, members of this superfamily are ion channels that open up and conduct an ionic current when an agonist binds on them. They share some homology with voltage-gated ion channels. In the case of the nicotinic acetylcholine receptor of the neuromuscular junction and the *Torpedo* electric organ, the ionic current is carried by positive monovalent cations, primarily sodium, whereas neuronal nicotinic receptors carry a rapidly desensitizing current of primarily calcium.[15] In the case of excitatory amino acid receptors, the ionic current is carried by both sodium and calcium, whereas inhibitory amino acid receptors (i.e., GABA and glycine receptors) carry a chloride current. The ligand-gated ion channels have a characteristic oligomeric structure consisting of different proteins (subunits) that come together to form the channel. Molecular cloning has revealed the existence of different structural groups of ligand-gated ions channels that are categorized on the basis of how many times the chain of amino acids composing their subunits crosses the membrane. Thus, hydropathy analysis of the primary sequences reveals at least three families:

1. The four transmembrane (4TM) receptors, which include nicotinic acetylcholine receptors, $5\text{-}HT_3$ receptors, glycine receptors, and $GABA_A$ receptors
2. The excitatory amino acid (3TM) receptors
3. The P2X purinergic (2TM) receptors

The overall structure of the ligand-gated ion channels shows homology with many of the voltage-regulated ion channels, such as the sodium channel and the L-type calcium channel.[6] Although the ligand-gated ion channels are primarily chemosensitive, their gating characteristics are modified by the potential of the membrane. Conversely, although the voltage-gated ion channels are primarily potential sensitive, they are also modified by a variety of agonistic and antagonistic ligands that bind at different sites on the channel and are often allosterically linked to one another. When considered from this viewpoint, the ligand- and voltage-gated ion channels form a large superfamily of receptors.

The 4TM receptors are pentameric complexes composed of at least two α subunits, which have been shown to contain the binding site for the endogenous ligand. These binding sites are thought to exist at the interface between one side of the α subunit and its adjacent subunit. As mentioned at the outset, precise information about nicotinic acetylcholine receptors has been obtained through analysis of its crystal structure. Accordingly, the nicotinic acetylcholine receptor of the neuromuscular junction has a pentameric structure consisting of two α_1 subunits and one β_1, one γ, and one δ subunit. These subunits are arranged like the staves in a barrel-like structure, with a central pore that is thought to be the channel of the receptor.[1] Although the precise subunit structure of neuronal nicotinic receptors and the other ligand-gated ion channels has not been determined unequivocally, it is thought to be analogous to that of the neuromuscular

nicotinic acetylcholine receptor, in that they are both pentameric with two α subunits. An approach that has been useful for drawing inferences about the subunit structure of other members of the 4TM family involves injecting the messenger RNA (mRNA) for different subunits into *Xenopus* oocytes and examining the functional activity of the expressed subunits pharmacologically.[16,17] For example, when an α subunit from the group α_2, α_3, and α_4 is expressed in combination with a β_2 subunit in *Xenopus* oocytes, functional receptors are formed, which presumably have a pentameric structure composed of two α and three β subunits. Similar results are obtained when an α subunit from the same group (i.e., α_2, α_3, or α_4) is expressed in combination with β_4 subunits. Also, α_5 subunit channels are thought to form in combination with α_3 and β_4 subunits. In most instances, the pharmacologic properties of each of the receptors exhibit different profiles from nicotinic agonists as well as some antagonists. It has also been shown that α_7, α_8, and α_9 subunits form functional homomeric channels in *Xenopus* oocytes, presumably consisting of five identical subunits. Moreover, recombinant homomeric $GABA_A$ receptors have been formed by injecting only mRNA for the α subunit into *Xenopus* oocytes, indicating that functional GABA-regulated ion channels can be formed from only α subunits.[18] However, these homomeric channels do not retain all the complex allosteric interactions characteristic of native $GABA_A$ receptors, and it is entirely possible that homomeric channels do not occur naturally. It is thought that the GABA binding sites form at the interface between α and β subunits of $GABA_A$ receptors and that benzodiazepine binding sites occur at the interface between α and γ subunits.[19] Several different subtypes of the individual subunits have been cloned for both the nicotinic and $GABA_A$ receptors, which raises the theoretical possibility of a large number of channel subtypes based on different combinations of the known subunits. However, functional studies in which the different mRNA subunits are expressed in *Xenopus* oocytes suggest a much smaller number of subtypes. These different subtypes of channels have different pharmacologic properties and sometimes unique developmental profiles.

Ligand-gated ion channels are widespread throughout the central and peripheral nervous systems and are responsible for rapid synaptic neurotransmission, characterized by synaptic delays of less than half a millisecond. The nicotinic acetylcholine receptor is present at the neuromuscular junction, where it is responsible for eliciting skeletal muscle contraction in response to impulse flow from motor neurons. These receptors are the targets for the neuromuscular blocking agents used as adjuncts to general anesthesia.[20] The $GABA_A$ receptor represents the major inhibitory neurotransmitter receptor in the brain, and it is an important target for a variety of drugs used to treat anxiety, convulsions, and insomnia.[21] Excitatory amino acid receptors are also abundant in the brain, and inhibitors of these ion channels may have a role in preventing the neuronal damage associated with brain ischemia following stroke.

G PROTEIN–LINKED RECEPTORS

Structure

The G protein–linked family of receptors is the largest, and it includes receptors for light, odorants, and a variety of endogenous neurotransmitters and signaling molecules, including acetylcholine (muscarinic acetylcholine receptor), catecholamines, histamine, serotonin, eicosanoids, lipids, amino acids, proteins, peptides, chemokines, nucleotides, and hormones.[6] These receptors trigger responses by binding with heterotrimeric G proteins, which in turn activate various effectors, including ion channels and enzymes that generate second messengers (see later discussion). Besides being involved in neurotransmission at a variety of synapses and junctions throughout the brain and peripheral autonomic nervous system, members of this family are also involved in the special sensory functions of vision, taste, and olfaction.[22] The light receptor in the retina, rhodopsin, consists of a tightly bound complex between a protein called opsin and a photoactive ligand called 11-*cis*-retinal.[23,24] When light shines on 11-*cis*-retinal, it isomerizes to the *trans* isomer, which induces a conformational change in rhodopsin, causing it to activate a G protein called transducin. Ultimately, transducin initiates a cascade of events leading to a hyperpolarizing response in the retinal ganglion cell. This signaling pathway is so highly amplified that a single photon of light has a 50% probability of triggering a response in the retinal ganglion cell. G protein–linked receptors are also involved in olfaction to a remarkable extent. The results of searches of genomic databases indicate that there may be approximately 400 to 500 types of genes for odorant receptors in the nose, each of which may be receptive to a different spectrum of odorants.[25] These searches also suggest the presence of about 400 nonolfactory G protein–coupled receptors.

Receptors belonging to the G protein–linked class all share a similar structure consisting of seven highly conserved, transmembrane-spanning domains of α helix that are connected to the less conserved amino-terminal, carboxy-terminal, and intra- and extracellular loops. Previously, it had been assumed that the three-dimensional structure of G protein–linked receptors conformed to that of bacteriorhodopsin, which had been determined by x-ray diffraction.[26] More recently, the x-ray structure of bovine rhodopsin was determined.[27] In bovine and bacteriorhodopsin, the transmembrane domains run perpendicular to the plane of the membrane and circumscribe a central pore. Retinal neurotransmitters and the neurotransmitters for muscarinic and catecholamine receptors are thought to bind at a site within the pore. Accordingly, point mutations in a highly conserved aspartic acid residue in the third transmembrane segment cause a loss in agonist binding at muscarinic[28] and beta-adrenergic receptors.[29] Not surprisingly, the part of the receptor involved in G protein coupling is a relatively large, hydrophilic domain that projects into the cytoplasm—namely, the third cytoplasmic (i3) loop. The strongest evidence for the coupling role of the i3 loop comes from studies of chimeric receptors in which the i3 loop of one receptor is replaced with that from another. For example, when the i3 loop of the muscarinic receptor was switched with that of the beta-adrenergic receptor, the chimeric receptor triggered beta-adrenergic effects in response to muscarinic agonists.[30,31] Analogous results have been observed in studies of chimeras constructed from a variety of other G protein–linked receptors. Interestingly, the i3 loops of several receptors are constitutively active by themselves.[32] Thus, the ligand binding domain (seven transmembrane segments) of G protein–linked receptors probably exerts a tonic inhibitory effect on the i3 loop, and the binding of neurotransmitter relieves this inhibition.

G Proteins

The G proteins involved in receptor signaling are heterotrimeric, consisting of α, β, and γ subunits.[33,34] The βγ subunits form a tightly bound complex that functions as a unit. The α subunits of heterotrimeric G protein are close relatives of many other low-molecular-weight G proteins that lack βγ subunits, such as the Ras protein mentioned earlier. These small G proteins participate in numerous metabolic processes within the cell, including some that have little to do with transmembrane signaling at the cell surface. The basic function that G proteins accomplish at the expense of GTP hydrolysis is transportation between two destinations. In the case of the low-molecular-weight G protein elongation factor Tu, there is a transport of transfer RNA complexes on the ribosome, whereas in the case of heterotrimeric G proteins, the G protein shuttles between the receptor and its effector. Thus, nature uses G proteins for a variety of roles, and the involvement of heterotrimeric G proteins in receptor signaling at the cell membrane probably represents a highly specialized function.

The α subunit of heterotrimeric G proteins shows the greatest diversity, and more than 20 different types of α subunits have been cloned.[22] By contrast, the βγ subunits seem to have fewer subtypes, and it appears that more than one type of α subunit can associate with the same dimer of βγ subunits. The α subunit confers selectivity for different receptors as well as effectors; however, the degree of selectivity is not absolute (see later discussion). For example, the M_2 subtype of the muscarinic receptor can interact with more than one type of G protein (e.g., G_o and $G_{i1\text{-}3}$[32]), and a single G protein of the G_i family can interact with more than one type of receptor (e.g., M_2 muscarinic and D_2 dopamine). However, receptors that interact with G_i and G_o are usually ineffective at interacting with G_s, and vice versa.[35] Generally, a given receptor usually, but not always, exhibits selectivity for one of three G protein families–$G_{i/o}$, G_s, or G_q. There is also selectivity at the level of the G protein–effector interaction. For example, members of the G_i family can mediate an inhibition of adenylyl cyclase activity; however, these G proteins are much less effective at coupling receptors to phospholipase Cβ (PLCβ). The α subunit of G proteins binds GTP, resulting in activation and a dissociation of the GTP-α complex from the βγ subunits. In addition, the α subunit has GTPase activity that hydrolyzes GTP to GDP, causing the inactive GDP-α complex to coalesce with the βγ subunits. The α subunits of some G proteins are also substrates for bacterial toxins that catalyze the adenosine diphosphate (ADP) ribosylation of the α subunit. For example, cholera toxin causes an ADP ribosylation of the α subunit of G_s, the G protein that stimulates adenylyl cyclase activity. This ADP ribosylation causes an inhibition of GTPase activity, resulting in an irreversible activation of G_s and, consequently, adenylyl cyclase. In contrast, pertussis toxin causes the ADP ribosylation of G_i and G_o, which prevents receptor-mediated activation of G_i and G_o. Transducin is a substrate for both cholera toxin and pertussis toxin.

GTPase Cycle

Figure 40-3 shows what happens inside the cell when an agonist activates a G protein–linked receptor:

1. Initially, the G protein is in its trimeric form, with GDP tightly bound to it. This inactive form of the G protein is a prerequisite for receptor interaction because the agonist-receptor complex cannot interact with free α or βγ subunits, only with the trimeric complex. Although the cell contains high concentrations (approximately 0.1 mM) of GTP, this nucleotide cannot compete GDP off the G protein because the dissociation rate of GDP from the α subunit is negligible.
2. The binding of agonist to its receptor causes a conformational change so that the i3 loop can interact with the G protein. This interaction allows the agonist to increase the rate of dissociation of GDP so that GTP can now bind to the G protein.
3. The binding of GTP causes a dissociation of the GTP α subunit from both the βγ subunits and the receptor, resulting in activation.
4. The GTP–α subunit complex and the free βγ subunits then turn on their respective effectors and ultimately trigger the cell's response to the agonist (Table 40-1).

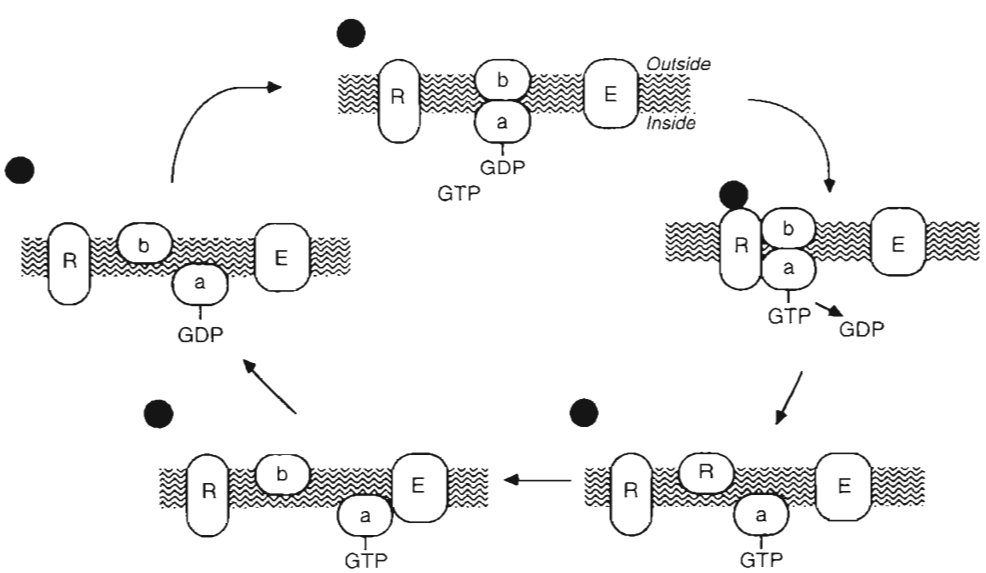

FIGURE 40–3. Receptor-activated GTPase cycle. Diagram of the interaction of an agonist *(black filled circle)* with its receptor (R) and the α (a) and βγ (b) subunits of a G protein. E, effector; GDP, guanosine diphosphate; GTP, guanosine triphosphate.

TABLE 40–1. SIGNALING MECHANISMS OF G PROTEIN–LINKED RECEPTORS

G Protein Family	Representative Receptors	Effect of G Protein Subunits on Enzymes and Ion Channels
G_s	β-adrenergic D_1 dopamine H_2 histamine	$G_{s\alpha}$ stimulates adenylyl cyclases (I to IX), opens calcium channels
G_i/G_o	M_2 and M_4 muscarinic D_2 dopamine α_2-Adrenergic	$G_{i\alpha}$ inhibits adenylyl cyclases (I, V, VI) $G_{i\beta\gamma}$ stimulates adenylyl cyclases (II, IV, VII), opens potassium channels $G_{o\beta\gamma}$ closes calcium channels
$G_{q/11}$	M_1, M_3, and M_5 muscarinic α_2-Adrenergic Angiotensin II	$G_{q\alpha}$ stimulates PLCβ $G_{11\alpha}$ stimulates PLCβ
G_T	Mammalian rhodopsin	Stimulates cGMP phosphodiesterase

cGMP, cyclic guanosine monophosphate; PLCβ, phospholipase Cβ.
Data from Hepler JR, Gilman AG: G-Proteins. Trends Biochem Sci 1992;17:383-387; and Tang WJ, Hurley JH: Catalytic mechanism and regulation of mammalian adenylyl cyclases. Mol Pharmacol 1998;54:231-240.

5. The turn-off mechanism is the GTPase activity of the α subunit, which hydrolyzes GTP. The resulting GDP α subunit then coalesces with the βγ subunits to form the trimeric complex, which is inactive.
6. The cycle can repeat itself, provided that agonist is occupying the receptor.
7. Another important protein, RGS (regulator of G protein signaling), increases the GTPase activity of the G protein (not shown in the figure).[36]

Several experimental observations support the scheme described, and a few of these are mentioned here. Muscarinic agonists cause the M_2 receptor to form a stable complex with G_i that can be identified on Western blots with antibodies to G_i or the M_2 receptor.[35] In contrast, antagonists do not promote the formation of a receptor–G protein complex. Moreover, the ability of the ligand to promote the ternary (agonist–receptor–G protein) complex is proportional to the intrinsic efficacy of the agonist.[37] This relationship is shown in Figure 40-4 for M_2 muscarinic receptors in the heart. The propensity of the agonist to generate the ternary complex can be measured in a binding assay; this parameter is denoted by "Receptor-Gi Cooperativity" in Figure 40-4*A*. It can be seen that the cooperativity is proportional to intrinsic efficacy for a number of agonists. Another conspicuous feature of most G protein–linked receptors is that the binding of ligands to the receptor is modified by GTP in manner that is proportional to the intrinsic efficacy of the ligand. Both GTP and GDP cause a reduction in agonist binding affinity, but not antagonist affinity. The relationship between intrinsic efficacy and the inhibitory effect of GTP (GTP shift) on ligand binding to M_2 muscarinic receptors in the heart is shown in Figure 40-4*B* for a number of ligands. The proportional relationship between the negatively cooperative effects of GTP on agonist binding and the intrinsic efficacy of the agonist is readily apparent from the plot.

The relationships shown in Figure 40-4 provide insight into how the receptor works. In considering the figure, it is important to note that both GDP and GTP inhibit agonist affinity, but not antagonist affinity. This effect is allosteric because the agonist and the guanine nucleotide act at different sites. Therefore, the nature of the interaction between the two types of ligands is called *negative heterotropic cooperativity.* One of the properties of allosteric interactions is that they are reciprocal; that is, if GDP or GTP reduces the affinity of the agonist, then the agonist must reduce the affinity of the guanine nucleotide to precisely the same extent.[38] This agonist-mediated reduction in the affinity of GDP causes it to dissociate from the G protein more rapidly, allowing GTP to compete it off the G protein. Although this increase in the dissociation kinetics of GDP is achieved at the cost of reducing the affinity of GTP, it does not result in a decrease in the binding of GTP, because GTP is maintained at saturating concentrations inside the cell. For example, the K_D of GTP analogs for the G protein is in the nanomolar (10^{-9} M) range, whereas the concentration of GTP inside the cell is in the millimolar (10^{-3} M) range. Thus, it can be seen that the agonist-receptor complex works by increasing the dissociation kinetics of GDP from the G protein and that this effect is mediated by negative heterotropic cooperativity.

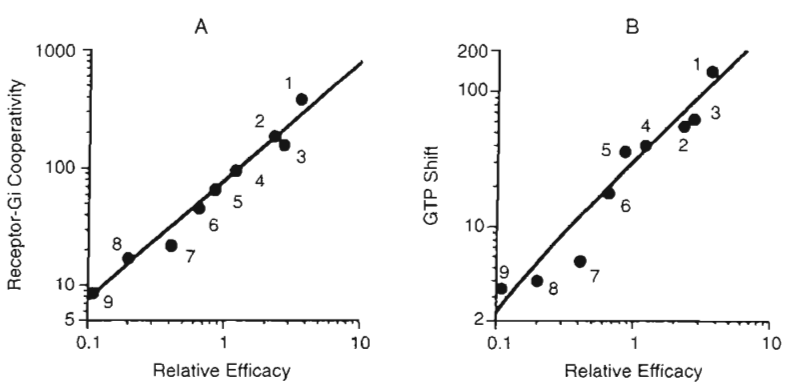

FIGURE 40–4. Correlation between relative efficacy and agonist binding properties at M_2 muscarinic receptors. *A*, The positive heterotropic cooperativity between the binding of the agonist and G_i is plotted against the relative efficacy of the agonist as determined by inhibition of adenylyl cyclase activity. *B*, The ratio of the concentration of the agonist in the presence and absence of guanosine triphosphate (GTP) is plotted against the relative efficacy of the agonist. 1, oxotremorine-M; 2, carbachol; 3, *cis*-dioxolane; 4, oxotremorine; 5, (+)-aceclidine; 6, (–)-aceclidine; 7, *N*-methylaceclidine; 8, BM5; 9, BOK1. SIGNALING MECHANISMS OF G PROTEIN–LINKED RECEPTORS

G protein–linked receptors mediate myriad responses at the level of the whole tissue; however, at the subcellular level, these responses seem to be triggered by a relatively small number of transduction mechanisms. This situation illustrates that diversity is achieved through divergence in the signaling pathway, and that the factors that determine the intermediate and distal parts of the signaling mechanism are tissue specific. Thus, calcium mobilization resulting from activation of a PLCβ-linked receptor in smooth muscle may cause contraction,[39] whereas in an exocrine gland, the same transduction mechanism may cause secretion. Some of the major transduction mechanisms of G protein–linked receptors are summarized here and listed in Table 40-1.

CALCIUM MOBILIZATION

Perhaps the most universal mechanism for triggering a response is to increase the concentration of calcium within the cell.[40] Not surprisingly, several different signaling mechanisms ultimately affect the level of calcium within the cytoplasm. One common mechanism for elevating calcium is through activation of PLCβ, an enzyme that hydrolyzes the phospholipid phosphatidylinositol-4,5-bisphosphate (PIP_2) into inositol-1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG).[41,42] This membrane-bound enzyme is activated by numerous receptors that signal through the G_q family of G proteins (see Table 40-1). The two hydrolysis products, IP_3 and DAG, act as second messengers within the cell.[42] IP_3 causes a release of calcium from the endoplasmic reticulum, and DAG activates protein kinase C. IP_3 is phosphorylated in some cells to inositol-1,3,4,5-tetrakisphosphate (IP_4), which appears to have a role in assisting IP_3 to mobilize calcium.[43] Both IP_3 and IP_4 are unstable and are sequentially hydrolyzed by phosphatases back to inositol, which is then recycled for synthesis of new PIP_2. The final phosphatase in the sequence, myoinositol-1-phosphatase, is inhibited by lithium. Ultimately, this inhibition leads to an accumulation of inositol-1-phosphate and a depletion in inositol and inositol-containing phospholipids (e.g., PIP_2) within the brain. This depletion can lead to a dampening in receptor signaling through the PLCβ pathway, and it has been suggested that this dampening is the mechanism by which lithium attenuates the symptoms of manic-depressive psychosis.[44] Once calcium is elevated in the cell, it can mediate a variety of effects by binding to calmodulin and activating a variety of kinases and phosphatases. The protein kinase C that is activated by DAG also mediates numerous effects, and it is the target for some tumor-promoting phorbol ester derivatives.

ADENYLYL CYCLASE

Another important signaling mechanism within the cell is the regulation of adenylyl cyclase (see Table 40-1). G protein–linked receptors that affect adenylyl cyclase can be divided into two categories, depending on whether they stimulate or inhibit the enzyme.[22] G_s mediates the stimulation, whereas in most instances, G_i mediates inhibition through a distinct group of receptors. Nine different isoforms of adenylyl cyclase (AC1 to AC9) have been identified, and all these are activated by the α subunit of G_s (i.e., α_s).[45,46] The α_i subunit inhibits AC1, AC3, AC5, AC6, AC8, and AC9, whereas βγ subunits increase the activity of AC2, AC4, and AC7 in a manner dependent on activation by α_s. Once cyclic adenosine monophosphate (cAMP) rises within the cell, it can mediate a variety of effects through activation of cAMP-dependent protein kinase (protein kinase A). The turn-off mechanism for cAMP is phosphodiesterase, which rapidly hydrolyzes cAMP into AMP.

RECEPTOR CROSS-TALK

There are several possibilities for cross-talk between receptors that stimulate adenylyl cyclase and those that activate PLCβ. For example, AC1 (abundant in brain), AC3, and AC8 are activated by calcium.[47] Also, calcium stimulates phosphodiesterase in some tissues. Moreover, the stimulation of adenylyl cyclase caused by G_s-linked receptors is enhanced by activation of protein kinase C in some tissues. Finally, α_s-mediated stimulation of AC2 and AC4 has been shown to be greatly potentiated by the βγ subunits, which provides yet another mechanism for receptor cross-talk.

In addition to the second messenger systems described earlier, G protein–linked receptors can affect a variety of ionic conductances.[48] In several instances, these effects are mediated indirectly by second messengers, whereas in other cases, there is direct coupling of G proteins to ion channels. One such example is in the heart, where muscarinic receptors and beta-adrenergic receptors cause reciprocal changes in the conductivity of inwardly rectified potassium channels. These effects are mediated by G_i and G_s, respectively, and represent the mechanisms by which the vagus nerve slows heart rate and the cardiac sympathetic nerves increase heart rate.

CELLULAR SIGNALING AND CANCER

Most cancer cells contain mutations in their DNA that presumably cause tumorigenesis.[49] These mutations are of two general forms: *recessive*, which result in a loss of function of tumor suppressor genes, and *dominant*, which result in a gain in function. The genes that contain these dominant mutations are designated oncogenes, and their normal counterparts are referred to as proto-oncogenes. Invariably, proto-oncogenes code for proteins that are part of normal receptor signaling cascades within the body. For example, truncated forms of the epidermal growth factor receptor lacking the ligand binding domain are constitutively active and cause tumorigenesis.[10] Relatively small changes in signaling proteins are oncogenic in numerous instances. For example, point mutations in G_i have been implicated in carcinoma of the ovary and adrenal gland, whereas point mutations in G_s are present in adenomas of the pituitary gland and carcinoma of the thyroid.[50] Interestingly, these point mutations result in a loss of the GTPase activity of these G proteins, causing them to become constitutively active. There are numerous other examples of oncogene products that are mutated signaling proteins, including ligand-regulated gene regulatory proteins, RTKs, G protein–linked receptors, and low-molecular-weight G proteins, including Ras. Thus, in numerous instances, tumorigenesis is caused by overactive, unregulated receptor signaling.

DIVERSITY AND REDUNDANCY

In considering the diverse mechanisms by which information is transmitted throughout the body by way of receptor signaling, one is struck by two seemingly opposite principles of nature: diversity and redundancy.[51] Nature is redundant in the sense that only four different types of mechanisms can account for the function of what may turn out to be more than a thousand different types of physiologic and sensory receptors. Also, the same general GTPase cycle is harnessed for innumerable functions within the cell, including protein synthesis, secretion, neurotransmission, taste, olfaction, and vision. To accomplish these diverse tasks, nature modifies a given mechanism in an extraordinary number of ways. An appreciation of the diversity and redundancy of nature will aid in the future unraveling of biologic mechanisms and in the development of therapeutic agents to treat disease.

Chapter 41

PROSTAGLANDINS, THROMBOXANES, LEUKOTRIENES, AND OTHER PRODUCTS OF ARACHIDONIC ACID

James A. Cook • Hongkuan Fan • Perry V. Halushka

KEY POINTS

1. **Eicosanoids include a broad range of arachidonic acid metabolites,** including the cyclooxygenase products thromboxane B_2, prostaglandin E_2, prostacyclin, and 15-deoxy-$\Delta^{12,14}$-prostaglandin J_2, and the lipoxygenase products leukotriene B_4, C_4, D_4, and E_4 and lipoxin A_4.
2. **Eicosanoid synthesis and action can be inhibited by a variety of receptor antagonists and synthesis inhibitors,** the most recently developed of which are the cyclooxygenase 2 inhibitors.
3. **Both cyclooxygenase products and lipoxygenase products are increased** in animal models of endotoxemia, sepsis, and lung injury.
4. **Employment of specific cyclooxygenase or lipoxygenase synthesis inhibitors or specific arachidonic acid metabolite receptor antagonists** attenuates the sequelae or improves survival in animal models of endotoxemia, sepsis, and lung injury.
5. **Lipoxin A_4 and the J series of prostaglandins (cyclopentenone prostaglandins) are anti-inflammatory** and may play a role in inflammation resolution.
6. **Studies demonstrate increased synthesis** of thromboxane, prostacyclin, and leukotriene in patients with septic trauma or acute respiratory distress syndrome and suggest a deleterious role for thromboxane.
7. **Clinical trials with the nonsteroidal anti-inflammatory drug ibuprofen in severely septic patients** did not improve survival but reduced the febrile response and tachycardia and increased oxygen consumption and lactic acidosis.
8. **Combination drug therapy** with eicosanoid synthesis inhibitors, receptor antagonists, or anti-inflammatory eicosanoids may be more effective in sepsis or acute respiratory distress syndrome.

The first report of the biologic activity of what were subsequently identified as prostaglandins (PGs) was published in 1930, when it was found that extracts of seminal fluid contracted uterine tissue.[1] Von Euler attributed the activity of the extract to lipid substances that he named *prostaglandins*, because he thought they came from the prostate.[2] The structures of two of the prostaglandins (PGE_2 and $PGF_{1\alpha}$) were subsequently elucidated by the use of gas chromatography–mass spectrometry, and with this discovery, research in the field grew rapidly.[3] Thromboxane B_2 (TXB_2) was isolated by Samuelsson and colleagues in 1978 from human platelets.[4] It is the stable metabolite of TXA_2, whose structure was deduced at the time and was later proved to be correct. The name *thromboxane* was chosen because the substance causes platelet aggregation (thrombosis) and has an oxane ring system. It was ultimately shown that a rabbit aorta-contracting substance was TXA_2.[5] Prostacyclin (PGI_2) was discovered in 1976.[6]

The next major group of arachidonic acid metabolites to be discovered and characterized was the leukotrienes (LTs). Their name derives from the observation that they are made by leukocytes and have triene structures.[7] The sulfidopeptide leukotrienes were shown to be the active principals of the slow-reacting substance of anaphylaxis, released from mast cells and neutrophils.[7] Arachidonic acid, dihomo-γ-linolenic acid, and eicosapentaenoic acid are precursors of prostaglandins, thromboxanes, and leukotrienes. The first two are also known as *eicosatetraenoic acid* and *eicosatrienoic acid*, respectively; thus, the name *eicosanoids* is used generically for the products of these fatty acids.

The products of fatty acid cyclooxygenase and lipoxygenase pathways are named with letters and numbers. The letters for the cyclooxygenase pathway metabolites refer to substitutions on the cyclopentane ring; for the leukotriene pathway, the letters refer to the amino acids coupled with the fatty acid.[7] The numbers refer to the number of double bonds present on the side chains.

SITES OF SYNTHESIS AND PHARMACOLOGIC ACTIVITY OF THE EICOSANOIDS

FATTY ACID CYCLOOXYGENASE PRODUCTS

The pathway for the metabolism of arachidonic acid is shown in Figure 41-1. PGA, PGB, and PGC are nonenzymatic

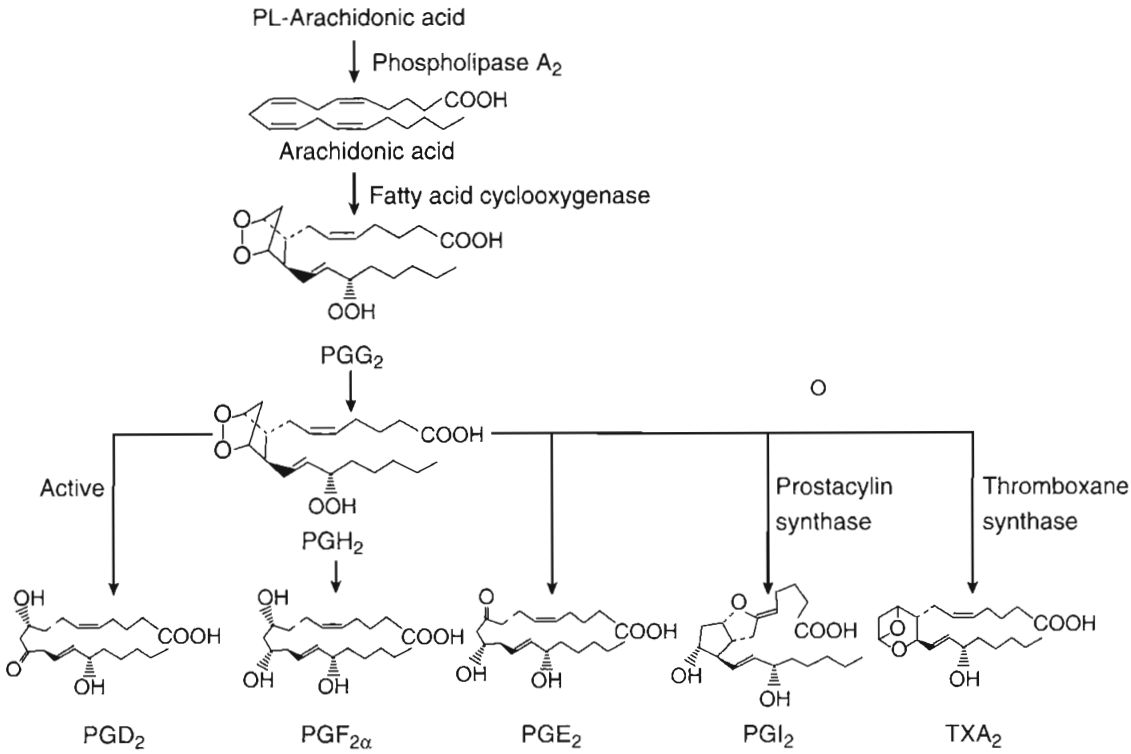

FIGURE 41–1. Metabolism of arachidonic acid. PG, prostaglandin; PGI_2, prostacyclin; PL, phospholipase; TXA_2, thromboxane A_2. (From Wagner TR, Halushka PV, Cook JA: Cyclooxygenase products in septic endotoxic shock. In Neugebauer EA, Holaday JW [eds]: Handbook of Mediators in Septic Shock. Boca Raton, Fla, CRC Press, 1993, pp 395-418.)

dehydration products of PGE_2 and are considered artifacts of the extraction procedure. However, PGA is a vasodilator. PGD_2 is synthesized in large quantities by mast cells, being the major cyclooxygenase metabolite in this cell. It and its major metabolite, 9α, 11β, $PGF_{2\alpha}$, are potent bronchoconstrictors and are overproduced in mastocytosis.[8] Depending on the vascular bed, it may be either a vasoconstrictor or a vasodilator. Vasodilatation usually occurs at lower doses; however, PGD_2 also constricts the pulmonary artery. It is synthesized by platelets and inhibits platelet aggregation by increasing intraplatelet cyclic adenosine monophosphate (cAMP) levels. It has yet to be determined whether its synthesis is increased in shock.

PGE_2 is synthesized mainly by the kidneys, platelets, and blood vessels, but it is also synthesized by many other tissues in smaller amounts. It is a vasodilator, natriuretic, and diuretic; inhibits gastric acid secretion; and contracts uterine tissue. Depending on the tissue, PGE_2 can bind to four subtypes of receptors, designated EP_1, EP_2, EP_3, and EP_4. Seven EP_3 splice variants have been identified in humans.[9] The EP receptors are classic heptahelical G protein–coupled receptors.[10] EP_1 is coupled to Gq and activates phospholipase C. EP_2 and EP_4 couple to G_s and stimulate the synthesis of cAMP, whereas EP_3 is coupled to G_i, which inhibits cAMP formation. The EP_1, EP_3, and EP_4 receptors have also been shown to be expressed on nuclear membranes of endothelial cells, suggesting a potential level of control in nuclear events.[11] PGE_2 synthesis is significantly increased in shock syndromes (discussed later).

$PGF_{2\alpha}$ is synthesized in many tissues in variable amounts and is increased in sepsis. It is a bronchoconstrictor and venoconstrictor, and it contracts uterine smooth muscle. All these actions are mediated by $PGF_{2\alpha}$ receptors (FP).[10,12]

PGI_2 is synthesized by endothelial cells, macrophages, lungs, and kidneys. It is a vasodilator and antiaggregatory substance with a half-life of about 10 minutes; it spontaneously hydrolyzes to form the stable but inactive metabolite 6-keto-$PGF_{1\alpha}$. The major urinary metabolite of 6-keto-$PGF_{1\alpha}$ is 2,3-dinor-6-keto-$PGF_{1\alpha}$. The major biochemical action of PGI_2 is to stimulate adenylate cyclase. To date, only one class of PGI_2 receptors (IP) has been identified.[10,12]

TXA_2 is synthesized in large quantities by platelets, macrophages, monocytes, and lungs. It is unstable and has a half-life of only 30 seconds; it spontaneously hydrolyzes to form the stable but inactive TXB_2. The major plasma metabolite of TXB_2 is 11-dehydro-TXB_2. The major urinary metabolites are 11-dehydro-TXB_2 and 2,3-dinor-TXB_2. TXA_2 is a potent vasoconstrictor, bronchoconstrictor, and proaggregatory substance. Based on pharmacologic criteria, two subtypes of receptors have been identified for TXA_2. One is associated with platelet aggregation, and the other is associated with vascular smooth muscle cell contraction.[8,10,12] There is also a splice variant of the platelet receptor, which was first discovered in endothelial cells. Platelet aggregation and TXA_2 synthesis are markedly increased in shock syndromes.

Leukotriene B_4 (LTB_4) is synthesized by white blood cells, macrophages, and synoviocytes.[13] It is a potent chemotactic substance for white blood cells.

LTC_4 is synthesized by white blood cells, lung parenchymal tissue, and macrophages. It is converted to LTD_4, an active metabolite of LTC_4. It is a vasoconstrictor and bronchoconstrictor and increases capillary permeability and bronchial mucus secretion. Its synthesis is increased during sepsis and acute respiratory distress syndrome (ARDS).[14] The urinary excretion of *N*-acetyl LTE_4, a metabolite of LTD_4, is increased in ARDS and shock.[15]

ARACHIDONIC ACID RELEASE

Release of arachidonic acid from membrane phospholipids is the rate-limiting step in the formation of eicosanoids in nonpathologic states.[16] Stimulation of cells by hormonal and nonhormonal agonists results in activation of phospholipase (PL) A_2, C, or D. Activation of PLA_2 results in the release of arachidonic acid from the *sn2* position of phosphatidylcholine and phosphatidylethanolamine.[17] Isozymes of PLA_2 have demonstrated a specificity for catalyzing the release of arachidonic acid preferentially from either phosphatidylcholine or phosphatidylethanolamine.[18] PLA_2 has several subtypes. There is cytosolic PLA_2, which is Ca^{++} dependent, and secretory forms of PLA_2 designated PLA_2-I and PLA_2-II.[14] PLA_2-I is secreted by pancreatic acinar cells and is important in phospholipid digestion in the diet. PLA_2-II is secreted by inflammatory cells and has been shown to increase in plasma in response to a variety of inflammatory conditions such as sepsis, trauma, and pancreatitis.[19-22] Cytosolic PLA_2 is intracellular and is activated by a number of stimuli, including tumor necrosis factor (TNF), interleukin (IL)-β, bradykinin, and many other inflammatory stimuli.[23,24] PLC cleaves phosphatidylinositol 4,5-bisphosphate, resulting in inositol-1,4,5-trisphosphate and 1,2-diacylglycerol, both of which function as intracellular second messengers.[25-28] Diglyceride lipase then releases the arachidonic acid from the diacylglycerol.[29,30] The metabolite 1,2-diacylglycerol stimulates protein kinase C.

A variety of agonists can stimulate PLD.[31] Both guanine nucleotide regulatory proteins and kinases are coupled to receptor-mediated regulation of PLD. PLD activation requires a cofactor, phosphatidylinositol 4,5-bisphosphate. The metabolite phosphatidic acid produced by PLD may play a role in growth regulation, activation of Ca^{++}-independent forms of protein kinase C, neutrophil respiratory burst activity, stimulation of lysophosphatide acid receptors, and vesicle trafficking.[32]

The particular phospholipid substrate providing arachidonic acid in response to a specific stimulus may influence whether lipoxygenase or fatty acid cyclooxygenase products are formed. Resident murine macrophages, in response to stimuli that activate the lipoxygenase pathway, demonstrate dependence on the PLC–diglyceride lipase pathway,[33] whereas endotoxin- or phorbol myristate acetate–induced prostaglandin formation is independent of the PLC–diglyceride lipase pathway.

FATTY ACID CYCLOOXYGENASE (PROSTAGLANDIN H SYNTHASE)

Fatty acid cyclooxygenase (PGH synthase) catalyzes the committed step in the conversion of arachidonic acid to the prostaglandin endoperoxides PGG_2 and PGH_2.[34] PGH_2 is the direct precursor for primary prostaglandins and TXA_2. Fatty acid cyclooxygenase has been found in most of the organs of all mammalian species but not in all cell types.[33] Subcellular studies demonstrate that cyclooxygenase is an integral membrane protein concentrated in the endoplasmic reticulum, as well as in the nuclear envelope and the plasma membrane.[35,36] Cyclooxygenase is approximately 68 kDa; species variations are attributed to different amounts of *N*-glycosylation and mannose carbohydrate side chains.[37] Two sites of enzymatic activity have been proposed,[38] and heme-binding sites are conserved.[39]

Cyclooxygenase possesses two enzymatic activities.[40] The first activity cyclizes an oxygen molecule in a bis-dioxygenase configuration at carbon (C)-9 and C-11, converting arachidonic acid to PGG_2. PGH synthase then uses another oxygen molecule to peroxidize this unstable metabolite at C-15, converting PGG_2 into PGH_2. The bound heme of cyclooxygenase is believed to act as the electron transfer site in these reactions. PGH_2 is the substrate for the enzymes responsible for the synthesis of PGD_2, PGE_2, $PGF_{2\alpha}$, PGI_2, and TXA_2. The final product profile is dependent on the specific cell type.

Many fatty acids are substrates for cyclooxygenase, but arachidonic acid is the most common in vivo.[32] Cyclooxygenase is inhibited by aspirin and all the nonsteroidal anti-inflammatory drugs (NSAIDs). Aspirin irreversibly inhibits the enzyme by covalently acetylating a serine residue. In platelets, the inhibition lasts for the life of the platelet (7 to 10 days), because platelets are not capable of synthesizing new enzyme.

In the early 1990s, two isoforms of cyclooxygenase were identified: COX-1 and COX-2. These two isoforms have been extensively characterized. COX-1 is the constitutive, continuously expressed form that is thought to play a role in normal homeostatic processes in platelets, the kidneys, and the gastrointestinal tract. COX-2 is the inducible form.[41] Its synthesis is stimulated by inflammatory stimuli such as lipopolysaccharide and IL-1 and by growth factors.[41,42] Both enzymes are inhibited by aspirin, indomethacin, and other NSAIDs.

Pharmacologic studies led to the development of a new generation of COX-2 inhibitors (e.g., celecoxib [Celebrex], rofecoxib [Vioxx]). The COX-2 inhibitors retain the anti-inflammatory properties of traditional nonselective NSAIDs, but without the gastrointestinal bleeding side effects. The widespread use of COX-2 inhibitors proved that they are as active as traditional NSAIDs in reducing pain and fever.[43,44] It became apparent, however, that although COX-2 inhibitors have a better profile in terms of gastrointestinal mucosal protection, they still have renal side effects.[45] They may also produce a prothrombotic state, but this is controversial. Studies suggest that COX-2 also has a physiologic role, particularly in the kidney. The COX-1–COX-2 model does not accommodate acetaminophen, which has antipyretic and analgesic properties but no anti-inflammatory effects. Because acetaminophen is not an anti-inflammatory drug, this suggests that its pharmacologic effects cannot be explained by COX-2 inhibition.[46] Recent studies by Chandrasekharan and coworkers suggest that COX-3, a COX-1 variant, is inhibited by acetaminophen and other analgesic and antipyretic drugs.[47]

LIPOXYGENASE

The lipoxygenase pathways of arachidonic acid metabolism involve three species of lipoxygenases: 5-lipoxygenase, 12-lipoxygenase, and 15-lipoxygenase.[48-50] These enzymes insert a molecule of oxygen into arachidonic acid at C-5, C-12, and C-15, respectively, forming the 5-, 12-, and 15-hydroxyeicosatetraenoic acids (HETEs).

5-Lipoxygenase demonstrates several unique characteristics compared with the other human lipoxygenases. It is dependent on adenosine triphosphate and Ca^{++} for activation, as well as three additional components.[51,52] One of these components is an 18-kDa protein, called 5-lipoxygenase-activating protein (FLAP), that is required for both the translocation and the activation of 5-lipoxygenase.[51,53] 5-Lipoxygenase metabolizes arachidonic acid to 5-hydroperoxyeicosatetraenoic acid

(5-HPETE). 5-HPETE is further metabolized to 5-HETE and LTA_4. LTA_4 is an unstable intermediate that is rapidly metabolized to LTB_4 by LTA_4 hydrolase or to LTC_4 by LTC_4 synthase. LTC_4 consists of glutathione covalently bound to arachidonic acid at the C-6 position (a sulfidopeptide leukotriene). The glutamic acid moiety of glutathione is cleaved by a γ-glutamyltranspeptidase to produce LTD_4. LTD_4 is further metabolized by a peptidase or a cysteinyl-glycinase to form LTE_4. LTE_4 can be *N*-acetylated and subsequently excreted in the urine.

12-Lipoxygenase metabolizes arachidonic acid to 12-HPETE and the metabolites di-HETE and tri-HETE. 12-Lipoxygenase is found in platelets and is the predominant lipoxygenase in brain tissue.

15-Lipoxygenase is approximately 70 kDa in size.[54] Its activity is preferentially expressed only in certain cells,[55] but the biologic role of 15-lipoxygenase in these cell types is not fully understood.[56] Recent evidence suggests that lipoxins (LX) that are generated by 15-lipoxygenase may be involved in inflammation resolution. Polymorphonuclear leukocytes (PMNs) and tissue resident cells can generate LXs, which appear to regulate leukocyte function. LXA_4 and its metabolically stable analogs can inhibit PMN-mediated inflammation in vivo in a variety of tissues.[57] The LXs can augment monocyte chemotaxis and phagocytosis of apoptotic leukocytes and can modulate the expression of chemokines and cytokines.[58] It has been proposed that peripheral blood PMNs exposed to PGE_2 (produced in inflammatory exudates) switch eicosanoid biosynthesis from the predominantly 5-lipoxygenase pathway leading to LTB_4 production to the 15-lipoxygenase pathway producing LXA_4. The latter may function as a "stop signal" for inflammation.[59]

OTHER METABOLITES

The J series of prostaglandins (cyclopentenone PGs) is formed by progressive nonenzymatic dehydration of PGD_2 (Fig. 41-2). What makes the cyclopentenone PGJ_2 family unique is that, unlike other prostaglandins, it has no known membrane receptor. Instead, PGJ_2 and its metabolites interact with a class of nuclear receptors that comprise the peroxisome proliferator-activating receptor (PPAR) family (specifically, PPAR-γ). The PPAR family is ligand-activated by nuclear transcription factors, which form a heterodimer with retinoid X receptor, and binds to a PPAR-responsive element, the promoter region of specific inflammatory genes.[60] The 15-deoxy-$\Delta^{12,14}$-PGJ_2 metabolite is the most potent ligand for PPAR-γ. Activation of PPAR-γ can transrepress the activation of many transcription factors, including nuclear factor kappa-B (NF-κB), activator protein-1, signal transducers of transcription, and nuclear factor of activated T cells. PPAR-γ is found in a variety of cells, including macrophages, dendritic cells, and B and T lymphocytes.[61-65] There is a rapidly expanding literature that PPAR-γ may play a role in regulating inflammation and immunomodulation.[66] However, many studies have shown that PPAR-γ ligands have anti-inflammatory effects only at concentrations that far exceed those required for activation of PPAR-γ.[67] It has been shown that these ligands (e.g., 15-deoxy-$\Delta^{12,14}$-PGJ_2) clearly have PPAR-γ–independent activities through the covalent modification of critical cysteine residues in the inhibitor of NF-κB, the p50 NF-κB subunit, and extracellular signal-regulated kinase (ERK).[68-70]

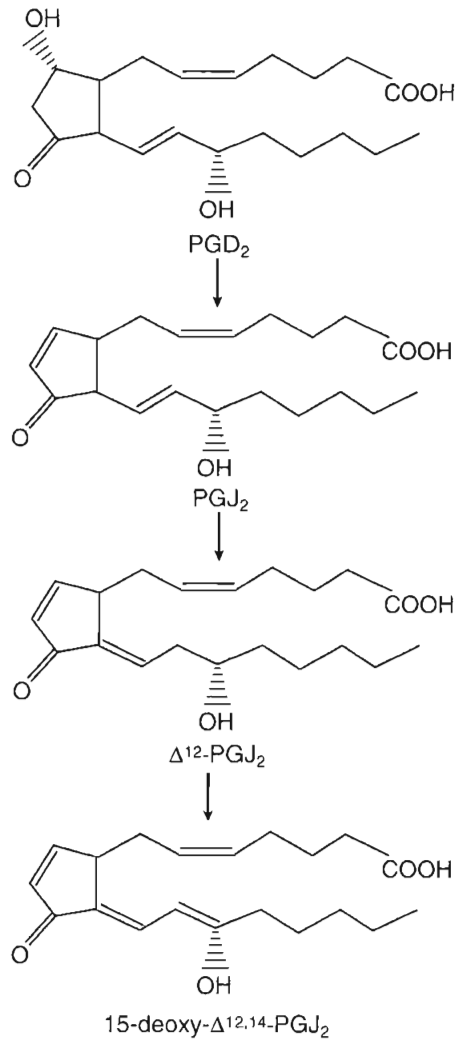

FIGURE 41–2. Metabolism of PGD_2 to 15-deoxy-$\Delta^{12,14}$-PGJ_2. PG, prostaglandin.

Cytochrome P_{450} can also oxygenate arachidonic acid at various sites.[71] This results in the production of a multitude of epoxides that have diverse biologic properties. These metabolites are usually synthesized in large quantities by the liver and kidneys. Whether these products are increased in sepsis remains unknown.

Isoprostanes are a novel group of nonenzymatically generated arachidonic acid metabolites.[72] They are formed directly by free radical oxidation of arachidonic acid while still esterified to the two positions of membrane phospholipids. Isoprostanes are structurally similar to prostaglandins and may exert some of their effects through the activation of TXA_2 receptors. They cause vasoconstriction, change in platelet shape, and increased pulmonary permeability.[73] Although they are generated under oxidative stress, the potential role of isoprostanes in ARDS and sepsis remains to be determined.

INCREASED SYNTHESIS OF EICOSANOIDS IN ENDOTOXEMIA AND SEPSIS

The seminal observation that eicosanoids may be involved in the pathogenesis of endotoxic shock was made by Northover and Subramanian in 1962.[74] They demonstrated that dogs treated with aspirin before exposure to endotoxin had an

improved survival compared with control animals. At that time, it was not known that aspirin inhibited prostaglandin synthesis. In 1976, Herman and Vane demonstrated increased levels of PGE-like material in the renal veins of dogs given endotoxin.[75] Taken together, these two observations suggested that eicosanoids were important in the pathogenesis of septic shock.

Increased synthesis of eicosanoids in response to endotoxemia and sepsis occurs in several animal species and in humans. Increased plasma levels of TXB_2 and 6-keto-$PGF_{1\alpha}$ can be demonstrated in rats with experimental endotoxemia and sepsis.[48,76-78] Similar profiles of TXB_2 and 6-keto-$PGF_{1\alpha}$ in plasma are observed in endotoxemic or septic sheep,[79,80] pigs,[76,81-85] and baboons.[86,87] The relative amounts of TXB_2 and 6-keto-$PGF_{2\alpha}$ are influenced by the experimental route and frequency of endotoxin administration.[88,89]

5-Lipoxygenase products are also increased in endotoxemic animals and in patients with sepsis and ARDS.[90] In endotoxemic rats, Hagman and colleagues reported increases in biliary *N*-acetyl LTE_4, a stable metabolite of sulfidopeptide leukotrienes.[91] LTC_4 levels are increased in the lungs of rats with experimental endotoxemia.[92] Increased LTB_4 levels are found in bronchoalveolar lavage fluid of endotoxemic pigs[93] and in lung lymph in endotoxemic sheep.[94] Induction of cecal ligation and puncture (CLP) in mice was associated with eightfold higher levels of LTB_4 in peritoneal exudate compared with the sham group.[95] Slotman and coworkers compared the effect of sepsis and hemorrhagic shock on eicosanoid protection in a porcine model.[96] In sepsis-induced by *Aeromonas hydrophila*, there was an early peak in plasma TNF (at 60 minutes), followed by a rise in peak LTB_4 and LTC_4/D_4 levels (180 minutes). TXB_2 and 6-keto-$PGF_{1\alpha}$ continued to increase over the 4-hour duration of the study. In contrast, there was no increase in eicosanoids or TNF in the hemorrhagic group. These studies have implications for the development of therapies for these pathologic insults. Indeed, increases in sulfidopeptide leukotrienes and LTB_4 have been demonstrated in the bronchoalveolar lavage fluid of patients with ARDS, a complication associated with sepsis.[15,97-101]

EFFECT OF EICOSANOID SYNTHESIS INHIBITORS, RECEPTOR ANTAGONISTS, AND ANTI-INFLAMMATORY EICOSANOIDS

More direct evidence that eicosanoids mediate endotoxin-induced sequelae is provided by observations that the inhibition of eicosanoid synthesis or the blockade of specific receptors protects animals from shock sequelae (Fig. 41-3). Because PLA_2-II is increased in sepsis,[20] some studies examined the potential beneficial effect of inhibitors of PLA_2-II. The putative selective PLA_2-II inhibitor SB203347 and eucalyptus bioflavonoids (Quercetin), which alter neutrophil PLA_2-II release, improved survival in murine endotoxic shock.[102] PLA_2-II enzyme-deficient mice exhibited prolonged survival and reduced plasma cytokine in response to endotoxemia compared with wild-type subjects. PLA_2-II may, in part, potentiate lipopolysaccharide (LPS) shock by augmenting cellular responses to LPS. PLA_2-II potentiated LPS-induced IL-6 production in whole blood and binding of LPS to PMNs.[103]

Numerous NSAIDs have been evaluated for potential therapeutic benefit in endotoxemia and sepsis in animal models.[48] These compounds, when used in experimental sepsis or endotoxemia, have generally been found to improve survival or survival time and to reduce cardiopulmonary dysfunction and indices of tissue injury.[48,76-78] Among the most extensively studied prototype NSAID is ibuprofen. In various species with endotoxemia and sepsis, ibuprofen has been shown to improve systemic hypotension, pulmonary hypertension, protein and fluid extravasation, lung water flux, airway resistance, and oxygen delivery.[48,78,83,88,104-106] In some studies, however, ibuprofen did not improve shock sequelae.[106] Ibuprofen also alters neutrophil function, including inhibition of neutrophil aggregation, organ infiltration, and adherence.[104,106] As with

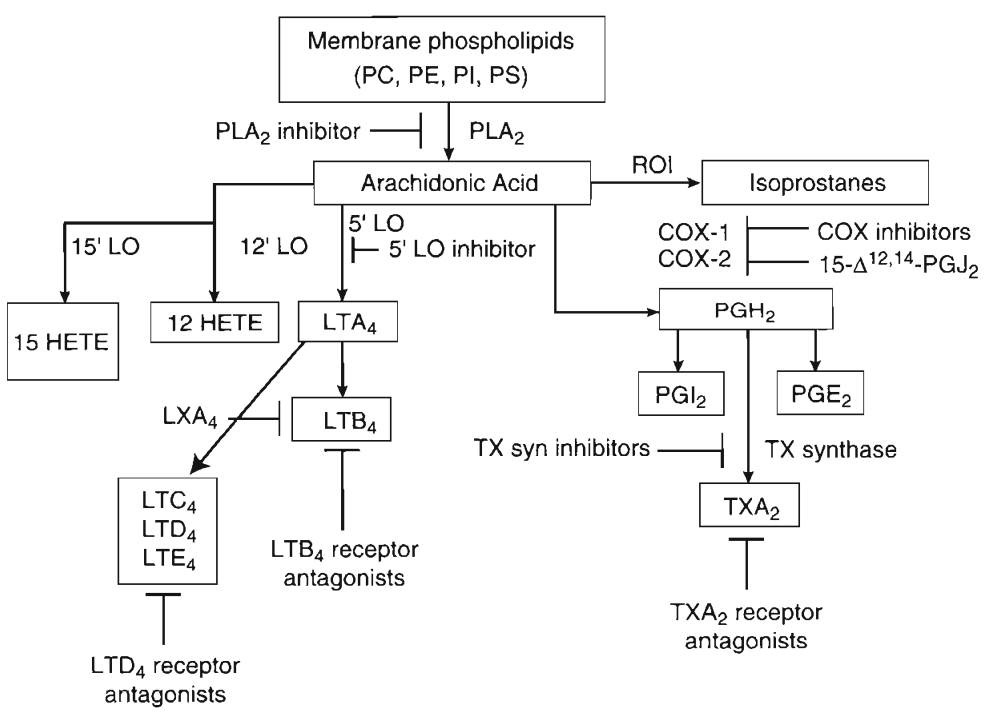

FIGURE 41–3. Metabolism of membrane phospholipids. COX, cyclooxygenase; HETE, hydroxyeicosatetraenoic acid; LO, lipoxygenase; LT, leukotriene; LXA_4, lipoxin A_4; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PG, prostaglandin; PI, phosphatidylinositol; PLA_2, phospholipase A_2; PS, phosphatidylserine; ROI, reactive oxygen intermediates; TXA_2, thromboxane A_2.

other NSAIDs, it is likely that some of these salutary effects are the result of pharmacologic actions of ibuprofen other than inhibition of fatty acid cyclooxygenase. These actions include potential inhibition of LTB_4 production,[106] superoxide anion production,[106] scavenging of hydroxyl radicals,[107] and burn-induced inhibition of fibrinolysis.[108]

A major concern in the use of NSAIDs is their renal and gastrointestinal side effects. By inhibiting COX-1–dependent prostaglandin synthesis in those organs, NSAIDs can render septic animals more susceptible to renal failure[109,110] and gastrointestinal ulceration. The renal effects of NSAIDs can be reversed, at least in part, by the use of dopamine.[111] These side effects are due to the fact that NSAIDs inhibit both COX-1, the enzyme responsible for homeostasis in the kidneys and gastrointestinal tract, and COX-2, which is induced by LPS and probably mediates the increase in prostaglandin synthesis in sepsis. COX-2–selective drugs are currently approved for the treatment of arthritis and pain, and they may prove to have some benefit in the treatment of sepsis. NS-398, a selective COX-2 inhibitor, blocks inflammatory prostaglandin synthesis but does not inhibit gastric prostaglandin production and does not produce gastric erosion.[112] L-745,337, also a COX-2–selective inhibitor, has been found to reduce the core body temperature increase induced by LPS in rats.[113] However, selective inhibition of COX-2 with NS-398 did not provide long-term protection to mice subjected to endotoxin shock or sepsis induced by CLP.[114] In another study, the effect of selective COX-2 inhibitors (DFU and NS-398) or nonselective COX inhibitors (diclofenac and proquazone) on survival in murine endotoxemia was assessed.[115] Only specific dosages of DFU, NS-398, and proquazone prevented endotoxin-induced lethality. The investigators concluded that the effect of COX inhibitors on endotoxin shock is highly dose- and compound-dependent. Other studies with multiple injury models have shown that treatment with NS-398 in mice subjected to burns and *Pseudomonas aeruginosa* infections improved survival and absolute neutrophil count and reduced macrophage PGE_2 production.[116] The survival of mice traumatized by femur fracture and hemorrhage was improved by N-398.[117] Increases in in vivo IL-6 and in vitro Kupffer cell IL-6 production were inhibited in mice subjected to hemorrhage and subsequent CLP-induced sepsis.[118] Recent studies in COX-2–deficient mice suggest that COX-2–derived eicosanoids are deleterious in endotoxemia. Compared with endotoxemic wild types, COX-2–deficient mice exhibited improved survival, blunted inflammatory cell infiltration of tissues, suppressed NF-κB activation, and increases in the anti-inflammatory cytokine IL-10.[119] As even more selective COX-2 inhibitory drugs become available, more definitive assessment of COX-2 involvement in trauma and sepsis may be ascertained.

Pretreatment with TXA_2 synthase inhibitors or TXA_2 receptor antagonists improves survival time or attenuates certain shock sequelae in endotoxemic animals. The pathophysiologic events ameliorated by these pharmacologic agents include pulmonary hypertension,[120,121] reduced cardiac output, hypotension,[122,123] decreased renal blood flow, decreased glomerular filtration rate,[121,123,124] thrombocytopenia,[120-125] renal glomerular fibrin deposition,[126] and renal glomerular microthrombi.[123] Most studies have shown that the beneficial effects of these drugs are not obtained if they are given after endotoxin. However, in a porcine study, the TXA_2 synthase inhibitor dazmegrel, when administered 3 hours after endotoxin infusion in a chronically instrumented young piglet model, was shown to reduce pulmonary hypertension and hypoxemia.[127] Other studies have not demonstrated improved outcome in sepsis and endotoxic shock.[128] Presumably, in these experiments, mediators other than TXA_2 dominate to produce pathophysiologic sequelae contributing to the development of shock and mortality. Use of TXA_2 receptor antagonists in endotoxemia may have several advantages over the use of TXA_2 synthase inhibitors. TXA_2 receptor antagonists block the effects of both PGH_2 and TXA_2 to activate TXA_2 receptors and do not produce shunting of PGH_2 to PGE_2 synthesis.

The 5-lipoxygenase inhibitor diethylcarbamazine improved the survival of mice in endotoxic shock,[93] and CGS8515 attenuated endotoxin-induced hemoconcentration and hypotension in rats.[129] AA-861, another 5-lipoxygenase inhibitor, attenuated endotoxin-induced neutropenia and concomitant oxygen radical synthesis in rats[130] and improved survival in endotoxemic mice.[131] L-651,392 blocked endotoxin-induced pulmonary hypertension and bronchoconstriction and increased arterial-alveolar oxygen difference and lung microvascular permeability in sheep.[94] Inhibition of 5-lipoxygenase by MK-886 attenuated hypotension and partially reversed the impaired vascular responsiveness to phenylephrine and acetylcholine.[132] MK-886 also inhibited coronary vasoconstriction and loss of myocardial contractility induced by *Escherichia coli* hemolysin in perfused rat hearts.[133]

Further evidence for the role of lipoxygenase products in endotoxin-induced shock sequelae is provided by studies using specific leukotriene receptor antagonists in experimental endotoxemia. The sulfidopeptide leukotriene receptor antagonist FPL57231 attenuated endotoxin-induced bronchoconstriction and pulmonary hypertension in sheep and cats.[134,135] The LTD_4 receptor antagonist SKF104353 prevented endotoxin-induced hemoconcentration and thrombocytopenia and improved survival time in rats.[136] The LTD_4/E_4 receptor antagonist LY171883 improved endotoxin-induced hypotension, hemoconcentration, and leukopenia in rats. SKF104353 and LY171883 were shown to prevent acute splanchnic permeability changes induced by endotoxin in rats[137] and mesenteric ischemia in pigs.[76] The LTB_4 receptor antagonist LY233978 has been shown to attenuate endotoxin-induced leukopenia, hemoconcentration, and hypotension in rats.[138] The LTB_4 antagonist LY306669 attenuated lung injury in a porcine endotoxemic model.[139] However, the protective effect of inhibitors of leukotriene biosynthesis or receptor antagonists may depend on the experimental model. MK-886 and an LTB_4 receptor antagonist, CP-105,696, reduced neutrophil infiltration into the peritoneal cavity, increased the peritoneal bacterial count, and reduced the survival rate in rats rendered septic by CLP.[95]

Some studies used combination therapy with cyclooxygenase inhibitors and leukotriene receptor antagonists or lipoxygenase inhibitors. Young and Passmore examined the effect of combined therapy with ibuprofen and LY171883 in canine endotoxic shock.[140] Combined blockade was more effective in maintaining blood pressure and cardiac output but provided no greater protection of renal blood flow or glomerular filtration rate. Turner and colleagues demonstrated good protection with a combined cyclooxygenase and lipoxygenase inhibitor (SKF86002) in a rat model of endotoxin-induced ARDS.[141] The inhibitor blocked the increase in lung wet-dry ratio, total bronchoalveolar lavage protein, hemoconcentration, and thrombocytopenia.

In contrast to the deleterious effects of certain eicosanoids (e.g., TXA_2), other prostanoids (e.g., PGE_1, PGI_2, 15-deoxy-$\Delta^{12,14}$-PGJ_2) may be beneficial in shock. PGI_2 infusion has been shown to be protective in canine endotoxic shock.[142] Prolonged PGE_1 infusion also had beneficial hemodynamic effects in hemorrhagic shock.[143] The cyclopentenone prostaglandin 15-deoxy-$\Delta^{12,14}$-PGJ_2 has been shown to be beneficial in several in vivo models of inflammation.[144-146] Although 15-deoxy-$\Delta^{12,14}$-PGJ_2 has been touted as the endogenous ligand for PPAR-γ, it is clear that it has PPAR-γ–independent effects that may be anti-inflammatory. The latter include inhibition of ERK1/2 and NF-κB signaling in response to microbial stimuli.[68,70,147,148] Recently, 15-deoxy-$\Delta^{12,14}$-PGJ_2 was found to improve the survival of rats subjected to polymicrobial sepsis induced by CLP and to inhibit tissue NF-κB and activator protein-1 signaling, tissue neutrophil infiltration, and cytokine production.[149]

SIGNIFICANCE OF EICOSANOIDS IN CRITICALLY ILL PATIENTS

Several studies have reported increased PLA_2-II, TXB_2, 6-keto-$PGF_{1\alpha}$, PGE_2, and $PGF_{2\alpha}$ levels in patients with septic shock.[150-152] Plasma PLA_2-II levels have been shown to correlate with hypotensive episodes and mortality in patients with acute sepsis and multiple organ failure. Oettinger and colleagues evaluated the relationship between plasma TXB_2 and 6-keto-$PGF_{2\alpha}$ levels and the severity of organ dysfunction in 106 patients with Gram-negative septic shock.[152] As in other studies, TXB_2 and 6-keto-$PGF_{1\alpha}$ levels were elevated throughout the course of sepsis but were highest during the early phase. TXB_2 levels were higher in hypodynamic patients than in hyperdynamic patients, whereas the opposite was observed for 6-keto-$PGF_{1\alpha}$. Patients in the hyperdynamic group had improved lung and kidney function, as determined by alveolar-arterial PO_2 gradient and creatinine clearance. In patients who underwent esophagectomy, which is associated with a high incidence of ARDS, there was a significant postoperative increase in postpulmonary TXB_2 levels only in patients who developed ARDS.[153] In patients with traumatic head injury, there was an increase in the TXB_2/6-keto-$PGF_{1\alpha}$ ratio in plasma, which positively correlated with the severity of injury and death.[154] Collectively, these studies demonstrate increased thromboxane and prostacyclin synthesis in patients with sepsis, trauma, or ARDS and suggest a deleterious role for thromboxane.

Leukotriene levels were also increased in several clinical situations. Seeger and coworkers reported increased LTB_4 metabolites in the bronchoalveolar lavage fluid of patients with ARDS.[101] Elevated sulfidopeptide leukotriene levels have also been reported in the bronchoalveolar lavage fluid, blood, and urine of patients with trauma or ARDS.[97,99,155] Higher leukotriene levels correlated with poor prognosis. Acutely ill patients with elevated plasma LTB_4 levels had a greater risk of developing ARDS than did those with lower levels.[100] Urinary excretion of LTE_4 was higher in trauma patients who developed ARDS than in those who did not have ARDS.[155]

There have been some clinical trials with eicosanoid inhibitors. Despite the association between increased plasma PLA_2-II concentration and sepsis severity, a human phase II trial in severe sepsis demonstrated that PLA_2-II inhibition was of no benefit.[156] The NSAIDs may have beneficial effects in the treatment of patients with trauma or sepsis. Faist and coworkers studied the effect of indomethacin in a randomized, prospective study of 43 patients undergoing major surgical trauma.[157] The cellular immune status was evaluated preoperatively and up to a week after surgery. In contrast to untreated patients, patients receiving indomethacin exhibited an improvement in delayed-type hypersensitivity responses and mitogen-induced lymphocyte transformation and a lower rate of opportunistic infection. These results suggest that NSAIDs, by preventing the impairment of cell-mediated immunity, may reduce susceptibility to sepsis after surgery.

Bernard and associates conducted a double-blind, placebo-controlled trial of intravenous ibuprofen (10 mg/kg; maximum dose, 800 mg) given every 6 hours for eight doses in 455 patients with a diagnosis of sepsis.[158] The ibuprofen-treated group did not experience any increased incidence of renal dysfunction, gastrointestinal bleeding, or other adverse effects. Short-term treatment with ibuprofen did not significantly affect the duration of shock or the 30-day survival rate. However, ibuprofen did produce significant declines in urinary 6-keto-$PGF_{1\alpha}$ and TXB_2 excretion, temperature, heart rate, oxygen consumption, and lactic acidosis. In a subsequent analysis of a subset of hypothermic septic patients in this study, ibuprofen treatment was demonstrated to improve 30-day survival.[159]

In contrast to studies with eicosanoid inhibitors, certain eicosanoids may have beneficial hemodynamic or anti-inflammatory effects. Liposomal encapsulated PGE_1 was shown to reduce hypoxemia and to improve lung compliance and survival in a study of 25 ARDS patients.[160] However, in a subsequent phase III clinical trial with a total of 350 ARDS patients, intravenous liposomal PGE_1 was shown to improve indices of oxygenation but did not decrease the duration of mechanical ventilation or improve 28-day survival.[161] Aerosolized PGI_2 has also been tested in ARDS patients. The effect of PGI_2 was similar to that of inhaled nitric oxide, in that it induced pulmonary vasodilatation and improved ventilation perfusion.[162-164] This treatment approach also prevented hypoxemia in ARDS patients with respiratory failure caused by pneumonia.[165]

These studies provide the impetus for more extensive studies of eicosanoids and eicosanoid-altering drugs in trauma, sepsis, and ARDS. Also, the new generation of COX-2 inhibitors, with fewer side effects than traditional NSAIDs in critically ill patients, remains to be tested. Experimentally, combinations of drugs have been more effective than single-drug treatments.[166-171] Of particular interest, in view of the demonstrated increase of lipoxygenase products in patients with ARDS, is the potential application of lipoxygenase inhibitors or leukotriene receptor antagonists. The potential beneficial effect of certain eicosanoids (e.g., PGI_2) in ARDS suggests that complete inhibition of eicosanoid synthesis may not be desirable. Finally, the new and evolving concept that specific eicosanoids play pivotal roles in inflammation resolution[59,67] may direct future therapeutic interventions.

This review examines lipid mediators that switch off inflammation. Endogenous mediators such as lipoxins and cyclopentenone prostaglandins suppress inflammatory gene expression, cell trafficking, inflammatory cell apoptosis, and phagocytosis, which are determinants of successful resolution of inflammation.

Chapter 42
NITRIC OXIDE

Sabah Hussain

KEY POINTS

1. **Nitric oxide (NO) has both direct and indirect modes of action.** Direct actions usually occur at relatively low levels of NO and include reaction with transition metals, including iron and copper. Activation of guanylate cyclase by NO is a prime example of a direct NO action. Indirect actions involve the reaction of NO with oxygen radicals and the formation of reactive nitrogen species, including the highly reactive peroxynitrite.
2. **NO is synthesized by three isoforms of nitric oxide synthase (NOS).** Neuronal NOS is constitutively expressed in central neurons, skeletal muscles, pulmonary epithelial cells, and nerve fibers supplying the lungs and intestinal system. Endothelial NOS is constitutively expressed mainly in endothelial cells. Inducible NOS has limited expression in normal cells; however, its expression is highly induced in response to proinflammatory cytokines and bacterial lipopolysaccharides.
3. **Activity of the human inducible NOS promoter** is less responsive to proinflammatory cytokines than is that of the murine promoter. Induction of inducible NOS expression in human cells is dependent on multiple transcription factors, including nuclear factor kappa-B and activator protein-1, and interferon regulatory factors.
4. **The gene of human neuronal NOS** is very complex, and both tissue-specific promoter activities and tissue-specific alternative splicing regulate its expression. Changes in gene expression of endothelial NOS have been documented in response to inflammatory mediators, changes in tissue PO_2, and alterations in regional blood flow.
5. **NOS activity can be inhibited in vivo** by many commercially available compounds, the majority of which are non–isoform selective. This category of nonselective inhibitors includes L-arginine analogs, aminoguanidine, and thiourea compounds. Highly selective inhibitors of inducible NOS have recently become available, including 1400W, GW273639, and GW274150.
6. **In normal vessels,** constitutive NO production by endothelial NOS localized in endothelial cells provides an important dilator mechanism that opposes the local myogenic response. This effect is mediated by activation of soluble guanylate cyclase and increased production of cyclic guanosine monophosphate in vascular smooth muscles. Inhibition of endothelial NO release induces a reduction in blood flow in various organs as a result of unmasking of the local myogenic tone.
7. **Basal NO production by endothelial cells** is sensitive to changes in shear stress and promotes higher local blood flow during increased metabolic demands (active hyperemia) and in response to transient interruptions of blood flow (reactive hyperemia).
8. **In septic patients,** many reports have documented high levels of plasma NO in adult patients with septic shock or severe sepsis and in pediatric patients with severe sepsis. The rise in plasma NO levels correlates negatively with patient survival. The exact isoform responsible for increased vascular NO production in septic humans remains to be documented.
9. **Infusion of nonselective NOS inhibitors in septic patients** restores arterial pressure and peripheral vascular resistance but significantly reduces cardiac output in septic patients. In one clinical trial, infusion of a nonselective NOS inhibitor in septic patients augmented mortality and resulted in early termination of the trial, leading to the conclusion that selective inhibitors of inducible NOS rather than nonselective NOS inhibitors should be administered to septic patients.
10. **Augmented NO production** has been documented in the livers of animals with severe sepsis or in hepatocytes exposed to proinflammatory cytokines. Administration of nonselective NOS inhibitors worsened liver injury in septic animals due to inhibition of constitutive endothelial NOS activity in hepatocytes and hepatic endothelial cells. Contradictory results have been reported in terms of whether inducible NOS plays a detrimental or a beneficial role in preventing hepatic injury in septic animals.

Nitric oxide (NO) may be the most intensively studied molecule over the past 20 years, by virtue of its functional centrality in almost every mammalian biologic system. It is most closely associated with the cardiovascular system, although thousands of publications have implicated NO in the

regulation of many other physiologic processes as well. Detailing all the biologic functions of NO is beyond the scope of this chapter. What is presented is a brief discussion of the basic chemistry of NO, the structure and biochemical characteristics of the enzymes that synthesize it, how they are regulated, and NO's role in regulating vascular tone and hepatic function under normal conditions and in humans with severe sepsis or inflammatory liver injury.

BASIC CHEMISTRY

NO is a signaling and effector molecule with a wide range of biologic functions, including the regulation of blood pressure, neurotransmission, and tissue metabolism. Although it is considered a free radical, NO is not highly reactive per se. It mediates biologic functions through direct and indirect effects. Direct effects are mediated by physiologic (nonmolar) concentrations that help maintain homeostasis in most systems. Direct actions include reactions with transition metal centers (particularly iron and copper) in proteins, with the result being either protein activation or inhibition.[1] However, the most well-known direct effect of NO is its activation of soluble guanylate cyclase, which results in an increase in intracellular cyclic guanosine monophosphate (cGMP), an important regulator of smooth muscle contractility, platelet aggregation, and leukocyte adhesion.[2]

Direct effects of NO also include its reaction with cysteine redox centers, a process known as S-nitrosylation.[1] Several proteins have recently been identified as undergoing S-nitrosylation by NO, resulting in either activation or inhibition of activity. These proteins include nuclear factor kappa-B (NF-κB), Ca^{++}-dependent K^+ channels, ryanodine receptors, and caspase-3. Finally, NO also diffuses into red blood cells and reacts with oxyhemoglobin, forming NO_2 and methemoglobin.

Indirect effects of NO are mediated through its interactions with O_2 and O_2^- and are usually elicited by relatively high (micromolar) concentrations of NO. In aqueous solutions, NO reacts with O_2 to form NO_2 and N_2O_3 (a potent S-nitrosylating agent), a reaction that is biologically relevant only at high concentrations of NO.[3] The most important indirect effect of NO is its near diffusion-limited reaction with O_2^- anions to generate peroxynitrite ($ONOO^-$), a highly reactive radical with a very short in vivo half-life (1 sec).[4] Peroxynitrite rapidly dissociates to peroxynitrous acid or a carbonate adduct, which in turn rapidly generates carbonate and NO_2 radicals.[4] Peroxynitrite is a major contributor to cellular oxidative stress as a result of enhancement of thiol oxidation and lipid peroxidation and inhibition and inactivation of major antioxidant defenses such as reduced gluathione and superoxide dismutases (SODs).[5] It also targets specific tyrosine residues in several proteins and generates 3-nitrotyrosine. The range of tyrosine-nitrated proteins so affected includes those involved in apoptosis, glycolysis, mitochondrial respiration, structural support, and antioxidant defenses.[6] Tyrosine nitration of even a single residue, as in the case of Mn-SOD, may result in drastic inhibition of protein activity.

Formation of 3-nitrotyrosine has also been linked to several human pathologies, including acute lung injury and severe sepsis. It should be emphasized that the formation of peroxynitrite is usually restricted to specific conditions in which the local levels of both NO and O_2^- are substantially elevated. Under normal conditions, however, O_2^- anions are converted to H_2O_2 by SODs without significant peroxynitrite formation. It is also noteworthy that despite the possibility of peroxynitrite formation under special circumstances, physiologic NO production is considered an antioxidant pathway because of the direct antioxidant actions of NO, which consist of reduction of toxic oxidants such as ferryl cations, inhibition of Fe^{+++}-catalyzed generation of hydroxyl radicals, and termination of lipid peroxidation.[7] Indirect antioxidant actions of NO include the induction of ferritin synthesis, which helps reduce free Fe^{++} levels. In addition, NO promotes the expression of heme oxygenase I, an important antioxidant enzyme by virtue of its products, carbon monoxide and bilirubin.[8] Finally, NO induces the expression of extracellular SOD, a key antioxidant enzyme responsible for dismutation of O_2^- anions in the vascular system.[9]

NITRIC OXIDE SYNTHASES

NO is produced by NO synthases (NOSs) from the terminal guanidine nitrogen of L-arginine through a reaction that requires two molecules of O_2 and 1.5 mol of the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH). Three distinct isoforms of NOS have been identified, each of which is a product of different genes and has different localization, regulation, catalytic properties, and inhibitor sensitivities. These isoforms are neuronal NOS (nNOS), which is expressed predominantly in neuronal tissue; inducible NOS (iNOS), which is inducible in a wide range of cells; and endothelial NOS (eNOS), which is expressed mainly in endothelial cells. NOS isoforms have also been classified on the basis of their constitutive (eNOS and nNOS) or inducible (iNOS) expression and their Ca^{++} dependence (eNOS and nNOS) or independence (iNOS). The nNOS gene (chromosome 12) has a complex structural organization with 29 exons and 28 introns and codes for a 1434–amino acid protein, whereas both the iNOS (chromosome 17) and eNOS (chromosome 7) genes consist of 26 exons and 25 introns, coding for 1153 and 1203 amino acids, respectively.[10]

All NOS isoforms consist of two domains—an N-terminal oxygenase domain that binds to heme, tetrahydrobiopterin (BH_4), and L-arginine, and a C-terminal reductase domain that binds to flavins (flavin adenine dinucleotide [FAD], flavin mononucleotide [FMN]) and NADPH (Fig. 42-1). NOSs are active only when they are homodimers, and they require an electron transfer from NADPH, which is catalyzed by bound FMN and FAD. BH_4 is required for dimerization, for coupling of NADPH oxidation to NO synthesis, and for protection against oxidation and autoinactivation. NOS proteins undergo autoinhibition when NO reacts with Fe^{++} atoms of the NOS-bound heme group, resulting in inhibition of NOS activity. The nNOS isoform is the most susceptible of the three to autoinhibition, with 95% of its activity being inhibited by self-derived NO.[11]

REGULATION OF NITRIC OXIDE SYNTHASES

The rate of NO production by NOS isoforms is regulated at several levels, including transcriptional and post-transcriptional regulation of NOS expression and pharmacologic regulation of NOS protein activity and localization.

TRANSCRIPTIONAL REGULATION

Human promoters of the three NOS isoforms have been cloned and characterized. With respect to iNOS, it has been well established that stimuli such as bacterial lipopolysaccharide

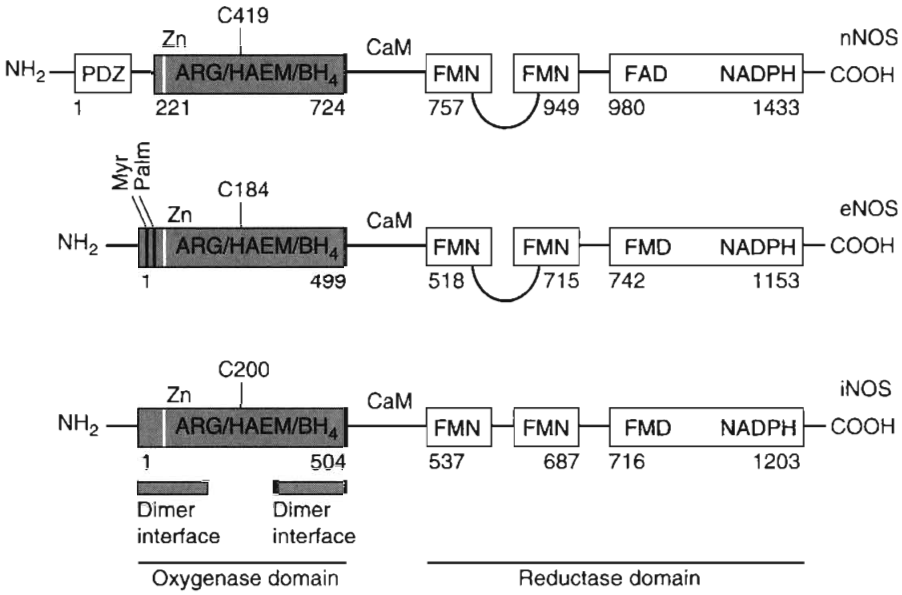

FIGURE 42–1. Domain structure of human neuronal nitric oxide synthase (nNOS), endothelial nitric oxide synthase (eNOS), and inducible nitric oxide synthase (iNOS). Oxygenase, reductase, and PDZ domains are denoted by solid boxes, and the amino acid residue number at the start or end of each domain is shown. The cysteine residue, which ligates the heme and the calmodulin binding site, is indicated for each isoform. Myristoylation (Myr) and palmitoylation (Palm) sites on eNOS are shown, as is the location of the zinc-ligating cysteines (Zn). The autoinhibitory loop within the flavin mononucleotide (FMN) regions of nNOS and eNOS is also shown, and gray bars indicate the dimer interface in the oxygenase domain. ARG, arginine; BH_4, tetrahydrobiopterin; NADPH, reduced form of nicotinamide adenine dinucleotide phosphate. (Adapted from Alderton WK, Cooper CE, Knowles RG: Nitric oxide synthases: Structure, function and inhibition. Biochem J 2001;357:593-615.)

(LPS) and cytokines, including tumor necrosis factor (TNF), interleukin (IL)-1, and interferon (IFN)-γ, are capable of inducing iNOS messenger RNA (mRNA) and protein in many human cells, including macrophages, hepatocytes, smooth muscles, and chondrocytes. In normal humans, iNOS mRNA expression is present in a few cell types, for example, airway epithelial cells. Cloning and expression of 8.3 and 16 kilobases (kb) of the human iNOS promoter revealed the following characteristics[12,13]: (1) Human promoter activity is only modestly induced in response to exposure of cultured cells to an LPS and cytokine mixture, compared with murine iNOS promoter activity. This difference has been attributed to the presence of multiple inactivating nucleotide substitutions in the enhancing elements responsible for LPS- and cytokine-induced expression in the human iNOS promoter. (2) Sequences conferring LPS and cytokine inducibility of the human iNOS promoter reside at upstream locations from the transcription initiation site (>4 kb). (3) Multiple transcription factors are involved in activating the human iNOS promoter, including the NF-κB family of transcription factors, activator protein-1 transcription factors, STAT-1α (signal transducer and activator of transcription) and INF regulatory factor-1. (4) Synergism between these transcription factors is required for enhancing iNOS promoter activity.

The expression of iNOS is also regulated by changes in mRNA stability and protein translation. The presence of several ATTTA sequence motifs (involved in protein-mRNA interactions) at the 3′ untranslated region (UTR) of human iNOS mRNA suggests that its stability may undergo significant regulation. Expression of iNOS mRNA is also regulated by alternative splicing within both 5′ UTR and the coding sequence.[14]

The human eNOS promoter possesses several binding sites for Sp1, GATA, activator proteins (AP-1, AP-2), $E_2$6 transformation specific (ETS), NF-κB, nuclear factor-1, NF-IL-6, shear stress, cyclic adenosine monophosphate response, acute-phase response, and IFN-induced transcription factors.[15] In vivo analysis of transgenic mice expressing 5200 base pairs of murine eNOS promoter elicited a robust expression in large and medium blood vessels, whereas small arterioles, capillaries, and venules showed very little transcriptional activity. In addition, many stimuli, including estrogens, angiotensin II, proinflammatory cytokines, and hypoxia, alter eNOS mRNA expression through changes in its half-life.

The nNOS gene is the most complex human gene yet described in terms of promoter diversity and alternative splicing. Wang and colleagues described nine unique exon 1 variants of nNOS (exons 1a through 1i) that are associated with transcript initiation in various tissues.[16] Exons 1a, 1b, and 1c are abundantly expressed in skeletal muscles, whereas exons 1f, 1g, and 1i are present mainly in the brain. All nine exons are expressed in the testis. Analysis of alternative splicing of nNOS mRNA uncovered two main variants, nNOSβ and nNOSγ, which have 136- and 125-kDa molecular masses and are capable of producing 80% and 3% of nNOSα activity, respectively. Another splice variant of nNOS is nNOSμ, which has an additional 34 amino acids inserted between exons 16 and 17. It is abundantly expressed in skeletal muscle and in penile and urethral tissues.[17] This variant has similar enzyme kinetics to those of nNOSα.[17]

POST-TRANSLATIONAL REGULATION

One of the most important regulators of NOS activity is calmodulin binding, which increases the rate of electron transfer from NADPH to the flavins and heme group. It is triggered by a rise in intracellular Ca^{++} and is inhibited by a motif of 40 to 50 amino acids localized in the FMN binding site. The absence of this motif in iNOS results in tight binding of calmodulin to the iNOS protein, rendering its activity insensitive to intracellular Ca^{++} fluxes (hence the term Ca^{++}- and calmodulin-independent). NOS activity is also regulated through interactions with specific proteins such as protein inhibitor of nNOS, which inhibits nNOS activity by preventing monomer dimerization.[18]

Another regulator of NOS activity is heat shock protein 90, which interacts directly with eNOS and augments its activity by promoting calmodulin binding.[19] Other eNOS protein modifications include dual acetylation by myristate and palmitate, which are required for localization of eNOS at the caveolae. Myristoylation is an irreversible process that involves a single N-terminus glycine, whereas palmitoylation is reversible and develops at Cys-5 and Cys-26 and is modulated by intracellular Ca^{++} levels.

NOS expression is also regulated when iNOS selectively interacts with two separate proteins, kalirin and a 110-kDa NOS-associated protein (NAP110).[20,21] Kalirin associates with iNOS in vitro and in vivo and inhibits its activity by preventing monomer dimerization. Similarly, NAP110 selectively interacts with the N-terminal portion of iNOS and inhibits its activity by about 90% in cultured cells.[21]

Finally, NOS activities are also mediated by phosphorylation of serine, threonine, and tyrosine residues. Increased shear stress and activation of protein kinase B induces eNOS phosphorylation at Ser-1177, which in turn activates this enzyme.[22] By contrast, phosphorylation of eNOS at Thr-495 inhibits its activity.[23] The nNOS protein is phosphorylated by Ca^{++} calmodulin-dependent kinases at Ser-847, thereby reducing nNOS activity.[24] There are also published reports of tyrosine phosphorylation of iNOS, which results in its activation.[25]

PHARMACOLOGIC REGULATION

Various biologic roles of NO have been uncovered as a result of the availability of pharmacologic inhibitors. However, many investigators have not been sufficiently careful in verifying the selectivity of these inhibitors, and a few have assigned in vivo isoform selectivity to inhibitors for which only in vitro selectivity has been established. Many NOS inhibitors, including L-arginine analogs such as N^G-monomethyl L-arginine (LNMMA), N^G-nitro-L-arginine (L-NA) and its methyl ester (L-NAME), thiocitrullines, 1400W, aminoguanidine, S-ethylisothiourea, N^5-iminoethyl-L-ornithine (L-NIO), N^6-iminoethyl-L-lysine (L-NIL), GW273629, and GW274150, bind NOSs at L-arginine binding sites and inhibit substrate binding. All these inhibitors require active enzyme activity and the presence of NADPH for their binding.[26] Aminoguanidine also inhibits NOS activity by forming complex covalent bonds with NOS proteins without interfering with NOS dimerization.[27]

Another class of inhibitors, including 4-amino BH_4 and BH_2, inhibit NOS activity by targeting the BH_4 binding site, whereas 7-nitroindazole and its related compounds compete for binding at both the L-arginine and BH_4 binding sites.[28] Additionally, the antifungal imidazoles hinder iNOS activity by binding to the heme group and competing with calmodulin binding.

Table 42-1 lists the selectivity and effective concentrations of various NOS inhibitors measured in vitro. Inhibitors with 10- to 50-fold selectivity are considered partially selective inhibitors. For example, S-ethyl- and S-methyl-L-thiocitrullines and ARL17477 are considered partially selective nNOS inhibitors. L-NIO and L-NIL are considered partially selective iNOS inhibitors. Recently, highly selective iNOS inhibitors have become available, such as 1400W, GW273639, and GW274150, which have enabled investigators to evaluate the functional roles of iNOS in a variety of physiologic contexts. It should be emphasized, though, that aminoguanidine, the most widely used iNOS inhibitor, has only about a 10-fold selectivity for iNOS relative to eNOS and has virtually no selectivity relative to nNOS. This inhibitor also attenuates catalase, diamine oxidase, and polyamine metabolism.

BIOLOGIC FUNCTIONS OF NITRIC OXIDE

NORMAL VASCULAR TONE

Vasodilatation is the earliest discovered and most widely studied action of NO in the cardiovascular system. In a 1980 landmark study, Furchgott and Zawadzki described the obligatory role of endothelium-derived relaxing factor in inducing vascular smooth muscle relaxation of large conduit vessels.[29] Two studies in 1986 and 1988 identified endothelium-derived relaxing factor as NO and proposed the presence of an NO synthesizing protein in endothelial cells.[2,30] The most important NOS isoform in the regulation of normal vascular tone is certainly eNOS. Although the nNOS isoform is expressed in perivascular nerves, cardiac conduction pathways, and myocardial sarcoplasmic reticulum, it is less important than eNOS in regulating vascular tone.

It is well established that eNOS-derived NO production by the endothelial cells is activated very rapidly by longitudinal shear forces acting on the endothelium and generated by blood flow and by the pulsatile stretch of the vasculature. This flow-dependent NO release provides a crucial mechanism for the dynamic coupling of tissue metabolic demands and upstream vascular resistance and has been documented in conduit arteries, resistance arteries, arterioles, and venules.[31] Because shear stress in blood vessels is determined by flow velocity, flow pulsatility, blood viscosity, and vessel diameter, these variables have significant effects on endothelial NO release both in vitro and in vivo (Fig. 42-2). Basal endothelial NO release in normal vessels is in dynamic equilibrium with the local constrictor provided by the intrinsic myogenic tone of smooth muscles and by sympathetic vasoconstrictor drive. When eNOS-derived NO synthesis is inhibited in vivo, the local myogenic tone becomes unmasked and causes a reduction in vessel diameter and a rise in vascular resistance in almost all vascular beds.[32] The dilator effect of NO on smooth muscles is triggered by soluble guanylate cyclase activation, which results in increased production of the second messenger cGMP. In turn, cGMP activates two cGMP-dependent protein kinases (PKGI and II), which regulate smooth muscle intracellular Ca^{++} levels and hence contractility by increasing Ca^{++} sequestration in and inhibiting Ca^{++} release from the sarcoplasmic reticulum.[33] In certain vascular beds, NO evokes smooth muscle relaxation by hyperpolarizing membrane potential, an effect that is mediated by the activation of Ca^{++}-dependent K^+ channels. Finally, NO-mediated smooth muscle relaxation can also be the result of a prejunctional effect on adrenergic nerve fibers, leading to inhibition of local catecholamine release.[34]

Increased shear stress also up-regulates eNOS expression when maintained for relatively long periods. Indeed, significant induction of eNOS mRNA and protein has been documented in cultured endothelial cell preparations in which shear stress was artificially maintained and in in vivo settings in which organ blood flow and shear stress were chronically elevated in response to exercise training or the result of arteriovenous fistulas.[35]

Vascular NO production is also acutely activated in response to agonist stimulation of endothelial membrane receptors by acetylcholine, adenosine triphosphate, bradykinin, and substance P. These agonists are synthesized and released by endothelial cells in response to shear stress and mechanical perturbations and act in an autocrine fashion to stimulate their prospective receptors. Activation of these receptors elicits a rise in intracellular Ca^{++} concentrations and thereby activates eNOS. Agonist-induced endothelial NO release, especially by adenosine triphosphate and bradykinin, provides another mechanism through which tissue metabolic demands are matched to local blood flow, as in human heart and forearm vasculatures.[36]

TABLE 42–1. SELECTIVITY OF NITRIC OXIDE SYNTHASE INHIBITORS

Inhibitor	IC_{50} (μM)			Selectivity (Fold)		
	iNOS	*nNOS*	*eNOS*	*iNOS*	*nNOS*	*eNOS*
L-NA*	3.1	0.29	0.35	0.09	0.11	1.2
LNMMA	6.6	4.9	3.5	0.7	0.5	0.7
7-NI*	9.7	8.3	11.8	0.9	1.2	1.4

In addition to the regulation of basal blood flow, endothelial NO contributes to the vasodilatory response to elevated metabolic demands (active hyperemia). The degree of this contribution, however, differs among vasculatures. For instance, Hussain and coworkers reported that endothelial NO contributes between 20% and 40% of the total active hyperemia of the in situ diaphragm in dogs,[37] whereas up to 50% of human myocardial active hyperemia induced by cardiac pacing was mediated by endothelial NO release.[38] Endothelial NO also participates in the reactive hyperemic response, which is the dilatation that follows transient vascular occlusion. This contribution is much more pronounced in tissues with high metabolic demands and manifests as prolongation of reactive hyperemia duration, with no influence on peak reactive hyperemic flow.[39] Another vascular phenomenon that is partly regulated by endothelial NO is autoregulation, defined as the ability of tissues to maintain their perfusion independent of changes in arterial pressure. It has been reported that inhibition of endothelial NO production and the subsequent augmentation of local myogenic tone lead to an improvement in flow autoregulation. However, this improvement is dependent on local metabolic rate and is more pronounced in tissues with relatively low metabolic rates, such as the mesenteric vasculature, than in tissues with high metabolic rates, such as the heart, kidneys, and brain; in the latter tissues, NOS inhibition only lowers blood flow levels, with no effect on the autoregulatory range.[40]

In addition to its role in the regulation of blood flow, NO has important functional significance for tissue metabolism, by virtue of its effect on mitochondrial respiration. It has been well established that NO donors or endogenous NO production inhibits, albeit reversibly, the activities of cytochrome

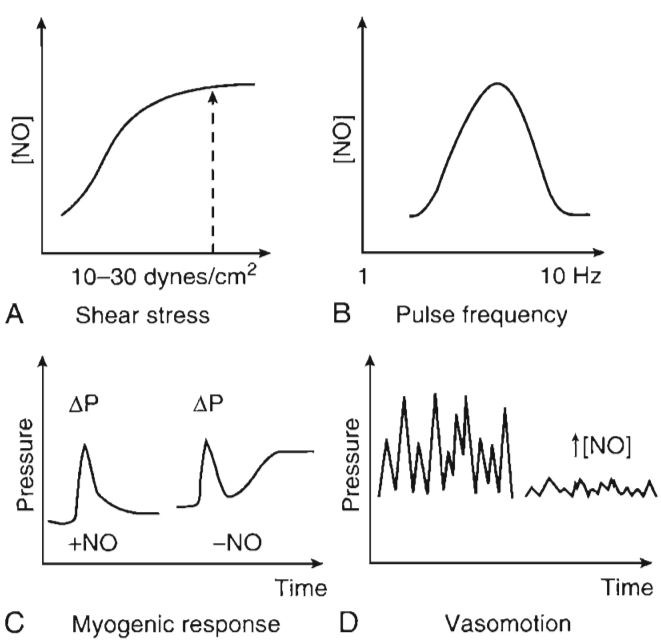

FIGURE 42–2. Key mechanisms involved in the regulation of perfusion by nitric oxide (NO). *A*, Endothelial NO production increases monotonically with time-averaged shear stress, reaching a plateau at 10 to 30 dynes/cm². *B*, NO release from the endothelium is sensitive to flow pulsatility, being maximal at pulse frequencies of about 5 Hz. *C*, In isolated vessels, acute increases in transmural pressure (ΔP) promote a myogenic constrictor response, normally attenuated by NO. Loss of NO activity also elevates basal constrictor tone. *D*, The amplitude of spontaneous oscillations in vascular caliber (vasomotion) is damped by NO. (Adapted from Griffith TM: Role of nitric oxide in the regulation of blood flow. In Ignarro LJ [ed]: nitric oxide Biology and Pathobiology. San Diego, Academic Press, 2000, pp 483-502.)

oxidase (the terminal enzyme of the mitochondrial respiratory chain) and aconitase (an important enzyme in the citric acid cycle).[41,42] Removal of this inhibition has been proposed as the mechanism behind the rise in whole body or organ oxygen consumption when NOS inhibitors are infused in vivo.[43]

Another vascular function of NO is the prevention of platelet aggregation. Many reports have confirmed that NO stimulates cGMP production inside the platelets and inhibits agonist-induced platelet aggregation through the regulation of intracellular Ca^{++} levels.[44] In addition, endothelial NO production has an important antiatherosclerotic function and protects against the early phase of atherosclerosis by inhibiting leukocyte adhesion to and migration through the endothelial cells. Both effects are achieved by reducing the expression of intercellular adhesion molecule-1, vascular cell adhesion molecule-1, and P-selectin.[45] The late stages of atherosclerosis are also inhibited by NO as a result of attenuation of endothelial permeability, reduction of lipoprotein influx into the vascular wall, and inhibition of oxidation of low-density lipoproteins.[46]

VASCULAR FAILURE DUE TO SEPSIS

The cardiovascular abnormalities associated with severe sepsis are characterized by low peripheral vascular resistance, hypotension, high cardiac output, maldistribution of blood flow, increased microvascular permeability, disseminated intravascular coagulation, and microthrombosis.[47] Many factors have been implicated in these dysfunctions, such as proinflammatory cytokines (TNF, IL-1, IFN-γ), reactive oxygen species, and prostaglandins that disrupt the normal balance between vasodilators (NO and prostacyclin) and vasoconstrictors (endothelins, catecholamines, angiotensin II). Numerous studies have also implicated excessive NO production by iNOS in the vascular dysfunction accompanying sepsis. The majority of these studies used models in which *Escherichia coli* LPS was administered as a bolus dose in mice or rats. In these models, arterial pressure declined within minutes of LPS injection, followed by partial recovery, then a sustained decline in pressure 3 to 4 hours later. It has now been well established that plasma concentrations of NO and its related products (NO_2^- and NO_3^-) rise severalfold in a progressive fashion a few hours after LPS injection. Moreover, many authors have documented iNOS mRNA and protein in endothelial cells, smooth muscles, cardiac myocytes, skeletal muscles, hepatocytes, and renal cells in LPS-injected rodents.[48] However, it should be emphasized that LPS rodent models of sepsis have limited clinical relevance, primarily because both rats and mice are less sensitive to LPS than humans are; thus, relatively large doses of LPS are required to elicit sepsis in these animals. A less dramatic rise or no change in NO production has been reported in rodent peritonitis models and in nonrodent models of sepsis. For instance, no significant changes in plasma NO levels were observed after short (<5 hours) or prolonged (9 to 18 hours) periods of endotoxemia in pigs. Moreover, only a 50% rise in plasma NO concentration was reported in endotoxemic dogs.[49]

Studies of humans with severe sepsis have also shown a significant increase in vascular NO production, but to a much lower degree than that observed in LPS rodent models. Ochoa and associates were the first to report that plasma NO_2^- and NO_3^- levels were higher in hyperdynamic septic patients than in trauma patients.[50] This finding was confirmed by Arnalich and colleagues, who also found that plasma NO_2^- and NO_3^- levels were higher in patients with septic shock than in those with only severe sepsis.[51] Moreover, plasma NO_x (combined NO, NO_2^-, and NO_3^-) concentrations were significantly greater in patients who died of postoperative sepsis compared with septic patients who survived.[52] In 53 pediatric patients with severe sepsis, Doughty and coworkers reported that plasma NO_2^- and NO_3^- concentrations measured on day 1 of admission predicted persistent failure of three or more organs and sequential organ failure, but not mortality.[53] This has prodded investigators to question whether the rise in plasma NO_x levels in septic patients is the result of iNOS expression or poor renal excretion of NO_x compounds. This question has not yet been answered; however, evidence is emerging that iNOS mRNA and protein are induced in many cells of septic patients, including neutrophils, alveolar macrophages, and skeletal muscles.[54-56] Whether this expression is sufficient to cause an increase in circulating plasma NO_x levels remains unclear.

Despite extensive documentation of elevated NO production in the vessels of septic animals and humans, the contribution of individual NOS isoforms to the pathogenesis of sepsis-induced vascular failure remains the focus of many investigators. In early studies published in 1990, the administration of nonselective NOS inhibitors (LNMMA, L-NA, L-NAME) in rodent LPS models of sepsis reversed early hypotension and improved vascular reactivity to vasoactive agents.[57,58] The initial euphoria triggered by these observations was dampened when severe reduction in cardiac output; worsening of cardiac function; exacerbated microvascular leakage; amplification of inflammation in the liver, kidney, and intestine; and augmented animal mortality were observed after several hours of LNMMA, L-NA, or L-NAME infusion in septic rodents. These findings led to the conclusion that nonselective NOS inhibitors are not beneficial for septic animals because they inhibit important homeostatic functions of eNOS. Subsequent studies using highly selective iNOS inhibitors revealed that selective elimination of iNOS activity in various animal models of sepsis reverses hypotension, restores vascular reactivity, improves myocardial function, attenuates acute lung injury, and partially restores mitochondrial function.[59-61]

Petros and coworkers were the first to report, in 1991, that the injection of nonselective NOS inhibitors (LNMMA and L-NAME) in septic human patients restored arterial pressure and peripheral vascular resistance.[62] Schilling and colleagues confirmed these findings but also reported that these inhibitors reduced cardiac output to 66% of initial values.[63] Restoration of vascular response to vasoactive agents, restoration of arterial pressure, and a significant decline in cardiac index have also been observed after L-NA injection in septic patients (Fig. 42-3).[64,65] Three subsequent prospective, uncontrolled trials used continuous infusion of either L-NAME (1 to 3 mg/kg/h for 12 to 24 hours) or LNMMA (up to 20 mg/kg/h for 8 hours) and reported sustained elevation of arterial pressure and peripheral vascular resistance, coupled with a significant decline in cardiac output.[66-68] Despite the restoration of arterial pressure, the effect of NOS inhibition on the outcome of septic patients is still being debated. A phase III prospective, randomized, double-blinded, placebo-controlled trial was conducted to treat septic patients with LNMMA, along with dobutamine to maintain cardiac output. This trial was recently terminated because of a statistically significant higher mortality in the treatment group.[69]

In addition to nonselective NOS inhibitors, investigators have used methylene blue (inhibitor of soluble guanylate cyclase) to counteract the effects of excessive NO production. Short-term infusion and bolus injection of this compound in septic patients raised mean arterial pressure by 10 mm Hg without affecting cardiac output.[70,71] Neither patient mortality nor the possibility that methylene blue might have effects other than inhibition of soluble guanylate cyclase was addressed.

In summary, it is apparent from animal and human studies that the use of nonselective NOS inhibitors to treat vascular failure due to sepsis is not warranted because of eNOS inhibition and elimination of the possible beneficial effects of iNOS, which include anti-inflammatory and anti–platelet aggregation effects. Future trials using highly selective iNOS inhibitors in patients with sepsis should aid in elucidating the extent to which overproduction of NO by this isoform contributes to sepsis-induced vascular failure.

LIVER FUNCTION

Under normal conditions, the eNOS isoform is the main source of NO in hepatic cells and is involved in the regulation of hepatic blood flow and the prevention of leukocyte infiltration and platelet adhesion.[72] Hepatic nNOS expression is limited to the nerve fibers supplying large hepatic vessels. All human liver cells are capable of expressing iNOS when exposed to LPS; cytokines such as TNF, IL-1β, and IFN; activators of protein kinase C; arachidonic acid metabolites; and platelet-activating factor.[73] Hepatic iNOS expression is strongly inhibited by glucocorticoids, NO or NO donors, and hepatocyte, epidermal, and transforming growth factors.[74] Hepatocyte NO synthesis is involved in many processes, such as protein synthesis, glucose synthesis from pyruvate and lactate, glucagon-stimulated glycogenolysis, and activity of cytochrome P_{450} enzymes, which are involved in drug metabolism.[75]

INFLAMMATORY LIVER INJURY

The involvement of NO in hepatic dysfunction has been investigated extensively in various models of liver injury. In LPS-induced models of sepsis, liver injury is characterized by the presence of neutrophil, lymphocyte, and macrophage infiltration and by hypertrophy, vacuolization, and chromosomal margination of hepatocytes. Moreover, elevated serum levels of aspartate transaminase (AST) and alanine transaminase (ALT) have been used extensively as an index of hepatic injury. It has been well established that in vivo LPS injection elicits a substantial rise in hepatic NO production, iNOS mRNA, and protein induction in hepatocytes and endothelial, Kupffer, and bile duct cells.[76]

Early studies in which nonselective NOS inhibitors (LNMMA and L-NAME) were used revealed that inhibition of all NOS isoforms worsens hepatic injury, causes a further rise in serum AST and ALT levels, increases hepatocyte necrosis and leukocyte infiltration, and enhances lipid peroxidation and oxidative DNA damage.[77] These changes have been attributed to interference with hepatic microcirculation and a severe reduction in sinusoidal blood flow as a result of the elimination of endothelial eNOS production. Similar worsening of liver injury with the use of nonspecific NOS inhibitors has been reported in hemorrhagic shock-induced hepatocyte injury[78] and alcoholic hepatitis.[79] Although these findings confirm a beneficial role for eNOS, the nature of iNOS involvement in liver injury is controversial, with deleterious, beneficial, or minimal roles being proposed.

Authors who have compared the in vivo effects of nonselective versus highly selective iNOS inhibitors in LPS models have concluded that iNOS promotes liver injury through the formation of peroxynitrite.[80] This is supported by Szabo and colleagues, who used S-methylisothiourea to inhibit iNOS activity and reported significant attenuation in serum AST, ALT, and bilirubin levels in septic mice.[81] By comparison, MacMicking and associates reported that the degree of LPS-induced liver injury in iNOS knockout mice was similar to that elicited in wild-type mice, suggesting that iNOS is not a major contributor to this injury.[82] It should be emphasized, however, that the degree of liver dysfunction in this study was mild, because relatively low doses of LPS were used. Alternatively, several authors have concluded that iNOS activity protects liver cells against injury and oxidative stress elicited by exposure to LPS or proinflammatory cytokines.

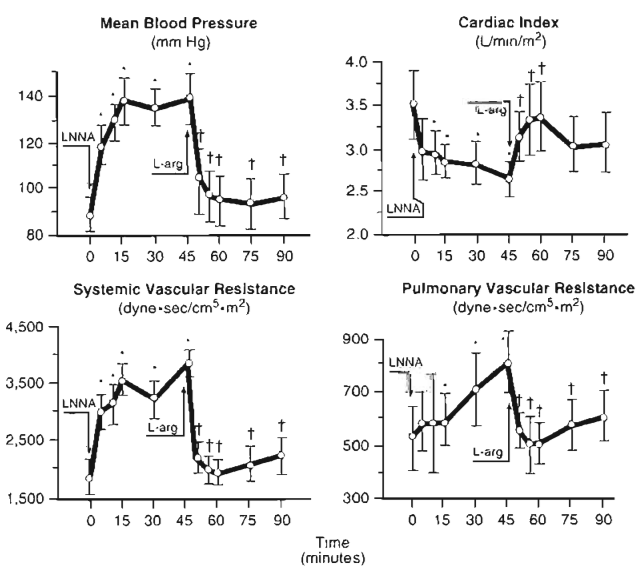

FIGURE 42–3. Hemodynamic changes induced by intravenous administration of Ng-nitro-L-arginine (LNNA) at minute 0 and L-arginine (L-arg) at minute 45 (mean ± standard error of the mean). *$P < 0.05$ for the comparison with minute 0; †$P < 0.05$ for the comparison with minute 45. (Adapted from Lorente JA, Landin L, De Pablo R, et al: L-Arginine pathway in the sepsis syndrome. Crit Care Med 1993;21:1287-1295.)

This proposal is supported by the observation that when iNOS mRNA was selectively expressed in the liver of transgenic mice, LPS-induced liver injury was attenuated by more than 50%, and the rise in plasma TNF and IL-1β levels was reduced as a result of NF-κB inhibition by iNOS activity.[83]

One possible mechanism by which iNOS activity may attenuate liver injury is through the inhibition of apoptosis. Ou and coworkers confirmed that continuous infusion of nonspecific NOS inhibitors into the portal vein significantly reduced serum AST and ALT levels and attenuated hepatic neutrophil infiltration 16 hours after LPS injection.[84] By comparison, selective iNOS inhibition with L-N-(1-iminoethyl)lysine did not alter AST and ALT levels or leukocyte infiltration; rather, it induced apoptosis of hepatocytes and endothelial cells, suggesting that hepatic iNOS activity may play an important antiapoptotic role. In summary, the contradictory conclusions regarding the role of iNOS in inflammation-induced liver injury are likely due to differences in the degree of liver damage, the rate of NO production, iNOS cellular localization, and the redox status of hepatic cells in various models of sepsis. Moreover, differences in the type, isoform selectivity, dosage, route, and timing of administration of NOS inhibitors should be taken into consideration when the role of iNOS is evaluated.

A proteomic approach was used for the first time to identify tyrosine-nitrated proteins in the lung and liver of septic animals. This study showed that nitration of tyrosine residues occurs in a wide variety of proteins, including glycolytic enzymes, protein involved in the regulation of apoptosis, and several important mitochondrial enzymes.

Furchgott RF, Zawadzki JW: The obligatory rule of endothelial cells in the relaxation of vascular smooth muscle by acetylcholine. Nature 1980;286:373-376.

This landmark study described the presence of endothelium-derived relaxing factor (EDRF), which is an important regulator of smooth muscle relaxation. In 1998, the first author was awarded the Nobel Prize for medicine for his discovery that EDRF is actually NO.

Jaffrey SR, Snyder SH: PIN: An associated protein inhibitor of neuronal nitric oxide synthase. Science 1996;274:774-777.

Protein inhibitor of nNOS (PIN), a subunit of the molecular motor dynein, was found to inhibit the activity of nNOS by preventing the dimerization of NOS monomers. The existence and tissue distribution of PIN were described for the first time.

Kilbourn RG, Gross SS, Adams J, et al: L-N^G-Methylarginine inhibits tumor necrosis factor–induced hypotension: Implications for the involvement of nitric oxide. Proc Natl Acad Sci U S A 1990;87:3629-3632.

This was one of the earliest studies to suggest that excessive NO production contributes to sepsis-induced hypotension. The authors found that infusion of TNF in dogs elicits systemic hypotension and that treatment with the NOS inhibitor L-NG-methylarginine reverses it.

Petros AJ, Bennett D, Vallance P: Effect of nitric oxide synthase inhibitors on hypotension in patients with septic shock. Lancet 1991;338:1557-1558.

The effect of NOS inhibition on the hemodynamics of patients with septic shock was described for the first time. In two septic patients whose blood pressure could not be restored by conventional therapy, administration of NG-monomethyl-l-arginine resulted in significant increases in blood pressure and systemic vascular resistance.

Chapter 43

CARBON MONOXIDE AND HEME OXYGENASE-1

Augustine M. K. Choi • Jigme Sethi

KEY POINTS

1. Heme oxygenase-1 (HO-1) is a unique enzyme with **dual roles in the cell—heme catabolism** and potent **cytoprotection**—and with antioxidant, antiapoptotic, antiproliferative, and anti-inflammatory activities.
2. HO-1 is **vigorously induced by** hypoxia, hyperoxia, heat shock, and a plethora of **oxidative and inflammatory stimuli.**
3. Increased activity of **HO-1** has been demonstrated to be **strongly protective** in a variety of models of oxidative stress and inflammation, including **acute lung injury, acute liver injury, acute renal failure, and cardiac xenotransplantation.**
4. All the **byproducts** of the reaction catalyzed by HO-1 **(ferritin, carbon monoxide) have major antioxidant and cytoprotective properties.**
5. **Carbon monoxide** has vasodilatory and bronchodilatory properties, functions as a neurotransmitter, and inhibits platelet and monocyte activation. It also demonstrates the cytoprotective properties attributed to HO-1 and **may be the major effector of the beneficial effects of HO-1 induction.**
6. **Carbon monoxide binds to heme proteins** such as **cytochrome P_{450},** which it inactivates, and **soluble guanylate cyclase,** which it activates, thus modulating cellular function.
7. **Carbon monoxide** also **can modulate signaling through the mitogen-activated protein kinase pathways,** thereby down-regulating inflammation.
8. **These beneficial effects of exogenous inhaled carbon monoxide** are noted at doses that are only a fraction of toxic levels—as low as 100 to 250 parts per million.

HISTORICAL PERSPECTIVE

Humans, like other obligate aerobes, are dependent on oxygen as the "molecule of life," but at a price—the potential for oxidative damage caused by free oxygen radicals. The introduction of molecular oxygen into the atmosphere forced adaptive changes in all existing forms of life, specifically to guard against oxidative damage. One such adaptation was the chelation of free iron, another essential molecule, into protoporphyrin complexes to prevent precipitation of the relatively insoluble oxidized ferric iron and the generation of toxic oxidant radicals by the reduction of ferric to ferrous iron. Recycling this sequestered iron between substrates in numerous biologic processes required the controlled catabolism of these protoporphyrin-iron, or heme, moieties. Thus it was no surprise when Tenhunen and associates identified heme oxygenase (HO) as the enzyme responsible for this reaction.[1] This enzyme uses the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH) and three molecules of oxygen to cleave the alpha-methenyl bridges between pyrroles I and II of the heme porphyrin ring, producing biliverdin and liberating free iron and carbon monoxide (CO) in equimolar amounts (Fig. 43-1).[2] The free iron thus released is liberated for the synthesis of other iron-containing proteins or sequestered for transport or storage in transferrin or apoferritin, respectively. Understandably, initial research focused on this important but less than exciting role of HO in heme catabolism, until Applegate and colleagues showed that HO could be vigorously induced not just by its substrate heme but also by a variety of agents that shared the ability to generate reactive oxygen species (ROS) in the cell.[3] Examples of such agents are lipopolysaccharide (LPS), phorbol esters, sodium arsenite, sulfhydryl reagents, hydrogen peroxide, and heavy metals, as well as hyperthermia, hyperoxia, heat shock, and ultraviolet radiation. This extraordinary diversity of inducers for an enzyme that seemingly functioned only in heme turnover was very surprising and fueled speculation that it also served a powerful role in protecting the cell against oxidative stress. The seminal observation, by Nath and coworkers in 1992,[4] that prior induction of HO could protect rats from renal failure caused by glycerol-induced rhabdomyolysis triggered a wave of research into the role of HO in oxidant-mediated cellular and tissue injury. This enzyme has now been firmly established as a crucial and potent cytoprotective molecule with strong anti-inflammatory, antiapoptotic, and antiproliferative properties. Just how remarkable this enzyme really is, is evident from its ubiquitous distribution in nature, not merely in mammalian and lower eukaryotic systems but also in plants, algae, fungi, and bacteria. It has been extraordinarily conserved through evolution, with approximately 80% identity between rat and human HO isoforms and nearly 70% homology between human HO-1 and that derived from the pathogen *Corynebacterium diphtheriae.*[5] Not surprisingly, targeted deletions of the HO-1 gene in mice result in HO-1 null mice that usually do not survive to term.[6] No known mutant forms of HO have been discovered, despite the near universal distribution of this enzyme in nature.

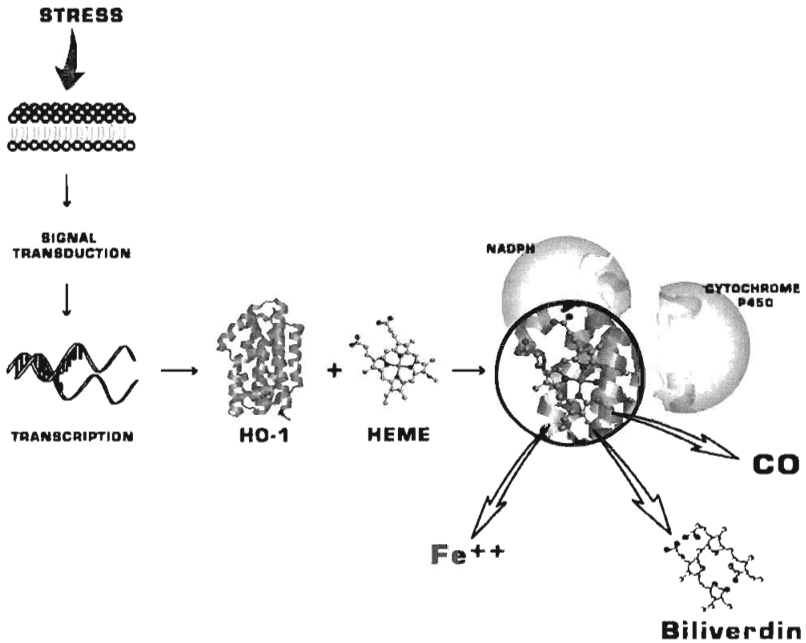

FIGURE 43–1. Reaction catalyzed by heme oxygenase-1. (See color section in this text.) (From Otterbein LE, et al: Heme oxygenase-1: Unleashing the protective properties of heme. Trends Immunol 2003;24:449-455.)

ENZYME STRUCTURE AND FUNCTION

Crystal analyses of the HO structure reveal the heme pocket to be sandwiched between two helices—the proximal and distal helices; histidine residues at positions 25 and 132 are critical for heme binding to each of these helices, respectively (Fig. 43-2).[7] The distal helix is most closely associated with heme and has the highest sequence identity between HO proteins derived from various species. Laboratory mutations that distort the structure of the distal helix decrease the efficiency of catalysis,[7] indicating that the distal helix might serve as a fingerprint motif for the HO proteins. There are several unique aspects of the HO protein that further its physiologic role. First, HO has an affinity for oxygen that is 30 to 90 times that of myoglobin, ensuring a steady supply of oxygen for substrate catalysis.[8] Second, the bound heme serves both as a cofactor for the enzyme and as its substrate.[9]

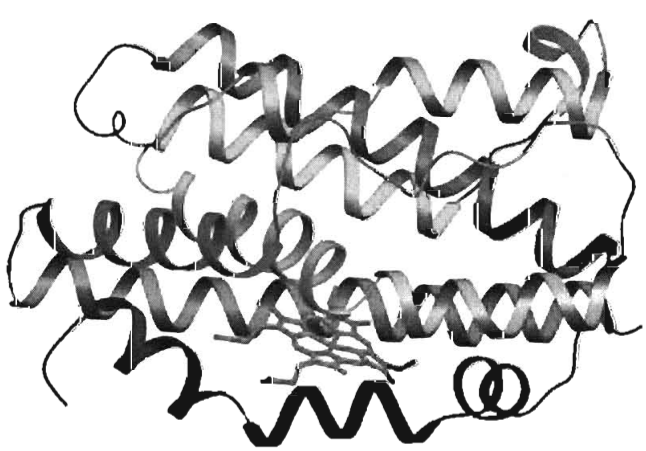

FIGURE 43–2. Structure of human heme oxygenase-1. The N-terminus is blue and the C-terminus is red, with green in the middle. The position of the heme ring is shown in pink. (See color section in this text.) (From Schuller DJ, et al: Crystal structure of human heme oxygenase-1. Nat Struct Biol 1999;6:860-867.)

Third, HO-1 is devoid of cysteine residues, making it insensitive to inactivation by reactive nitrogen and oxygen species, a critical property for a protein that serves as an antioxidant defense.

GENE STRUCTURE AND REGULATION

There are three distinct isoforms of human HO, coded for by three distinct genes.[10,11] HO-1 (inducible) and HO-2 (constitutionally expressed) share 42% identical residues; HO-3 is 90% homologous with HO-2 but is not known to be functional.[11] HO-1 is widely distributed throughout the body; HO-2 is highly concentrated in the brain and testes; and HO-3 is localized to the prostate, liver, and kidney. Whereas HO-1 is induced to serve a protective role in pathophysiologic states, HO-2 may have a more routine physiologic function, such as control of blood pressure or neurotransmission (see later).[12]

The structure of the mouse HO-1 gene is best characterized, and the deduced amino acid sequence of mouse HO-1 exhibits 93.4% and 82.3% homology with rat and human sequences, respectively. It has five exons, the relative positions of which are similar in all three species.

Heme-dependent stimulation of HO activity can be inhibited by prior treatment with the RNA synthesis inhibitor actinomycin D, suggesting that enzymatic activation is regulated at the level of gene transcription.[13] This appears to be true not just for heme but for most other inducing agents as well, although it has been suggested that increased expression of HO-1 by nitric oxide may, in part, be due to increased HO-1 messenger RNA (mRNA) stability.[14] This increased stability has also been invoked as the mechanism for hypoxic induction of HO-1 in human skin fibroblasts.[15] The *cis*-acting DNA elements of the gene that interact with their cognate-inducing proteins are becoming better understood through experiments that mutate the potential binding sites and observe the effects on the induction of the HO-1 protein by various inducers. In the case of the mouse gene,

the regulatory elements in the 5′ flanking region are arranged into three distinct areas: the proximal promoter region and two distal enhancers, DE 1 and 2, located 4 and 10 kilobase pairs upstream of the transcription initiation site, respectively.[16,17]

Although the promoter region has motifs that are variations of well-known transcription factor binding sites, the functionality of these transcription binding sites is not clearly understood.[18] However, the human gene promoter region, but not that of the mouse or rat, has a $(GT)_n$ repeat that is highly polymorphic, called a microsatellite polymorphism, with n varying from 15 to 40. These repeats may serve to modulate promoter activity or induction. In fact, promoter activity may decrease with increasing n.[19] Cigarette smokers with long repeats ($n > 31$) have a greater risk of developing emphysema than do those with shorter repeats ($n < 31$), perhaps because reduced HO-1 expression may be unable to protect against the oxidative stress of smoking.[19]

The dominant functional sequence motif in the enhancers is the stress response element (StRE). It is 10 base pairs in length; occurs repeatedly in the two distal enhancers; and, at least in the mouse, is required for the induction of HO-1 by all agents tested, except for hypoxia. In particular, induction by heme requires the entire 10 base pairs of the StRE.[20] Most likely, the DNA binding transcription factors v-Maf, NF-E2, and Nrf 1 and 2 are all involved in mediating the response to heme.[21] To respond to hypoxia, however, the hypoxia-inducible factor (HIF-1) that activates transcription of erythropoietin and vascular endothelial growth factor must bind to distinct hypoxia response elements that reside in DE 2.[22]

The first three residues of the StRE are the antioxidant-electrophile response elements, necessary for induction by oxidants and electrophiles.[23] The StRE also contains the heptad that recognizes the fos/jun (activator protein-1 [AP-1]) family of DNA-binding, transcription-activating proteins. Mutation of this site results in loss of activation by heavy metals, hydrogen peroxide, arsenite, and LPS.[17,24] Many potent antioxidant chemicals, including pyrrolidine dithiocarbamate and diphenylene iodonium, also activate HO-1 by activating AP-1 binding.[25] Another pathway of HO-1 activation during oxidative stress involves thioredoxin, a protein that keeps disulfide bonds in the reduced state, protecting intracellular proteins against oxidation.[26] Thioredoxin is induced by oxidative stress, translocates into the nucleus, and binds to intranuclear redox factor 1, which in turn reduces and activates the DNA binding activity of AP-1. This can lead to HO-1 induction.[27]

A unique situation pertains to the activation of HO-1 by interleukin (IL)-6 or interferon, both of which use the JAK-STAT pathway to induce gene transcription. When IL-6 binds to a surface receptor, a JAK factor is activated, which in turn phosphorylates and dimerizes a STAT factor, which then binds to the IL-6 response element in the PE locus of the mouse HO-1 gene.[28] In some unknown manner, a protein bound to the StREs located 4 kilobase pairs away is also needed for IL-6 induction of HO-1.[29] The mechanism of this "cooperativity" is not fully understood.

Hyperoxia also strongly induces HO-1 via the IL-6 response element.[30] Because IL-6 mRNA is induced by hyperoxia in 4 to 8 hours, well before the peak induction of HO-1 at 24 to 48 hours, it may simply be that IL-6 acts on the IL-6 response element to induce HO-1. However, both c-jun and c-fos, components of the AP-1 transcription factor, are induced by hyperoxia and could directly induce STAT binding to DNA via this site.

When organisms are exposed to hyperthermia or heat shock, a specific family of heat shock proteins is induced that confers cytoprotection against the oxidative and inflammatory stress resulting from hyperthermia. HO-1 is also known as heat shock protein 32, because it is involved in the heat shock response. Although the rat HO-1 gene is induced by heat shock, mediated by two heat shock elements in the PE region, human HO-1 heat shock induction is observed only in HeLa cells, skin fibroblasts, and the Hep3B hepatoma cell line. This is because the single heat shock element in the human HO-1 gene is constitutively repressed in vivo by a flanking sequence and the silencing action of $(GT)_n$ repeats.[31] A similar phenomenon of HO-1 repression has been demonstrated in cultured human astrocytes and coronary artery endothelial cells in response to hypoxia,[32] the significance of which is unknown. It has been suggested, however, that hypoxic repression of HO-1 may benefit some hypoxic cell types by conserving energy (given the high utilization of molecular oxygen by this enzyme), thereby protecting mitochondrial cytochrome oxidase against inhibition by CO.[33]

HO-1 AND CELLULAR PROTECTION

ANTIOXIDANT PROPERTIES

The realization that the wide variety of inducers of HO-1 all serve to generate oxidant stress led investigators to explore the potential beneficial effects of HO-1 induction in disease models characterized by overwhelming oxidant injury. One such condition, acute lung injury, involves widespread inflammatory damage to the alveoli of the lung caused by infectious pathogens, inhaled environmental toxins, trauma to nonpulmonary organs, blood transfusions, noxious gases, near drowning, or drug exposure. It is well known that many injurious agents, such as LPS derived from Gram-negative bacteria; drugs, such as bleomycin; exposure to 100% oxygen; or even host-derived tumor necrosis factor (TNF) all lead to the generation of ROS, generated from the oxidative burst of infiltrating inflammatory cells. These ROS are thought to initiate the damage to the alveolar epithelium in acute lung injury. Similarly, acute renal failure can result from many different insults, including glycerol-induced acute rhabdomyolysis, in which free heme is the nephrotoxic agent, or exposure to the nephrotoxic agent cisplatin. Again, ROS mediate the extensive tissue injury that occurs in this condition. Not surprisingly, HO-1 is intensely up-regulated in inflamed tissues in both these conditions.

Acute Lung Injury

Rats exposed to greater than 95% oxygen or sublethal injections of LPS develop acute lung injury that is remarkably similar to the human disease. Lung edema and particularly pleural effusions develop within 48 to 60 hours of exposure to greater than 95% oxygen, and rats uniformly die after 60 to 72 hours of continuous exposure. Intraperitoneal injections of LPS stimulate intense neutrophilic infiltration of the alveoli, together with hemorrhagic edema. Increased immunohistochemical staining for HO-1 protein is seen diffusely throughout the alveolar and bronchiolar epithelium and the infiltrating cells, accompanied by marked increases in HO-1 activity in the lung homogenates.[24,34]

The functional significance of this induction of HO-1 has been elucidated by experiments in which rats were pretreated with inhibitors of HO-1 activity. Pretreatment with tin protoporphyrin (SnPP) abrogated the induction of lung HO-1 in LPS-treated rats and increased susceptibility to a lethal dose of LPS; conversely, pretreatment with hemoglobin (a potent inducer of HO-1) conferred marked protection against neutrophilic alveolitis and hemorrhagic edema resulting from sublethal doses of LPS.[35] When an adenoviral vector containing the coding region of the HO-1 gene was instilled into rat lungs, it was taken up by the bronchiolar epithelium and resulted in increased protein expression of HO-1 in this region. These rats, when subsequently exposed to hyperoxia, exhibited a greater than 90% reduction in pleural effusions and survived longer than their control counterparts, which had received instillations of the adenoviral vector without the HO-1 gene insert.[36]

Acute Renal Failure

In models of acute renal failure, increased HO-1 mRNA and protein expression are noted along the tubules,[4,37] whereas in acute renal transplant rejection, the staining is localized to the infiltrating inflammatory cells.[38] As with acute lung injury, pretreatment with SnPP led to increased renal injury and death in rats undergoing rhabdomyolysis-initiated, heme-mediated acute renal failure, whereas prior treatment with hemoglobin unequivocally reduced mortality and renal damage in the same model.[4] A similar result was seen in cisplatin-induced acute renal injury,[37] implying that the benefit of HO-1 induction goes beyond protection against heme-induced injury alone.

These fundamental observations of the beneficial effects of HO-1 induction in states of oxidant injury have been extended with the availability of the HO-1$^{-/-}$ knockout mouse. (Normally, HO-1 knockout mice die in utero, so in vitro fertilization techniques were used to salvage the homozygous knockout mice.) As expected, fibroblasts derived from these mice were more sensitive to oxidant injury, and the mice exhibited increased mortality and increased liver damage resulting from LPS administration.[39] In the model of glycerol-induced rhabdomyolysis and acute renal failure, knockout mice demonstrated 100% mortality and increased tubular injury compared with their wild-type controls.[40] Similarly, administration of cisplatin to HO-1$^{-/-}$ mice resulted in more severe nephron damage than that seen in HO-1$^{+/+}$ mice.[41]

Acute Liver Injury

There is a unique topographic distribution of HO in the liver: HO-1 is prominent in Kupffer cells, and HO-2 predominates in hepatocytes.[42] This could explain the ability of HO-1, via CO, to regulate both biliary flow[43] and sinusoidal pressure (see later). Once again, it appears that ischemic stress, which liberates oxidant radicals, can be ameliorated by the induction of HO-1. Partial ligation of the portal vein in rats with portal hypertension strongly induced HO-1 in the liver.[44] Mice deficient in HO-1 demonstrated increased susceptibility to injury by endotoxin,[6] and in a model of compensated hemorrhagic shock, blockade of HO-1 was shown to increase centrilobular necrosis.[45]

Effects in the Brain

Mice lacking the HO-2 gene suffer a larger brain infarct than do controls after temporary occlusion of the middle cerebral artery, but this effect is not seen with deletion of HO-1.[46] Inhibition of HO with SnPP increases the size of the infarct in wild-type mice, again suggesting a role for HO-2 in cerebral protection against transient ischemia.[47] HO protects neurons from hydrogen peroxide–mediated injury and limits neuronal apoptosis in cell culture, indicating the potential to limit neuronal cell death in the ischemic penumbra.[47]

Oxidative stress plays a central role in the pathogenesis of Alzheimer's disease and Parkinson's disease. HO-1 protein is greatly increased in the senile plaques and neurofibrillary tangles that are characteristic of Alzheimer's disease.[48] *Tau* protein, which forms the neurofibrillary tangles, is greatly reduced in cells that overexpress HO-1.[49] Amyloid precursor protein, which is believed to be the neurotoxic agent in Alzheimer's disease, may bind to and inhibit HO, leading to more oxidative neurotoxicity,[50] but HO-1 induction can reduce both the protein and the cytotoxicity from hydrogen peroxide in neuronal cells.[51] It appears that subjects who develop Alzheimer's disease have lower levels of protective HO-1 in plasma and cerebrospinal fluid and lower lymphocyte HO-1 mRNA than do healthy elderly controls.[52] HO-1 immunoreactivity is also enhanced in the substantia nigra of patients with Parkinson's disease[48] and even in mouse brains infected with the scrapie prion,[53] which induces HO-1.[54]

Atherosclerosis

HO-1 can be induced in both endothelial and vascular smooth muscle cells by proatherogenic stimuli, such as oxidized low-density lipoprotein (LDL), lipid metabolites, shear stress, and angiotension II, among others.[55] HO-1 is highly up-regulated in the endothelium and in the foam cells of intimal lesions from humans and apolipoprotein E–deficient mice.[56] The induction of HO-1 reduces atherosclerotic lesions in LDL receptor knockout mice.[57] HO-1 can also protect against atherosclerosis by producing CO, which is known to inhibit platelet aggregation.

Clearly, these observations implicate HO-1 as a potent antioxidant protein, but the beneficial effects of its induction seem to extend beyond this antioxidant role. Astonishingly, accumulating evidence suggests that this protein can also function in an antiapoptotic role, as a regulator of cell growth and proliferation, and as an anti-inflammatory agent; it may even modulate the immune system.

ANTIAPOPTOTIC PROPERTIES

Apoptosis, or programmed noninflammatory cell death, plays an important role in human disease. For example, in acute lung injury in both humans and rodents, soluble Fas ligand mediates the apoptotic cell death of distal airway epithelium, which expresses the receptor for this so-called death ligand. Soluble Fas ligand is present in the bronchoalveolar lavage fluid from humans with early acute lung injury, but not in those at risk for the development of this disease; high levels of this ligand are associated with increased mortality.[58] Overexpression of HO-1 has been shown to protect both cultured fibroblasts from TNF-induced apoptosis[59] and bovine aortic endothelial cells from peroxynitrite-mediated apoptotic cell death.[60] Exogenous transfer of adenoviral vector–encoded HO-1 into mouse lungs attenuates the degree of hyperoxia-induced lung cell apoptosis in vivo.[61]

Bleomycin, a chemotherapeutic agent, causes acute pulmonary inflammation in humans, but when given to mice,

it results in lung fibrosis that is used as a model of the human disease idiopathic pulmonary fibrosis. Cellular apoptosis in the lung is a characteristic feature of this model, so a recent report that adenoviral-mediated overexpression of HO-1 in the lungs protected against pulmonary fibrosis caused by bleomycin is not surprising.[62]

CELL GROWTH AND PROLIFERATION

In vitro, HO-1 modulates cell growth. If pulmonary epithelial cells grown in culture are transfected with adenoviral vectors encoding the HO-1 gene, the resulting overexpression of HO-1 protein is associated with decreased cell proliferation, increased numbers of cells in the G_0/G_1 phase of the cell cycle, and reduced entry into the S phase, compared with cells transfected with the adenoviral vector alone, without the HO-1 insert. Cells that overexpress HO-1 are blocked in the G_2/M phase and are unable to progress through the cell cycle, despite serum stimulation. When SnPP is added, these effects are reversed, proving that growth arrest results from the actions of HO-1.[63] Similar growth slowing is seen in vascular smooth muscle cells transfected with HO-1,[64] and because pulmonary hypertension is associated with pronounced hypertrophy of smooth muscle in the media of the pulmonary arteries, this might well be the mechanism by which chemical preinduction of HO-1 protects rats against pulmonary hypertension from chronic hypoxia.[65] Transgenic mice overexpressing HO-1 in the lungs also develop less pulmonary hypertension in response to hypoxia.[66] HO-1 appears to regulate vascular remodeling in systemic vessels as well. In vivo, induction of HO-1 by hemin reduces neointimal thickness and medial wall thickness in the balloon-injured carotid arteries of rats.[67]

Not surprisingly, this antigrowth effect of HO-1 is applicable to tumor biology as well. A549 pulmonary epithelial cells injected into immunodeficient mice form tumors that grow rapidly. If, however, the cells are made to overexpress HO-1 before transfer to the mice, the tumors formed are half the size, and survival is improved by greater than 90%.[68] Expression of HO-1 in oral squamous cell carcinoma may be a marker for a low risk of regional lymph node metastases.[69]

THE IMMUNE SYSTEM

Increases in HO-1 protein are seen in alveolar macrophages obtained by sputum induction in humans with asthma, but not in healthy subjects.[70] In mice that develop an asthmatic phenotype brought about by prior sensitization and then challenge with inhaled ovalbumin aerosols, HO-1 induction in lung tissue can be readily demonstrated.[71] Higher HO-1 expression is seen in alveolar macrophages from humans who have acute or chronic graft rejection after lung allotransplantation, compared with those without overt rejection.[72] HO-1 is induced in the transplanted kidney after the development of acute rejection,[73] and adenoviral transfer of HO-1 dramatically protects rat liver transplants against rejection,[74] perhaps by modulating the T helper 1–T helper 2 cytokine balance.[75] HO-1 induction can protect islet cell transplants from apoptosis[76] and ameliorate the severity of graft-versus-host disease.[77] Dramatic proof of the immunomodulatory role of HO-1 comes from a mouse-to-rat cardiac xenotransplantation model.[78] Normally, mouse hearts survive indefinitely when they are transplanted under the skin of immunosuppressed rats, but pretreatment with SnPP to block HO-1 leads to rapid rejection. Transplantation of mouse hearts from HO-$1^{-/-}$ knockout mice also leads to rapid rejection. Together, these experiments prove that despite immunosuppression, HO-1 is necessary for xenograft survival.

ANTI-INFLAMMATORY EFFECTS

The mitogen-activated protein kinases (MAPKs) constitute hierarchic phosphorylation cascades responsible for transducing inflammatory signals from the cell surface to the nucleus, resulting in cellular activation and the production of cytokines that amplify inflammation. Thus, for example, when human neutrophils are stimulated by the peptide nFMLP, the ERK family of MAPKs transduces the inflammatory signals to the nucleus, resulting in a broad array of activation responses, including calcium influx, superoxide production, granule release, and chemotaxis. Similarly, LPS stimulates the p38 MAPK, resulting in TNF release. In vivo, selective chemical inhibition of p38 abrogates TNF release, and hence acute lung injury, in a rat model of pancreatitis-associated lung injury. Phosphorylation of the ERK 1/2 kinase cascade results in induction of the transcription factors AP-1 and nuclear factor kappa-B, both of which induce the expression adhesion molecules on endothelium and induce the production of IL-8 from endothelial cells.

HO-1 can modulate inflammation by changing signal transduction through the ubiquitous MAPK pathways. For example, HO-1 suppresses the phosphorylation of ERK 1/2 by TNF in rat pulmonary artery endothelial cells, providing a mechanism for the down-regulation of TNF-induced inflammation.[79] Stimulation of macrophages with LPS causes them to produce TNF, but if the macrophages are treated to overexpress HO-1 before stimulation with LPS, the production of TNF declines and the production of IL-10 (an anti-inflammatory cytokine) increases. Again, in a lethal endotoxic shock mouse model, the protective effects of IL-10 require the induction of HO-1.[80] On an organ system level, this translates to reduced inflammation and injury. For example, in a model of pleural inflammation, HO-1 up-regulation reduced inflammatory exudates and cellular infiltration, and these effects were reversed by HO-1 inhibition.[81] The protective effect of HO-1 in changing the T helper 1–T helper 2 balance in organ transplantation was alluded to earlier.

ISCHEMIA-REPERFUSION INJURY

HO-1 mRNA, protein, and activity are strongly induced in models of ischemia-reperfusion injury, both in the rat kidney[82] and in ischemic myocardium.[83] Preinduction of HO-1 can result in ischemic conditioning, ameliorating the injury caused by subsequent ischemia and reperfusion, as noted in guinea pig lung transplants[84] and in rats undergoing liver transplantation.[85]

MEDIATORS AND END PRODUCTS OF HO-1 INDUCTION

The heme moiety, despite being the cofactor for numerous enzymes and a critical component of hemoglobin, is highly toxic and can cause renal injury, as noted earlier. In addition, free heme is a potent pro-oxidant molecule, capable of oxidizing

and damaging almost all the constituents of a cell, such as the lipid membranes, mitochondria, cytoskeleton, and even nucleus.[86] It would be reasonable to suppose that all the protective effects of HO-1 induction could be explained by the degradation of this toxic free heme moiety, but a closer look at the products of the enzymatic reaction catalyzed by HO-1 shows that they too may subserve antioxidant functions directly.

FERRITIN

Ferritin, which stores free iron, has been suggested to mediate the beneficial effects of HO-1. Ferrous iron, if left free in the cytoplasm, can donate an electron to hydrogen peroxide and thus generate, via the Fenton reaction, the highly reactive hydroxyl radical. Free iron can also stimulate lipid peroxidation. However, induction of HO-1 is associated with a simultaneous increase in ferritin, which immediately sequesters the free heme and thus resolves the paradox whereby an antioxidant protein such as HO-1 generates a potentially toxic free iron radical. For example, heme-mediated induction of HO-1 results in increased transcription of ferritin,[87] and in human skin fibroblasts, oxidative injury produced by ultraviolet radiation results in HO-1–dependent induction of ferritin and thereby protection from oxidative injury.[88] In addition, HO-1 can repress the expression of a highly active ferrous iron–adenosine triphosphatase transporter involved in iron efflux from cells.[89] This transporter is colocalized with HO-1 in the microsomal fraction of the cell, and it is notable that mice with a genomic deletion of HO-1 display increased tissue accumulation of iron. This coregulation of ferritin, the iron transporter, and HO-1 may partially explain the protective effects of HO-1 induction, but in an elegant experiment, Otterbein and colleagues provided evidence of additional mechanisms.[90] In their experiments, rats pretreated with both heme to induce HO-1 and with desferrioxamine to bind ferritin were fully protected against LPS-mediated lethal endotoxic shock; conversely, pretreatment of rats with inorganic iron alone, to induce ferritin but not HO-1, could not protect the animals against endotoxic shock. Exogenous apoferritin did not confer any protection in this model.[90]

CARBON MONOXIDE

A wealth of evidence now suggest that CO, the final byproduct of the heme catabolism pathway, is the main mediator of the cytoprotection exhibited by HO-1 induction. Sjostrand first discovered endogenous production of this gas in 1949,[91] 19 years before the discovery of HO itself. This gas was known to be a poison, with the initial description of CO poisoning attributed to Aristotle. In 1857, Bernard first noted its high affinity for hemoglobin. The toxicity of this gas in exogenously inhaled concentrations results from its ability to impair the oxygen-carrying capacity of hemoglobin in two ways. First, it binds to hemoglobin with an affinity 245 times that of oxygen (at pH 7.4), competitively inhibiting oxygen binding. Second, it causes an allosteric conformational change, from sigmoid to hyperbolic, in the hemoglobin molecule, such that the oxygen molecules bound to hemoglobin are less easily released, effectively left-shifting the hemoglobin dissociation curve and reducing tissue oxygen extraction from hemoglobin. It also binds to and inactivates the reduced form of cytochrome a_3, impairing tissue respiration.

CO is a colorless and odorless gas. Its solubility in water is about 30% less than that of oxygen (O_2). Given this low solubility and its high affinity for heme moieties, CO may be shuttled from heme moiety to moiety, based on the reaction constants within the different heme groups. Because O_2 also binds to heme moieties, it competes with these reactions; the relationship is defined in terms of the Warburg coefficient (K),

$$K = (n/1 - n)\ (CO/O_2),$$

where n is the fraction of heme moiety bound to CO. Thus, the Warburg coefficient is the ratio of the concentration of CO to that of O_2 required for 50% saturation of the heme compound (i.e., when n = 0.5). Because the Warburg coefficient is 0.4 for myoglobin, it follows that CO binds readily to myoglobin and that hemoglobin shuttles its CO content to myoglobin when the O_2 concentration in muscle drops to low levels during exercise.[92,93] In the case of cytochrome a_3, however, for which K ranges from 5 to 15, it does so only when present in high concentrations (estimated at >20%)[94] or in the presence of severe O_2 depletion (e.g., in the mitochondria of asphyxiated tissues). As excellently reviewed by Piantadosi,[95] CO *has* been shown to bind to cytochrome *a*, a_3 in vivo (e.g., in the brains of rats perfused with perfluorocarbons instead of blood, while exposed to CO).[96] Despite the fact that these ratios are defined from in vitro experiments, they help explain how a gas that is apparently toxic can be readily formed endogenously and how the reaction was retained through millions of years of evolution, without adverse effects to the organism.

CO is produced endogenously at a rate of about 0.42 ± 0.07 mL/h, or approximately 10 mL/day.[97] Nearly all the CO produced endogenously results from the catabolism of heme—about 85% from the erythron, and the remainder from nonhemoglobin heme. Minute amounts can be generated by NADPH- or iron ascorbate–dependent lipid peroxidation.[98] The cytochrome P_{450} system can metabolize dihalomethanes to CO in vivo,[99] which may be significant in cases of toxic inhalation of these compounds. The majority of CO produced in the body is excreted by exhalation, although, intriguingly, CO can also be oxidized to carbon dioxide by cytochrome a_3, the cellular target of CO.[100] The importance of this reaction as a pathway of elimination of CO from the body is unknown.

The first suggestion that CO could exert physiologic effects came in 1991, around the time that gaseous nitric oxide (NO) was recognized as a physiologic effector molecule.[101] Experiments in which exogenous CO has the same effects as up-regulation of HO-1, or in which CO can "rescue" the effects of HO-1 blockade, provide evidence for its role as a mediator of HO-1 cytoprotection. For example, pretreatment of rats with 250 parts per million (ppm) of CO protects against hyperoxia (Fig. 43-3) and LPS-induced injury in a manner comparable to overexpression of HO-1.[61] Likewise, CO inhibits lung cell apoptosis in hyperoxia-injured animals.[61] Exogenous CO in the same low doses can protect against TNF-induced apoptosis to the same extent as overexpression of HO-1.[59,102] In vitro, low-dose CO reduces TNF-induced ERK 1/2 phosphorylation in rat pulmonary artery endothelial cells in the same manner as does overexpression of HO-1.[79] In this system, p38 phosphorylation is increased by HO-1 overexpression and by CO, while the other MAPK pathway, JNK, is unaffected. This argues against these effects being the result of the general cellular toxicity of CO. Exposure of

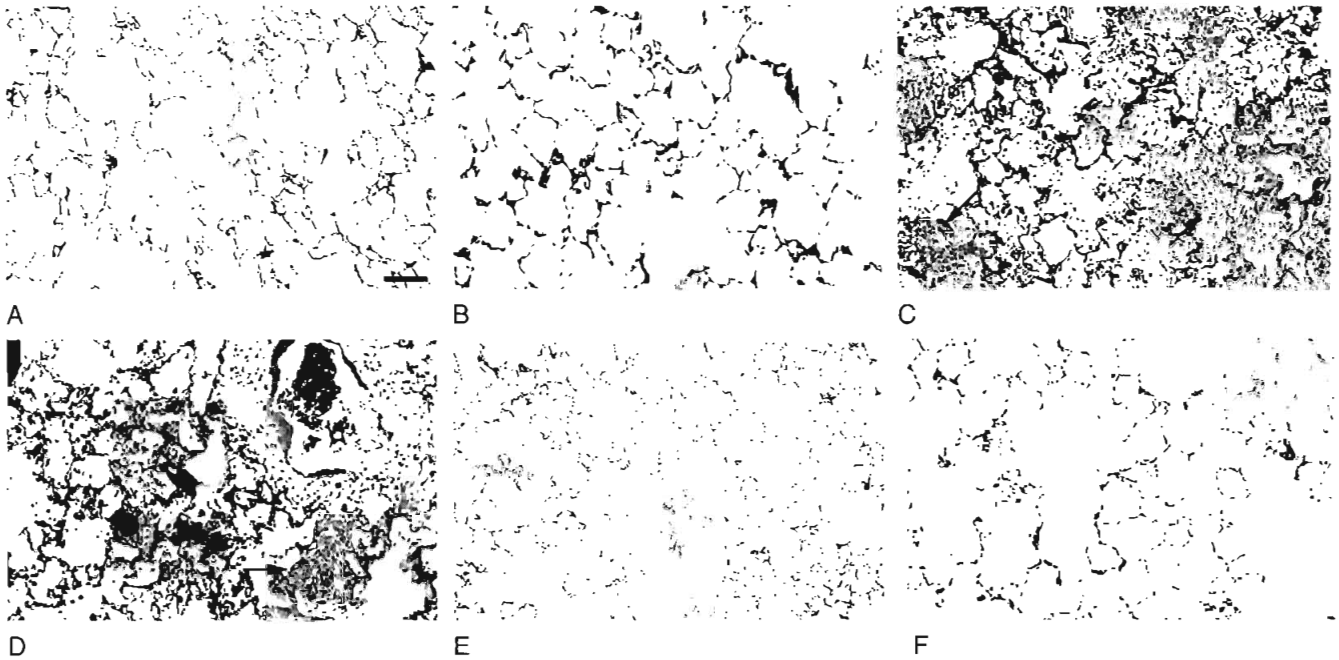

FIGURE 43–3. Protective effect of exogenous carbon monoxide (CO; 250 ppm) on hyperoxia-induced lung injury in rats. Histologic sections of rat lungs: *A*, normoxia control; *B*, CO control (256 ppm × 56 h); *C* and *D*, hyperoxia (× 56 h); *E* and *F*, hyperoxia (250 ppm CO × 56 h). (See color section in this text.) (From Otterbein LE, Mantell LL, Choi AM: Carbon monoxide provides protection against hyperoxic lung injury. Am J Physiol 1999;276:L688-L694.)

LPS-stimulated macrophages to low-dose CO results in the same constellation of reduced TNF generation and enhanced IL-10 production as seen with overexpression of HO-1 in these cells.[103] Low-dose CO retards the growth of tumors in vivo, just as is noted with HO-1 overexpression in A549 tumor cells injected into mice.[68] In mice sensitized and then challenged with aeroallergen, inhaled CO can selectively reduce the production of the eosinophil chemoattractant IL-5 and, consequently, eosinophil accumulation in the lung.[104] In the mouse-to-rat cardiac xenotransplantation model described earlier, treatment of both donor and recipient with exogenous CO results in indefinite survival of the xenotransplant, even in the face of inhibition of HO-1 by SnPP, exemplifying the ability of CO to substitute for HO-1.[105] Similar to the effects of HO-1 induction in preventing neointimal hyperplasia after balloon injury in rat carotid arteries, inhalation of low-dose CO for just 1 hour also virtually ablates neointimal hyperplasia (Fig. 43-4).[106]

Clearly, CO must be a major effector of the protection imparted by HO-1 induction. Nevertheless, CO has other physiologic roles of its own that might protect the body in a variety of disease states.

Vasodilator. Exogenous CO in high concentrations (10%) causes a reversible increase in coronary blood flow in isolated perfused rat hearts.[107] Although this may be an effect of hypoxia rather than a physiologic effect of CO, direct relaxation of vascular smooth muscle by CO has been shown in isolated porcine coronary arteries and veins[108] and in rabbit[109] and rat[110] aortas. In isolated perfused rat livers, inhibition of HO activity increased hepatic vascular resistance, but this effect was reversed by exogenous low-dose CO (1 μM).[111] CO generated by the induction of HO-1 lowers blood pressure in spontaneously hypertensive rats,[112] whereas inhibition of HO-1 raises blood pressure and total peripheral resistance in rats.[113] In the kidney, CO can attenuate the effect of vasoconstrictors on renal arterioles, and CO can reverse phenylephrine-induced vasoconstriction in rat tail arteries.[114] Some of the vasodilator effects of CO may be mediated centrally, through the nucleus tractus solitarius.

Bronchodilator. Exogenous CO can reverse the bronchoconstriction due to histamine in anesthetized, ventilated guinea pigs, albeit at a high concentration (100%).[115] Inhibition of HO-1 with ZnPP also inhibits hypoxia-associated bronchoconstriction in vivo.[116] Recently, even low-dose exogenous CO has been shown to reverse the bronchoconstriction produced by methacholine in ventilated mice[117] and in guinea pig tracheal muscle ex vivo.[118]

Inhibitor of Platelet Function. CO inhibits the activation and aggregation responses of platelets,[119] which might explain the cardioprotective effect of CO in the mouse-to-rat xenotransplant described earlier. The surviving transplants had markedly reduced vascular thromboses.[105]

Neurotransmitter. In the myenteric plexus of the intestine, CO exhibits effects identical to those of NO, another gas molecule that functions as a neurotransmitter. Intestines of HO-2–deficient mice have impaired relaxation, and HO inhibitors cause intestinal contractions in NO synthase–deficient mice.[120] In the brain, intraventricular injection of HO inhibitors blocks the production of adrenocorticotropic hormone in response to electroshock; this action appears to be localized to the brain, not the pituitary.[121] There is evidence too that CO functions in long-term potentiation in the hippocampus,[122,123] and chemical inhibition of HO-1 activity can block glutamate receptor activation in the rat nucleus tractus solitarius.[124] In endotoxin-induced injury, CO inhibits the release of vasopressin.[125] CO regulates the nerve output of the carotid body, suppressing sensory discharge under basal conditions. During hypoxia, sensory discharge from the carotid body increases because of reduced CO generation.[126] Taken together, these effects are remarkably similar to those of the other diatomic gaseous neurotransmitter, NO.

Mechanism of Action. In the body, CO undergoes two types of reactions that have special significance (Fig. 43-5).

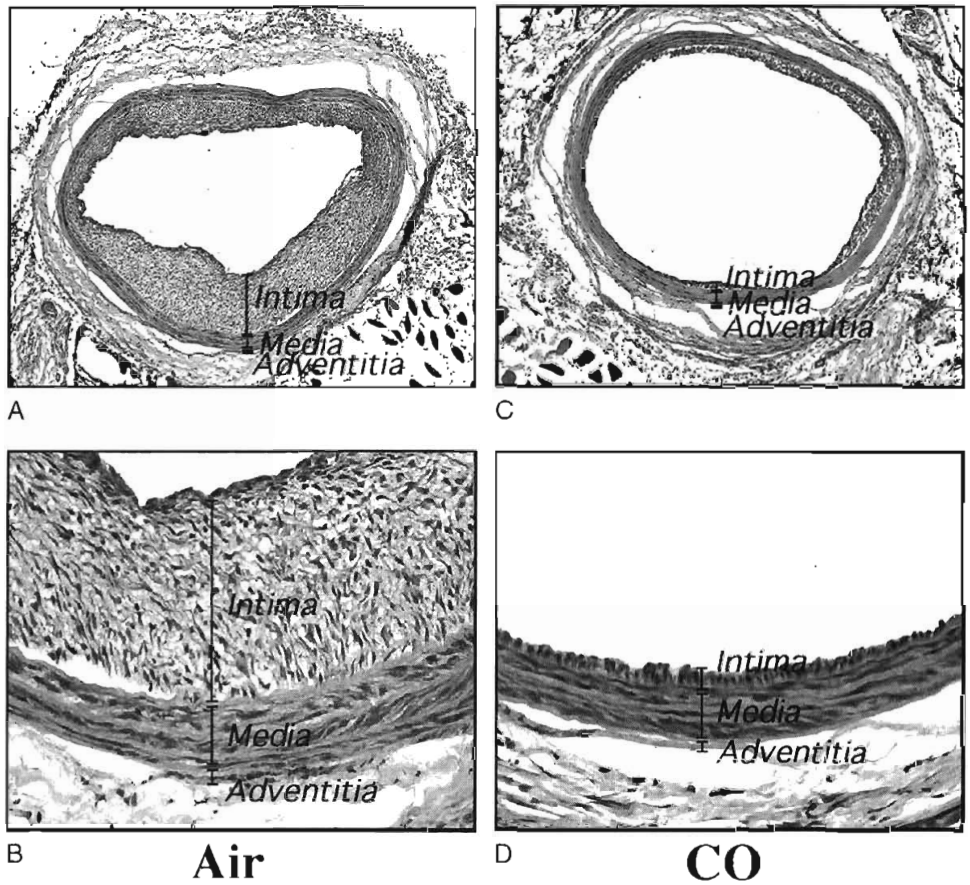

FIGURE 43–4. Pretreatment with exogenous carbon monoxide (CO; 250 ppm) greatly reduces the intimal proliferation after balloon injury in rat arteries. Rats were exposed to air (*A* and *B*) or exogenous CO for 1 h (*C* and *D*). Magnification is ×10 in the upper panels (*A* and *C*) and ×50 in the lower panels (*B* and *D*). (From Otterbein LE, Zuckerbraun BS, Haga M, et al: Carbon monoxide suppresses arteriosclerotic lesions associated with chronic graft rejection and with balloon injury. Nat Med 2003;9: 183-190.)

There are undoubtedly other reactions that may account for some of the biologic properties of CO, but these are not yet well delineated.

First, CO readily reacts with transitional metals to form metal carbonyls, and these may act as stores of CO in the body. Under some conditions, such as exposure to light, interaction with other ligands, or interaction with molecular oxygen, these metal carbonyls may gradually release CO. Motterlini and coworkers recently demonstrated the ability of synthetic metal carbonyls to deliver CO in vivo, and the actions of these chemicals mimic those of endogenously produced CO.[127]

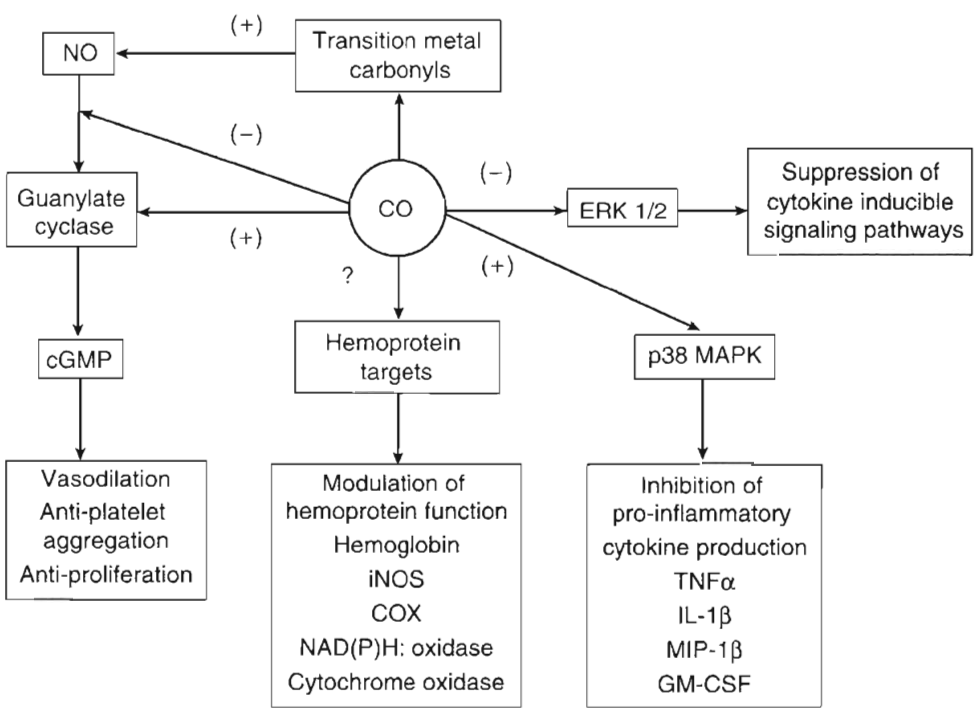

FIGURE 43–5. Mechanism of action of carbon monoxide (CO). cGMP, cyclic guanosine monophosphate; COX, cyclooxygenase; GM-CSF, granulocyte-macrophage colony-stimulating factor; IL, interleukin; iNOS, inducible nitric oxide synthase; MAPK, mitogen-activated protein kinase; NO, nitric oxide; TNF, tumor necrosis factor. (Adapted from Slebos DJ, Ryter SW, Choi AMK: Heme oxygenase-1 and carbon monoxide in pulmonary medicine. Respir Res 2003;4:7.)

Second, CO binds to the ferrous heme moieties of hemoproteins but does not bind to ferric heme, unlike NO, which binds in both redox configurations. NO has an extremely high affinity for ferrous heme in comparison to CO, but the dissociation constant for CO bound to ferrous heme is much longer than that for NO,[128] resulting in the gradual dissociation of NO from ferrous hemoproteins in the presence of CO.[129] Thus, CO could exert some of its effects indirectly, through NO. Such effects have been described in the endothelium. For example, nitrotyrosine levels (the "footprint" or "signature" of NO release) increase in aortic endothelium within 1 hour of ventilating rats with 50 ppm of CO,[129] and cultured endothelial cells release peroxynitrite upon exposure to 100 ppm of CO.[130]

The binding of CO to the hemoprotein cytochrome P_{450} (Warburg coefficient = 1) inactivates the enzyme, decreasing the metabolism of drugs such as barbiturates. Inactivation of cytochrome P_{450}–dependent synthesis of endogenous vasoconstrictors has been proposed to explain the vasodilatation induced by CO, but it is unclear whether oxygen concentrations are low enough in organs such as the liver to allow such reactions to proceed physiologically.

The binding of CO to the heme moiety of soluble guanylate cyclase (sGC), and the consequent activation of sGC, is a major mechanism by which CO exerts many biologic effects. The effects of CO on platelets and neutrophils, and the vasodilating effects of CO described earlier, are all mediated by sGC and can be abrogated by chemical inhibition of sGC. In the brain, HO-1 and HO-2 are colocalized with sGC, suggesting that many of the putative neurotransmitter effects of CO are also sGC mediated. CO exerts these effects even though it is, at best, a weak activator of sGC and produces a minimum of the conformational change that activates sGC, at least in comparison to the tremendously more potent NO. Curiously, a synthetic compound, YC-1, has been discovered that increases the activation of sGC by CO by an astounding 4000%, secondary to stabilization of the conformational change that accompanies sGC activation.[131] Similar endogenous compounds may bring about more marked activation of sGC by CO than is seen in vitro.

Another interesting feature of the relatively weak interaction between CO and sGC explains how CO can either facilitate or antagonize the activation of sGC by NO. In the absence of NO, CO would activate sGC. Low concentrations of CO bound to sGC might actually inhibit NO binding and thereby inhibit activation of sGC by NO. In high concentrations, it is possible that CO would act much like an NO and amplify the effect of NO on sGC activation. For example, transgenic mice that have HO-1 overexpression targeted specifically to the endothelium actually show a significant *increase* in blood pressure, and aortic rings from these mice demonstrate impaired vasodilatation in response to NO, despite intact sGC activity. Because nitrovasodilatory activity is restored by the inhibition of CO, it appears that, in this context, CO is acting as a partial antagonist of NO.[132] This concentration-dependent ability of CO to function as a potentiator or partial inhibitor of NO-mediated sGC activation has been demonstrated in vitro.[133]

Not all the biologic activity of CO can be attributed to hemoprotein binding, however. The effect of exogenous low dose CO on the MAPKs is not mediated by sGC, and the kinases do not have heme groups. The TNF-mediated ERK 1/2 phosphorylation in rat pulmonary artery endothelial cells, described earlier, is also inhibited by n-acetylcysteine, a scavenger of oxidant species, suggesting that CO can exert indirect effects on the MAPK system by reducing free radical generation.[79] Similarly, CO can block vasoconstriction in rat tail arteries by both stimulating sGC and increasing the open probability of large-conductance, calcium-activated potassium channels.[114] Piglet pial arterioles vasodilate in response to infusions of heme, which stimulate HO-1 and lead to the local production of CO. These effects are blocked by HO-1 inhibition, as well as by blockade of the calcium-activated potassium channels described earlier. It is postulated that there is an interaction between CO and the histidine residues of the channel.[134]

CONCLUSION

Heme oxygenase's rise to fame—from a lowly enzyme serving to "recycle" hemoglobin to one of the most powerful cytoprotective proteins in nature—makes for fascinating reading. Equally exciting is the saga of carbon monoxide, as investigators around the world struggle to rehabilitate its image from poisonous gas to astoundingly multifunctional physiologic mediator. But these two biologic entities also underline how the relentless process of scientific discovery can overturn entrenched paradigms. HO was discovered in 1968, but it took another 23 years for its role beyond heme catabolism to be uncovered. And if not for the discovery of the remarkable physiologic role of NO, research into CO may have been stalled by those convinced only of its poisonous properties.

Although knowledge of the physiologic role of this HO-1–CO system is burgeoning, some experiments suggest that much more research is required before it can be fully understood and its power harnessed in pharmacology. For example, in contrast with the beneficial effects of HO-1 induction in protecting against heme- or cisplatin-induced renal failure, HO-1 is up-regulated in experimental gentamicin nephrotoxicity, but in this case, inhibition of the enzyme by SnPP does not modify the resulting renal injury.[37] Although moderate overexpression of HO-1 in fibroblasts confers protection against hyperoxic injury, higher levels of HO-1 overexpression lead to increased susceptibility to hyperoxia, suggesting a dosing threshold.[135] Similarly, CO in low concentrations (100 ppm) can generate oxidant radicals in vascular endothelium. Clearly, the preponderance of evidence favors the view that HO-1 and CO are vital to the organism's defense against injury, but much still needs to be learned. With more research into dosing and delivery, inhaled low-dose CO may well become a pharmacologic agent in the not-so-distant future.

ANNOTATED REFERENCES

Applegate LA, Luscher P, Tyrrell RM: Induction of heme oxygenase: A general response to oxidant stress in cultured mammalian cells. Cancer Res 1991;51:974-978.

In this seminal paper, the authors detected increases in HO-1 mRNA in a human fibroblast cell line in response to a variety of oxidants and agents that alter cellular glutathione levels. This induction of HO-1 by oxidants led the authors to propose a secondary cytoprotective role for this enzyme, previously thought to function only in heme catabolism.

Nath KA, Balla G, Vercellotti GM, et al: Induction of heme oxygenase is a rapid, protective response in rhabdomyolysis in the rat. J Clin Invest 1992;90:267-270.

This paper provided the first in vivo evidence of the protective effect of HO-1 induction against acute renal failure in a rat rhabdomyolysis model. Conversely, chemical inhibition of HO-1 exacerbated kidney dysfunction.

Otterbein L, Chin BY, Otterbein SL, et al: Mechanism of hemoglobin-induced protection against endotoxemia in rats: A ferritin-independent pathway. Am J Physiol 1997;272:L268-L275.

In this elegant study, the authors studied whether the protective effect of HO-1 on LPS-induced multiorgan failure in rats was mediated by ferritin. Rats pretreated with hemoglobin and desferoxamine (which induced HO-1 but blocked ferritin) were protected against LPS-induced organ failure and death, whereas rats pretreated with iron dextran (which induced ferritin but not HO-1) died.

Otterbein LE, Mantell LL, Choi AM: Carbon monoxide provides protection against hyperoxic lung injury. Am J Physiol 1999;276:L688-L694.

In this paper, the authors showed that exogenous gaseous CO in low doses (50 to 500 ppm) markedly attenuates the acute lung injury, inflammatory cell infiltration, cellular apoptosis, and pleural effusions that result when rats are exposed to hyperoxia. Survival was also improved, and this benefit was evident even when endogenous HO-1 was chemically inhibited, proving that CO may mediate or replace the benefits of HO-1 induction in oxidant-induced tissue injury.

Sato K, Balla J, Otterbein L, et al: Carbon monoxide generated by heme oxygenase-1 suppresses the rejection of mouse-to-rat cardiac transplants. J Immunol 2001;166:4185-4194.

It was known that HO-1 expression in the graft vasculature was critical to the survival of mouse-to-rat cardiac transplants by preventing platelet aggregation, endothelial cell apoptosis, and vascular thrombosis. In this study, HO-1 was chemically inhibited, but exogenous CO restored long-term graft survival, replicating the effects of HO-1 induction.

Chapter 44

MOLECULAR AND BIOCHEMICAL MONITORING

J. Perren Cobb • T. Philip Chung

KEY POINTS

1. The term **molecular monitoring** refers to the evaluation of patient status and disease using measurement methods derived from applied molecular biology.
2. The term **biochemical monitoring** usually refers to the use of sensitive protein detection methods to measure biomarkers to aid in establishing a diagnosis and prognosis.
3. Molecular biologic techniques, recently expanded by **technologic breakthroughs that span the entire genome**, promise to transform diagnostics in all fields of medicine, especially critical care.
4. The **sequences of the human and mouse genomes have been reported**, and efforts are under way to make the sequencing of each person's genome practical by means of readily available, high-throughput, automated DNA sequencing.
5. There are common, heritable genetic variations that contribute to susceptibility or resistance to disease. These common variants most frequently take the form of **single-nucleotide polymorphisms.**
6. The term **transcriptome** refers to the complete set of messenger RNAs (mRNAs) encoded by the genome for a particular cell type.
7. By varying the source of the target mRNA, investigators can compare relative levels of mRNA abundance using **DNA microarrays**, in practice generating a genome-wide expression profile—the *transcriptome*—for the cell or tissue of interest.
8. The term ***proteome*** was coined to describe the set of proteins encoded by the genome, and it defines the entire protein complement in a given cell or tissue.
9. The technology necessary to make protein "chips"—the tools needed to readily generate **genome-wide "snapshots" of the proteome**—is still emerging, some 5 years behind its DNA microarray cousin.
10. **The analytic process of classification** refers to the ability to distinguish between samples based on inherent, measurable features. Ideally, these features are easily quantitated, stable, and widely divergent between classes.
11. The overarching strategy for **molecular classification** includes the description of informational features in a training data set associated with the phenotype of interest—in essence, defining a molecular profile of the phenotype. Application of these features to unknown samples in a test data set determines the accuracy with which the features can classify unknown samples.
12. Although comprehensive reviews of **gene association studies** indicate that the majority of reported associations are not robust, meta-analysis indicates that larger, appropriately powered studies will likely find many single-nucleotide polymorphisms that are convincingly informational.
13. **Microarray gene expression analysis** has been used experimentally in the field of cancer to classify samples, addressing important clinical issues such as response to chemotherapy and propensity to metastasize. It is logical to assume that these same techniques will be widely applicable to many complex human diseases, including critical illness and injury.
14. Circulating leukocyte mRNA and protein abundance is a dynamic that varies as patients move along various **clinical trajectories (phenotypes) during sepsis**. Preliminary data in animals and human patients suggest that these trajectories can be characterized, monitored, and ultimately used to recognize infection in patients in whom sepsis is particularly difficult to diagnose. Important clinical advances in sepsis diagnostics are anticipated.

This chapter describes the current state of molecular monitoring and highlights recent advances in high-throughput genomic technology. The latter, when coupled with robust computational approaches, promises to yield more accurate diagnoses, improved understanding of underlying molecular mechanisms, and better therapeutic targets. Because of its central role as a determinant of organ dysfunction and mortality in ICUs, monitoring of systemic inflammation and infection is used as a case example.

MOLECULAR AND BIOCHEMICAL MONITORING IN CRITICAL CARE

The term *molecular monitoring* refers to the evaluation of patient status and disease using measurement methods derived from applied molecular biology. This is different

from simply monitoring molecules (e.g., serum electrolytes, urinalysis, complete blood counts), as reviewed elsewhere. The term initially was used to describe the detection of minimal disease or tumor recurrence in patients with cancer using sensitive DNA or RNA detection methods[1,2]; more recently, applications in infectious disease have been reported.[3-5] These techniques are based on the polymerase chain reaction, an in vitro technique introduced in 1985 that can amplify by several orders of magnitude the abundance of a short stretch of DNA (typically <3000 base pairs) using a thermostable polymerase and sequence-specific primers. RNA can be used as the polymerase template for the chain reaction if reverse transcriptase is applied first to convert the RNA to DNA; this is called reverse transcription polymerase chain reaction. A more detailed description of these standard molecular techniques is beyond the scope of this chapter; interested readers are referred to several recent reviews for additional information (see also Chapter 28).[6-8]

The term *biochemical monitoring* usually refers to the use of sensitive protein-detection methods to measure biomarkers that can aid in diagnosis and prognosis (e.g., prostate-specific antigen).[9] There has been great interest in the past decade in pursuing markers for a number of conditions, including acute cardiac injury and sepsis. Regarding the former, the success of monitoring troponin I has revolutionized the workup and diagnosis of acute myocardial syndromes (see Chapter 95 for additional information).[10,11] The search for an accurate marker of sepsis, however, has largely failed, as evidenced by the report of a recent consensus conference.[12] Although the reasons for this failure are complex and incompletely understood, several lessons have been learned. The first is that a set of rigorous, specific, objective, measurable diagnostic criteria to use as a "gold standard" significantly aids the search for biochemical markers. This is characteristic of acute myocardial infarction but remains elusive for sepsis. Second, whereas acute myocardial syndromes involve a single, relatively homogeneous type of specialized tissue (myocardial cells) in a critical mass that carries out two readily observed functions (contraction and relaxation), sepsis involves an overwhelmingly complex interaction of multiple cell types (infecting agent, leukocytes, endothelial cells) in multiple compartments (blood, spleen, liver) that are in constant flux. In this context, the lack of success in the field of sepsis can be more readily understood. Examples of marker proteins that continue to generate interest are interleukin-6 and procalcitonin. Both reportedly serve as markers of systemic inflammation and the severity of the host response to sepsis.[12] However, insufficient and conflicting data confound the discussions supporting their use as sepsis biomarkers. It is to this end that molecular biologic techniques, recently expanded by technologic breakthroughs that span the entire genome, promise to transform diagnostics in all fields of medicine, especially critical care.

MONITORING IN THE GENOMIC ERA

It remains exceedingly difficult to gauge the clinical trajectory and response to therapy in any given patient. There are a host of probabilistic tools available (e.g., Acute Physiology and Chronic Health Evaluation [APACHE] III), based on clinical examination and physiologic parameters. What the current tools lack is an ability to measure or gauge a heritable predisposition to a given clinical trajectory and a patient's response to current therapy. Today, however, it is possible to both gauge heredity and measure the response to therapy at the molecular, whole-genome level. The biologic assumptions underlying these efforts are that (1) predisposition is determined to a greater or lesser degree by our genetics, and (2) response to therapy can be measured, predicted, and individualized at the level of RNA and protein. The promise of molecular monitoring is that it will be possible in the near future to get preliminary data when patients are admitted and, with a few repeated measures, to answer the questions "what is going on?" and "how are they going to do?" This will be important to families in terms of offering hope (or not) for the patient's recovery. It will be important to physicians because it will provide guidance for optimal and individualized therapy for the critically ill or injured.

THE GENOME (DNA)

The sequence of the human genome has been reported,[13-15] and efforts are under way to make the sequencing of each person's genome practical by means of readily available, high-throughput, automated DNA sequencing (e.g., dideoxynucleotide chain termination, or Sanger, method). Despite the overwhelming similarity in sequences among individuals (99.9%), there are common, heritable genetic variations that contribute to susceptibility or resistance to disease. These common variants most frequently take the form of single-nucleotide polymorphisms. Technically, single-nucleotide polymorphisms refer to DNA sequence variations that are present in at least 1% of the population. It is important to recognize that the approximately 10 million single-nucleotide polymorphisms in the human genome occur frequently because they have been conserved in our species, ostensibly because they provide an adaptive advantage to the organism under specific circumstances. Thus, single-nucleotide polymorphisms do not cause disease but likely influence the risk of developing a disease or the outcome from a disease (e.g., death from sepsis). Single-nucleotide and other polymorphisms exist in nonrandom patterns, or haplotypes (variant alleles located together along portions of individual chromosomes). In light of recent reports,[16,17] it has been argued that accurate characterization of genotype-phenotype associations will require the definition of haplotypes rather than the examination of individual single-nucleotide polymorphisms.[18] Thus, many in the field of functional genomics are awaiting the results of the HapMap (www.hapmap.org) efforts and are simply collecting DNA samples from at-risk patients for later analysis.[19] It is expected that successful mapping of human haplotypes will provide a critical resource for biomedical researchers who study health, disease, and variations in drug response based on genotypic differences (pharmacogenomics).

THE TRANSCRIPTOME (mRNA)

The term *transcriptome* refers to the complete set of messenger RNAs (mRNAs) encoded by the genome for a particular cell type. Unlike the genome, the transcriptome and the proteome (see later) are dynamic, characteristic of a particular cell type in a particular cell state at a specific time. For example, changes in the relative abundance of RNA and protein are what cause the dramatic changes induced by pregnancy, not the underlying maternal DNA "blueprint" that has been present since conception. Until recently, polymerase chain

reaction technology was the mainstay for detecting RNA. In particular, real-time polymerase chain reaction is a popular method of quantitating changes in relative mRNA abundance between samples, usually on the order of a handful of genes. Although most genes have coding sequences that are hundreds of nucleotides in length, only a relatively short sequence (<100 nucleotides) is required to uniquely identify each gene. Advances in robotic and miniaturization technology have made it possible to study simultaneously the relative abundance of several thousand RNA species. Developers exploited these advances by fashioning glass slides ("chips") with minute quantities of short, gene-specific nucleotides. These gene-specific "probe" nucleotides—ideally, one for each gene in the genome—are arrayed on the chip surface to produce a DNA *microarray*. From cells or tissue of interest, mRNA can be isolated and labeled to produce "target" nucleotides. Hybridization of the microarray probes with the complementary-labeled targets results in the formation of a labeled heteroduplex. With the aid of a laser scanner and computational software, the relative degree of label signal intensity, correlating to the relative mRNA abundance for each gene, can be calculated. By varying the source of the target mRNA, investigators can compare relative levels of mRNA abundance, in practice, generating an expression profile—the *transcriptome*—for the cell or tissue of interest. It is now possible to profile the entire human and mouse transcriptomes using the latest-generation microarrays.

THE PROTEOME (PROTEIN)

The term *proteome* was coined to describe the set of proteins encoded by the genome, and it defines the entire protein complement in a given cell or tissue.[20] Comprehensive mechanistic insight into cellular behavior depends on detailed knowledge of protein interactions. Thus, although gene expression "snapshots" have been enormously helpful in providing our first glimpses of molecular systems, genome-wide proteomics will be required to take our understanding to the next level and facilitate the application of systems analysis. Unlike their oligonucleotide counterparts, peptides are more difficult to study for several reasons (see the accompanying box).[21-24] As a result, the technology necessary to make protein "chips"—the tools needed to readily generate genome-wide "snapshots" of the proteome—is still emerging, some 5 years behind its DNA microarray cousin. Thus, even though there are technologic hurdles to overcome, the promise of the proteome continues to engage the imagination of investigators and speculators alike, especially for clinical diagnostics and drug development.

To monitor and later identify different proteins in a given sample, they must be separated into relatively homogeneous fractions. Two-dimensional gel electrophoresis and mass spectrometry are mainstay technologies for proteomics.[21,23-26] Two recent advances are discussed here: two-dimensional differential gel electrophoresis and isotopic-coded affinity tagging. Single-dimensional gel electrophoresis has been used for decades to separate and study small numbers of proteins (e.g., Western immunoblot analysis). The technique exploits the negatively charged nature of proteins, which move in an electric field toward the cathode, with the rate of movement determined largely by size. Two-dimensional gel electrophoresis separates in the first dimension based on isoelectric point, and then orthogonally based on size. Fluorescent two-dimensional differential gel electrophoresis is a new multiplexed method that enables the comparison of up to three experimental conditions in the same physical gel.[27] Two-dimensional differential gel electrophoresis is used to determine changes in the level of protein expression from arrays of approximately 2000 proteins (i.e., ~2000 gel spots are usually observed from plasma). The resulting differential protein expression profiles can be interpreted with greater confidence, with far fewer replicates, than with conventional two-dimensional gels. This methodology has been successfully applied in diverse systems.[28-33] The advantages of this method are that it is quantitative and allows image analysis; the disadvantage is that it poorly resolves proteins that are very high or low molecular weight, very alkaline, or hydrophobic.[34]

Isotopic-coded affinity tagging is a complementary technique that has significant advantages over two-dimensional differential gel electrophoresis for the identification of membrane proteins, proteins of lower abundance, and highly basic proteins (pI > 10).[24,35,36] Its disadvantages are that it poorly resolves proteins that are cysteine-poor and very acidic.[34] Typically, both two-dimensional differential gel electrophoresis and isotopic-coded affinity tagging are linked to subsequent analysis and identification by mass spectrometry, which measures mass-to-charge ratios of ionized analytes in the gas phase.[37] Mass spectrometry has demonstrated an ability to identify molecular signatures of peptides ("peptide-mass fingerprinting") that are diagnostic in cancer case-control studies.[22,38,39] It is expected that the proven utility of proteomics in cancer will be extended to the field of critical illness and injury, analogous to efforts in transcriptomics using DNA microarrays. Again, the expectation is that genes and pathways that are useful for diagnostics, this time at the protein level, will provide important molecular insight into regulation of the host response to critical illness and injury.

CLASSIFICATION USING MOLECULAR PROFILES

The analytic process of classification refers to the ability to distinguish between samples based on inherent, measurable features. Ideally, these features are easily quantitated, stable, and widely divergent between classes. The clinical application of classification strategies spans diagnosis, prognosis, and gauging the response to therapy. Although traditional statistics provides many robust classification tools using high-dimensional data in the fields of physics and economics, the application of classification strategies to functional genomic data is as new as the technology itself; both are evolving rapidly. Moreover, direct application of traditional computational strategies to high-dimensional biologic data can be hazardous, given that these strategies were not designed to account for the many limitations of biologic systems, such as nongaussian distributions and saturation (nonlinear) properties of probe-target interactions (microarray hybridizations). Despite these limitations, however, the power of molecular classification using genome, transcriptome, and proteome data is evident, as described later. The overarching strategy involves the description of informational features in a training data set associated with the phenotype of interest—in essence, defining a molecular profile of the phenotype. Application of these features to samples in a test data set determines the accuracy with which the features can classify unknown samples. The test data samples can be added to the training data set, typically

improving the predictive ability of the model; then, new unknowns are tested in an iterative manner. Classification is based on recognition of a defined "fingerprint" characteristic of a particular phenotype; it is not necessary to know the identity or function of the features or genes that determine it. Application of these classification strategies in the ICU promises improved diagnostics and prognostics based on real-time monitoring of changes in relative RNA or protein abundance, in the context of predisposition data from DNA sequences (single-nucleotide polymorphisms). A more detailed description of the computational strategies used to analyze data from high-throughput technologies can be found in several recent reviews.[40-46]

CLASSIFICATION USING DNA SEQUENCE VARIATIONS

There is an established association between genetics and predisposition to infection, although the mechanisms are unknown. In a seminal paper, Sorensen and colleagues calculated the heritable predisposition for early death from several complex diseases in adoptees compared with their biologic or adoptive parents.[47] These investigators found that premature death in adults has a strong genetic correlation, especially death from infectious causes, suggesting a significant underlying genetic basis. The search for genetic clues to this predisposition for critical illness from infection and other causes has been accelerated dramatically by sequencing of the human and mouse genomes and identification of informational single-nucleotide polymorphisms.[13,48] A number of reports suggest a role for single-nucleotide polymorphisms as markers of sepsis severity and outcome after injury (reviewed in reference 49). For example, association studies have linked single-nucleotide polymorphisms in innate immunity genes (e.g., Toll-like receptors, CD14), cytokine genes (e.g., tumor necrosis factor, interleukin-1 beta), and endothelial genes (plasminogen activator inhibitor-1) with important clinical phenotypes, such as increased disease susceptibility and poor outcome.[49] The exact role of any given single-nucleotide polymorphism in determining outcome in critical illness and injury, however, remains controversial, primarily because of inadequate study design (underpowered studies).[17,50] Although comprehensive reviews of association studies indicate that the majority of reported associations are not robust (<5% were consistently replicated when three or more reports existed),[16] meta-analysis indicates that larger, appropriately powered studies will likely find many single-nucleotide polymorphisms that are convincingly informational.[17] Even when confirmed, these associations are unlikely to be causal, and additional research will be required to determine the reason for the association and its molecular link to disease pathophysiology.

CLASSIFICATION USING RELATIVE RNA ABUNDANCE

Microarrays have been touted as the divining rods of the 21st century,[51] given that transcriptome characterization using DNA microarrays has the potential to revolutionize molecular diagnostics. Notably, microarray analysis has been used experimentally in the field of cancer to classify samples, addressing important clinical issues such as response to chemotherapy and propensity to metastasize.[52] It has been suggested that expression profile typing for some tumors may be significantly better than traditional diagnostic methods. With the appropriate confirmatory studies and attention to study design, it is expected that gene expression profiles will move from the bench to clinical reality shortly.[53] These studies can also be designed to couple sample classification (diagnosis, recovery trajectory, and response to therapy) with a study of gene function, discovery, interaction, and coregulation—in other words, making genomics "functional." It is logical to assume that these same techniques will be widely applicable to many complex human diseases, including critical illness and injury.[54-56]

To illustrate the power of this approach for cells of the immune system, Figure 44-1 depicts the classification of gene expression profiles of normal blood leukocytes, isolated T cells, and isolated monocytes. What differences in gene expression contribute to the differences observed among T cells, monocytes, and mixed cell populations? Shown at the right in Figure 44-1 is one version of the transforming growth factor-beta signaling pathway, arbitrarily chosen from one of the pathway discovery tools for microarray data, GenMAPP (www.genmapp.org). These data are consistent with a recent report indicating that human leukocyte expression profiles are cell specific.[57] Once a robust training data set has been collected describing the responses of isolated leukocytes in critically ill or injured patients, gene expression profiles will likely be monitored in the ICU to classify response to therapy and gauge clinical trajectories.[58]

CLASSIFICATION USING RELATIVE PROTEIN ABUNDANCE

Although DNA microarrays provide a molecular fingerprint that is useful in understanding the regulation of gene transcription, less than half the changes at the mRNA level are translated into changes at the protein level in the majority of systems. Thus, analyses of both the circulating transcriptome and proteome are indicated. Moreover, full mechanistic insight requires that changes in the transcriptome be linked to changes in the proteome, because the correlation between changes in relative mRNA and protein abundance varies, depending on the cellular role of the pathways studied.[59-61] This is irrelevant to the use of gene expression profiles for class prediction or modeling of gene coregulation, but it *is* relevant to understanding the biology of the host response. For example, close correlation was found between mRNA and protein abundance ratios for glycolysis genes in yeast, whereas abundance ratios for mitochondrial and protein synthesis genes were discordant, suggesting novel regulatory mechanisms.[61]

There are approximately 500 known (annotated) proteins in the circulating plasma proteome in humans.[22] Ideally, it would be desirable to employ "protein chips" in tandem studies to discover genome-wide protein expression profiles to complement our gene expression profiles. The combined data would allow us to find not only informational changes in blood that correlate with clinical trajectory and phenotype but also key regulatory information regarding control of gene and protein expression. However, this is not yet possible, because genome-wide proteomic technology is years behind transcriptomic technology. Despite the technologic challenges, however, recent reports highlight the potential of high-throughput proteomics. For example, simultaneous comparison of the proteome and transcriptome of human

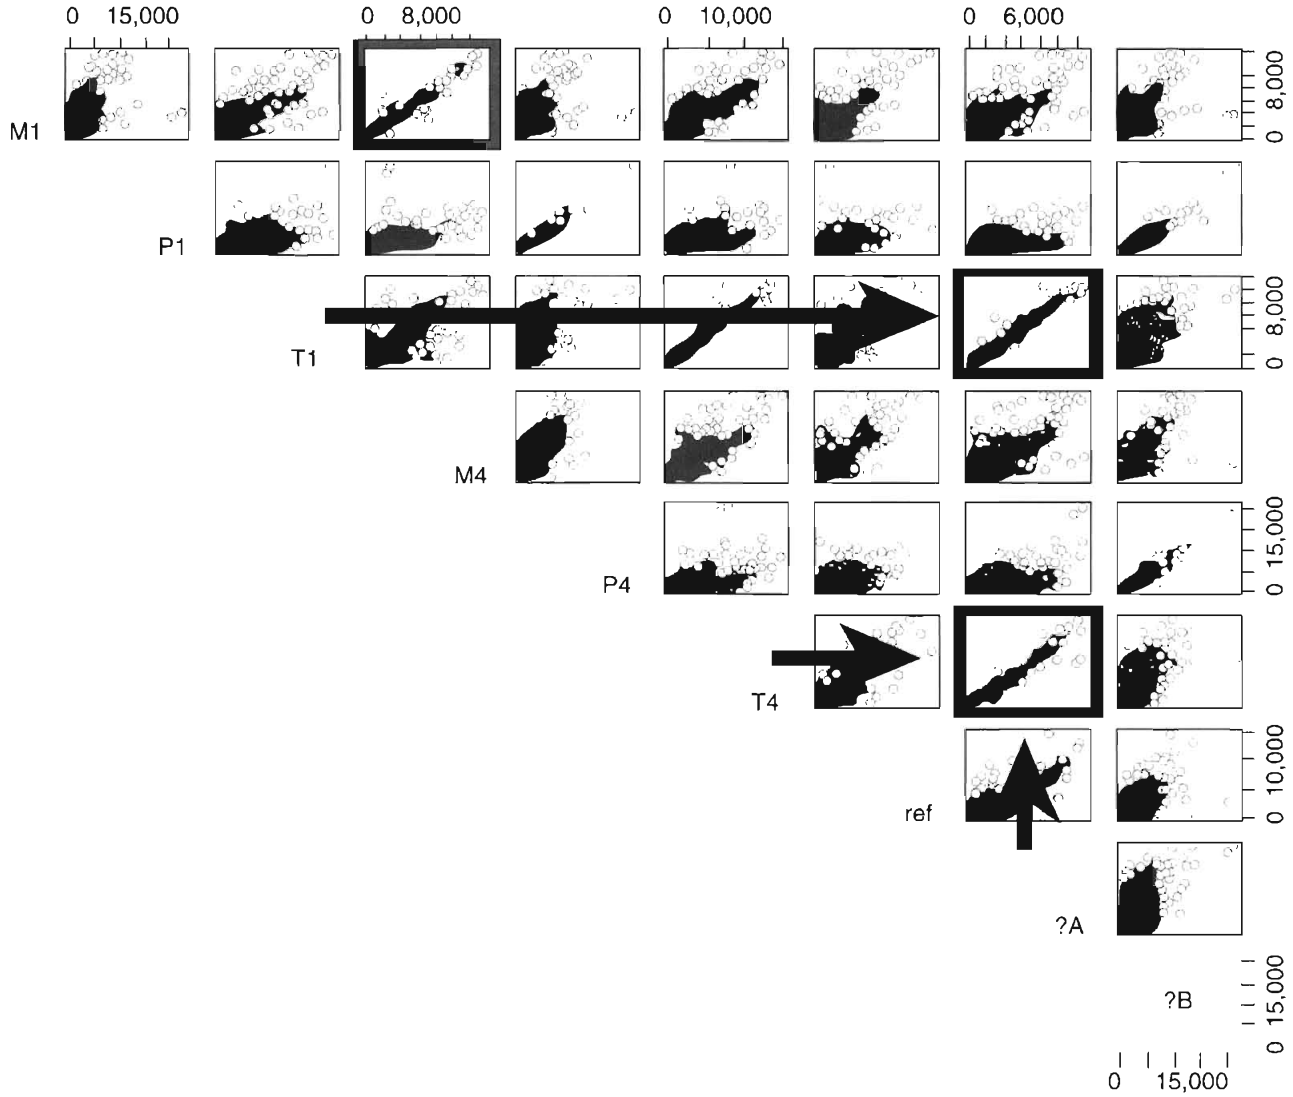

FIGURE 44–1. (A) Human transcriptome profiles of circulating T lymphocytes (T), monocytes (M), and mixed blood leukocytes (P) from normal volunteers (#1 and #4), compared with reference human RNA and two unknown samples (?A and ?B). At left, pair-wise comparisons of U95Av2 GeneChip expression signal for approximately 12,000 genes and expressed sequence tags show good pair-wise correlations between profiles of like cell types but not between different cell types in the same individual (e.g., compare good M1 to M4 correlation [yellow box] with poor M1 to T1 or P1 correlations). Moreover, assigning a cell type to the unknown samples A and B is easily accomplished, as shown by the orange arrows (?A to T cells, and ?B to mixed leukocytes). At right, the GenMAPP transforming growth factor-beta (TGF-β) pathway indicates differences in gene expression among T cell (red), monocyte (green), and PAXgene (blue). This program allows one to visually compare apparent levels of gene expression by color-coding genes that have increased expression in a given data set. In this example comparing blood leukocyte, isolated T cell, and isolated monocyte GeneChip signals, apparent gene expression for the type III TGF-β receptor (betaglycan) was greatest in T cells (red box); stress-induced protein 1 (SIP1) and c-FOS were greatest in monocytes (green boxes); and STAT3 was greatest in blood (mixed) leukocytes (blue box). The other genes shown (uncolored) were not changed. Thus, this figure indicates that apparent gene expression for the type III accessory receptor for TGF-β was greater in T cells, whereas apparent gene expression for SIP1 repressor and c-FOS cofactor was higher in monocytes. In contrast, there was higher apparent gene expression in blood (mixed) leukocytes only for the STAT3 cofactor. (See color section of this text.)

Continued on next page

neutrophils stimulated with lipopolysaccharide ex vivo indicated that isolated neutrophils have a much more complex and dynamic transcriptional response than previously appreciated.[60] Importantly, this study also highlighted the poor concordance between mRNA transcription and protein translation in a human neutrophil model of innate immune activation.

THE PROMISE OF MOLECULAR MONITORING IN THE ICU: SEPSIS

MH is a 74-year-old woman with a 3-day history of progressive dyspnea associated with crampy abdominal pain, nausea, and vomiting. Her past medical history is significant for childhood tuberculosis (left pneumonectomy) and dysfunctional uterine bleeding (open hysterectomy 3 years previously). In the triage area, her whole-body computed tomography scan was most consistent with partial small bowel obstruction and a mild basilar infiltrate in the remaining lung. The absence of a uterus and left lung was confirmed. Her peripheral leukocyte count was 11,000; the gene expression profile was consistent with inflammation. Plasma markers of infection were absent. She was admitted to the hospital with a working diagnosis of partial small bowel obstruction and treated with i.v. fluid hydration and nasogastric tube decompression. Her symptoms and signs of abdominal distention improved. On hospital day 2, however,

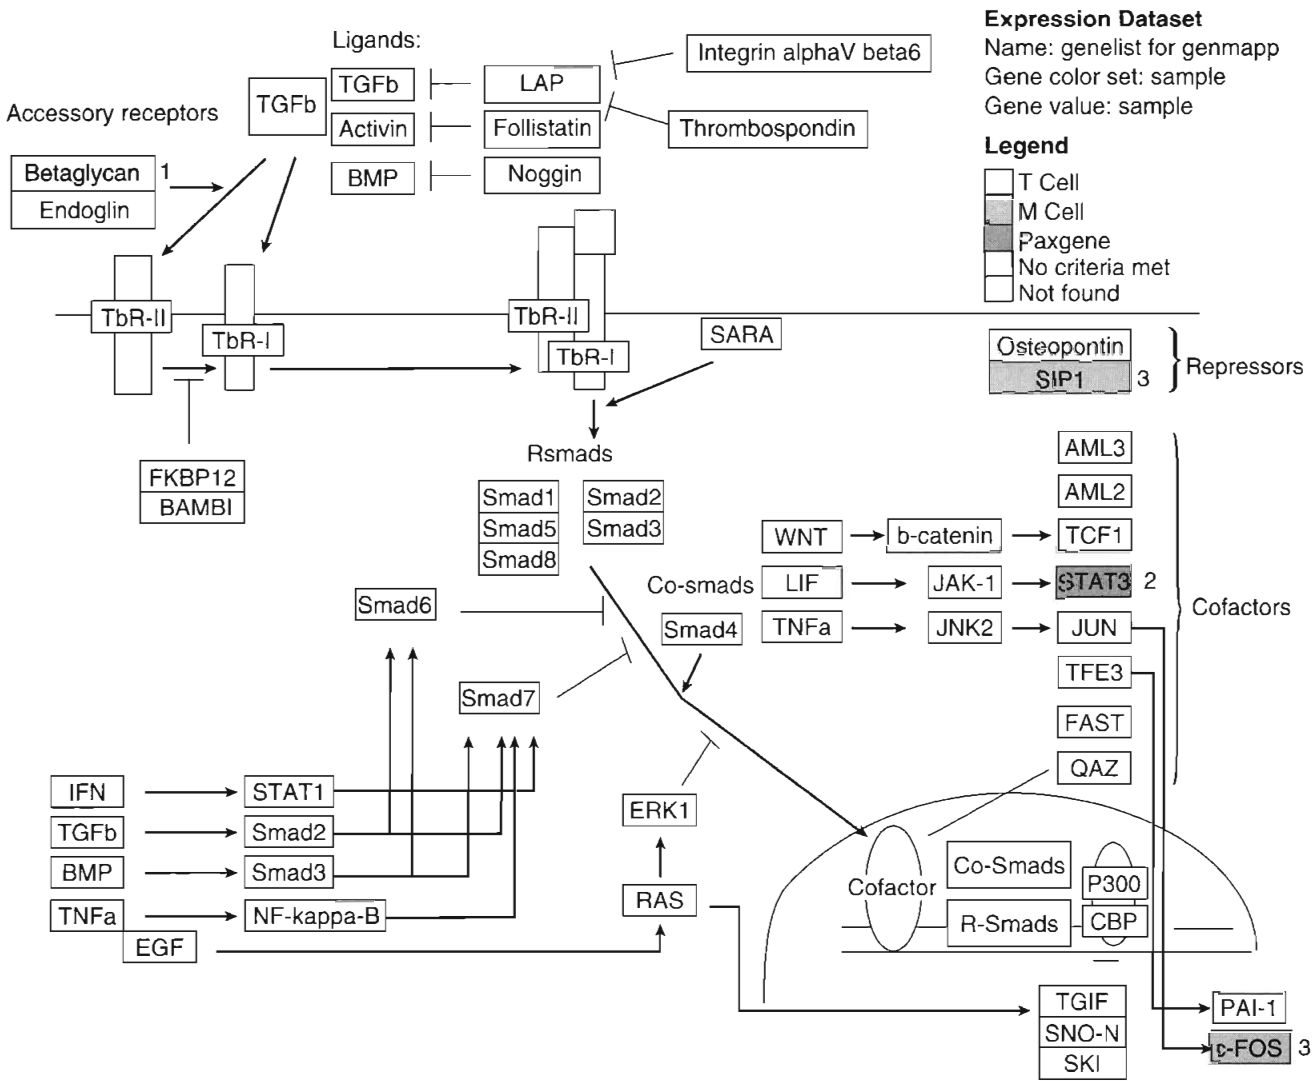

FIGURE 44–1—cont'd. (B)

her respiratory insufficiency worsened, requiring endotracheal tube insertion, mechanical ventilatory support, and admission to the ICU. Repeat leukocyte studies showed that her count had fallen to 6000, but the circulating gene expression patterns remained consistent with inflammation, and plasma markers of systemic infection were absent. On hospital day 5, the leukocyte count rose to 9000, and the pattern of sepsis molecular markers changed, indicating an expression profile consistent with Gram-positive infection. A diagnosis of Gram-positive bacterial pneumonia was made, and the patient was started on a narrow-spectrum antibiotic to treat Gram-positive organisms. The patient's abdominal examination and scans improved, and she was extubated with signs of resolving bowel obstruction and pneumonia on day 9.

As noted earlier, sepsis in the ICU presents several common diagnostic dilemmas. The hypothetical case just presented provides an example of how the advanced molecular diagnostics described herein will help discriminate between systemic infection and inflammation in the future. The assumption is that circulating leukocyte mRNA and protein abundance is a dynamic that varies as patients move along various clinical trajectories (phenotypes) during sepsis. We also anticipate that these trajectories can be characterized, monitored, and ultimately used to recognize infection in patients in whom sepsis is particularly difficult to diagnose.[55] The promise of this line of investigation is that these patterns of change in gene expression and protein abundance will become, in effect, new genomic "vital signs."[62] The human tissue that is most easily accessible for such longitudinal profiling is peripheral (circulating) blood. Further, it has been hypothesized that this systematic approach, using genome-wide gene and protein expression profiling, can be used to identify molecular classification schemes that provide novel insight into the adaptive response to inflammation and infection.[54,55]

Sepsis is particularly appropriate for this type of diagnostic approach. Although still controversial, modifications of sepsis criteria continue to be useful, as evidenced by a recent randomized, prospective, controlled clinical trial testing the only agent reported to increase the survival of patients with severe sepsis.[63] The authors of that study noted that the resulting pool of "septic" patients had a wide range of clinical features and were heterogeneous with regard to a number of biochemical inflammatory classifiers, including serum plasma D-dimer, interleukin-6, and protein C. More important, the inability to reliably distinguish between different degrees of septic injury continues to frustrate

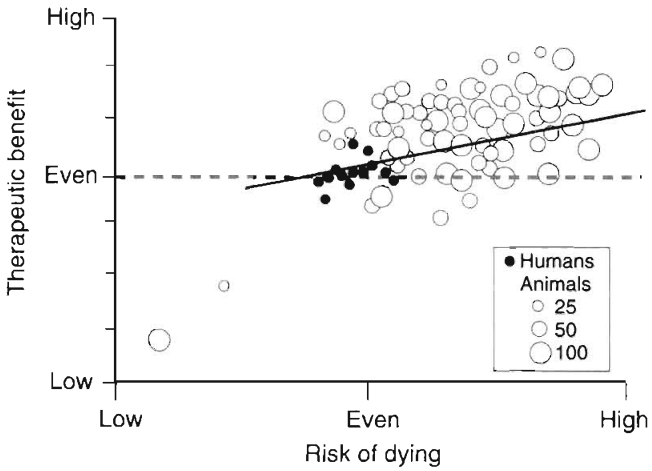

FIGURE 44–2. Relationship between the effect of anti-inflammatory treatment and the odds of the control group dying in animal and human sepsis trials. There is a significant correlation between the severity of illness and the likelihood of beneficial effect with treatment. Note that current enrollment in human studies centers around the point where therapies have no effect in animal models (in other words, the results of preclinical trials suggest that the human studies are unlikely to show benefit, given the current odds of dying in the human control groups). These data suggest that the ability to identify subpopulations of sicker patients would probably increase the likelihood of efficacy of anti-inflammatory agents. The technology needed to better classify septic patients is described in the text. (From Minneci PC, Deans KJ, Banks SM, et al: Should we continue to target the platelet-activating factor pathway in septic patients? Crit Care Med 2004;32:585-588.)

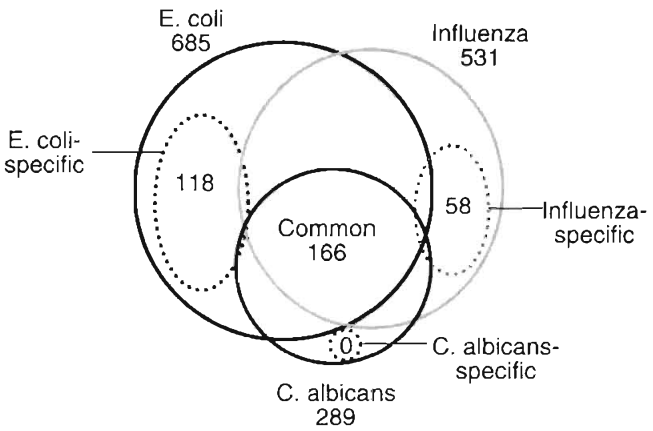

FIGURE 44–3. Overlapping sets of genes identified by DNA microarray analysis applied to human dendritic cells stimulated ex vivo with *Escherichia coli*, influenza virus, or *Candida albicans*.[67] Note that there were 166 genes in common, suggesting that there are both generic and stimulus-specific genes activated by infectious or inflammatory stimuli.

investigators and slow the development of sepsis therapeutics. For example, the efficacy of anti-inflammatory agents in treating sepsis is dependent on the severity of illness, with sicker patients and animals appearing to benefit the most from anti-inflammatory agents (Fig. 44-2).[64,65] Moreover, investigators must not only identify the infectious organism (e.g., Gram-positive bacteria versus fungi) to optimize outcome but also distinguish temporally among potential host responses to the invading organism, including the systemic inflammatory versus counterregulatory anti-inflammatory response syndromes. These tasks remain exceedingly difficult, despite ongoing improvements in diagnostic technology, and are still based largely on history, physical examination, and the results of common laboratory tests. As an example, recent evidence indicates that patients with ventilator-associated pneumonia are frequently misdiagnosed, based on an examination of postmortem specimens, radiographic findings, and clinical criteria.[66] Clearly, the ability to classify patients rapidly based on presence of infection, type of organism, and temporal phase of the host's adaptive response would increase the likelihood of therapeutic success. Thus, new strategies and tools are needed to correctly identify those who are most ill with sepsis, and thereby those who are most likely to benefit in clinical trials of sepsis therapeutics.

Recent reports using DNA microarray analysis indicate that inflammatory and infectious insults produce distinct molecular signatures. For example, microarray analysis of dendritic cells stimulated ex vivo exhibit both common and pathogen-specific immune responses.[67] Specifically, there were 166 genes expressed in response to bacterial, fungal, and viral stimulation, consistent with a common cluster of genes expressed in response to infection (Fig. 44-3).[67] Interestingly, yeasts were found to respond similarly to diverse insults, expressing a so-called common stress response cluster.[68] In another study, gene expression profiles of human whole blood stimulated ex vivo with heat-killed *Staphylococcus aureus* or *Escherichia coli* lipopolysaccharide had both generic and bacteria-specific features.[69] It follows, then, that it may be possible to define clusters of mammalian genes that are commonly up-regulated or, conversely, down-regulated in response to sepsis—what could be called a "common sepsis response" cluster.[70] Finally, recent data from animal models of abdominal and pulmonary sepsis suggest that measurements of RNA relative abundance in blood can be used to predict not only whether a mouse is infected but also the type of infecting organism.[70,71] It is expected that proteomic data will be equally or even more revealing.[72] These preliminary data suggest that important advances in sepsis diagnostics can be anticipated in the near future based on analysis of blood transcriptomes and proteomes.

CONCLUSION

Critically ill and injured patients have suffered from clinicians' inability to accurately classify and gauge clinical trajectory and response to therapy. Coincident with the sequencing of the human and mouse genomes, the technology has become available to move critical care monitoring and diagnostics into the genomic era. This will be characterized by the appearance of novel tools capable of profiling DNA, RNA, and protein in a search for molecular fingerprints associated with clinically important phenotypes and, more important, individualized response to therapy. To realize the full potential of this technology, support for ongoing, large-scale, collaborative research projects using genomic and proteomic technology to define the immunoinflammatory phenotypes in response to critical illness and injury will be essential.* As described earlier, diagnosing sepsis and

Technical Challenges to Monitoring the Proteome

At least 35% of proteins exist in multiple isoforms, secondary to alternative splicing and post-translational modification, a "seemingly infinite universe of post-transcriptional complexities."[22]

Proteomic analysis is substrate limited, as there is no means to amplify product (i.e., there is no polymerase chain reaction–equivalent for proteins).

Protein concentrations cover a huge dynamic range (10^6 in cells and 10^9 in plasma), yet current proteomic technology can measure changes over a range of only three to four orders of magnitude.

Only a portion of a given proteome (i.e., a subproteome) can be interrogated at one time, owing to limited substrate in the sample and limited dynamic range of the technology. Therefore, subtraction and enrichment strategies, and their limitations, are commonly encountered.

Current proteomic technology is primarily qualitative and inherently more complex than DNA or RNA technology, resulting in lower throughput.

monitoring the response to antibiotic therapy are prime examples. Annotated databases linking these data, with free access to the public, are sorely needed. Using gene and protein expression profile analysis, novel strategies for sepsis recognition, pathogen identification, and modeling of the leukocyte response are being tested. Industry reports suggest that the results of such tests will soon be available in hours, as opposed to the several days currently required. In the absence of new therapies, such a strategy will be essential to improving outcomes among the critically ill and injured.

Chapter 45
GENETICS OF CRITICAL ILLNESS

Richard G. Wunderink

KEY POINTS

1. **Association studies**, comparing the frequency of polymorphisms in patients with a disease or a complication to that in a control population, are most likely to determine the genetic components of complex critical illnesses.
2. **The risk of dying from infection is familial**, and a good family history of infection should be obtained in all patients.
3. **The genetic predisposition to a disease**, such as septic shock, **may be different from the genetic predisposition to a specific manifestation**, such as acute respiratory distress syndrome or disseminated intravascular coagulation.
4. **Large databases and multivariate analyses are required** to tease out the relative contributions of genetic factors to infection, within the context of underlying diseases, the variable pathogenicity of microorganisms, treatment factors, and so forth.
5. **Establishing the genetic risk of developing a disease** will be clinically relevant when the genetic variability allows risk stratification of patients and leads to differences in management, and when diagnostic or screening tests are readily available.
6. The great hope of **pharmacogenomics**—use of genetic information to individualize drug therapy—is not only to identify the right dose of medication to use safely but also to individualize the choice of drug in specific circumstances and specific patients.

Understanding the genetic variability in the response to critical illness, with its implications for individualization of therapy, is likely to be a focus of research in the next few decades. Recent technologic advances have made routine genotyping in a clinically relevant time frame feasible. Unfortunately, knowledge about the clinical implications of individual genetic variation on the course or risk of critical illness lags far behind.

Genetic variability is likely to affect many aspects of the care of critically ill patients. The initial focus is on three main areas—the host immune response to infection, the risk of coagulation or thrombosis, and the effects on drug metabolism. Although research interest in other areas will undoubtedly develop, these three topics illustrate the importance of unraveling the role of genetic variability in the outcome of critical illness.

GENETIC PRINCIPLES

Variability is incredibly common in the human genome. A variant allele occurs in approximately 1 of every 300 to 500 bases in human DNA. Although new mutations can cause isolated disease, the majority of genetic variation is in the form of polymorphisms. Polymorphisms are allelic variations that exist stably in a population at a frequency (generally ≥1%) that cannot be accounted for by new mutations alone. The implication is that these mutations do not confer a strong selective disadvantage and may even be associated with a beneficial effect in specific circumstances.

Genetic polymorphisms can occur in a variety of forms. The most common is a single-nucleotide polymorphism (SNP), which is a variation in a single nucleotide. This can be a substitution of one base for another, a deletion, or an addition of a base pair. Larger sections of the chromosome can also be deleted. Variable tandem repeats are sections of the chromosome (minisatellites) that contain multiple copies of a segment of DNA. These usually occur in the large stretches of the chromosome that do not encode a gene. Multiple two, three, or four base pair repeats (microsatellites) are also common. The number of repeats in these microsatellites is highly variable, a fact that is useful in forensic medicine. Large chromosomal mutations can be seen in critically ill patients and are common causes of neonatal ICU admissions.

The area where a SNP occurs determines the resultant effect. If a mutation occurs in an exon of the gene, an abnormal protein is more likely. Because of the redundancy of codons coding for specific amino acids, the polymorphic allele may not result in a different amino acid sequence—a silent mutation. Association of disease or disease severity with a silent mutation most likely indicates that it is a marker for a different functional polymorphism. Mutations that change the codon to one that signals the end of gene transcription can occur but are rare, because of their generally deleterious effect. The area of chromosome before the first gene sequence, called the promoter region, is critical in initiating gene transcription. Mutations in the promoter region are therefore more likely to affect the amount of gene product produced as a result of differential binding of nuclear transcription factors, such as nuclear factor kappa-B. The variable amount of messenger RNA (mRNA) still codes for a normal protein. Mutations in introns, areas within the gene that code for sections of mRNA but are clipped off before translation into the final protein, are less likely to result in a functional difference in the amount of protein or a structural difference in the protein itself. However, a biologic effect from polymorphisms in these areas is possible.

Genetic Terminology

Allele: One of the variant forms of a gene at a particular locus, or location, on a chromosome.
Codon: Three bases in a DNA or RNA sequence that specify a single amino acid.
Exon: Region of a gene that contains the code for producing the gene's protein. Each exon codes for a specific portion of the complete protein.
Haplotype: Set of genetic markers on the same chromosome linked closely enough to be inherited as a unit.
Heterozygous: Possessing two different forms of a particular gene, one inherited from each parent.
Homozygous: Possessing two identical forms of a particular gene, one inherited from each parent.
Intron: Noncoding sequence of DNA that is initially copied into RNA but is cut out of the final RNA transcript.
Linkage: Association of genes or markers that lie near one another on a chromosome. Linked genes and markers tend to be inherited together.
Linkage disequilibrium: Two alleles at different loci that occur together in an individual more often than would be predicted by random chance.
Locus: Place on a chromosome where a specific gene is located—a kind of address for the gene. (The plural is loci.)
Lod score: Statistical estimate of whether two loci are likely to lie near each other on a chromosome and are therefore likely to be inherited together. A lod score of three or more generally indicates that the two loci are close.
Marker: Segment of DNA with an identifiable physical location on a chromosome whose inheritance can be followed. Because DNA segments that lie near each other on a chromosome tend to be inherited together, markers are an indirect way of tracking the inheritance pattern of genes that have not yet been identified but whose approximate locations are known.
Microsatellite: Repetitive DNA sequence with a repeat unit of 2 to 4 base pairs.
Minisatellite: Repetitive DNA sequence with a repeat unit of 5 to 30 base pairs.
Penetrance: The frequency of expression of genotype.
Polymorphism: A common variation in the sequence of DNA among individuals.
Promoter: The part of a gene that contains the information to turn the gene on or off. The process of transcription is initiated at the promoter.
Single-nucleotide polymorphism (SNP): Common but minute variations that occur in human DNA at a frequency of 1 every 1000 bases. (SNP is pronounced "snip.")
Variable number tandem repeats: Generic term for mini- and microsatellites. Often used as genetic markers to track inheritance in families.

From http://www.genome.gov/glossary.cfm.

Micro- and minisatellites can cause disease, such as the fragile X syndrome and Huntington's disease, but they are more likely to be markers for other functional polymorphisms.

DEMONSTRATION OF GENETIC RISK

A variety of methods are available for demonstrating the genetic component of critical illness. The two main methods are linkage analysis and association studies. Each type of analysis is appropriate or advantageous in different situations (Fig. 45-1).

LINKAGE ANALYSIS

Traditional family studies and pedigrees are powerful techniques to find rare mutations that consistently result in clinical disease (high penetrance). This type of genetic pattern is usually studied with linkage analysis. Linkage analysis involves genotyping specimens for multiple polymorphisms to determine which polymorphic alleles are transmitted together in affected individuals. The strength of the association can be described by the lod (logarithm of the odds) score—an estimate of whether the observed data are due to linkage or to random variation. Generally, a lod score of three or more is evidence of linkage between the marker and the causative gene.

Linkage analysis is less helpful in illnesses requiring ICU care because of the impact of environmental exposure, the frequent variability in gene penetrance, and the multiple-loci nature of complex illnesses. For these and other reasons, critical illness does not appear to occur in a familial pattern. Therefore, the only way linkage studies can be performed is to compare unrelated affected and unaffected individuals. The additional variability introduced by this factor precludes finding all but the strongest associations. Newer molecular technologies, including the use of gene array chips, hold great promise for future studies but are still both difficult to interpret and very expensive.

ASSOCIATION STUDIES

The most common type of study supporting a role for genetic variability in the complex diseases affecting the critically ill is the association study. Association studies essentially look for a different frequency of specific alleles in patients with a disease or complication compared with the frequency in a control population.

Association studies have a variety of problems.[1] The initial assumption of the association study is that the gene of interest is involved in the illness being studied. A strong physiologic rationale for the candidate gene is required to ensure that associations are not spurious. Association studies therefore are dependent on basic research and animal studies to identify

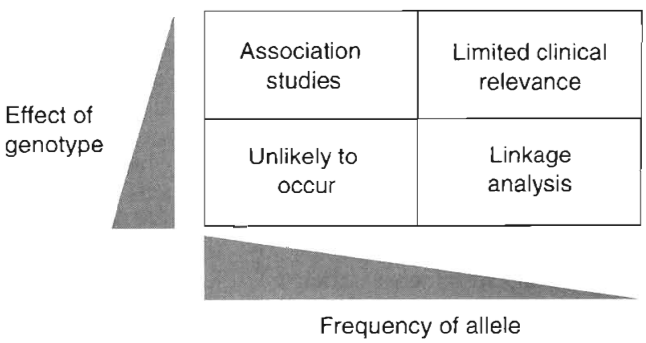

FIGURE 45–1. Approaches to determining genetic predisposition.

appropriate or novel candidate genes. Gene expression arrays are increasingly important as a method to identify unknown genes or genes with previously unrecognized importance.

In addition, the specific polymorphism studied may not be the causative locus. Genes are not inherited independently; they are inherited as whole chromosomes. Multiple mutations may occur in the gene of interest or in adjacent genes on the same chromosome, each of which may or may not affect either the actual protein structure or the amount of protein produced. For example, at least 10 mutations occur in the tumor necrosis factor (TNF) promoter region, several of which are known to affect the TNF response to a standard stimulus. Many of these mutations are in linkage disequilibrium with each other. An association between a specific mutation and an outcome, predisposition, or even physiologic response does not prove that the mutation causes the response. Therefore, any polymorphism associated with a clinical condition or outcome should be considered a marker for genetic risk until more extensive studies confirm that the mutation leads to a change in biologic function and that the change induced produces the outcome observed.

For complex diseases, the mutation must be common enough to affect a significant portion of the population. Although rare mutations can cause unique infection syndromes, such as disseminated bacille Calmette-Guérin infection after immunization, the majority of patients with a common infection such as community-acquired pneumonia are unlikely to carry these rare mutations. The known genetic mutations that have an impact on immunity, such as immunoglobulin deficiencies or cilia dysfunction, clearly do not explain the majority of cases of pneumonia or sepsis. Therefore, most association studies have examined polymorphisms.

Complex medical illnesses, such as those that present to the ICU, are likely to be polygenic, with multiple genes on different chromosomes interacting to cause the effect. Teasing out these interactions with association studies is difficult and requires large populations. Many published association studies are underpowered.

The appropriate comparison population is critical to association studies.[2] Ethnicity, age, gender, and exposure are important factors, but they do not guarantee a valid control group. Choosing the appropriate control population for critically ill patients is even more difficult and controversial. The appropriate controls for the development of an illness may be different from the controls for a specific manifestation once that illness has occurred. Simple tests, such as Hardy-Weinberg equilibrium (i.e., the genotype frequencies should equal that predicted by allele frequencies in the population), in the control population are needed to ensure selection bias. Newer statistical techniques of genomic controls may help exclude a spurious association based on nonrandom sampling.

Specific phenotypes are also difficult to define for the critically ill. The physiologic response to sepsis may be different based on whether the cause is Gram-negative bacteria, Gram-positive bacteria, fungi, or viruses; however, the distinction is often difficult to make clinically. Similarly, the risk for simple deep venous thrombosis may be different from that for pulmonary emboli, even though they are combined in many clinical studies. Many studies have focused on more objective outcomes, such as death, septic shock, or bacteremia, because of the difficulties in defining other phenotypic presentations.

Finally, environmental or nongenetic host factors complicate the interpretation of association studies. The host response (and therefore the genes involved) is very different for *Mycoplasma* pneumonia than for pneumococcal pneumonia. The effect of active alcohol ingestion can lead to a phenotypic change (increased risk of septic shock, neutropenia, or acute respiratory distress syndrome [ARDS]) that is not genetically based. Therefore, association studies should include multivariate analysis, with inclusion of known clinical risk factors (as well as other genetic risks) as part of the analysis.

The statistical analysis of association studies is not necessarily less complex than that of linkage analysis. Many studies examine several SNPs in the same population. The usual statistical correction for multiple comparisons may be too conservative and is probably inappropriate, because it assumes the comparison of independent factors when, in fact, multiple SNPs in the same or adjacent genes do not sort independently. Haplotype analysis may overcome this statistical issue, but it introduces greater complexity in other ways.

Despite these limitations, association studies are presently the most commonly used genetic study for complex multifactorial diseases, and most of the subsequent information presented in this chapter is derived from association studies. The genetic influence on complex illnesses continues to be a difficult area of research. Knowledge of the role of genetics in critical illness will continue to expand, and any discussion of specific genetic factors will likely be quickly outdated. However, reviewing the data currently available illustrates some of the principles that are important in evaluating future studies of genetic risk.

GENETIC INFLUENCE ON THE HOST IMMUNE RESPONSE

The strongest support for the role of genetics in infection is the adoptee study by Sorenson and colleagues.[3] They linked cause of death in adoptees to cause of death in both the natural parents and the adoptive parents. The risk of dying of infection if either natural parent died of infection by age 50 years was nearly six times greater than if neither died of infection. The increased risk exceeded the genetic risk of early death from cardiovascular disease or cancer (Fig. 45-2). In addition, the excess genetic risk for death from infection

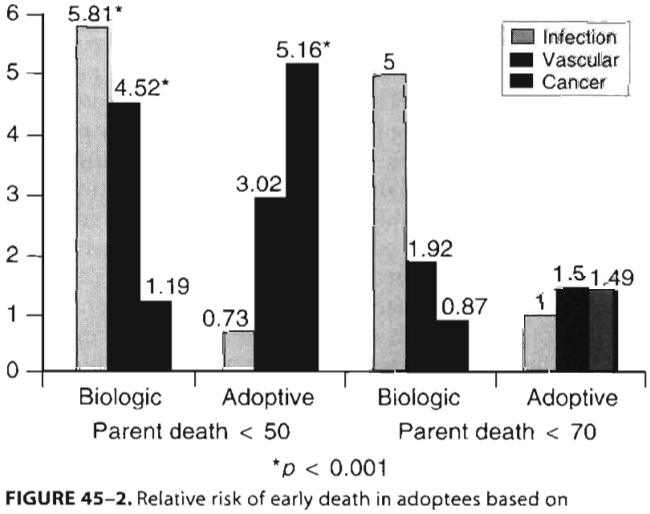

FIGURE 45–2. Relative risk of early death in adoptees based on identical cause of death in either natural or adoptive parents. (From Sorensen TI, Nielsen GG, Andersen PK, et al: Genetic and environmental influences on premature death in adult adoptees. N Engl J Med 1988;318:727-732.)

extended to parental death any time in the first 70 years of life. Despite well-documented genetic factors, familial risk of death from cardiovascular disease and malignancy is negligible when parental death occurs between ages 50 and 70 years.

Although these findings strongly support the role of genetic factors in infectious mortality, neither the type of infection nor the specific genetic factors can be determined from this type of study. Epidemiologic data suggest that pneumonia and bacteremia are the major causes of septic deaths in the United States. More unusual causes of severe sepsis, such as meningitis and endocarditis, also have high fatality rates. Although some of the earliest and strongest evidence for a genetic influence on response to infectious disease came from malaria studies, many studies of genetic risk focus on severe sepsis, pneumonia, and meningitis.

Ethnic and racial differences in mortality from infectious diseases have been known for centuries and provide additional evidence of the influence of genetic factors. Even accounting for socioeconomic differences, racial differences in death rates from pneumonia are consistently found. However, the type and degree of differences are not consistent. In many past studies, African Americans had higher mortality rates than white Americans, and Asian Americans had lower rates. However, recent data demonstrate that, for bacteremic pneumococcal pneumonia, mortality rates for Asian Americans are significantly greater than those for black and white Americans.[4] Several explanations for these contradictory findings are possible. For instance, different genetic backgrounds may be more important for bacteremic pneumococcal pneumonia than for pneumonia in general. However, the more likely explanation is that different subpopulations with different genetic backgrounds were sampled and that the statistical lumping of ethnically diverse populations into broad "races" confuses the issue. Other studies have demonstrated that the risk of death from pneumonia varies widely among different ethnic groups categorized as Hispanic American or Asian American. This variability within demographic groups actually supports the importance of genetic factors in the outcome of severe infection.

Because the genetic risk for severe infection likely involves multiple gene loci (many of which demonstrate variable penetrance), and because there is clearly a major environmental component (i.e., exposure to an infectious agent), several authors have suggested that family studies of infection cannot be done. However, classic family studies, such as triad studies (sampling the affected child and both parents), are possible if a careful and comprehensive family history is obtained.[5] Figure. 45-3 illustrates a family pedigree demonstrating a type of familial infection syndrome. Certain key features allow the recognition of a genetic predisposition to infection. Index cases of death from infection at an age younger than age 50 to 60 years, especially when no underlying systemic disease confuses the issue, are critical to recognize. Awareness that the genetic risk for infection may be generic in terms of site, such that different family members may be affected by a variety of infections, is also important.

From a practical standpoint, one of the more important reasons to take a complete and comprehensive family history is to increase suspicion of the myriad rare genetic causes of altered immunity. Although too extensive to discuss in this chapter, genetic defects in neutrophil or lymphocyte function, immunoglobulin deficiencies, cilia dysfunction, and the like can be seen (rarely) in the critically ill. In adults, the first manifestation is unlikely to be a critical illness; however,

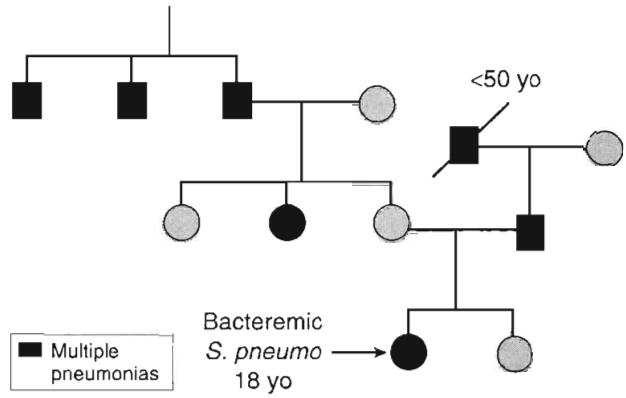

FIGURE 45–3. Pedigree of familial infection syndrome.

this may be the initial presentation in neonatal and pediatric ICUs. Simply because of their higher frequency, polymorphisms in the innate response are likely to affect a greater proportion of the critically ill.[6]

INNATE IMMUNE RESPONSE

Because of the rapidity and severity of onset, the types of illness precipitating ICU admission, especially infection, likely involve the innate immune response more often than the acquired immune response. The three main components of the innate immune response are pattern recognition molecules, inflammatory response mediators, and the important counterregulatory anti-inflammatory response mediators.

Pattern Recognition Molecules

Key to the innate immune response is the recognition of invading microorganisms. Pattern recognition molecules are inherited through the germ line; therefore, though common to all cells, their number is more limited than the remarkable diversity of receptors possible on individual lymphocytes involved in the acquired immune response. Because of this limited repertoire, pattern recognition receptors are usually focused on highly conserved structures present in large classes of microorganisms. These pathogen-associated molecular patterns are unique to microbial pathogens, without human homologues. In addition, the structures recognized are usually essential for either survival or pathogenicity of the microorganism.

Pattern recognition molecules can be secreted into the circulation and function by binding to microorganisms and facilitating recognition by phagocytes or the complement system. Mannose-binding lectin not only activates the complement system when bound to bacteria but also regulates inflammatory mediators. Several mutations in the gene or promoter region can lead to little or no serum mannose-binding lectin. The incidence of homozygous variant coding alleles appears to be almost twice as common in pneumococcal bacteremia as in noninvasive disease.[7] Mannose-binding lectin is phylogenetically related to surfactant proteins, rare mutations of which have also been associated with infection and lung disease.

Lipopolysaccharide-binding protein is another secreted pattern recognition molecule. Rare alleles of lipopolysaccharide-binding protein have been found to be increased in septic patients, and all septic patients homozygous for these alleles died.[8] No associations between sepsis and polymorphisms

in the related bactericidal permeability increasing protein gene were found in the same population. Interestingly, the frequency of rare alleles was more common in males in one study; in another, it was more common in African Americans of both genders. The site may therefore be a marker for an as yet unidentified adjacent SNP that is important in sepsis. Support for this possibility comes from the finding that the originally described restriction length polymorphism cleavage site is actually at an adjacent nucleotide, resulting in a silent mutation.[9]

Pattern recognition molecules can also be located on cell surfaces, where they function either by mediating uptake into lysosomes for destruction and antigen processing or by activating signaling pathways to induce the expression of a variety of host response genes, especially inflammatory cytokines. Toll-like receptors (TLRs) are important examples. At least 10 different TLRs exist, with different affinities for various microorganisms. TLR4 appears to be essential for the recognition of endotoxin, whereas TLR2 is more important for the recognition of Gram-positive bacteria. Two polymorphisms, TLR4 Asp299Gly and Thr399Ile, were examined in a French cohort of 91 patients with septic shock and 73 healthy controls.[10] Both polymorphisms were uncommon, but carriage of 299Gly was found only in the shock cohort. This SNP did not appear to increase the risk or severity of meningococcal meningitis.

Increased levels of soluble CD14, a component of the endotoxin-lipopolysaccharide recognition pathway, may be an important risk factor for septic shock. A polymorphism at the −159 site has been associated with higher circulating levels of soluble CD14 and greater TNF production in peripheral blood mononuclear cells after stimulation with lipopolysaccharide or *Escherichia coli*. The CD14 −159 TT genotype was more common in patients with septic shock than in controls (71% versus 48%; $P = 0.008$).[11] In addition, mortality from shock was significantly higher in patients who carried a T allele.

Theoretically, functional polymorphisms in pattern recognition receptors should increase susceptibility to infection, but so far, the majority of data has found associations with indices of severity. This may be a function of study design. One of the few longitudinal studies in this literature found that TLR4 mutations increased the risk of serious bacterial infections.[12] The greatest risk appeared to be in patients with the 299Gly mutation in the absence of the 399Ile mutation. Although susceptibility to infection was not the primary focus of this particular study, longitudinal studies are a better design than cross-sectional studies to demonstrate such susceptibility.

Proinflammatory Mediators

Not surprisingly, much of the initial research into the role of genetic variability in infectious disease focused on the gene for TNF, a key mediator initiating the inflammatory cascade.[13-16] The TNF locus, especially the promoter region, is highly polymorphic. Several polymorphisms appear to be functional, with variable levels of TNF release in response to either infection in vivo or stimulation in vitro. Carriage of the A allele of TNF-308 SNP has been associated with an increased risk of septic shock, especially in surgical and trauma populations. The risk of septic shock appears to be less if the cause of infection is community-acquired pneumonia.[16,17] This discrepancy may relate to a differential effect in predominantly Gram-negative versus Gram-positive infections.

A SNP in the adjacent lymphotoxin alpha (LTA) gene has also been associated with increased TNF levels. Carriage of this LTA+250 AA genotype was associated with a substantially greater risk of septic shock and death from septic shock,[18] including in patients with community-acquired pneumonia.[16] Interestingly, respiratory failure in the absence of shock in community-acquired pneumonia strongly correlated with the opposite GG genotype (Fig. 45-4). This finding has important implications for the clinical definitions of severe sepsis and the systemic inflammatory response syndrome. Genetic predisposition to septic shock may be different from that to one manifestation of severe sepsis—hypoxemia. Similarly, the coagulation abnormalities of severe sepsis may be associated with polymorphisms in different genes, such as plasminogen activator inhibitor-1.[19]

The discrepancies in association studies of the TNF-308 SNP may be explained by significant linkage disequilibrium with the LTA SNP.[16] Linkage disequilibrium occurs when polymorphisms within the same or different genes are usually inherited together, resulting in a more frequent association than would be expected by chance of one allele in one gene with a specific allele in a nearby SNP. For example, the LTA+250 A allele is nearly always associated with a G allele at the TNF-308 site. Because the LTA+250 A allele is much more common than the TNF-308 A allele, provided that the degree of influence of each of these polymorphic sites is roughly equivalent, the LTA effect is much easier to observe when both sites are examined in the same population.

In addition to the very important HLA loci, the TNF and LTA genes are in close proximity to other immunologically important genes on chromosome 6, such as complement components and heat shock protein (HSP). The association between one HSP70 gene SNP and septic shock in a cohort of patients with community-acquired pneumonia was even stronger than that of the LTA+250 site mentioned earlier.[20] However, the two sites are in linkage disequilibrium, and haplotype analysis suggests that chromosomes containing an adenine at both the LTA+250 and the HSP70 loci are associated with the greatest risk of septic shock. These data suggest that

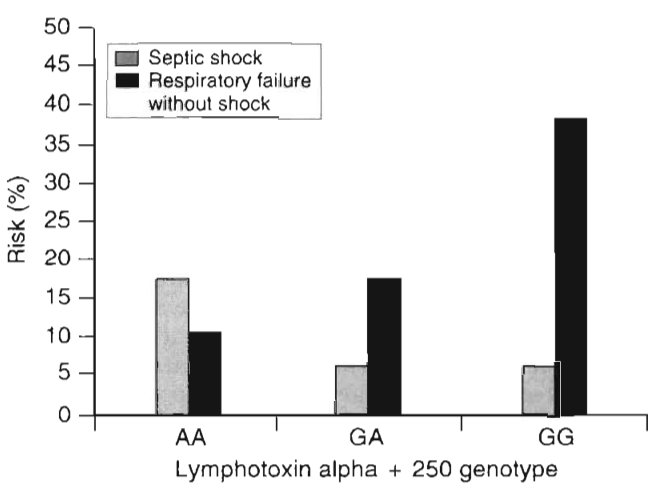

FIGURE 45–4. Relative risk of septic shock and hypoxemia without shock in different genotypes of the LTA+250 single-nucleotide polymorphism in a community-acquired pneumonia cohort. (From Waterer GW, Quasney MW, Cantor RM, et al: Septic shock and respiratory failure in community-acquired pneumonia have different TNF polymorphism associations. Am J Respir Crit Care Med 2001;163: 1599-1604.)

neither site is the true causative mutation; instead, they may be markers for some other important mutation in this area, which is rich in genes that are important in the inflammatory response.

Interleukin (IL)-6 levels are a marker of the severity and outcome of sepsis. Carriage of the low IL-6 secretor phenotype of the −174 SNP was associated with improved survival in those with severe sepsis. However, the in vitro IL-6 response is affected more by levels of TNF, IL-10, and IL-1 (and possibly gender) than it is by this polymorphism, casting doubt on the clinical importance of this SNP and emphasizing the importance of multivariate analysis in association studies.[17]

Anti-inflammatory Mediators

The ability to modulate the proinflammatory response is important for avoiding persistent inflammation and organ failure. An association study from a large cohort of meningitis patients illustrates the importance of this balance, as well as other issues involved in genetic association studies.[21] The IL-1 family includes the agonists IL-1α and IL-1ß and the IL-1 receptor antagonist IL-1RN, with genes located in a cluster on chromosome 2. IL-1β and IL-1RN SNPs were examined concurrently in 1106 patients with meningococcal meningitis. The investigators consciously chose SNPs that were not likely to be causative mutations but were known to be in tight linkage disequilibrium with functional genetic variants in the same gene. Mortality was independently related to age, serogroup of the infecting microorganism, and both genotypes. This study illustrates the ability of multivariate analysis in association studies to determine the effect of genotype independent of nongenetic host factors and the variable pathogenicity of the infecting microorganism.

The IL-1RN polymorphism considered most likely to be causative is a variable 86–base pair tandem repeat, which contains at least three sites for DNA-binding proteins. Alleles are designated A1, A2, A3, A4, and A5, based on their relative frequencies in healthy populations. Although the results regarding the risk of infection with the A2 allele have been inconsistent, an increased risk of death from infection (up to 6.47-fold higher) has been found for IL-1RN A2 carriers in several studies.[14,22] Similar to the findings in meningitis patients, the combination of proinflammatory gene polymorphisms (IL-1α, IL-1β, or LTA+250) and the IL-1RN A2 polymorphism was associated with an even greater risk of death.

Another major anti-inflammatory protein is IL-10. Like TNF, IL-10 is highly polymorphic. Family members of children who died from meningococcemia had significantly greater IL-10 production after lipopolysaccharide stimulation than did family members of children who survived.[5] A specific IL-10 SNP (−1082) was not randomly distributed in first-degree relatives of patients with meningococcal disease.[23] These family studies suggest that genetic differences in IL-10 production may be important in the outcome of severe sepsis, and they are supported by population-based association studies. Homozygotes for the G allele of the IL-10 −1082 SNP had an increased risk of septic shock (odds ratio, 6.1) among patients with pneumococcal bacteremia.[24] The −592 SNP A allele was associated with death in a cohort of critically ill patients. Interestingly, the excess deaths occurred both in patients who developed sepsis and in critically ill patients without sepsis. Generally, the IL-10 association studies suggest that polymorphisms may play a role in disease severity while not predisposing to infection.

ACQUIRED IMMUNE RESPONSE

Because the acquired immune response does not occur immediately, its role in critically ill patients is not as well studied as the innate response. Genetic variation may still play a role in illnesses requiring ICU care.

Infection

Attachment of immunoglobulin bound to specific bacterial antigens occurs via their receptors on the surface of leukocytes. Several polymorphisms in immunoglobulin receptors lead to reduced binding affinity. The most well studied is the CD32 (FcγRII) subclass polymorphism associated with decreased binding of the immunoglobulin G2 subclass, important for encapsulated microorganisms as well as C-reactive protein.

Homozygosity for the lower-affinity allele was more common in patients with bacteremic pneumococcal pneumonia than in either nonbacteremic or control populations, with all early deaths in homozygotes.[25] Complicating the association is the fact that the Fcγ receptor genes are located on chromosome 1, near other immunologically important genes, especially IL-10. Although not clearly in linkage disequilibrium with known IL-10 SNPs, the SNP combinations were not randomly distributed in first-degree relatives of patients with meningococcal disease.[23]

Autoimmune Disease

The acquired immune response can result in autoimmune disease if it is directed at antigens similar to host antigens. Autoimmune diseases such as systemic lupus erythematosus or Wegener's granulomatosis are common causes of ICU admission. The extremely variable responses and presentations of these diseases strongly suggest a genetic component, and associations with multiple polymorphisms have been suggested. The risk of complications, such as renal failure with lupus, may be increased in certain genotypes. In addition, many of the chronic inflammatory disorders, such as rheumatoid arthritis and inflammatory bowel disease, have been associated with the same inflammatory response polymorphisms studied in sepsis and other infections. Although the increased risk of infectious complications is usually ascribed to the use of immune-modulating agents, the genetic risk may also play a role.

Organ Transplant Immunology

Although the importance of matching donor and recipient for HLA and other tissue antigens is well known, evidence is accumulating that genetic variation in the inflammatory response may play a role in both acute and chronic graft rejection. For example, a hypersecretory polymorphism in the transforming growth factor-ß gene results in a significantly increased risk of bronchiolitis obliterans after lung transplantation.[26] This is a rapidly expanding area of research. Once again, the increased risk of infection in these patients may reflect a genetic predisposition, in addition to the effect of immunosuppressants.

Specific Organ Failure Modulators

With severe infection, a variety of organs can fail. Most of the attention has focused on the risk of septic shock. However, not every patient with septic shock experiences failure of the same organs. Differences in resuscitation are probably the major explanation, but genetic variability probably plays a role as well.

One of the worst complications is the development of ARDS. An insertion-deletion polymorphism in the angiotensin-converting enzyme gene has been associated with an increased risk for the development of ARDS, as well as increased mortality once ARDS had occurred.[27] This fact illustrates the importance of appropriate control groups. As seen in Figure 45-5, ICU patients without ARDS have a slightly lower incidence of the DD genotype than do normal controls or cardiac surgery patients. If the difference in incidence were smaller, a statistically significant difference might have been seen only if compared with a control group of non-ARDS ICU patients, whereas a nonsignificant difference would have been found if healthy controls or post–cardiac surgery patients were chosen as the control group. Use of three control groups adds to the reliability of the association found. A SNP in the surfactant protein B gene has also been associated with a 2.4-fold increase in the odds of developing ARDS, particularly ARDS due to pneumonia.

The coagulation abnormalities of sepsis are also likely to have a genetic component. The prototypical coagulation abnormality with sepsis is meningococcemia, and several cohorts have been studied. This disease is more common in children, facilitating family-based association studies. The relatively common factor V Leiden mutation has been associated with an increased risk of complications in heterozygotes.[28] The plasminogen activator inhibitor-1 insertion-deletion polymorphism is also associated with an increased risk of shock and other complications.[19] The availability of drotrecogin alfa for the treatment of sepsis will undoubtedly increase interest in the variability in coagulation pathways in sepsis and inflammation.

RISK OF COAGULATION OR THROMBOSIS

Genetic hypercoagulability syndromes play a role in many disorders leading to ICU admission. Chief among these are deep venous thrombosis, pulmonary emboli, myocardial infarction, cerebrovascular disease, and complications of pregnancy. Because of the frequency of these diseases, large-scale studies can be performed, allowing highly significant statistical associations to be found despite a very small attributable risk. These associations tend to be more apparent in younger patients, in whom the effect of comorbid illnesses and environmental factors cause less interference with the genetic risk signal.

Deficiencies in protein C, protein S, or antithrombin are the classic examples of genetic risk factors for deep venous thrombosis and pulmonary emboli.[29] However, the genetic basis of these deficiencies is the combination of more than 120 specific mutations for each factor. Screening based on genotyping is therefore impractical, and the diagnosis of these genetic diseases relies on the measurement of blood levels. With the discovery of the factor V Leiden and prothrombin G20210A polymorphisms, the percentage of patients (especially whites) with venous thromboemboli who can be documented to have a hypercoagulable state increased from less than 10% to approximately 30%. In patients with a family or personal history suggesting an increased risk, the proportion diagnosed may reach 70%. A functional assay, activated protein C resistance, screens for factor V Leiden and several less common polymorphisms. However, genotyping is routinely available.

Factor V Leiden in thromboembolic disease illustrates the goal for most gene association studies in common clinical illnesses. This SNP impacts clinical management in that homozygous patients or heterozygotes with other concomitant causes of thrombophilia warrant prolonged treatment with anticoagulants. Clinical suspicion can lead to a high frequency of confirmed diagnoses, and a screening test is readily available. A definite diagnosis has implications for the individual, as well as family members. The role of this polymorphism is unquestioned, despite interactions with other genes and environmental factors. In spite of large studies, the clinical utility of diagnosing genetic variations in patients with myocardial infarction or stroke is poor compared with that in the hypercoagulable model.

PHARMACOGENOMICS

Pharmacogenomics is the use of genetic information to individualize drug therapy. It has been heralded as one of the most likely immediate benefits of the Human Genome Project. This is clearly another area in which genetics will have an impact on critical care medicine. The genetic influence will be seen in two main areas—effects on drug metabolism and individualized therapy.

DRUG METABOLISM

Interindividual differences in drug metabolism are well known. These differences commonly are responsible for adverse drug reactions. It is logical to assume that functional genetic polymorphisms may be a major component of these interindividual differences and, by extension, the adverse drug reactions associated with them.[30] Polymorphisms most often result in poor drug metabolism, but occasionally they can cause ultrarapid metabolism.

One of the more extensively studied metabolic pathways is the cytochrome P_{450} (CYP) enzyme superfamily. More than 30 CYP enzymes are known, with functional polymorphisms described in most of the common ones. Table 45-1 lists such enzymes that alter the metabolism of drugs commonly used in the ICU. At least 55% of the drugs cited in studies of acute drug reactions are metabolized by enzymes with variant alleles. Interestingly, simply altering drug metabolism may not increase the number of acute drug

TABLE 45–1. COMMON ICU DRUGS METABOLIZED BY ENZYMES WITH VARIANT ALLELES

Enzyme	Drugs
CYP1A2	**Verapamil, isoniazid, acetaminophen, haloperidol,** theophylline, diltiazem, erythromycin, imipramine, phenytoin, rifampin, fluoxetine
CYP2C9	**Warfarin, rifampin, ibuprofen, imipramine,** phenytoin, tolbutamide, fluoxetine, naproxen, isoniazid, verapamil
CYP2C18	Fluoxetine, imipramine, rifampin
CYP2C19	**Isoniazid,** omeprazole, diazepam, cyclophosphamide, nortriptyline, S-mephenytoin, rifampin, warfarin, fluoxetine
CYP2D6	**Metoprolol, imipramine, nortriptyline, codeine, encainide, flecainide,** dextromethorphan, fluoxetine, theophylline, diltiazem
CYP2E1	Theophylline, isoniazid, verapamil, fluoxetine
NAT2	**Isoniazid**

CYP, cytochrome P_{450}; NAT, *N*-acetyltransferase.
Bold indicates a major metabolic pathway.

reactions directly. Although CYP1A2 is the metabolic pathway for only 5% of all prescribed drugs, it is at least partially involved in the metabolism of 75% of the drugs that are associated with adverse reactions and metabolized by enzymes with variant alleles.[30]

One of the better examples of the clinical application of genetically determined drug metabolism is in the dosing of warfarin (Coumadin). Warfarin is metabolized by the CYP2C9 enzyme, and variant alleles of this enzyme lead to poor metabolism. Patients who carry these alleles (6% to 9% of whites) require significantly lower doses of warfarin. However, the risk of adverse drug reactions has not been shown conclusively to be greater. The genetic effect is partially offset by the individualization of dose and is clearly affected by environmental factors (diet) and other medical conditions (liver disease, cor pulmonale). However, time to therapeutic dosing, an important cost issue, may be optimized if the genotype is known. Lack of a commercially available assay limits the clinical use of individualized dosing regimens based on genotyping.

In addition to drug metabolism, drug receptor polymorphisms may play a role in therapeutic response. Polymorphisms in genes coding for a variety of common drug receptors are known, such as the beta-adrenergic agonist or glucocorticoid receptors.

INDIVIDUALIZED THERAPY

Although the polymorphisms involved in drug metabolism may be able to determine the appropriate individual dose, one of the nebulous goals of pharmacogenomics is individualizing drug choice in a specific clinical scenario. In the ICU, these decisions are increasingly important because of the availability of expensive drugs with low therapeutic ratios, such as drotrecogin alfa.

One concern is that not accounting for genetic variability may have sidetracked the development of effective agents. For example, would use of anti-TNF strategies or therapeutic use of IL-10 be beneficial in septic patients with TNF hypersecretor genotypes? Many of the novel agents studied in sepsis trials had good theoretical, experimental, and animal study support for their efficacy. The failure to document any benefit in large human trials may reflect the inability to choose appropriate patient groups rather than the agents' ineffectiveness.

The ultimate goals of genetic studies in critically ill patients revolve around two issues: to better understand the pathogenesis of the disease (in order to design better treatment interventions) and to better define the patient group at increased risk (in order to choose the appropriate patients for treatment). In future editions of this textbook, discussions of genetics will no doubt be incorporated into individual chapters on the risks and treatment options of specific diseases.

BIOCHEMICAL, CELLULAR, AND MOLECULAR MECHANISMS OF NEURONAL DEATH AND SECONDARY BRAIN INJURY IN CRITICAL CARE

Robert S.B. Clark • Larry Jenkins • Yi-Chen Lai • Xiaopeng Zhang • Patrick M. Kochanek

KEY POINTS

1. Many of the biochemical, cellular, and molecular mechanisms that are important to the evolution of secondary damage after insults in neurointensive care, including cardiopulmonary arrest, stroke, traumatic brain injury, subarachnoid hemorrhage, status epilepticus, and hypoglycemia, share cerebral ischemia and/or energy failure as a critical initiator of damage.
2. Global cerebral ischemic insults, such as those that result from cardiopulmonary arrest, are generally brief in cases of patients who can be resuscitated successfully. The pathobiologic condition that results is characterized by delayed neuronal death in selectively vulnerable brain regions, and the biochemical and molecular cascades in these cases involve components of programmed cell death. However, classic apoptosis has not been observed.
3. Focal cerebral ischemic insults, such as those that result from stroke and subarachnoid hemorrhage, generally include an ischemic focus surrounded by peri-ischemic penumbral regions. The biochemical and molecular cascades involve necrosis and/or infarct expansion into the penumbra. Cell death in the penumbra can include phenotypes that span the continuum from necrosis to apoptosis.
4. In cases of traumatic brain injury, the biochemical and molecular mechanisms involved depend on the specific type of insult, ranging from focal contusion (in which local osmolar swelling and excitotoxicity predominate) to diffuse axonal injury (in which secondary axotomy from proteolysis predominates).
5. Excitotoxicity, resulting from increases in brain interstitial concentrations of a number of excitatory amino acids, is a common mediator of secondary injury across insults.
6. Programmed cell death, or apoptosis, involves several distinct pathways, including an extrinsic pathway triggered by external cell signals such as death receptor-ligand interaction; an intrinsic pathway triggered by signals from mitochondrial or endoplasmic reticulum; and a caspase-independent pathway involving mitochondrial dysfunction. However, delayed neuronal death in patients with critical central nervous system insults in the intensive care unit does not demonstrate classic apoptotic features but rather commonly exhibits a mixed phenotype.
7. Cerebral swelling can result from a variety of cellular mechanisms, including vasogenic edema, astrocyte swelling, increased tissue osmolar load, or vascular dysregulation with increased cerebral blood volume.
8. Inflammation appears to have a dichotomous role after cerebral ischemia or traumatic brain injury, including early exacerbation of damage by inflammatory mediators but secondary benefit through the link between inflammation and regeneration.

In this chapter, we provide a general discussion of the biochemical, cellular, and molecular mechanism of neuronal death and secondary brain injury that are germane to the central nervous system (CNS) insults that require neurointensive care, highlighting the important shared mechanisms in these conditions. In the chapter that follows, Dr. Kofke builds upon the biochemical and molecular mechanisms to address general pathophysiologic principles in neurointensive care, focusing on intracranial dynamics and the cerebral circulation. Finally, the chapters that follow address other important facets of neurointensive care, such as monitoring and coma, along with the specific pathophysiology and treatment of the key disease processes central to neurointensive care in both adults and children. This includes traumatic brain injury (TBI), cardiopulmonary arrest, stroke, subarachnoid hemorrhage (SAH), and seizures, among other insults.

A thumbnail sketch of the most important mechanisms of secondary injury involved in the brain after a traumatic or ischemic insult is provided in Figure 46-1. Central to all brain insults relevant to neurointensive care is the occurrence of cerebral ischemia and/or cerebral energy failure. Indeed, for cardiopulmonary arrest and stroke, global or focal brain

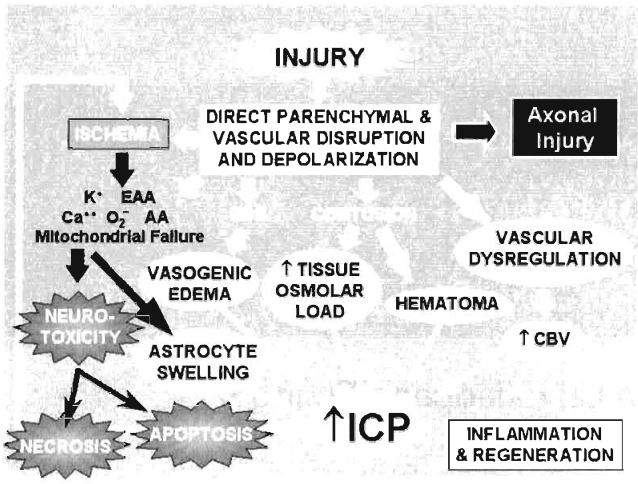

FIGURE 46–1. Categories of biochemical, cellular, and molecular mechanisms proposed to be involved in the evolution of secondary damage after ischemic or traumatic brain injury. Three major categories for these secondary mechanisms include (1) ischemia, excitotoxicity, energy failure, and cell death cascades; (2) cerebral swelling; and (3) axonal injury. A fourth category, inflammation and regeneration, contributes to each of these cascades.

ischemia, respectively, energy failure defines the insult. In cases of TBI, direct parenchymal or vascular disruption or vasospasm often leads to cerebral ischemia, although tissue deformation such as axonal and vascular stretching and shearing along with hemorrhage and dendritic injury also are involved. In cases of SAH, hemorrhage is often followed by delayed vasospasm, with subsequent secondary cerebral ischemia. Finally, seizures and hypoglycemia can lead to neuronal death and represent situations in which relative ischemia is produced, either from enhanced metabolic demands that are greater than supply or from reduced substrate delivery, respectively. Energy failure ensues, and if the insult is sufficient in duration, cellular injury or death can occur. Clearly, ischemia and energy failure are key culprits in producing the pathophysiology of neurointensive care insults.

The principal consequence of ischemic injury and/or energy failure is neuronal death. The two principal forms of ischemia in neurointensive care are global and focal, as seen in cases of cardiopulmonary arrest and stroke, respectively.

GLOBAL CEREBRAL ISCHEMIA

In patients with global cerebral ischemia, insults are dense and often square-wave in nature.[1] The classic example of a global cerebral ischemic insult in neurointensive care is ventricular fibrillation cardiopulmonary arrest (see Chapter 50). Using conventional approaches, patients can be successfully resuscitated from these insults only if they are brief in nature; that is, circulation must be restored in approximately 5 to 12 minutes, although the maximal duration compatible with intact neurologic outcome can depend on a variety of factors, such as temperature. In cases of complete global cerebral ischemia, adenosine triphosphate (ATP) and phosphocreatine levels in brain are depleted in less than 2 minutes.[1-3] Membrane failure ensues, with loss of ion homeostasis that includes cellular release of K^+ and uptake of Ca^{++}, Na^+, and Cl^-.[2,3] Upon reperfusion, a complex sequence of events is set into motion that depends on the duration of the insult. Disturbances in lipid metabolism such as free fatty acid release and DNA damage result, along with a series of deleterious cascades including oxidative and nitrosative stress, excitotoxicity, poly-ADP-ribose polymerase (PARP) activation, mitochondrial and endoplasmic reticulum (ER) dysfunction, and a host of cell-signaling abnormalities. A number of endogenous neuroprotectant responses are also initiated. The specific biochemical, cellular, and molecular events are discussed later. The aforementioned increases in intracellular calcium level are believed to play a critical role in initiating many of these events. In situations in which there is potential salvage of the patient, such as with threshold insults, reperfusion results in transient hyperemia (minutes) followed by delayed hypoperfusion (hours).[1,4,5] The pattern of neuronal damage that is seen after global cerebral ischemia is classically termed *selective vulnerability*. This is often delayed and primarily neuronal in nature, and it is believed to result from complex biologic cascades involving some features of programmed cell death (discussed later).

A number of brain regions are specifically vulnerable to ischemia, including the CA1 region of the hippocampus, cortical layers 3, 5, and 6, portions of the amygdaloid nucleus, and cerebellar Purkinje cells, among others.[2,3,5] Global ischemic insults from cardiopulmonary arrest from which there is some potential for recovery are generally believed to be devoid of important increases in intracranial pressure, since, based on studies in animal models, it has been shown that the threshold for producing poor outcome in patients with global ischemic insults is less than that needed to generate clinically significant intracranial hypertension.[6] Thus, brain edema and vascular injury are not believed to represent important therapeutic targets after global cerebral ischemia. Two relevant but atypical global insults in neurointensive care are asphyxial cardiopulmonary arrest (particularly important in children and discussed in Chapter 59), and near-hanging episodes. In the latter, obstruction of cerebral venous drainage during the asphyxial insult compounds the ischemic insult.

FOCAL CEREBRAL ISCHEMIA

Focal ischemic insults in neurointensive care are produced by thrombotic or embolic events and generally produce a dense ischemic focus that is surrounded by a peri-ischemic penumbral region with intermediate cerebral blood flow (CBF) values.[2] The ischemic focus is generally believed to be unsalvageable unless reperfused almost immediately. In contrast, the ischemic penumbra is a region with some collateral flow and represents a therapeutic target for reperfusion with thrombolytics and/or pharmacological therapy. In cases of focal cerebral ischemia, a hierarchy of CBF thresholds has been demonstrated in experimental studies, with inhibition of protein synthesis being the most sensitive to CBF reductions, followed by loss of electrical activity (evoked potentials and electroencephalogram), and eventually membrane failure.[7,8] Unlike the selective vulnerability seen in global ischemic insults, focal cerebral ischemia produces pan-necrosis of the vasculature and astrocytes, resulting in infarction. However, cell death in the penumbra can demonstrate necrotic, apoptotic, and mixed phenotypes. Again, however, classic apoptosis is not seen. Astrocyte swelling and blood-brain barrier injury, with focal cerebral edema, can play important roles. In the penumbra, spreading depression waves resulting in depolarization can enhance excitotoxic damage with expansion of the lesion core. Reperfusion can occur spontaneously or

with the administration of thrombolytics and can produce a microcosm of the aforementioned oxidative and nitrosative stress, mitochondrial and ER damage, and cell signaling abnormalities seen in global cerebral ischemia. In patients with focal cerebral ischemia, with large infarcts, brain swelling can be substantial enough that secondary ischemia can result from intracranial hypertension. Dr. Kofke discusses these concepts in greater detail in Chapter 47. Focal cerebral ischemia from delayed vasospasm is also the most common critical complication of SAH and is discussed in Chapter 52.

TRAUMATIC BRAIN INJURY

In cases of severe TBI, the biochemical and molecular mechanisms involved depend on the specific type of injury. In cases of focal contusion, direct disruption of parenchyma with local necrosis and hemorrhage results in superimposed vascular disruption, blood-brain barrier permeability, and local ischemia. This sets the stage for excitotoxicity and necrotizing cascades in the contusion penumbra, including oxidative and nitrosative stress, and calpain-mediated proteolysis, among other mechanisms.[9,10] Local axonal injury is also seen in patients with contusions. Focal contusions are commonly complicated by marked local swelling and often by intracranial hypertension with the potential for secondary focal or global ischemic insults or herniation syndromes. In contrast, in diffuse injury, a constellation of diffuse axonal and vascular disruption can be seen with characteristic findings of petechial hemorrhages in the white matter.[11] This insult can be devastating even in the absence of intracranial hypertension.[12] The biochemical and molecular events involved in axonal injury are discussed later. In cases of severe TBI, combined insults that include both multiple contusions and diffuse injury are also common. Finally, in addition to secondary ischemia from refractory intracranial hypertension, secondary extracerebral insults such as hypotension and hypoxemia can also negatively affect outcome and, importantly, complicate the biochemical and molecular response to severe TBI, markedly enhancing delayed neuronal death in brain regions that might otherwise have recovered.[13,14]

KEY BIOCHEMICAL AND MOLECULAR MECHANISMS OF NEURONAL SECONDARY DAMAGE

A number of pathologic cascades are shared by these important insults in neurointensive care, including excitotoxicity, programmed cell death, axonal injury, and inflammation, along with a spectrum of endogenous neuroprotectant responses.

EXCITOTOXICITY

Excitotoxicity describes the process by which glutamate and other excitatory amino acids cause neuronal damage. Lucas and Newhouse[15] first described the toxicity of glutamate. Olney[16] subsequently reported that intraperitoneal administration of glutamate produces brain injury in experimental animals. Although glutamate is the most abundant neurotransmitter in the brain, exposure to toxic levels produces neuronal death.[17] Glutamate exposure produces neuronal injury in two phases. Minutes after exposure, sodium-dependent neuronal swelling occurs.[18] This is followed by delayed, calcium-dependent degeneration. These effects are mediated through both ionophore-linked receptors, labeled according to specific agonists (*N*-methyl-D-aspartate [NMDA], kainite, and α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid [AMPA]), and receptors linked to second messenger systems, called metabotropic receptors. Activation of these receptors leads to calcium influx through receptor-gated or voltage-gated channels, or through the release of intracellular calcium stores. Increased intracellular calcium concentration is the trigger for a number of processes that can lead to cellular injury or death (Fig. 46-2). One mechanism involves activation of neuronal nitric oxide (NO) synthase, leading to NO production, peroxynitrite formation, and resultant DNA damage. PARP is an enzyme operative in DNA repair, and in the face of DNA damage, PARP activation leads to ATP depletion, metabolic failure, and cell death.[19-21] This may be important, since PARP knockout mice exhibit improved outcome versus controls after experimental stroke or TBI.[20,22]

There is considerable evidence in experimental laboratory models supporting an important contribution of excitotoxicity to the evolution of secondary damage in cases of global and focal cerebral ischemia, severe TBI, SAH, and status epilepticus.[23-30] Evidence supporting an important role for excitotoxicity in humans has similarly been provided in cases of severe TBI, stroke, and SAH. Persson and Hillered[31] reported increases in brain interstitial levels of glutamate in a patient with SAH as early as 1992. Palmer and associates[32] first demonstrated increased concentrations of excitatory amino acids in ventricular cerebrospinal fluid (CSF) from adult patients with TBI. Glutamate concentrations were about fivefold greater than in control patients (up to 7 μM)—levels sufficient to cause neuronal death in cell culture.[33] Bullock and associates[34] characterized patterns of glutamate release by measuring excitatory amino acids by microdialysis in patients after TBI. Patients with a normal head computed tomography scan and no secondary ischemic events had interstitial concentrations of glutamate that were increased early in their course, then returned to normal. In contrast, patients with a progressively rising level of glutamate died. Similarly, in cases of human stroke, Bullock and associates[35] reported massive increases in the excitatory amino acids glutamate and aspartate in a patient who required decompressive craniectomy to prevent brainstem herniation.

Despite these and many other clinical reports, clinical trials with anti-excitotoxic therapies have been unsuccessful in patients with either stroke or TBI. This may be due to problems with patient selection, side effects of the anti-excitotoxic agents that were tested, and the likelihood that treatment was initiated too late.[36] Inhibition of plasticity by anti-excitotoxic therapies may also limit their efficacy, especially at the interface between the acute and subacute periods after injury.[37]

APOPTOSIS/PROGRAMMED CELL DEATH CASCADES

It is now increasingly clear from experimental models and human data that cells dying after global or focal cerebral ischemia or TBI can be categorized on a morphologic continuum ranging from necrosis to apoptosis.[38,39] Apoptosis is a morphologic description of cell death defined by cell shrinkage and nuclear condensation, internucleosomal DNA fragmentation, and the formation of apoptotic bodies.[40] In contrast, cells dying of necrosis display cellular and nuclear swelling with dissolution of membranes. Apoptosis requires

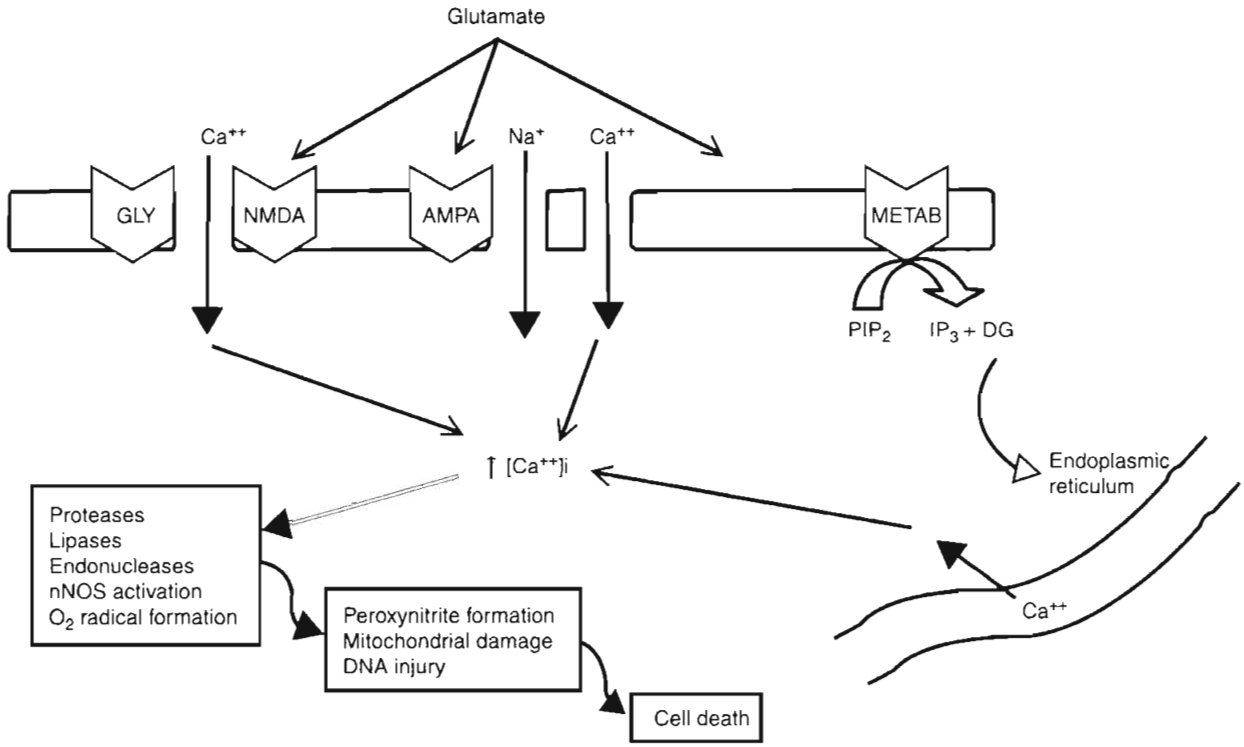

FIGURE 46–2. Mechanisms involved in excitotoxicity. Glutamate causes an increase in intracellular calcium concentration through stimulation of (1) the NMDA receptor with opening of the receptor-linked calcium ionophore, (2) the AMPA receptor with opening of the voltage-gated calcium channels, and (3) the metabotropic receptor, with the release of intracellular calcium stores via the second messengers inositol triphosphate and diacylglycerol. Increased intracellular calcium concentration leads to activation of proteases, lipases, and endonucleases, along with neuronal NOS (nNOS) stimulation and production of oxygen radicals. This results in peroxynitrite formation, mitochondrial damage, and DNA injury with subsequent cellular injury and death. AMPA, α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid receptor; DG, diacylglycerol; GLY, glycine co-agonist site; IP_3, inositol triphosphate; METAB, glutamate metabotropic receptor; NMDA, *N*-methyl-D-aspartate receptor; PIP_2, phosphoinositide.

a cascade of intracellular events for completion of cell death; thus, *programmed cell death* is the currently accepted term for the process of cell death that leads to apoptosis.[41] In diseases with complex and multiple mechanisms, such as stroke and TBI, it is typically difficult to distinguish clinical apoptotic from necrotic cell death as classically defined.[42] Some cells may display DNA fragmentation and activation of proteases involved in programmed cell death, despite having nuclear and cellular swelling. Dying cells with mixed phenotypes are very common and may represent particularly difficult therapeutic targets.

Biochemical Pathways in Delayed Neuronal Death

Programmed cell death is an evolutionarily conserved process required for selective cell elimination during development, and it occurs in all tissues, including brain. Execution of programmed cell death requires novel gene expression and protein synthesis.[43-45] Programmed cell death is an intricate and critical mechanism for balancing cell proliferation, remodeling of tissues during development, and maintenance of tissues with a high rate of cell turnover. Programmed cell death can be thought of as "molecular débridement," delicately eliminating unwanted cells with minimal disturbance of neighboring cells. Programmed cell death is cybernetic and may occur via multiple pathways that can be independent (Fig. 46-3); however, cross-talk between these pathways also may occur.[46] At present, neuronal programmed cell death can be segregated into two pathways, one involving the activation of a family of cysteine proteases termed *caspases*, and one that is caspase independent.[47]

Caspase family proteases include 14 currently identified members that are synthesized as pro-enzymes,[48] which for the most part are proteolytically activated.[49] Initiator caspases, including caspase-8, -9, and -10, are activated by autocleavage and aggregation. Executioner caspases, including caspase-3, -6, and -7, are cleaved and activated by initiator caspases. The proteolytic cleavage of caspase substrates produces the phenotypic changes characteristic of programmed cell death, including cytoskeletal disintegration, DNA fragmentation, and disruption of cellular and DNA repair processes (Fig. 46-4). Cytoskeletal caspase targets include spectrin and nuclear lamin[50]; in addition, caspase-3 activates the enzyme gelsolin, which cleaves actin.[51] Active caspase-3 can also cleave the inhibitor of caspase-dependent deoxyribonuclease, permitting caspase-dependent deoxyribonuclease to digest DNA into small oligonucleosomal fragments.[52] These small DNA fragments (multiples of approximately 180 base pairs) can be seen on a DNA gel as a ladder and are a hallmark of caspase-dependent programmed cell death. Caspase-3 also inhibits DNA repair by proteolytically inactivating many DNA repair proteins, including PARP.[53-55] This combination of features—silencing of the genome and incapacitation of DNA repair processes, and destruction of key cytoskeletal components, all with surgical-like precision and ultimately leading to cell death—illustrates why programmed cell death has been referred to as "cell suicide."

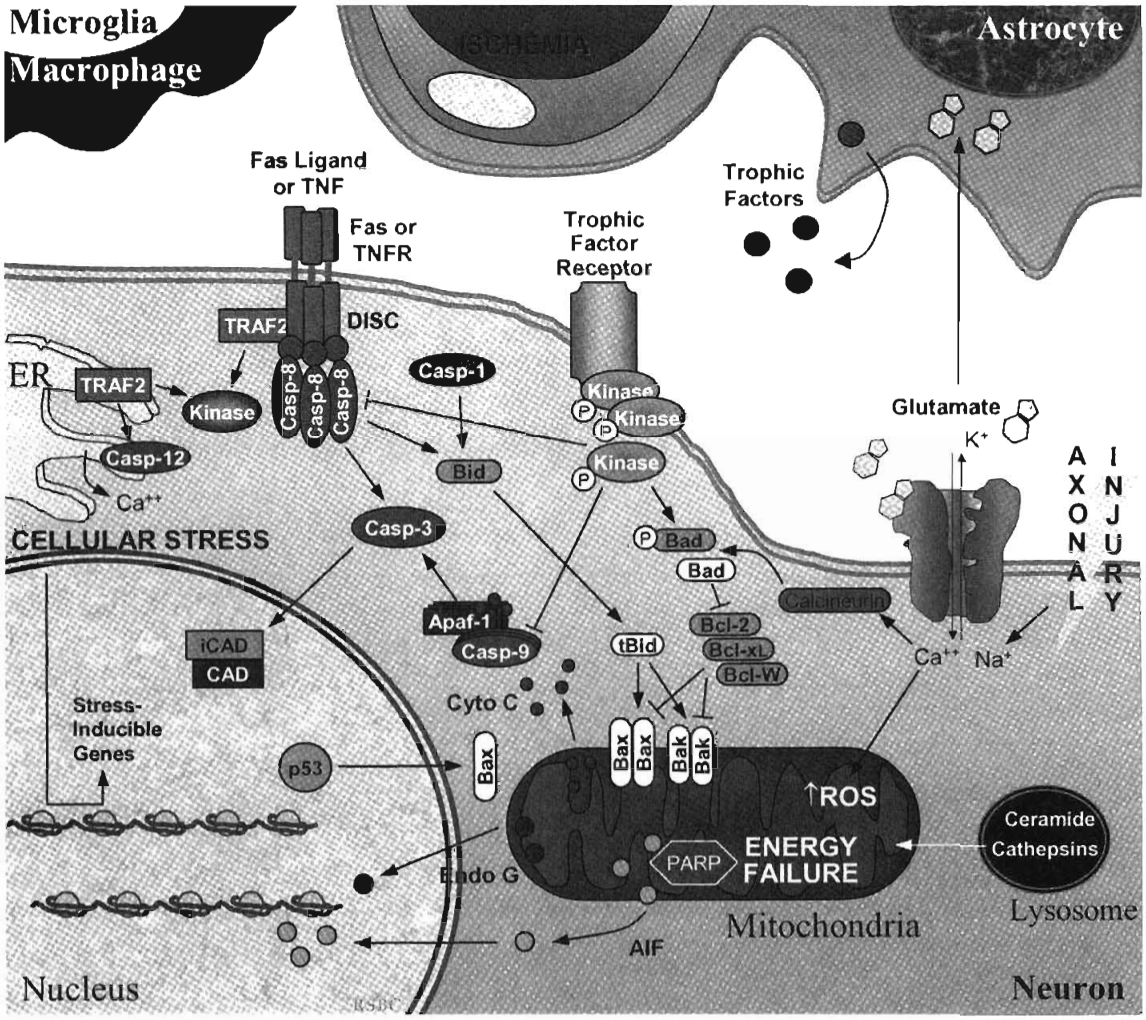

FIGURE 46–3. A simplified schematic representation of the initiation and regulation of neuronal programmed cell death after brain injury. Pathologic mechanisms triggering programmed cell death after brain injury include ischemia, oxidative stress, energy failure, excitotoxicity (primarily excess glutamate), axonal injury, trophic factor withdrawal, ER stress, and death receptor-ligand binding (e.g., TNF, Fas). Regulation of programmed cell death occurs via multiple pathways, including kinase-dependent intracellular signaling pathways and Bcl-2 family proteins. AIF, apoptosis inducing factor; Apaf-1, apoptotic protease activating factor-1; Bcl, B-cell lymphoma; CAD, caspase-activated deoxyribonuclease; casp, caspase; cyto c, cytochrome c; DISC, death-inducing signaling complex; Endo G, endonuclease G; ER, endoplasmic reticulum; iCAD, inhibitor of CAD; ROS, reactive oxygen species; tBid, truncated Bid; TNF, tumor necrosis factor; TNFR, TNF receptor; TRAF2, TNF receptor associated factor.

Extrinsic Pathways of Programmed Cell Death

Programmed cell death can be initiated by extrinsic or intrinsic signals. Extrinsic signals include cell surface death receptor-ligand interactions and cell signaling pathways. The most prominent cell death receptor family is the tumor necrosis factor (TNF) receptor superfamily, which includes TNF-α and Fas.[56] The coupling of cell surface TNF or Fas receptors with extracellular TNF-α or Fas ligand induces trimerization of the receptors that leads to the formation of submembrane complexes with intracellular death domain-signaling molecules. This death-inducing signaling complex then activates caspase-8[57] or -10.[58] Caspase-3 is then cleaved and activated, perpetuating the cascade. The extrinsic pathway can also be regulated by multiple intracellular signal transduction pathways that are initiated by G-protein coupled cell surface receptors, which can be either activated by neurotransmitters (e.g., cyclic nucleotides) or inactivated by interruption of trophic factors (e.g., nerve growth factor) after injury.[59] Perturbations in neurotransmitters and trophic factors controlling these pathways occur after ischemia and TBI. Multiple interrelated pro-death or pro-survival kinase pathways have been identified, including those involving mitogen-activated protein kinases, and protein kinase B and protein kinase C.[60,61]

Intrinsic Pathways of Programmed Cell Death

The intrinsic programmed cell death pathway is triggered by stress on cellular organelles, notably mitochondria and ER. Mitochondrial stress can lead to caspase-dependent programmed cell death via mitochondrial release of cytochrome C induced upon mitochondrial membrane depolarization. Egress of cytochrome C into the cytosol enables interaction with apoptotic protease activating factor-1 (Apaf-1), dATP, and pro-caspase-9 to form a complex termed an *apoptosome*. Apaf-1 activates caspase-9 and subsequently caspase-3.[62] Several mitochondrial proteins are capable of inducing programmed cell death without direct activation of the caspase cascade, thus exemplifying pathways that are caspase-independent. Apoptosis-inducing factor (AIF) within the mitochondria serves as an antioxidant[63]; however, upon

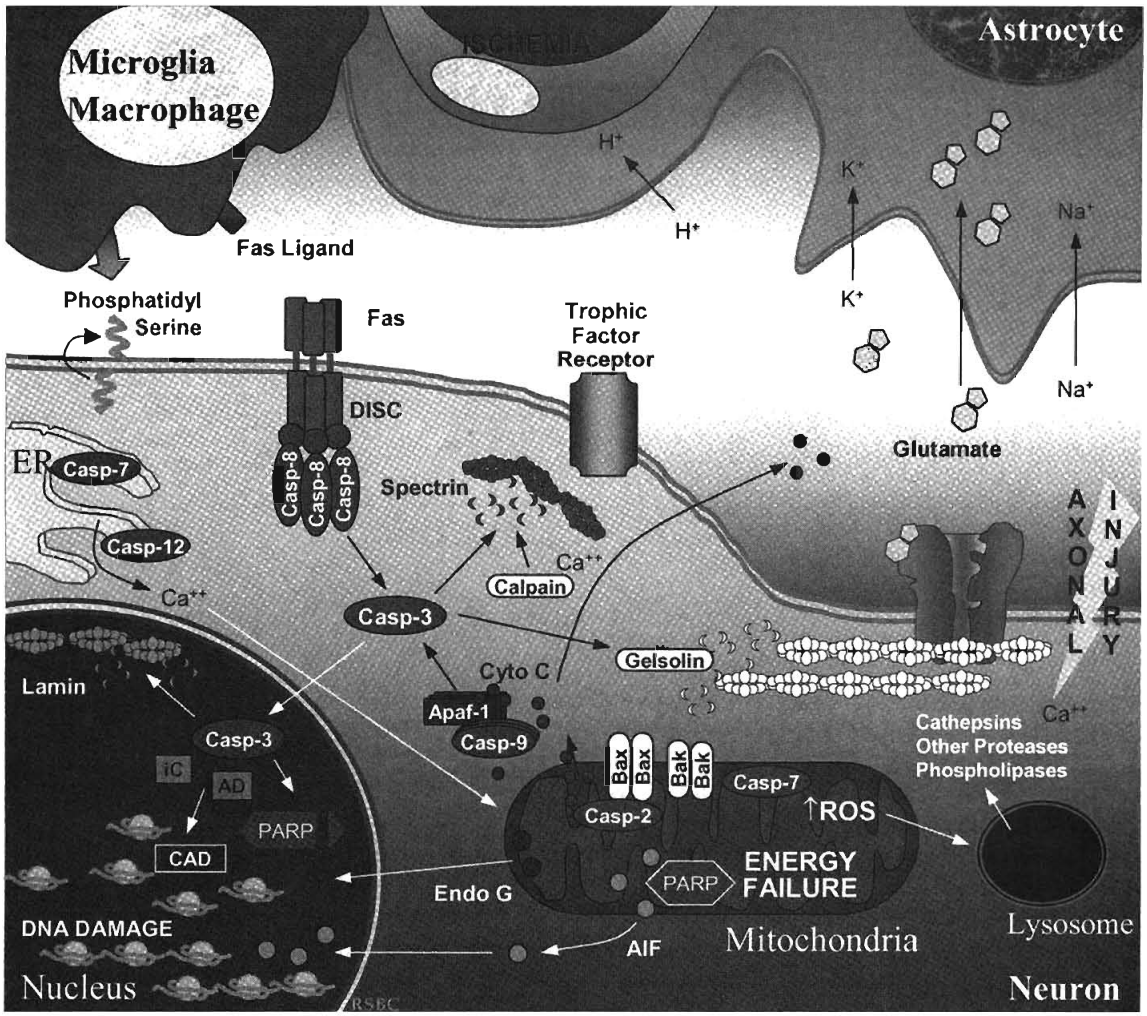

FIGURE 46–4. A simplified schematic representation of the execution of neuronal programmed cell death after brain injury. Execution of programmed cell death involves the caspase cascade and/or release of apoptogenic factors from organelles such as mitochondria. Ultimately, DNA fragmentation, cytoskeletal disintegration, and externalization of membrane phosphatidyl serine occur, signaling macrophages and microglia to engulf cellular debris. AIF, apoptosis inducing factor; Apaf-1, apoptotic protease activating factor-1; Bcl, B-cell lymphoma, CAD, caspase-activated deoxyribonuclease; casp, caspase; cyto c, cytochrome c; DISC, death-inducing signaling complex; Endo G, endonuclease G; ER, endoplasmic reticulum; ICAD, inhibitor of CAD; ROS, reactive oxygen species.

mitochondrial membrane depolarization, it can translocate from the mitochondria to the nucleus, where it is sufficient to induce programmed cell death.[64] Translocation of AIF into the nuclei induces the formation of large-scale DNA fragmentation (>50 kilobase pairs), in contrast to cytochrome C-mediated, caspase-dependent programmed cell death, which leads to oligonucleosomal DNA fragmentation (180-1200 base pairs). AIF-mediated programmed cell death occurs in neurons under conditions of experimental TBI[65] and cerebral ischemia.[66] Other mitochondrial proteins related to programmed cell death include endonuclease G,[67] Htr2A/Omi,[68] and Smac/Diablo[69]; however, their roles in neuronal death after brain injury remain unexplored. Disruption of ER calcium homeostasis and/or accumulation of excess proteins can lead to ER stress, which in turn can trigger programmed cell death via activation of ER-localized caspase-12, an upstream initiator caspase. ER stress–related activation of caspase-12 has been detected in experimental models of cerebral ischemia[70] and TBI.[71]

Regulation of Programmed Cell Death by the Bcl-2 Protein Family

Both caspase-dependent and caspase-independent programmed cell death are regulated by the B-cell lymphoma-2 (Bcl-2) family of proteins. The Bcl-2 family contains both pro-death and pro-survival members.[72] Bcl-2 family proteins regulate changes in permeability of the mitochondrial outer membrane independent of permeability transition pore formation. Bcl-2 family proteins contain highly conserved Bcl-2 homology domains (BH 1-4) essential for homo- and hetero-complex formation.[73] Complexes formed between proteins containing BH-3 domains such as Bax, truncated Bid, and Bad can facilitate mitochondrial cytochrome C release.[74,75] The anti-apoptotic members Bcl-2, Bcl-xL, and Mcl-1L prevent the release of mitochondrial proteins by inhibiting the pore formation.[76] Bax expression is associated with neuronal cell death after cardiac arrest in dogs.[77] Transgenic mice overexpressing Bcl-2 are partially protected from the neuropathologic sequelae of TBI versus wild-type

mice.[78] Overexpression of Bcl-xL also inhibits neuronal cell death after focal cerebral ischemia.[79]

Programmed Cell Death in Human Brain Injury

Phenotypic descriptions of programmed cell death occurring after brain injury in humans date back to the 1940s.[80,81] However, biochemical evidence of programmed cell death after brain injury in humans has been reported only within the last decade and has now been reported after TBI,[82-84] stroke,[85] and epilepsy.[86] Brain tissue samples from TBI patients requiring decompressive craniectomy for the treatment of life-threatening intracranial hypertension were found to have evidence of DNA fragmentation by terminal deoxynucleotidyl transferase-mediated nick-end labeling (TUNEL) and cleavage of caspase-1 and -3, suggesting activation of the programmed cell death cascade.[82] Recently, the up-regulation of caspase-8 in human brain after TBI at both transcriptional and translational levels has been reported.[84] Caspase-8 was found predominantly in neurons and was associated with relative levels of the death receptor Fas, providing evidence of the extrinsic programmed cell death pathway within neurons. Increases in Fas and Fas ligand have also been reported in cerebrospinal fluid from TBI patients, with Fas levels correlating with intracranial pressure.[87,88] Activation of the intrinsic pathway also occurs after TBI. Alteration of Bcl-2 family proteins has been reported in human brain from adults and in CSF from infants and children after TBI.[82,83,89] In pediatric patients, lower concentrations of Bcl-2 were detected in patients who died than in those who survived, supporting a pro-survival role for Bcl-2.[83] After TBI in adults, the presence of pro-death Bcl-2 family protein Bax in patients in whom Bcl-2 was also detectable represented a more favorable outcome as compared with patients in whom Bax but not Bcl-2 was detectable.[90] In contrast to TBI patients, patients after stroke demonstrate reductions in soluble Bcl-2 and soluble Fas within CSF,[85] suggesting dysregulation of programmed cell death after stroke. In adolescents and young adults with refractory seizures, increases in Bcl-2 and Bcl-xL, as well as increases in expression and proteolysis of caspase-1 and -3, occur in resected temporal lobe.[86] These patients have had medically refractory seizures for several years, implying protracted as well as acute programmed cell death within the brain. Protracted programmed cell death after TBI also occurs. Cells with apoptotic morphologies and DNA damage detected by TUNEL have been reported in autopsy specimens from patients dying up to 12 months after injury,[91] perhaps implying that a relatively wide therapeutic window exists for the administration of treatments aimed at reducing programmed cell death.

Several notes of caution are in order. First, it is unclear what the quantitative contribution of programmed cell death is in clinical cases of cerebral ischemia or TBI.[92] It is likely that dying cells demonstrate some biochemical and phenotypic features of programmed cell death, but that the actual deathblow to the cell is not dependent on an active process.[92,93] In addition, even if programmed cell death mechanism plays a key role, it is not clear whether inhibiting neuronal death after injury is entirely beneficial, since programmed cell death is a vital mechanism for biologic systems to eliminate abnormal or aging cells. In other words, quiet elimination, via "cell suicide" of damaged or dysfunctional cells may lead to overall benefit of the patient, in essence "molecular débridement." Only clinical trials of novel therapies targeting programmed cell death will be able to determine whether this mechanism represents an important target in neurointensive care. Recent studies of the efficacy of mild hypothermia after experimental and clinical cardiopulmonary, however, suggest that the success of this intervention may be derived from its effects on programmed cell death.[94-96]

AXONAL INJURY

White matter damage is important in infarction that results from stroke but probably plays only a limited role in the pathology of reversible global cerebral ischemia. In contrast, axonal injury is of paramount importance in patients with TBI. This has been demonstrated both clinically[97-100] and in experimental models.[101-103] The extent and distribution of traumatic axonal injury depends on injury severity and category (focal versus diffuse).[104] The classic view that traumatic axonal injury occurs because of immediate physical shearing is represented primarily in cases of severe injury in which frank axonal tears occur.[97,98,105,106] However, recent experimental studies suggest that axonal damage predominantly occurs by a delayed process termed *secondary axotomy.*[102,107,108] Two hypothetical sequences have attempted to explain secondary axotomy, one attributing axolemmal permeability and calcium influx as the initiating event (Fig. 46-5), and the other a direct cytoskeletal abnormality impairing axoplasmic flow.[102,108,109] It has been posited that both forms of reactive axonal swelling take place but in different proportions depending on the severity of injury. Superimposed on these theories is the finding that hypoxic/ischemic insults can also produce axonal swelling. As a result, differing as well as unifying theories for axonal injuries in patients with brain injury have been proposed.[102,108-111] Common mechanistic features include focal ion flux, calcium dysregulation, and mitochondrial and cytoskeletal dysfunction.

Traumatic axonal injury contributes to the morbidity after TBI.[102,104-106] Until recently, the contributions of axonal injury to morbidity have remained speculative, since traumatic axonal injury has remained refractory to treatment even in the laboratory. However, recent studies in experimental TBI models have shown that hypothermia or cyclosporin-A can both reduce white matter damage.[112,113] These therapeutic advances should help determine more definitively the contributions of traumatic axonal injury to secondary damage. Recent application of magnetic resonance imaging (MRI) to the study of traumatic axonal injury[114,115] and axonal connectivity[116,117] may improve our understanding of both this injury mechanism and axonal regeneration.

CEREBRAL SWELLING

In addition to cascades of neuronal death and axonal damage, brain swelling is a hallmark finding in cases of focal cerebral ischemia, severe TBI, and severe global cerebral ischemia from prolonged cardiopulmonary arrest. Brain swelling often results in the development of intracranial hypertension. Cerebral swelling and accompanying intracranial hypertension contribute to secondary damage in two ways. Intracranial hypertension can compromise cerebral perfusion, leading to secondary ischemia. It can also produce the devastating consequences of brain deformation and vascular compression through herniation syndromes. Intracranial hypertension results from increases in intracranial volume

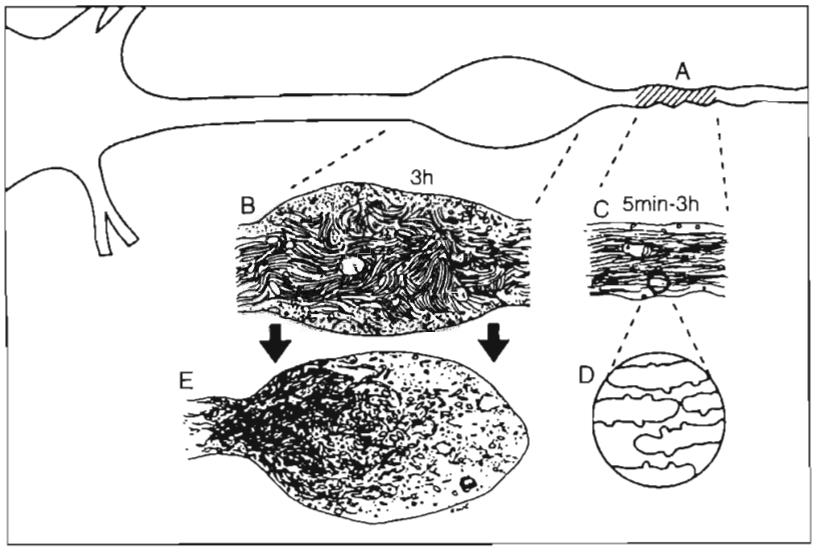

FIGURE 46–5. Reactive axonal swellings have been proposed to result from focal axolemmal disruption, ionic shifts, and neurofilamentous compaction at site *A* results in a reactive swelling at site *B* in an upstream region of the axon. At the site of ionic influx, neurofilamentous compaction and mitochondrial swelling is seen (*C*). Neurofilament compaction is associated with neurofilament sidearm loss (*D*). Obstructed axonal transport results in upstream axonal enlargement, neurofilament misalignment, organelle accumulation, and formation of the typical reactive axonal swelling (*E*).

from a variety of sources, which are outlined in Figure 46-1. In some cases of TBI or spontaneous intracranial hemorrhage, such as with epidural, subdural, or parenchymal hematoma formation, an extra-axial or parenchymal blood collection is the key culprit and can be addressed by surgical evacuation.[118] However, there are several important mechanisms that are more uniformly involved in the development of intracranial hypertension. These are related to either brain swelling from vasogenic edema, astrocyte swelling, and an increase in tissue osmolar load, or vascular dysregulation with swelling secondary to an increase in cerebral blood volume (CBV).

Most of the mechanistic work in this area has come from studies in the field of TBI. Recent data suggest that brain swelling after severe TBI results from edema rather than increased CBV. Marmarou and colleagues[119] measured both CBV and brain water in adults with TBI. Using a dye indicator technique (coupled to computed tomography) to measure CBV and MRI to quantify brain water, increases in brain water were commonly observed but were generally associated with reduced (not increased) CBV (see Fig. 46-6).

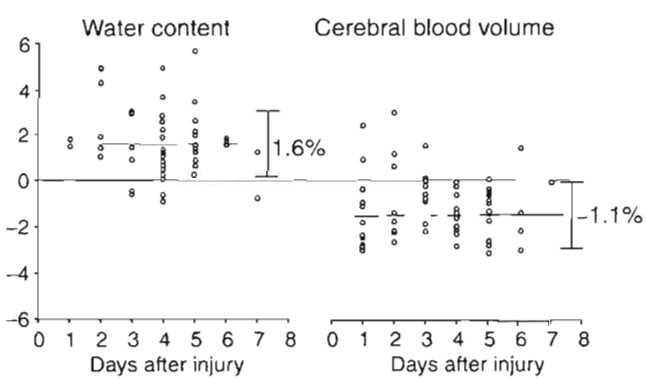

FIGURE 46–6. The percentage change in brain water content as assessed by magnetic resonance imaging and cerebral blood volume (CBV) as measured by computed tomography and indicatory dilution technique in 109 studies of adults with traumatic brain injury (TBI). Brain water is increased and CBV is reduced in adults with severe TBI. (From Marmarou A, Barzo P, Fatouros P, et al: Traumatic brain swelling in head injured patients: Brain edema or vascular engorgement? Acta Neurochir Suppl [Wien] 1997;70:68-70.)

Thus, edema rather than increased CBV appears to be the predominant contributor to cerebral swelling after TBI. Both cytotoxic and vasogenic edema may play important roles in cerebral swelling. However, the biochemical and molecular pathways involved in our traditional concept of cytotoxic and vasogenic edema are evolving. There appear to be four putative mechanisms for edema formation in the injured brain. First, vasogenic edema may form in the extracellular space as a result of disruption of the blood-brain barrier. Second, cellular swelling can be produced in two ways. Astrocyte swelling can occur as part of the homeostatic uptake of substances such as glutamate. Glutamate uptake is coupled to glucose utilization via a sodium/potassium ATPase, with sodium and water accumulation in astrocytes. Astrocyte swelling appears to be importantly linked to water movement through the aquaporin-4 channel found in the astrocyte foot processes near capillaries.[120-123] Recent studies have demonstrated reduced cerebral edema in mice genetically deficient in this channel.[124] Swelling of both neurons and other cells in the neuropil can also result from ischemia- or trauma-induced ionic pump failure. This can be important in the penumbral regions of focal cerebral ischemia and around cerebral contusions. Finally, osmolar swelling may also contribute to edema formation in the extracellular space, particularly in maturing cerebral contusions. Osmolar swelling, however, is actually dependent on an intact blood-brain barrier or an alternative solute barrier.

In both ischemic and traumatic brain injury, cellular swelling may be of greatest importance. Using a model of diffuse TBI in rats, Barzo and colleagues[125] applied diffusion-weighted MRI to localize the increase in brain water. A decrease in the apparent diffuse coefficient after injury suggested predominantly cellular swelling, rather than vasogenic edema, in the development of intracranial hypertension. Cellular swelling may be of even greater importance in the setting of TBI with a secondary hypoxemic-ischemic insult.[126] Katayama and colleagues[127] also suggested that the role of blood-brain barrier in the development of post-traumatic edema might have been overstated, even in the setting of cerebral contusion. One intriguing possibility is that as macromolecules are degraded within injured brain regions, the osmolar load in the contused tissue or infarcts increases. As the blood-brain barrier reconstitutes (or as other osmolar

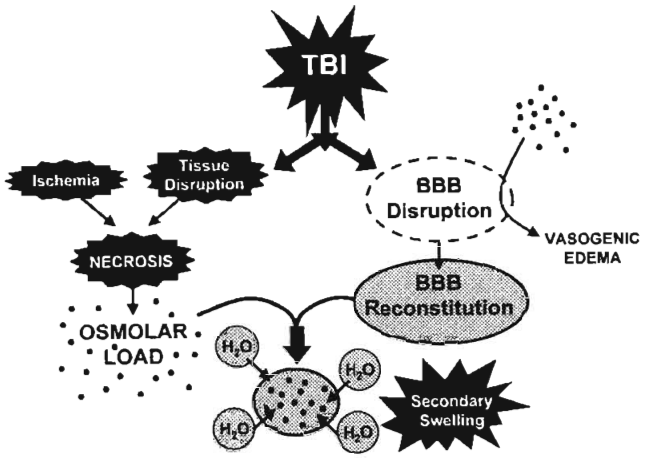

FIGURE 46–7. Schematic based on hypothesis of Katayama and colleagues[127] suggesting that as the osmolar load increases (breakdown of macromolecules in the region of contusion necrosis), a considerable driving force develops for the accumulation of water, resulting in the secondary swelling so often seen in and around cerebral contusions.

barriers are formed), a considerable osmolar driving force for the local accumulation of water develops, resulting in the marked swelling so often seen in and around cerebral contusions (Fig. 46-7). This has been supported by recent clinical studies of human cerebral contusion.[128]

In some cases, increases in CBV can be seen after TBI and contribute to intracranial hypertension. When an increase in CBV is seen, it may result from local increases in cerebral glycolysis, "hyperglycolysis" as described by Bergsneider and colleagues.[129] In regions with increases in glutamate levels, such as in contusions, increases in glycolysis are observed because astrocyte uptake of glutamate is coupled to glycolysis rather than oxidative metabolism. Recall that oxidative metabolism is generally depressed by approximately 50% in comatose victims of severe TBI in the intensive care unit.[130] Hyperglycolysis results in a marked local increase in cerebral glucose utilization with a coupled increase in CBF and CBV and resultant local brain swelling. A detailed discussion of this topic is beyond the scope of this chapter, but an expanded discussion of intracranial dynamics and vascular dysregulation in neurointensive care is provided in the next chapter.

As MRI and magnetic resonance-spectroscopic methods continue to develop and become applied to critically ill patients,[131] our knowledge of the mechanisms involved in cerebral swelling should greatly advance. It must be remembered that although neuronal and axonal injury are key downstream events in the evolution of damage after severe TBI, brain swelling and resultant intracranial hypertension is still the principal target for titration of therapy in the intensive care unit.

INFLAMMATION AND REGENERATION

There appear to be both acute detrimental and subacute/chronic beneficial aspects of inflammation in cerebral ischemia and TBI. Inflammatory mechanisms in the evolution of secondary injury and repair have the greatest support in stroke and TBI, although some support for a role of inflammation in the regulation of neuronal death has been suggested even in cases of transient global ischemic insults.[132-135] There is robust acute inflammation after stroke and TBI.[136,137] This has been shown in experimental models and in patients.[138-146] Nuclear factor-κB,[147] TNF-α,[85,148-151] interleukin (IL)-1β,[152,153] eicosanoids,[154] neutrophils,[139,155,156] and macrophages[157,158] contribute to both secondary damage and repair.

Markers of inflammation after TBI have been assessed in humans using two general strategies, (1) examination of inflammation in contused brain tissue or cerebral infarcts resected from patients with refractory intracranial hypertension, and (2) study of mediator levels in CSF. Consistent with a role for IL-1β in the evolution of tissue damage in cases of human TBI, Clark and associates[39] performed Western analysis of brain samples resected from adults with refractory intracranial hypertension secondary to severe contusion. Interleukin-1-converting enzyme (ICE) was activated, as evidenced by specific cleavage in patients with TBI. ICE activation is critical to the production of IL-1β. ICE activation was not detected in patients who died of non-CNS causes (Fig. 46-8). This supports the production of IL-1β, a pivotal proinflammatory mediator, in the traumatically injured brain in humans. Similar support for increases in a variety of inflammatory mediators exists in human stroke.[85,145,146,150,151,156]

Studies of CSF further support a role for inflammation in TBI. Marion and associates[142] demonstrated increases in IL-1β in CSF after severe TBI in adults. These increases were attenuated by the use of moderate therapeutic hypothermia. Similarly, there are increases of a number of cytokines in CSF after severe TBI and stroke, including IL-6 and IL-8.[85,144,150,151,159] Contusion and local tissue necrosis

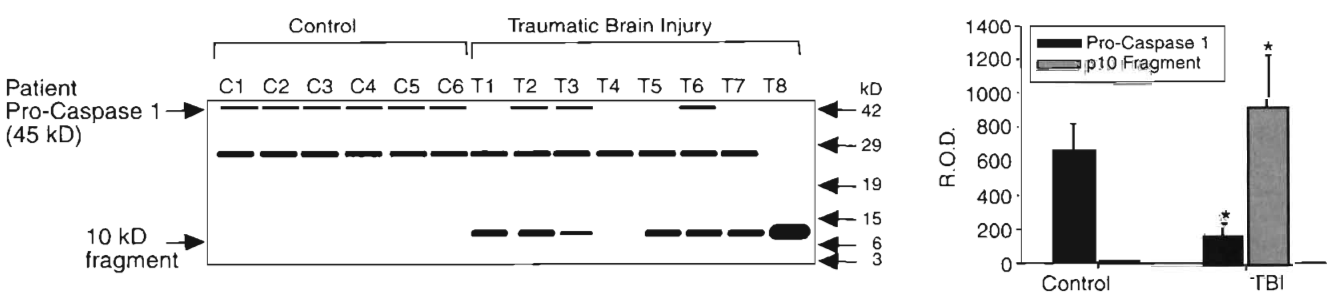

FIGURE 46–8. Evidence for activation of interleukin-1β converting enzyme (ICE) activation in cerebral contusions resected from adult patients with severe traumatic brain injury (TBI) and refractory intracranial hypertension. Western analysis demonstrating cleavage of the intact 45 kD pro-caspase-1 to the 10 kD fragment in each of eight victims of severe TBI but in none of six control brain samples from patients who died of non-central nervous system causes. (From Clark RS, Kochanek PM, Chen M, et al: Increases in Bcl-2 and cleavage of caspase-1 and caspase-3 in human brain after head injury. FASEB J 1999;13:813-821.)

appear to be important to trigger neutrophil influx with resultant secondary tissue damage.[139] Neutrophil influx is accompanied by increases in inducible nitric oxide synthase (iNOS) in brain[140,146] and is followed by macrophage infiltration, which peaks between 24 and 72 hours after injury.[160] Macrophage infiltration and the differentiation of endogenous microglia into resident macrophages may signal the link between inflammation and regeneration, with elaboration of a number of trophic factors (i.e., nerve growth factor [NGF], nitrosothiols, vascular endothelial growth factor).[153,159,161,162] Kossmann and associates[159] reported a link between IL-6 production and the production of neurotrophins, such as NGF in human head injury. Cultured astrocytes treated with either IL-6 or IL-8 in CSF from brain-injured adults produced NGF. Cytokine production after cerebral ischemia and TBI may be important to neuronal plasticity and repair, as discussed later.

Studies in models of TBI[149,163] suggest early detrimental effects of a number of inflammatory mediators but beneficial effects of inflammation on long-term outcome. Mice deficient in TNF-α exhibit improved functional outcome (versus wild-type) early after TBI. However, the long-term consequences of TNF-α deficiency on outcome are detrimental.[149] Similarly, despite a detrimental role for iNOS in the initial 72 hours after trauma,[165] iNOS-deficient mice demonstrated impaired long-term outcome versus controls.[164] iNOS is important in wound healing, and iNOS-derived nitrosylation of proteins may play a role.[162,165] Regeneration and plasticity play important roles in mediating beneficial long-term effects on recovery, and these responses are linked to inflammation. Analogs of these beneficial consequences of inflammation are anticipated in humans but remain to be demonstrated.

The contribution of the inflammatory response to cerebral ischemia and TBI remains to be determined. Although there are a few promising reports in models of the use of anti-inflammatory therapies in TBI and ischemia (targeting IL-1β, ICE, and TNF-α), it is unclear whether anti-inflammatory therapies will improve outcome after stroke or TBI in humans. Some of the initial trials have not been promising.[156] Finally, the consequences of anti-inflammatory therapies on the incidence of sepsis or secondary infectious complications must also be considered.[166] Similarly, the potential deleterious (or beneficial) CNS consequences of novel immunostimulatory therapies (such as GCSF or GMCSF) for the treatment of sepsis and multiple organ failure must also be carefully considered when these agents are used in patients with multisystem disease that includes CNS injury.[167]

ENDOGENOUS NEUROPROTECTANTS

Ischemia, excitotoxicity, or their combination, are a key facet of secondary injury. These mechanisms are linked to calcium overload, oxidative stress, and mitochondrial failure. There is, however, a coupled endogenous retaliatory response to these ischemic and excitotoxic insults. Two important components of this cascade are adenosine and heat shock protein 70 (HSP-70). Adenosine is an endogenous neuroprotectant produced in response to both ischemia and excitotoxicity. It antagonizes a number of events thought to mediate neuronal death.[168] Breakdown of ATP leads to formation of adenosine, a purine nucleoside that decreases neuronal metabolism and increases CBF, among other mechanisms. Adenosine binding to A1 receptors decreases metabolism by increasing K^+ and Cl^- and decreasing Ca^{++} conductances in the neuronal membrane. A1 receptors bind adenosine with high affinity and are located on neurons in brain regions that are susceptible to injury and are spatially associated with NMDA receptors.[169] Thus, locally released adenosine minimizes excitotoxicity. Binding of adenosine to lower affinity A2 receptors (on cerebrovascular smooth muscle) causes vasodilation, although binding to A2a receptors on neurons may be detrimental. Brain interstitial levels of adenosine are increased 50- to 100-fold early after experimental cerebral ischemia or TBI.[170-173]

In clinical studies, marked increases in brain interstitial levels of adenosine in adults with TBI were seen during episodes of jugular venous desaturation (secondary insults), supporting a role of adenosine as a "retaliatory" defense metabolite.[174] Surprisingly, increases in CSF levels of the commonly consumed adenosine receptor antagonist caffeine were associated with favorable outcome after severe TBI in humans, a finding that may be explained by up-regulation of A1 receptors by chronic caffeine exposure.[175,176] Another endogenous neuroprotectant that plays a role after cerebral ischemia, severe TBI, and SAH is HSP-70. HSP-70 optimizes protein folding as a molecular chaperone. It also inhibits proinflammatory signaling.[177] HSP-70 is induced as part of the preconditioning response in brain and has been shown to be increased in both CSF and brain tissue after severe TBI in humans.[178-180] Thus, the brain mounts an important endogenous defense response to TBI. Therapies designed to augment these pathways have not been examined adequately.

SUMMARY

Biochemical, cellular, and molecular mechanisms involved in the evolution of secondary brain injury after global and focal ischemia and TBI have been reviewed with particular attention to clinical studies relevant to neurointensive care. Our understanding of the biochemical, cellular, and molecular responses has progressed, particularly with the application of molecular biology methods to human materials. Future investigation should integrate these findings with bedside physiology and an improved assessment of outcome. Finally, novel imaging and diagnostic methods, particularly MRI, magnetic resonance spectroscopy, and positron emission tomography must be coupled with biochemical and molecular methods to clarify the mechanisms involved in secondary damage and the local effects of novel therapies, including the study of brain pharmacodynamics.

SELECTED BIBLIOGRAPHY

Barone FC, Feuerstein GZ: Inflammatory mediators and stroke: New opportunities for novel therapeutics. J Cereb Blood Flow Metab 1999; 19:819-834.

A superb review article describing the molecular components and temporal sequence of events in the inflammatory cascade that is set into motion in cases of ischemic brain injury.

Bullock R, Zauner A, Woodward JJ, et al: Factors affecting excitatory amino acid release following severe human head injury. J Neurosurg 1998;89:507-518.

A superb clinical report on excitotoxicity that used cerebral microdialysis to assess levels of glutamate in 80 consecutive severely head-injured patients. Four patterns of brain interstitial levels of excitatory amino acids were described, and increases in glutamate were as much as 50 times normal in 30% of the patients. This manuscript raises the important point that mechanisms such as excitotoxicity appear to vary greatly depending on the type of traumatic injury, time after injury, and presence of secondary insults such as hypoxemia or intracranial hypertension.

Clark RS, Kochanek PM, Chen M, et al: Increases in Bcl-2 and cleavage of caspase-1 and caspase-3 in human brain after head injury. FASEB J 1999; 13:813-821.

This is a bench-to-bedside study of a number of key molecular events in cases of secondary damage in human cerebral contusions including activation caspase-1 and caspase-3. These two processes are central to inflammation and programmed cell death. This was the first report of caspase activation in either ischemic or traumatic brain injury in humans.

Povlishock JT: Traumatically induced axonal injury: Pathogenesis and pathobiological implications. Brain Pathol 1992;2:1-12.

This is an outstanding review on the biochemical and molecular events that are involved in the evolution of axonal damage after severe traumatic brain injury. This article discusses the evidence supporting the now accepted concept of secondary axotomy and its consequences.

Siesjo BK: Cell damage in the brain: A speculative synthesis. J Cereb Blood Flow Metab 1981;1:155-185.

Highly quoted classic reference discussing a number of speculative biochemical mechanisms involved in the evolution of secondary damage after cerebral ischemia, epilepsy, and hypoglycemia. Despite being written before the molecular explosion, many of these hypotheses have shown merit as research in this area has progressed over the subsequent 25 years.

Siesjo BK, Katsura K, Zhao Q, et al: Mechanisms of secondary brain damage in global and focal ischemia: A speculative synthesis. J Neurotrauma 1995; 12:943-956.

This is an outstanding review article that contrasts the biochemical and molecular alterations seen in focal versus global cerebral ischemia. The discussion is based on studies done in experimental models but is germane to the clinical conditions of cardiopulmonary arrest and stroke.

Snyder JV, Nemoto EM, Carroll RG, Safar P: Global ischemia in dogs: Intracranial pressures, brain blood flow and metabolism. Stroke 1975;6:21-27.

Experimental animal study that constituted the first description of the development of early postischemic hypoperfusion after complete global cerebral ischemia, a fundamental finding in cardiopulmonary arrest and resuscitation that has withstood the test of time.

Chapter 47
CRITICAL NEUROPATHOPHYSIOLOGY

W. Andrew Kofke

KEY POINTS

1. The contributors to intracranial hypertension are defined by the contents of the brain: brain tissue, cerebrospinal fluid, blood, and masses. Brain tissue becomes important in the presence of edema, cerebrospinal fluid in the presence of hydrocephalus, blood volume in the presence of vasodilating or vasoconstricting conditions, and masses when of an unacceptable size. In clinical practice, physiologic and pharmacologic manipulations have the most impact on blood volume.
2. There are two types of intracranial hypertension, categorized according to cerebral blood flow as hyperemic or oligemic. Abrupt noxious stimuli briefly increase intracranial pressure (ICP) in the setting of decreased intracranial compliance. Such situations are associated with hyperemia, strongly suggesting that brief hyperemic intracranial hypertension is not a dangerous situation. However, it is reasonable to be concerned about such hyperemia related to herniation risk. In contrast, oligemic intracranial hypertension is associated with compromised cerebral perfusion and is clearly deleterious.
3. One category of pressure waves has been identified as plateau waves, which are known to be associated with increased cerebral blood volume (CBV). CBV increases exponentially as perfusion pressure decreases to levels of 80 mm Hg and below. A small decrease in blood pressure produces exponential increases in CBV in a setting of abnormal intracranial compliance with the ICP at the elbow of the ICP-intracranial volume curve.
4. Positive end-expiratory pressure can increase ICP in two ways. The first is through impedance of venous return, increasing cerebral venous pressure and ICP. The second is through decreased blood pressure and reflex increase of CBV increasing ICP.
5. Intracranial pressure can also be influenced by antihypertensive drugs. In general, vasodilator drugs such as nitroprusside, nitroglycerin, and nifedipine can be expected to increase ICP. Conversely, nonvasodilator antihypertensive drugs, generally sympatholytic drugs such as trimethaphan or beta-adrenergic blocking drugs such as esmolol or labetalol, can be expected to have little or no effect on ICP.
6. Temperature management can be critical in neurointensive care. In animal models, hyperthermia has been shown to have deleterious effects on outcome after cerebral ischemia, head trauma, and seizure. Conversely, mild hypothermia (32-36°C) has been shown to be protective.
7. Cerebrovascular reserve is compromised in many intracranial pathologic processes. Normally, the brain compensates for decrements in supply of oxygen and substrates by vasodilating to maintain or increase flow. Clinical examples of attenuated cerebrovascular reserve include cerebral edema, hypoxemia, carotid artery stenosis, peri-infarct penumbra, and anemia. In each of these situations, although not easy to quantitate, it is clear that added situations of compromised O_2 supply to the brain will risk neuronal injury.
8. Hyperglycemia is clearly deleterious in the context of global cerebral ischemia. Clinical studies suggest a deleterious effect in head trauma and stroke. It seems most appropriate to maintain blood glucose levels as close to normal as possible and feasible.
9. Ample laboratory and clinical evidence supports the notion that endogenous and exogenously administered catecholamines can be deleterious with compromised cerebral perfusion.

Neural function is essential to human existence. Thus, loss of any neural element in the course of a critical illness represents a major loss to a given individual. Neurons or supporting elements can be lost in a small, virtually unnoticeable manner, or there can be widespread selective neuronal loss or tissue infarction. Based on the notion that neural function is the essence of acceptable survival from critical illness, it is crucial for critical care management to include considerations of neural viability and the impact and interactions of the primary diseases and therapeutics on the nervous system.

There are numerous clinical scenarios in which a critically ill patient may present with a primary neurologic illness. In a general sense, these scenarios often involve ischemia, trauma, or neuroexcitation. Each of these may include a period of decreased cerebral perfusion pressure (CPP), usually due to elevated intracranial pressure, eventually compromising cerebral blood flow (CBF) sufficiently to produce permanent neuronal loss, infarction, and possibly brain death. In this chapter, I review the physiologic factors and intracranial

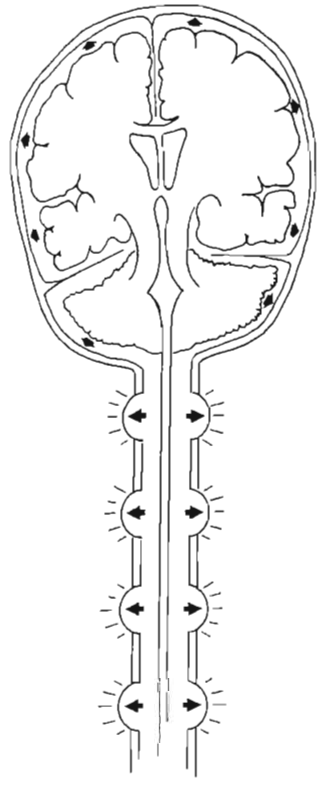

FIGURE 47–1. The brain, spinal cord, and blood are encased in the skull and vertebral canal, thus constituting a nearly incompressible system. System capacitance is thought to be provided via intervertebral spaces. (From Kofke W, et al: Neurologic intensive care. In Albin M [ed]: Textbook of Neuroanesthesia. New York, McGraw-Hill, 1997.)

pressure (ICP) considerations critical to contemporary neurointensive care.

ELEVATED INTRACRANIAL PRESSURE

PHYSIOLOGY

The brain, spinal cord, cerebrospinal fluid (CSF), and blood are encased in the protecting but noncompliant skull and vertebral canal, constituting a nearly incompressible system (Fig. 47-1). In a totally incompressible system, pressure would rise linearly with increased volume. However, there is capacitance in the system, thought to be provided by the intervertebral spaces. Once this capacitance is exhausted, the ICP increases dramatically with increased intracranial volume.

Based on the following relationship:

$$CBF = (MAP - ICP)/CVR,$$

the concern is raised mathematically that increasing ICP is associated with decrements in CBF. However, the effect of increasing ICP on CBF is not straightforward, as mean arterial pressure (MAP) may increase with ICP elevations,[1] and cerebral vascular resistance (CVR) adjusts with decreasing CPP (increasing cerebral vessel diameter) to maintain CBF until maximal vasodilatation occurs.[2,3] This results in an increase in cerebral blood volume (CBV). This is thought to occur at a CPP less than 50 mm Hg, although considerable individual heterogeneity in this value exists. Thus, increasing ICP initially is often associated with vasodilatation and/or increasing MAP to maintain CBF without a nutritive decrement.

Normal ICP is less than 10 mm Hg. ICP greater than 20 mm Hg is generally treated with ICP-reducing agents.[4] However, this is an epidemiologically derived action. Head trauma studies have indicated that patients with ICP greater than 20 mm Hg generally do poorly,[4] although simply elevating ICP to greater than 20 mm Hg (in experimental animals) is not necessarily associated with decrements in CBF or permanent sequelae, provided the above-noted compensatory mechanisms occur.[5]

Nonetheless, increasing ICP due to mass lesions or obstruction of CSF outflow can exhaust compensatory mechanisms with compromise of CBF. Initially, distal runoff of the cerebral circulation increases. As the process continues, the normally continuous (through systole and diastole) cerebral perfusion becomes discontinuous (systolic perfusion only) (Fig. 47-2).[6] Further compromise of CPP results in further oxygen extraction progressing to anaerobic metabolism, exacerbation of edema, and ultimately intracranial circulatory arrest.[6] Thus, when ICP increases, early recognition is important to determine whether a deleterious sequence of events is starting.

CONTRIBUTORS TO INTRACRANIAL HYPERTENSION

Brain. The brain normally occupies about 80% of the contents of the skull, but its volume can be increased by edema. There are two types of edema, cytotoxic and vasogenic, referring to swelling produced by cellular or vascular processes, respectively.[7] Any edema can increase ICP. It can be heterogeneously distributed such that pressure gradients occur, leading to a variety of herniation syndromes.

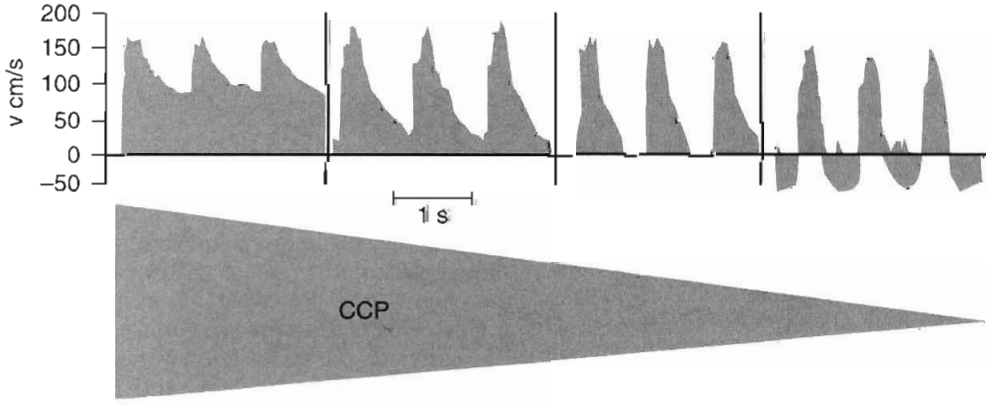

FIGURE 47–2. Progression of transcranial Doppler waveforms with decreasing cerebral perfusion pressure after head injury. Progression is apparent from a normal-appearing transcranial Doppler waveform to intracranial hypertension sufficient to induce intracerebral circulatory arrest. (From Hassler W, Steinmetz H, Gawlowski J: Transcranial Doppler ultrasonography in raised intracranial pressure and in intracranial circulatory arrest. J Neurosurg 1988;68:745.)

Cerebrospinal Fluid. CSF is generated in the choroid plexus and absorbed in the arachnoid villi. An equilibrium normally exists between production and absorption. Disruption of this equilibrium can lead to increased ICP with hydrocephalus, the condition wherein there is an excess of fluid in all or part of the CSF in the brain. Hydrocephalus is generally categorized as communicating or noncommunicating. In communicating hydrocephalus, the CSF circulation between the site of CSF production and absorption is intact. However, abnormally decreased absorption or increased production results in increased CSF accumulation. In noncommunicating hydrocephalus, the pathways are blocked such that CSF cannot circulate to the convexity of the brain to be absorbed. This results in accumulation of CSF in the ventricles, producing distension.[8]

Blood. CBV is an important contributor to variations in ICP, in part due to the wide variations in CBV that can occur with normal physiologic homeostasis and with the effects of drugs and disordered physiology. When CBV increases due to increased CBF, this can produce a dramatic increase in ICP, if intracranial compliance is abnormal. However, unlike ICP elevation due to increased CSF volume, edema, or a tumor, in which decreased CBF is expected, this variety of ICP increase is often produced by increased CBF, making the significance of the ICP elevation unclear. This is discussed later.

Another mechanism of increased CBV occurs with obstruction of venous outflow. This results in brain engorgement and CBV-mediated increased ICP, but without increased CBF.[9]

Masses. The fourth cause of increased ICP is pathologic masses. These can be in the form of hematoma or neoplastic tumors. In both cases, the faster the onset of the mass effect is, the more acute the rise in ICP. Evidently, there are compensatory mechanisms in intracranial compliance that can allow quite large slow-growing masses to arise in the brain without elevated ICP. On the other hand, similarly sized masses, arising acutely, are associated with symptomatic increases in ICP.

TYPES OF INTRACRANIAL HYPERTENSION

There are two types of intracranial hypertension, categorized according to CBF as hyperemic or oligemic (Fig. 47-3). In the normal state, increases in CBF are not associated with increased ICP, because capacitive mechanisms compensate for the CBV-mediated increased intracranial volume. However, in the situation of disturbed intracranial compliance, small increases in intracranial volume produce significant increases in ICP.[2,3]

This suggests an important issue: raised ICP has traditionally been considered to be a concern because it indicates that cerebral perfusion might be jeopardized. It is unclear whether it is appropriate to be concerned about the potential for ICP-induced intracranial oligemia when the cause of the high ICP is intracranial hyperemia with associated increased CBV. There have been no detailed examinations of this question, although there have been some studies that allow reasonable inferences about the significance of hyperemic intracranial hypertension.

For many years it has been known that abrupt noxious stimuli briefly increase ICP in the setting of decreased intracranial compliance. Recent studies have revealed that such situations are associated with hyperemia, strongly suggesting that brief hyperemic intracranial hypertension is not a dangerous situation.[10] However, it is reasonable to be concerned about such hyperemia for three reasons. First, elevated ICP due to hyperemia in one portion of the brain may increase ICP to compromise CBF in other areas of the brain in which CBF is marginal. Secondly, increased pressure in one area of the brain may produce gradients that might lead to a herniation syndrome. Thirdly, there is theoretical concern that inappropriate hyperemia predisposes the brain to worsened edema or hemorrhage as occurs with hyperperfusion syndromes. Thus, hyperemic intracranial hypertension has a theoretical potential to be deleterious, although this has yet to be demonstrated in a systematic fashion. For brief periods, as may occur during intubation or other limited exposure to noxious stimuli, it is suggested (but not proven) that it may not be problematic.[11] An example of this conundrum is illustrated in Figure 47-4.

In contrast, oligemic intracranial hypertension is associated with compromised cerebral perfusion and is clearly deleterious.[6] This is supported by the high mortality rate observed in head trauma patients in whom ICP rises due to brain edema with decrements in CBF.[6,12] Transcranial Doppler echography and CBF studies on these patients have demonstrated that CBF is low and perfusion is discontinuous

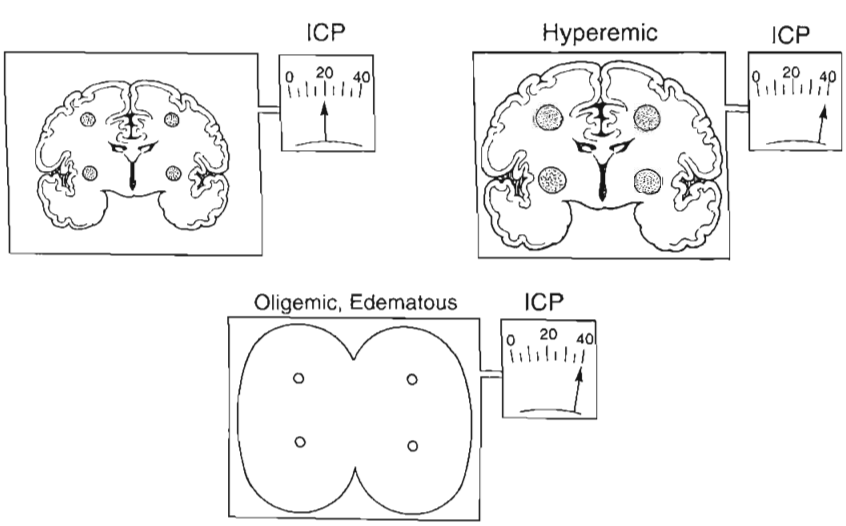

FIGURE 47–3. Two types of intracranial hypertension. From a baseline condition, ICP can increase in two ways. One is via an increase in cerebral blood volume associated with reflex vasodilation due to moderate blood pressure decreases. The second is via malignant brain edema or other expanding masses encroaching on the vascular bed to produce intracranial ischemia. The stippled circles in each coronal brain section represent the cerebral vasculature/blood volume. (From Kofke W, et al: Neurologic intensive care. In Albin M [ed]: Textbook of Neuroanesthesia. New York, McGraw-Hill, 1997.)

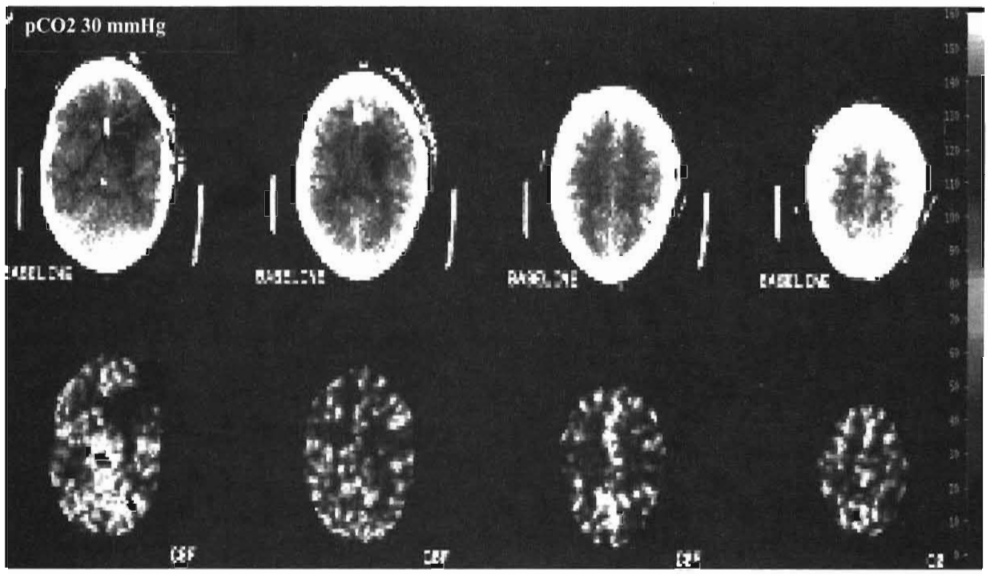

FIGURE 47–4. Computed tomography scans of a head-injury patient with an intracranial pressure (ICP) of 70 mm Hg and $Paco_2$ of 30 mm Hg but diffusely normal to hyperemic cerebral blood flows. (See color section in this text.) (Courtesy of Howard Yonas, University of Pittsburgh.)

during the cardiac cycle (see Fig. 47-2).[6,13] Moreover, jugular venous bulb data indicate that oxygen extraction is markedly increased, suggesting loss of reserve with occurrence of anaerobic metabolism.[13] In this setting, noxious stimuli can further increase the ICP, thus producing the situation of hyperemic, added to oligemic, intracranial hypertension. Presumably, in this setting, the hyperemic rise in ICP acts to further reduce regional CBF in compromised areas with brain edema and may contribute to vasogenic edema.

BLOOD PRESSURE EFFECTS ON INTRACRANIAL PRESSURE: PLATEAU WAVES

Lundberg, in a pioneering 1960 study,[13] monitored ICP in hundreds of patients, identifying characteristic pressure waves. One category of these waves has been identified as *plateau waves*, which are known to be associated with increased CBV (Fig. 47-5).[2] Such waves occur when the ICP abruptly increases to systemic blood pressure levels for about 15 to 30 minutes, occasionally accompanied by neurologic deterioration. Rosner[3] had synthesized the data and convincingly suggests that intracranial blood volume dysautoregulation is responsible for plateau waves. He induced mild head trauma in cats and subsequently intensively monitored the animals after the insult. With normal fluctuations in blood pressure, while in the normal range, he observed that mild blood pressure decrements to a mean of approximately 70 to 80 mm Hg preceded the development of plateau waves (Fig. 47-6). Cerebral blood volume in normally autoregulating brain tissue increases with decreasing blood pressure. However, the increase in CBV is nonlinear. There is an exponential increase in CBV as CPP decreases to levels of 80 mm Hg and below (Fig. 47-7).[3] A small decrease in blood pressure, although in the normotensive range, produces exponential increases in CBV in a setting of abnormal intracranial compliance with the ICP at the elbow of the ICP-intracranial volume curve. Thus, a small decrease in blood pressure introduces an exponential CBV change upon an exponential

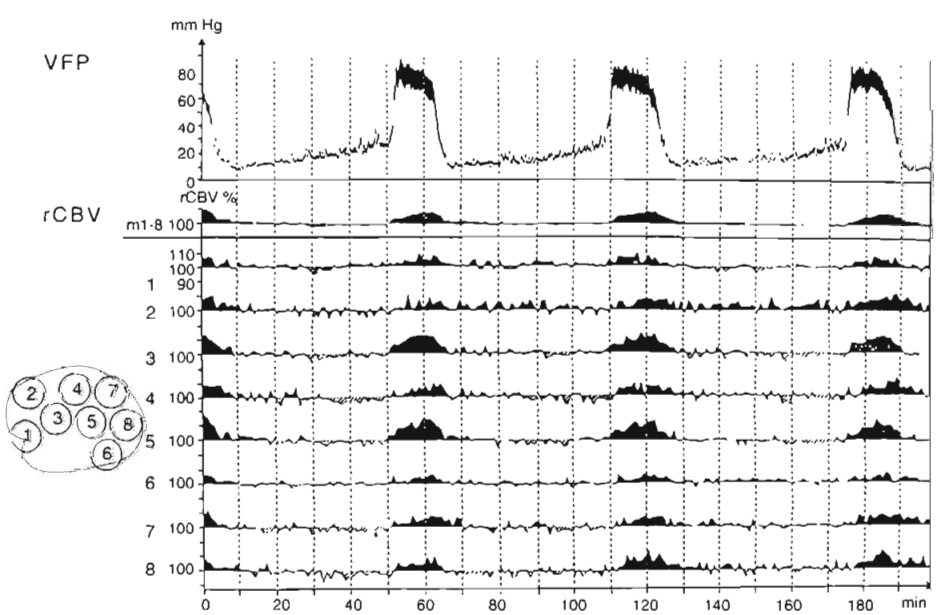

FIGURE 47–5. Plateau waves. Simultaneous recordings of regional cerebral blood volume (rCBV) and ventricular fluid pressure (VFP) during three consecutive plateau waves. The rCBV was measured in eight regions over the left hemisphere. The mean changes in the eight regions are shown in the uppermost curve of the rCBV diagram. Note that the rCBV and VFP curves show a very similar course during the three waves. (From Risberg J, Lundberg N, Ingvar DH: Regional cerebral blood volume during acute transient rises in the intracranial pressure (plateau waves). J Neurosurg 1969;31:303.)

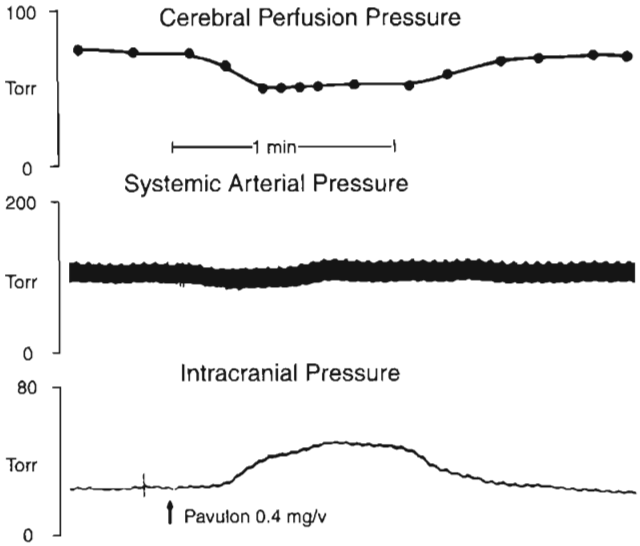

FIGURE 47–6. In an animal head trauma model, a trivial-appearing and transient decrease in systemic arterial blood pressure in the setting of borderline cerebral perfusion pressure precipitates sufficient cerebral vasodilatation to markedly increase the intracranial pressure. Restoration of cerebral perfusion pressure is associated with abolition of the plateau wave. (From Rosner MJ, Becker DP: Origin and evolution of plateau waves: Experimental observations and a theoretical model. J Neurosurg 1984;50:312.)

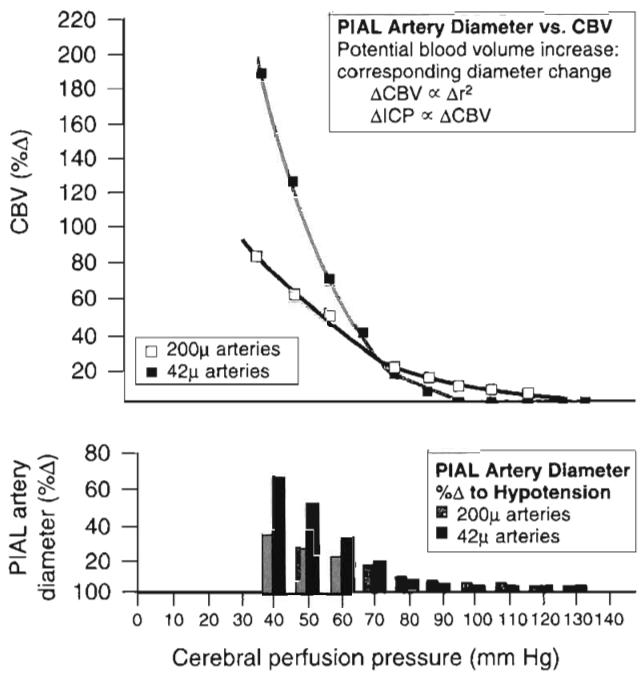

FIGURE 47–7. Cerebral vasodilatation occurs exponentially as cerebral perfusion pressure is reduced. (From Rosner MJ, Becker DP: The etiology of plateau waves: A theoretical model and experimental observations. In Ishii S, Nagai H, Brock M [eds]: Intracranial Pressure V. New York, Springer-Verlag, 1983, p 301.)

ICP relationship such that ICP will increase abruptly and to a significant extent.

Plateau waves spontaneously resolve with a hypertensive response or with hyperventilation that will act to oppose the increase in CBV. Clearly, to develop a plateau wave there must be a portion of the brain with normally reactive vasculature in the presence of other brain areas with a mass effect and raised ICP, a situation of *heterogeneous autoregulation.* In addition to preventing and treating plateau waves, data indicate that it is probably important to maintain MAP in the 80 to 100 mm Hg range in patients with high ICP.

Conversely, hypertension can also increase ICP, with animal models showing increased brain water with dopamine-induced increased blood pressure.[14] Typically, within the normal autoregulatory range, changes in blood pressure have no effect on ICP. However, with brain injury and associated vasoparalysis, blood pressure increases mechanically produce cerebral vasodilatation, increasing ICP (Fig. 47-8).[15]

It appears that both increasing and decreasing blood pressure can increase ICP, suggesting the presence of a CPP optimum for ICP, probably 80 to 100 mm Hg, although this has not been definitively determined experimentally (Figs. 47-9 and 47-10).

POSITIVE END-EXPIRATORY PRESSURE AND INTRACRANIAL HYPERTENSION

Positive end-expiratory pressure (PEEP) can increase ICP in two ways. The first is through impedance of venous return, increasing cerebral venous pressure and ICP. The second is through decreased blood pressure and reflex increase of CBV, increasing ICP (Fig. 47-11). The latter is likely the most

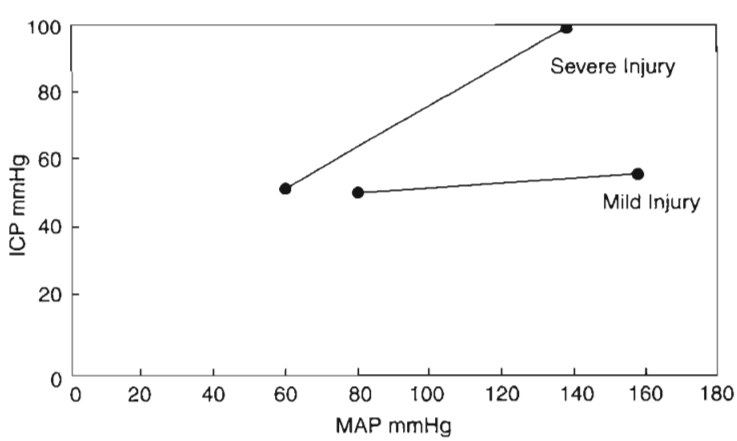

FIGURE 47–8. Blood pressure changes within the normal autoregulatory range have no effect on intracranial pressure (ICP). However, with brain injury, increases in mean arterial pressure (MAP) produce increases in ICP with this effect more pronounced with more severe injury. Presumably, this effect is due to distention of vasoparalyzed blood vessels with a consequent increase in cerebral blood volume. (From Kofke W, et al: Neurologic intensive care. In Albin M [ed]: Textbook of Neuroanesthesia. New York, McGraw-Hill, 1997.)

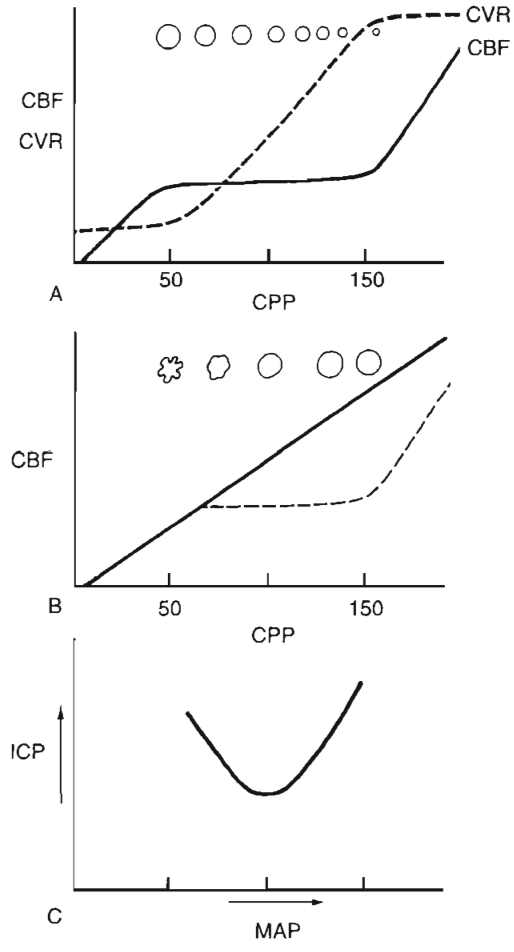

FIGURE 47–9. Cerebral perfusion pressure (CPP) versus cerebral blood flow (CBF) and cerebrovascular resistance (CVR). (**A**) Blood flow is normally maintained constant through changes in CVR, depicted as changes in vascular diameter (and therefore cerebral blood volume [CBV]) in the figure. CBV varies inversely with CPP. (**B**) With vasoparalysis due to injury, CVR does not change with CPP variations, such that CBF and CBV vary directly with CPP. (**C**) In the situation of decreased intracranial compliance, both of the factors illustrated in parts **A** and **B** may interact to increase ICP. Normally autoregulating tissue as in part **A** will predispose to CBV-mediated ICP elevation with decreasing blood pressure, whereas vasoparalyzed tissue (**B**) will predispose to CBV-mediated ICP elevations with increasing blood pressure, leading to the notion of an ICP optima (probably approximately 80 to 100 mm Hg) with varying CPP. (From Kofke W, et al: Neurologic Intensive Care. In Albin M [ed]: Textbook of Neuroanesthesia. New York, McGraw-Hill, 1997.)

common mechanism, as Huseby's data[16] suggest that cerebral venous effects only occur with very high PEEP.

Shapiro and colleagues[17] demonstrated increases in ICP in head-injured humans during intracranial hypertension with application of PEEP (Fig. 47-12). Examination of their data suggests that the most profound decreases in CPP occurred in patients with PEEP-induced decrements in MAP. This is consistent with the notion put forth by Rosner[3] that decreases in blood pressure increase CBV and ICP. Aidinis and colleagues,[18] in studies on cats, confirmed these observations in a more controlled setting. In addition, they assessed the role of pulmonary compliance, finding that decreased pulmonary compliance induced by oleic acid injections results in less effect of PEEP to increase ICP. In situations in which PEEP is likely to be needed, with decrements in pulmonary compliance, such observations indicate that any adverse effects on ICP are less likely to be manifest. This may be related to observations that hemodynamic effects of PEEP are less apparent with noncompliant lungs,[18,19] such that hypotensive-mediated increases in CBV do not occur.

The intuitive notion that PEEP increases cerebral venous pressure to increase ICP is not as straightforward as it initially may seem. For PEEP to increase cerebral venous pressure to levels that will increase ICP, the cerebral venous pressure must at least equal the ICP. Thus, the higher the ICP, the higher PEEP must be to have such a direct hydraulic effect on ICP. This concept was nicely proved by Huseby and colleagues[16] in dog studies in which PEEP was increased progressively with different starting levels of ICP (Fig. 47-13). It is important to note that they prevented PEEP-induced decrements in blood pressure, thus avoiding any reflex increases in cerebral blood volume. They suggested a hydraulic model to better conceptualize this (Fig. 47-14). For example, if all of a 10 cm H_2O PEEP application were transmitted to the cerebral vasculature, which is unlikely given the decreased pulmonary compliance associated with the need for such PEEP, ICP will only be affected if it is less than 10 cm H_2O (7.7 mm Hg), increasing to a level no higher than the applied PEEP. This presupposes no PEEP-induced arterial pressure decrement.

ANTIHYPERTENSIVE THERAPY EFFECTS ON INTRACRANIAL PRESSURE

Intracranial pressure can also be influenced by antihypertensive drugs. In general, vasodilator drugs such as nitroprusside,[20-22] nitroglycerin,[23] and nifedipine[24] can be expected to increase

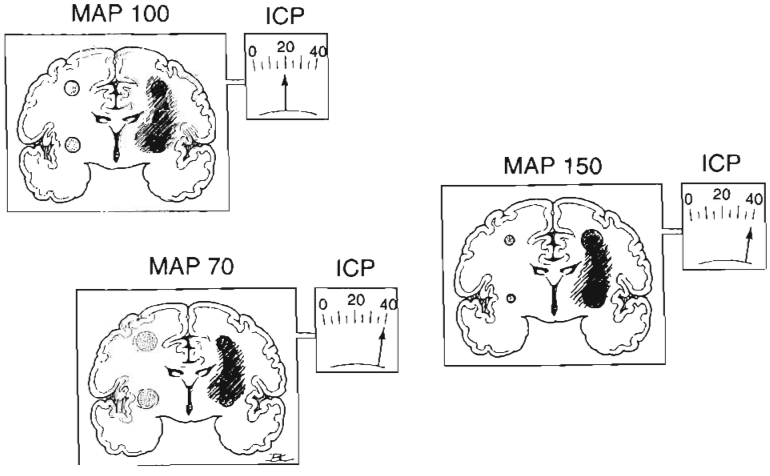

FIGURE 47–10. In the setting of heterogeneous autoregulation in the brain, conditions may predispose to cerebral blood volume (CBV)–mediated increases in intracranial pressure (ICP) with both increases or decreases in blood pressure. The stippled circles in each coronal brain section represent the cerebral vasculature/blood volume.

Low PEEP → ↓CO → ↓BP → ↑CBV → ↑ICP

High PEEP → ↑CVP → ↑P_{SS} > ICP → ↑ICP

FIGURE 47–11. Two mechanisms of positive end-expiratory pressure (PEEP)–mediated increases in intracranial pressure (ICP). The addition of PEEP decreases cardiac output (CO) and blood pressure (BP), leading to a reflex increase in cerebral blood volume (CBV). If cerebral perfusion pressure is marginal with heterogeneous autoregulation, this can lead to further increases in ICP. Conversely, to increase sagittal sinus pressure to an extent sufficient to further increase ICP, which is already elevated, PEEP levels at or greater than the ICP must be applied. Pss, sagittal sinus pressure.

ICP. Conversely, nonvasodilator antihypertensive drugs, generally sympatholytic drugs such as trimethaphan, or beta-adrenergic blocking drugs such as esmolol or labetalol,[25] can be expected to have little or no effect on ICP. These observations suggest that the rise in ICP due to vasodilators is caused by increased CBF with attendant increase in CBV. The increase in ICP thus does not threaten ischemia, although herniation and hyperperfusion syndromes may occur and might be problematic. There has been a report of neurologic deterioration with nitroprusside use despite no change in blood pressure.[22] Another consideration in the use of vasodilators is the propensity to reflexively increase plasma catecholamines.[26] Such increases in plasma catecholamines may be deleterious to the marginally perfused injured brain.[27-29]

HYPERPERFUSION SYNDROMES

In a variety of clinical situations, CBF may be inappropriately increased for a given blood pressure. In the extreme case of such situations, vasoparalysis is present and CBF becomes more or less a linear function of blood pressure. Such hyperperfusion syndromes may occur early in cases of severe hepatic encephalopathy,[30] 2 to 3 days after severe head injury,[13] after resection of large arteriovenous malformations (AVMs),[31-33] after carotid endarterectomy of severely stenotic lesions with poor collaterals,[34] probably after cerebral arterial thrombolysis,

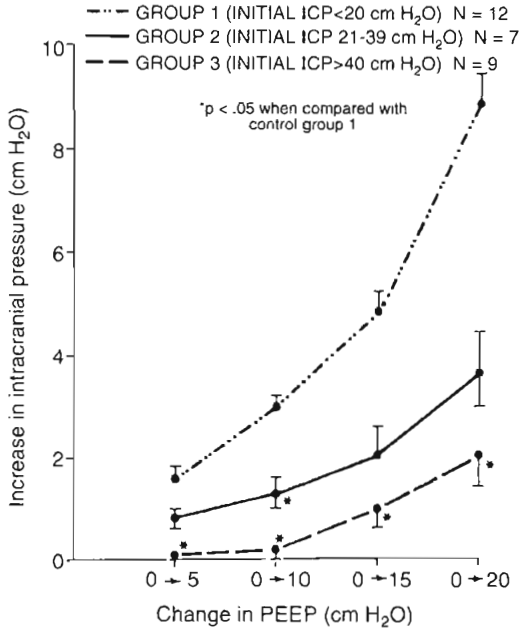

FIGURE 47–13. Increases in intracranial pressure (ICP) with positive end-expiratory pressure (PEEP) in dogs. Values are mean ± standard error of the mean. Group 1 included 12 animals with initial ICP less than 20 cm H_2O; group 2 included seven animals with initial ICP of 21 to 39 cm H_2O; group 3 included nine animals with initial ICP greater than 40 cm H_2O. Blood pressure was maintained constant in all animals. Note that with blood pressure maintained constant, the most significant increases in PEEP occur in the animals with the lowest starting PEEP level. (From Huseby JS, Luce JM, Cary JM, et al: Effects of positive end-expiratory pressure on intracranial pressure in dogs with intracranial hypertension. J Neurosurg 1981;55:704.)

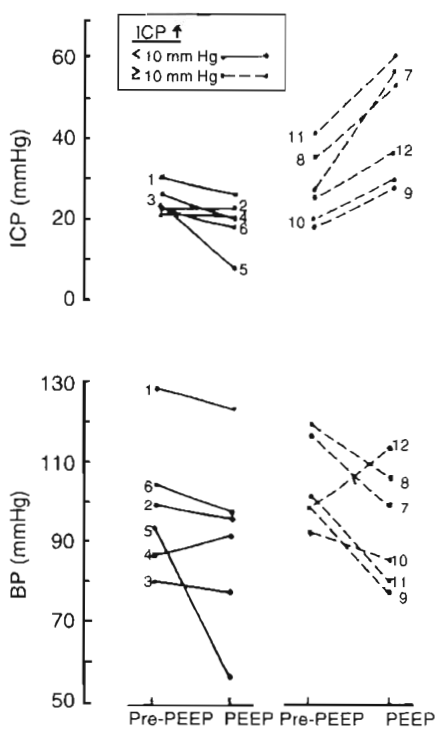

FIGURE 47–12. Intracranial pressure (ICP) and arterial blood pressure (BP) before and with the application of positive end-expiratory pressure (PEEP) (4-8 cm H_2O) in severely head-injured patients. The patients are arbitrarily divided into two groups: those with an ICP increase of 10 mm Hg or greater and those with ICP gains below 10 mm Hg. Note that PEEP-induced blood pressure decreases appear to be more marked in patients sustaining larger ICP increases. (From Shapiro HM, Marshall LF: Intracranial pressure responses to PEEP in head-injured patients. J Trauma 1978;18:254.)

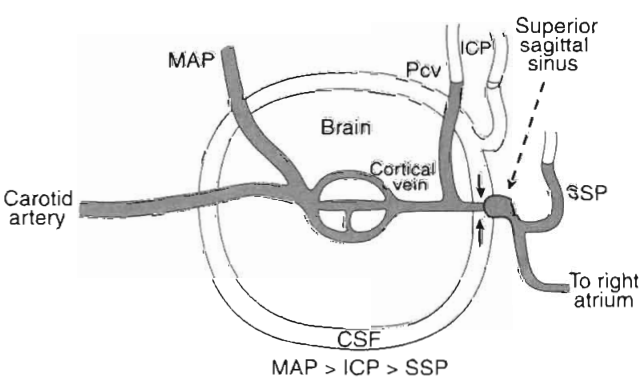

FIGURE 47–14. Schematic illustration of the intracranial space during raised intracranial pressure (ICP). The arrows indicate the position of the hypothesized Starling resistor. Here, the mean arterial pressure (MAP) is greater than ICP, which is greater than sagittal sinus pressure (SSP). Cortical vein pressure (Pcv) cannot fall below ICP, and thus flow is dependent on MAP minus ICP and independent of small changes in SSP. (From Huseby JS, Luce JM, Cary JM, et al: Effects of positive end-expiratory pressure on intracranial pressure in dogs with intracranial hypertension. J Neurosurg 1981;55:704.)

and possibly during administration of cerebral vasodilators at high systemic blood pressure.

Fulminant hepatic failure produces widespread physiologic changes, including altered cerebral physiology.[30] Aggarwal and coworkers[30] systematically examined cerebral hemodynamics and metabolism in severe hepatic encephalopathy and during recovery after hepatic transplantation. They have identified phases that are traversed in the course of going from normal cerebral physiology to brain death. Patients initially demonstrate elevated CBF at normotension. This is usually followed by hyperemic (high CBF and/or CBV) intracranial hypertension, then edema with oligemic intracranial hypertension, and finally intracranial circulatory arrest and brain death. The data clearly suggest that the hyperemia may be deleterious, possibly contributing to the development of subsequent cerebral edema. This is supported by observations that the cerebral edema seems to be prevented through the use of barbiturates and hyperventilation during the hyperemic phase.

Several investigators, in the course of examining cerebrovascular physiology after head trauma, have observed that patients with severe head injury initially have normal or low CBF. This is followed a few days later by increased CBF, which is associated with intracranial hypertension.[12] This may contribute to subsequent oligemic intracranial hypertension.

The concept of normal perfusion pressure breakthrough indicates hyperperfusion at normal blood pressure, such as after resection of a large AVM, when the remaining blood vessels lack the ability to constrict normally and regulate blood flow, resulting in abnormally high regional CBF. The pathogenesis is thought to be related to chronic arterial hypotension proximal to the AVM. The larger the AVM, the lower the intracranial blood pressure to which the patient is acclimated (i.e., the cerebral vasculature locally down-regulates the CBF-MAP autoregulatory relationship). Removing the AVM abruptly exposes the cerebral arterial vessels and arterioles to pressure never before experienced.[32] Thus, despite the blood pressure being within normal limits, the pressure-naive vasculature is unable to autoregulate and the physiology of malignant hypertension may ensue to cause cerebral edema and/or hemorrhage. This is an attractive hypothesis that makes physiologic sense. However, Young and coworkers[33] report that autoregulation of the vascular bed after AVM resection is generally intact, indicating that vasoparalysis due to chronic hypotension may not be the most important contributor to normal perfusion pressure breakthrough.

One cause of neurologic deterioration after carotid endarterectomy is cerebral edema and/or hemorrhage. This is rather unusual, but the presence postoperatively of a unilateral throbbing headache suggests that it may be present. Blood flow studies reveal such patients to have cerebral hyperemia associated with removal of a large proximal obstruction. While normotension is usually well tolerated, hypertension probably increases the risk of hemorrhage, especially if there was a preoperative cerebral infarction. Similar to the AVM situation, described earlier, vasculature that has acclimated to low proximal pressure now is presented with arterial pressure that is much higher, although within the epidemiologic norm.[34]

After thrombolysis of a cerebral artery, one important source of morbidity is edema or hemorrhage of the reperfused territory. With reperfusion of the ischemic tissue, hyperemia occurs for a period of time. If sustained, this suggests that irreversible endothelial damage has occurred and that the patient is at risk for secondary edema or hemorrhage, particularly if the depth of ischemia is sufficient to produce early changes on a computed tomography scan.[35]

Vasodilators such as nitroprusside are frequently used in patients with severe arterial hypertension. When CBF is measured, it is noted that nitroprusside has minimal CBF effect with induced hypotension.[36] However, data are not available on its CBF-CBV effects with treatment of hypertension. Such vasodilators are known to cause an increase in ICP,[22,37] suggesting an element of cerebral hyperemia. This is supported by reports of cerebral dysautoregulation induced by nitroprusside.[38] This ICP elevation and hyperemia[36,39] appear to decrease as blood pressure is lowered. This notion is supported by observations during neurosurgery with cerebral swelling present when nitroprusside is administered.[40] With its use for induced hypotension during neurosurgery, the brain is noted to be flaccid with no hyperemia evident. Thus, cerebral vasodilators can produce a cerebral dysautoregulation/hyperperfusion syndrome, the extent of which is likely dependent on blood pressure. Their use has not yet been reported to be associated with exacerbation of cerebral edema/hemorrhage.

All of the above syndromes describe a clinical course in humans consisting of inappropriate hyperemia for a given blood pressure followed by cerebral edema or hemorrhage. This suggests that the failure to autoregulate at normal pressure results in exposure of arterioles and capillaries to unacceptably high pressure. This then results in disruption of the blood-brain barrier with consequent transudation of fluid or frank bleeding.

HYPERTHERMIA

Temperature management can be critical in neurointensive care. In animal models, hyperthermia has been shown to have deleterious effects on outcome after cerebral ischemia,[41] head trauma,[41] and seizure.[42] Conversely, mild hypothermia has been shown to be protective.[43] It is of interest that the extent of hypothermia required to produce protection is modest (32-36°C). The extent of protection is not adequately explained by reduction in cerebral metabolic rate,[44] suggesting that hypothermia has additional beneficial effects, such as decreased free radical production or reduction in neurotransmitter neurotoxicity.[45]

Preliminary reports from a multicenter trial of head trauma indicate that moderate hypothermia confers cerebral protection when applied within 6 hours of insult and maintained for 24 to 48 hours.[43] This observation was not confirmed in a subsequent multi-institutional trial, although head-injured patients who presented with hypothermia had a better outcome.[46] In addition, two recent reports of hypothermia after cardiac arrest provide strong support for the notion that mild hypothermia is protective after cerebral ischemia.[47,48] Based on these reports, the American Heart Association has adopted hypothermia as a recommended therapy after resuscitation from cardiopulmonary arrest.[49]

Further complicating the role of hypothermia, however, are the recent results of the IHAST2 trial showing no protection from mild hypothermia during cerebral aneurysm surgery.

GAS EXCHANGE

Cerebrovascular reserve is compromised in many intracranial pathologic processes. Normally, the brain compensates for

decrements in supply of oxygen and substrates by vasodilating to maintain or increase flow.[50] Animal experiments indicate that it is possible to produce a condition in which cerebrovascular reserve is compromised with increased tendency to cerebral infarction. For example, occlusion of one carotid artery or inducing moderate hypoxemia does not produce symptoms as cerebral vasodilatation occurs to compensate. Indeed, some investigators contend that arterial hypoxemia occurring with normal cerebral vascular compensatory mechanisms does not cause brain damage. Of course, one contributing factor to this notion is that hypoxic myocardial dysfunction produces circulatory collapse and death such that isolated post-hypoxic (without ischemia) neuronal injury cannot occur. However, if hypoxemia is added to carotid occlusion, or vice versa, a stroke can occur because compensatory mechanisms, already fully utilized, cannot accommodate the further decrease in oxygen supply.[51,52] Examples of variants of this situation abound clinically.[53] Such examples of attenuated cerebrovascular reserve include cerebral edema, hypoxemia, carotid artery stenosis, peri-infarct penumbra, and anemia. In each of these situations, although not easy to quantitate, it is clear that added situations of compromised oxygen supply to the brain will risk neuronal injury.

Changes in $Paco_2$ have a profound impact on CBF. Normally, CBF varies linearly with $Paco_2$ between 20 and 60 mm Hg.[53] $Paco_2$-mediated changes in CBF occur with corresponding changes in CBV. Thus, in situations of abnormal intracranial compliance in which small changes in intracranial volume have large ICP effects, decreasing $Paco_2$ reduces ICP and increasing $Paco_2$ raises ICP.

The primary concern with raised ICP is that it may be associated with cerebral oligemia. Thus, these effects of $Paco_2$ on ICP are paradoxical. That is, decreasing $Paco_2$ reduces ICP, but at the expense of CBF (Fig. 47-15).[54] Minhas and colleagues[55] report that mild hyperventilation in brain-injured patients produces dangerous perilesional CBF decrements. However, Gupta and colleagues,[56] using tissue measures of brain-injured humans, reported sequential increases in $Ptio_2$ with decreasing $Paco_2$ with an optimum at 26 to 30 mm Hg. Nonetheless, data from head trauma studies indicate that routine use of hyperventilation can worsen outcome.[57] Conversely, allowing hypercapnia to occur, although leading to increased ICP, is associated with increased CBF. These observations pertain to normally autoregulating tissue. The CBF effects in injured brain tissue can be unpredictable. For example, allowing $Paco_2$ to increase CBF in autoregulating brain areas, by increasing ICP, may compromise flow in other injured, already fully vasodilated regions.

Related to these concerns is the growing practice of permissive hypercapnia in some types of respiratory failure, performed to reduce the risk of ventilator-mediated lung injury. Reports are somewhat conflicting regarding its safety in the brain-injured patient. In a non-trauma porcine model, van Huls and colleagues[58] found that hypercapnia to 90 mm Hg increased tissue po_2 while increasing ICP from 20 to 30 mm Hg. Their data and those of others suggest no harmful effects in the noninjured brain, but, theoretically, it seems this hyperemic elevation still might introduce a risk of hyperemia-mediated herniation. A recent report by Tasker and Peters,[59] however, suggests that the negative hyperemic effects associated with hypercapnia resolve over a day or so such that the pulmonary benefits of the hypercapnia can be gained as the adverse neurologic effects subside. This does raise the possibility of an unacceptable respiratory alkalosis on cessation of the permissive hypercapnia. Moreover, in neonates, hypercapnia increases CBF[60] that may lead to cerebral edema, increased ICP, and intraventricular hemorrhage.[61-64] Concerns are also raised by a pediatric case report of nonaneurysmal subarachnoid hemorrhage associated with and seemingly caused by permissive hypercapnia.[65]

The possibility of a neuroprotective effect of respiratory acidosis has also been reported.[66] Brain homogenates develop far fewer free radicals and less lipid peroxidation when pH is lowered by carbon dioxide than when it is lowered by hydrochloric acid,[67] and greater inhibition of tissue lactate production occurs when lowered pH is due to carbon dioxide than when it is due to hydrochloric acid.[68] Vanucci and collegues[69] report a protective effect of modest hypercapnia in an in vivo model of neuronal hypoxia. In trauma patients with multiple organ dysfunction, Gentiello and colleagues[70] found permissive hypercapnia to increase ICP but adjusted the level of hypercapnia if ICP rises occurred. Similar problematic ICP

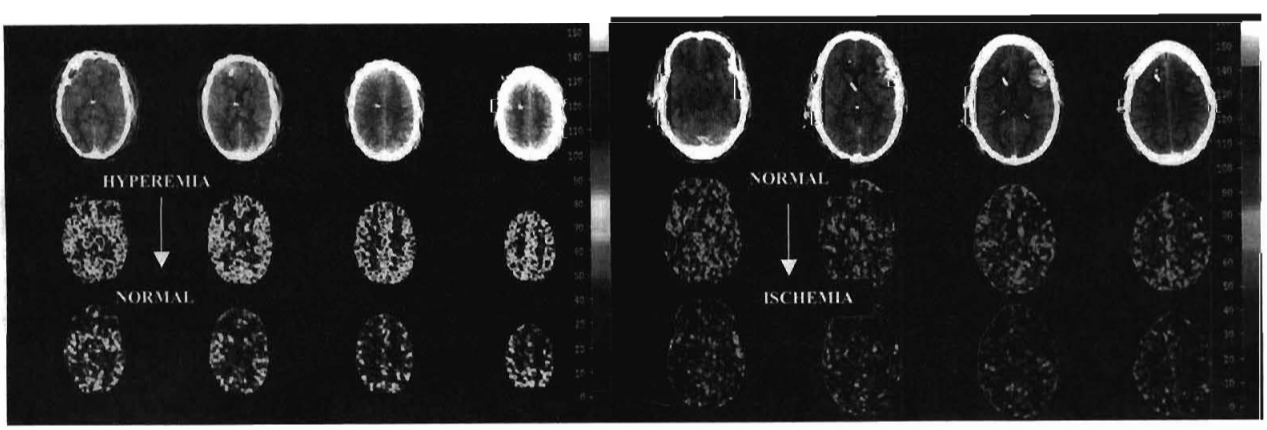

FIGURE 47–15. Effects of $Paco_2$ changes on cerebral blood flow (CBF). Two examples of disparate effects of hyperventilation on CBF. Both figures are stable xenon CBF scans in head trauma patients with and without hyperventilation. CBF scale is indicated on the right in mL/100 g/min and Pco_2 is indicated above each study. Computed tomography images are indicated in the upper figures and CBF maps in the lower figures. In the left figure, $Paco_2$ was decreased from 40 to 30 mm Hg. The baseline scan shows hyperemia and the hyperventilated scan shows CBFs of approximately 60 to 70 mL/100 g/min, probably acceptable flows. In the right figure, $Paco_2$ was decreased from 38 to 30 mm Hg. The baseline CBFs were acceptable. The effect of this modest extent of hyperventilation was to produce widespread areas of CBF less than 20 mL/100 g/min, probably unacceptable flows. (See color section in this text.) (Courtesy of Howard Yonas, University of Pittsburgh.)

increases were also observed in two head-injured patients by Levy and colleagues,[71] which they managed through the use of tracheal gas insufflation, which may be a compromise solution in this conundrum of conflicting physiology and no outcome data. In summary, the data are not conclusive regarding the safety of permissive hypercapnia in the presence of brain injury. It seems that the optimal approach would be to cautiously apply it and adjust according to the ICP response. If unacceptable ICP elevations arise, then the options would include abandoning permissive hypercapnia, treating the ICP to allow normalization of the CBF response to the CO_2 elevation over a few days, and possibly adding tracheal insufflation to the ventilator strategy.

HYPERGLYCEMIA

Hyperglycemia has been associated with exacerbation of brain damage with both head trauma and cerebral ischemia,[72-74] but it is not a straightforward issue. Clearly, neuronal damage after global cerebral ischemia is exacerbated by hyperglycemia.[75] Some studies have suggested that a blood glucose level over 120 mg% is deleterious in stroke patients.[72] However, subsequent studies with subhuman primates subjected to global ischemia have suggested a threshold of around 180 mg%.[58] Clearly, a blood glucose concentration greater than 400 mg% causes striking worsening of neurologic outcome with global ischemia.[73,76]

With focal cerebral ischemia, the situation is less clear. There have been animal and human studies showing that brain damage is worsened, not affected, or lessened with hyperglycemia.[77-81] One report by Prado and colleagues[81] in rats suggested that the discriminating factor regarding worsened brain damage with hyperglycemia is whether there is collateral flow. Areas of the brain with minimal or absent collateral vessels were not affected or were improved with hyperglycemia. Brain areas with a continued trickle of flow sustained worse damage. Presumably, the continued substrate supply in oligemic (not ischemic) areas allowed greater accumulation of organic acids in the cells, leading to worsening brain damage.[77,82] Unfortunately, these observations are difficult to apply clinically to individual patients with focal ischemia.

Hyperglycemia has not been shown to have either deleterious or protective effects in two animal models of status epilepticus.[83,84] The model used in Swan's report[84] produced limbic system damage, whereas Kofke and colleagues[83] used a model producing substantia nigra damage. Seizure-induced nigral damage in rats is associated with hypermetabolic lactic acidosis,[85] which was not exacerbated with hyperglycemia. The fact that nigral damage was not exacerbated with hyperglycemia suggests that metabolic acidosis may not be the sole factor in the development of brain damage after seizure.

SEPSIS

Sepsis is known, in animal models, to decrease CBF while increasing cerebral metabolic rate and disrupting the blood-brain barrier.[86] In addition, it can decrease blood pressure in a manner that may not be well tolerated by the brain with abnormal cerebrovascular reserve. Sepsis-induced decreases in blood pressure can turn an area of cerebral oligemia into an area of ischemic cerebral infarction; however, specific study of this is limited.

SODIUM

Hypernatremia. Hypernatremia can occur in neurologic intensive care unit patients because of nonketotic diabetic coma, dehydration from lack of fluid intake or diuretic use, hypertonic fluid administration, diabetes insipidus, or panhypopituitarism.[87] It can be associated with thirst, irritability, seizures, intracranial hemorrhage, or coma, although the rate of increase in sodium concentration is thought to be an important factor in the clinical presentation. For example, a sodium level of 170 mEq/L can be associated with little neurologic symptomatology if the rise occurs over a prolonged period. Indeed, hypertonic saline is occasionally used as a primary therapy for raised ICP,[88,89] in which case the elevation in sodium should be considered desirable, with desirable ICP, vasoregulatory, and neurochemical effects. Moreover, treating it could precipitate a rebound increase in ICP.

Diabetes insipidus can occur when disease processes affect the pituitary gland or its vascular supply. It should be suspected when urine output is inappropriately increased. Typically, urine output can increase abruptly to greater than 1 L per hour and be associated with severe hypernatremia and hypovolemic hypotension. Diagnosis of diabetes insipidus is based on continued output of dilute urine in the context of hypertonic serum. The specific gravity of urine will be close to 1.001 with osmolarity less than 200 mOsm/L despite serum osmolarity that may be greater than 320 mOsm/L.[90]

Hyponatremia. Hyponatremia can occur because of the syndrome of inappropriate secretion of antidiuretic hormone, so-called cerebral salt wasting, or excessive free water administration. Syndrome of inappropriate secretion of antidiuretic hormone is generally associated with hypervolemia and cerebral salt wasting with hypovolemia. Both syndromes can be associated with elevated urinary sodium concentrations, making differentiation between the two syndromes difficult in routine clinical practice.[91] Rapidly increasing the sodium concentration can produce permanent neurologic damage due to central pontine myelinolysis.[92] When the sodium level achieved with such overcorrection is extreme (i.e., 168 to 195 mMol/L), then extrapontine myelinolysis has also been reported.[93]

CATECHOLAMINES

Subarachnoid hemorrhage (SAH) is an entity particularly notable for catecholamine effects, some of which are described elsewhere in this book. However, catecholamine effects also occur with increased ICP, stroke, head trauma, or any situation of compromised midbrain-hindbrain oxygen delivery.

Serum catecholamine levels increase dramatically after SAH, notably peaking at the same time as the peak incidence of post-SAH vasospasm with symptom development corresponding to serum catecholamine levels.[94-98] This leads to the notion that hypothalamic injury with excess catecholamine release may be an important factor in the genesis of post-SAH spasm and stroke.[95] Several lines of evidence further support this hypothesis:

1. The cerebral vasculature is invested somewhat with adrenergic nerves. With SAH, the adrenergic receptors in the cerebral vessels decrease in quantity.[98,99] This suggests that denervation hypersensitivity may be occurring such that the increase in humoral catecholamines with SAH produces spasm in hyperreacting vessels.

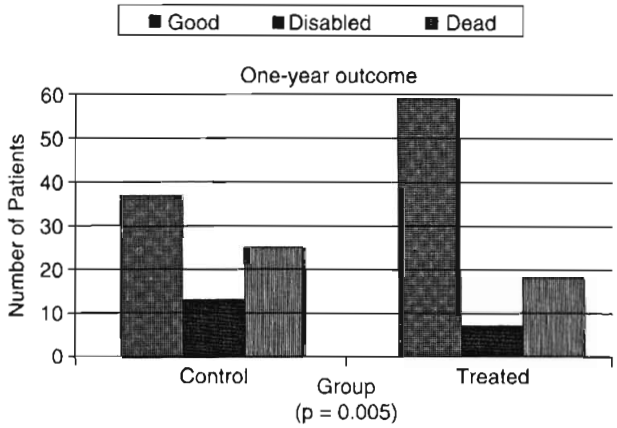

FIGURE 47–16. Subarachnoid hemorrhage patients were randomly treated with propranolol or placebo. Neurologic outcome was better in patients undergoing beta-blockade. (Data from Neil-Dwyer G, Walter P, Cruickshank JM: Beta-blockade benefits patients following a subarachnoid hemorrhage. Eur J Clin Pharmacol 1985;28[suppl]:25.)

2. Catecholamine release after SAH is sufficient to produce electrocardiographic changes[94,96,100,101] with ventricular wall motion abnormalities[102] and myocardial injury.[103,104]
3. Treatment of humans with SAH with beta- and alpha-adrenergic antagonists is associated with an improvement in neurologic outcome (Fig. 47-16)[28] and electrocardiographic abnormalities.[101]
4. In animal models, selective destruction of hindbrain adrenergic nuclei with cephalad projections prevents the development of vasospasm.[104] Moreover, laboratory studies indicate an important role for vasopressin in cases of vasospasm, because vasospasm cannot be produced in vasopressin-deficient rats.[105]
5. Studies in cerebral ischemia models provide strong support for the notion that catecholamines can exacerbate ischemic injury. Compared with hemorrhage-induced hypotension, ischemic damage was decreased with hypotension induced through the use of ganglionic blockade with hexamethonium,[27] central adrenergic blockade with alpha-2 agonists,[29] and angiotensin converting enzyme inhibition.[106] Hemorrhaged control rats were noted to sustain an increase in exogenous catecholamine concentrations. To test the hypothesis that these catecholamines contributed to brain damage, some of the animals treated with hexamethonium also received intravenous catecholamine infusions. Reversal of the hexamethonium brain protective effect was observed in these animals (Fig. 47-17).[27]
6. Brain protection has been observed in laboratory studies with preischemic[107] and preseizure[108] treatment using reserpine, a drug that depletes presynaptic catecholamine stores.
7. Application of catecholamines directly to nonischemic cortical tissue has also been observed to have neurotoxic potential.[109] In addition, intravenous administration can exacerbate brain swelling after head trauma, although this is most likely a direct effect of blood pressure on a dysautoregulating brain (see Fig. 47-8) rather than a manifestation of biochemical neurotoxicity.[14]

SUMMARY

Brain damage can arise from a variety of seemingly disparate neurologic disease states. Such conditions, discussed in subsequent chapters, include ischemia, seizures, trauma, or other adverse processes. Raised ICP typically occurs as these types of conditions progress. When episodes of intracranial hypertension occur, it is important to distinguish hyperemic (with high CBV) from oligemic causes. Any brain injury is significantly impaired by the extracranial environment. Such extracranial factors include temperature, gas exchange, glucose, sepsis, sodium, and catecholamines. Optimal physiology-guided therapy is essential to optimize outcomes in neurointensive care.

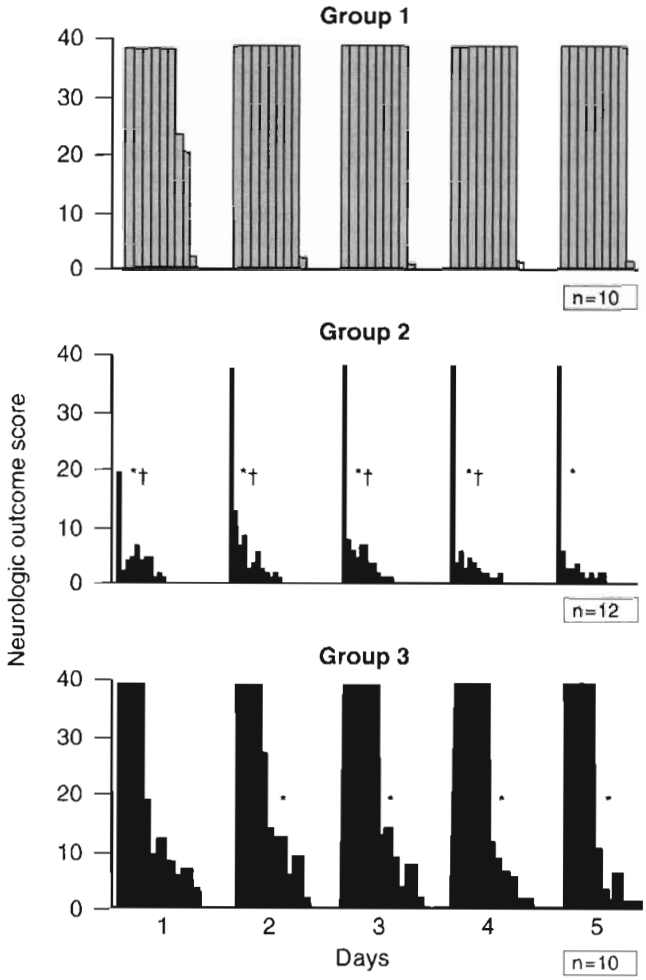

FIGURE 47–17. Neurologic deficit scores after incomplete focal cerebral ischemia in rats over a 5-day examination period. Each bar represents the neurologic score for each rat (*$P < .05$ vs. group 1; †$P < .05$ vs. group 3). The rats are ranked according to total outcome score in descending order (0 = normal). Cerebral ischemia was induced with occlusion of one carotid artery with hemorrhagic hypotension. Group 1 rats received no vasoactive drugs; group 2 rats received preischemic hexamethonium; and group 3 rats received hexamethonium plus intravenous epinephrine and norepinephrine. Protection was conferred by hexamethonium in a catecholamine-reversible manner. (From Werner C, Hoffman WE, Thomas C, et al: Ganglionic blockade improves neurologic outcome from incomplete ischemia in rats: Partial reversal by exogenous catecholamines. Anesthesiology 1990;73:923.)

ANNOTATED REFERENCES

Huseby JS, Luce JM, Cary JM, et al: Effects of positive end-expiratory pressure on intracranial pressure in dogs with intracranial hypertension. J Neurosurg 1981;55:704.

This study in dogs identified the role of hydraulic issues in the genesis of PEEP-induced increases, or lack of increases, in the presence of varying

levels of ICP. The authors nicely showed, while maintaining MAP constant, that the higher the ICP was, the less likely it was for PEEP to increase sagittal sinus pressure to an extent sufficient to increase ICP.

Levine S: Anoxic-ischemic encephalopathy in rats. Am J Pathol 1960;36:1.
This article demonstrated the importance of cerebrovascular reserve. Rodents exposed to either hypoxia or carotid ligation sustained no deficits. However, induction of both insults reproducibly caused a stroke.

Lundberg N: Continuous recording and control of ventricular fluid pressure in neurosurgical practice. Acta Psychiatr Neurol Scand 1960;36(suppl 149):1.
This is the original paper, now a classic, describing plateau waves in a large number of patients. Lundberg placed ICP monitors in patients with nontraumatic intracranial hypertension and recorded his observations, identifying three types of plateau waves.

Neil-Dwyer G, Walter P, Cruickshank JM: Beta-blockade benefits patients following a subarachnoid hemorrhage. Eur J Clin Pharmacol 1985; 28(suppl):25.
This paper in humans with SAH showed an improvement in neurologic outcome when sympatholytic drugs were employed.

Rosner MJ, Becker DP: Origin and evolution of plateau waves: Experimental observations and a theoretical model. J Neurosurg 1984;50:312.
This important paper identified the relationship between blood pressure variations and plateau waves, then synthesized it with work of others to suggest an important role for changes in cerebral blood volume in still autoregulating brain to produce plateau waves.

Werner C, Hoffman WE, Thomas C, et al: Ganglionic blockade improves neurologic outcome from incomplete ischemia in rats: Partial reversal by exogenous catecholamines. Anesthesiology 1990;73:923.
This paper (and that of Hoffman et al[29]) on rodents provides excellent support for the notion that catecholamines can worsen the results of brain ischemia.

Chapter 48
ADVANCED BEDSIDE NEUROMONITORING

Roman Hlatky • Claudia Robertson

KEY POINTS

1. Evaluation of **neurologic** and mental **status** should be included in the monitoring protocol whenever possible.
2. **Intracranial pressure (ICP)** cannot be reliably estimated from any clinical feature in critically ill patients. On computed tomography (CT) scans, signs of brain swelling, such as midline shift and compressed basal cisterns, are predictive of raised ICP, but intracranial hypertension can occur without these findings.
3. Patients with traumatic brain injury who are at particular **risk for developing elevated ICP** include those with Glasgow coma scale (GCS) scores of 8 or less after resuscitation and abnormal CT scans, as well as those with GCS scores of 8 or less, normal CT scans, but adverse features such as age older than 40 years, systolic blood pressure of 90 mm Hg or less, and motor deficit.
4. The **ventriculostomy catheter** remains the preferred device for monitoring ICP and is the standard against which all new monitors are compared.
5. The two major **complications of ICP monitoring** are ventriculitis (1% to 10% of cases) and intracranial hemorrhage (1% to 2%).
6. **Normal** resting **ICP** is less than 10 mm Hg. Transient elevations of ICP occur normally with straining, coughing, or the Trendelenburg position. A sustained ICP greater than 20 mm Hg is clearly abnormal. An ICP greater than 40 mm Hg represents severe, usually life-threatening, **intracranial hypertension.**
7. The simplest measure of cerebral perfusion is **cerebral perfusion pressure** (CPP). For equivalent levels of CPP, cerebral perfusion is impaired more by reductions in blood pressure than by increases in ICP.
8. In head-injured patients, the average **jugular venous oxygen saturation ($Sjvo_2$)** is higher than normal (55% to 71%), and the range for $Sjvo_2$ is considerably wider than it is in normal subjects. If the strategy is to use $Sjvo_2$ as a monitor of global oxygenation, cannulating the **dominant jugular vein** is logical, because it is the most representative of the whole brain.
9. Transcranial **Doppler ultrasonography** is a noninvasive monitor that provides indirect information about cerebral blood flow in one of the major arteries at the base of the brain. In the absence of vessel stenosis or vasospasm or changes in arterial blood pressure or blood rheology, the **pulsatility** reflects the distal cerebrovascular resistance.
10. The **Lindegaard (hemispheric) index** is a ratio of flow velocity in the middle cerebral artery and internal cerebral artery. The mean hemispheric index in normal individuals is 1.76 ± 0.1, and pathologic values suggestive of vasospasm are generally above 3.
11. The major limitation of $Sjvo_2$ as a monitor of the adequacy of cerebral blood flow is that regional ischemia is not identified. In situations in which regional differences in cerebral blood flow may occur, such as brain trauma, **brain tissue oxygen partial pressure ($Pbto_2$)** as a monitor of cerebral oxygenation may have an important advantage.
12. **Normal values for $Pbto_2$** are 20 to 40 mm Hg, and critical reductions are 8 to 10 mm Hg.
13. **Microdialysis** is a technique for sampling the extracellular space of a tissue. It is based on the diffusion of water-soluble substances through a semipermeable membrane and allows continuous and on-line monitoring of changes in brain tissue chemistry.
14. The use of **electroencephalograms (EEGs)** in the ICU to detect early subclinical seizures may help reduce mortality and morbidity in status epilepticus. Continuous EEG monitoring is also useful in detecting ischemic cerebral events, including vasospasm following subarachnoid hemorrhage and intracranial hypertension after head injury.

Currently, little can be done to reverse the primary brain damage caused by an insult; however, one of the major factors influencing outcome in patients with acute brain injury is the additional brain damage that occurs from secondary injury processes. Intracranial hypertension and cerebral ischemia are the most significant secondary injury processes that can be monitored and treated in the ICU. In addition, secondary ischemic insults of extracerebral origin (e.g., arterial hypotension, hypocapnia) can be prevented or treated before they become severe enough to injure the brain. The purpose of continuous monitoring of the brain in the ICU is to detect

these secondary insults, allowing for a more informed, individualized approach to treatment.

MONITORING OF NEUROLOGIC STATUS

Evaluation of neurologic and mental status should be included in the monitoring protocol whenever possible. Glasgow coma scale (GCS) score, motor function, status of cranial nerves, and any trend in neurologic status changes should be easily obtainable from the records. A 24-hour record of the patient's neurologic evaluation should be available on one sheet, together with information about vital signs and laboratory values. Computerized information systems are becoming more widespread in ICUs and can markedly reduce the burden of such record keeping. In critically ill patients, however, the neurologic examination is often obscured by the need to use sedation or neuromuscular blocking agents in the treatment of intracranial hypertension or other associated injuries or disorders.

One relatively new addition to the neurologic examination, which may reduce observer variability, is the hand-held pupillometer. A recent technical note reported good reliability in measuring pupillary diameter using the pupillometer; in addition, this device provides a quantitative measure of the velocity of the pupillary response to light.[1] Studies are needed to determine whether changes in the velocity of the pupillary response might be a sensitive measure of worsening neurologic status.

MONITORING OF INTRACRANIAL PRESSURE

Intracranial pressure (ICP) cannot be reliably estimated from any clinical feature in critically ill patients. Clinical symptoms of raised ICP, such as headache, nausea, and vomiting, are impossible to elicit in comatose patients. Papilledema is not a reliable sign of raised ICP in acute disorders. In one study of 426 patients with traumatic brain injury, only 3.5% had papilledema on funduscopic examination, although 54% of patients had increased ICP.[2] Other neurologic signs, including pupillary dilatation and decerebrate posturing, can occur in the absence of intracranial hypertension. On computed tomography (CT) scans, signs of brain swelling, such as midline shift and compressed basal cisterns, are predictive of raised ICP, but intracranial hypertension can occur without these findings.[3]

Because intracranial hypertension cannot be reliably determined clinically, the direct monitoring of ICP plays an important role in guiding therapy and assessing prognosis in patients with acute neurologic disorders. The ideal ICP monitor would be noninvasive; would provide an accurate, stable measure of pressure; and would provide continuously updated information. A number of noninvasive technologies have been explored as possible replacements or even adjuncts for the ICP monitor. These techniques include tissue resonance,[4] measurements of skull movement associated with ICP pulsations,[5] measurement of venous outflow pressure by ophthalmodynamometry,[6] measurement of tympanic membrane displacement,[7] and monitoring of visual evoked responses.[8] None of these tests is sufficiently reliable to replace the ventriculostomy catheter in the management of critically ill patients.

INDICATIONS

Monitoring of ICP can result in serious complications and is therefore indicated only in patients at significant risk of developing intracranial hypertension. In patients with traumatic brain injury, ICP has been systemically studied by many investigators, and there is a general consensus on the indications for invasive monitoring. Patients with traumatic brain injury who are at particular risk for developing raised ICP include those with GCS scores of 8 or less after resuscitation and abnormal CT scans, as well as those with GCS scores of 8 or less, normal CT scans, but adverse features such as age older than 40 years, systolic blood pressure of 90 mm Hg or less, and motor deficit.[9] More recent studies have shown that comatose patients without these adverse features may also have transiently elevated ICP, suggesting that all patients with GCS scores of 8 or less should have ICP monitoring.[10] Patients with GCS scores greater than 8 might be considered for ICP monitoring if they require treatment that would not allow serial neurologic examinations.[11] A severe coagulopathy is the only major contraindication to ICP monitoring. For critically ill patients with other, nontraumatic neurologic disorders, the indications for ICP monitoring are less clear, but the same general guidelines are often used.

TECHNIQUES

Although several new types of monitors have recently been marketed, the ventriculostomy catheter remains the preferred device for monitoring ICP and is the standard against which all new monitors are compared (Table 48-1).

TABLE 48-1. MONITORING OF INTRACRANIAL PRESSURE AND CEREBRAL PERFUSION

Monitoring Domain	Attributes of Ideal Monitor	Current Strategy of Choice		Current Alternatives
Intracranial pressure	Accurate, noninvasive	Ventriculostomy: most accurate, highest rate of complications		Parenchymal devices: cannot rezero, lower rate of complications Spiegelberg catheter: accurate pressure, also monitors intracranial compliance
Cerebral perfusion	Continuous or frequent serial bedside imaging of regional CBF	Early CBF imaging (xenon CT or perfusion CT) to determine nature of neurologic disorder		Plain CT imaging could substitute for CBF imaging by suggesting the likely nature of the disorder
		If diffuse: $Pbto_2$ or $Sjvo_2$ to monitor for secondary insults	If focal: $Pbto_2$ in area of hypoperfusion and $Sjvo_2$ as global monitor	Local CBF probes (laser Doppler or thermal diffusion) could substitute for $Pbto_2$ Global measures (CPP, flow volume) could substitute for $Sjvo_2$

CBF, cerebral blood flow; CPP, cerebral perfusion pressure; CT, computed tomography; $Pbto_2$, brain tissue oxygen partial pressure; $Sjvo_2$, jugular venous oxygen saturation.

The ventriculostomy catheter is positioned with its tip in the frontal horn of the lateral ventricle and is coupled by fluid-filled tubing to an external pressure transducer that can be reset to zero and recalibrated against an external standard. The ventriculostomy ICP monitor allows intracranial hypertension to be treated by the intermittent drainage of cerebrospinal fluid. However, the risk of ventriculitis and of intracranial hemorrhage is high with ventriculostomy,[9] and proper placement of the catheter tip in the lateral ventricle can be difficult in patients with small, compressed ventricles.

When the ventricle cannot be cannulated, alternative devices can be used. The microsensor transducer[12] and the fiberoptic transducer[13] are the most widely available. These miniature transducer-tipped catheters can be inserted in the subdural space or directly into brain tissue. The main advantage of these monitors is their ease of insertion, especially in patients with compressed ventricles; however, the transducers cannot be reset to zero after they are inserted into the skull, and they exhibit drift over time.[14] Another ventricular catheter, employing an air pouch balloon catheter technology, allows automated monitoring of the intraventricular volume-pressure relationship, in addition to the intraventricular pressure.[15] Investigations are needed to determine whether intracranial compliance can provide an earlier indication of a developing mass lesion or worsening brain swelling than does the simple measurement of ICP.

COMPLICATIONS

The two major complications of ICP monitoring are ventriculitis and intracranial hemorrhage. Infection may be confined to the skin wound, but in 1% to 10% of cases, ventriculitis occurs. Most studies have found a higher rate of infection in ventriculostomy-monitored patients than in those monitored with subarachnoid bolts or subdural catheters.[9,16] An analysis of data from the Traumatic Coma Data Bank study also suggests that there is no benefit in changing ventriculostomy catheters at 5-day intervals.[17] The best strategy for reducing the risk of ventriculitis associated with ICP monitoring is to minimize the duration of monitoring. No controlled studies have demonstrated that prophylactic antibiotics can reduce the incidence of ventriculostomy-related infections. A randomized trial of ventriculostomy catheters impregnated with minocycline and rifampin demonstrated that the impregnated catheters were half as likely to become colonized as the control catheters were (17.9% and 36.7%, respectively, $P < .0012$).[18] Positive cerebrospinal fluid cultures were seven times less frequent in patients with antibiotic-impregnated catheters compared with those in the control group (1.3% and 9.4%, respectively, $P = .002$).

The second major complication of ICP monitoring is intracerebral hemorrhage. Although the risk of hemorrhage is low (1% to 2%), it is an important complication to recognize and treat.[9] Patients with coagulopathies have a greater risk of developing this complication.

NORMAL VALUES

Normally, resting ICP is less than 10 mm Hg. Transient increases in ICP occur normally with straining, coughing, or the Trendelenburg position. A sustained ICP greater than 20 mm Hg is clearly abnormal; an ICP between 20 and 40 mm Hg is considered moderate intracranial hypertension; and an ICP greater than 40 mm Hg represents severe, usually life-threatening, intracranial hypertension.[19] These guidelines for determining the severity of intracranial hypertension assume a normal blood pressure. When a temporal mass lesion is present, however, herniation can occur at ICP values less than 20 mm Hg.[20] Both the American and European head injury guidelines recommend treatment of ICP that is greater than 20 to 25 mm Hg.[21,22]

MONITORING OF CEREBRAL PERFUSION AND OXYGENATION

The ideal neuromonitor for ischemia would provide continuously updated information about regional cerebral blood flow (CBF) and metabolism throughout the brain (see Table 48-1). Continuously updated information is needed because acute neurologic disorders evolve over time, and early intervention provides the best chance for a successful outcome. Regional information is required because neurologic disorders tend to develop regionally in the brain, especially early in the course.

An ideal monitor for ischemia does not currently exist. High-resolution maps of regional CBF are available with current imaging techniques; however, this type of study generally required that patients be taken out of the ICU to the radiology department. High-quality CT imaging, including of CBF, can now be obtained in the ICU. Reports suggest that this arrangement is safer for critically ill patients and is cost-effective.[23] It is likely that in the future, such imaging will be used in the ICU similar to a bedside monitor. The best monitoring strategy at present is the use of a monitor of global cerebral perfusion and a monitor of local cerebral perfusion placed strategically in the area of the brain considered most vulnerable to the development of ischemia.

There are several choices for measuring global and local cerebral perfusion. These monitors fall into two categories: those that measure CBF directly, and those that provide indirect information about CBF by measuring oxygen extraction. Measures of cerebral oxygenation, such as jugular venous oxygen saturation ($Sjvo_2$) or brain tissue oxygen partial pressure ($Pbto_2$), are widely used in place of quantitative CBF measurements in critically ill patients because they indicate the adequacy of CBF relative to cerebral metabolic requirements. Because cerebral metabolic requirements may be reduced after traumatic brain injury, normal CBF values may not be optimal. For instance, when CBF is low (25 to 30 mL/100 g per minute), it can be difficult to decide whether this is an appropriate response to lower cerebral metabolic requirements or whether the brain is hypoperfused. A measure of cerebral oxygenation can be helpful in making this distinction. If the brain is hypoperfused, oxygen extraction will be increased, and $Sjvo_2$ will be reduced. If CBF is appropriate for the brain's metabolic requirement, $Sjvo_2$ will be normal. This information is often more clinically useful than are absolute CBF values.

GLOBAL MONITORS

Cerebral Perfusion Pressure

The simplest measure of cerebral perfusion is cerebral perfusion pressure (CPP), which is calculated by subtracting the ICP from the mean arterial blood pressure. The normal lower limit of autoregulation for CPP is 50 mm Hg. In severely head-injured patients, the ability to autoregulate

TABLE 48–2. NORMAL VALUES FOR NEUROPHYSIOLOGIC PARAMETERS

Parameter	Normal Values	Critical Values
Cerebral blood flow		
Global	52±12 mL/100 g/min[67]	18-20 mL/100 g/min
Cortical	80 mL/100 g/min[68]	
Flow volume	268±60 mL/min[69]	
Cerebral oxygenation		
$Pjvo_2$	40 mm Hg[68]	20-30 mm Hg
$Sjvo_2$	55-71%[39]	50%[39]
$Pbto_2$	20-40 mm Hg[70]	8.5-10 mm Hg[70]
$AVDo_2$	4.5-8.5 mL/100 mL[67]	
Cerebral metabolism		
$CMRO_2$	3.4 mL/100 g/min[32]	0.6 µmol/g/min
CMRG	0.325 µmol/g/min[32]	
CMRL	−0.02 µmol/g/min[32]	
MD-glucose	1.7±0.9 µmol/L[71]	
MD-lactate	2.9±0.9 mmol/L[71]	
MD-pyruvate	166±47 mmol/L[71]	
MD-glutamate	16±16 µmol/L[71]	

$AVDo_2$, arteriovenous oxygen difference; CMRG, cerebral metabolic rate of glucose; CMRL, cerebral metabolic rate of lactate; $CMRO_2$, cerebral metabolic rate of oxygen; MD, microdialysate; $Pbto_2$, brain tissue oxygen partial pressure; $Pjvo_2$, jugular venous oxygen partial pressure; $Sjvo_2$, jugular venous oxygen saturation.

may be impaired, and CBF may be inadequate even with CPP values greater than 50 mm Hg. CPP can be reduced through either decreases in blood pressure or increases in ICP. For equivalent levels of CPP, cerebral perfusion is impaired more by reductions in blood pressure than by increases in ICP.[24] As a monitor for cerebral perfusion, CPP is widely available and convenient; its limitation is that only ischemia caused by increased ICP or decreased blood pressure is assessed. A normal CPP does not confirm that CBF is adequate.

Kety-Schmidt Technique

Measurement of global CBF by the classic Kety-Schmidt technique (based on the Fick principle) uses nitrous oxide as the diffusible indicator. It can be performed at the bedside with a minimum of expense and equipment. Instruments for measuring regional CBF using the stable xenon-enhanced CT technique are also commercially available.[25-27] However, both these measurements of CBF are intermittent and require the patient to be hemodynamically stable during the time required for the measurements. Therefore, transient CBF reductions or CBF reductions in an acutely unstable patient are difficult to document with these technologies.

Jugular Venous Oxygen Saturation

Placement of an internal jugular vein catheter, similar to the type used for central venous pressure monitoring but directed cephalad into the jugular bulb, allows repetitive sampling of $Sjvo_2$ without repeated needle punctures.[28-32] More recently, the development of in vivo reflectance oximetry using fiberoptic catheters has allowed continuous monitoring of $Sjvo_2$ without the need to sample blood, except for calibration purposes.[33-35]

Side of Catheterization. Studies comparing bilateral measurements of $Sjvo_2$ or comparing $Sjvo_2$ to oxygen saturation in the confluence of the cerebral sinuses clearly indicate that when there are focal lesions after traumatic brain injury, there may be significant differences in oxygen saturation measured in the left and right jugular bulbs.[36,37] If the strategy is to use $Sjvo_2$ as a monitor of global oxygenation, cannulating the dominant jugular vein is logical, because it is most representative of the whole brain. However, if the strategy is to identify the most abnormal oxygen saturation, the recommendations of Metz and colleagues should be followed.[37]

Normal $Sjvo_2$. Gibbs and coworkers studied 50 normal young males and observed that their $Sjvo_2$ ranged from 55% to 71% (mean, 61.8%; Table 48-2).[38] In head-injured patients, the average $Sjvo_2$ is higher than normal, and the range for $Sjvo_2$ is considerably wider than it is in normal subjects. In a series of 116 patients with continuous measurement of $Sjvo_2$ for the first 5 to 10 days after severe head injury,[39] $Sjvo_2$ averaged 68.1 ± 9.7% (range, 32% to 96%) in 1329 measurements. $Pjvo_2$ averaged 37 ± 7 mm Hg (range, 22 to 85 mm Hg).

Experimental studies have extensively examined the ischemic thresholds for CBF. Only a few studies have examined the $Sjvo_2$ threshold associated with the depletion of energy stores in animals and with loss of consciousness or electroencephalogram (EEG) changes during anoxia in normal humans.[40-42] From these studies, it appears that normal brain metabolism can be altered at $Sjvo_2$ values less than 50%, but that values less than 20% are required for irreversible ischemic injury.

LOCAL OR REGIONAL MONITORS

Transcranial Doppler Flow Velocity and Flow Volume

Transcranial Doppler ultrasonography is a noninvasive monitor that provides indirect information about CBF in one of the major arteries at the base of the brain. A 2-MHz pulsed ultrasound signal is transmitted through the skull (usually through the temporal bone) and, using the Doppler shift principle, measures red cell flow velocity. Flow volume is directly proportional to flow velocity and can be calculated by multiplying the velocity by the cross-sectional area of the vessel insonated.

Several studies have assessed the relationship between peak flow velocity and changes in CBF, suggesting that changes in middle cerebral artery flow velocity can be used as an indicator of relative changes in blood flow. Kofke and associates, investigating the relationship between middle cerebral artery flow velocity and CBF assessed by stable xenon CT during balloon test occlusion of the carotid artery in 31 patients, found a significant correlation in the alteration of

flow detected by the two methods.[43] More recently, changes in middle cerebral artery flow velocity and changes in CBF assessed by stable xenon CT in patients with various intracranial pathologies, including eight with closed-head injuries, showed a close correlation.[44]

In the absence of vessel stenosis or vasospasm or changes in arterial blood pressure or blood rheology, pulsatility reflects the distal cerebrovascular resistance. This resistance is usually quantified by the pulsatility (or Gosling) index, which is calculated as follows: (systolic flow velocity – diastolic flow velocity)/mean flow velocity. The pulsatility index (normal, 0.6 to 1.1) has been shown to correlate better with CPP than with ICP.

During arterial spasm, flow velocity increases through the narrowed segment proportional to the reduction in the vessel's diameter. Severe vasospasm, with a greater than 50% reduction in vessel diameter, is associated with a flow velocity greater than 200 cm/sec.[45] However, an increase in flow velocity may also reflect hyperemia, which often occurs as a post-traumatic event. To differentiate between these two hemodynamic phenomena in the absence of direct CBF measurements, the middle cerebral artery–extracranial internal carotid artery flow velocity ratio, also known as the Lindegaard or hemispheric index, can be measured. In the presence of hyperemia, a raised flow velocity in both extracranial and intracranial vessels does not alter the ratio; however, in vasospasm, flow velocity is high only in the intracranial vessels, resulting in a high hemispheric index. The mean hemispheric index in normal individuals is 1.76 ± 0.1, and pathologic values suggestive of vasospasm are generally above 3.[46]

Doppler devices that are capable of measuring the diameter of the vessel being insonated may be a better way to differentiate between these two hemodynamic causes of increased flow velocity by calculating flow volume. Flow volume of the internal carotid artery has a close correlation to hemispheric CBF measured by the ^{133}xenon clearance technique[47] and may be useful as a bedside estimation of hemispheric CBF.

Thermal Diffusion and Laser Doppler Methods

Two methods for continuously measuring local CBF are now commercially available: thermal diffusion and laser Doppler. Both methods are invasive, requiring that the probe be placed on the surface of the brain or in the brain parenchyma. Both methods measure CBF in only a small volume of brain, which may or may not be representative of the whole brain. However, the continuous nature of the measurements provides a dynamic picture of brain perfusion. Although there is extensive documentation of the reliability of these methods in the laboratory, there is limited experience in the ICU.[48-50] Especially for patients undergoing craniotomy, these may become practical methods for monitoring CBF postoperatively.

Thermal diffusion flowmetry uses heat transfer as a tracer in the measurement of blood flow. The sensor consists of two gold disks embedded in a 3-mm Silastic leaf. One disk is heated to slightly greater than brain temperature (to a maximum of 44° C), and the other is neutral. The probe is laid on the surface of the brain. The temperature difference between the two disks is monitored and converted to blood flow in milliliters/100 g per minute by the monitor, using a digital display. Carter and Atkinson[51] modified a thermal sensor described by Brawley[52] and were able to quantify the flow measured by the thermal sensor. They derived a mathematical formula by comparing thermal diffusion CBF with ^{133}xenon CBF[53] and confirmed the reliability through a comparison with hydrogen clearance.[54]

Gopinath and colleagues compared thermal diffusion CBF with global CBF values measured using the nitrous oxide saturation technique in a group of 35 patients with severe head injury.[55] As expected, the thermal diffusion CBF, which measures cortical flow, was significantly higher than the global CBF, which is a mixture of gray and white matter flow. However, there was a close temporal correlation between the two measures of CBF, and changes in thermal diffusion CBF reliably predicted a change in global CBF. These studies suggest that thermal diffusion CBF provides an accurate measure of local CBF under the probe and is a reasonable estimate of trend changes in global CBF.

Laser Doppler flowmetry is a technique whereby CBF is measured indirectly, based on the magnitude of frequency shift of monochromatic light by a moving column of blood. The laser light is directed at the region of interest through a small probe that illuminates about 1 mm^3 of tissue. With this high spatial resolution, it is designed primarily for measuring flow in capillaries.[56]

Brain Tissue Oxygen Partial Pressure

The major limitation of $Sjvo_2$ as a monitor of CBF adequacy is that regional ischemia is not identified. In cases of brain trauma, regional differences in CBF may occur, giving $Pbto_2$ an important advantage as a monitor of cerebral oxygenation.[57,58] Figure 48-1 illustrates the changes in $Pbto_2$ in a focal area of evolving ischemia. $Sjvo_2$ remains well preserved until the brain swelling from the infarction causes severe intracranial hypertension.

With recent technologic advances, two commercially available sensors have been produced. One sensor measures only brain tissue oxygen tension using a polarographic Clarke-type electrode; the other multiparameter sensor measures brain tissue oxygen, carbon dioxide, and pH using fiberoptic technology. Both these methods have the ability to measure brain temperature using a thermocouple. Both sensors are approximately 0.5 mm in diameter and can be inserted through a craniotomy intraoperatively or through a specially designed bolt that allows insertion and fixation to the skull in the ICU.

Normal values for $Pbto_2$ are 20 to 40 mm Hg, and critical levels are 8 to 10 mm Hg (see Table 48-2). Hoffman and coworkers, using single photon emission computed tomography, found that $Pbto_2$ in patients with ischemia averaged 10 ± 5 mm Hg, compared with 37 ± 12 mm Hg in normal brain.[59] Valadka and associates found that the likelihood of death following a severe head injury increased the longer the $Pbto_2$ remained at less than 15 mm Hg, and with any occurrence of $Pbto_2$ less than 6 mm Hg.[60] Kiening and colleagues correlated serial measurements of both $Sjvo_2$ and $Pbto_2$ and found that an $Sjvo_2$ of 50% generally correlates with a $Pbto_2$ of 8.5 mm Hg.[61]

Near-Infrared Spectroscopy

The principle of near-infrared spectroscopy is based on the fact that light in the near-infrared range (700 to 1000 nm) can pass through skin, bone, and other tissues relatively easily. Oxygenated hemoglobin, deoxygenated hemoglobin, and cytochrome aa_3 have different absorption spectra, depending on their oxygenation status. Changes in the concentration of

FIGURE 48–1. Monitoring in a patient with severe traumatic brain injury. Brain tissue oxygen partial pressure ($Pbto_2$) and microdialysis probes were placed in the left frontal lobe, where subarachnoid hemorrhage was present on the admission computed tomography (CT) scan. The $Pbto_2$ decreased, followed shortly by the microdialysate glucose and pyruvate. A follow-up CT scan showed a stroke developing in the brain surrounding the local probes. Cerebral perfusion pressure (CPP) and jugular venous oxygen saturation ($Sjvo_2$) provide measures of global cerebral perfusion, which is fairly well preserved until intracranial hypertension becomes severe and refractory to treatment. ICP, intracranial pressure; MAP, mean arterial pressure.

near-infrared light as it passes through these compounds can be quantified using a modified Beer-Lambert law, which describes optical attenuation. The main advantage of near-infrared spectroscopy is that it is a noninvasive method of estimating regional changes in cerebral oxygenation. However, its clinical use is limited by an inability to differentiate between intracranial and extracranial changes in blood flow and oxygenation, which adversely affects the reliability of the readings.[62]

MONITORING OF BRAIN METABOLISM

GLOBAL CEREBRAL METABOLIC RATE OF SUBSTRATES

The cerebral metabolic rate (CMR) of a substrate can be calculated by multiplying the arterial-jugular venous difference of the substrate by the global CBF. Measuring the CMR of oxygen, glucose, and lactate gives a comprehensive picture of

the brain's overall metabolism. However, the measurements are not continuous, and regional abnormalities may not be reflected.

Glucose is the major energy substrate for the brain. The average CMR of glucose in adults is 0.325 μmol/g per minute, and the gray matter has higher metabolic requirements than the white matter does. More than 90% of the normal brain's metabolic demands are met by aerobic metabolism of glucose through the glycolytic pathway, citric acid cycle, and respiratory chain, providing 38 moles of adenosine triphosphate per mole of glucose.

In the resting state, anaerobic glycolysis represents less than 10% of the total glucose usage, yielding only 2 moles of adenosine triphosphate and lactate per mole of glucose metabolized. Neuronal stimulation results in an increase in glucose metabolism compared with oxygen consumption, signifying the importance of glycolytic metabolism in electrical activation. Normally, there is a small production of lactate by the brain, and the mean CMR of lactate is –0.02 μmol/g per minute.

The normal CMR of oxygen in the healthy adult brain averages 3.4 mL/100 g per minute (1.5 μmol/g per minute) but may range from 1.8 to 3.9 mL/100 g per minute without neurologic sequelae. The CMR of oxygen increases minimally during changes in mental activity, with the increased energy expenditure being provided by the anaerobic metabolism of glucose. In acute neurologic disorders resulting in coma, the CMR of oxygen is typically reduced by about 50%. A CMR of oxygen less than 0.6 μmol/g per minute is insufficient to maintain normal cellular function.

MICRODIALYSIS

Microdialysis is a technique of sampling the extracellular space of a tissue. It is based on the diffusion of water-soluble substances through a semipermeable membrane. Small molecules (<20,000 Da) from the extracellular fluid can diffuse across the membrane and enter the perfusate. Conversely, substances that have been added to the perfusate can diffuse across the membrane to gain entry to the tissue. The degree of permeability of the membrane determines the molecular weight of the substances that cross it.

The concentration of substances in the dialysate depends on the flow rate and chemical composition of the perfusate, the length of the dialysis membrane, the type of dialysis membrane, and the diffusion coefficient or "tortuosity" of the tissue. The recovery of a particular substance is defined as the concentration in the dialysate divided by the concentration in the interstitial fluid. If the membrane is long enough and the flow slow enough, the concentration in the perfusate will be the same as that in the interstitial fluid (i.e., 100%). The parameters that are commonly used in clinical studies (i.e., 10-mm membrane, perfusion with Ringer's solution, and flow rate of 0.3 μL/min) provide an in vivo recovery rate (extrapolation to zero flow method) of approximately 70%.[63]

The technique of cerebral microdialysis allows continuous and on-line monitoring of changes in brain tissue chemistry. In common with brain tissue oxygenation monitoring, microdialysis involves inserting a fine catheter (diameter 0.62 mm) into the brain. The catheter has a polyamide dialysis membrane at the tip and is perfused with a physiologic solution (e.g., Ringer's) at ultra-low-flow rates (0.1 to 2.0 μL/min) using a precision pump. This allows measurement of the concentration of chemicals in the extracellular space of the brain. Molecules below the cutoff size of the semipermeable membrane (approximately 20,000 Da) diffuse from the extracellular space into the perfusion fluid, which is collected in vials that are changed every 10 to 60 minutes. The collected dialysate is then analyzed by sensitive assays.

In theory, any substance small enough to diffuse through the dialysis membrane can be measured,[63] but the key substances can be categorized as follows:

1. Energy-related metabolites (glucose, lactate, pyruvate, adenosine, xanthine)
2. Neurotransmitters (glutamate, aspartate)
3. Markers of tissue damage and inflammation (glycerol)
4. Exogenous substances (administered drugs)

Continuous on-line measurements of glucose, lactate, pyruvate, glutamate, and glycerol can be achieved using a bedside CMA600 microdialysis analyzer (CMA Microdialysis, Stockholm, Sweden). Cerebral microdialysis has been applied to patients in many different clinical situations, including those with head injury, subarachnoid hemorrhage, epilepsy, ischemic stroke, and tumor, as well as during neurosurgery.[64] Figure 48-1 illustrates the changes in these parameters that can be seen with evolving ischemia. Although the role of microdialysis as a reliable clinical tool in the ICU is not yet established, its usefulness as a research tool is undeniable.

MONITORING OF ELECTROENCEPHALOGRAPHIC ACTIVITY

An EEG represents spontaneous electrical activity of the cerebral cortex and is generated mainly by the summation of excitatory and inhibitory postsynaptic potentials of cortical neurons. It does not reflect activity in subcortical levels, cranial nerves, or the spinal cord. The electrical signal is amplified, filtered, and then displayed as either 8 or 16 channels (8 channels per hemisphere) to give an accurate representation of electrical activity throughout the cortex. EEG activity is usually interpreted in terms of frequency, amplitude, and location (focal or generalized activity).

To facilitate continuous EEG monitoring, several automated EEG processing systems have been developed. Power spectral analysis allows fast Fourier transformation of small intervals of an EEG to provide a graphic representation of the relative power content of the various frequency bands in each segment of the EEG. These spectral diagrams are then stacked to show how the frequency of the EEG alters with time to produce a compressed spectral array. This spectral analysis can also provide a single number (either the mean frequency or the frequency below which 95% of the signal lies) that can be tracked over time.

Cerebral function monitoring provides a single trace of total power that varies with both the amplitude and the frequency of raw EEG data. The cerebral function analyzing monitor is a similar method that produces displays of both amplitude and frequency and avoids the loss of information when these are processed together.

Use of EEGs in the ICU to detect early subclinical seizures may help reduce mortality and morbidity in status epilepticus.[65] Continuous EEG monitoring is also useful in detecting ischemic cerebral events, including vasospasm following subarachnoid hemorrhage and intracranial hypertension after head injury.[66] In sedated patients, EEGs may help detect

focal neurologic disease, especially in those who cannot be fully examined and in those who are too unstable to undergo neuroradiographic imaging. Metabolic suppression using intravenous anesthetic agents can be monitored using cerebral function monitoring, where burst suppression or isoelectricity is a useful endpoint to titrate suppression of cortical electrical activity.

CONCLUSION

Many tools are currently available for monitoring cerebral physiology. Some of these methods, such as ICP monitoring, have established roles in the management of critically ill patients. For other methods, such as microdialysis, their roles have yet to be determined. Clearly, the use of these advanced monitoring tools must be based on an understanding of the nature of the patient's neurologic disorder and a knowledge of the type of secondary injury processes that are likely to complicate the patient's course.

Chapter 49
COMA

Joerg-Patrick Stübgen • Fred Plum

KEY POINTS

1. **Altered arousal** is due to an acute or subacute brain insult and reflects either diffuse and bilateral cerebral dysfunction, failure of the brainstemthalamic ascending reticular activating system, or both.
2. **Coma is not a permanent state.** Patients who survive evolve through and into altered behavioral states that reflect various degrees of recovery.
3. **Urgent steps are required to minimize additional brain damage** often before the cause of coma is definitely established.
4. The initial assessment must focus on vital signs to determine the appropriate resuscitation measures **(airway/breathing/circulation).**
5. When the patient's condition is stable, **clues to the cause of coma** must be sought from informative sources.
6. A **systematic, detailed examination** is necessary of the comatose patient, who is in no condition to describe past or current medical history.
7. The correct interpretation is required of neurologic signs that reflect the **integrity or impairment of brain functional levels** to determine the cause and evolution of coma.
8. The **categorization of coma** (supratentorial or infratentorial structural lesions, metabolic-toxic encephalopathy, or psychogenic unresponsiveness) is important in deciding the sequence of diagnostic and therapeutic steps that ensure the best possible patient outcome.
9. **CT is the most expedient imaging technique** to give rapid information about a brain structural lesion and its consequences.
10. Although the outcome of a comatose patient cannot be absolutely predicted, **a highly probable poor prognosis should be made within 24 hours after admission** to ration ICU services and protect families from false hope.
11. As a rule, patients in coma due to exogenous agents carry a favorable prognosis and patients in post-traumatic coma fare better than those in a medical coma.

Altered states of consciousness are a common reason for visits to the emergency department and admission to ICUs. Few problems are more difficult to manage than the unconscious patient because there are many potential causes of an altered mental status and the time for diagnosis and effective intervention is short. *Consciousness* is defined as the state of awareness of the self and the environment. The phenomenon of consciousness requires two intact and interdependent physiologic and anatomic components: (1) arousal (or wakefulness) and its underlying neural substrate, the ascending reticular activating system (ARAS) and diencephalon, and (2) awareness, which requires the functioning cerebral cortex of both hemispheres. Most disorders that acutely disturb consciousness are, in fact, impairments of arousal that create circumstances under which the brain's capacity for consciousness cannot be accurately assessed; in other words, failure of arousal renders it impossible to test awareness.

Alterations of arousal may be transient, lasting only several seconds or minutes (after seizures, syncope, and cardiac dysrhythmia), or sustained, lasting hours or longer. Four terms describe disturbed arousal of a patient. *Alert* refers to a normal state of arousal. *Stupor* describes a state of unarousability in which strong external stimuli can transiently restore wakefulness. Stupor implies at least a limited degree of cognitive activity accompanies the arousal, even if transient. *Coma* is characterized by an uninterrupted loss of the capacity for arousal. The eyes are closed, sleep-wake cycles disappear, and even vigorous stimulation elicits at best only reflex responses. *Lethargy* describes a range of behavior between arousal and stupor. Only the terms *alert* and *coma* have enough precision to be used without further qualification; possibly *coma* has gradations in depth, but this cannot be accurately assessed once the patient no longer responds to external stimuli. *Stupor* and *coma* imply an acute or subacute brain insult. The cerebral reserve capacity is large; therefore, altered consciousness reflects either diffuse and bilateral cerebral dysfunction, failure of the brainstem/thalamic ARAS, or both. All alterations in arousal should be regarded as acute and potentially life-threatening emergencies.

The evaluation of a comatose patient demands a systematic approach with appropriate, directed diagnostic and therapeutic endeavors; time should not be wasted on irrelevant considerations. Urgent steps are required to prevent or minimize permanent brain damage from reversible causes. Patient evaluation and treatment must necessarily occur simultaneously. Such a systematic approach demands an understanding of the pathophysiology of consciousness and mechanisms by which it may be deranged.

ANATOMY, PATHOLOGY, PATHOPHYSIOLOGY

Consciousness depends on an intact ARAS in the brainstem and adjacent thalamus that acts as the alerting or awakening element of consciousness together with a functioning cerebral cortex of both hemispheres that determines the content of that consciousness.[1,2] The ARAS lies within a more or less isodendritic core that extends from the medulla through the tegmentum of the pons to the midbrain and paramedian thalamus. The system is continuous caudally with the reticular intermediate gray matter of the spinal cord and rostrally with the subthalamus, the hypothalamus, the anterior thalamus, and the basal forebrain.[3] The ARAS itself arises within the rostral pontine tegmentum and extends across the mesencephalic tegmentum and its adjacent intrathalamic nuclei. ARAS functions and interconnections are considerable and likely contribute more than only a cortical arousal system. The specific role of the various links from the reticular formation to the thalamus has yet to be fully identified.[4] Furthermore, the cortex feeds back on the thalamic nuclei to contribute an important loop that amplifies arousal mechanisms.[5,6]

The ascending arousal system contains cholinergic, monoaminergic, and γ-aminobutyric acid (GABA) systems, none of which has been identified as the arousal neurotransmitter.[2,7,8] Acute structural damage to, or metabolic-chemical disturbance of, either the ascending brainstem/thalamic activating system or the thalamocorticothalamic loop can alter the aroused, attentive state. Consciousness depends on the continuous interaction between the mechanisms that provide arousal and awareness. The brainstem and thalamus provide the activating mechanism, and the cerebrum provides full cognition and self-excitation. Content of consciousness is best regarded as the amalgam and integration of all cognitive function that resides in the thalamocortical circuits of both hemispheres. Altered awareness is due to disruption of this cortical activity by diffuse pathology. Focal lesions of the cerebrum can produce profound deficits, such as aphasia, alexia, amnesia, and hemianopsia, but only diffuse bilateral damage, sparing the ARAS and diencephalon, can lead to wakeful unawareness. Thus, there are two kinds of altered consciousness: (1) altered arousal due to dysfunction of the ARAS-diencephalon and (2) altered awareness due to bilateral diffuse cerebral hemisphere dysfunction.

Four major pathologic processes can cause such severe, global, acute reductions of consciousness.[1,9] In the presence of diffuse or extensive multifocal bilateral dysfunction of the cerebral cortex, the cortical gray matter is diffusely and acutely depressed or destroyed. Concurrently, cortical-subcortical physiologic feedback excitatory loops are impaired, with the result that brainstem autonomic mechanisms become temporarily, profoundly inhibited, producing the equivalent of acute "reticular shock" below the level of the lesion.[2] Direct damage to a paramedian upper brainstem and posteroinferior diencephalic ascending arousal system blocks normal cortical activation.[3] Widespread disconnection between the cortex and subcortical activating mechanisms acts to produce effects similar to both these conditions.[4] Diffuse disorders, usually metabolic in origin, concurrently affect both the cortical and subcortical arousal mechanisms, although to a different degree according to the cause.

STRUCTURAL LESIONS CAUSING COMA

Intracranial mass lesions that cause coma may be located in the supratentorial or infratentorial compartments. From either location, impaired arousal or coma is caused by compression of the brainstem/hypothalamic activating mechanisms secondary to swelling and displacement of deep lying intracranial contents; the ultimate event occurs either by halting axoplasmic flow or by sustained neuronal depolarization because of ischemia or hemorrhage. Factors important to the degree of loss of arousal are the rate of development, the location, and the ultimate size of the lesion. Cerebral mass lesions distort the intracranial anatomy and thereby alter the cerebrospinal fluid (CSF) circulation and brain blood supply. These changes result in increased bulk of the injured tissue and a reduction in intracranial compliance.

Intercompartmental pressure gradients result in herniation syndromes that are not necessarily associated with large increases in intracranial pressure (ICP). Recently sustained or evolving mass lesions can disturb cerebrovascular autoregulation that results in abrupt, briefly lasting vasodilatation. This, in turn, causes recurrent increases in ICP (pressure waves), with additional compromise of cerebral blood supply to injured regions.

Two herniation syndromes demonstrate the mechanism by which *supratentorial lesions* produce coma. The rate of evolution of a mass dictates whether the anatomic distortion precedes (in slowly evolving lesions) or parallels the patient's deterioration of wakefulness. Transtentorial herniation can be central or predominantly unilateral. *Central herniation* results from caudal displacement by deep midline supratentorial masses, large space-occupying hemisphere lesions, or large unilateral or bilateral compressive extra-axial lesions, with compression of the ARAS. The progressive rostrocaudal clinical and pathologic stages of this herniation syndrome have been outlined.[1] Pathologically, bilateral symmetrical displacement of the supratentorial contents occurs through the tentorial notch into the posterior fossa. Alertness is impaired early, pupils become small (to 3 mm) and reactive, and bilateral upper motor neuron signs develop. Cheyne-Stokes breathing, grasp reflexes, roving eye movements, or depressed escape of oculocephalic reflexes are the clinical manifestations. In the absence of effective therapy at this diencephalic stage, herniation progresses caudally to compress the midbrain, leading to a deep coma and fixed, midposition (3 to 5 mm) pupils, signifying both sympathetic and parasympathetic interruption. Spontaneous eye movements cease and oculovestibular and oculocephalic reflexes become difficult to elicit. Spontaneous extensor posturing may occur. Once this stage is reached, full recovery becomes unlikely. As the caudal compression-ischemia process advances, pontine and medullary function becomes destroyed, with variable breathing patterns and absent reflex eye movements. Finally, autonomic cardiovascular and respiratory functions cease as medullary centers fail.

Uncus herniation results from laterally placed hemisphere lesions, particularly of the temporal lobes, which cause side-to-side cerebral displacement as well as transtentorial herniation. Focal hemisphere dysfunction (hemiparesis, aphasia, seizures) precedes unilateral (usually ipsilateral) compression paralysis of the third cranial nerve. An early sign of uncus herniation is an ipsilateral (rarely contralateral) enlarged pupil that responds sluggishly to light followed by a fixed,

dilated pupil and an oculomotor palsy (eye turned downward and outward).[1] The ipsilateral posterior cerebral artery can become compressed as it crosses the tentorium and causes ipsilateral occipital lobe ischemia. Progressively, the temporal lobe compresses the midbrain, with loss of arousal and bilateral or contralateral extensor posturing. Ipsilateral to the intracranial lesion, a hemiparesis may develop if the opposite cerebral peduncle becomes compressed against the contralateral tentorial edge (Kernohan's notch). Abnormal brainstem signs become symmetrical, and herniation proceeds in the same pattern seen with central herniation, as rostrocaudal brainstem displacement progresses.

Infratentorial lesions cause coma by displacement, compression, or direct destruction of the pontomesencephalic tegmental activating system. Displacement of the medulla downward sufficient to push the brainstem and cerebellar tonsils into the foramen magnum causes cardiorespiratory collapse. Acute intrinsic lesions of the brainstem, usually hemorrhagic or ischemic, cause abrupt onset of coma and are associated with abnormal neuro-ophthalmologic findings. Pupils are pinpoint, owing to disruption of pontine sympathetic pathways, or they are dilated, owing to destruction of the third cranial nerve nuclei or intra-axial exiting fibers. Dysconjugate eye movements and nystagmus occur, whereas vertical eye movements are relatively spared. Ocular bobbing signifies pontine damage. Upper motor neuron signs develop and patients can become quadriplegic; flaccidity in the upper extremities and flexor withdrawal responses in the lower extremities often accompany midbrain-pontine damage. Pathologically, *basilar artery occlusion* leads to asymmetric ischemia of the brainstem, with involvement of the ARAS, the neighboring densely packed neuropil, as well as the descending and ascending motor and sensory tracts. Thrombosis of the rostral basilar artery leads to infarction of the midline thalamic nuclei and brief coma without other obvious brainstem signs. Hemorrhage into the ventral pons sometimes spares consciousness but produces neuro-ophthalmologic signs and motor dysfunction. Extension of the hemorrhage into the rostral pontine tegmentum results in stupor, coma, or death. *Basilar artery migraine* can produce altered consciousness possibly by interfering with arterial blood flow in the basilar artery system. Rapidly developing, extensive central pontine myelinolysis may cause coma by extension into the pontine tegmentum. Other intrinsic brainstem lesions (e.g., tumor, abscess, granuloma, demyelination) tend to progress slowly and usually spare arousal mechanisms; however, they may reduce attention and other cognitive functions, leading to severe psychomotor retardation.

Extra-axial posterior fossa lesions cause coma by direct compression of the ARAS in the brainstem and in the diencephalon by upward transtentorial herniation. Compression of the pons may be difficult to distinguish from intrinsic lesions but is often accompanied by headache, vomiting, and hypertension due to a Cushing reflex. Upward herniation at the midbrain level is initially characterized by coma, reactive miotic pupils, asymmetric or absent caloric eye responses, and decerebrate posturing; caudal-rostral brainstem dysfunction then occurs, with midbrain failure and midposition, fixed pupils.[10] Causes of brainstem compression include cerebellar hemorrhage, infarction, and abscess; rapidly expanding cerebellar or fourth ventricle tumors; or, less commonly, infratentorial epidural or subdural hematomas. Drainage of the lateral ventricles to relieve obstructive hydrocephalus due to posterior fossa masses can potentially precipitate acute upward transtentorial herniation.[11,12]

Downward herniation of the cerebellar tonsils through the foramen magnum causes acute medullary dysfunction and abrupt respiratory and circulatory collapse. Less severe impaction of the tonsils in the foramen magnum can lead to obstructive hydrocephalus and consequent bihemispheric dysfunction with altered arousal. Clinical manifestations include headache, nausea, vomiting, lower cranial nerve signs, vertical nystagmus, ataxia, and irregular breathing. Lumbar puncture in this setting carries a risk of catastrophic consequences.[11]

NONSTRUCTURAL CAUSES OF COMA

Nonstructural disorders, such as metabolic or toxic disturbances, produce coma by diffusely depressing the function of the brainstem and cerebral arousal mechanisms. The anatomic locus of metabolic brain diseases has not been clearly defined. The onset of coma can be abrupt, as with toxic drug ingestion, general anesthesia, or cardiac arrest, or it may evolve slowly after a period of confusion and inattention. The chief manifestations of metabolic encephalopathy are disturbances in arousal and cognitive function. Other findings include abnormalities of the sleep-wake cycle, autonomic disturbances, and abnormal breathing variations.

A helpful distinguishing clinical feature of a diffuse encephalopathy is the preservation of the pupillary light response; the only exceptions are overdose of anticholinergic agents, near-fatal anoxia, or malingering. Usually, lack of pupillary reactivity requires a search for an underlying structural lesion. The neurologic examination shows a decreased level of arousal and a widespread cognitive decline. Deeply comatose patients without brainstem or hemisphere function and no known cause for coma must be assumed to have suffered accidental or intentional poisoning. Metabolic disturbances of arousal and cognition particularly affect elderly patients who suffer serious systemic illnesses or who have undergone complicated surgery.

Metabolic encephalopathy is clinically characterized by multilevel CNS dysfunction. At onset, abnormalities in cognition are at least as severe as the disturbance of arousal. Misperception, disorientation, hallucinations, concentration, and memory deficits, and, occasionally, hypervigilance, may progress to profound stupor and coma. The patient's level of arousal and consciousness often fluctuates between examinations. Motor abnormalities, if present, usually are symmetrical and bilateral. Patients often suffer tremor, asterixis, and multifocal myoclonus. Spontaneous motor activity may range from hypoactivity (in cases of sedating drug or endogenous metabolic disturbances) to hyperactivity (after drug withdrawal or overdose of stimulants, such as cocaine and phencyclidine). Seizures occasionally occur, particularly after alcohol or drug withdrawal, and in patients with established cortical pathology. Focal seizures may occur even without structural disease during hypoglycemia, hepatic encephalopathy, uremia, abnormal calcium levels, or toxin ingestion. Autonomic dysfunction can manifest as hypothermia due to hypoglycemia, myxedema, or sedative drug overdose. Hyperthermia can occur in withdrawal states, particularly delirium tremens, anticholinergic drug overdose, infection, neuroleptic malignant syndrome, or malignant hyperthermia.

The metabolic needs of the brain depend largely on the oxidation of glucose to carbon dioxide and water. Certain fatty

acids and ketone bodies can supply part of the metabolic needs in emergency circumstances, but these alternate fuels never provide an entirely sufficient substrate to meet all energy requirements. Normal cerebral blood flow (CBF) is around 55 mL/100 g tissue/min. With a CBF of less than 20 mL/100 g/min oxygen delivery becomes insufficient for normal levels of oxidative metabolism and cerebral glycolytic rate increases. Patients lose consciousness and the electroencephalogram (EEG) is suppressed owing to synaptic failure at CBF levels between 16 and 20 mL/100 g/min. The cortical evoked response is abolished below about 15 mL/100 g/min. At CBF around 8 mL/100 g/min the energy-dependent membrane pump fails and the membrane potential collapses. Unless CBF is restored promptly, irreversible neuronal injury will ensue. However, the threshold for ischemic neuronal injury is time dependent. Complete cessation of CBF leads to loss of consciousness in 8 seconds, and EEG suppression occurs at 10 to 12 seconds. Adenosine triphosphate exhaustion and ionic pump failure occurs in 120 seconds. Selective neuronal damage starts after periods as brief as 5 minutes, and severe neuronal damage occurs after 20 to 30 minutes. Brain necrosis or infarction starts in 1 to 2 hours.

Under physiologic conditions, glucose is the brain's only substrate and crosses the blood-brain barrier by facilitated transport. The normal brain uses about 55 mg glucose/100 g/min. If there is *hypoglycemia*, defined in adults as blood glucose concentration less than 40 mg/dL, signs and symptoms of encephalopathy result from dysfunction of the cerebral cortex before the brainstem. Neurologic presentation of hypoglycemia can vary from focal motor or sensory deficits to coma. Acute symptoms of hypoglycemia are better correlated with the rate at which blood glucose levels decrease than with the degree of hypoglycemia. The blood glucose level at which cerebral metabolism fails and symptoms develop varies among individuals, but, in general, confusion occurs at levels less than 30 mg/dL and coma at less than 10 mg/dL. The brain stores about 2 g of glucose and glycogen. Thus, a patient in hypoglycemic coma may survive 90 minutes without suffering irreversible brain damage. The pathophysiology of coma from hypoglycemia is not well understood. The disorder cannot solely be attributed to glucose starvation of neurons. Rather than such an internal catabolic death, evidence suggests than neurons are killed from without. Around the time the EEG becomes isoelectric, endogenous neurotoxins are produced and released by the brain into tissue and CSF. The distribution of necrotic neurons is unlike that of ischemia and is related to white matter and CSF pathways. The toxins act by first disrupting dendritic trees, sparing the intermediate axons, an indication of excitotoxic neuronal injury. The exact mechanism of excitotoxic neuronal necrosis is now becoming clear and involves hyperexcitation culminating in cell membrane rupture. Also, during hypoglycemia, the synthesis is suppressed of amino acids such as GABA, glutamate, glutamine, and alanine, as well as acetylcholine. Whether reduction of these molecules or alteration in nerve synaptic transmission significantly contributes to the onset of coma associated with severe hypoglycemia is not established.

The pathophysiology of other metabolic encephalopathies is less well established and is extensively discussed elsewhere.[1] *Hepatic encephalopathy* is caused not merely by ammonia intoxication but likely also involves accumulation of neurotoxins such as short- and medium-chain fatty acids, mercaptans, and phenols. Altered neurotransmission may play a role with accumulation of benzodiazepine-like substances, imbalance of serotonergic and glutaminergic neurotransmission, and the accumulation of false neurotransmitters. The identity of the neurotoxin in *uremic encephalopathy* is uncertain and includes urea itself, guanidine and related compounds, phenols, aromatic hydroxy acids, amines, various peptide "middle-molecules," myoinositol, parathormone, and amino acid imbalance. The cause of the dysequilibrium syndrome may entail more than osmotic water shifts from plasma into brain cells, and reduction is reported in cortical potassium, with intracellular acidosis due to increased production of organic acids in the brain. The pathogenesis of *pancreatic encephalopathy* may involve patchy demyelination of brain white matter owing to liberated enzymes from a damaged pancreas, disseminated intravascular coagulation, or fat embolism.

The mechanism of action of exogenous toxins or drugs depends partly on the structure and partly on the dose. As well as can be determined, none of the sedatives taken acutely produces permanent damage to the nervous system, making prompt diagnosis and effective treatment particularly important.

DIFFERENTIAL DIAGNOSIS

Several different behavioral states appear similar to, and can be confused with, coma. Differentiation of such states from true coma has important diagnostic, therapeutic, and prognostic implications. Moreover, coma is not a permanent state; patients who survive initial coma may evolve through and into these altered behavioral states. All patients who survive beyond the stage of acute, systemic complications reawaken and either proceed to recovery (with no or varying degrees of disability) or remain in a vegetative state.

The vegetative state can be defined as wakefulness without awareness and is the consequence of various diffuse brain insults.[1,13] It may be a transient phase through which patients in coma pass as the cerebral cortex recovers more slowly than the brainstem. Clinically, vegetative patients appear to be awake and to have cyclical sleep patterns; however, such individuals do not show evidence of cognitive function or learned behavioral responses to external stimuli. Vegetative patients may feature spontaneous eye opening and eye movements and stereotypic facial and limb movements; however, they are unable to speak or comprehend and they lack purposeful activity. Vegetative patients generate normal body temperature, usually have normally functioning cardiovascular, respiratory, and digestive systems, but are doubly incontinent. The vegetative state should be termed persistent at 1 month after injury and permanent at 3 months after nontraumatic injury or 12 months after a traumatic injury.[14,15] Extended observation of the patient is required to assess behavioral responses to external stimulation and to demonstrate cognitive unawareness. The EEG is never isoelectric but shows various patterns of rhythm and amplitude, inconsistent from one patient to the next. Normal EEG sleep-wake patterns are absent.

In *the locked-in syndrome*, patients retain or regain arousability and self-awareness but because of extensive bilateral paralysis (i.e., de-efferentation) can no longer communicate except in severely limited ways. Such patients suffer bilateral ventral pontine lesions with quadriplegia, horizontal gaze palsies, and lower cranial nerve palsies. Voluntarily, they are capable only of vertical eye movements and/or blinking.[1]

Sleep may be abnormal with marked reduction in non-rapid-eye-movement and rapid-eye-movement sleep phases. The most common cause is pontine infarction due to basilar artery thrombosis, but other causes are pontine hemorrhage, central pontine myelinolysis, and brainstem mass lesions. Neuromuscular causes of locked-in syndrome include severe, acute inflammatory demyelinating polyradiculoneuropathies, myasthenia gravis, botulism, and neuromuscular blocking agents. In these peripheral disorders, upward gaze is not selectively spared.

Akinetic mutism describes a rare subacute or chronic state of altered behavior in which an alert-appearing patient is both silent and immobile but not paralyzed.[16] External evidence of mental activity is unobtainable. The patient usually lies with eyes opened and retains cycles of self-sustained arousal, giving the appearance of vigilance. Skeletal muscle tone can be normal or hypertonic but usually not spastic. Movements are rudimentary even in response to unpleasant stimuli. Affected patients are usually doubly incontinent. Lesions that cause akinetic mutism may vary widely. One pattern consists of bilateral damage to frontal lobe or limbic-cortical integration with relative sparing of motor pathways. Vulnerable areas involve both basal medial frontal areas. Somewhat similar behavior also can follow incomplete lesions of the deep gray matter (paramedian reticular formation of the posterior diencephalon and adjacent midbrain), but such patients usually suffer double hemiplegia and act slowly yet are not completely akinetic or noncommunicative.

Catatonia is a symptom complex associated most often with psychiatric disease. This behavioral disturbance is characterized by stupor or excitement and variable mutism, posturing, rigidity, grimacing, and catalepsy. Catatonia can be caused by a variety of illnesses, both psychiatric (affective more than psychotic) disorders and structural or metabolic diseases (toxic- and drug-induced psychosis, encephalitis, and alcoholic degeneration). Psychiatric catatonia may be difficult to distinguish from organic disease because patients often appear lethargic or stuporous rather than totally unresponsive. Such patients also may have a variety of endocrine or autonomic abnormalities. Patients in catatonic stupor do not move spontaneously and appear unresponsive to the environment despite what appears to be a normal level of arousal and consciousness. This impression is supported by a normal neurologic examination and a subsequent recall of most events that took place during the unresponsive period. Patients usually lie with eyes opened and may not blink to visual threat, but one can usually elicit optokinetic responses. The pupils are semi-dilated and reactive to light, oculocephalic reflexes are absent, and vestibulo-ocular testing evokes normal nystagmus. Patients may hypersalivate and be doubly incontinent. Passive movement of the limbs meets with waxy flexibility, and catalepsy is seen in 30% of patients. Choreiform jerks of the extremities and facial grimaces are common. The EEG, both of catatonic excitement and stupor, most often shows a reactive, low-voltage, fast-normal record rather than the slow record of a comatose patient.

APPROACH TO COMA

The initial approach to stupor and coma is based on the principle that all alterations in arousal are acute, life-threatening emergencies. Urgent steps are required to prevent or minimize permanent brain damage from reversible causes often before the cause of coma is definitely established. Patient evaluation and treatment must necessarily occur simultaneously. Serial examinations are needed with accurate documentation to determine a change in state of the patient. Accordingly, management decisions (therapeutic and diagnostic) must be made. The clinical approach to an unconscious patient logically entails the following steps: (1) emergency treatment; (2) history (from relatives, friends, and emergency medical personnel); (3) general physical examination; (4) neurologic profile, the key to categorizing the nature of coma; and (5) specific management.

EMERGENCY MANAGEMENT

The initial assessment must focus on the vital signs to determine the appropriate resuscitation measures; the diagnostic process begins later. Urgent, and sometimes empirical, therapy must be given to avoid additional brain insult.

Oxygenation must be ensured by the establishment of an airway and ventilation of the lungs. The threshold for intubation should be low in the comatose patient, even if respiratory function is sufficient for proper ventilation and oxygenation: the level of consciousness may deteriorate and breathing may decompensate suddenly and unexpectedly. An open airway must be ensured and protected from aspiration of vomitus and blood. While preparing for intubation, maximal oxygenation can be ensured by suction of the upper airway, gentle extension of the neck, elevation of the jaw, and manual ventilation with oxygen using a mask and bag. Bag-valve mask ventilation with 100% oxygen and 1 mg of atropine given intravenously helps prevent cardiac dysrhythmias. If a severe neck injury is a possibility, or has not been excluded, intubation should be performed by the most skilled practitioner with cervical spine precautions. A brief neurologic examination is mandatory before sedation required for intubation.

The key points of the "rapid neurologic examination" are hand drop from over the head (to assess for malingering or hysterical loss of consciousness); pupillary size and response to light; abnormal eye movements (active dysconjugate, unilaterally paralytic, passively induced, or absent); grimacing and withdrawal from noxious stimulation; and abnormal plantar response (unilateral or bilateral Babinski's sign).[17] Assisted ventilation should continue during the examination if necessary. Neuromuscular blockade required for patient management and care should be deferred, if possible, until the neurologic examination is completed (3 to 5 minutes). Signs of arousal or inadequate sedation include dilated, reactive pupils, copious tears, diaphoresis, tachycardia, systemic hypertension, and increased pulmonary artery pressure. Thereafter, monitoring patients neurologically may require head CT more frequently.

Evaluate *respiratory excursions:* arterial blood gas measurement is the only certain method to determine adequate ventilation and oxygenation. Pulse oximetry is useful, however, because it provides immediate, continuous information regarding arterial oxygen saturation. The comatose patient ideally should maintain a PaO_2 greater than 100 mm Hg and a $PaCO_2$ between 34 and 37 mm Hg. Hyperventilation ($PaCO_2 < 35$ mm Hg) should be avoided unless herniation is suspected. Positive end-expiratory pressure (PEEP) should be avoided if increased ICP is suspected, unless hypoxemia is not responsive to supplemental oxygen. Place a nasogastric tube to facilitate gastric lavage and prevent regurgitation.

Maintain *circulation* to ensure adequate cerebral perfusion. Appropriate resuscitation fluid is lactated Ringer's solution;

normal saline is also used when intracranial hypertension is suspected. A mean arterial pressure at about 100 mm Hg is adequate and safe for most patients. While obtaining venous access, collect blood samples for anticipated tests (Table 49-1). Treat hypotension by replacing any blood volume loss, and use vasoactive agents (preferably dopamine). Judiciously manage systemic hypertension with hypotensive agents that do not substantially raise ICP by their vasodilating effect (labetalol, hydralazine, or a titrated nitroprusside infusion are the favored agents for managing uncontrollable hypertension). For most situations systolic blood pressure should not be treated unless it is greater than 160 mm Hg. Maintain urine output at at least 0.5 mL/kg/h; accurate measurement requires bladder catheterization.

Glucose (and *thiamine*) levels need to be determined. Hypoglycemia is a frequent cause of altered consciousness; administer glucose (25 g as a 50% solution i.v.) immediately after drawing blood for baseline values. Empirical glucose treatment will prevent hypoglycemic brain damage and outweighs the theoretical risks of additional harm to the brain in hyperglycemic, hyperosmolar, or anoxic coma. Thiamine (100 mg) must be given with the glucose infusion to prevent precipitation of Wernicke's encephalopathy in malnourished, thiamine-depleted patients. Rarely, an established thiamine deficiency can cause coma.

Repeated generalized *seizures* damage the brain and must be stopped. Initial treatment should include intravenous benzodiazepines, lorazepam (2 to 4 mg), or diazepam (5 to 10 mg). Seizure control can be maintained with phenytoin (18 mg/kg i.v. at a rate of 25 mg/min). Seizure breakthrough requires additional benzodiazepines.

Careful and mild *sedation* should be given to the agitated, hyperactive patient to prevent self-injury. Sedation facilitates ventilator support and diagnostic procedures. Small doses of intravenous benzodiazepines, intramuscular haloperidol (1 mg as often as hourly until desired effect), or morphine (2 to 4 mg, i.v.) are appropriate.

Consider specific *antidotes.* Drug overdose is the largest single cause (30%) of coma in the emergency department. Most drug overdoses can be treated by supportive measures alone. However, certain antagonists specifically reverse the effects of coma-producing drugs. Naloxone (0.4 to 2 mg i.v.) is the antidote for opiate coma. The reversal of narcotic effect, however, may precipitate acute withdrawal in an opiate addict. In suspected opiate coma the minimal amount of naloxone should be administered to establish the diagnosis by pupillary dilatation and to reverse respiratory depression and coma. Do not attempt to reverse completely all drug effects with the first dose. Intravenous flumazenil reverses all benzodiazepine-induced coma. Coma unresponsive to 5 mg of flumazenil in divided doses given over 5 minutes is not due to benzodiazepine overdose. Recurrent sedation can be prevented with flumazenil (1 mg i.v.) every 20 minutes.[18] The sedative effects of drugs with anticholinergic properties, particularly tricyclic antidepressants, can be reversed with physostigmine (1 to 2 mg i.v.). Pretreatment with 0.5 mg of atropine will prevent bradycardia. Only full awakening is characteristic of an anticholinergic drug overdose, because physostigmine has nonspecific arousal properties. Physostigmine has a short duration of action (45 to 60 minutes), and doses may have to be repeated.

Adjust *body temperature.* Hyperthermia is dangerous because it increases brain metabolic demand and, at extreme levels, denatures brain proteins.[19] Hyperthermia greater than 40° C requires nonspecific cooling measures, even before the underlying etiology is determined and treated. Hyperthermia most often indicates infection, but it may be due to intracranial hemorrhage, anticholinergic drug intoxication, or heat exposure. A body temperature of less than 34° C should be slowly increased to greater than 35° C to prevent cardiac dysrhythmia. Hypothermia accompanies profound sepsis, sedative-hypnotic drug overdose, near-drowning, hypoglycemia, or Wernicke's encephalopathy.

Viral and fungal titers

HISTORY

Once vital functions have been protected and the patient's condition is stable, clues to the cause of coma must be sought by interviewing relatives, friends, bystanders, or medical personnel who may have observed the patient before or during the decline in consciousness. The history should include:

- Witnessed events—head injury; seizure; details of a motor vehicle accident; circumstances under which the patient was found.
- Evolution of coma—abrupt or gradual; headache; progressive or recurrent weakness; vertigo; nausea and vomiting.
- Recent medical history—surgical procedures; infections; current medication.
- Past medical history—epilepsy; head injury; drug or alcohol abuse; stroke; hypertension; diabetes; heart disease; cancer; uremia.

- Previous psychiatric history—depression; suicide attempts; social stresses.
- Access to drugs—sedatives; psychotropic drugs; narcotics; illicit drugs; drug paraphernalia; empty medicine bottles.

GENERAL PHYSICAL EXAMINATION

A systematic, detailed examination is helpful and necessary in the approach to the comatose patient who is in no condition to describe prior or current medical problems. This examination is an extension of the initial evaluation and includes the following:

- The repeated assessment of vital signs to determine efficacy of resuscitation measures
- External evidence of trauma
- Evidence of acute or chronic medical illnesses
- Evidence of ingestion or self-administration of drugs (needle marks, alcohol on breath)
- Evaluation for nuchal rigidity. Care is required if severe neck injury is possible or has not been excluded. (Nuchal rigidity may disappear in deeply comatose patients with meningeal infection/inflammation.)

NEUROLOGIC PROFILE

The establishment of the nature of coma is critical for appropriate management and requires the following:

- The correct interpretation of neurologic signs that reflect the integrity, or impairment, of various functional levels of the brain
- Determination whether the pattern and evolution of these signs are best explained by a supratentorial or infratentorial structural lesion, a metabolic-toxic encephalopathy, or a psychiatric cause (Tables 49-2 and 49-3)

The clinical neurologic functions that provide the most useful information in making a categorical diagnosis are outlined in Table 49-4. These indices are easily and quickly obtained. Furthermore, they have a high degree of interexaminer consistency and, when applied serially, they accurately reflect the patient's clinical course. Once the cause of coma can be assigned to one of these categories, specific radiographic, electrophysiologic, or chemical laboratory studies can be used to make a disease-specific diagnosis and to detect existing or potential complications.

SPECIFIC MANAGEMENT

Supratentorial Mass Lesions

If the cause of coma is a presumed supratentorial mass, determine the severity and rate of evolution of signs. A stabilized patient next requires an emergency head CT or MRI. Carotid angiography is considerably less informative; a skull radiograph is a waste of time. The priority in deep coma or established/threatening transtentorial herniation is to apply successfully medical treatment of intracranial hypertension. Brief hyperventilation to a $PaCO_2$ between 25 and 30 mm Hg is the most rapid method to reduce intracranial hypertension. This is achieved by adjusting the ventilation rate to 10 to 16 breaths/min and tidal volume to 12 to 14 mL/kg. An osmotic agent must be administered concurrently. Sustained hyperventilation at less than 30 to 35 mm Hg removes all future value of this procedure. The preferred osmotic agent is a 20% mannitol solution as a 1g/kg intravenous bolus. Maximum reduction in ICP occurs within 20 to 60 minutes, and the effect of a single bolus lasts about 6 hours. Corticosteroids are not indicated in the emergent, empirical management of increased ICP, because full effects are observed only after a few hours. Furthermore, because corticosteroids are effective only for certain lesions (e.g., edema around a brain tumor or abscess), use can be delayed until a diagnosis has been made by head CT. After such initial ICP management, a head CT or MRI is required. The scan will demonstrate the nature of the supratentorial lesion and associated mass effect. Arrangements must be made to evacuate promptly an epidural or subdural hematoma. Intraparenchymal masses that acutely

TABLE 49–3. CORRELATION BETWEEN LEVELS OF BRAIN FUNCTION AND CLINICAL SIGNS

Structure	Function	Clinical Sign
Cerebral cortex	Conscious behavior	Speech (including any sounds) Purposeful movement Spontaneous To command To pain
Brainstem activating and sensory (reticular activating system) pathways	Sleep/wake cycle	Eye opening Spontaneous To command To pain
Brainstem motor pathways	Reflex limb movements	Flexor posturing (decorticate) Extensor posturing (decerebrate)
Midbrain CN III	Innervation of ciliary muscle and certain extraocular muscles	Pupillary reactivity
Pontomesencephalic MLF	Connects pontine gaze center with CN III nucleus	Internuclear ophthalmoplegia
Upper pons CN V CN VII	 Facial and corneal Facial muscle innervation	 Corneal reflex-sensory Corneal reflex-motor response Blink Grimace
Lower pons CN VIII (vestibular portion) connects by brainstem pathways with CN III, IV, and VI	 Reflex eye movements	 Doll's eyes Caloric responses

Spinal cord	Primitive protective responses	Deep tendon reflexes Babinski response

CN, cranial nerve.

produce deep stupor or coma initially are best managed nonsurgically. When corticosteroids are indicated for severe vasogenic edema, a dexamethasone bolus should be given (up to 100 mg i.v.), followed by 6 to 24 mg every 6 hours. Once signs of herniation have abated, the ventilator rate should be carefully reduced to achieve a $PaCO_2$ of 34 to 37 mm Hg.

The patient's vital signs and neurologic condition require repeated examination. The head should be kept slightly elevated (15 degrees). Mannitol may be repeated, if necessary, every 4 to 6 hours; serum electrolytes and fluid balance must be monitored.

When patients with presumed increased ICP do not respond clinically as expected to medical management, or when obstructive hydrocephalus complicates a supratentorial mass lesion, we favor placement of a ventriculostomy into the lateral ventricle. The ventriculostomy allows accurate measurement of intraventricular ICP and provides a method for CSF drainage, if necessary. The placement of a ventriculostomy allows calculation of cerebral perfusion pressure (CPP) (mean systemic arterial pressure minus ICP), a critical determinant of CBF and, therefore, of oxygen and substrate delivery. Monitoring of ICP also allows adjustment of therapeutic intervention before clinical deterioration occurs in patients with diminished intracranial compliance. Drainage of CSF aims to relieve raised ICP to maintain CPP (greater than 60 mm Hg) and to improve intracranial compliance. After increased ICP has responded to emergency management and the patient's condition has stabilized, definitive treatment of the mass lesion is required as deemed appropriate.

TABLE 49–4. CHARACTERISTICS OF CATEGORIES OF COMA

Supratentorial Mass Lesion Affecting the Diencephalon/Brainstem

Initial focal cerebral dysfunction
Dysfunction progresses rostral to caudal
Signs reflect dysfunction at one level
Signs often asymmetric

Infratentorial Structural Lesion

Symptoms of brainstem dysfunction or sudden-onset coma
Brainstem signs precede/accompany coma
Cranial nerve and oculovestibular dysfunction
Early onset of abnormal respiratory patterns

Metabolic-Toxic Coma

Confusion/stupor precede motor signs
Motor signs usually symmetrical
Pupil responses generally preserved
Myoclonus, asterixis, tremulousness, and generalized seizures common
Acid-base imbalance common with compensatory ventilatory changes

Psychogenic Coma

Eyelids squeezed shut
Pupils reactive or dilated, unreactive (cycloplegics)
Oculocephalic reflex unpredictable; nystagmus on caloric tests
Motor tone normal or inconsistent
No pathologic reflexes
(Awake-pattern EEG)

Infratentorial Lesions

The evolution of neurologic symptoms and signs and the neurologic examination generally give sufficient information to localize the lesion to the posterior fossa; the lesions themselves may be intrinsic or extrinsic to the brainstem.

Rapid neurologic deterioration of a patient suspected of harboring an infratentorial lesion sometimes demands emergency treatment before CT of the head is performed.

Treatment of a presumed extrinsic compressive lesion of the brainstem entails measures that decrease ICP as outlined earlier. Patients who are stuporous or showing signs of progressive brainstem compression from a cerebellar hemorrhage or infarction require urgent evacuation of the lesion. Intrinsic brainstem lesions are best treated conservatively; an incompleted stroke may benefit from thrombolysis and/or heparin anticoagulation. Posterior fossa tumors are managed initially with osmotic agents and corticosteroids; definitive treatment includes surgery and/or radiation. The placement of a ventricular catheter for acute hydrocephalus must be considered cautiously and in consultation with a neurosurgeon; the danger exists of potentially fatal upward transtentorial herniation.[12]

Metabolic Toxic Coma

The task of the physician in first contact with the patient in metabolic coma is to preserve and protect the brain from permanent damage. Metabolic and toxicologic studies must be performed on the first blood sample drawn (see Table 49-1). There are several treatable conditions that quickly and irreversibly damage the brain.

Hypoglycemia. As noted earlier, glucose (50 mL of a 50% solution i.v.) should be administered during emergency treatment before blood results return. Prolonged hypoglycemic coma that has considerably damaged the brain will not be reversed by a glucose load; a glucose bolus may transiently worsen hyperglycemic, hyperosmolar coma. In contrast, the osmolar load of intravenous glucose may transiently decrease elevated ICP and lighten nonhypoglycemic coma. A glucose infusion is needed to prevent recurrent hypoglycemia.

Acid-Base Imbalance. The hyperventilating comatose patient with acute, severe metabolic acidosis and threatening cardiovascular collapse requires emergency treatment. For accurate assessment an arterial blood gas is required. Administration of sodium bicarbonate (1 mEq/kg i.v.) can be life saving; simultaneously, a search for, and specific treatment of, the cause must be conducted.

Hypoxia. Carbon monoxide poisoning requires hyperoxygenation with 100% oxygen to facilitate excretion of this toxin. Closely monitor and correct blood pressure and cardiac rhythm abnormalities. Idiopathic and drug-induced methemoglobinemia is treated with methylene blue (1 to 2 mg/kg i.v. over a few minutes; repeat dose after 1 hour if needed). Anemia alone does not cause coma but exacerbates other forms of hypoxemia. Transfusion of packed red cells is appropriate for severe anemia (hematocrit < 25%). Cyanide poisoning causes histotoxic hypoxia of the brain. Treatment entails amyl nitrite (vapor or crushed ampule inhaled every minute), sodium nitrite (300 mg i.v.) followed by sodium thiosulfate (12.5 g i.v.).

Acute Bacterial Meningitis. A lumbar puncture must be considered in any unconscious patient with fever and/or signs of meningeal irritation. If possible, an emergency head CT should be performed before lumbar puncture on a comatose patient to rule out unexpected mass lesions. Increased ICP is present in all cases of bacterial meningitis, but a lumbar puncture is not contraindicated when this diagnosis is suspected. Cerebral herniation seldom, if ever, occurs except in small children.[20] Clinical correlates of impending herniation demand a more cautious approach to lumbar puncture: coma or rapidly deteriorating level of arousal, focal neurologic signs, and tonic or prolonged seizures. Papilledema is rare in acute bacterial meningitis. Should unexpected herniation occur after lumbar puncture, treatment with hyperventilation and intravenous mannitol is indicated. Appropriate antibiotic treatment can usually await the results of CSF Gram stain. If the Gram stain is negative yet a bacterial cause is suspected, empirical, broad-spectrum antibiotic treatment with a third-generation cephalosporin and vancomycin is appropriate.

Drug Overdose. Certain general principles apply to all patients suspected of having ingested sedative drugs.[21,22] Most drug overdose is treated by emergent and supportive measures (see Table 49-5). Once vital signs are stable, attempts should be made to remove, neutralize, or reverse the effects of the drug. Patients in coma from recent drug ingestion require gastric lavage after endotracheal intubation. A large, preferably double-lumen, gastric tube must be placed orally. The lavage is performed in the head-down position on the left side. Lavage is performed with 200 to 300 mL bolus of tap water or 0.45% saline and continued until the return is clear. After lavage, 1 or 2 tablespoons of activated charcoal is passed down the lavage tube. With meticulous supportive measures, patients with uncomplicated drug-induced coma should recover without neurologic deficit. The recovery from coma due to massive doses of barbiturates or glutethimide can be hastened by hemodialysis.

Constant vigilance and attention to the patient's condition, with timely and appropriate diagnostic and therapeutic evaluation, ensures the best possible outcome of metabolic coma. Effective care demands meticulous attention to the maintenance of tissue perfusion and oxygenation, the documentation and anticipation of acute neurologic events (particularly diminished cerebral perfusion, herniation, or seizures), aggressive, rapid treatment of initial or subsequent infections, and prevention of agitation. Deep venous thrombosis can be prevented with either subcutaneous heparin (5000 units q 12h) or full-length leg pneumatic compression boots. Enteral or parenteral feeding within 36 to 48 hours is required to satisfy nutritional needs. Corneal injury can be prevented by protecting the eyes with lubricants and taping the lids shut.

THE ROLE OF SPECIAL INVESTIGATIONS

NEURODIAGNOSTIC IMAGING

Once the patient with an altered mental status is appropriately resuscitated and stabilized, further investigation may be necessary to document the location and type of the lesion and to provide guidance for therapeutic intervention. CT and MRI provide an anatomic and/or functional assessment of the central nervous system (CNS) and provide helpful information for defining the localization of lesions that produce coma. For details on the use of these modalities in neurointensive care, see Chapter 48.

Cranial CT is currently the most expedient imaging technique in the comatose patient and gives the most rapid information about possible structural lesions with the least risk. The value of CT to demonstrate mass lesions, hemorrhage, and hydrocephalus is well established. CT shows tissue shifts due to intracranial intercompartmental pressure gradients but compared with MRI may underestimate the anatomy of herniation.[11] Certain lesions such as early infarction (less than 12 hours' duration), encephalitis, and isodense subdural hemorrhage may be difficult to visualize. Posterior fossa pathology may be somewhat obscured by bone artifact

TABLE 49–5. NEUROLOGIC MANIFESTATIONS OF COMMON DRUG POISONING

Drug	Signs and Symptoms	Diagnostic Test	Treatment
Carbon monoxide	Confusion, agitation, headache, convulsions, coma, respiratory failure, cardiovascular collapse	History Carboxyhemoglobin level	Remove patient from area; administer 100% oxygen until carboxyhemoglobin levels fall to < 5%. Administer hyperbaric oxygen if central nervous system affected. Treat cerebral edema with hyperventilation, diuretics, and cerebrospinal fluid drainage, if necessary.
Salicylate	Tinnitus, hyperpnea, confusion, convulsions, coma, hyperthermia	Blood	Provide supportive care, gastric lavage, charcoal, systemic alkalinization, hemodialysis for coma or seizures.
Cyanide	Agitation, confusion, headache, vertigo, hypertension, hypotension, seizures, paralysis, apnea, coma	Blood	Use amyl nitrate, sodium nitrate, sodium thiosulfate, 100% oxygen, or hyperbaric oxygen for refractory signs. Vitamin B12 injection.
Anticonvulsants: Phenytoin Carbamazepine Phenobarbital (see Barbiturates) Valproic acid Primidone Ethosuximide Felbamate Clonazepam (see Benzodiazepines)	Drowsiness, ataxia, nystagmus, tremulousness, coma. Dysrhythmias with carbamazepine or phenytoin overdose.	Blood Ammonia level in patients taking valproic acid.	Provide supportive care, gastric lavage, charcoal. Watch for withdrawal seizures.
Sedative hypnotics: Benzodiazepines Barbiturates Chloral hydrate Meprobamate Ethchlorvynol (Placidyl)	Confusion, lethargy, ataxia, nystagmus, hypothermia, dysarthria, respiratory depression, coma. Pupillary reactions preserved except in instances of deep barbiturate coma. Possible withdrawal seizures.	Blood	Provide supportive care, gastric lavage, flumazenil for benzodiazepine overdose, hemoperfusion for extreme barbiturate intoxication.
Methaqualone	Agitation, hypertonic, hyperreflexia, ataxia, hallucinations, convulsions	Blood	As above
Ethanol	Confusion, agitation, delirium, ataxia, nystagmus, dysarthria, coma	Blood, breath	Provide supportive care, lavage if within 1 hour of ingestion, thiamine, glucose.
Opioids	Lethargy; small reactive pupils; hypothermia; hypotension, urinary retention; shallow, irregular respirations; convulsions	Urine Response to naloxone	Administer naloxone, 0.4 mg IV or IM; continuous naloxone infusion, if necessary. Provide supportive care with intubation as necessary. Lavage if overdose is by ingestion.
Stimulants: Amphetamine Methylphenidate Cocaine	Hypervigilance, paranoia, violent behavior, tremulousness, dilated pupils, hyperthermia, tachycardia or arrhythmia, focal neurologic signs secondary to CNS stroke or hemorrhage, seizures	Blood, urine	Provide supportive care; sedation with benzodiazepines. Watch for rhabdomyolysis.
Psychedelics (LSD, mescaline, phencyclidine)	Delirium, delusions, marked agitation, hallucinations, hyperactivity, dilated pupils, hyperreflexia, nystagmus	Blood Measure phencyclidine levels in gastric juice.	Use gastric lavage, charcoal. Give benzodiazepines and haloperidol for sedation.
Antidepressants: Tricyclic antidepressants	Anticholinergic effects: dry mouth, agitation, restlessness, ataxia, tachycardia or arrhythmias, hyperthermia, hysteria, convulsions, mydriasis	Blood, urine	Use cardiac monitoring, gastric lavage, charcoal, mild systemic alkalinization. Administer physostigmine for refractory arrhythmias and anticonvulsants for seizures.
Monoamine oxidase inhibitors	Drowsiness, ataxia, seizures, hypertensive crisis; hypotension with severe overdose		Provide symptomatic care, gastric lavage; avoid narcotics.
Neuroleptics	Dystonia, drowsiness, coma, convulsions, hypotension, miosis, tremor, hypothermia, neuroleptic malignant syndrome	Urine	Use gastric lavage. Treat extrapyramidal signs with diphenhydramine or benztropine mesylate.
Lithium	Lethargy, tremulousness, weakness, polyuria, polydipsia, ataxia, seizures, coma	Blood	Perform hemodialysis for delirium, seizures, or coma.
Methanol, ethylene glycol	Drunkenness, hyperventilation, stupor, convulsions, coma. Blindness with methanol use.	Blood	Provide symptomatic care, gastric lavage, ethanol infusion, hemodialysis. For methanol intoxication, 4-methylpyrazole is under investigation.
Antihistamines	Anticholinergic effects: dry		Provide supportive care, gastric lavage;

TABLE 49–5. NEUROLOGIC MANIFESTATIONS OF COMMON DRUG POISONING—CONT'D

	mucosa, flushed skin, hyperthermia, dilated pupils, delirium, hallucinations, seizures, coma		control seizures with benzodiazepines; use physostigmine for life-threatening anticholinergic effects.
Organophosphates	Cholinergic crisis: cramps, excessive secretions, diarrhea, bronchoconstriction. inherent in the CT technique. Raised ICP is suggested by effacement of cortical sulci, a narrow third ventricle, and obliteration of the suprasellar or quadrigeminal cisterns but cannot be otherwise quantified. MRI can be performed, depending on the clinical setting and the stability of the patient's condition. The use of MRI is limited in the urgent setting of coma evaluation because of the length of time required to perform the imaging, image degradation by even a slight movement of the patient, and the relative inaccessibility of the patient for emergencies that may occur during the imaging process. Nevertheless, MRI provides superb visualization of posterior fossa structures that is useful when intrinsic brainstem lesions are suspected as the cause of coma.[11] MRI images anatomic lesions, such as those resulting from acute stroke, encephalitis, central pontine myelinolysis, and traumatic shear injury with greater resolution and at an earlier time than CT. The injection of the paramagnetic substance, gadolinium, helps delineate areas of blood-brain barrier breakdown and may augment the sensitivity of this scanning technique. Diffusion-weighted imaging can demonstrate ischemic brain virtually immediately. Sagittal MRI views are particularly useful in the documentation of the degree of supratentorial or infratentorial herniations and may enable intervention before clinical deterioration (Fig. 49-1).[11] Newer MRI techniques allow functional imaging of the CNS by measurement of CBF to a particular region. Future application of this technique may allow rapid determination of diminished CBF, such as occurs in stroke or vasospasm, and will probably be useful in assessing the effect of therapeutic interventions.

ELECTROENCEPHALOGRAPHY

The EEG can sometimes gives useful additional information in the evaluation of the unresponsive patient. With metabolic and toxic disorders, the EEG changes generally reflect the degree and severity of altered arousal or delirium characterized by a decreased frequency of the background rhythm and the appearance of diffuse slow activity in the theta (4 to 7 Hz) and/or delta (1 to 3 Hz) range. Bilaterally synchronous and symmetrical, medium to high-voltage broad triphasic waves are seen in various metabolic encephalopathies, most often in hepatic coma. Rapid beta activity (greater than 13 Hz) in a comatose patient suggests the ingestion of sedative hypnotics, such as barbiturates and benzodiazepines. Acute, focally destructive lesions show focal slow activity; when periodic lateralized epileptiform discharges appear in one or both temporal lobes, herpes simplex encephalitis must be strongly considered. A nonreactive, diffuse alpha pattern in a comatose patient usually implies a poor prognosis and is most often seen after anoxic insults to the brain or acute, destructive pontine tegmentum damage.[23,24] A normally reactive EEG in an unresponsive patient suggests psychiatric disease; however, a relatively normal EEG can accompany the locked-in syndrome, some examples of akinetic mutism, and catatonia, all of which can be caused by structural brain lesions. Attempts to correlate the pattern and frequency spectra of a post-resuscitative EEG with neurologic outcome have been unsatisfactory because its predictive value is at best 88% accurate.[25] At present, the most useful information regarding patient prognosis is still obtained by the correct interpretation of physical signs.

Nonconvulsive generalized status epilepticus and repeated complex partial seizures may produce altered levels of awareness or arousal; the EEG is an indispensable tool in the diagnosis and management of both these disorders. Continuous EEG monitoring optimizes management of status epilepticus because clinical assessment is insufficiently sensitive to detect continued electrographic seizures. Furthermore, continuous EEG monitoring in the ICU has shown an unsuspected high incidence of electrographic seizure activity in critically ill neurologic patients.[26,27]

JUGULAR VENOUS OXIMETRY

Changes in jugular venous oxygen saturation measure the relationship between cerebral metabolic rate and CBF, and this monitoring tool is discussed in Chapter 48.[28] This form of monitoring offers the potential to minimize secondary insults after traumatic brain injury by providing warning of cerebral ischemia. It should be considered in comatose patients in conjunction with ICP monitoring (discussed later) to provide a logical approach to the treatment of brain injury.

TRANSCRANIAL DOPPLER ULTRASONOGRAPHY

Transcranial Doppler imaging (see Chapter 48) allows noninvasive measurement of blood flow velocity in basal cerebral arteries.[29] The high dynamic resolution provided, and confirmed correlation with other hemodynamic modalities, encourages increasing numbers of neurointensivists to adopt the technique. Its importance in coma is in early detection of vasospasm in subarachnoid hemorrhage and at the time of brain death,[30] where an oscillating reverbatory

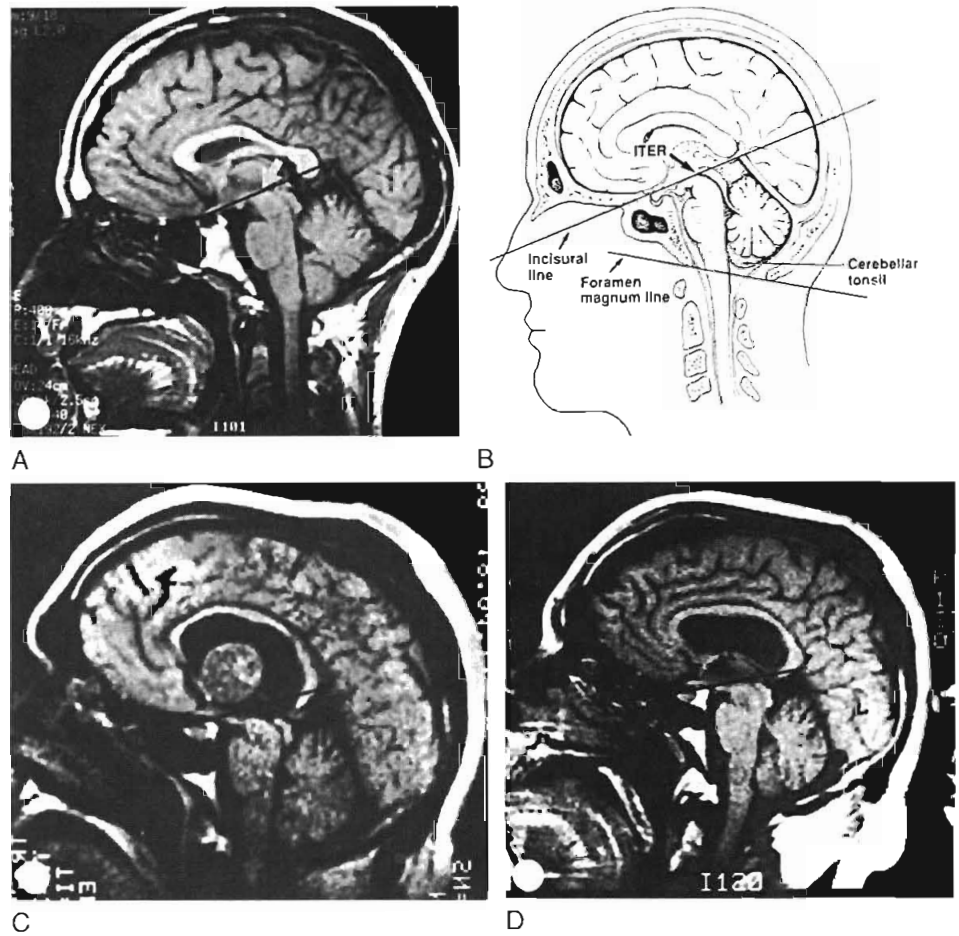

FIGURE 49–1. Midsagittal MRI views of a normal adult brain and of a brain with reversible downward transtentorial herniation. **A** and **B,** MRI view of a normal adult male brain and accompanying diagram. The opening of the tentorium of the cerebellum or anterior cerebellar notch lies along a line (incisural line) defined anteriorly by the anterior tubercle of the sella turcica and posteriorly by the junction of Galen's vein, the inferior sagittal sinus, and the confluence of the straight sinus. The proximal opening of the aqueduct of Sylvius, the iter ad infundibulum *(arrow),* lies within 2 mm of the incisural line. The foramen magnum line is defined between the inferior tip of the clivus anteriorly and the bony base of the posterior lip of the foramen magnum. **C,** A 47-year-old man who experienced 1 week of headache, nausea, vomiting, and gait ataxia presented with abrupt-onset coma, palsy of cranial nerve III, hyperreflexia, and bilateral extensor plantar responses. MRI revealed a third ventricular mass, obstructive hydrocephalus, and displacement of the iter ad infundibulum inferiorly by 6.5 mm. The cerebellar tonsils were not displaced. **D,** Subsequent MRI view in the patient in **C** at 2 weeks after surgical removal of a colloid cyst. The iter ad infundibulum is 1.2 mm below the incisural line. The patient had full neurologic recovery. (A, C, and D from Reich JB, Sierra J, Camp W, et al: Magnetic resonance imaging measurements and clinical changes accompanying transtentorial and foramen magnum brain herniation. Ann Neurol 1993;33:159-170.)

movement has been noted in the flow velocity waveforms. The diagnosis is suspected based on the finding of the reflux phenomenon during late systole after anterograde injection of blood into the vascular tree.

EVOKED POTENTIALS

Evoked potentials (EPs) are used to follow the level of CNS function in comatose patients.[31] Clinical use of brainstem auditory evoked potential (BAEP) and short latency somatosensory evoked potential (SEP) responses stem from the correlation between EP waveform and presumed generators within certain CNS structures. The SEP shows special promise in the ICU field because EP components generated supratentorially in the thalamus and primary sensory cortex can be identified and followed over time. Shifts of intracranial structures that lead to herniation syndromes are reflected in abnormalities in SEPs, whereas BAEPs are generated entirely at or below the lower midbrain and are less often affected. EPs are less affected than EEG readings by sedative medications and septic or metabolic encephalopathies, factors that frequently confound interpretations in comatose patients. Anatomic specificity and physiologic and metabolic immutability are the basis of clinical utility of EPs. Abnormal test results, however, are etiologically nonspecific and must be carefully integrated into the clinical situation by a physician familiar with their clinical use. Caution is needed in the interpretation of SEPs to ensure that absent responses are not due to technical problems. Repeat SEPs are useful in following patients' progress. A progressive decline in response amplitude appears to be associated with worsening prognosis. Studies have shown that all patients with anoxic coma and bilaterally absent SEPs had died or remained in persistent vegetative state.[32] In traumatic coma, absent SEPs may be a less definitive prognostic indicator, because recovery of consciousness has been reported in some patients.[33] Furthermore, comatose patients, especially those with motor response of flexor posture or better, with an initial poor prognostic EEG pattern but normal SEPs, may have the potential for recovery and should be supported until the patient's condition has

changed to a more prognostically definitive category.[34] BAEPs and median SEPs obtained within 24 hours of coma onset had a 3-month predictive outcome (compared with Glasgow outcome score) in patients with head injury, brain hemorrhage, or neoplasm.[35] Diagnostic sensitivity for an unfavorable outcome was low for both parameters, although specificity and positive predictive value was equally high for abnormal wave VI of BAEPs and median SEPs.

MONITORING OF INTRACRANIAL PRESSURE

Monitoring of ICP in neurointensive care is discussed in detail in Chapter 47. A review of published randomized controlled studies of real-time ICP monitoring by invasive or semi-invasive means in acute coma (traumatic or nontraumatic etiology) versus no ICP monitoring (i.e., clinical assessment of ICP) looked at outcome measures of all-cause mortality and severe disability at the end of a given follow-up period.[36] The conclusion drawn is that there are insufficient data to clarify the role of routine ICP monitoring in all severe cases of acute coma. However, it is of value in traumatic brain injury and should be considered on a case-by-case basis in other cases of coma.

PROGNOSIS

A complete evaluation of the comatose patient must include an estimate of prognosis. The outcome in a given comatose patient cannot be predicted with absolute certainty. Available serial data are not sufficiently specific or selective to help in establishing the prognosis in an individual patient. Guidelines on the outcome of coma have been compiled based on serial examinations. Although the status of the comatose patient on admission is valuable in providing early, informed discussion with relatives of patients and medical colleagues, that moment in most instances does not provide sufficient information to withhold immediate therapy. However, the early establishment of a highly probable poor outcome ideally should be made within 24 hours after hospital admission to ration intensive care services and protect families from false hope in futile cases. A logical and sensible approach to prognostication includes an etiologic subcategorization into medical, drug-induced, and traumatic coma.

Numerous prehospital descriptive scoring systems are used in an attempt to assess the severity of illness and predict outcome of patients. A 2-year prospective study compared severity of illness scoring systems (Acute Physiology and Chronic Health Evaluation [APACHE] II and Mainz Emergency Evaluation System [MEES]) to mental status measurement (Glasgow Coma Score [GCS]) in predicting outcome of 286 consecutive adult patients hospitalized for nontraumatic coma.[37] There were no statistically significant differences among the scoring systems to correctly predict outcome. APACHE II and MEES should not replace GCS. For the prediction of mortality, the GCS score provides the best indicator also in nontraumatic comatose patients (it is simple, less time consuming, and accurate in an emergency situation). Factors that are useful in determining the outcome of medical coma include the cause, the depth, and the duration of coma. Clinical signs reflecting brainstem, motor, and verbal function are the most helpful and best validated predictors (confidence interval 0.95).[38-41] Overall, only 15% of patients in established medical coma for 6 hours will make a good or moderate recovery; others will die (61%), remain vegetative (12%), or become permanently dependent on others for daily living (11%). Prognosis depends on etiology of medical coma. Patients in coma due to a stroke, subarachnoid hemorrhage, or cardiorespiratory arrest have only about a 10% chance of achieving independent function. Thirty-five percent of patients will achieve moderate to good recovery if coma is due to other metabolic reasons, including infection, organ failure, and biochemical disturbances. As noted earlier, almost all patients who reach hospital after sedative overdose or other exogenous agents will recover moderately or completely. The depth of coma affects the individual prognosis. Patients who open their eyes in response to noxious stimuli after 6 hours of coma have a 20% chance of making a good recovery versus 10% if the eyes remain closed. The longer coma persists, the less likely are the chances for recovery; 15% of patients in coma for 6 hours make a good or moderate recovery compared with only 3% who remain unconscious at 1 week.[38,39] Coma after head trauma has a somewhat better prognosis (see later).

The severity of signs of brainstem dysfunction on admission inversely correlates with the chance of good recovery in medical coma. Absent pupillary responses at any time after onset and absent caloric-vestibular reflexes 1 day after onset indicate a poor prognosis (<2% recovery except in barbiturate or phenytoin poisoning). Except for sedative drug poisoning, no patient with absent pupillary light reflexes, corneal reflexes, oculocephalic or caloric responses, or lack of a motor response to noxious stimulation at 3 days after onset is likely to ever regain independent function. In a prospective study of 500 patients in medical coma, a uniform group of 210 patients suffered anoxic injury: 52 of these had no pupillary reflex at 24 hours, all of whom died. By the third day, 70 were left with a motor response worse than withdrawal and all died. By the seventh day, the absence of roving eye movements was seen in 16 patients, all of whom died.[38,39]

Patients likely to recover to functional independence will within 1 to 3 days speak words, open their eyes to noise, show nystagmus on caloric testing, or have spontaneous eye movements. More than 25% of patients with anoxic injury who show roving conjugate eye movements within 6 hours of the onset of coma or who show withdrawal responses to pain or eye opening to pain will recover independence and make a moderate or good recovery. The use of combinations of clinical signs helps to improve the accuracy of prognosis: at 24 hours the absence of a corneal response, pupillary light reaction, or caloric or doll's eye response is not compatible with recovery to independence.

Postanoxic convulsive status epilepticus and/or myoclonic status epilepticus reflect a poor prognosis. Occasional patients recover consciousness but remain handicapped. Most die or become vegetative.[42,43] Associated clinical findings, such as loss of brainstem reflexes or eye opening at the onset of myoclonic jerks, and sinister EEG patterns, such as suppression or burst-suppression, confirm a grim neurologic outcome in this group. Autopsy studies show that cerebral and cerebellar damage can be ascribed to the initial ischemic hypoxic event; there is no evidence that status epilepticus further contributes to this damage. We initially treat patients with an intravenous loading dose of a major anticonvulsant (phenytoin, 13 to 18 mg/kg at 25 mg/min, and/or phenobarbitol, 20 mg/kg at 50 mg/min). Myoclonic status epilepticus is generally resistant to therapy; we give intermittent doses of benzodiazepines (lorazepam, 2 to 4 mg, or clonazepam, 0.5 mg i.v.) as needed to suppress particularly severe

myoclonus that interferes with ventilatory support. Anesthetic agents are rarely indicated and are unlikely to alter outcome.

A meta-analysis of prognostic studies in anoxic-ischemic coma examined the value of biochemical markers of brain damage in CSF or serum.[44] Only concentrations of CSF markers (creatine kinase brain isoenzyme, neuron-specific enolase, lactate dehydrogenase, and glutamate oxaloacetate) reached 0% false-positive rate. Because of small numbers of patients involved in studies (wide confidence levels) and methodologic limitations of studies the results available are not sufficiently accurate to provide a solid basis for management decisions of patients in coma.

The most accurate prediction of outcome in a patient in medical coma is obtained from the use of a combination of clinical signs and there is little to be added by more sophisticated testing other than in identifying the cause of the coma.[38,39] Within the first week, it is hard to justify the withdrawal of therapy from patients in medical coma unless they are already brain dead or lack all signs of brainstem function. After that, the probability of being able to predict the quality of life increases steadily. A multisociety task force of neurologists and neurosurgeons obtained a large number of data concerning the persistent vegetative state that provides guidelines to outcomes in patients remaining vegetative 1 month after severe head trauma or coma-producing medical illness (mostly anoxic).[15]

Among adults with head trauma who were in a vegetative state at 1 month (n = 434), 33% died, 15% remained vegetative, and 28% suffered severe disability at 1 year. Among children vegetative for 1 month after trauma (n = 106), 9% died, 29% remained in a persistent vegetative state, and 35% were severely disabled at 1 year; only 27% attained moderate/good recovery.

Nontraumatic (medical) coma results were even worse. Among 169 adults with nontraumatic brain injury and vegetative at 1 month, 53% died within a year, 32% remained vegetative, and only 14% made a moderate/good recovery. Outcome of 45 children in similar circumstances showed 22% dead, 65% still vegetative, and only 6% who made a moderate/good recovery at 1 year.

It is possible in a fraction of patients to predict within the first week those who will recover, those who will die in coma or enter a vegetative state, and those who will survive with severe disability. It is well established that patients in anoxic coma who are in a vegetative state at 1 month will never recover their full preanoxic physical or cognitive function.

Patients in coma due to *exogenous agents* (except carbon monoxide poisoning) carry an overall good prognosis provided that circulation and respiration are protected by avoiding or correcting cardiac dysrhythmia, aspiration pneumonia, and respiratory arrest. Despite absent brainstem reflexes (electrocerebral silence on EEG), patients with deep sedative drug intoxication have the potential for complete recovery. Therefore, in the emergent situation, patients in coma of uncertain etiology should be supported vigorously until the precise cause of coma has been fully established.

The outcome of *traumatic coma* is generally better than that of medical coma, and prognostic criteria are somewhat different[15,33,45]:

1. Many patients with head injury are young.
2. Prolonged, post-traumatic unconsciousness of up to several months does not always preclude a satisfactory outcome.
3. Compared with the initial degree of neurologic abnormality, patients in traumatic coma improve more than patients in medical coma. Patients in coma for longer than 6 hours after traumatic brain injury have a 40% chance to recover to moderate disability or better at 6 months.

The most reliable predictors of outcome at 6 months are:

1. Patient age (worse outcome especially after 60 years).
2. Depth and duration of coma (an inverse correlation with GCS score).
3. Pupil reaction and eye movements (absence at 24 hours predicts death or a vegetative state in 90%).
4. Motor response in the first week of injury (Table 49-6).

An independent poor prognostic indicator is sustained, uncontrollably increased ICP (greater than 20 mm Hg). Additional factors play a role in the eventual outcome from traumatic coma. Specific lesions, such as subdural hematoma, that result in coma can have a less than 10% recovery rate.[46] In studies with blunt trauma, comatose patients with increased plasma glucose, hypokalemia, or elevated blood leukocyte counts were associated with lower GCS scores and an increased probability of death.[47] There are some reports of patients who have suffered coma as a result of traumatic brain injury in whom an improvement from the vegetative state has been recognized after months, but these anecdotal cases of recovery are difficult to validate, and it seems possible that such patients were not truly vegetative, rather in a

state of profound disability but with cognition, at the beginning of the observation.[48]

A systematic review of trials reporting on multisensory stimulation programs in patients with traumatic brain injury in coma or the vegetative state found no reliable evidence of the effectiveness of such techniques when compared with standard rehabilitation.[49] Outcome measures included duration of unconsciousness (time between injury and response to verbal commands), level of consciousness (GCS), level of cognitive functioning, functional outcomes (GCS), or disability rating scale. The overall methodologic quality was poor, and studies differed widely in design and conduct. Because of the diversity in reporting of outcome measures a meta-analysis was not possible.

The prognostic guidelines for medical and traumatic coma should be applied with care. One must be sure that evaluation and interpretation of clinical signs are correct. The prognostic signs, however, predict general outcomes in large patient groups and cannot be applied with absolute precision to every individual comatose patient. In addition, the effect of anticholinergic agents, used during resuscitation, on pupillary reactivity and the effect of paralytic agents on motor response must be excluded.

The ability to predict prognosis after coma can benefit the patient, family, and physician. Families can be spared both the emotional and financial burdens of caring for individuals with an insignificant chance of independent function and quality life. Physicians can then properly allocate limited resources to patients with the potential to benefit from advanced medical care.

There are recognized difficulties in interpreting the outcome of studies of coma prognosis: the lack of prospective studies, failure to state confidence intervals, and the fact that patients in coma may die of a non-neurologic disease. The self-fulfilling nature of poor prognoses is difficult to eliminate: the care of a patient will reflect the treating physicians' impressions and opinions on patient outcome. Ideally, prognostic studies should only be performed on patients who will receive maximal life support for as long as possible, but this is inconsistent with the humane and sensitive management of patients and their relatives.

A recent analysis used data from the SUPPORT (Study to Understand the Prognoses and Preferences for Outcomes and Risks of Treatments) trial to estimate the cost-effectiveness of aggressive care for patients in nontraumatic coma.[50,51] Patients with reversible metabolic causes of coma were excluded. The incremental cost-effectiveness was calculated for aggressive care versus withholding cardiopulmonary resuscitation and ventilatory support after day 3 of coma. The incremental cost-effectiveness of the more aggressive strategy was $140,000 (1998 dollars) per quality-adjusted life year for high-risk patients and $87,000/quality-adjusted life year for low-risk patients (five risk factors were age older than 70 years, absent verbal response, absent withdrawal to pain, abnormal brainstem response, and serum creatinine value greater than 1.5 mg/dL). Earlier decisions to withhold life-sustaining treatments for patients with very poor prognoses may yield considerable cost savings. On moral and ethical grounds physicians may object to consideration of the cost factor when it comes to treatment decisions of more-or-less sick patients. Financial constraints imposed on the medical fraternity from "top down" by politicians and the business culture may no longer afford such "luxury" even in a country as wealthy as the United States.

ANNOTATED REFERENCES

This textbook on neurocritical care gives concise access to causes and treatment of medical and neurologic coma. It is easy to access because topics are discussed in short, easy to read chapters with a short list of references.

Jennett B, Teasdale G, Braakman R, et al: Prognosis of patients with severe head injury. Neurosurgery 1979;4:283-301.

This article helps guide physicians to focus on the important clinical prognostic factors when managing severely head-injured patients. Because the prognosis of traumatic coma is better than medical coma, these guidelines potentially minimize management errors in patients with other severe injuries.

Levy DE, Bates D, Caronna JJ, et al: Prognosis in non-traumatic coma. Ann Intern Med 1981;94:293-301; and Levy DE, Caronna JJ, Singer BH, et al: Predicting outcome from hypoxic-ischemic coma. JAMA 1985;253: 1420-1426.

These two articles recognize the value/importance of the bedside evaluation in the prediction of outcome of medical (hypoxic-ischemic) coma. This bedside knowledge helps clinicians orient patient care in an increasingly high-tech hospital environment.

Plum F, Posner JB: The Diagnosis of Stupor and Coma. Philadelphia, FA Davis, 1980.

This book is a convenient "one-stop" reference to stupor/coma. It is an excellent source of information about the pathophysiology and etiology of altered consciousness.

Synek VM: Prognostically important EEG coma patterns in diffuse anoxic and traumatic encephalopathies in adults. J Clin Neurophysiol 1988;5:161-174.

The EEG is often used by clinicians (and requested by family) to help establish cause and prognosis of stupor and coma. This article usefully categorized EEG patterns according to a severity scale that can be incorporated into the bedside evaluation of a patient with altered consciousness.

Chapter 50
CARDIOPULMONARY-CEREBRAL RESUSCITATION

Clifton W. Callaway

KEY POINTS

1. **Improvement in outcome after cardiac arrest** requires attention both to the reversal of cardiopulmonary arrest at the scene and to restoration of consciousness in the intensive care unit. Isolated attention to only the heart or only the brain is unlikely to improve outcomes for many patients (see Fig. 50-8).
2. **Increased emphasis on the basic mechanics of artificial circulation**, specifically uninterrupted vigorous chest compressions, may increase the number of individuals reaching the intensive care unit.
3. It is necessary to **prioritize the various adjunct tools for cardiac resuscitation.** For example, time devoted to endotracheal intubation may delay drug therapy and interrupt chest compressions without altering overall hemodynamics.
4. **The cornerstone of drug therapy during resuscitation** attempts is the administration of vasoconstrictor drugs that will increase coronary perfusion pressure developed by chest compressions.
5. Induction of mild hypothermia, optimal management of blood pressure and serum glucose level, and a prothrombotic state, along with proper treatment of the root cause of the cardiac arrest may **increase the number of initially comatose patients who awaken.**
6. **Neurologic prognosis** is best established by serial clinical examinations over the first 48 to 72 hours after restoration of circulation. Constant reassessment of the likelihood of meaningful recovery can guarantee that continued care and interventions are appropriate.

Cardiopulmonary arrest may occur as the endpoint or consequence of many diseases. Examples include acute dysrhythmias, cardiac pump failure, hypoxemia, sepsis, hemorrhage, drug toxicity, and metabolic disturbances. Often the mechanism is unknown when treatment is initiated, and an algorithmic approach titrated to real-time monitoring (electrocardiography, capnometry, oximetry, blood pressure) is used. When the cause is known or suspected, therapy may be individualized and directed at that cause. In all cases, management has two priorities: (1) rapid restoration of cardiopulmonary function and (2) minimization of ischemic damage to end organs, primarily the brain. Restoration of circulation is composed largely of mechanical and electrical treatment. In contrast, brain injury involves primarily cellular and molecular events that are treated with specific and detailed intensive care. Meaningful survival is unlikely without attention to both heart and brain.

Previously, there has been little consensus on intensive care management of the patient resuscitated from cardiac arrest, but there is increasing evidence that differences in post-resuscitation management influence final outcomes.[1,2] Despite decades of attention to acute cardiac resuscitation, there has been little or no change in long-term survival.[3,4] Meaningful improvements in outcome will require an integrated approach to the patient that includes not only immediate resuscitation but also intensive care management after restoration of circulation (Fig. 50-1). The epidemiology of cardiac arrest, the initial approach for reversing cardiopulmonary arrest, modifications of this approach appropriate for specific disease states, and post-resuscitation care designed to minimize brain injury are reviewed.

EPIDEMIOLOGY

In the United States, heart disease is the overall leading cause of death. Cardiopulmonary arrest outside the hospital has an age-adjusted incidence of 100 to 120 events per 100,000 people per year.[5,6] Overall survival after out-of-hospital cardiac arrest in the United States is estimated at 6.4%,[7] with several large U.S. cities reporting a survival rate less than 2%.[8,9] The incidence of cardiac arrest in the hospital is about 0.17 event per hospital bed per year.[10] For inpatients experiencing cardiac arrest, survival to hospital discharge is estimated at 17%. Fewer than one half of cardiac arrests occur in an intensive care unit (ICU) setting, and survival does not appear to be related to the location of collapse.[11]

Demographic features of sudden cardiac death are similar to the characteristics of cardiovascular disease. Sudden cardiac death is more common in males than females both outside of the hospital[6] and in the hospital.[10] However, the incidence of cardiac arrest is higher in women (6.0%) than in men (4.4%) who are admitted to the hospital for acute myocardial infarction.[12] Cardiac arrest outside the hospital affects blacks more than whites or Asians.[6,8] Whereas sudden death can affect patients of all ages, the mean age for sudden cardiac arrest is between 65 and 70 years in most studies.[6,10]

Two temporally and mechanistically separate processes contribute to mortality: (1) cardiopulmonary collapse and (2) neurologic injury. In evidence of the first process, only one third of patients who collapse outside the hospital have

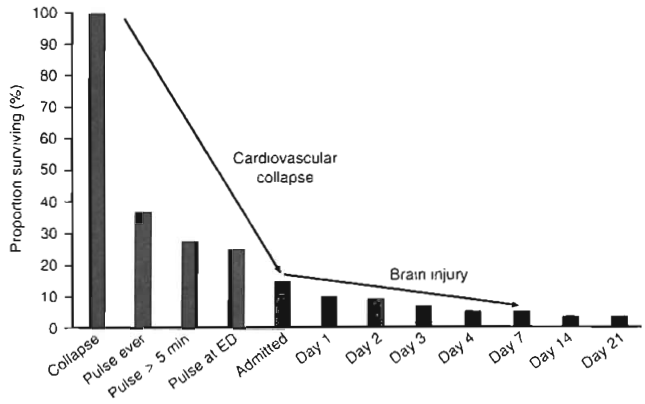

FIGURE 50–1. The survival curve for patients treated for out-of-hospital cardiac arrest in one city illustrates that risk of death occurs in two phases. Early death after cardiac arrest results from irreversible cardiopulmonary collapse, precluding survival to hospital admission for 70% to 80% of patients. Death during the first few days after hospital admission is usually related to brain injury and failure to awaken, precluding long-term survival for an additional 10% to 15% of patients. (Unpublished data from City of Pittsburgh.)

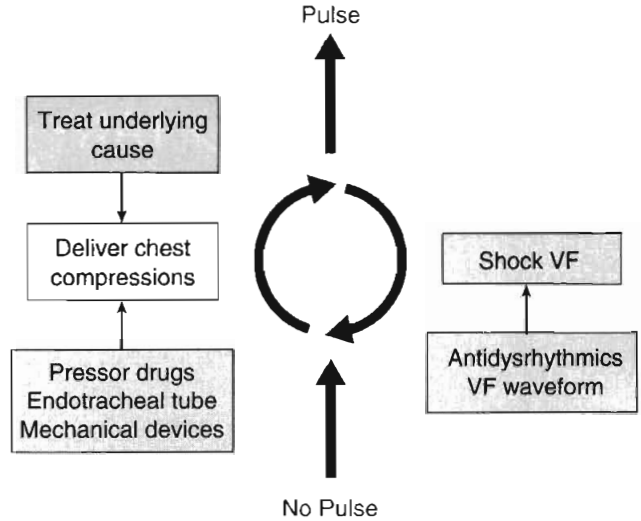

FIGURE 50–2. Prioritization of activities must occur during cardiac resuscitation. The central circle emphasizes that the core activity of artificial perfusion should be interrupted only to provide rescue shocks when appropriate. All drugs, airway devices, and other interventions are designed to augment either artificial circulation or defibrillation. None of these adjuncts should interrupt or detract from performing the two core activities.

restoration of circulation long enough to be admitted to the hospital (see Fig. 50-1). Likewise, only 44% of patients who collapse in the hospital have return of circulation.[10] In evidence of the second process, two thirds of patients admitted to the hospital after out-of-hospital collapse die before discharge from the hospital.[13] Likewise, over 60% of patients initially resuscitated from cardiac arrest in the hospital do not survive to hospital discharge.[10] The most common reason for death among patients after restoration of circulation is post-ischemic brain injury. Failure to awaken leads to withdrawal of care and in-hospital death for as many as 44% to 68% of subjects after initial restoration of circulation.[10,14]

RESTORING CIRCULATION

Acute treatment of cardiac arrest consists of two essential, goal-directed activities: (1) artificial circulation (usually chest compressions augmented by peripheral vasoconstrictors) to circulate oxygenated blood to heart and brain and (2) electrical shock to terminate ventricular fibrillation (VF) and unstable tachyarrhythmias. Of these two procedures, artificial circulation (including ventilation) occupies most of the time and electrical rescue shock is invoked only when appropriate. Rescue shock is the only procedure for which interruption of artificial circulation is absolutely necessary and justified.

The recommended division of time and prioritization of activities is depicted in Figure 50-2. All other activities, including antidysrhythmic medications and advanced airway maneuvers, are designed to supplement these two core activities. Optimization of resuscitation requires that any interruption in the two core activities, especially artificial circulation, be minimized. In addition, continuous reassessment of the patient can be reduced to constant awareness of two parameters (Fig. 50-3). The organization of the electrocardiogram (ECG) and the presence of pulses will prompt appropriate selection of therapy.

The American Heart Association (AHA) and European Resuscitation Council provide consensus scientific statements about the acute management of cardiac arrest.[15] Those guidelines have a detailed review of specific drugs and procedures. The following section provides an overview of airway management, circulation support, rescue shock for defibrillation, and drug therapy during cardiac arrest.

AIRWAY AND VENTILATION

Obstruction of the airway can occur in any patient with impaired consciousness, including cardiac arrest.[16] If uncorrected, this obstruction prevents oxygenation and

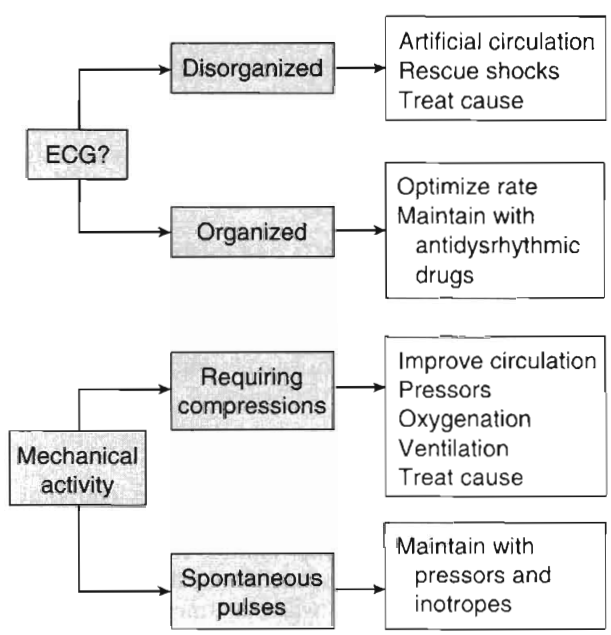

FIGURE 50–3. Continuous reassessment of the patient during cardiac resuscitation can focus on the electrocardiogram (ECG) and on the presence of cardiac activity (pulses). If an organized ECG is not present, interventions should be undertaken to restore an organized ECG. If mechanical cardiac activity is not present, interventions should be undertaken to improve mechanical cardiac activity.

ventilation, leading to or perpetuating cardiopulmonary collapse. In patients who are comatose because of primary cardiac arrest, the airway usually is not patent. Animal models typically do not mimic ventilation through the human airway because the most common research animals (dogs and swine) have straight orotracheal passages.

Agonal respirations occur after acute cardiac arrest for an additional 1 to 2 minutes.[17] These respirations may confuse lay people, delaying recognition of cardiac arrest. It is unclear whether these agonal respirations can generate sufficient ventilation to support life. The presence of gasping is associated with survival, but it also may be a surrogate marker for brief collapse-to-resuscitation intervals.[18] Regardless, the amplitude and frequency of agonal respirations declines over 1 to 2 minutes, necessitating artificial ventilation for all patients requiring more than momentary resuscitation efforts.

Simple maneuvers can establish patency of the human airway. Extension of the neck (head tilt) and forward displacement of the mandible (chin lift) straightens and opens the pharynx. The tongue can be displaced from the posterior pharynx by insertion of an oropharyngeal airway. With these steps, positive-pressure ventilation can be provided using mouth-to-mouth or bag-valve-mask ventilation. A positive-pressure breath of 10 to 15 mL/kg delivered over 2 to 3 seconds will fill the lungs. Ventilation with as little as 400 mL in adults (6 to 7 mL/kg) will cause the chest to rise.[19] While that volume is inadequate for conscious subjects, it is unclear what tidal volume is necessary to provide adequate gas exchange during cardiac arrest.

The minute ventilation required to accomplish resuscitation in humans has not been established. The need for gas exchange must be balanced against the fact that interrupting chest compressions lowers coronary perfusion (Fig. 50-4).[20] Comparison of different ratios of chest compressions to ventilation in swine suggests that two breaths per 50 chest compressions or more may be optimal for resuscitation.[21] An extreme point of view is that chest compressions without any artificial ventilation may be sufficient to accomplish resuscitation in certain individuals.[22] This position is contrary to early work demonstrating that the human airway collapses in most unconscious subjects and that compressions alone are unable to provide ventilation.[16] Therefore, the optimal ratio of chest compressions to ventilations remains to be established but may be greater than the 15:2 currently recommended in the AHA guidelines.

Ventilation can be confirmed with capnometry. During cardiac arrest, end-tidal CO_2 measurement is related to cardiac output and pulmonary blood flow.[23] Therefore, CO_2 levels may be very low (<10 mm Hg) at the onset of resuscitation. Adequate artificial circulation will cause CO_2 levels to increase, and these levels may be used as a feedback to improve or modify chest compressions. Data from emergency department patients suggest that an end-tidal CO_2 level greater than 15 to 16 mm Hg is associated with successful cardiac resuscitation.[24,25] Conversely, end-tidal CO_2 less than 10 mm Hg after 20 minutes of resuscitative efforts predicts nonsurvival.[26] However, drugs commonly used during resuscitation can disrupt the association between capnography readings and pulmonary blood flow. For example, epinephrine infusion reduces CO_2 levels and sodium bicarbonate infusion produces a transient, but profound, elevation of CO_2 levels. An abrupt increase in end-tidal CO_2 levels, usually to levels greater than 35 mm Hg, accompanies the return of spontaneous circulation.

AIRWAY DEVICES

The most common ventilation device used by rescue personnel, paramedics, and other health care providers is a self-inflating bag attached to a facemask (bag-valve-mask), which has several pitfalls. First, it is difficult to maintain an air-tight seal between the mask and the face of the patient, particularly when simultaneously performing head-tilt, chin-lift maneuvers. Adequate training and practice increases ventilation success by a single provider, but two providers achieve more reliable airway management. One provider squeezes the bag, while the second provider uses two hands to hold the mask on the face and position the head.

A second difficulty with bag-valve-mask ventilation is insufflation of the stomach.[27] Excessive air in the stomach can promote emesis, and the abdominal distention may impair venous return and lung compliance.[28] The esophagus prevents air entry into the stomach unless upper airway pressures exceed 15 to 20 cm H_2O.[29] However, during cardiac arrest, esophageal muscle tone declines, and air will enter the stomach with upper airway pressures greater than 5 to 8 cm H_2O.[30] If the upper airway is not patent, providers may try to ventilate with increased pressure to achieve chest rise. Furthermore, rapid squeezing of the bag during the excitement of the situation results in too high upper airway pressures. By avoiding these problems, mechanical ventilators with regulated flow rates and peak pressures may perform better than bag-valve-mask during resuscitation.

Endotracheal intubation can secure the airway definitively. A cuffed endotracheal tube protects from emesis and maintains airway patency. However, laryngoscopy requires an interruption in chest compressions and the endotracheal tube by itself does not correct cardiac arrest. Therefore, endotracheal intubation must be considered an adjunct to initial resuscitation that should not delay or interrupt more definitive interventions. Obviously, any patient with restoration of circulation and subsequent coma will require endotracheal intubation, but the interruption in artificial circulation required for this procedure should be carefully considered.

Alternative airway adjuncts, such as double-lumen, combination endotracheal-esophageal tubes (Combitube) or laryngeal mask airways can be used to temporarily manage the airway during resuscitation.[31,32] The Combitube and laryngeal mask airways have the advantage that they can be inserted blindly in seconds without laryngoscopy, thereby minimizing any interruption of chest compressions.[27] The degree to which these devices can protect from aspiration is debated.

ARTIFICIAL CIRCULATION

In the patient without pulses, circulation of blood can be accomplished by mechanical compression of the heart and chest. The critical parameter for restoring spontaneous circulation is the development of adequate coronary perfusion pressure (CPP). The CPP is quantified by the pressure gradient between the aorta and the inside of the ventricles (usually approximated by the pressure in the right atrium or the central venous pressure [CVP]). Measurement of CPP in clinical practice is difficult unless the patient has invasive monitoring before cardiopulmonary collapse. CVP can be estimated from a central line, and peripheral arterial pressures can be developed from approximate aortic pressures. In the spontaneously beating heart, most blood flows through the ventricular walls

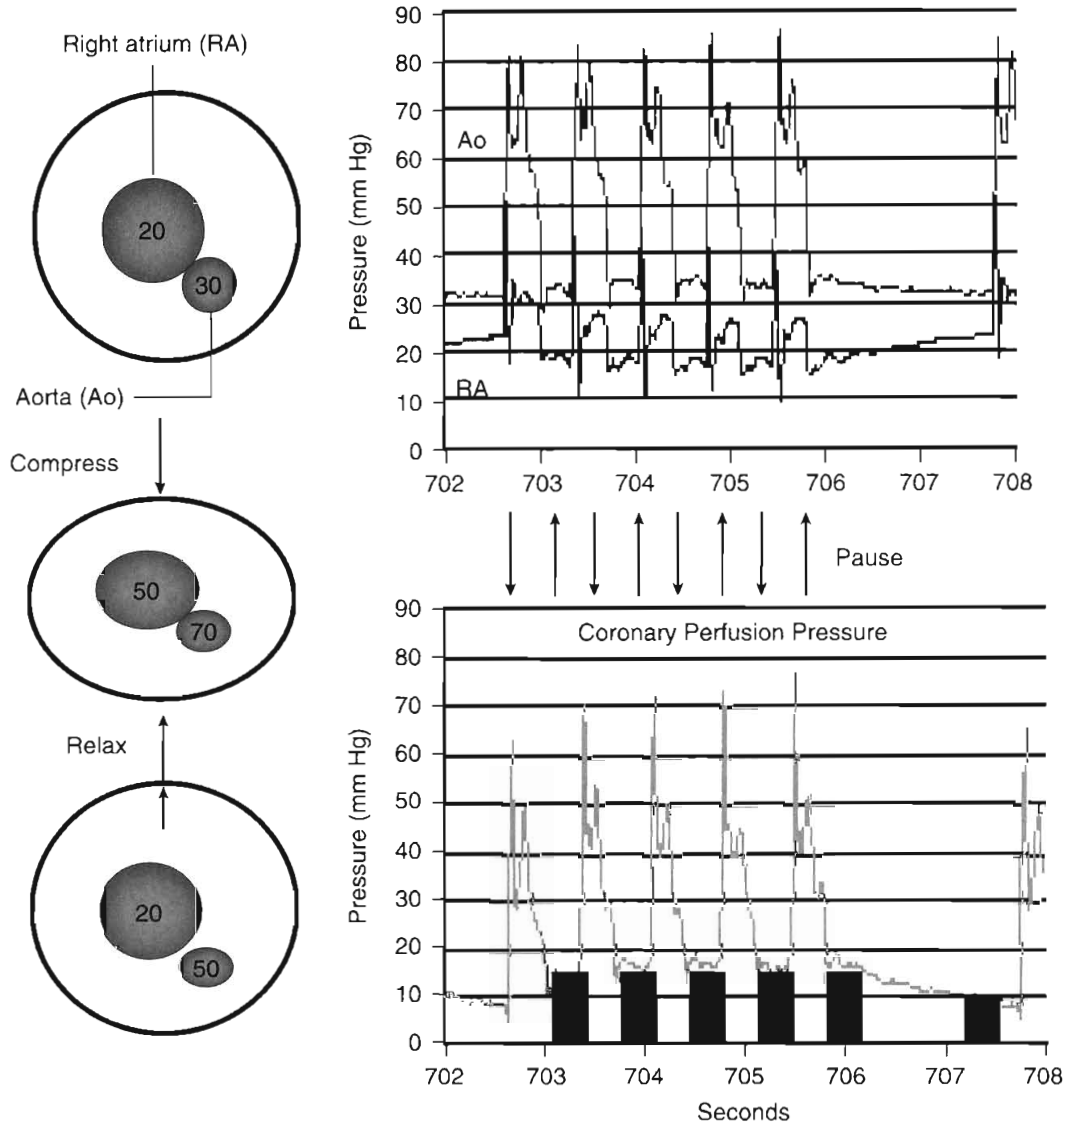

FIGURE 50–4. Chest compressions provide coronary perfusion by creating a pressure gradient between the aorta (Ao) and the inside of the ventricles (approximated by the right atrium [RA]). The gradient between these sites is the coronary perfusion pressure (CPP). During chest compression *(down arrows)* pressure increases in both Ao and RA. During relaxation *(up arrows)*, pressure persists in Ao more than RA. Thus, myocardial blood flow is most related to CPP during the relaxation phase of chest compressions. Note that the CPP declines within 1 to 2 seconds when compressions are interrupted for ventilation. (Unpublished laboratory data.)

during diastole, when the ventricular pressure is lowest. With mechanical compression of the heart and chest during resuscitation, the primary perfusion of the heart occurs during the relaxation phase (see Fig. 50-4).

CPP is highly correlated with myocardial perfusion, and consequently with the likelihood of resuscitation.[33] In humans, return of circulation requires that the developed CPP exceeds 15 to 20 mm Hg. It is likely that with CPP less than 15 mm Hg, perfusion is inadequate to replete the energy state of the myocardium during cardiac arrest. It is important to recognize that peak arterial pressure or palpable pulses measured during chest compressions do not necessarily represent CPP because ventricular pressures are simultaneously elevated. Consequently, it is more useful to follow the "diastolic" or relaxation phase arterial pressure. If unable to follow these pressures, the clinician must rely on indirect evidence of myocardial perfusion, such as improved electrical and mechanical activity or increased pulmonary CO_2 excretion.

Direct cardiac compression via a thoracotomy is more effective than external chest compressions, producing roughly threefold increases in CPP.[34] This approach also allows recognition of cardiac tamponade and treatment by pericardiotomy. Mechanical activity and fibrillation are immediately visible, and electrical rescue shocks or pacing can be applied directly to the heart. In the setting of cardiopulmonary collapse due to exsanguination, thoracotomy also allows aortic compression to shunt blood to heart and brain, as well as the potential for direct control of intrathoracic bleeding. Until the 1960s, thoracotomy was the standard approach for treatment of sudden cardiac arrest, but this procedure has now been supplanted by closed-chest compressions. Case series describe how cardiac massage continues to be successful, and its use should be considered when closed-chest compressions are ineffective.[34] Open-chest cardiac massage is most likely to succeed if initiated early during resuscitation.[35]

Delivery of chest compressions is often inadequate, and uninterrupted chest compressions are critical for restoration of circulation.[20,36,37] A variety of mechanical devices have been developed to provide more consistent and continuous chest compressions.[38] Some of these devices exploit

circumferential compression or active compression-decompression of the chest to increase the efficiency of artificial circulation. However, none has gained widespread use because of their weight and cost. Whereas no current device is poised to solve this challenge, the constant attention of industry to this area illustrates the need for strategies to improve delivery of chest compressions.

Extracorporeal perfusion for restoration of circulation is highly effective and can be used to resuscitate subjects for whom chest compressions have failed.[39,40] With extracorporeal support, more time becomes available to address the primary cause for cardiac arrest. However, this approach requires specialized technical skill and has increased cost and increased risk. Logistical issues include limited availability of perfusion equipment, increased set-up time for circuit priming, and delays in establishing adequate venous and arterial access. Development of portable cardiopulmonary bypass devices that can be primed quickly along with improved techniques for rapid vascular access could broaden the use of this technology.

ECG MONITORING

Continuous three-lead ECG monitoring provides information that can be used to titrate resuscitation. A practical division of the ECG is to divide rhythms into organized and not organized. Organized rhythms include supraventricular rhythms or ventricular tachycardia. Disorganized rhythms include VF and asystole. Disorganized rhythms cannot support the pumping of blood, regardless of volume status, cardiac muscle state, and vascular integrity. Therefore, restoring cardiac electrical activity to an organized rhythm is an essential step in resuscitation. Organized rhythms can support pumping of blood unless they are too slow (<30 to 40 complexes per minute) or too fast (>170 to 180 complexes per minute). An organized rhythm in the absence of pulses is termed *pulseless electrical activity* (PEA).

Any organized complex that is not associated with perfusion should be considered PEA. The absence of perfusion in the presence of organized electrical activity may result from damage to heart muscle (as in massive myocardial infarction) or from uncoupling of electrical and mechanical activity (as in prolonged circulatory arrest). Perfusion may be so poor that pulses are absent in ventricular tachycardia, supraventricular tachycardia, and atrial fibrillation with rapid ventricular response that are unresponsive to the filling of the heart. These tachyarrhythmias should be corrected by electrical cardioversion. Outside of these tachyarrhythmias, the rate of complexes in PEA is related to the ischemic state of the heart and may be used to monitor resuscitation efforts. With increasing ischemia, energy depletion will occur in the electrical system and the rate of PEA will slow. If resuscitation is improving the energy state of the heart, the rate of PEA will accelerate. Anecdotally, narrow complexes reaching rates of 80 to 100 beats/min often herald the return of pulses. Falling rates of complexes in PEA reflect unsuccessful resuscitation efforts, probably because of inadequate perfusion of the cardiac conduction system.

VF and asystole lie along a continuum of disorganized ECG. Arbitrary peak-to-peak amplitude of the ECG is usually used to distinguish asystole (amplitude < 0.1 to 0.2 mV) from VF (amplitude > 0.2 mV).[41] However, VF also exhibits temporal structure that may be absent in asystole.[42] VF is a chaotic electrical activity formed by multiple interacting waves of activation within the heart.[43] VF emerges from broken wave fronts that result from an area of ischemia (as in myocardial infarction), an area of prolonged refractoriness (as in drug-induced or inherited prolonged QT intervals), or too rapid succession of activation potentials (as in tachycardia or an R-on-T premature beat). As the organization and amplitude of these waves decline, because of ischemia or hypoxemia, the amplitude of the ECG also declines. Reperfusion of the heart in asystole may restore VF. Furthermore, the amplitude and organization of the VF increase with reperfusion, providing a marker of adequate artificial perfusion.

RATIONAL USE OF RESCUE SHOCKS FOR DEFIBRILLATION

Delivery of immediate transthoracic electrical (rescue) shocks to patients in VF can convert it into an organized cardiac rhythm (Fig. 50-5). Rescue shocks are highly effective when VF is of very brief duration (<1 to 2 minutes). These shocks may work by depolarizing the heart, canceling the original wave fronts, or by prolonging the refractory periods.[43] Although rescue shocks can successfully restore an organized rhythm, repeated shocks may directly damage the myocardium. The precise magnitude of this damage is still unclear.[44] Nevertheless, optimal therapy should provide rescue shocks at the lowest effective energy while minimizing the number of unsuccessful rescue shocks.

Rescue shocks are more likely to fail when cardiac arrest has lasted more than a few minutes. In the out-of-hospital setting, only 9% of rescue shocks restore an organized ECG if the collapse was not witnessed by the paramedic.[45] Furthermore, resuscitation is less likely after rescue shocks that convert VF into asystole.[46] In one model for defibrillation, a "critical mass" of the heart must be depolarized by

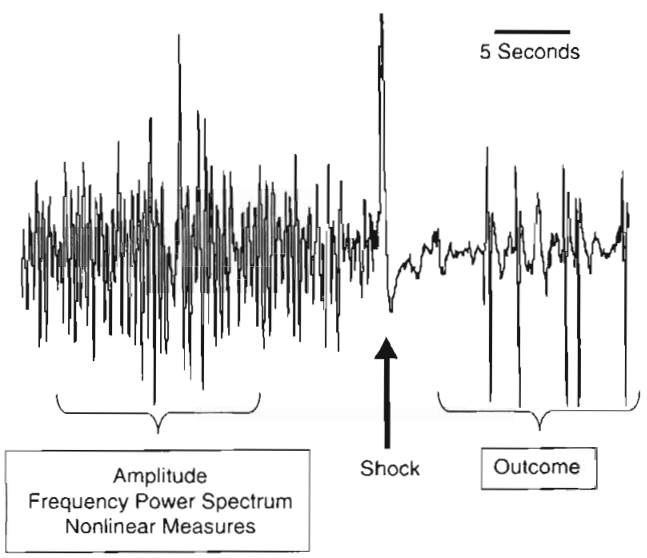

FIGURE 50–5. Rescue shock converts ventricular fibrillation into an organized rhythm. Note that several seconds pass between the rescue shock and the first appearance of complexes. Quantification of the waveform of ventricular fibrillation before shock using amplitude, frequency components, or nonlinear measures can predict the likelihood that the outcome will be an organized rhythm. The appearance of an organized rhythm does not guarantee pulses, and continued reevaluation is essential. (Unpublished data from City of Pittsburgh.)

a rescue shock to ensure that VF activation potentials are extinguished.[43] If a critical mass is not defibrillated, chaotic activity in the remaining regions will spread throughout the heart, rekindling VF. However, even when the entire heart is depolarized by the shock, VF may recur, perhaps because of heterogeneous areas of refractoriness or persistent foci.[47] Regardless, shocks must be of sufficient intensity to deliver depolarizing current to the majority of the heart.

Several maneuvers can facilitate electrical defibrillation. Increased pressure of paddles from 0.5 to 8.0 kg on the chest will decrease transthoracic impedance by as much as 14%, increasing delivery of current to the heart.[48,49] This advantage of paddles must be weighed against the increased safety and convenience afforded by hands-free adhesive defibrillation pads. Multiphasic shock waveforms that produce more effective depolarization of individual myocytes (e.g., biphasic waveforms) tend to accomplish defibrillation with less energy.[43] In the past, multiple shocks would be delivered in rapid succession to decrease chest impedance. However, repetitive shocks decrease chest impedance only about 8% in actual patients.[48] Rescue shock energy can be increased by much greater amounts, and this modest decrease in impedance afforded by repetitive shocks probably does not justify prolonging the interruption of artificial circulation. Together, these data suggest that rescue shocks of sufficient energy with multiphasic waveforms should be delivered singly to the patient in VF using firm paddle pressure on the chest.

For VF that has lasted more than 3 to 4 minutes, delaying rescue shocks until after a few minutes of chest compressions can improve the rescue shock success. In animals, reperfusion before rescue shocks appears to be preferable to immediate rescue shock after more than 5 minutes of untreated VF.[50-53] Researchers in two clinical studies have found that either 90 seconds or 3 minutes of chest compressions before delivery of the initial rescue shock improved resuscitation rates for subjects with VF outside the hospital, particularly when rescuer response intervals are longer than 4 minutes.[4,54] Thus, defibrillation should be provided immediately for VF shortly after a witnessed collapse, but a brief period of artificial circulation should precede any shock delivery to VF that has lasted longer.

Quantitative analysis of the VF waveform can distinguish early VF from late VF and may be useful for estimating the likelihood of rescue shock success (see Fig. 50-5).[55] Larger amplitude of VF suggests early VF and is associated with more successful resuscitation.[56] However, amplitude can be affected by body habitus and other recording conditions. Frequency-based measures, as well as nonlinear dynamic measures, also can be used to quantify VF and to estimate the probability of rescue shock success and are less dependent on recording conditions.[57-60] All of these measures, or some combination of these measures, are likely to be implemented in future generations of defibrillators. These devices will provide real-time, semi-quantitative estimates of the probability that a rescue shock will succeed in restoring an organized rhythm. Using this information, the clinician will be able to choose to shock VF when the probability of shock success is high or to concentrate on improving the situation with artificial perfusion when the probability of shock success is low.

DRUG THERAPY

All drug therapy in cardiac arrest can be divided into three categories: pressors, antidysrhythmics, and metabolic drugs. There is good evidence that pressors improve artificial circulation, making resuscitation more likely. Antidysrhythmic drugs are effective for preventing dysrhythmias and therefore have a role in stabilizing the heart once circulation is restored. The value of an antidysrhythmic drug for terminating VF or reversing asystole is less clear. Metabolic drugs, primarily bicarbonate, can be used to reverse acidosis or other electrolyte problems when they are recognized. However, there are no data to support the routine use of these drugs for all patients.

Pressors used during resuscitation include epinephrine and vasopressin. Both of these drugs can increase CPP through actions on alpha-adrenergic (epinephrine) or vasopressin receptors (Fig. 50-6).[61,62] Epinephrine is usually administered in 1 mg (~0.015 mg/kg) increments. In laboratory studies, the pressor effects of epinephrine during cardiac arrest are brief (~5 minutes). Vasopressin has been administered as 40-unit boluses (~0.5 unit/kg) and produces a longer-lasting increase in CPP (~10 minutes). Both drugs should be titrated to improvement in clinical indicators (ECG waveform, mechanical activity, changes in end-tidal CO_2 or coronary perfusion pressure).

The 1-mg dose of epinephrine is widely believed to be subtherapeutic in the setting of circulatory arrest lasting more than a few minutes. Trials in out-of-hospital patients comparing higher initial boluses of epinephrine (15 mg vs. 1 mg) found a higher rate of restoration of pulses (13% vs. 8%) and admission to the hospital (18% vs. 10%).[63] However, overall survival was not different. Comparison of a lower dose (7 mg vs. 1 mg) of epinephrine in both in-hospital and out-of-hospital cardiac arrest found no change in restoration of pulses or survival.[64] Likewise, comparison of 0.02 mg/kg versus 0.2 mg/kg epinephrine found no change in restoration of pulses or survival.[65]

It is possible that the beta-adrenergic effect of these higher doses of epinephrine produces toxicity that limits long-term survival. Post-resuscitation impairment of cardiac index and oxygen delivery has been related to epinephrine dose.[66] No trial has completed a direct comparison of epinephrine with more selective alpha-adrenergic agents such as phenylephrine. However, one trial found no advantage from administration of 11 mg of norepinephrine.[63]

Vasopressin can increase coronary perfusion pressure without complicating beta-adrenergic effects. Resuscitation rates and survival are identical for inpatients resuscitated with vasopressin and standard doses of epinephrine.[67] For out-of-hospital cardiac arrest, vasopressin appears to be superior for resuscitation and survival of patients whose first ECG rhythm is asystole.[68] Post hoc analyses suggest that vasopressin may be superior for those subjects requiring multiple doses of vasopressors. At present, use of either drug is justified in the setting of cardiac arrest. None of the studies on these pressors standardized post-resuscitation care, and therefore all are limited in their ability to define drug effects on neurologic recovery.

The role of antidysrhythmic drugs during cardiac arrest is equivocal.[69,70] Atropine may relieve bradycardia when it is vagally mediated. However, nervous system influences on the heart are largely eliminated after more than 1 to 2 minutes of circulatory arrest. Lidocaine, procainamide, and bretylium have a long history of use in the treatment of VF. The basis for this use is principally the observation that these drugs can suppress dysrhythmias before cardiac arrest. Once VF is established, lidocaine can actually increase the electrical energy required

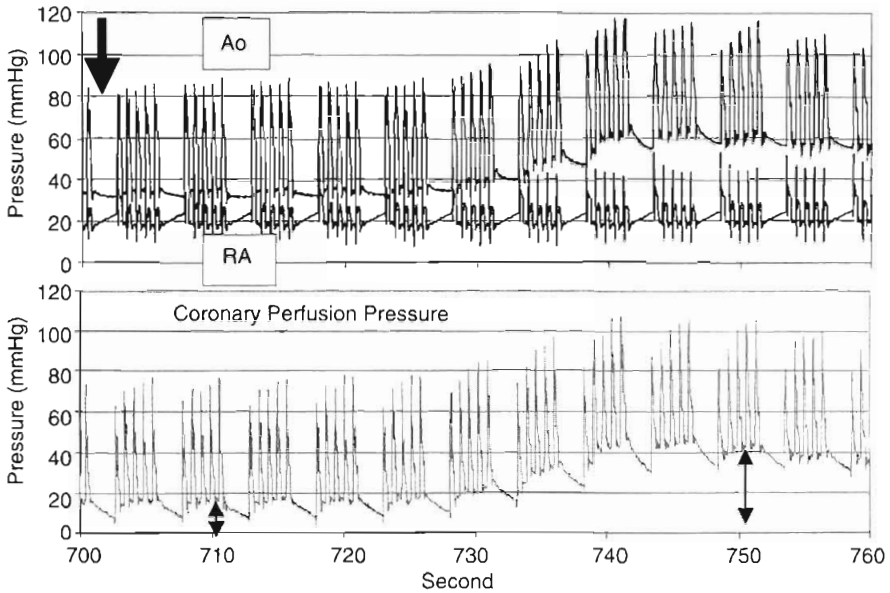

FIGURE 50–6. Administration of a pressor drug *(arrow)*, in this case vasopressin, can increase coronary perfusion pressure (CPP) produced by chest compressions. Note that the CPP generated by chest compressions alone (at ~710 seconds) is below the 15 to 20 mm Hg believed necessary for restoration of circulation. However, at 40 to 60 seconds after drug administration (at ~750 seconds) CPP increases above this threshold *(long, double-headed arrow)*. When treating cardiac arrest, it is unreasonable to expect physiologic responses to pressor drug administration until after at least 60 more seconds of chest compressions. (Unpublished laboratory data.)

to defibrillate by more than 50%.[71] This effect is not true for agents that are less potent as sodium channel antagonists. For example, administration of amiodarone (5 mg/kg) is superior to placebo[72] and to lidocaine[73] for restoration of pulses in out-of-hospital patients with VF that is not terminated by three rescue shocks. These studies did not control subsequent critical care and are thus not designed to determine any effect on long-term survival. In summary, antidysrhythmic drugs are commonly used during resuscitation, but only amiodarone use has supporting human data.

Empirical treatments of metabolic disturbances during cardiac arrest are not supported by prospective human data. Bicarbonate or other buffers may improve acidemia resulting from ischemia, but no efficacy study of human administration is available.[74] Aminophylline has been proposed as an antagonist of adenosine released during ischemia. Adenosine is hypothesized to suppress cardiac electrical activity. Two prospective studies of aminophylline administration to subjects with PEA or asystole failed to demonstrate any improvement in resuscitation.[75,76] Use of dextrose-containing fluids versus dextrose-free fluids did not alter outcome for out-of-hospital cardiac arrest.[77] Other metabolic therapies including calcium and magnesium also lack supporting data.[78,79] However, specific use of these agents for specific causes of cardiac arrest, such as known hyperkalemia, calcium channel blocker overdose, torsades, or hypomagnesemia remains appropriate.

Taken together, data support a simple pharmacologic approach to treatment of cardiac arrest. First, the vasopressors epinephrine and vasopressin are useful for augmenting CPP generated during chest compressions. Other vasopressors should also be useful but lack prospective data. Second, antidysrhythmic drugs are useful for maintaining organized rhythms but not for terminating VF. Only amiodarone has clinical data supporting its use during VF that persists after rescue shocks. All other drug therapy should be based on the clinical situation and the response of the patient.

ASPECTS OF CARDIAC ARREST IN SPECIFIC SITUATIONS

The original cause of cardiac arrest may not be known during acute resuscitation. However, if this information is available, treatment and prognosis can be individualized to the specific patient. Among out-of-hospital patients, as many as 66% have primary cardiac disturbances.[80] For in-hospital patients experiencing cardiac arrest, dysrhythmia and cardiac ischemia account for 59% of events.[10] This section reviews unique features of cardiac arrest resulting from both cardiac and noncardiac causes.

PRIMARY CARDIAC EVENTS

Cardiac arrest is most commonly attributable to cardiac disease. A primary dysrhythmia or cardiogenic shock is the most common proximate cause of cardiac arrest.[80,81] Patients undergoing angioplasty have 1.3% incidence of cardiac arrest, and survival in these patients resembles survival in other populations.[82] Among patients admitted to the hospital with acute myocardial infarction, cardiac arrest occurs in 4.8%.[12] Dysrhythmias are common during the hours after reperfusion therapy,[82] although reperfusion therapy reduces the overall risk of cardiac arrest.[83] During acute myocardial infarction, cardiac arrest is most likely in patients with lower serum potassium levels, more than 20 mm of total ST segment elevation, and a prolonged QTc interval during the first 2 hours of their event.[83] With a mean follow-up of 43 months, 3.3% of subjects surviving acute myocardial infarction suffered sudden cardiac death.[84] Abnormalities of the heart are present in most cases of cardiac arrest, with coronary artery disease present in at least 65% of autopsies.[85] Taken together, these data suggest that most patients with cardiac arrest will have contributing cardiovascular disease.

An acute coronary syndrome is present in more than one half of patients presenting with primary cardiac arrest outside the hospital. When angiography was performed on

consecutive patients resuscitated from cardiac arrest, coronary artery occlusion was identified in 48%.[86] Similarly, 51% of initially resuscitated outpatients exhibited cardiac enzyme elevation or ECG evidence of acute myocardial infarction.[87] In one series, troponin T was elevated in 40% of out-of-hospital patients undergoing cardiopulmonary resuscitation (CPR), regardless of whether circulation was restored.[88] The direct myocardial injury from defibrillation and CPR may cause spurious elevations of creatine kinase that are unrelated to cardiovascular disease.[89] However, cardiac troponin elevations are believed to reflect acute myocardial infarction rather than injury from electrical shocks.[90] Thus, the 40% of subjects undergoing CPR with elevated troponin probably suffered myocardial injury before collapse.

The high likelihood of an acute coronary syndrome in the patient suffering cardiac arrest should prompt consideration of antiplatelet therapy, anticoagulation, beta blockade, and nitrates during the post-resuscitation care. Unless a clearly noncardiac etiology for cardiac arrest is evident, acute coronary angiography may reveal an indication for angioplasty, thrombolysis, or other reperfusion therapy. Early angioplasty or reperfusion therapy is associated with improved survival and outcome.[12,86,91]

Primary ventricular tachyarrhythmias are rapidly reversible and may be more likely than PEA or asystole for patients with a primary cardiac cause of collapse. Ventricular tachyarrhythmias are the initially recorded rhythm in 38% to 41% of out-of-hospital cardiac arrests[6,92] and in 25% of in-hospital cardiac arrests.[10] Because VF is rapidly reversible, patients with this rhythm comprise the majority of survivors of cardiac arrest. Data collected over three decades in one city noted that the prevalence of VF in out-of-hospital cardiac arrest has declined since 1978.[10] This trend may reflect a change in preventive medicine or in the epidemiology of cardiovascular disease over time. Once defibrillation is accomplished, short-term suppression of ventricular dysrhythmias with infusions of lidocaine, amiodarone, procainamide, or other antidysrhythmics is reasonable for these patients.

For subjects who survive sudden cardiac arrest and have decreased left ventricular function, long-term antidysrhythmia treatment should be considered.[93] Subjects surviving a life-threatening ventricular dysrhythmia had a 15% to 20% risk of death during a mean of 16 months of follow-up, even when a reversible cause of the dysrhythmia, such as electrolyte disturbance or hypoxemia, could be identified.[94] Implantable defibrillators have been found to be superior to antidysrhythmic drugs for reducing this risk of subsequent death.[95] This benefit is primarily in subjects with a left ventricular ejection fraction less than 0.35.[96] Implantable defibrillators were not better than antidysrhythmic drugs in a European trial that enrolled subjects resuscitated from cardiac arrest secondary to ventricular dysrhythmia without regard to left ventricular ejection fraction.[97] Nevertheless, these devices offer significant hope of preventing sudden cardiac death, and identification of patients whom they may benefit is an active area of research. At present, implantable defibrillators should be discussed for patients with left ventricular ejection fraction less than 0.35 and prior evidence of ventricular arrhythmias, particularly after acute myocardial infarction.

ASPHYXIA

Asphyxia-induced cardiac arrest can result from drowning, choking, asthma, progressive respiratory failure with hypoxemia, or traumatic coma with hypoventilation. Acute asphyxia causes transient tachycardia and hypertension, followed by bradycardia and hypotension, progressing to PEA or asystole. This period of blood flow with severe hypoxemia before cardiac arrest may make asphyxiation a more severe injury than VF or other rapid causes of circulatory arrest.[98] Brain edema was more common on computed tomography after resuscitation when cardiac arrest was caused by pulmonary rather than cardiac causes.[99]

During cardiac arrest, pulmonary edema develops from redistribution of blood into the pulmonary vasculature.[100] Thus, oxygenation is only worsened in the asphyxiated patient. Attention to the primary cause of asphyxia, as well as to maneuvers that will increase oxygenation, such as increased end-expiratory pressure or increased inspiration to expiration time ratios may be necessary.

PULMONARY EMBOLISM

Pulmonary emboli may occur in the postsurgical patient, as well as in medical patients with impaired mobility.[101] In one series, pulmonary emboli were present in 10% of in-hospital deaths,[102] and the prevalence among out-of-hospital deaths was similar.[103] Pulmonary emboli can result in rapid cardiopulmonary collapse and should be considered as a possible cause of cardiac arrest in the proper clinical setting or when collapse is preceded by sudden shortness of breath, hypoxemia, and/or pleuritic chest pain.

Physiologically, pulmonary emboli can result in cardiac arrest if a large thrombus obstructs right ventricular outflow into the pulmonary arteries. This situation results in a dilated, distended right ventricle and an empty left ventricle. Right ventricular dilation is sufficiently profound that it can be seen on transthoracic echocardiogram. Circulation cannot be restored unless this obstruction is relieved. Because the primary disturbance is hypoxemia and decreased cardiac output, cardiac arrest from pulmonary embolism should present as an initial rhythm of PEA or asystole.

Administration of bolus fibrinolytic drugs (tissue plasminogen activator, streptokinase, or urokinase) may help acutely during resuscitation of a patient with a suspected pulmonary embolism. Smaller pulmonary emboli can lead to cardiac arrest because of hypoxemia, and resuscitation may be possible before fibrinolysis if adequate oxygen exchange can be restored. Thrombolytic drugs have been used in a nonrandomized trial during resuscitation of undifferentiated patients with some success.[104] However, a randomized clinical trial of tissue plasminogen activator to patients with out-of-hospital cardiac arrest and an initial rhythm of PEA failed to demonstrate any benefit, although drug administration was late during resuscitation.[105]

ELECTROLYTE DISTURBANCES

Potassium disturbances are the most likely electrolyte disturbance to result in cardiac arrest. In cardiac patients, hypokalemia has been linked to the incidence of VF after myocardial infarction.[83,106] Hypokalemia also may account for the increased incidence of sudden death in patients taking large doses of diuretics. VF is rare in patients where the serum potassium concentration is maintained greater than 4.5 mEq/L. Conversely, hyperkalemia can prolong repolarization, increasing the likelihood of VF initiation. Hyperkalemia may also suppress automaticity in the myocardial electrical

system, leading to bradycardic PEA or asystole. Cardiac arrest occurring during hemodialysis is not associated with high or low potassium levels but is more common when patients are dialyzed against a low (0 or 1.0 mEq/L) potassium dialysate.[107] These data suggest that rapid changes in potassium rather than the absolute value are important triggers of cardiac arrest in this population. Derangements of calcium and magnesium may produce similar or synergistic changes in cardiac conduction.

The clinical setting of cardiac arrest may suggest a primary electrolyte disturbance. Heavy diuretic use or intestinal fluid loss, for example, suggests potassium depletion. Suspected hypokalemia will not change acute resuscitation but must be addressed promptly in the post-resuscitation stabilization of the patient. Cardiac arrest in a patient with renal failure or during potassium infusion suggests hyperkalemia. Widened ventricular complexes with repolarization abnormalities on ECG would heighten this suspicion. If hyperkalemia is suspected, the usual acute resuscitation maneuvers can be supplemented by bolus injection of calcium carbonate (1 mg), bicarbonate (1 mEq/kg), and perhaps insulin (0.1 units/kg) with glucose (0.5 to 1 g/kg). These drugs may improve cardiac electrical stability, facilitating restoration of circulation.

POISONING

Cardiac arrest can result from drug overdose. Therapy does not change except when specific antidotes or countermeasures to the poison are available. For example, calcium channel blocker overdose may be countered by administration of intravenous calcium.[108] Beta-blocker toxicity may require large doses of inotropic agents[109] or may respond to glucagon.[110] Digoxin overdose may respond to digoxin-binding antibodies.[111] In the case of narcotic-induced respiratory depression, subsequent cardiac arrest is a specific result of asphyxia. One principle of poisonings is that the patient was often healthy before the event and may recover well once the poison is eliminated. This potential for a better outcome may justify longer and more aggressive efforts at resuscitation.

SEPSIS

Cardiac arrest can develop from sepsis for several reasons. Direct myocardial depression occurs, probably owing to humoral factors.[112,113] Vasodilation results in apparent hypovolemia. Finally, impaired oxygen extraction, shunting, and mitochondrial depression can produce cellular hypoxia. Because pump and vascular failure are the principal physiologic derangements, the most common initial ECG rhythm would be expected to be a rapid PEA that slows to asystole with ischemia. When these processes have progressed to cardiac arrest, large doses of inotropes, vasoconstrictors, and volume may be needed to restore circulation. Because the underlying sepsis physiology will still be present if pulses are restored, these patients may prove exceedingly unstable during the subacute recovery period and have a reduced chance for survival.[18,114-116]

TRAUMA/HEMORRHAGE

Hypovolemic cardiac arrest occurs after severe trauma, gastrointestinal hemorrhage, or other blood loss. Absence of venous return results in an empty heart, which cannot produce cardiac output despite normal inotropic state and normal or increased vascular tone. As with sepsis, this situation would most likely present with a rapid PEA that slows to asystole, but VF can develop in response to the global ischemia. Because cardiac function and vascular function are initially normal, inotropes and vasoconstrictors are unlikely to benefit hypovolemic cardiac arrest. Rapid replacement of volume with crystalloid infusion is indicated. Colloid or blood infusion should correct the situation more rapidly.[117] After restoration of circulation, patients with hemorrhagic cardiac arrest are likely to develop multisystem organ failure.[117]

During hypovolemic cardiac arrest the empty cardiac ventricles render external chest compressions ineffective. If blood loss is ongoing or if massive volume replacement cannot be instituted rapidly, thoracotomy allows clamping or compression of the aorta, perhaps retaining sufficient blood in the proximal aorta to perfuse the coronary and cerebral arteries. This procedure has produced success in the treatment of penetrating traumatic injuries[118] but not in blunt trauma.[119] Survival is better if thoracotomy occurs in the operating room after brief loss of pulses and best if the penetrating injury has created cardiac tamponade that is directly relieved by pericardotomy. Restoration of circulation must be accompanied by repair of the site of hemorrhage.

HYPOTHERMIA

Hypothermia represents an important situation in which prolonged resuscitative efforts are justified. If hypothermia develops before circulatory arrest, the tolerance of the heart and brain to ischemia is greatly prolonged. Survival with favorable neurologic recovery has been reported after cold-water submersion or exposure with cardiac arrest and resuscitation efforts lasting several hours.[120,121] Although all data are retrospective, subjects in whom circulatory arrest occurs because of hypothermia appear to be more salvageable than subjects who asphyxiate or have circulatory arrest before becoming cold.[122]

Treatment should be based on the initial temperature of the patient. Between 32°C and 37°C, no change in drug or electrical treatment is required, and this level of hypothermia may be beneficial for resuscitation of both brain and heart.[123,124] Between 29°C and 32°C, cardiac activity may be preserved, and external warming (warm air, heating lights, warm blankets) and warm intravenous fluids should accompany usual resuscitation efforts. The likelihood of generating sufficient perfusion to rewarm the body declines as temperature decreases from 32°C to 29°C, and more invasive warming should be considered if there is not a rapid response with external warming. More invasive and aggressive treatment will almost certainly be required for cooler patients, because both mechanical and electrical activity of the heart are disrupted at temperatures below 28°C. Patients below this temperature may exhibit PEA, VF that is refractory to defibrillation attempts, or asystole. Repetitive rescue shocks in such patients are not justified and may be detrimental. Efficacy of most resuscitation drugs may be impaired.

Several techniques for active rewarming during resuscitation of victims of severe hypothermia are available. Given the potentially prolonged tolerance of the cold patient to ischemia, there may be sufficient time to establish arterial and venous access for partial or complete cardiopulmonary bypass. Extracorporeal circulation is particularly useful in these subjects because it can provide artificial circulation at the same time as rewarming.[122,125,126] In the absence of extracorporeal

circulation, placement of thoracostomy tubes and lavage of the chest with warm fluids is an option.[127] Thoracostomy is intuitively preferable to peritoneal lavage because the heart will be directly warmed. Warm air forced over the body surface can rewarm a patient, although this technique may provide the least heat exchange.[128] In any case, it is difficult to determine whether circulation can be reestablished in the profoundly hypothermic patient until near physiologic core temperatures (33°C to 37°C) are restored.

OTHER MEDICAL CONDITIONS

Comorbidities have a tremendous influence on the outcome from cardiac arrest.[81,129,130] In some cases, cardiac arrest may be an expected progression of the patient's disease but guidelines about limiting resuscitation were not defined. For example, no survivors were reported among cancer patients with expected cardiac arrest.[130] Therefore, it may be appropriate to set limits on resuscitation efforts in certain medical conditions before cardiopulmonary collapse. Ideally, discussion about the expectations for resuscitative efforts should be held with the patient, the family, or the patient representatives before cardiac arrest. If those discussions did not occur before the first cardiac arrest, they should follow promptly any initially successful resuscitation.

POST-RESUSCITATION CARE TO MINIMIZE BRAIN INJURY

Management of the patient after restoration of circulation affects ultimate outcome. For example, long-term survival differed for comparable patients treated by a single ambulance service but delivered to separate hospitals.[1,2] Institutional differences in in-hospital management, particularly in the permitted frequency of hyperthermia and hyperglycemia, were identified that may have accounted for these differences. Despite the apparent importance of post-resuscitation critical care, there are few guidelines for treatment.

Brain injury appears not to be acute neuronal necrosis during ischemia but instead to be an active process that develops over hours to days after resuscitation. Multiple cellular and molecular mechanisms contribute to neurologic injury after global brain ischemia.[131] These are discussed in greater detail in Chapter 46. Germane to cardiac arrest, during brain ischemia and immediately after reperfusion, studies have detected increased release of excitatory amino acids, free radicals, and energy failure. Protein synthesis is inhibited at the level of translation initiation for several hours.[132] There are focal disturbances of cerebral blood flow.[133] Specific intracellular and extracellular signaling pathways are activated for several hours after brain ischemia,[134,135] which may lead to specific changes in gene transcription. Finally, activation of specific proteases between 24 and 72 hours after reperfusion is associated with appearance of histologic signs of neuronal death.[136] The relative contribution of each of these processes to neuronal injury is unknown, and all may contribute synergistically to brain injury. All represent potential targets for therapeutic intervention.

Despite detailed knowledge of the mechanisms involved with brain ischemia, drugs that target specific pathways provide modest effects in laboratory studies, and no drug to date has demonstrated clear benefit in human trials. Randomized clinical trials have examined thiopental, the calcium-channel blocker lidoflazine, magnesium, and diazepam.[137-139] One explanation for this failure is that multiple mechanisms contribute simultaneously to the process of ischemic neuronal death. Antagonizing one pathway leading to neuronal death may leave other mechanisms unaffected. Less-specific therapies or multifaceted therapies that affect multiple pathways may prove more effective.

In support of this idea, prospective randomized clinical trials confirm that induction of mild hypothermia (33°C to 34°C) for 12 to 24 hours after resuscitation improves survival and neurologic recovery.[123,140] Observational data also support avoidance of fever, hypotension, and hyperglycemia.[1,141-143] Therefore, systematic brain-oriented intensive care rather than a single therapeutic drug or intervention is required to improve outcome (Table 50-1).

TABLE 50–1. POST-RESUSCITATION INTENSIVE CARE

Temperature
Avoid fever for 48 hours
Induce mild hypothermia of 33°C to 34°C for 12-24 hours
Rewarm slowly (<1°C/hr)
Cardiovascular
Mean arterial pressure > 100 mm Hg for first day
Inotropic and vasopressor support as needed
Invasive monitoring as needed
Must be balanced by concern for injured heart
Suppress dysrhythmias
Reperfusion therapy for acute myocardial infarction
Medical management for acute coronary syndromes
Beta blockade, antiplatelet drugs, anticoagulation
Nitrates as tolerated
Pulmonary
Usual care
Pneumonia common
Gastrointestinal
Usual care
Consider early refeeding to reduce translocation
Fluids/Electrolytes
Monitor central venous pressure and urine output with hypothermia/rewarming
Monitor potassium/electrolytes during temperature changes
Keep potassium ≥4.5 mEq/L
Monitor glucose concentration frequently, and avoid hyperglycemia
Hematologic
Prothrombotic state is common
Anticoagulation is of unproven benefit but reasonable
Infection
Bacteremia and pneumonia are common
Prophylactic antibiotics are of unproven benefit
Antipyretics are reasonable
Neurologic
Sedation as needed for hypothermia induction
Most clinical improvement occurs over first 72 hours
Clinical examination for prognosis
Electroencephalography and evoked potentials may add to clinical examination for selected patients

TEMPERATURE CONTROL

Meticulous avoidance of fever is important during the first 24 to 48 hours after ischemic brain injury. Temperature control after cardiac arrest may be confounded by the fact that the occurrence of bacteremia and spontaneous fever is common in the resuscitated patient.[144,145] The benefit of lower temperatures for injured brain tissue has been demonstrated after traumatic brain injury, stroke, and cardiac arrest.[141,146,147] Mechanistically, temperature probably affects more than brain metabolic rate. For example, manipulations of temperature that improve neurologic recovery in laboratory studies produce no effect on jugular venous lactate or oxygen uptake.[148] Recent laboratory investigations suggest that a variety of signaling pathways and cellular responses are sensitive to relatively small (1°C to 2°C) changes in brain temperature.[134,135]

Induction of mild hypothermia for resuscitated patients produces a 24% to 30% relative risk reduction for death or poor neurologic outcome (Fig. 50-7).[149] Mild hypothermia (33°C to 34°C) maintained for 12 or 24 hours significantly improved the odds of survival and good neurologic outcome for subjects resuscitated from VF cardiac arrest.[123,140] There is no reason to believe that this neurologic benefit of induced hypothermia is specific to patients with one type of cardiac rhythm, and use in all post-resuscitation patients seems reasonable. At the time of resuscitation, many patients are already mildly hypothermic with core temperatures between 35°C and 35.5°C.[123,140,150] This spontaneous cooling may result from equilibration of core and peripheral blood compartments during circulatory arrest. Subsequent to restoration of circulation, patients will rewarm within a few hours unless specific interventions are instituted.[141]

The optimal duration of cooling, the maximum delay in achieving target temperatures, the optimal target temperature, and the preferred rate of rewarming are unknown. Laboratory studies suggest that cooling to between 32°C and 35°C for 12 to 24 hours is beneficial, particularly if cooling is achieved within 6 hours after resuscitation. These studies also suggest that temperature is less important more than 48 hours after resuscitation and that rewarming should be performed slowly (<1°C/hr). Clinical data to answer these practical questions are likely to become available over the next few years as the use of therapeutic hypothermia becomes widespread.

After cardiac arrest, mild hypothermia can be induced by a variety of techniques. Surface cooling with ice packs and cooling blankets is tolerated by the comatose patient.[140,151] Neuromuscular blockade and sedation can help prevent shivering or other compensatory reflexes. However, surface cooling alone is slow and may require 4 to 6 hours to reach 34°C.[123,146,152] Lavage of the stomach with ice-cold water can accelerate cooling but is labor intensive. Local cooling of the head is unlikely to produce brain hypothermia when there is adequate perfusion by warm core blood,[150] although the head can be an effective site for removing heat from the body.[153] Intravascular devices can provide direct cooling of blood in the vena cava, but these devices are expensive and invasive.[124] Rapid infusion of 30 mL/kg cold (4°C) crystalloid produces a rapid decrease in core temperature and is tolerated by the post-resuscitation patient.[154] The volume required may limit this intervention to those patients without renal failure or pulmonary edema. Taken together, these data support the rapid induction of mild hypothermia by surface cooling and bolus

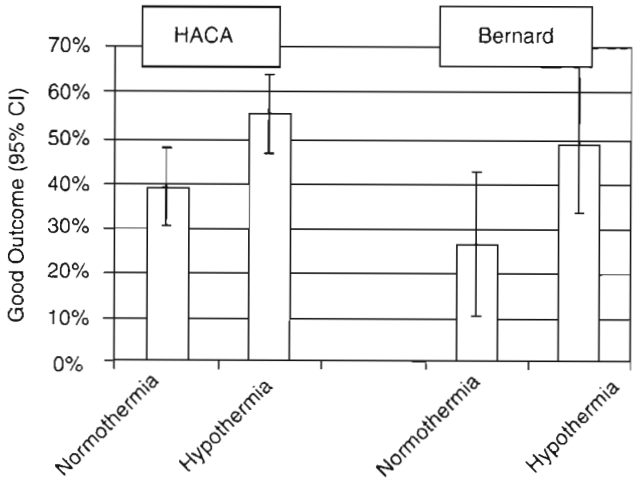

FIGURE 50-7. Improvement in good neurologic outcome was reported in two randomized clinical trials of therapeutic hypothermia. HACA[123] studied 275 subjects, with 137 receiving 24 hours of cooling to 32°C to 34°C. Bernard and colleagues[140] studied 77 subjects, with 43 receiving 12 hours of cooling to 33°C.

infusion of cold intravenous fluids (unless contraindicated), followed by maintenance of hypothermia by surface cooling, neuromuscular blockade, and sedation (Fig. 50-8.)

Fluid and electrolyte shifts are the primary management concerns during induction of hypothermia. Induction of cooling can result in peripheral vasoconstriction, with an apparent reduction in vascular volume.[155] CVP will increase, followed by diuresis. Conversely, at the time of rewarming, vessels will dilate, CVP will decrease, and the patient may become relatively hypovolemic. Volume status should be followed closely, and a need for additional volume infusion to maintain blood pressure and urine output should be anticipated at the time of rewarming. Inattention to this fluid shift was cited as a pitfall in trials of therapeutic hypothermia for traumatic brain injury.[155] The initial diuresis, along with shifts between intracellular and extracellular compartments, can result in hypokalemia, hypophosphatemia, and hypomagnesemia at cooling, followed by hyperkalemia at rewarming.[156,157] Frequent monitoring and correction of electrolytes during these transitions is warranted.

Cardiovascular complications of hypothermia are rare with temperatures greater than 30°C. Cooling from 37°C to 31°C actually has a positive inotropic effect, increasing stroke volume to a greater extent than it decreases heart rate.[158] Systemic vascular resistance does not appear to change greatly. Clinical data report a transient 18% decline in cardiac index with cooling to 33°C.[159] Conscious patients undergoing angioplasty for acute myocardial infarction tolerate mild hypothermia.[124] In these patients, cooling did not interfere with defibrillation when it was required.

Other complications of mild hypothermia are few when the cooling period lasts less than 24 hours. Infections do become more common if cooling is prolonged for more than 24 hours. There is a suggestion that infections were slightly more common in post-resuscitation patients cooled for 24 hours,[123] but not in those cooled for 12 hours.[140] Although mild hypothermia can inhibit platelet function and coagulation,[160] these changes are of small magnitude, leading to no bleeding complications in studies to date. These studies included subjects with concurrent trauma or administration of heparinoids

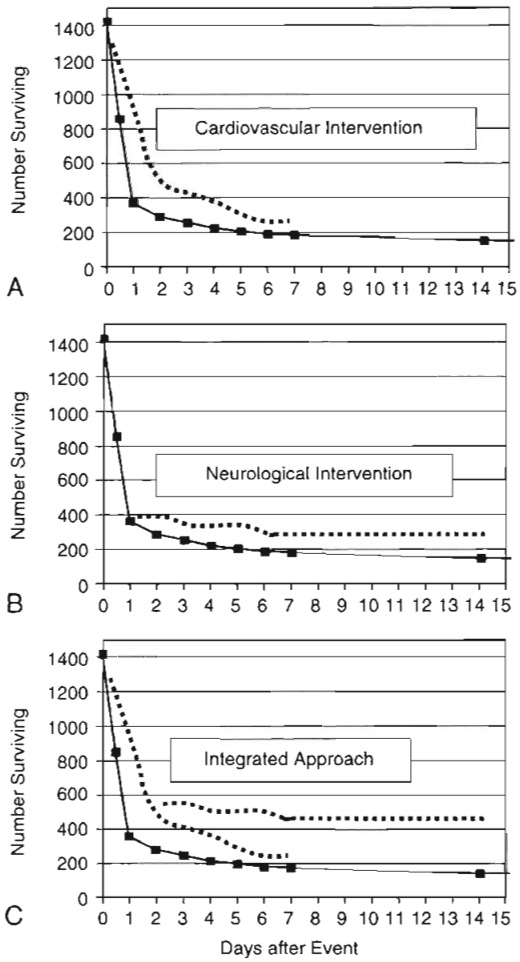

FIGURE 50–8. An integrated approach to cardiopulmonary-cerebral resuscitation is most likely to generate significant changes in patient survival after cardiac arrest. Hypothesized benefits are superimposed on recent survival curves from one city. **A,** Compared with current care, an intervention that improves cardiovascular resuscitation may increase admission to the hospital without preventing later death due to brain injury. **B,** An intervention that improves neurologic recovery may improve the proportion of subjects who awaken from coma, but the magnitude of this benefit for the population is obscured by the large number of deaths due to cardiopulmonary collapse. **C,** Combined care directed at both cardiopulmonary and neurologic injury may provide more than additive increases in meaningful survival.

and glycoprotein IIb/IIIa inhibitors.[124,146] Elevations of pancreatic enzymes have been reported in cooled patients, but these changes resolve with rewarming.[123,159] Creatinine clearance and platelet count may decrease during cooling, but both parameters normalize with rewarming.[159]

BLOOD PRESSURE AND CEREBRAL BLOOD FLOW

After cardiac arrest, the heart experiences a reversible period of decreased mechanical function.[161] The biochemical basis for this dysfunction is an active area of study. Moreover, reperfusion at the time of resuscitation includes oxidative stress or other triggers that can lead to myocyte death.[162] From a clinical standpoint, inotropic support will almost certainly be necessary for any patient resuscitated from cardiac arrest lasting more than 3 or 4 minutes. This dependence on inotropes should decline over the subsequent 24 to 48 hours.

Autoregulation of cerebral blood flow is disturbed after cardiac arrest. Measurement of oxygen saturation in the jugular bulb venous blood allows calculation of brain oxygen extraction. Furthermore, cerebral blood flow can be estimated using transcranial Doppler ultrasound or nuclear imaging. During the first day after resuscitation from cardiac arrest, patients exhibit increased cerebral vascular resistance[163] and impaired cerebral autoregulation.[164,165] When autoregulation is present, it is right shifted such that brain perfusion declines when mean arterial pressure declines below 80 to 120 mm Hg. When blood pressure is maintained, clinical PET studies suggest that regional perfusion remains matched to metabolic activity after cardiac arrest.[166]

Therefore, after cardiac arrest, relative hypertension (mean arterial pressure greater than 100 to 110 mm Hg) should be maintained to prevent brain hypoperfusion. Maintaining this level of hypertension will require infusions of inotropes and/or pressors. In support of this recommendation, hypotension during the first 3 hours after resuscitation is associated with poor neurologic recovery in patients admitted to the hospital after cardiac arrest.[142] Future research is needed to develop hemodynamic support strategies that optimize both cerebral and cardiac perfusion and metabolism during ICU care after cardiac arrest.

GLUCOSE CONTROL

Elevated serum glucose is associated with poor outcome after cardiac arrest[77] and may be a marker of prolonged or difficult resuscitation. Both epinephrine and physiologic stress can elevate serum glucose levels. However, multivariate models that accounted for resuscitation time and medication usage still show an effect of serum glucose on admission and during the first 48 hours of intensive care on long-term outcome.[1,167] Despite this association, both studies noted that monitoring of glucose in nondiabetic patients was infrequent. Because no randomized clinical trial has been performed, it remains unclear whether aggressive management of serum glucose concentration will improve outcome.

HEMATOLOGIC CHANGES

Cardiac arrest is associated with activation of coagulation that is not balanced by fibrinolysis. This hematologic profile is reminiscent of DIC and may contribute to subsequent end-organ dysfunction. Markers of thrombogenesis that have been reported include increased thrombin-antithrombin complexes and fibrinopeptide A.[168,169] These increases are not balanced by fibrinolytic factors for at least 24 hours. The cause of these changes is unknown and may be related to ischemic injury to the endothelium.

At present, use of anticoagulation is variable and there are no prospective trials evaluating the effect of anticoagulation after resuscitation. Anticoagulation and even fibrinolytic drugs are safe after CPR.[169,170] A retrospective series noted a univariate relationship between anticoagulation and 6-month survival that was not significant in a multivariate model.[167] In a series of patients with cardiac arrest related to VF and cardiac ischemia, administration of thrombolytic drugs was associated with better neurologic outcome.[171] Given the

hematologic evidence of active thrombogenesis, these data suggest that at least anticoagulation should be considered immediately after resuscitation.

INFECTION

The physiology of the post-resuscitation patient resembles that of systemic inflammatory response syndrome. Bacteremia has been noted in 39% of patients during the first 12 hours after resuscitation.[144] Fever is common in patients within 48 hours after resuscitation from cardiac arrest. Potential causes include contamination during emergent line placement, aspiration or transient bacteremia during airway management, and mesenteric ischemia contributing to bacterial translocation from the gut. Endotoxin and various cytokines are increased in serum after resuscitation.[172] Whereas an intestinal origin of endotoxin was suspected, pulmonary infections were more common than bacteremia. When they develop, severe infections are associated with mortality.[145] Despite these observations, the role of routine antibiotics and antipyretics has not been examined.

PREDICTING NEUROLOGIC RECOVERY

The goal of clinical practice always is to restore the patient to full consciousness and function.[173] All subjects with circulatory arrest of more than a 1 or 2 minutes will be comatose at initial presentation, but some of these same patients can recover and awaken. Therefore, signs of neurologic activity immediately after restoration of circulation are encouraging, but their absence does not preclude eventual recovery. Unfortunately, many cardiac arrest survivors fail to completely awaken and may meet criteria for a persistent vegetative state.[174,175] The status of patients who do not quite meet these criteria but are not awake has been described as a minimally conscious state.[176] Assessment of neurologic prognosis after resuscitation becomes increasingly reliable over the first 3 days of recovery.[177-179]

Several clinical signs have been used to assess awakening after cardiac arrest. A classic case series found that pupillary reaction to light, corneal reflexes, and motor activity can change over the first 72 hours after resuscitation.[179] By 72 hours, absence of eye reflexes and failure to have a localizing response to pain are highly predictive of permanent coma. A systematic review of literature since that initial report confirms the value of these clinical findings.[177] For individual patients who remain in coma, these series show how specific clinical signs can provide quantitative estimates of the probability of awakening.

NEUROPHYSIOLOGY

It is common for electroencephalography (EEG) to be done for prognostic purposes. However, the predictive value of EEG after resuscitation from cardiac arrest is unclear, and the timing of this test in relation to the ischemic event is rarely standardized. A burst-suppression pattern or an isoelectric electroencephalogram during the first week after resuscitation is associated with poor neurologic prognosis.[177] Recovery of longer-latency event-related potentials or evoked potentials (EPs) is associated with awakening.[180-182] Absence of early somatosensory EPs is very specific for poor neurologic outcome.[177] Both EEG and EPs vary with the elapsed time since resuscitation.[182] There are no data about the influence of induced hypothermia or other treatments on EEG and EPs.

BLOOD MARKERS

Several neuronal peptides appear in the blood after injury to the brain, including neuron-specific enolase (NSE) and S-100B. After cardiac arrest, NSE reaches a maximum level in serum at 72 hours. High NSE levels at 48 to 72 hours after resuscitation are associated with poor outcome.[181,183,184] Serial NSE levels that continue to rise over the first 72 hours also predict poor outcome.[184] In contrast to NSE, peak levels of S-100B in serum occur during the first 24 hours after resuscitation.[183] Higher S-100B levels are also associated with poor neurologic outcome.[183,185]

These data suggest that initial S-100B levels and the change in NSE over the first 72 hours after resuscitation may provide blood markers to follow brain injury. For example, in subjects treated with induced hypothermia, S-100B levels were not altered but decreasing NSE levels were more common.[186] More research is necessary to determine whether initial S-100B can be used to select patients for specific therapies or whether those therapies could be titrated to the changes in NSE.

IMAGING STUDIES

Imaging of the brain is important to exclude injury incurred at the time of collapse and to exclude intracranial causes of collapse. Cranial CT to exclude hemorrhage may be prudent in the comatose resuscitated patient before beginning anticoagulation or fibrinolytic therapy. Experience with more advanced imaging for making neurologic prognoses is limited. Cortical abnormalities on fluid-attenuated inversion recovery (FLAIR) MRI are associated with poor neurologic outcome.[187] In the long-term, cognitive deficits are associated with global brain volume loss after cardiac arrest.[188] At present, use of brain imaging beyond the cranial CT scan remains largely investigational.

WITHDRAWAL OF SUPPORT AND REHABILITATION

For adults who are neurologically devastated after cardiac arrest in North America, it is more common to die in the hospital than to receive long-term care. An estimated 44% of patients who are initially resuscitated from cardiac arrest in the hospital have withdrawal of care later during their hospitalization.[10] For patients resuscitated from out-of-hospital cardiac arrest, 68% have do not resuscitate (DNR) status established in the hospital, perhaps representing a comparable outcome.[14] These decisions are often based on the neurologic prognosis of the patient, and these decisions limit the number of neurologically impaired individuals who are discharged from the hospital. Quality of life for those patients who do leave the hospital is generally high.[13,189,190]

The role of rehabilitation or other therapy in recovery from neurologic impairment after cardiac arrest is relatively unstudied. It is clear that both patients and their caregivers have complex needs if neurologic injury is severe.[191] Unfortunately, long-term improvement is less common when neurologic devastation follows a medical cause, like cardiac arrest, than when it results from traumatic brain injury.[175] Popular reports

of awakening after long coma may cause inappropriate optimism for families of patients or surrogate decision makers. Partial awakening of the patient into a persistent vegetative state or minimally conscious state can further confuse their expectations. These individuals should receive information about these syndromes, expectations of recovery, and any specific considerations for the patient. Religious, cultural, and personal beliefs will contribute to their decisions, and appropriate social service and pastoral support should be provided.

ANNOTATED REFERENCES

HACA—Hypothermia after Cardiac Arrest Study Group: Mild therapeutic hypothermia to improve the neurologic outcome after cardiac arrest. N Engl J Med 2002;346:549-556.

This prospective multicenter trial found that induction of mild hypothermia (33°C to 34°C) for 24 hours after restoration of circulation improved survival and neurologic recovery. Mild hypothermia reduced the relative risk of poor outcome by 26%.

Langhelle A, Tyvold SS, Lexow K, et al: In-hospital factors associated with improved outcome after out-of-hospital cardiac arrest: A comparison between four regions in Norway. Resuscitation 2003;56:247-263.

This cohort study examined survival of patients in the hospital after initial resuscitation from out-of-hospital cardiac arrest. Survival varied between regions, and survival was independently associated with lower temperature and lower serum glucose. While not a prospective trial, these data suggest that control of these parameters may be important.

Paradis NA, Martin GB, Rivers EP, et al: Coronary perfusion pressure and the return of spontaneous circulation in human cardiopulmonary resuscitation. JAMA 1990;263:1106-1113.

This prospective study placed central monitors in 100 subjects during chest compressions. Failure to develop coronary perfusion pressures of more than 15 mm Hg guaranteed the failure of resuscitation.

Wik L, Hansen TB, Fylling F, et al: Delaying defibrillation to give basic cardiopulmonary resuscitation to patients with out-of-hospital ventricular fibrillation. JAMA 2003;289:1389-1395.

In this prospective, randomized trial, subjects with ventricular fibrillation outside the hospital received either immediate rescue shocks or 3 minutes of chest compressions before rescue shocks. The subgroup of subjects for whom response intervals were longer than 5 minutes had better outcomes if chest compressions were performed first. Immediate rescue shocks may be appropriate for brief ventricular fibrillation, but reperfusion first may be better for prolonged ventricular fibrillation.

Zandbergen EG, de Haan RJ, Stoutenbeek CP, et al: Systematic review of early prediction of poor outcome in anoxic-ischaemic coma. Lancet 1998;352:1808-1812.

This paper reviews studies of prognostic tests for predicting neurologic outcome after cardiac arrest. The literature suggests that by the third day of recovery, pupillary response and motor response to pain are predictive of outcome and that, during the first week of recovery, somatosensory evoked potentials are also predictive. Other diagnostic tests are less specific.

Chapter 51

MANAGEMENT OF ACUTE ISCHEMIC STROKE

Lawrence R. Wechsler • Carol A. Barch

KEY POINTS

1. The success of acute stroke management begins with a patient's family member or bystander recognizing the symptoms of stroke (see Table 51-1) and calling 911 immediately.
2. On arrival, the prehospital team should complete a quick assessment. The assessment includes following the basics of the *ABCs-N: a*irway, *b*reathing, *c*irculation, and *n*eurology evaluation. Oxygen saturation should be maintained at least 96% to provide adequate oxygenation to the brain tissue. Continuous monitoring of the electrocardiogram is recommended because almost 30% of ischemic stroke patients have arrhythmias (e.g., atrial fibrillation). Blood pressure should be determined, but treatment should be considered only if blood pressure is greater than 220/120 mm Hg.
3. A stroke team consists of individuals from multiple disciplines with specialized knowledge and interest in acute stroke care. The team approach brings together the necessary skills to administer emergently whatever care is best suited to the situation and divides the workload so that tasks can be performed simultaneously rather than sequentially.
4. Studies do not support a reduced recurrence rate or improved outcome with anticoagulation when administered within 24 to 48 hours of stroke onset. There is little value in anticoagulating all patients with acute stroke.
5. In June 1996, the U.S. Food and Drug Administration (FDA) approved intravenous tissue plasminogen activator (tPA) for treatment of stroke within 3 hours of onset.
6. A growing body of evidence suggests a small benefit of intravenous tPA up to 4.5 hours after stroke onset, but the earlier treatment is initiated, the greater the likelihood of a good clinical outcome.
7. Patients receiving antiplatelet therapy usually are not excluded from thrombolytic therapy, although additional studies are needed to clarify the relative risk of thrombolysis in these patients.
8. Good outcomes have been reported with intra-arterial thrombolysis of basilar thrombosis well beyond the usual 6-hour time limit. Intravenous tPA also may result in improvement, but the large clot burden favors the intra-arterial approach.
9. Surgical decompression for hemispheric infarction should be considered for younger patients with a greater potential for recovery from massive stroke and particularly for nondominant strokes.
10. The availability of effective treatment to alter outcome within the first few hours after stroke onset necessitates dramatic changes in the evaluation of stroke. Patients with symptoms suggesting cerebral ischemia must be treated emergently from the prehospital encounter to the emergency department and the treating physicians. Imaging must be performed rapidly and provide useful information for the decision-making process.

Stroke is a medical emergency. The rationale for acute stroke treatment is based on the concepts of the ischemic penumbra. When an arterial occlusion occurs, an area of infarcted brain is surrounded by a region that has reduced blood flow impairing function, but not sufficiently severe to result in irreversible infarction. If adequate blood flow can be restored within a critical time frame, this area at risk may return to normal function. Experimental models of stroke indicate that lower levels of blood flow are tolerated for brief periods, whereas slightly higher blood flow can be maintained for several hours without developing infarction.[1] The precise relationships between blood flow levels and duration for human stroke are not known, but the more quickly flow is restored, the greater the likelihood that the tissue will be spared.

In 1995, the National Institute of Neurological Disorders and Stroke (NINDS) tPA study[2] was published showing for the first time in a randomized controlled trial a reduction in stroke morbidity with acute treatment. Other treatments, such as intra-arterial thrombolytics, clot disruptive devices, and neuroprotective agents, continue to be investigated. At present, intravenous tPA is approved by the FDA for treatment of acute stroke within 3 hours of onset.

New medical-surgical advances in stroke led to the development of acute stroke teams and stroke centers. The NINDS Stroke Group initiated the conceptual groundwork during the NINDS Stroke Trial to facilitate recruitment. The Brain Attack Coalition[3] published recommendations for the organization of these teams and health care delivery systems to facilitate a rapid response. The American Heart Association and the Joint Commission of Health Organizations support disease-specific stroke certification to measure the standards necessary to deliver high-quality

stroke care. Stroke specialists, stroke centers, and future clinical trials will continue to drive advances in acute stroke management.

STROKE MECHANISMS

Appropriate treatment of ischemic stroke depends on identification of the mechanism of stroke. The duration of symptoms and the time course are not as important as the underlying etiology of the ischemic syndrome. Ischemic strokes generally are classified as large vessel thrombotic, small vessel thrombotic, or embolic. An embolic occlusion of a major intracranial artery may require a different therapeutic approach than an atherosclerotic occlusion. Similarly, small vessel thrombosis has different implications for treatment and a better prognosis than large vessel thrombosis.

In the first few hours after stroke, identification of stroke mechanisms may be difficult or impossible. Even distinguishing ischemic from hemorrhagic stroke may be hazardous based on clinical evaluation alone. Information obtained from history and rapid examination provides clues to pathophysiology,[3] but definitive diagnosis usually requires additional testing, such as ultrasound and imaging. Large vessel thrombotic strokes are often preceded by transient ischemic attacks or a stepwise progression of deficits. Risk factors include hypertension, smoking, diabetes, and elevated serum cholesterol level. Clinical deficits typically correspond to the territory of major cerebral arteries or their border zones. In embolic strokes, the onset is usually sudden, although in occasional cases a stepwise progression occurs in the first few hours. The presence of atrial fibrillation, rheumatic heart disease, or a recent myocardial infarction increases the probability of embolism. Several clinical syndromes are attributable to small vessel thrombotic or lacunar stroke, including pure motor stroke involving the face, arm, and leg; pure sensory stroke; ataxia hemiparesis; and dysarthria–clumsy hand syndrome. Other syndromes also may be due to lacunar strokes, but in such cases the mechanism is less certain, illustrating the hazards of deciding on stroke mechanism from clinical findings alone.

Pathophysiologic diagnosis is enhanced greatly by imaging modalities, including computed tomography (CT) and magnetic resonance imaging (MRI). These studies take time to complete, delaying administration of acute stroke therapy and potentially leading to irreversible brain injury before the diagnosis can be established. The time needed for imaging studies must be weighed against the benefit of the information obtained. Studies need to be performed rapidly with minimal delay, and the results must be used to decide on optimal treatment. Acute stroke treatment is likely to differ depending on stroke mechanism, and rapid imaging modalities should become increasingly important in acute stroke management.

PREHOSPITAL EVALUATION OF STROKE

The success of acute stroke management begins with a patient's family member or bystander recognizing the symptoms of stroke (Table 51-1) and calling 911 immediately. When there was no acute treatment for stroke, only primary and secondary preventive measures, health care professionals did little to educate the public on recognizing stroke, identifying risk factors, or promoting stroke prevention.

TABLE 51–1. STROKE RECOGNITION

Sudden onset of:
Numbness or weakness of the face, arm, or leg
Slurred speech or difficulty with speech
Blurred or loss of vision in one or both eyes
Onset of severe headache
Onset of clumsiness or loss of balance

On average, across the United States, stroke patients arrive at the hospital 24 hours after symptom onset. A huge effort is under way to educate the public at large of the warning signs of stroke, especially in individuals at risk and their family members (Table 51-2). The key message is how to recognize stroke, to take action, and to get to the hospital immediately.

In recent years, prehospital systems across the United States have begun to implement an acute stroke protocol. The protocol is published in the American Heart Association's *Advanced Cardiac Life Support 1997-1999* manual.[4] An algorithm for acute stroke was developed from the experience of conducting acute stroke trials.[5-7] Similar to the concept of time-focused field management of myocardial infarction, acute stroke now is being approached as a medical emergency. Rapid identification of the problem as a stroke, determining onset to be less than 6 hours, appropriate field assessment and management, rapid transport, and prenotification of the incoming stroke patient to the receiving emergency department are the key elements for prehospital personnel.

The process begins at dispatch. Any calls with complaints of "weakness, numbness, changes in speech, headache, confusion, found down, or unconscious," are considered a possible stroke. A crew is sent immediately to the scene.

On arrival, the prehospital team should complete a quick assessment, which includes following the basics of the *ABCs-N: a*irway, *b*reathing, *c*irculation, and *n*eurology evaluation. Oxygen saturation should be maintained at least 96% to provide adequate oxygenation to the brain tissue. Continuous monitoring of the electrocardiogram is recommended because almost 30% of ischemic patients have arrhythmias (e.g., atrial fibrillation). Blood pressure should be determined, but treatment should be considered only if it is greater than 220/120 mm Hg. Intravenous access should be established if this does not delay transport to the emergency department. If administering intravenous fluids, only isotonic solutions, such as normal saline or lactated Ringer's solution, should be used. Glucose should be avoided in intravenous fluids because it may be detrimental to ischemic brain tissue and can lead to unnecessary cerebral edema. Hypoglycemia can mimic stroke symptoms, and serum glucose should be checked. Glucose should be administered if hypoglycemia is found. Hyperglycemia needs to be treated on arrival to the emergency department.

TABLE 51-3. CINCINNATI PRE-HOSPITAL STROKE SCALE

Facial droop—have patient show teeth or smile	Normal—both sides of face move equally Abnormal—one side of the face does not move as well as the other side
Arm drift—patient closes eyes and holds both arms out	Normal—both arms move the same or both arms do not move at all Abnormal—one arm does not move or one arm drifts down compared with the other
Speech—have patient say "you can't teach an old dog new tricks"	Normal—patient uses correct words with no slurring Abnormal—patient slurs words, uses inappropriate words, or is unable to speak

It is important for the prehospital personnel to gather information about the onset of stroke symptoms. First, it is crucial to determine the time of onset of the symptoms; this is important because the emergency department may not have access to individuals who were present at the onset. Time of onset is determined by when the patient was last seen without a neurologic defect. When the deficit is present on awakening, the time of onset is considered the previous night before going to bed. If thrombolytic treatment is considered, it is important to obtain a history of trauma or falling when the symptoms occurred. The examiner should check for any signs of ecchymosis or laceration. Also, a history of seizure activity after the onset of symptoms should be obtained. Todd's paralysis, a syndrome that occurs after a seizure, often is confused with stroke symptoms.

To assess the patient's neurologic status, the best tool to use in the field is the Pre-hospital Stroke Scale developed by the University of Cincinnati (Table 51-3). This quick screen allows for uniformity in assessing stroke deficits that clarify communication of the results to the receiving team at the hospital.

Information that should be communicated to the receiving hospital includes age, sex, past medical history, current medications, presenting problem, onset time, neurologic status, vital signs, estimated time of arrival to hospital, and any concerns while in transport. Fieldwork can save precious minutes of additional work in the emergency department. The importance of care given by paramedics should not be underemphasized.

EMERGENT STROKE EVALUATION

GENERAL ASSESSMENT

Emergent assessment of the stroke patient begins immediately on arrival at the emergency department. If prenotification is obtained from emergency medical services, a physician should meet the patient at triage and begin the evaluation. Initial concerns include assessment of respiratory function, cardiovascular stability, and level of consciousness. An adequate airway must be established to ensure proper ventilation, particularly in obtunded or comatose patients. Aspiration is a serious concern and leads to subsequent pneumonia and is a major cause of morbidity and mortality during hospitalization.[8] Supplemental oxygen is often administered, but the benefit is uncertain when oxygenation is already adequate. Hypoxemia should be corrected immediately, however, and its source aggressively investigated. Arrhythmias are common in acute stroke. Bradycardia may signal underlying increased intracranial pressure or cardiac ischemia. Atrial fibrillation associated with rapid ventricular response often impairs cardiac output requiring immediate treatment. Atrial fibrillation also may be an embolic source for stroke. Ventricular tachycardia or fibrillation rarely occurs with stroke[9] and when present usually is due to coexistent myocardial infarction. Hypotension should be corrected with intravenous fluids. Seizures should be controlled with anticonvulsants. The initial physician evaluation should be completed within 15 minutes.

BLOOD PRESSURE MANAGEMENT

Hypertension commonly accompanies ischemic and hemorrhagic stroke.[10] In most cases of ischemic stroke, abrupt lowering of blood pressure is not advised because of the risk of causing further impairment of perfusion in the ischemic region.[11] When a systemic or cardiac reason for reducing blood pressure is present, such as aortic dissection or acute myocardial infarction, the relative importance of the systemic and neurologic issues must be considered. Hypertensive encephalopathy is a syndrome of extreme hypertension, papilledema, altered mental status, microangiopathic hemolytic anemia, and renal insufficiency that responds to lowering blood pressure. In the absence of papilledema or systemic features, it is unlikely that acute neurologic deficits are due to hypertensive encephalopathy, and acutely lowering blood pressure is more likely to worsen deficits rather than improve them.

When thrombolytic therapy is considered, reducing blood pressure within limits is necessary. Before thrombolytic therapy is administered, systolic blood pressure should be less than 185 mm Hg and diastolic less than 110 mm Hg.[12] Labetalol typically is administered in increasing doses every 5 to 10 minutes to control blood pressure. If beta blockers cannot be used, enalapril is a reasonable alternative. Sublingual nifedipine should be avoided because of the potential to lower blood pressure precipitously. If these agents do not provide adequate control, thrombolytic therapy probably should be avoided. Although some authors recommend limiting treatment to one or two doses of labetalol before excluding the patient from thrombolytics, we generally proceed with treatment as long as the blood pressure is controlled within the time frame for treatment with thrombolytic therapy.

TRIAGE AND LABORATORY STUDIES

The immediate concern for the emergency department evaluation after initial cardiovascular stabilization is confirming the diagnosis of stroke, excluding stroke mimics, and establishing whether acute stroke intervention is appropriate for the patient. It is crucial to establish the time of onset with certainty. The time of onset should be considered the time

the patient was last seen without a neurologic deficit, rather than the time the patient was found with a deficit. If deficits were present on awakening, the onset time should be considered the previous night when the patient was last seen neurologically normal. This time of onset may exclude some patients who otherwise would benefit, but it avoids the risk of causing hemorrhages in patients with long established infarction. For intravenous tPA, the window for treatment is currently 3 hours. The evaluating physician must allow for time needed for CT scanning and interpretation and preparing and administering tPA. Completion of CT scanning should take no more than 25 minutes from arrival, and interpretation should be completed within 45 minutes. tPA treatment should be initiated within 1 hour of arrival in the emergency department.

Conditions other than stroke that cause acute neurologic deficits must be considered before proceeding with acute stroke treatment. Occasionally, intracranial mass lesions present with acute deficits. Migraine, seizures, and metabolic aberrations such as hypoglycemia may present with focal neurologic signs. A brief history obtained from the patient or family usually excludes these possibilities. Two intravenous catheters should be established as soon as possible. Blood glucose should be checked and corrected if needed. Additional blood tests obtained immediately include coagulation studies, complete blood count, and electrolytes.

GLUCOSE

Evidence from animal models of stroke suggests that hyperglycemia increases the severity of ischemic injury.[13] Increased glucose concentration in the area of ischemia causes higher lactate concentrations and local acidosis; this increases generation of oxygen free radicals damaging neurons. Hyperglycemia also may increase ischemic edema, release excitatory amino acid neurotransmitters, and weaken blood vessels in the ischemic area.

Studies of stroke in humans show an inconsistent association between stroke outcome and initial blood glucose; however, admission glucose concentration correlates with initial stroke severity. Initial hyperglycemia also has been associated with higher mortality rates after stroke. Some authors have suggested that hyperglycemia in acute stroke is a stress reaction, but the relationship between initial blood glucose concentration and outcome is independent of initial stroke severity, arguing against a stress phenomenon.

Although a relationship exists between hyperglycemia and stroke outcome, no study has examined the effect of lowering glucose acutely on outcome. At least one randomized trial is currently in progress,[14] and others are planned.[15] In the absence of such data, it seems prudent to lower blood glucose in the first few hours after stroke when it is markedly elevated. Glucose levels greater than 200 mg/dL should be treated with insulin on a sliding scale to keep the level less than 200 mg/dL (ideally <150 mg/dL).

TEMPERATURE

Fever also has been associated with worse outcomes after stroke.[16] It is unclear, however, whether fever is a response to the stroke or a cause of neurologic worsening. Hypothermia reduces stroke severity in animal models of stroke,[17] but no randomized trials have been completed in humans with stroke to test the benefits of this therapy. Despite the uncertainty of benefit, maintenance of normothermia is advised after stroke. Cooling blankets and antipyretics should be used to treat temperature elevations. Intravascular cooling devices currently are being tested. These devices rapidly reduce body temperature and allow the temperature to be maintained within a narrow range.

Although "central" fever occasionally occurs after stroke, most temperature elevations are due to infection. A thorough search for the cause of fever is paramount. Appropriate antibiotic treatment must be instituted as quickly as possible.

FLUID MANAGEMENT

Most patients with acute stroke are volume depleted. Intravenous fluids should be replaced with either normal saline or lactated Ringer's solution. In patients with large strokes in danger of developing brain edema, fluid administration should be titrated carefully, and free water must be limited. Mild hyponatremia need not be treated acutely. More severe hyponatremia should be corrected slowly and usually reverses with infusion of normal saline.

STROKE TEAM

A stroke team consists of individuals from multiple disciplines with specialized knowledge and interest in acute stroke care. The team approach brings together the necessary skills to administer emergently the care best suited to the situation and divides the workload so that tasks can be performed simultaneously rather than sequentially. Ideally, a stroke team consists of a neurologist, neuroradiologist, nurse coordinator, and neurosurgeon. Not all hospitals have the resources necessary to provide a complete stroke team at all times, but at least one individual should be available with the ability to evaluate acutely the neurologic status of a stroke patient, interpret the CT scan, and institute acute stroke therapy in appropriate cases. The more components of the team involved in acute stroke care, the more rapidly treatment can be initiated. The stroke team is usually responsible for confirming the onset time, evaluating the CT scan, establishing the diagnosis, reviewing the inclusion/exclusion criteria for thrombolytic therapy, and making the final decision to proceed with treatment.

IMAGING OF ACUTE STROKE

Evaluation of patients with acute stroke depends heavily on imaging. Although CT and MRI of stroke is a component of standard stroke care, emergent imaging of stroke raises several new issues. For additional details on neuroimaging in intensive care, see Chapter 48. It is paramount to differentiate ischemic from hemorrhagic stroke before deciding on the use of thrombolytics. In the future, selection of appropriate neuroprotective agents also may depend on the presence of hemorrhage. Although still investigational, it is likely that identification of an arterial occlusion and information about cerebral blood flow would help triage acute stroke patients to a treatment regimen most likely to produce benefit, while limiting the potential for complications.

At present, selection of patients for thrombolytics or other acute stroke therapy is based entirely on clinical evaluation

and historical time of onset. It is likely, however, that some patients within the 3-hour time window already have established infarction that would not reverse with thrombolysis and may result in hemorrhage owing to reperfusion of infarcted brain. In contrast, others may have salvageable brain tissue despite a greater than 3-hour interval since onset. A physiologic estimate of tissue viability would be preferable to a fixed time interval, if a study were found that reliably predicted viability of brain after stroke.[18] CT and MRI have the potential to provide this measurement.

COMPUTED TOMOGRAPHY

CT has been the imaging procedure of choice for patients with recent stroke to exclude hemorrhage as the etiology. CT has the potential to provide a great deal more information, however, in an acute stroke patient. Subtle parenchymal abnormalities show evidence of early edema or infarction. Spiral CT allows CT angiography and imaging of the intracranial and extracranial circulation. Cerebral perfusion can be examined with stable xenon CT and mapped to the arterial distribution of the major cerebral arteries. This battery of tests is performed without moving the patient from the CT scanner, minimizing the time delay before deciding on optimal treatment.

Not all patients can complete the entire battery of tests. CT angiography requires contrast administration and cannot be performed in patients with renal failure or contrast allergies. There is a potential problem in patients undergoing angiography for possible intra-arterial therapy after CT angiography because the dye load is increased by the combination of procedures. If digital angiography is used and arterial injections of contrast material are minimized, however, the contrast load should not be prohibitive. Xenon CT has few limitations, but excessive movement reduces the accuracy of the acquired blood flow information. Blood flow data may not be reliable in agitated patients. Vomiting occasionally occurs after xenon inhalation, and care must be taken to avoid aspiration.

Early Computed Tomography Changes

It previously was thought that parenchymal changes did not occur on CT for at least 6 hours after ischemic stroke. More recent studies indicate, however, that early changes of ischemia frequently occur within a few hours of stroke onset and have been seen 1 hour after stroke.[19] These changes include reduced attenuation in the basal ganglia,[1] loss of gray-white differentiation particularly in the insular region,[20] low density in the cortex and subcortical white matter, and loss of sulcal markings suggesting early mass effect and edema (Fig. 51-1A and B).[21] A hyperdense middle cerebral artery occurs in 20% to 37%,[22] indicating acute thrombus within the artery, but rarely occurs without at least one other early CT abnormality. Hyperdensity in the basilar artery associated with thrombosis also has been reported.[23] In 100 patients studied within 14 hours of stroke onset (mean 6.4 hours), multiple early CT abnormalities correlated with size of subsequent infarct and poor outcome.[22] In the ECASS trial of tPA for acute stroke (see later), early CT changes correlated with larger subsequent infarct volume[24] and a greater likelihood of hemorrhagic conversion after tPA.[25] Based on these results, some experts recommend withholding thrombolytic therapy in patients with extensive early CT changes[26]; however, whether these abnormalities represent irreversible brain infarction is controversial. A report of a patient with hypodensity in 60% of the middle cerebral artery territory and clinical and CT resolution after reperfusion with intra-arterial urokinase suggests this is not always the case.[27] In the NINDS recombinant tPA trial of intravenous treatment within 3 hours of stroke onset, early ischemic changes did not predict symptomatic hemorrhage or response to treatment.[28] CT scanners used in this study from the early 1990s are likely less sensitive than modern-day scanners. In addition, the association of early CT changes with infarction, and risk of hemorrhage may be greater with longer intervals from stroke onset. Half of the patients in the NINDS trial were treated within 90 minutes. Extensive hypodensity may have greater predictive value than other early ischemic changes.

Computed Tomography Angiography

CT angiography can be performed using spiral CT technology adding only 15 to 20 minutes to the routine CT examination. Either the intracranial or the extracranial circulation may be imaged. In a patient with acute stroke, the intracranial study may be sufficient to diagnose proximal arterial occlusion. When extracranial carotid disease is suspected, both parts of the circulation can be studied. A single bolus of contrast material similar to that used for a contrast CT scan is given for this examination, limiting use in patients with renal failure or contrast hypersensitivity. In acute stroke, CT angiography has been shown to be highly reliable for diagnosis of intracranial occlusions and correlates with other imaging modalities (Fig. 51-1C and D).[29,30] Examination of the carotid bifurcation with CT angiography provides a three-dimensional view of carotid lesions and shows eccentric lesions or ulceration not seen by conventional angiography.[31] When used in combination with conventional CT and xenon CT, the major limitation is tube heating. The studies must be sequenced properly and the area of interest on CT angiography selected carefully to minimize the number of slices needed to obtain the necessary anatomic information. CT angiography in acute stroke patients provides important information about arterial occlusions and possibly collateral blood flow[32] and may be useful to triage patients with large proximal occlusions to thrombolytic therapy and avoid interventions in patients without demonstrable arterial occlusions. It is hoped that future acute stroke trials will incorporate these imaging modalities to assess the value of triaging patients based on anatomic evidence of occlusion.

Computed Tomography Perfusion

In addition to imaging the parenchyma with CT and the cerebral vasculature with CT angiography, CT perfusion adds assessment of cerebral blood flow and blood volume. Using a helical scanner during a bolus of intravenous contrast, the time-dependent concentration curve of contrast in each pixel can be acquired (see Chapter 48). Mean transit time and subsequently cerebral blood flow can be calculated. In patients with acute stroke, perfusion-weighted CT images, similar to cerebral blood volume, correlate with final infarct size and outcome, particularly after recanalization.[33] CT perfusion maps combining cerebral blood flow and cerebral blood volume information identify tissue that progresses to infarction if not reperfused, consistent with ischemic penumbra.[34]

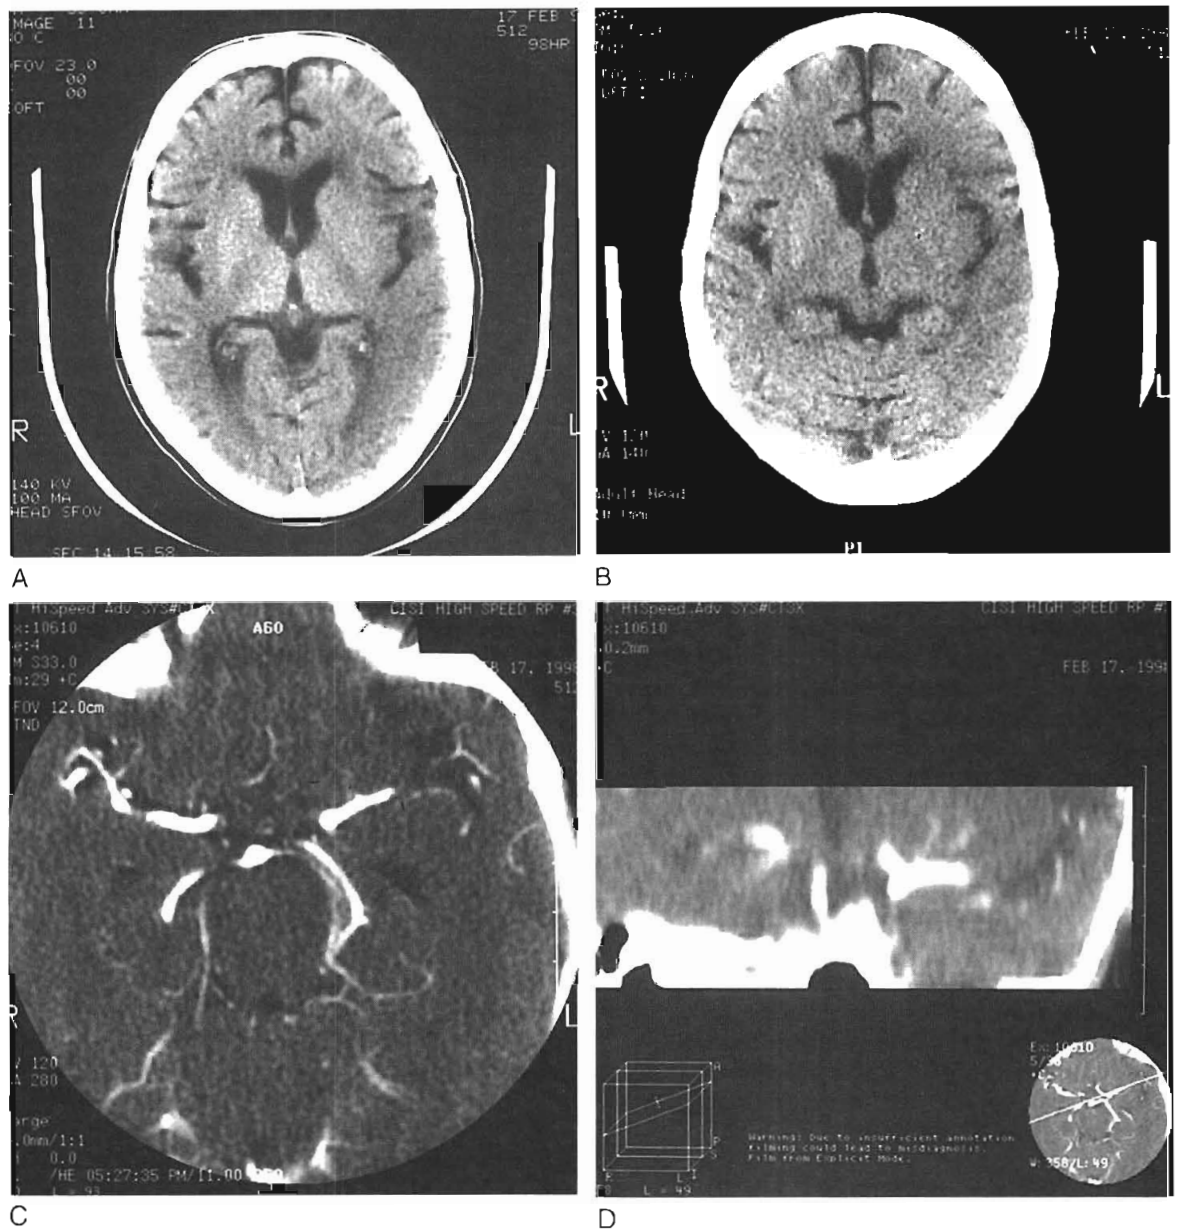

FIGURE 51–1. A, Normal computed tomography (CT) scan of brain 2 hours after onset of aphasia and left hemiparesis. **B,** Repeat CT scan at 5 hours after stroke onset shows early CT changes, including basal ganglia hypodensity, loss of the insular ribbon, and slight effacement of the sulci on the left. **C,** CT angiogram at 5 hours after stroke onset shows complete occlusion of the left middle cerebral artery. **D,** Rapid reconstruction of the CT angiogram again shows occlusion of the left middle cerebral artery.

Xenon Computed Tomography

Measurement of brain perfusion should be particularly beneficial in patients with stroke. Several methods of measuring cerebral blood flow are available; however, quantitative blood flow can be obtained only with xenon CT or positron emission tomography. Positron emission tomography has the advantage of providing corresponding metabolism data, but is more difficult to perform, particularly in acutely ill patients with stroke.

Stable xenon is an inert gas that is inhaled as a mixture of 27% xenon and 73% oxygen. During a 4-minute inhalation, rapid scanning is performed, and pixel-by-pixel blood flow values are calculated at three brain levels. Corresponding brain CT sections allow anatomic correlation. Xenon CT cerebral blood flow studies require about 15 minutes for completion. Reconstruction of images is accomplished within 5 minutes. In acute stroke patients, xenon CT identifies ischemic regions in patients without acute changes on CT. Patients with occlusion of the proximal middle cerebral artery have significantly lower cerebral blood flow in the middle cerebral artery distribution than patients with more distal occlusion (Fig. 51-2).[35] In addition, normal cerebral blood flow in a patient with an acute ischemic deficit is associated with rapid clinical improvement.[36] In a series of patients with middle cerebral artery occlusion studied with xenon CT, penumbral values of cerebral blood flow were present in all patients, and the percentage of middle cerebral artery territory in the penumbral range (cerebral blood flow 8 to 20 mL/100 g/min) remained relatively constant across the group. In contrast, the percentage of middle cerebral artery territory with cerebral blood flow values representing infarcted tissue (cerebral blood flow <8 mL/100 g/min) varied greatly.[37] Outcome was highly correlated with the area of infracted middle cerebral artery territory, not the amount

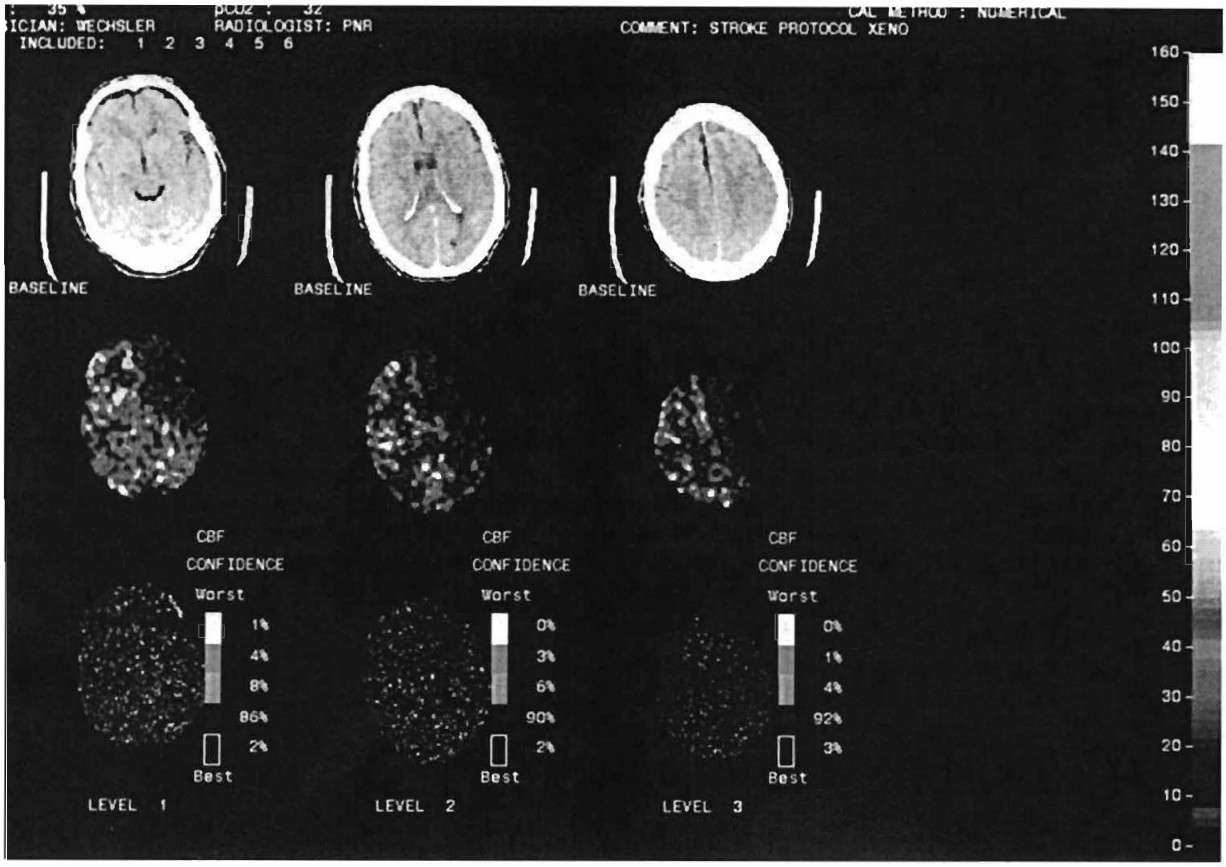

FIGURE 51-2. Xenon computed tomography blood flow study from a patient with large left hemisphere stroke 3 hours after onset of symptoms. Flow is nearly absent throughout the middle cerebral artery territory on the left.

of penumbra. These results suggest that after the first few hours, the size of the already infarcted tissue, not the amount of penumbra, may be the most important imaging parameter to determine suitability for acute stroke therapy.

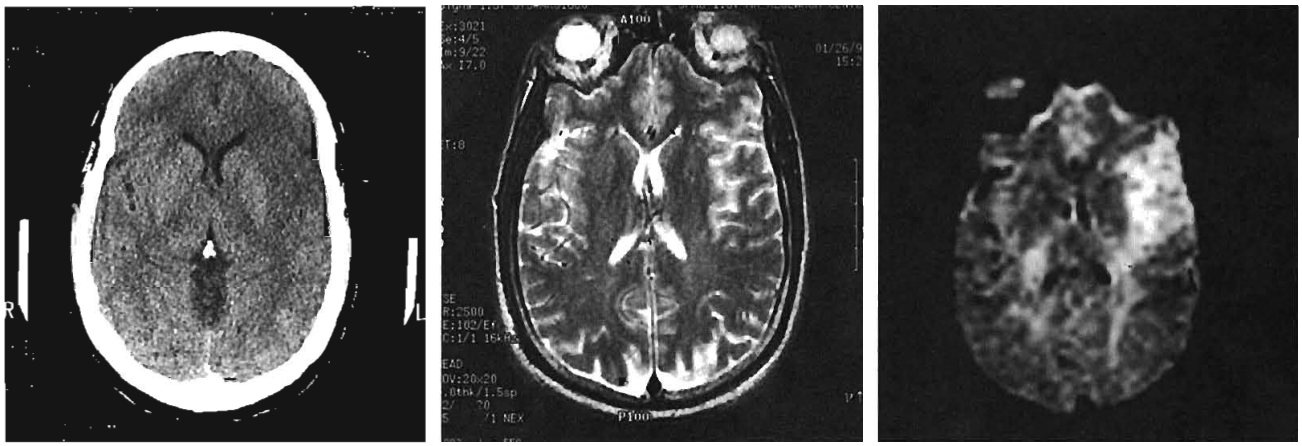
The combination of CT, CT angiography, and CT perfusion or xenon CT represents a battery of tests easily and rapidly performed with the CT scanner and capable of providing important data for decision making regarding acute stroke interventions.[38] Patients with large vessel occlusion on CT angiography, minimal early CT changes, and the presence of penumbra with small areas of cerebral blood flow in the infarction range should be optimal candidates for reperfusion therapy.

MAGNETIC RESONANCE IMAGING

In many hospitals, MRI is available on an emergent basis and reliably identifies cerebral ischemia. Compared with CT, MRI is more sensitive to cerebral infarction, particularly in the brainstem and deep white matter.[39-41] Most comparisons preceded the recognition of early CT changes, however, and may favor MRI unfairly for diagnosis of cortical infarction. Absence of flow void in major cerebral arteries suggests occlusion or slow flow in that artery; this provides important information about arterial occlusion even without angiography that may be valuable particularly in the setting of acute stroke. The major drawback of MRI is the difficulty identifying hemorrhage. MRI signal abnormalities vary depending on the age of the hemorrhage.[42] Knowledge of the signal characteristics of hemorrhage of varying ages on specific imaging sequences is necessary for accurate diagnosis. More knowledge, experience, and skill are needed for MRI interpretation of hemorrhage compared with CT. There is uncertainty about the reliability of MRI for detection of hyperacute hemorrhage and subarachnoid hemorrhage, although it is likely that experienced readers would make few mistakes.[43,44] Results of studies comparing modalities suggest that MRI is at least as sensitive as CT for detection of hemorrhage in patients with acute stroke. As MRI is more commonly used for multimodality imaging in acute stroke, the need for CT to detect hemorrhage should diminish.

Diffusion Weighted Imaging and Perfusion Imaging

Diffusion weighted imaging (DWI) shows parenchymal abnormalities earlier than conventional T2-weighted images in patients with acute stroke.[45] Perfusion imaging is based on transit times for contrast material through brain parenchyma. DWI detects the diffusion of water in the brain and shows hyperintensity in areas of reduced diffusion (Fig. 51-3). As water moves from the extracellular to the intracellular space, there is less movement of water and loss of signal resulting in hyperintensity.[46] DWI has potential advantages in the evaluation of acute stroke. First, early detection of lesions helps differentiate cerebral ischemia from other conditions that mimic stroke, such as seizures or toxic-metabolic states.[47] Hyperintensity on DWI may not be entirely specific for ischemia,[48] however, and at least one false-negative DWI scan has been reported (although a perfusion abnormality was present).[49] Second, combining DWI with perfusion imaging may identify reversibly ischemic tissue. In some cases, the area of perfusion abnormality is larger than the



A B C

FIGURE 51–3. A, Computed tomography scan of the brain in a patient with sudden onset of expressive speech difficulty and right arm weakness 2.5 hours after onset of symptoms. There is early low density and sulcal effacement in the perisylvian region. **B,** T2-weighted magnetic resonance imaging study of the same patient 5 hours after stroke onset. Subtle increased signal intensity is seen in the perisylvian region. **C,** Diffusion-weighted image also at 5 hours after stroke onset. A larger area of signal abnormality is present in the left hemisphere.

DWI abnormality, indicating a region of brain that has impaired flow but has not yet become ischemic. Expansion of DWI abnormalities between the first few hours after stroke and repeat studies many hours later also suggests the existence of tissue at risk.[50] Several studies found that the size of DWI abnormalities correlated with clinical outcome.[51] Abnormal DWI does not always represent irreversible ischemia, however. In animal models of stroke, reduction in the size of DWI abnormalities after treatment has been shown,[52,53] and similar findings have been reported in humans after treatment with intra-arterial thrombolysis[54] and neuroprotective agents.[55] Progression to infarction is a complex phenomenon that depends on many factors in addition to cerebral blood flow.[56] The total DWI abnormality seen in the first few hours after stroke likely represents the core infarction and a portion of the penumbra.

In patients with stroke, the size of the diffusion abnormality and the growth of areas of abnormal DWI are strong predictors of outcome. Lesion growth may be an effective surrogate marker to be used in clinical trials of acute stroke therapy, particularly neuroprotective agents.[57] In acute stroke, a marker of tissue viability is needed, and some authors have suggested that the extent of mismatch between perfusion and diffusion abnormality can be used in this manner. Patients with a large mismatch might be more likely to respond to reperfusion therapy, whereas patients without mismatch have little to gain.[58] Patients without mismatch and with large areas of DWI abnormality may be at greater risk for hemorrhage. These concepts currently are undergoing testing in clinical trials. In some trials, only patients with DWI/perfusion imaging mismatch are selected for treatment expecting that they are most likely to respond. In others, after MRI all patients are treated to compare the response to treatment between patients with and without mismatch at baseline. These trials should add to understanding of the ability of a mismatch to select patients for acute stroke therapy.

Magnetic resonance angiography provides a noninvasive method of imaging the intracranial and extracranial circulation. Several techniques are available; most require no contrast and are based on time-of-flight techniques.[59] The arteries comprising the circle of Willis and the extracranial vertebral and carotid arteries can be examined, allowing detection of occlusions in acute stroke. Occlusions of small peripheral branch arteries may not be detected by magnetic resonance angiography. Gadolinium-enhanced magnetic resonance angiography allows visualization of the intracranial and the extracranial circulation. Patients with claustrophobia or implanted metal devices, such as pacemakers, cannot undergo magnetic resonance angiography. Artifacts in some cases obscure proper identification of arterial pathology. Signal dropout may occur at the site of arterial stenosis owing to the effects of turbulent flow. If an artery is tortuous, it may extend out of the imaging section and appear occluded. In addition, construction of maximal intensity projections is subject to a variety of errors.[60] Experience and careful examination of studies typically avoids these pitfalls. In patients with stroke, magnetic resonance angiography correlates well with angiographic evidence of stenosis or occlusion of arteries in the intracranial[61,62] and the extracranial circulation.[63,64] In patients undergoing MRI and particularly DWI and perfusion imaging, the addition of magnetic resonance angiography to the battery provides evidence of arterial pathology and may add important diagnostic information when considering treatment options.

TREATMENT OF ACUTE STROKE

ANTICOAGULATION

The use of anticoagulants in acute stroke is controversial, although several randomized clinical trials provide information regarding its efficacy. Retrospective data previously suggested a significant incidence of early recurrences after ischemic stroke with reported rates of 20%. These studies also suggested that anticoagulation with heparin reduced recurrences. Hemorrhagic complications were acceptably low, particularly when patients with large strokes and uncontrolled hypertension were excluded from treatment. The results of more recent randomized clinical trials have challenged these findings and call into question the value of anticoagulation for treatment of acute stroke.[65]

The randomized studies completed to date include trials of low-molecular-weight heparin, heparinoid, and

subcutaneous heparin. All have serious flaws in design that limit the ability to make definitive conclusions. The major results of these studies are summarized in Table 51-4. The studies do not support a reduced recurrence rate or improved outcome with anticoagulation when administered within 24 to 48 hours of stroke onset. Hemorrhage rates ranged from 1% to 2.5%. These results suggest that there is little value in anticoagulation for all patients with acute stroke, but it remains possible that some subgroups benefit. The TOAST study suggested that patients with large vessel disease may achieve better functional outcome.[66] The relatively high hemorrhage rate in some studies also may have obscured some benefit. In the International Stroke Trial (IST), a significant reduction in recurrent strokes from 3.8% in the control group to 2.9% in patients treated with subcutaneous heparin ($P < .01$) was offset by an increase in hemorrhagic stroke from 0.4% in controls to 1.2% in patients receiving heparin ($P < .00001$).[67] Even in patients with atrial fibrillation, the value of early anticoagulation is uncertain with studies showing benefit and lack of benefit in reducing recurrent stroke.[65]

Antiplatelet Therapy

There is less uncertainty about the benefit of aspirin in acute stroke. Two large randomized controlled trials, the Chinese Aspirin Stroke Trial (CAST)[68] and the IST,[67] showed a small but significant improvement in outcome in patients treated with aspirin. In the IST, patients received 300 mg of aspirin daily for 14 days. There was a significant reduction in stroke recurrence within 14 days in the aspirin group (2.8%) versus avoid-aspirin groups (3.9%) and a significant decrease in the risk of death or nonfatal recurrent stroke in the aspirin group (11.3%) versus avoid-aspirin groups (12.4%). In the CAST trial, 160 mg of aspirin was given per day for 4 weeks or until hospital discharge. In the aspirin group, there was a significant reduction in death within 4 weeks (3.3%) versus placebo (3.9%) and a significant reduction in death or nonfatal stroke during hospitalization. There also was a significant reduction in recurrent ischemic strokes in the aspirin group (1.6%) versus placebo (2.1%), which was offset only by a nonsignificant trend of excess of hemorrhagic strokes (aspirin 1.1% versus placebo 0.9%).

The CAST and IST were designed to be considered together and include more than 40,000 patients. Combining the results of both studies shows a significant reduction in recurrent stroke of 7 per 1000 ($P < .000001$) and reduction of death or dependency of 12 per 1000 ($P = .01$).[69] The risk of aspirin in the absence of thrombolytics is minimal, and the small but significant benefit argues in favor of routine treatment.

INTRAVENOUS THROMBOLYSIS

Trials of intravenous thrombolytic agents in acute stroke date back to the early 1960s. At that time, several trials of streptokinase,[70] fibrinolysin,[71] and urokinase[72] were performed and showed either no effect or higher mortality in patients treated with thrombolysis. These studies preceded CT scanning, and patients with hemorrhage were not excluded. The discouraging results inhibited further acute stroke trials until the 1980s, when several reports appeared showing favorable outcomes with intra-arterial thrombolytic therapy within a few hours of stroke onset.[73,74] These reports led to small randomized trials and feasibility studies of intravenous thrombolytics.[75,76] The results of two multicenter randomized controlled trials of intravenous tPA for acute ischemic stroke have been published more recently, with one showing for the first time a beneficial effect of acute stroke treatment when given within 3 hours of onset.

Tissue Plasminogen Activator within 3 Hours

The NINDS acute stroke study showed the benefit of intravenous tPA for patients within 3 hours of onset of stroke. This study was performed in two parts and included more than 600 patients with acute ischemic stroke.[77] All patients were treated within 3 hours, and half were treated within 90 minutes. Patients were randomly assigned to receive either intravenous tPA, 0.9 mg/kg to a maximum of 90 mg, or intravenous placebo. Primary outcome measures were favorable outcomes at 90 days measured by the National Institutes of Health stroke scale, Barthel index, Glasgow outcome scale, and Rankin scale. By all four measures, significantly more patients had a favorable outcome at 90 days in the tPA group compared with placebo. Treatment with tPA resulted in an 11% to 13% absolute increase in good outcomes and a slight, nonsignificant decrease in mortality at 3 months. The benefit was sustained at 12 months.[78] Intracerebral hemorrhage with clinical deterioration occurred in 6.4% of tPA-treated patients but only 0.6% of placebo patients. Despite the increase in hemorrhages, there was no significant increase in mortality or severe disability in the tPA group compared with placebo. The relationship between benefit and time from onset suggested there was little to be gained by treatment beyond 3 hours and possibly beyond 2.5 hours.

When strokes were classified according to initial impression of stroke subtype, all types of strokes had more favorable outcomes with tPA. There were no clear factors that predicted response to tPA.[79] Patients with large strokes as measured by the National Institutes of Health Stroke Scale (NIHSS, >20) and evidence of early low density or edema on CT had a higher rate of hemorrhage after tPA.[80]

TABLE 51–4. RANDOMIZED TRIALS OF ANTICOAGULATION IN ACUTE STROKE

Study	Treatment	Patients	Recurrence: Treatment Versus Control	Favorable Outcome: Treatment Versus Control	Hemorrhage: Treatment Versus Control
FISS	Nadroparin	308	1% vs. 4.7%	48% vs. 35%	0% vs. 1%
IST	Subcutaneous heparin	19,435	1.6% vs. 2.2%	17% vs. 17%	1.8% vs. 0.3%
TOAST	Danaparoid	1281	1.1% vs. 1.1%	49% vs. 47%	2.9% vs. 0.9%
HAEST	Daleparin	449	8.5% vs. 7.5%	23% vs. 21%	2.8% vs. 1.8%
TAIST	Tinzaparin	1486	3.3% vs. 3.1%	38% vs. 43%	1.4% vs. 0.2%

On the strength of the NINDS study results, in June 1996 the FDA approved intravenous tPA for treatment of stroke within 3 hours of onset. Since then, reports of small groups of patients suggest similar efficacy can be obtained at community hospitals without an increase in hemorrhages as long as the NINDS protocol is used for patient selection.[81] Not all patients respond to intravenous tPA. In a dose escalation trial of intravenous tPA (Duteplase, Burrows-Welcome), angiography was performed before thrombolysis in all patients documenting the site of arterial occlusion and repeated 2 hours later.[82] Only 31% of arterial occlusions recanalized. Proximal occlusions in the middle cerebral artery opened less frequently than distal branch occlusions, and only 8% of carotid occlusions recanalized. The resistance of carotid occlusion to intravenous thrombolysis also has been noted by others.[83]

Tissue Plasminogen Activator beyond 3 Hours

Several other tPA trials attempted to extend the window for treatment beyond 3 hours (Table 51-5). ECASS I and II[84,85] and the ATLANTIS study[86,87] treated patients with intravenous tPA 6 hours after stroke onset but failed to show a significant benefit compared with placebo. Several design differences between these studies and the NINDS trial could have contributed to the different results, but the major factor was likely the longer time to treatment. In these studies, few patients were treated within 3 hours, and most were 4 to 6 hours from onset of stroke.

Combined Analysis

Although no individual trial showed a statistically significant benefit of intravenous tPA beyond 3 hours based on the primary prespecified analysis, several post-hoc analyses suggest that a small benefit might exist. ECASS II did not find a significant benefit based on the prespecified endpoint of modified Rankin score 0 to 1 at 90 days; however, a significant benefit would have been shown had the endpoint of modified Rankin score 0 to 2 been used,[88] similar to the Prolyse in Acute Cerebral Thromboembolism (PROACT) II study of intra-arterial thrombolysis.[89] The latter endpoint encompasses independent functioning rather than normal or near-normal neurologic status. For studies with moderate-to-severe strokes and longer time windows, functional independence may be a more appropriate endpoint. In addition, a meta-analysis of eight intravenous tPA trials including more than 2800 patients found a significant reduction in death and disability (modified Rankin score 3 to 6) in patients treated 6 hours after stroke onset.[90] This finding translates into 57 fewer patients dead or disabled for every 1000 treated.

More recently, a combined analysis of intravenous tPA trials has been performed, including NINDS, ECASS I and II, and ATLANTIS A and B.[91] In contrast to a meta-analysis, the combined study pooled original patient information from all trials into a single database. A total of 2776 patients were analyzed for outcomes and hemorrhage rates. The odds ratio for good outcome (modified Rankin score 0 to 1) was greatest for treatment within 90 minutes but remained significant for treatment between 91 and 180 minutes (Table 51-6). In contrast to the individual trials, the combined analysis also showed a statistically significant benefit for treatment between 181 and 270 minutes. The odds ratio was only slightly lower than for between 91 and 180 minutes. No treatment effect was observed beyond 270 minutes. It is likely that the greater number of patients in the later time-to-treatment group allowed detection of a small but significant benefit between 3 and 4.5 hours. In patients treated between 3 and 4.5 hours, 37% reached the endpoint of modified Rankin score 0 to 1 at 90 days, whereas only 32% of controls achieved this outcome. There was no difference in mortality for treatment up to 4.5 hours, although mortality was increased beyond 4.5 hours in the tPA group. Overall symptomatic hemorrhage rate was 5.8%, and there was no relationship between time to treatment and the rate of symptomatic hemorrhage 6 hours after stroke onset. A growing body of evidence suggests a small benefit of intravenous tPA 4.5 hours after stroke onset, but the earlier treatment is initiated, the greater the likelihood of a good clinical outcome.

SITS-MOST and ECASS III

Approval for intravenous tPA (Actilyse) was granted in Europe for treatment within 3 hours, but was conditional on review of a safety monitoring study (Safe Implementation of Thrombolysis in Stroke [SITS-MOST]) of patients treated and a new randomized controlled trial of patients treated 3 to 4 hours after stroke onset (ECASS III). SITS-MOST is a mandatory registry of patients treated in Europe with intravenous tPA under the conditional approval. The goal of the registry is to confirm the rate of symptomatic intracerebral hemorrhage, mortality, and independence at 3 months equal or better than the data from randomized controlled trials. All patients treated throughout Europe will be entered into this registry for future analysis.

In addition to SITS-MOST, the European authorities mandated a randomized controlled trial of intravenous tPA for patients 3 to 4 hours from stroke onset. This placebo-controlled trial is expected to enroll 800 patients at 110 sites in 15 European countries and help settle the issue of benefit for intravenous tPA 4 hours after stroke onset. Patients with NIHSS greater than 24 are excluded. The primary efficacy endpoint is modified Rankin score 0 to 1 at 90 days.

TABLE 51-5. INTRAVENOUS TISSUE PLASMINOGEN ACTIVATOR TRIALS BEYOND 3 HOURS

Study	Design	Time To Treatment (h)	Symptoms On Hemorrhage: tPA/PL (%)	Good Outcome: tPA/PL (%)	Results
ECASS I	Intravenous tPA vs. PL	6	19.8/6.5	41/29	No benefit
ECASS II	Intravenous tPA vs. PL	6	8.8/3.4	40/36	No benefit
ATLANTIS A	Intravenous tPA vs. PL	6	11.3/0	47/49	No benefit
ATLANTIS B	Intravenous tPA vs. PL	3-5	7/1.1	34/32	No benefit

PL, placebo; tPA, tissue plasminogen activator.

TABLE 51–6. ODDS RATIOS FOR MODIFIED RANKIN SCORE 0-1 IN THE COMBINED TPA ANALYSIS

Time	N	Odds Ratio	95% CI
0-90	311	2.83	1.77, 4.53
91-180	618	1.53	1.11, 2.11
181-270	801	1.40	1.06, 1.85
271-360	1046	1.16	0.91, 1.49

CI, confidence interval.
Data from The ATLANTIS, ECASS and NINDS rt-PA Study Group Investigators: Association of outcome with early stroke treatment: Pooled analysis of ATLANTIS, ECASS and NINDS rt-PA stroke trials. Lancet 2004;363:768-774.

Other Thrombolytic Agents

At present, only tPA is approved by the FDA for treatment of acute stroke. Many other thrombolytic agents are in various stages of investigation, however. These alternative treatments offer the potential for greater efficacy with lower hemorrhage rates and improved convenience of administration. Whether these advantages are clinically relevant and sufficient to replace tPA for stroke therapy awaits the results of future clinical trials.

Desmoteplase is a plasminogen activator with higher selectivity and far greater specificity for fibrin than tPA. Additional advantages over tPA include a long half-life that allows bolus administration and the lack of hypofibrinogenemia. Desmoteplase is currently in phase 2 clinical trials. Tenecteplase is a modification of human tPA designed to achieve more effective thrombolysis. The half-life of tenecteplase is significantly longer, allowing administration as a single bolus. Similar to desmoteplase, tenecteplase has greater fibrin specificity and less fibrinogen depletion than tPA.[92] A pilot safety study of tenecteplase for acute ischemic stroke is currently in progress.[93] Reteplase is another genetically modified form of human tPA. It also has been shown to be effective in treatment of acute myocardial infarction. Because of a longer half-life, reteplase is administered as two bolus injections 30 minutes apart. A small trial of intra-arterial reteplase for acute ischemic stroke was reported.[94] Sixteen patients were treated 9 hours after stroke onset with complete recanalization in 88% and clinical improvement in 44% at 24 hours. Only one symptomatic hemorrhage occurred. An ongoing study (ROSIE) combines abciximab and intravenous reteplase treatments in patients 24 hours after stroke onset with an endpoint of MRI-based reperfusion at 24 hours. Abciximab alone has been studied in a phase 2b trial.[95] A glycoprotein IIb and IIIa inhibitor, abciximab may improve outcome through its powerful antiplatelet effects or by direct thrombolytic activity. The AbBEST study included 400 patients randomized to treatment with intravenous abciximab or placebo 6 hours after stroke onset. Based on a responder analysis, outcomes at 3 months were improved with abciximab in patients with mild or moderate strokes but not in patients with NIHSS greater than 15. The effect also was greater in patients treated within 5 hours of symptom onset. Symptomatic hemorrhage occurred in 3.6% of patients treated with abciximab. A larger phase 3 randomized controlled trial is under way.

Tissue Plasminogen Activator in Specific Subgroups

Further analysis of the results of the NINDS study did not identify any specific subgroups of patients with a greater or lesser likelihood of responding to tPA. The number of patients treated in many subgroups was quite small, however. Clinical experience has raised questions about treatment of several patient subgroups with conflicting evidence concerning the advisability of treatment with thrombolytics.

Age and Risk of Thrombolysis

One group of concern is elderly patients, in whom the incidence of cerebral amyloid angiopathy is greater and might predispose to hemorrhage after tPA. Some studies of anticoagulation with warfarin indicate a higher rate of intracerebral hemorrhage in the elderly.[96] In the NINDS study, older patients were less likely to have a favorable outcome but fared better with tPA than without.[97] In ECASS II, older patients had a greater risk of severe hemorrhagic transformation.[98] In contrast, a retrospective survey of patients treated with intravenous tPA at multiple centers did not find any difference in outcome or hemorrhage rate in 30 patients older than age 80 compared with 159 younger patients.[99] Advanced age should not be considered a contraindication to thrombolysis, but requires consideration of a lower probability of good outcome after treatment and possibly a higher rate of intracerebral hemorrhage.

Computed Tomography Findings on Baseline Scan

Another point of controversy is the significance of early CT abnormalities as a predictor of hemorrhage after thrombolysis for acute stroke. Before the randomized controlled tPA trials, several studies suggested that the presence of early changes in CT predicted a greater likelihood of hemorrhagic transformation.[100,101] In ECASS I, hypodensity greater than one third of the middle cerebral artery territory was an exclusion; however, many patients were entered despite such findings on CT. These patients had an increased mortality and showed no benefit from tPA.[84] In ECASS II, additional training of investigators reduced the number of protocol violations; however, in a subsequent analysis, the extent of hypodensity on baseline CT was found to be an independent risk factor for intracerebral hemorrhage.[98] The STARS study, a multicenter registry of 389 consecutive patients treated with intravenous tPA, found that the absence of extensive hypodensity on initial CT predicted a favorable outcome.[102,103] Quantitative assessment of CT changes using the ASPECTS scoring system in patients treated with intravenous tPA also showed a relationship between early CT hypodensity (ASPECTS <8) and hemorrhage.[104]

The NINDS group examined the association between early CT changes and hemorrhage and arrived at a different conclusion. Although outcomes were worse in patients with mass effect or edema on initial CT scan, more such patients had good outcomes if treated with tPA. The odds ratio of symptomatic hemorrhage was increased (2.9 versus 1.5) with hypodensity greater than one third of the middle cerebral artery territory. Few patients had this finding on baseline CT scan, however, and the difference did not reach significance.[105] Analysis of the Australian Streptokinase study including patients treated within 4 hours of stroke onset also failed to show any significant relationship between early ischemic changes and intracerebral hemorrhage.[106] The significance of early CT changes as a risk for hemorrhage and poor outcome after intravenous tPA therapy is unclear. At present, most tPA protocols continue to exclude patients from treatment with extensive low density

on initial CT. In the future, MRI or cerebral blood flow measurement might allow more appropriate exclusion of patients with high risk of hemorrhage.

Stroke on Awakening

Frequently, patients arrive in the emergency department after awakening with a new neurologic deficit due to stroke. Because the time of onset cannot be established with certainty, these patients usually are excluded from thrombolytic therapy. Some of these patients may be within the time window for acute stroke treatment, however, and might benefit from thrombolysis.[107,108] Stroke-on-awakening patients may be an ideal group to undergo physiologic imaging studies to select patients appropriate for acute stroke treatment.

Aspirin Pretreatment

Many individuals at risk for stroke are treated with aspirin or other antiplatelet agents. Others take aspirin on the way to the hospital after onset of stroke symptoms. Whether aspirin pretreatment increases the risk of thrombolytic therapy is unclear. In the MAST-I study, patients treated with aspirin and streptokinase had a higher incidence of death from intracranial hemorrhage.[109,110] In ECASS II, there was a higher incidence of symptomatic hemorrhage in patients pretreated with aspirin. In the multicenter recombinant tPA Acute Stroke Survey, aspirin therapy was associated with a higher risk of symptomatic hemorrhage, but did not remain significant after adjustment for other factors. In contrast, a report of 300 patients treated with intravenous tPA failed to find any association between pretreatment with aspirin and hemorrhagic complications.[111] Aspirin pretreatment also was not associated with intracerebral hemorrhage in the NINDS intravenous tPA trial.[112] Patients receiving antiplatelet therapy usually are not excluded from thrombolytic therapy, although additional studies are needed to clarify the relative risk of thrombolysis in these patients.

Severe Stroke

In most studies of thrombolysis, prognosis and risk of hemorrhage are strongly related to initial severity of stroke as measured by the NIHSS score. In the NINDS trial, at 3 months 48% of patients with NIHSS greater than 20 were dead, and 21% were severely disabled. Symptomatic hemorrhage occurred in 17% compared with 6% in the entire cohort.[112] Despite the poor outcomes and increased hemorrhage rate, more patients had good outcomes with tPA than without (10% tPA versus 4% placebo). Severe stroke should not be considered a contraindication to thrombolytic therapy, although the overall poor prognosis and increased hemorrhage rate must be considered in deciding on treatment in individual cases.

INTRA-ARTERIAL THROMBOLYSIS

An alternative approach to intravenous thrombolysis is direct delivery of thrombolytic agents by a microcatheter embedded in the clot (Fig. 51-4).[113] The advantage of the intra-arterial approach is direct visualization of the occluded artery and knowledge of the recanalization status as thrombolysis proceeds. Delivery of the thrombolytic agent to the site of the clot should be more effective than intravenous infusion. The disadvantage is the additional time needed to bring the patient to angiography, prepare the groin, catheterize the femoral artery, and guide the catheter from the femoral artery to the intracranial circulation. Start of thrombolytic therapy typically is delayed by 45 to 60 minutes. Urokinase was used in most early studies of intra-arterial thrombolysis but is no longer available. Prourokinase (recombinant prourokinase) was used in clinical trials, but has not been approved by the FDA. Most intra-arterial thrombolysis is now done with tPA. Doses of 20 to 50 mg have been infused over 1 to 2 hours, but no systematic dose escalation studies have been completed. Some interventionalists advocate extremely small doses of intra-arterial tPA (e.g., 0.1 to 0.2 mg), but most use higher doses. A few reports of intra-arterial therapy with reteplase (Retavase) have appeared, and small pilot studies of intra-arterial Retavase are now in progress. Other issues with intra-arterial thrombolysis include whether to use mechanical catheter manipulation in conjunction with thrombolysis, the optimal dose of heparin, and the use of boluses of thrombolytic agents beyond and within the thrombus before starting an infusion. Most protocols include a small bolus (e.g., 2 mg of tPA) beyond the thrombus followed by 2 mg within, then an infusion over 1 to 2 hours. Progress is assessed every 15 to 30 minutes with an injection of contrast material, and the catheter is repositioned if the thrombus is partially dissolved. When recanalization is achieved, infusion of the thrombolytic agent can be discontinued.

The PROACT trial was the first randomized controlled trial of intra-arterial thrombolysis. PROACT I randomized 40 patients with occlusion of the M1 or M2 segment of the middle cerebral artery to either 6 mg of intra-arterial recombinant prourokinase infused over 2 hours or direct intra-arterial injection of saline within 6 hours of stroke onset.[114] Both groups also received intravenous heparin. In this small pilot study, there was a trend toward improved outcome in the recombinant prourokinase group, but the difference did not reach statistical significance. Based on these encouraging findings, PROACT II was initiated. Over 2.5 years, 180 patients were randomized in a 2:1 ratio to 9 mg of intra-arterial recombinant prourokinase in addition to heparin or to heparin alone.[115] More than 12,000 patients were screened at 50 centers to enter these trials. The primary endpoint of modified Rankin scale 2 at 90 days was achieved by 40% of the recombinant prourokinase group and only 15% of controls ($P = .043$). At least partial recanalization at 2 hours occurred in 67% of recombinant prourokinase patients. Complete recanalization was found in 20%. Symptomatic hemorrhage occurred in 10% of patients treated with recombinant prourokinase and in 2% of controls. Although the hemorrhage rate was higher than previous intravenous thrombolytic studies, the median NIHSS score of 17 indicates that the patients in the PROACT study had more severe strokes treated at a later time interval. A higher hemorrhage rate is expected. Based on factors predicting outcome in this group of patients, the treatment and control groups can be stratified according to risk. There was no differential effect of recombinant prourokinase across risk strata, indicating that all patients, regardless of risk, benefit equally from recombinant prourokinase.[116]

The PROACT study is the only acute stroke trial to show a statistically significant improvement of outcome when given 6 hours after stroke onset. The median time to treatment was 5.5 hours, and most patients were treated after 5 hours from stroke onset.[115] The clinical benefit was apparent despite this late time to treatment, and possibly a greater benefit would have been found had patients been treated earlier.

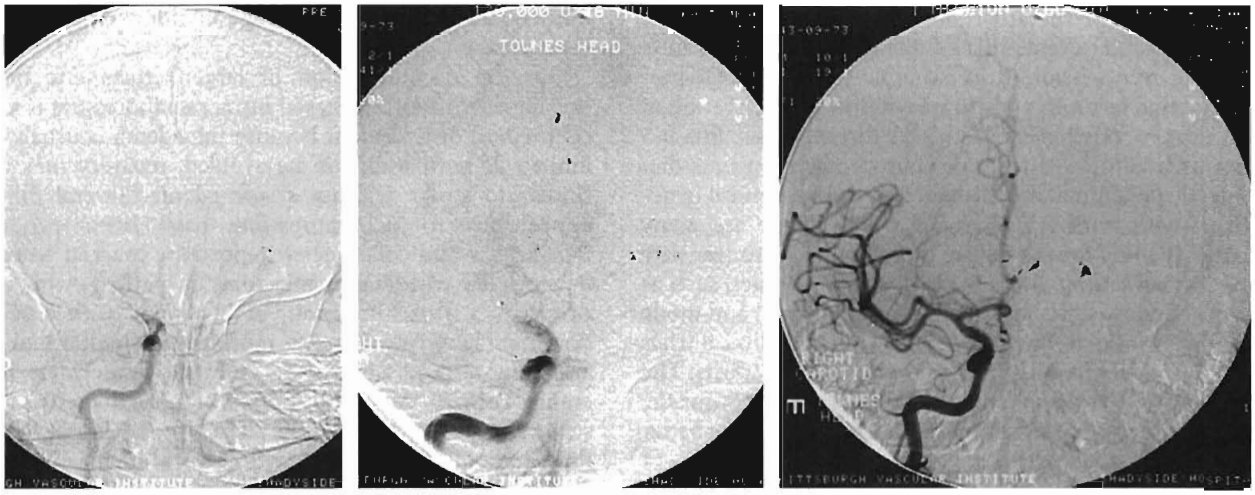


FIGURE 51–4. A, Right carotid angiogram from a patient with embolic occlusion of the right middle cerebral artery 4 hours after onset of symptoms. **B,** Angiogram from the same patient after placement of a microcatheter into the middle cerebral artery clot and infusion of 120,000 U of urokinase. There is no recanalization. **C,** Angiogram after infusion of 1 million U of urokinase directly into the clot, showing complete recanalization of the middle cerebral artery.

Several other factors may have limited the effectiveness of thrombolysis in this study. Infusion of the thrombolytic agent extended over 2 hours, and mechanical manipulation was not allowed. The thrombolytic regimen used in the PROACT study may not represent the optimal parameters, leaving considerable room for future improvement.

Basilar artery thrombosis carries a high morbidity and mortality[117] and may be particularly amenable to intra-arterial thrombolysis. Anecdotal reports indicate successful recanalization of the basilar artery is associated with good outcomes in 25% to 50% of patients,[118-120] a considerable improvement on the reported natural history. Good outcomes have been reported with intra-arterial thrombolysis of basilar thrombosis well beyond the usual 6-hour time limit.[121] Intravenous tPA also may result in improvement, but the large clot burden favors the intra-arterial approach.

Combination Therapy

The major problem with intra-arterial thrombolysis is the additional time necessary to place a catheter into the intracranial arteries; this requires 45 to 60 minutes beyond the time intravenous therapy could be given. If transport to a tertiary care center is needed, the delay may be longer. Combined therapy offers the prospect of beginning intravenous therapy, then proceeding to intra-arterial therapy if needed. If the patient presents within 3 hours of stroke onset, therapy is begun with intravenous tPA in a reduced dose of 0.6 mg/kg over 30 minutes. While the intravenous tPA is infusing, the patient is transported to angiography, and a catheter is placed in the intracranial circulation. If thrombus is present despite intravenous therapy, additional tPA is given intra-arterially in an attempt to clear the thrombus. This approach was used in a small group of patients randomized to either intravenous followed by intra-arterial tPA or placebo followed by intra-arterial tPA.[122] There was a greater recanalization rate in the combined group (partial or complete 81% combined versus 50% intra-arterial alone). Bleeding complications were slightly more common in the combined treatment group.

Mechanical Devices

Although most thrombolytic studies concentrate on time to treatment, the most important factor is probably time to recanalization. When infusion of thrombolytic agents requires 1 to 2 hours for complete thrombus dissolution, time to recanalization can be quite long. Mechanical devices offer the possibility of considerably shortening time to recanalization. In contrast to thrombolytic infusions, devices may be able to clear thrombus from large arteries within a few minutes. Thrombolytic agents may not have to be used, possibly reducing the rate of intracranial hemorrhage. Several devices are now being tested. Catheters capable of reaching the middle cerebral artery or basilar artery use lasers, ultrasound, or high-speed saline jets to agitate or emulsify thrombus. Simple snares to capture thrombotic material also are under development. These devices are now undergoing initial clinical trials but hold great promise for reducing time to recanalization and improving outcomes in acute stroke.

NEUROPROTECTIVE AGENTS

The extent of ischemic injury in the brain depends on the level of cerebral blood flow in the effected territory. Cerebral blood flows less than 10 mL/100 g/min are probably tolerated only for minutes, whereas intermediate levels of blood flow of 20 to 30 mL/100 g/min may be tolerated for several hours before irreversible changes occur.[123] During ischemia, there is insufficient energy for maintenance of normal membrane pump activity. Sodium diffuses into the cell across its gradient causing neuronal depolarization and impairing the ability of the neuron to generate an action potential. In addition, there is a tremendous outpouring of excitatory neurotransmitters, particularly glutamate.[124] Glutamate activates *N*-methyl-D-aspartate and non–*N*-methyl-D-aspartate receptors causing influx of calcium into neurons.[125] This influx results in production of toxic products, including nitric oxide, free radicals, and activation of phospholipases. The duration of this reversible ischemic state is uncertain, but animal models of focal stroke suggest it is only a few hours.[126]

Neuroprotective therapy is designed to interfere with the cascade of cellular events that results in cell death. Blocking any of the events involved in ischemic cell death may preserve function or prolong the time window for restoration of blood flow by other means, such as thrombolysis. Phase 3 randomized controlled trials of neuroprotective agents that are effective in animal models failed to show a clinical benefit in patients with stroke (Table 51-7). There are many potential reasons for the failure of animal trials to translate to the clinical setting. Aspects of the animal studies, such as the time window, dose equivalent, stroke subtype, and mode of administration, frequently were modified in clinical trials to maximize patient entry and to minimize side effects. The expected benefit from treatment often was overly optimistic, and in some cases outcomes in the control group were better than expected, making it more difficult to show a benefit from therapy. Neuroprotective agents may improve certain neurologic functions, such as cognitive activity, which is poorly measured by most commonly used stroke scales. It is also possible that what works in animals simply does not work in humans.

Despite these failures, several new neuroprotective agents are currently in phase 3 trials. NXY-059 is a nitrone spin-trap agent that has been shown to improve outcomes in rodent and primate models of acute stroke. Two randomized controlled trials are in progress to assess the efficacy of this drug for stroke within 6 hours of onset. A phase 3 trial of the serotonin agonist, repinotan, also is in progress for patients with hemispheric stroke. ONO-2506 is a neuroprotectant that modulates the uptake capacity of glutamate transporters and expression of gamma-aminobutyric acid receptors. A phase 3 trial using this agent is currently in progress. Magnesium is undergoing testing in a randomized controlled trial including patients 12 hours from stroke onset. Another study is examining hyperacute prehospital administration of magnesium. Finally, hypothermia is a promising neuroprotective therapy, and clinical trials of mild hypothermia in acute stroke are under way.

STROKECTOMY

Cerebral edema and herniation is the most frequent cause of death from stroke in the first few days.[127] Cerebral edema usually gradually increases and peaks 2 to 3 days after stroke onset. Steroids, do not effectively reduce edema due to stroke, and antiedema measures, such as mannitol or hyperventilation, are of limited benefit. Control of intracranial pressure is associated with improved outcome, but whether intracranial pressure monitoring to guide therapy is helpful is uncertain.

Surgical decompression of large hemispheric infarcts causing edema and increased intracranial pressure is a logical method of treatment because the edema is usually self-limited. If herniation can be avoided, recovery may occur similar to stroke without severe edema. Several different approaches to decompression have been proposed. Rengachary and colleagues[128] reported a marked reduction in mortality with hemicraniectomy in patients with severe edema after stroke. In a group of 32 patients with large nondominant hemisphere stroke, mortality was reduced to 40%, and long-term disability was only moderate after hemicraniectomy.[129] Kalia and Yonas[130] reported the results of strokectomy based on results of xenon CT cerebral blood flow studies in four patients with cerebral edema after stroke and impending herniation. Blood flow studies identify areas of nearly absent flow. This is a more reliable indicator than CT changes of irreversibly damaged brain and helps guide surgical removal avoiding areas of intact cortex. This procedure prevents fatal herniation, but whether long-term outcome is truly improved must be determined by randomized clinical trials. Until then, surgical decompression for hemispheric infarction should be considered for younger patients with a greater potential for recovery from massive stroke and particularly for nondominant strokes. The optimal timing of decompression is uncertain. If herniation is already in progress, irreversible brainstem damage may occur limiting the benefit of the procedure. Early edema may not progress to herniation, and surgery could be performed unnecessarily. Xenon CT findings of extensive areas of near-absent cerebral blood flow may help identify patients liable to have massive edema and herniation[131] and help select patients most likely to require surgical decompression.

Cerebellar infarction is a special case that clearly requires urgent surgical intervention.[132] Compression of the brainstem and fourth ventricle leading to hydrocephalus or severe pontomedullary compromise can be reversed by rapid surgical decompression of the infarcted cerebellum. The clinical syndrome of inferior cerebellar infarction, including vertigo and imbalance, may be mistaken for a vestibulopathy, and CT changes may be subtle or nonexistent. It is critical to suspect this diagnosis in patients at risk for cerebrovascular disease because surgical intervention may be lifesaving with little residual deficit.

TABLE 51-7. FAILED NEUROPROTECTIVE TRIALS

Study	Type	Time to Treatment (h)	Results
Lubeluzole	Phase 3	8	No benefit
Cerestat	Phase 3	6	No benefit
Selfotel	Phase 3	6	No benefit
Enlimomab	Phase 3	6	Treatment worse
Cervene	Phase 3	6	No benefit
GM1 Ganglioside	Phase 3	12	No benefit
Nimodipine	Phase 3	24	No benefit
Fosphenytoin	Phase 3	6	No benefit
Citicoline	Phase 3	24	No benefit
GV150526	Phase 3	6	No benefit

SUMMARY

The availability of effective treatment to alter outcome within the first few hours after stroke onset necessitates dramatic changes in the evaluation of stroke. Patients with symptoms suggesting cerebral ischemia must be treated emergently from the prehospital encounter to the emergency department and the treating physicians. Imaging must be performed rapidly and provide useful information for the decision-making process. Therapy for acute stroke includes much more than thrombolysis. Appropriate management of blood pressure, glucose, intravenous fluids, and temperature all contribute to the overall outcome from acute stroke. Understanding of the benefits and hazards of thrombolysis continues to evolve with greater experience and additional studies. Neuroprotection holds great promise for further improvement of outcomes and possibly enhancement of effectiveness of thrombolysis or extension of the time window for reperfusion. At present, only

a small percentage of patients with stroke arrive at an emergency department in time for acute stroke therapy.[133,134] Development of new acute stroke therapies and improvements in outcome with lower hemorrhage rates should encourage the medical system further to treat a greater number of stroke patients earlier. Rapid advancements in acute stroke therapy may necessitate a system of stroke centers similar to the trauma system to ensure that all stroke patients receive the optimal available therapy in the shortest time possible.

ANNOTATED REFERENCES

Chen ZM, Sandercock P, Pan HC, et al: Indications for early aspirin use in acute ischemic stroke: A combined analysis of 40,000 randomized patients from the Chinese Acute Stroke Trial and the International Stroke Trial. On behalf of the CAST and IST collaborative groups. Stroke 2000;31:1240-1249.

This article represents a combined analysis of two clinical trials, each with 20,000 patients, showing a significant reduction of recurrent stroke and death with aspirin treatment. There was a highly significant reduction of 7 per 1000 in recurrent ischemic stroke in patients treated with aspirin versus control, and a significant reduction of 4 per 1000 in death with aspirin treatment. The authors concluded that early aspirin treatment is of benefit for a wide range of patients and its prompt use should be widely considered for all patients with suspected acute ischemic stroke to reduce the risk of early occurrence.

Furlan A, Higashida R, Wechsler L, et al: Intra-arterial prourokinase for acute ischemic stroke. The PROACT II study: A randomized controlled trial. JAMA 1999;282:2003-2011.

Randomized controlled clinical trial of the use of intra-arterial thrombolytics in 180 patients at 50 centers showing significant improvement in outcome with treatment given up to 6 hours from stroke onset. Patients were randomized to receive 9 mg of IA r-pro UK plus heparin (n=121) or heparin only (n = 59). The primary outcome was based on the proportion of patients with slight or no neurologic disability at 90 days as defined by a modified Rankin score of 2 or less.

This publication provides the National Institutes of Health algorithm for the pre-hospital and emergency management of acute stroke that was developed from the experience of conducting acute stroke trials.

Rieke K, Krieger D, von Kummer R, et al: Decompressive surgery in space occupying hemispheric infarction. Crit Care Med 1995;73:1576-1587.

Clinical report of reduced mortality rate and favorable long-term outcome in 32 patients with large nondominant hemisphere stroke treated with hemicraniectomy. At follow-up in surgically treated patients, the Barthel Index showed an excellent level of daily activity in one patient, minimal assistance in 15 patients, and dependency in five patients. The Oxford Handicap Scale indicated no handicap in one patient, moderate handicaps in 15 patients, and moderately severe handicaps in five patients. In the control group, all five surviving patients needed assistance, and all but one patient demonstrated a moderately severe handicap.

The ATLANTIS, ECASS and NINDS rt-PA Study Group Investigators: Association of outcome with early stroke treatment: Pooled analysis of ATLANTIS, ECASS and NINDS rt-PA stroke trials. Lancet 2004;363:768-774.

This article represents a combined analysis of five clinical studies in 2775 patients randomly allocated to rt-PA or placebo. The study addresses the use of intravenous rt-PA and provides specific insight into its use beyond three hours of the onset of stroke. The authors concluded that the sooner that rt-PA is given to stroke patients, the greater the benefit, especially if started within 90 minutes. Their findings also suggested a potential benefit from this therapy applied beyond 3 hours, but this potential might come with some risks.

The National Institute of Neurological Disorders and Stroke rt-PA Stroke Study Group: Tissue plasminogen activator for acute ischemic stroke. N Engl J Med 1995;333:1581-1587.

A key clinical report in the field of stroke that showed, for the first time in a randomized controlled trial, a reduction in stroke morbidity with acute treatment. In June 1996, the FDA approved intravenous tPA for the treatment of stroke within 3 hours of onset.

Chapter 52

NONTRAUMATIC INTRACEREBRAL AND SUBARACHNOID HEMORRHAGE

Allyson R. Zazulia • Michael N. Diringer

KEY POINTS

INTRACEREBRAL HEMORRHAGE

1. **Intracerebral hemorrhage (ICH) injures the brain not only through direct mechanical compression** but also through secondary mechanisms such as ischemia and edema.
2. **Hematoma expansion occurs within the first few hours after symptom onset** in approximately one third of patients.
3. **In-hospital neurologic deterioration may occur in as many of two thirds of patients;** among these patients, one quarter will be found to have increased hematoma size.
4. **There appears to be no compelling reason to reduce blood pressure in the acute period after ICH.** If there are systemic concerns, modest reduction (15% to 20%) in patients with severe hypertension (mean arterial pressure >130 to 140) using short-acting agents with minimal cerebrovascular effects (e.g., labetalol, nicardipine, enalapril) appears to be safe.
5. **Randomized trials of surgical hematoma evacuation and corticosteroid treatment have failed to show a consistent benefit in the management of ICH.** The efficacy of osmotic agents has not been evaluated in a randomized trial.
6. **The most common cause of death after ICH is withdrawal of care,** followed by transtentorial herniation and medical complications of immobility.

SUBARACHNOID HEMORRHAGE

1. **Subarachnoid hemorrhage (SAH) typically presents as the sudden onset of a severe headache,** often associated with nausea, vomiting, and syncope. Focal neurologic deficits are uncommon.
2. **Rebleeding, which is often fatal, occurs most commonly within the first 24 hours** and is heralded by a sudden worsening of headache, vomiting, new neurologic deficit, or arrhythmia.
3. **Hydrocephalus may develop acutely within hours of SAH or gradually up to weeks later** and usually manifests as an insidious decline in mental status.
4. **Delayed vasospasm occurs in more than two thirds of patients, especially those with large amounts of subarachnoid blood,** and produces a new focal neurologic deficit in more than one third. Management options include nimodipine, hemodynamic augmentation, and endovascular maneuvers.
5. **Management of SAH-associated "cerebral salt wasting" often requires the administration of large volumes of fluid replacement** to prevent intravascular volume contraction and restriction of free water to treat hyponatremia.
6. **Cardiac abnormalities, including electrocardiographic changes, mildly elevated cardiac enzymes, and arrhythmias, are common after SAH** and are thought to be related to elevated catecholamine levels rather than myocardial ischemia.

INTRACEREBRAL HEMORRHAGE

Spontaneous (nontraumatic) intracerebral hemorrhage (ICH) accounts for approximately 10% of all strokes in North America and about 20% to 30% in East Asia. It is associated with greater mortality and more severe neurologic deficits than any other stroke subtype.[1-3] Nearly half of all patients die within the first 30 days; survivors often have significant residual disability.[4,5]

PATHOPHYSIOLOGY

The pathophysiologic mechanisms of brain injury due to ICH are complex. The primary injury is one of local tissue destruction as rupture of a cerebral blood vessel introduces a sudden stream of blood into the brain parenchyma. In more than one third of patients, continued bleeding or rebleeding results in hematoma enlargement and further mechanical injury within the first few hours after onset.[6] The mass of blood produces tissue shifts within the intracranial cavity.

In addition to the primary mechanical injury, further damage is believed to occur after the bleeding stops.

The mechanisms underlying this secondary injury are unknown, but ischemia and edema have been implicated. Experimental models of ICH suggest that ischemia is an important part of its pathophysiology.[7,8] Periclot and ipsilateral hemispheric hypoperfusion has been demonstrated almost uniformly in clinical studies,[9-11] but the importance of ischemia in patients with ICH has not been settled.[12,13] Positron emission tomography studies in humans performed 10 to 22 hours after symptom onset showed that both cerebral blood flow (CBF) and metabolism are reduced around the clot, suggesting that the hypoperfusion reflects the reduced metabolic demand of the damaged tissue surrounding the hematoma rather than ongoing ischemia.[13]

Cerebral edema occurs within hours of experimental ICH, variably thought to result from the toxic effects of blood-derived enzymes, from increased osmotic pressure exerted by clot-derived serum proteins, or from ischemia.[14-16] The presence, time course, and importance of edema in humans are debated. Part of the difficulty stems from the inability to unequivocally quantify edema in humans. Signal changes on radiographic studies after ICH indicate increased water content in the area surrounding the clot, but the clinical and pathophysiologic significance of this is not known.

Hemostasis after hemorrhage is initially achieved at the site of vascular injury by the formation of a platelet-fibrin plug. After several days, red blood cells within the clot begin to lyse, cellular infiltrates appear, and the process of reabsorption begins. Months later, a residual collapsed cavity is all that remains.

CAUSES AND RISK FACTORS

The leading risk factor for ICH, occurring in more than half of all cases, is chronic hypertension.[17,18] Long-term adequate treatment of chronic hypertension significantly reduces this risk.[19] Increasing age is another risk factor, with a doubling of the rate of hemorrhage with each decade of life until age 80, when the incidence plateaus at nearly 25 times that of the previous decade.[20]

Other risk factors include black race[21] and alcohol abuse.[22] The relationship of ICH to smoking[22,23] and low serum cholesterol[24,25] has not been convincingly established. Similarly, the impact of diabetes on the risk of ICH is disputed.[26,27]

Hypertensive Hemorrhage

Hypertensive ICH occurs predominantly deep in the cerebral hemispheres, most often in the putamen (Fig. 52-1).[17] Other frequently involved sites include the thalamus, lobar white matter, cerebellum, and pons. The common link among these sites is that they are all supplied by small penetrating arteries,[28] perpendicular branches directly off major arteries that are subject to high sheer stress and that have no collaterals. These features make them vulnerable to the effects of increased blood pressure. Chronic hypertension damages the tunica media, resulting in lipohyalinosis, fibrinoid necrosis, and microaneurysms (Charcot-Bouchard aneurysms). Although Charcot-Bouchard aneurysms have been demonstrated in the weakened vessel walls of patients with ICH, their pathogenetic role in vascular rupture is uncertain.[29] The occurrence of ICH in an atypical location, in multiple locations, or in association with subarachnoid hemorrhage raises the suspicion of a nonhypertensive cause, such as a cerebral vascular anomaly, blood dyscrasia, or trauma.

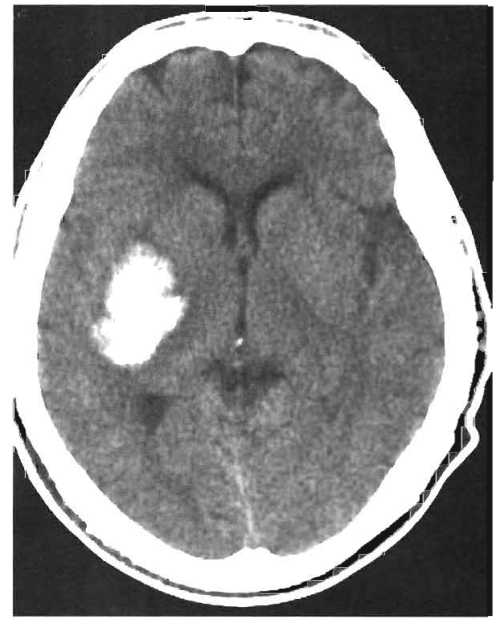

FIGURE 52–1. Typical moderate-sized putaminal hemorrhage. (From Diringer MN, Pucllicino P, Chan R: Intracerebral hemorrhage. Continuum 2003;9:170.)

Intracranial Aneurysms and Vascular Malformations

Up to one quarter of hemorrhages are due to bleeding from rupture of an intracranial aneurysm (fusiform and saccular) or vascular malformation (arteriovenous malformation [AVM] or angioma). Rupture of a saccular berry aneurysm produces ICH in 5% to 25% of cases. Although aneurysmal rupture is most commonly associated with hemorrhage in the subarachnoid space, the blood may also be directed into the substance of the brain if the aneurysm is adherent to the brain parenchyma. Rarely, aneurysms located at the middle cerebral artery bifurcation produce hemorrhages that appear identical to hypertensive hemorrhages into the basal ganglia, and anterior communicating artery aneurysms can produce flame-shaped hemorrhages in the base of the frontal lobes.

Approximately half of intracranial AVMs in adults present with hemorrhage.[30] In 60% of cases, the hemorrhage is parenchymal, involving virtually any location within the cerebrum, brainstem, or cerebellum.[31] The majority of AVMs become symptomatic by age 40; thus, hemorrhage due to AVMs occurs in a younger population than that due to aneurysms or hypertension. Multiple calcified vascular channels may be seen within the hematoma on computed tomography (CT) scans, suggesting the presence of an AVM. Magnetic resonance imaging (MRI) and four-vessel cerebral angiography are useful adjuncts in the diagnosis of these lesions.

Other Causes

Cerebral amyloid angiopathy is an important cause of predominantly lobar, often recurrent ICH in the elderly. Histopathologic studies demonstrate the deposition of β-amyloid protein in the media and adventitia of small meningeal and cortical vessels; deposition in the typical sites for hypertensive hemorrhage is rare, but it has been reported in the cerebellum.[32] The prevalence of amyloid in cerebral vessels increases dramatically with age[33,34] and may partially

account for the exponential rise in the risk of ICH with increasing age. There is an overrepresentation of the apolipoprotein E ε2 and ε4 genotypes in hemorrhages related to cerebral amyloid angiopathy, and these alleles are associated with a younger age at hemorrhage onset and a higher risk of early recurrence.[35,36] Although there is no radiographic technique for diagnosing cerebral amyloid angiopathy, the finding of recurrent lobar ICH in an elderly nonhypertensive patient strongly suggests the diagnosis.

Approximately 10% of ICHs are due to hematologic causes.[37] Coagulopathy-related ICH most often results from warfarin therapy[38] but may also be associated with the use of other antithrombotic and thrombolytic agents, as well as with systemic diseases (e.g., thrombocytopenia, leukemia, hepatic and renal failure) or congenital or acquired factor deficiencies.

Hemorrhage from an underlying neoplasm is rare; however, it occasionally occurs with malignant primary central nervous system tumors such as glioblastoma multiforme and lymphoma and with metastatic tumors such as melanoma, choriocarcinoma, renal cell carcinoma, and bronchogenic carcinoma.[39] Benign tumors are almost never associated with ICH.

ICH may also occur in association with infection (e.g., infiltration of vessel wall by fungal organisms),[40] necrotizing hemorrhagic encephalitis with herpes simplex virus,[41] vasculitis,[42] venous sinus occlusion,[43] in a delayed fashion after head trauma,[44] following reperfusion (e.g., after carotid endarterectomy or acute thrombolysis),[45] and with the use of various drugs, particularly sympathomimetics (e.g., cocaine, amphetamines, pseudoephedrine, phenylpropanolamine).[46,47] Finally, some degree of hemorrhagic transformation of acute cerebral infarcts is common,[48,49] although symptomatic ICH in this setting is rare in the absence of anticoagulation or thrombolytic therapy.[50,51]

CLINICAL FEATURES

The clinical presentation of ICH is often indistinguishable from that of ischemic stroke but more commonly includes altered level of consciousness, headache, and vomiting, reflecting the presence of increased intracranial pressure (ICP).[17] Blood pressure is elevated in the majority of patients (see later). Seizures occur in 15% to 25% of patients within the first 48 hours and are nearly always associated with lobar hemorrhages or underlying vascular or neoplastic lesions.[52,53] Symptoms are maximal at onset or develop over minutes to hours. Neurologic deterioration after hospital admission has been reported to occur in 33% to 61% of patients with ICH.[54,55] The cause for clinical worsening is not always evident, but increased hematoma size is found in more than 25% of cases.[54] The role of edema in clinical deterioration is much more elusive.

DIAGNOSTIC STUDIES

Noncontrast CT scanning remains the gold standard for the diagnosis of acute ICH. The typical CT appearance of an acute hematoma consists of a well-defined area of increased density surrounded by a rim of decreased density. Over time, the borders of both the high- and low-attenuation regions become increasingly indistinct, such that the hematoma is isodense with adjacent brain parenchyma by 2 to 6 weeks.[56,57] Peripheral contrast enhancement can often be seen at this time.[58] By 2 to 6 months, there may be no CT evidence of previous hemorrhage, or there may be an area of hypodensity or a slitlike scar.[59]

Although the ability of MRI to reliably detect acute hemorrhage is controversial,[60] MRI is better than CT for determining the approximate age of a hematoma. This is because each hemoglobin oxidation state during the evolution of the hematoma produces a predictable pattern of signal intensity.[61] In addition, gradient-echo sequences may be useful in demonstrating the iron-containing deposits of previous asymptomatic hemorrhages.[62,63]

MRI and conventional angiography can be useful in evaluating the cause of ICH if an underlying aneurysm, vascular malformation, or neoplasm is suspected, but the yield of such studies is extremely low when the patient has chronic hypertension and the hemorrhage is in one of the typical sites associated with hypertensive hemorrhage.[64]

TREATMENT

Initial Stabilization

Acute ICH is a medical emergency requiring attention to airway and respiratory management, hemodynamic status, and correction of any underlying coagulopathy. As many as half of all patients with ICH undergo mechanical ventilation.[65] Blood pressure is often elevated at presentation, sometimes markedly so. Recent evidence indicates that the majority of hematomas enlarge over the first few hours, suggesting that aggressive correction of coagulopathies might be helpful.

Airway and Respiratory Management

Airway obstruction in ICH may occur for two reasons. First, there may be diminished consciousness, resulting in relaxation of the pharyngeal musculature and tongue and suppression of the cough and gag reflexes. Second, in ICH involving the posterior fossa, there may be complete loss of pharyngeal tone and absent cough, swallow, and gag reflexes.

Initial airway management includes proper positioning, frequent suctioning, and placement of an oral or nasal airway. Frequent assessments for sonorous respiration, inability to manage oral secretions, or decreased oxygen saturation are necessary. If conservative measures are ineffective, intubation may be necessary. Intubation of patients with ICH requires adequate sedation and jaw relaxation, as well as prevention of ICP elevation. Several factors may conspire to raise ICP during intubation, including hypoxemia, hypercarbia, and direct tracheal stimulation. Intravenous lidocaine (1 to 1.5 mg/kg) has been recommended to block this response,[66] although data supporting its use are lacking.[67] Short-acting intravenous anesthetic agents (thiopental 1 to 5 mg/kg or etomidate 0.1 to 0.5 mg/kg) also block this response[68] and additionally suppress brain metabolic rate,[68a] theoretically improving tolerance of a transient fall in cerebral perfusion pressure (CPP), should it occur. Etomidate is generally preferred over thiopental because it is less likely to lower blood pressure. Paralytic agents are usually unnecessary, but if needed, short-acting agents should be used. Intubated patients are at high risk for pneumonia via colonization of the oropharynx, sinuses, trachea, and gastrointestinal tract or contamination from hospital personnel or equipment. Appropriate measures should be taken to minimize this risk.

Hemodynamics

Arterial blood pressure is elevated on admission in the majority of patients with ICH, even in the absence of a history of hypertension.[17] Mean arterial pressure (MAP) is greater than 120 mm Hg in more than two thirds of patients and greater than 140 mm Hg in more than one third.[69] Although this acute increase in blood pressure is often implicated as the cause of the hemorrhage, it may simply be a reflection of chronic hypertension, the brain's attempt to maintain CPP in response to the sudden increase in ICP, pain and anxiety, and sympathetic activation. Even without pharmacologic intervention, blood pressure tends to decline to premorbid levels during the first 7 to 10 days after hemorrhage.[70]

There is substantial controversy over whether and when to lower blood pressure after acute ICH and how aggressive any intervention should be.[71,72] Proponents of rapid treatment of acute hypertension argue that high blood pressure may predispose to hematoma enlargement and may exacerbate vasogenic edema by increasing capillary hydrostatic pressure, especially in areas with a damaged blood-brain barrier. Yet an association between hypertension and edema has never been demonstrated, and data on the effect of hypertension on hematoma enlargement are inconsistent.[6,73,74] Another potential reason to lower blood pressure is that hypertension during the acute phase of ICH has been shown to correlate with a poor prognosis in some studies.[75,76] Causality has not been established, however, so it does not necessarily follow that lowering blood pressure will improve outcome. In fact, other studies have found no relationship between admission blood pressure and mortality.[55] In one report, patients whose mean blood pressure could be lowered to less than 125 mm Hg had a better outcome,[72] but it is unknown whether lowering the blood pressure improved the outcome or whether patients who respond to antihypertensive medications have less severe injury. Perhaps the most compelling reason to consider lowering blood pressure in ICH patients with moderate to severe hypertension is the potential for end-organ damage. Such patients are at risk for systemic complications of elevated blood pressure, including myocardial ischemia, congestive heart failure, and acute renal failure. Therefore, if hypertension is not treated, monitoring for such end-organ dysfunction is necessary.

The major argument against the treatment of elevated blood pressure is that lowering blood pressure might exacerbate ischemic damage in the tissue surrounding the hematoma by impairing CBF.[71] Chronic hypertension shifts the cerebral autoregulatory curve to the right, such that a higher CPP is required to maintain adequate CBF.[77,78] Thus, lowering the blood pressure to "normal" levels in these patients could lead to inadequate CBF. Similarly, because CPP is equal to the difference between MAP and ICP, lowering blood pressure may reduce CPP below the autoregulatory limit in patients with elevated ICP due to a large space-occupying clot or hydrocephalus.

Seeking to determine whether lowering blood pressure produces cerebral ischemia in acute ICH, several studies of CBF autoregulation in patients with recent ICH and elevated blood pressure (MAP >130 to 140 mm Hg) have been carried out.[79-81] Taken together, these studies demonstrate that regional and global autoregulation is preserved after ICH, down to a lower MAP limit that averages 110 mm Hg, or about 20% of the admission MAP, but there is substantial individual variation. MAP reductions in excess of 20%, or below approximately 85 mm Hg, may reduce CBF. None of these studies provided data on ICP, and, with the exception of one in which hematoma size was not specified, all were carried out on patients with small to moderate hematomas. Although these data do not address the issue of whether early pharmacologic reduction in blood pressure is beneficial, they do challenge the assumption that such reductions are harmful and may provide useful guidelines when blood pressure treatment is deemed necessary in patients with acute ICH.

In summary, unless there are signs of systemic complications, there appears to be no compelling need to aggressively treat hypertension in the early period after ICH, especially in the setting of large hemorrhages and raised ICP. However, modest blood pressure reductions (15% to 20%) in very hypertensive patients (MAP >130 to 140 mm Hg) with small- to moderate-sized hemorrhages appear to be safe.

If the decision is made to treat hypertension in the setting of acute ICH, the most appropriate antihypertensive agent would have a short half-life and minimal cerebrovascular effects, and it would be administered in such a way as to avoid sudden large reductions in blood pressure. Vasodilators, especially those that dilate veins, can raise ICP by increasing cerebral blood volume and hence should be avoided. Sodium nitroprusside and nitroglycerin increase ICP and lower CBF in patients with reduced intracranial compliance. Ganglionic blockers may also lower CBF. Calcium channel blockers, beta blockers, and angiotensin-converting enzyme (ACE) inhibitors have minimal effects on CBF within the autoregulatory range of MAP and do not alter ICP. Therefore, popular agents in the setting of acute ICH include the combined alpha and beta blocker labetalol, the calcium channel blocker nicardipine, and the ACE inhibitor enalapril. It should be noted that large doses of labetalol may be required to counteract the sympathetic nervous system stimulation associated with ICH. Another useful agent is hydralazine.

Prevention of Hemorrhage Extension

Because hemorrhage extension is known to occur within the first few hours after symptom onset in approximately one third of patients (Fig. 52-2),[6] any coagulopathy should be corrected as rapidly as possible. Patients taking warfarin should receive intravenous vitamin K and enough fresh frozen plasma to normalize the coagulation profile. Cryoprecipitate may be a useful alternative. Care must be taken not to precipitate congestive heart failure, however, and diuretics may be required to maintain an appropriate fluid balance. Additionally, the administration of fresh frozen plasma carries the risk of transfusion-related acute lung injury, which can complicate the process considerably. Correcting coagulopathy associated with thrombolytic-induced ICH is discussed later.

Even in those patients without coagulopathy, promoting early hemostasis might limit ongoing bleeding and decrease hematoma volume. Factor VIIa is a coagulation factor that interacts with tissue factor exposed in the wall of a damaged blood vessel to drive a burst of thrombin that initiates platelet aggregation and accelerates formation of a stable fibrin clot. A recently completed international phase IIb placebo-controlled dose-ranging proof-of-concept study found that treatment with recombinant factor VIIa (rVIIa) given as a single i.v. bolus within four hours of ICH onset decreases hematoma growth and improves clinical outcome despite a small increase in thromboembolic events. The percent increase in ICH volume at 24 hours was significantly

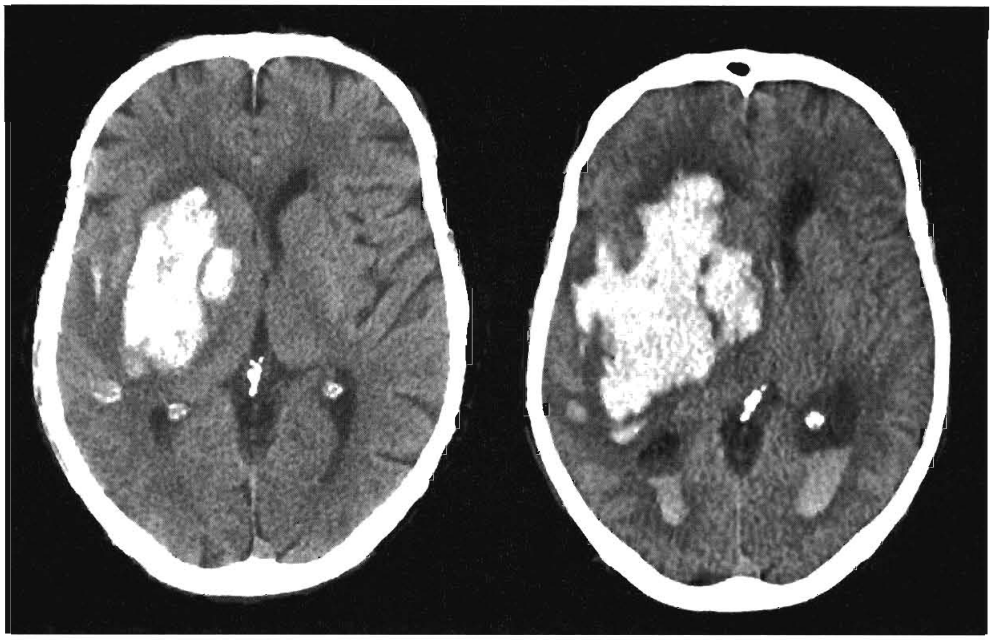

FIGURE 52–2. Hematoma enlargement with intraventricular extension. CT scan on the left was obtained 2 hours after symptom onset. CT scan on the right was obtained 2 hours later.

lower in the highest rVIIa dose group (160 μg/kg; 11%) compared with the placebo group (29%).[81a]

Intraventricular Hemorrhage and Hydrocephalus

In approximately 40% of patients with ICH, blood extends into the ventricular system (intraventricular hemorrhage).[82] Mortality in these patients is high.[83,84] Intraventricular hemorrhage may contribute to poor outcome by blocking cerebrospinal fluid pathways, with resultant hydrocephalus and increased ICP. In addition, intraventricular blood or its breakdown products may exert direct chemical irritative effects on periventricular structures.

Hydrocephalus may develop after ICH either in association with intraventricular hemorrhage or because of direct mass effect on a ventricle (e.g., on the third ventricle with a thalamic hemorrhage) (Fig. 52-3). External ventricular drainage (ventriculostomy) is frequently used to treat hydrocephalus and intraventricular hemorrhage, but its efficacy has never been established, and retrospective data suggest that it does not improve outcome.[85] Ventriculostomy in the setting of intraventricular hemorrhage is difficult to manage because the catheter frequently becomes obstructed with thrombus, interrupting drainage and raising ICP. Flushing the system helps remove thrombus from the catheter but increases the risk of ventriculitis. Recently, investigators attempted to facilitate the removal of blood from the ventricles by the direct intraventricular administration of thrombolytic agents. A preliminary study using urokinase (which is no longer available) showed no increase in complications and a trend toward reduced mortality in the group receiving the thrombolytic.[86] A multicenter randomized study is currently under way to investigate the efficacy of this promising therapy.

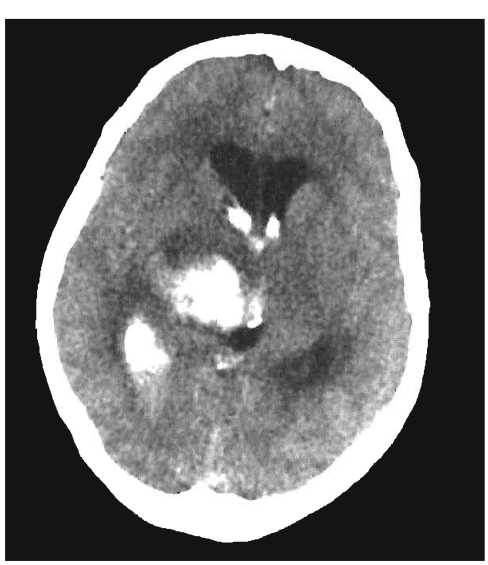

FIGURE 52–3. Small thalamic hemorrhage with blood obstructing the foramina of Monro, causing hydrocephalus.

Intracranial Hypertension

The incidence, impact, and appropriate management of intracranial hypertension in ICH are not well understood. Factors likely to contribute to elevated ICP in this population include large hematoma size, minimal degree of underlying cerebral atrophy, and hydrocephalus, but the true incidence of intracranial hypertension is unclear because routine ICP monitoring is not performed. Because the hematoma is localized and the increase in volume it produces can be partially compensated for by the reduction in the size of the ventricles and subarachnoid space, a global increase in ICP may not be seen unless the hemorrhage is massive or is associated with marked hydrocephalus. In addition, mass effect with local tissue shifts can compress the brainstem or result in herniation in the absence of a global increase in ICP.[87,88]

Invasive ICP monitoring devices can be placed in extradural, subdural, intraparenchymal, intraventricular, or intraspinal locations, but ventricular catheters have the additional capacity to manage hydrocephalus. If ICP is elevated or there are clinical signs of herniation, treatment options include hyperventilation, diuretics, osmotic agents (mannitol, hypertonic saline), and, if the ventricles are enlarged, cerebrospinal fluid drainage. A recent case series suggested that the rapid reversal of clinical transtentorial herniation

(decreased level of consciousness and dilated pupil) with hyperventilation and osmotic agents improved long-term outcome,[89] but the efficacy of these approaches in controlling ICP or altering outcome has not been evaluated in a randomized trial. Corticosteroids have no role in the management of increased ICP associated with ICH because they do not provide any benefit and increase the rate of complications.[90]

Surgical Evacuation

The rationale for surgical evacuation of a hematoma is that reducing mass effect and removing neurotoxic clot constituents should minimize injury to adjacent brain tissue and hence improve outcome. Unfortunately, several randomized, controlled trials of surgery for supratentorial ICH dating back to 1961 all failed to show a benefit.[91-94] A meta-analysis of three of these trials reported that patients undergoing surgical evacuation via open craniotomy had a higher rate of death or dependency at 6 months compared with those managed medically (83% versus 70%).[95] Criticisms of these trials are that the surgical techniques are outdated, patient selection was inadequate, and surgery was delayed too long.

Because open craniotomy is complicated by tissue damage sustained during the approach to the hematoma, a variety of new techniques for clot removal have been proposed, including an Archimedes screw, ultrasonic aspirator, modified endoscope, modified nucleotome, double-track aspirator, intraoperative CT monitoring, and instillation of thrombolytics. However, the recurrence of bleeding due to loss of the tamponade effect on adjacent tissue, which occurs in 10% of patients treated with open craniotomy, remains an issue with these techniques. In addition, because the new techniques involve limited surgical exposure, there is concern that rebleeding will be more difficult to control than with open craniotomy. One study comparing endoscopic aspiration to medical management found a better outcome in the surgical group (74% death or disability, compared with 90%), but the benefit was limited to patients with lobar hematomas.[94] Another study comparing stereotactic hematoma evacuation to conservative treatment in a select group of patients with putaminal hemorrhage found that surgery within 24 hours resulted in reduced mortality (11.8% vs. 23.5%) and greater likelihood of independent functional outcome (47.1% vs. 21.6%) in those patients who on admission had closed eyes that opened in response to strong stimuli. Of note, however, the authors provided no information regarding medical management or surgical technique.[95a] Three studies addressed the feasibility of early craniotomy for ICH. In one, 34 patients were treated within 12 hours of ICH.[96] Mortality was 18% in the surgical group and 23% in the medical group. In another study, 20 patients were randomized, with a median time to surgery of 8.5 hours from onset.[97] Good outcomes (Glasgow outcome scale score >3) were achieved in 56% of the surgical group and 36% of the medically treated group (P = NS). The third, a study of ultra-early surgery (<4 hours), found a disturbingly high rate of postoperative rebleeding.[98]

A lack of benefit of surgery in ICH was also shown in a recently completed multicenter trial in which 1033 patients were randomized within 72 hours of ICH onset to surgical hematoma evacuation (open craniotomy or stereotactic aspiration, at surgeon's discretion) or initial conservative management. Favorable outcome occurred in 26.1% in the surgery group and 23.8% in the initial conservative treatment group, a nonsignificant difference (odds ratio 0.89; 95% confidence interval 0.66 to 1.19). There was also no difference in mortality (surgery 62.6% vs. conservative treatment 63.7%). Subgroup analysis suggested a possible benefit of surgery in patients with superficial hematomas (less than 1 cm from cortical surface).[98a]

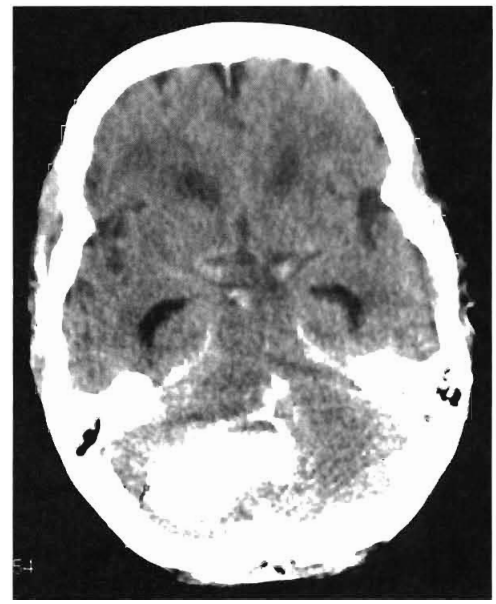

FIGURE 52–4. Typical cerebellar hemorrhage with early hydrocephalus evident by enlargement of the temporal horns of the lateral ventricles.

Whether cerebellar hemorrhage represents a unique case with regard to the role of surgery is unclear. In the pre-CT era, urgent surgery was advocated for all patients with cerebellar hemorrhage because of the perceived likelihood of severe disability or death.[99,100] With the advent of CT, however, it became evident that many patients had a benign outcome without surgery.[101-104] Proposed criteria for when to evacuate a cerebellar hematoma include diminished level of consciousness, large hematoma size (>3 cm^3), midline location, compression of basal cisterns or brainstem, and hydrocephalus (Fig. 52-4),[105-107] but whether these criteria select for patients who will benefit from surgery remains to be demonstrated in a randomized trial.

Thrombolytic-Induced Hemorrhage

Symptomatic ICH is a feared complication of thrombolytic therapy and is associated with considerable morbidity and mortality. It occurs after thrombolytic treatment of acute ischemic stroke in 3% to 20% of patients.[51,108-110] Symptomatic ICH is substantially less common after thrombolytic treatment of extracerebral thrombosis (myocardial infarction, pulmonary embolism, deep venous thrombosis, arterial and graft occlusion)[111] but results in a similarly poor outcome.[112] Factors that increase the risk of symptomatic ICH include higher dose of thrombolytic agent,[113] intra-arterial rather than intravenous route of administration,[114] elevated blood pressure before treatment,[115] and concomitant use of heparin.[116]

In the setting of thrombolytic therapy, any new neurologic deficit, especially a decline in consciousness, should be assumed to be due to hemorrhage. When ICH is suspected, the thrombolytic infusion is stopped, the patient's airway is reassessed, and an emergent CT scan is obtained. Blood studies (prothrombin time, partial thromboplastin time, thrombin and fibrinogen levels) should be performed to assess fibrinolytic state. At the first suspicion of hemorrhage, preparations should be made for giving fresh frozen

plasma, cryoprecipitate, and platelets if needed. The National Institute of Neurological Disorders and Stroke (NINDS) study of tissue plasminogen activator stipulated 6 to 8 units of cryoprecipitate or fresh frozen plasma and 6 to 8 units of platelets, but only rarely was this amount of blood product given to an individual patient during the study.[51] Although neurosurgical consultation was frequently obtained in patients with symptomatic ICH in the NINDS trial, only one patient in the study underwent surgery, and that patient died.

PROGNOSTIC FACTORS AND CAUSES OF MORTALITY

Mortality following ICH is high (25% to 50%), with more than half of the deaths occurring in the first 48 hours. Although patients who have small hemorrhages and mild deficits may recover completely, the majority of ICH survivors have significant residual disability.[4,5,117] Many clinical and radiographic prognostic indicators have been identified, but they are not consistently recognized across studies. Clinical factors reported to predict poor prognosis include older age, reduced level of consciousness on admission, elevated blood pressure on admission, and in-hospital neurologic deterioration. Radiographic features include large initial hematoma size, intraventricular spread of the hemorrhage, midline shift, hydrocephalus, and hematoma growth.[6,54,55,75,82,118-120] It has been demonstrated, however, that withdrawal of support in patients thought likely to have a poor outcome biases predictive models in ICH and negates the predictive value of all other variables.[121] Thus, the most frequent cause of death after ICH is withdrawal of care, followed by early (within 48 hours) transtentorial herniation and progression to brain death. Medical complications of immobility (pulmonary embolism, pneumonia, sepsis) account for most of the other deaths.[117] For survivors of ICH, the risk of recurrent stroke is approximately 4% per year. Recurrent ICH occurs about twice as often as ischemic stroke, especially in those with previous lobar hemorrhage.[122]

SUBARACHNOID HEMORRHAGE

Although it is the least common form of stroke, subarachnoid hemorrhage (SAH) has a great impact on its sufferers. One quarter of patients die before reaching medical attention,[123] and because of the consequences of secondary insults—rebleeding, hydrocephalus, and delayed ischemia due to vasospasm—more than half of those who reach medical attention either die or are left with neurologic deficits.

PATHOPHYSIOLOGY

In SAH, the primary site of bleeding is within the subarachnoid space, but depending on the cause, it may also involve hemorrhage into the brain parenchyma, ventricular system, or subdural space. Rupture of an intracranial saccular aneurysm is by far the most common cause of spontaneous SAH. Saccular or berry aneurysms are small, rounded protrusions of the arterial wall occurring predominantly at arterial bifurcations of the circle of Willis at the base of the brain. The most common sites of ruptured aneurysms are the internal carotid artery, including the posterior communicating artery junction (41%); anterior communicating artery–anterior cerebral artery (34%); middle cerebral artery (20%); and vertebrobasilar arteries (4%).[124] About 20% of patients have multiple aneurysms.[125]

Aneurysmal pathogenesis remains controversial, with the importance of developmental versus acquired factors in dispute. Proponents of the congenital theory suggest that aneurysms arise at sites of faulty fusion between muscular segments within the arterial wall. Supporters of the acquired-degenerative theory focus on the role of vascular damage caused by hemodynamic stress.[126] Citing the age-dependent occurrence of arterial defects and aneurysms' predilection for arterial bifurcations (sites of maximal hemodynamic stress), those favoring the importance of acquired features postulate that degenerative changes within the internal elastic lamina and media result in a local weakness that allows for aneurysm formation. The obvious third possibility is that aneurysms develop at sites harboring congenital defects with superimposed degenerative changes.

What leads to aneurysm growth and rupture is also debated. Hemodynamic stress and other factors intrinsic to the involved vessels may play a role. The time course over which aneurysms grow and subsequently rupture is unknown, although some aneurysms appear to grow rapidly, over weeks, whereas others grow slowly, over years.

The site of rupture of most aneurysms is the dome, where the wall may be as thin as 0.3 mm. Aneurysm rupture may cause local tissue damage due to the jet of blood under high pressure, as well as cause a global increase in ICP. Tension on the aneurysm wall is determined by the radius of the aneurysm and the pressure gradient across the wall (Laplace's law). The probability of rupture is related to size; aneurysms less than 7 to 10 mm in diameter have a very low rate of rupture.

CAUSES AND RISK FACTORS

Rupture of a saccular cerebral aneurysm is the cause of hemorrhage in more than three quarters of patients with nontraumatic SAH. Thus, genetic conditions that predispose to aneurysm formation, such as polycystic kidney disease, connective tissue disorders, and coarctation of the aorta, also predispose to SAH.[126] Other types of aneurysms that less commonly cause SAH include atherosclerotic, mycotic, and traumatic aneurysms. Among the causes of nonaneurysmal SAH, trauma is the most common. Arteriovenous malformations, cocaine and stimulant abuse, neoplasia, and vasculitis account for the bulk of the remainder. In a significant number of cases, no source of bleeding is identified.

The risk of SAH increases with age, peaking at 55 to 60 years. There is a slight male predominance in younger age groups and a slight female predominance among older patients.[127] Potentially reversible risk factors for SAH include cigarette smoking, oral contraceptive use, alcohol abuse, and hypertension.[128] Prospective cohort studies reported a relative risk of SAH as high as 5.7 for female and 4.7 for male smokers,[129] but no increased risk in former smokers. Oral contraceptive use, in addition to being an independent risk factor for SAH, dramatically increases the risk among smokers.[130] A dose-response relationship exists between alcohol consumption and incidence of SAH.[131,132] Finally, hypertension appears to be a risk factor[133] and may be the mechanism by which conditions such as polycystic kidney disease and stimulant drug use increase the risk for SAH.

Recently it has become clear that, in some patient populations, genetic factors play a role in aneurysm formation.[134,135] Individuals with two first-degree relatives with cerebral

aneurysms should undergo diagnostic evaluation for an aneurysm. Conventional angiography remains, at present, the appropriate test.

CLINICAL FEATURES

Presentation

The most common initial symptom of SAH, occurring in more than 90% of patients, is sudden severe headache. Less severe "sentinel" headaches[136] may precede the presenting event in as many as half of patients and are thought to represent minor leaks. In 45% of patients, transient or persistent loss of consciousness accompanies the headache.[137] The mechanism responsible for this acute loss of consciousness is that, at the moment of hemorrhage, the sudden surge in ICP approaches systemic arterial pressure, resulting in inadequate cerebral perfusion. Vomiting can be prominent in awake patients. Seizure activity may be reported.[138] In some cases, it is unclear whether this represents true epileptic seizures or reflex posturing related to the sudden rise in ICP. Focal deficits at the onset of hemorrhage occur in less than 10% of cases but, when present, may point to the location of a thick extra-axial or intraparenchymal blood clot. After a few hours, a stiff neck can develop, reflecting the sterile meningeal inflammation induced by the presence of blood in the subarachnoid space.

Complications

A worsening neurologic status following stabilization or improvement of symptoms often indicates one of the three major complications of SAH: rebleeding, hydrocephalus, or vasospasm. An understanding of the timing and nature of the deterioration facilitates rapid diagnosis and treatment. It must be emphasized that systemic perturbations, such as infection, disturbance in serum sodium levels, fever, hypoxemia, and hypotension, may produce similar symptoms and should be sought and corrected as part of the evaluation process.

Early Complications

Rebleeding. Rebleeding is heralded by a sudden worsening of headache, vomiting, development of a new neurologic deficit, or arrhythmia. It occurs in up to one third of patients and is often fatal. The risk of rebleeding is greatest during the first 24 hours and declines rapidly over the next 2 weeks.[139] Rates of rebleeding are highest in women, those with a poor clinical grade, those in poor medical condition, and those with elevated systolic blood pressure.

Hydrocephalus. Hydrocephalus occurs after SAH because of disturbances in cerebrospinal fluid flow or reabsorption; subarachnoid blood may impair cerebrospinal fluid reabsorption at the arachnoid granulations, and ventricular blood may obstruct its flow. Acute hydrocephalus can develop within hours of SAH,[140] often in the absence of intraventricular blood. Hydrocephalus may also develop gradually at any time, even weeks later. It usually manifests as an insidious decline in level of responsiveness and must be distinguished from metabolic derangements, infection, and vasospasm. CT scan is essential in making the diagnosis. The natural history of untreated acute hydrocephalus is that about one third of patients progress, one third spontaneously improve, and one third remain static.[141]

Cardiac Abnormalities. Cardiac abnormalities are common in the first 48 hours after SAH. Electrocardiographic changes (Fig. 52-5), including tall peaked T waves ("cerebral T waves"), ST segment depression, and prolonged QT segments,[142] are frequent and have been linked to elevated levels of circulating catecholamines. It appears that these changes do not represent true myocardial ischemia; the myocardial lesions reported are pathologically distinct from ischemia. Cardiac enzymes may be mildly elevated.[143] Arrhythmias are typically benign but can be severe or fatal. In rare cases, "stunned myocardium" may occur, with impairment of myocardial contractility leading to a fall in cardiac output, hypotension, and pulmonary edema.[144] This phenomenon is transient, usually lasting 2 to 3 days, after which cardiac function returns to baseline.[145]

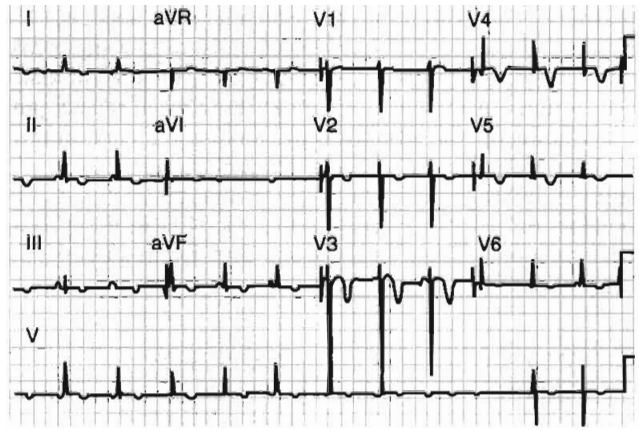

FIGURE 52-5. Electrocardiographic abnormalities following subarachnoid hemorrhage. (From Diringer MN: Subarachnoid hemorrhage. Continuum 2003;9:188.)

Delayed Complications

Vasospasm. Defined as segmental or diffuse narrowing of intracerebral arteries, vasospasm is a leading cause of morbidity and mortality following SAH. It can be detected angiographically (Fig. 52-6) in up to 70% of patients,[146] almost half of whom become symptomatic. The pathogenesis of vasospasm is complex and is not fully understood, but sustained exposure of vessels to extraluminal blood constituents and catecholamines is thought to play a role. It involves structural changes in the vessel walls and in adrenergic nerve fibers. The onset of vasospasm is delayed, most commonly developing in the latter half of the first week after the initial hemorrhage, and it may persist for up to 3 weeks. The strongest predictor of vasospasm is the amount and distribution of subarachnoid blood on the initial CT scan, with the greatest risk occurring in those having subarachnoid clots larger than 5 by 3 mm in the basal cisterns or layers of blood 1 mm thick or greater in the cerebral fissures (Fisher grade 3).[147] Focal neurologic deficits resulting from vasospasm reflect the territory of the involved arteries. They may appear abruptly or gradually and may fluctuate, exacerbated by hypovolemia or hypotension. Infarction may occur.

Serial transcranial Doppler studies have been used to screen for vasospasm. Criteria for vasospasm use an absolute linear blood flow velocity to define mild (>120 cm/sec), moderate (>160 cm/sec), or severe (>200 cm/sec) vasospasm.[148-150] Alternatively, the rate of rise in the linear blood flow velocity is used to define the onset of vasospasm. The sensitivity of transcranial Doppler in detecting vasospasm is about 80% when compared with angiography, at

FIGURE 52–6. Baseline angiogram after subarachnoid hemorrhage (left) showing normal basilar artery caliber and distal flow, and repeat angiogram after 1 week (right) showing severe vasospasm of the basilar artery, with reduced distal flow. (From Diringer MN: Subarachnoid hemorrhage. Continuum 2003;9:191.)

least partly due to the fact that it samples only a small segment of the vasculature.[151]

Medical Complications

Blood pressure is often elevated after SAH and is associated with a greater risk of rebleeding and vasospasm, as well as higher mortality. Multiple factors may underlie the rise in blood pressure, including increased catecholamine production induced by hypothalamic dysfunction, agitation, and pain. Early on, the management of blood pressure focuses on preventing rerupture of the aneurysm. Following surgical or endovascular repair, the risk of rebleeding is virtually eliminated, and spontaneous elevations in blood pressure should be allowed to occur without intervention, because the risk of exacerbating vasospasm with hypotension is now the predominant concern.

Disturbances in sodium and water balance occur in approximately one third of patients, and hyponatremia and volume depletion after SAH are correlated with an increased risk of symptomatic vasospasm and poor outcome.[152,153] Although hyponatremia was once attributed to inappropriate secretion of antidiuretic hormone and was therefore treated with fluid restriction, later evidence suggested that both sodium and water are lost. In fact, when administered in normal "maintenance" volumes of fluid (2 to 3 L/day), as many as half of patients develop intravascular volume contraction.[154-158] The mechanisms underlying the volume contraction and the inability to conserve sodium ("cerebral salt wasting") are unknown.

Cardiac rhythm disturbances occur in about 30% to 40% of patients, although life-threatening cardiac arrhythmias occur in only about 5%.[159,160] Cardiac arrhythmias are most common on the day of hemorrhage and in the perioperative period. Although pulmonary edema has been reported in up to one quarter of patients,[161,162] its incidence is lower with careful monitoring of hemodynamic treatment for vasospasm.[163]

In a review of more than 450 patients with SAH, Solenski and colleagues reported some degree of hepatic dysfunction in 24%.[161] The majority had only mild abnormalities of hepatic enzymes, but severe hepatic dysfunction occurred in 4%. Thrombocytopenia was found in 4% of patients, usually in the setting of sepsis. Renal dysfunction occurred in 7% of patients and was considered life threatening in about 15% of those.

DIAGNOSTIC STUDIES

CT is the imaging modality of choice in screening for SAH, having a sensitivity of greater than 90%.[164] Blood appears as high attenuation within the perimesencephalic and interpeduncular cisterns surrounding the brainstem, basal cisterns, sylvian fissure, and sulci (Fig. 52-7). Certain bleeding patterns are associated with specific aneurysm locations; for example, blood in the anterior interhemispheric fissure commonly occurs with anterior communicating artery aneurysms. When blood is spread diffusely throughout the cerebrospinal fluid spaces, its site of origin may be difficult to detect.

The amount of subarachnoid blood on CT is graded using the Fisher scale (Table 52-1).[147] The risk of vasospasm is proportional to the Fisher grade. Early hydrocephalus is suggested by enlargement of the third ventricle and of the temporal horns of the lateral ventricles.

CT may fail to demonstrate SAH if the volume of blood is small, if the hemorrhage occurred several days before the CT scan, or if the hematocrit is extremely low.[164] If CT is negative and clinical suspicion is high, lumbar puncture is indicated for cerebrospinal fluid analysis. Following SAH,

FIGURE 52–7. Subarachnoid hemorrhage with a thick layer of hyperdense blood filling the basal cisterns.

cerebrospinal fluid contains red blood cells indicative of the hemorrhage, as well as a few white blood cells reflecting the secondary inflammatory response. A yellow pigment (xanthochromia), resulting from red cell breakdown, can be detected in the centrifuged fluid 2 to 6 hours after hemorrhage, allowing differentiation from a traumatic spinal puncture.[165] The common technique of comparing cell counts in the first and last tubes collected is not reliable in making this distinction. Xanthochromia persists for 1 to 4 weeks after SAH.

Once SAH has been diagnosed, cerebral angiography is performed to identify the responsible vascular lesion, search for other lesions (multiple aneurysms are found in 20% to 30% of patients with aneurysmal SAH), and assist in operative management. Angiography is negative in 10% to 15% of patients with nontraumatic SAH. In some cases, this may be due to vasospasm or inadequate views to detect a subtle aneurysm, especially in the region of the anterior communicating artery or in the posterior circulation. Repeat angiography in 1 to 2 weeks is therefore often recommended.[166] If the blood on CT is localized to the perimesencephalic cisterns and angiography is negative, the prognosis is excellent, and repeat angiography is almost always negative.[167]

MRI is not as sensitive as CT for the detection of SAH, and magnetic resonance angiography and CT angiography are not sufficiently sensitive to replace conventional angiography, because they tend to miss smaller aneurysms. Magnetic resonance angiography and CT angiography may be of assistance in planning surgical or endovascular approaches to aneurysm treatment, however.

TREATMENT

Initial Stabilization

The initial steps in the evaluation of a patient with suspected SAH should include assessment of ability to protect the airway and level of neurologic function. The Hunt and Hess scale[168] and the more recently developed World Federation of Neurological Surgeons scale[169] provide standardized measures of the patient's clinical condition (Tables 52-2 and 52-3).

As in ICH, some patients with SAH may not be able to protect the airway because of diminished consciousness. If the patient is lethargic or agitated, elective intubation should be considered before angiography. Sedation is often necessary for angiography, and in lethargic patients or those with mild early hydrocephalus, this can lead to airway obstruction.

Routine Care and Monitoring

The routine monitoring of all patients with acute SAH should include serial neurologic examinations, continuous electrocardiogram monitoring, and frequent determinations of blood pressure, electrolytes, body weight, and fluid balance.

Because seizures can increase the risk of rebleeding, anticonvulsants are indicated if seizures occur. The value of prophylactic anticonvulsants in patients who have not had a seizure is unknown. Dexamethasone is widely used to reduce meningeal irritation and intra- and postoperative edema, but there is no convincing evidence documenting its efficacy.

Fluid Management

A stable intravascular volume should be maintained by the use of hydration with isotonic saline and daily monitoring of fluid balance, body weight, and hematocrit. In some patients with severe cerebral salt wasting, large volumes of fluid are required to prevent intravascular volume contraction.[152] Hyponatremia can often be managed with the restriction of all *free* water by administering only isotonic intravenous fluids, minimizing oral liquids, and using concentrated enteral feedings. It is important to adjust the *tonicity*, not the *volume*, of fluids administered.[153] Fludrocortisone is of marginal benefit in treating salt wasting.[154,170] Persistent hyponatremia can be treated by using mildly hypertonic solutions (1.25% to 2% saline) as the sole intravenous fluid.

Hypertension

Initial attempts to treat hypertension should consist of analgesics and nimodipine; other antihypertensive agents should follow if needed. Useful medications include beta blockers (often in higher-than-usual doses to block the high level of sympathetic nervous system activity), hydralazine, nicardipine, and nitroprusside. When significant hydrocephalus is present, hypertension should not be treated until after the hydrocephalus is addressed. This is because the hypertension may be acting to maintain adequate cerebral perfusion in the face of elevated ICP.

Surgical and Endovascular Treatment

In aneurysmal SAH, the definitive way to prevent rebleeding is to obliterate the aneurysm by surgically clipping its neck. The optimal timing of surgery is controversial, but in patients

with a good clinical grade (Hunt-Hess grades I to III), favorable neurologic outcome is more common when surgery is performed early (within 72 hours).[171] Clipping of aneurysms has the additional advantage of permitting a safe elevation of blood pressure to treat vasospasm.

Endovascular techniques, using either detachable balloons that trap the aneurysm or electrolytically detachable coils that thrombose the aneurysm,[172] have been used to repair acutely ruptured aneurysms (Fig. 52-8). Initial experience was limited to patients who were considered poor surgical candidates owing to aneurysm configuration or poor medical condition.[173] Subsequent reports in which surgical considerations did not heavily influence the selection of patients for endovascular procedures suggest a similar outcome for the two treatments. A recent, somewhat controversial study suggested that for acutely ruptured aneurysms that were deemed equally amenable to surgical or endovascular repair, morbidity and mortality were lower with coiling.[174]

Management of Secondary Complications

Rebleeding

Multiple clinical trials have demonstrated that antifibrinolytic agents such as ε-aminocaproic acid and tranexamic acid reduce the risk of rebleeding, but this benefit is offset by an increased incidence of vasospasm and hydrocephalus.[175,176] With the advent of early surgery and endovascular treatment, the use of these agents has declined dramatically. A shorter course of antifibrinolytic therapy while awaiting surgery or endovascular treatment (before the risk period for vasospasm begins) has been suggested, but it appears that the negative effects persist.[177]

Initial management directed at the prevention of rebleeding includes avoiding situations that produce sudden changes in the transmural pressure across the wall of the aneurysm (i.e., sudden increases in arterial or venous pressure or decreases in ICP). Patients are placed on bed rest with minimal stimulation. In an agitated patient, sedation is indicated, though care must be taken to preserve the ability to assess the patient's responsiveness to stimulation. Opiates are a good choice for sedation because they also provide analgesia for headache. Because of the risk of impairing the ability to evaluate for clinical deterioration, long-acting sedative agents such as phenobarbital should be avoided. Measures should be taken to minimize cough and Valsalva's maneuvers. In intubated patients, repositioning of the endotracheal tube, suctioning, and antitussive agents (codeine, lidocaine) may be needed. Stool softeners are administered to avoid straining. If lumbar puncture or ventriculostomy is performed, rapid drainage of a large volume of cerebrospinal fluid should be avoided so as not to induce sudden changes in the transmural pressure.

Definitive prevention of rebleeding is accomplished by obliteration of the aneurysm, as described earlier. This should be performed as soon as possible.

Hydrocephalus

The decision to treat hydrocephalus is usually based on the CT appearance of enlarging ventricles in a patient whose level of consciousness is deteriorating to the point of obtundation. Upon placement of a ventriculostomy, the cerebrospinal fluid pressure is reduced slowly to lessen the risk of aneurysm rerupture. Cerebrospinal fluid drainage via ventriculostomy may be needed for many days to clear intraventricular blood before it can be determined whether a permanent shunt is required.

Vasospasm

Prevention. Routine measures to prevent or ameliorate the effects of vasospasm include mechanical removal of subarachnoid blood at the time of aneurysm surgery, administration of the centrally acting calcium channel antagonist nimodipine, and avoidance of intravascular volume contraction (see earlier) and hypotension. Nimodipine treatment (60 mg orally every 4 hours) for 3 weeks after SAH reduces the impact of symptomatic vasospasm and improves outcome.[178-181] It is not clear whether this beneficial effect is due to action on the cerebral vessels or prevention of calcium influx into ischemic

neurons. Hypotension that develops with nimodipine administration can usually be managed with fluids or by adjusting the dosage schedule to 30 mg every 2 hours. In patients receiving hemodynamic augmentation for symptomatic vasospasm, it may be difficult to maintain blood pressure goals following nimodipine administration.

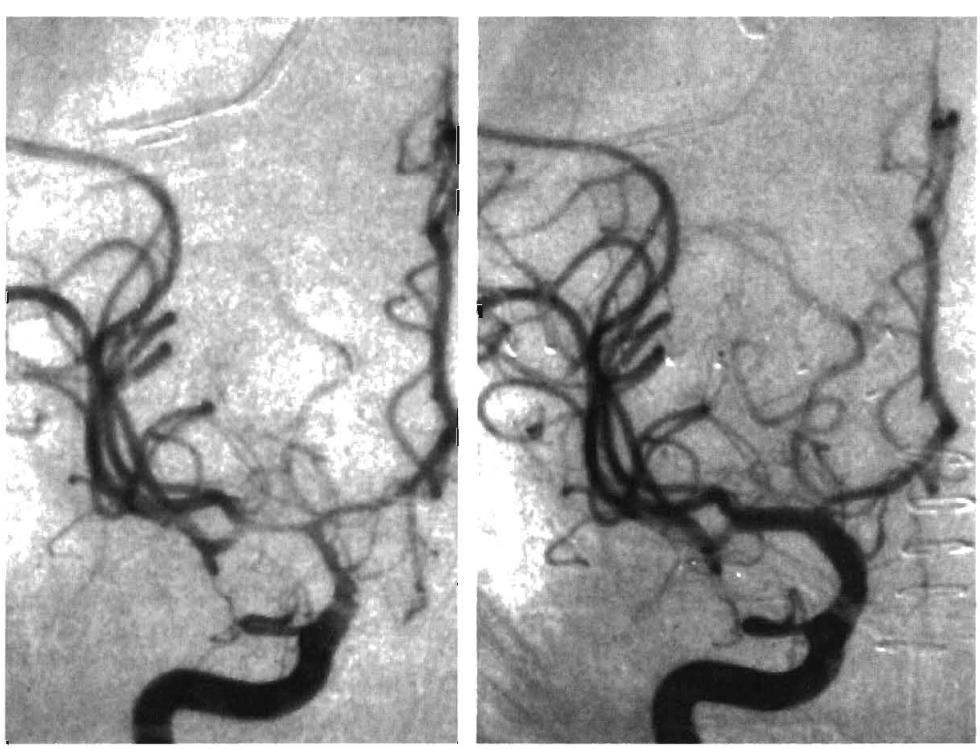
Treatment of Delayed Ischemic Deficits. Because of the disparity in the incidence of vasospasm detected angiographically, by transcranial Doppler, and clinically, there is disagreement about the management of vasospasm when it is detected. Although the aggressive management of clinical vasospasm with hemodynamic augmentation and endovascular maneuvers to open constricted vessels is widely accepted, there is dispute over how aggressive to be in an asymptomatic patient with vasospasm detected by transcranial Doppler or angiography.

Hemodynamic Augmentation. Treatment of symptomatic vasospasm in patients with surgically clipped aneurysms begins with hemodynamic augmentation, in which blood volume and cardiac output are optimized with fluids, and blood pressure is increased by the administration of vasoactive agents to enhance CBF and prevent cerebral infarction.[182,183] The initial step is to rapidly correct hypovolemia with isotonic crystalloid or colloid. No data exist to indicate that hypervolemia is more beneficial than euvolemia,[184-186] but the potential complications of hypovolemia are clear. Some degree of volume expansion may be helpful in improving cardiac output, but this effect may plateau at pulmonary capillary wedge pressures greater than 14 mm Hg.[187] If there is no immediate response to fluid administration, vasoactive agents are required—either inotropes (dobutamine, dopamine) to improve cardiac output or vasopressors (phenylephrine, norepinephrine) to raise MAP.

It is unclear whether augmenting volume, cardiac output, or MAP is the most efficacious intervention.[185] One approach is to measure pulmonary capillary wedge pressure, cardiac output, and systemic vascular resistance with a Swan-Ganz catheter to titrate hemodynamic management. Use of a Swan-Ganz catheter is also beneficial in patients with cardiac disease to help guide therapy and prevent the congestive heart failure and myocardial ischemia that may complicate hemodynamic augmentation.

Goals for intravascular volume and blood pressure should be defined as a percent change from baseline (beginning with about a 15% change), rather than prespecified levels. Although defining such goals is useful to guide therapy, the degree of hemodynamic augmentation should be titrated continuously to the patient's neurologic status; thus, if a goal is reached but there is no neurologic improvement, the goal should be reassessed. Hemodynamic augmentation is weaned gradually over several days, guided by neurologic status.

Endovascular Treatment. The second strategy involves endovascular treatment of constricted vessels with either balloon angioplasty or intra-arterial infusion of vasodilating agents such as papaverine or nicardipine. Angioplasty on the proximal segments of vasospastic cerebral vessels yields impressive angiographic changes (Fig. 52-9) that appear to be long lasting,[188-191] but clear clinical efficacy has been difficult to establish because the procedure is typically used in conjunction with hemodynamic augmentation. One study suggested that "prophylactic" angioplasty in high-risk patients might reduce the incidence of symptomatic vasospasm.[192] The direct infusion of papaverine and nicardipine into vasospastic vessels has also been used to treat vasospasm. Papaverine produces clear vasodilatation and improvement in global blood flow, but the response is often transient, with



A B

FIGURE 52–9. Severe distal internal carotid and proximal middle cerebral artery vasospasm before *(A)* and after *(B)* angioplasty.

vasospasm returning after 24 to 48 hours.[193-195] Multiple treatments are frequently necessary to yield a sustained angiographic effect.

The timing of when to initiate endovascular therapy is debated. It is generally used if, after a few hours, the response to hemodynamic augmentation is inadequate, but it may be the initial therapy in patients with poor cardiac function who are at high risk of complications of hemodynamic augmentation. Potential complications of endovascular treatments include arterial perforation, cerebral infarction, and rebleeding of unprotected aneurysms.

PROGNOSTIC FACTORS AND CAUSES OF MORTALITY

Aneurysmal SAH carries a poor prognosis, with death occurring in 20% to 40% of those who reach medical care. Causes of death are about equally distributed among direct effects of the initial hemorrhage, rebleeding, vasospasm, and medical complications.[161] Overall, less than one third of patients achieve good neurologic recovery. Predictors of poor prognosis include loss of consciousness or poor neurologic condition (i.e., high Hunt-Hess grade) on admission, older age, hypertension, preexisting medical illness, subarachnoid blood 1 mm thick or greater on CT scan (Fisher grade 3), seizures, cerebral edema, aneurysm in the basilar artery, and symptomatic vasospasm.[196-200]

This review article summarizes the available data on the diagnosis, theories of pathogenesis, pathophysiology, and treatment of SAH-induced cerebral vasospasm.

Molyneux A, Kerr R, Stratton I, et al: International Subarachnoid Aneurysm Trial (ISAT) of neurosurgical clipping versus endovascular coiling in 2143 patients with ruptured intracranial aneurysms: A randomised trial. Lancet 2002;360:1267-1274.

This prospective, multicenter, randomized trial evaluated the efficacy of surgical aneurysm clipping versus endovascular treatment by detachable platinum coils in patients with acutely ruptured intracranial aneurysms deemed equally amenable to either treatment. In this carefully selected population, with follow-up limited to 1 year, treatment with coils resulted in better outcome.

Chapter 53
SEIZURES IN THE CRITICALLY ILL

Sarice L. Bassin • Thomas P. Bleck

KEY POINTS

1. Although conventional definitions of status epilepticus have used a cutoff of 30 or 60 minutes of sustained seizure duration, or discrete seizures without recovery, clinicians should recognize that most seizures will terminate spontaneously within a few minutes. Therefore, seizures that persist longer than 5 to 7 minutes should probably be treated as status epilepticus.
2. Patients begin to awaken within 15 to 20 minutes after the successful termination of status epilepticus; many regain consciousness much faster. Patients who do not start to awaken after 20 minutes should be assumed to have entered nonconvulsive status epilepticus. Nonconvulsive status epilepticus demands emergency treatment guided by electroencephalographic monitoring to prevent further cerebral damage, since there are no clinical criteria to indicate whether therapy is effective.
3. Observation is the most important activity to perform when a patient has a single seizure. This is the time to collect evidence of a partial onset to implicate structural brain disease. The postictal examination is similarly valuable; language, motor, sensory, or reflex abnormalities after an apparently generalized seizure are evidence of focal pathology.
4. In contrast to the patient with a single or a few seizures, the status epilepticus patient requires concomitant diagnostic and therapeutic efforts. Although 30 minutes of continuous or recurrent seizure activity usually define status epilepticus, one should not stand by waiting for this period to pass to start treatment. Since most seizures in critically ill patients stop within 2 to 3 minutes, it is reasonable to start treatment after 5 minutes of continuous seizure activity or after the second or third seizure occurs without recovery between the spells.
5. Electroencephalographic monitoring after control of convulsive status epilepticus can be essential in directing the course of treatment.
6. The intensive care unit patient with central nervous system disease who has even one seizure should usually be given chronic anticonvulsant therapy, and this approach should be reviewed before the patient is discharged. Initiating this treatment after the first *unprovoked* seizure may help prevent subsequent epilepsy. In the intensive care unit setting, phenytoin is frequently selected because of its ease of administration and lack of sedative effects.
7. The conventional agents used in the first-line of treatment of status epilepticus are the benzodiazepines (especially lorazepam, diazepam, and midazolam), phenytoin, and phenobarbital. Status epilepticus that is refractory to the traditional agents is treated with continuous infusions of the short-acting barbiturates, midazolam, or propofol.

Seizures complicate the course of about 3% of adult intensive care unit (ICU) patients admitted for non-neurologic conditions. The medical and economic impact of these seizures confers importance on them out of proportion to their incidence. A seizure is often the first indication of a central nervous system (CNS) complication, and delay in recognition and treatment of seizure is associated with an increased risk of mortality[2]; thus, the rapid diagnosis of this disorder is mandatory. In addition, since epilepsy affects 2% of the population, patients with preexisting seizures occasionally enter the ICU for treatment of other problems. Since the initial treatment of these patients is the province of the intensivist, he or she must be familiar with seizure management as it affects the critically ill patient. Patients developing status epilepticus often require a critical care specialist in addition to a neurologist.

Seizures have been recognized at least since Hippocratic times, but their relatively high rate of occurrence in critically ill patients has only recently been appreciated. Seizures complicating critical care treatments (e.g., lidocaine use) are also a recent phenomenon. Early attempts at treatment included bromides[3] and morphine[4] as well as ice applications. Barbiturates were first employed in 1912, and phenytoin in 1937.[5] Paraldehyde was popular in the next two decades.[6] More recently, emphasis has shifted to the benzodiazepines, which were pioneered in the 1960s.[7] Newer agents for treatment of seizures in critically ill patients include the phenytoin prodrug fosphenytoin, the anesthetic agent propofol, and the water-soluble benzodiazepine midazolam.

Status epilepticus refers to prolonged seizure episodes. Status epilepticus may be the primary indication for admission to the ICU or it may occur in any ICU patient with CNS disease. The definitions employed in studies of status epilepticus have varied substantially. Although conventional definitions of status epilepticus have used a cutoff of 30 or

60 minutes of sustained seizure duration, or discrete seizures without recovery, clinicians should recognize that most seizures terminate spontaneously within a few minutes. Recent data suggest that in only half of patients with seizure episodes lasting 10 to 29 minutes will the seizure self-terminate.[8] Therefore, seizures that persist longer than 5 to 7 minutes should probably be treated as status epilepticus.[9]

EPIDEMIOLOGY

Limited data are available on the epidemiology of seizures in the ICU. A 10-year retrospective study of all ICU patients with seizures at the Mayo Clinic revealed that 7 patients had seizures per 1000 ICU admissions.[10] Our 2-year prospective study of medical ICU patients identified 35 with seizures per 1000 admissions.[11] These two studies are not exactly comparable, as the patient populations and methods of detection differed. A recent series found 8% of comatose patients without clinical signs of seizure activity to be in electrographic status epilepticus.[12]

Up to 34% of hospital in-patients experiencing a seizure die during their hospitalization.[10] Our prospective study of neurologic complications in medical ICU patients showed that having even one seizure while in the ICU for a non-neurologic reason doubled in-hospital mortality.[12] Incidence estimates for generalized convulsive status epilepticus in the United States vary from 50,000 cases per year[13] to 195,000 cases per year.[14] Some portion of this difference can be accounted for by different definitions; however, the latter estimate represents the only population-based data available and may be more accurate. Mortality estimates similarly vary from 1% to 2% in the former study to 22% in the latter. This disagreement follows from a conceptual discordance: the smaller number describes mortality that the authors directly attribute to status epilepticus, whereas the larger figure estimates the overall mortality rate, even though death was frequently caused by the underlying disease rather than by status epilepticus itself. The elderly have an incidence of status epilepticus almost twice that of the general population and the highest associated mortality rate of any age group at 38%.[15]

Table 53-1 summarizes the most common causes of status epilepticus in adults in the community. Almost 50% of the cases were attributed to cerebral vascular disease.[13] Garzon and colleagues[16] found anti-epileptic drug noncompliance as the main cause of status epilepticus in patients with a prior history of epilepsy, and CNS infection, stroke, and metabolic disturbances predominated in the group without previous seizures.

Three major factors determine outcome in patients with status epilepticus: the type of status epilepticus, its cause, and its duration. Generalized convulsive status epilepticus has the worst prognosis for neurologic recovery; myoclonic status epilepticus following an anoxic episode carries a very poor prognosis for survival. Complex partial status epilepticus can produce limbic system damage, usually manifested as a memory disturbance. Causes associated with increased mortality included anoxia, intracranial hemorrhages, tumors, infections, and trauma. The mortality of patients with nonconvulsive status epilepticus has been reported as high as 33%[17] and correlates with the underlying cause, severe impairment of mental status, and the development of acute complications, especially respiratory failure and infection.[18] Data strongly suggest that prolonged seizure duration is a negative prognostic factor. A study of 253 adult status epilepticus patients demonstrated a 30-day mortality rate of 2.7% in patients with seizures lasting 30 to 59 minutes, compared with 32% in those with seizures of 60 minutes or longer.[19]

Limited data are available concerning the functional abilities of generalized convulsive status epilepticus survivors, and no data reliably permit a distinction between the effects of status epilepticus and effects of its causes. One review concluded that intellectual ability declined as a consequence of status epilepticus.[20] Survivors of status epilepticus frequently seem to have memory and behavioral disorders out of proportion to the structural damage produced by the cause of their seizures. Case reports of severe memory deficits following prolonged complex partial status epilepticus have been published.[21] Conversely, one prospective study of 180 children with febrile status epilepticus demonstrated no deaths and no cases of new cognitive or motor handicap.[22] Experimental animal[23] and human epidemiologic[24] studies suggest that status epilepticus may be a risk factor in the development of future seizures. Whether treatment of prolonged seizures reduces the risk of subsequent epilepsy remains uncertain.

CNS, central nervous system.

CLASSIFICATION

The most frequently used classification scheme is that of the International League Against Epilepsy (Table 53-2).[25] This scheme allows classification on clinical criteria without inferring cause. *Simple partial seizures* start focally in the cerebral cortex, without invading other structures. The patient is aware throughout the episode and appears otherwise unchanged. Bilateral limbic dysfunction produces a *complex partial seizure*; awareness and ability to interact are diminished (but may not be completely abolished). *Automatisms* (movements that a patient makes without awareness) may occur. *Secondary generalization* results from invasion by epileptic electrical activity of the other hemisphere or subcortical structures.

Primary generalized seizures arise from the cerebral cortex and diencephalon at the same time; no focal phenomena are visible, and consciousness is lost at the onset. *Absence seizures* are frequently confined to childhood; they consist of the abrupt onset of a blank stare that usually lasts 5 to 15 seconds, after which the patient abruptly returns to normal. *Atypical absence seizures* occur in children with the Lennox-Gastaut

TABLE 53–2. INTERNATIONAL CLASSIFICATION OF EPILEPTIC SEIZURES

I. Partial seizures (seizures beginning locally)
  A. Simple partial seizures (consciousness not impaired; simple partial seizures)
    1. with motor symptoms
    2. with somatosensory or special sensory symptoms
    3. with autonomic symptoms
    4. with psychic symptoms
  B. Complex partial seizures (with impairment of consciousness; complex partial seizures)
    1. beginning as simple partial seizures and progressing to impairment of consciousness
      a. without automatisms
      b. with automatisms
    2. with impairment of consciousness at onset
      a. with no other features
      b. with features of simple partial seizures
      c. with automatisms
  C. Partial seizures (simple or complex), secondarily generalized
II. Primary generalized seizures (bilaterally symmetric, without localized onset)
  A. Absence seizures
    1. true absence ("petit mal")
    2. atypical absence
  B. Myoclonic seizures
  C. Clonic seizures
  D. Tonic seizures
  E. Tonic-clonic seizures ("grand mal")
  F. Atonic seizures
III. Unclassified seizures

TABLE 53–3. CLINICAL CLASSIFICATION OF STATUS EPILEPTICUS

I. Generalized seizures
  A. Generalized convulsive status epilepticus
    1. Primary generalized status epilepticus
      a. tonic-clonic status epilepticus
      b. myoclonic status epilepticus
      c. clonic-tonic-clonic status epilepticus
    2. Secondarily generalized status epilepticus
      a. partial seizure with secondary generalization
      b. tonic status epilepticus
  B. Nonconvulsive status epilepticus
    1. absence status epilepticus (petit mal status)
    2. atypical absence status epilepticus (e.g., in the Lennox-Gastaut syndrome)
    3. atonic status epilepticus
    4. nonconvulsive status epilepticus as a sequel of partially treated generalized convulsive status epilepticus
II. Partial status epilepticus
  A. Simple partial status epilepticus
    1. typical
    2. epilepsia partialis continua
  B. Complex partial status epilepticus
III. Neonatal status epilepticus

syndrome. *Myoclonic seizures* start with brief synchronous jerks, without alteration of consciousness initially followed by a generalized convulsion. They frequently occur in patients with genetic epilepsy; in the ICU, they commonly follow anoxia or metabolic disturbances.[26] *Tonic-clonic seizures* start with tonic extension, evolve to bilaterally synchronous clonus, and conclude with a postictal phase. Clinical judgment is required to apply this system in the ICU. In patients in whom consciousness has already been altered by drugs, hypotension, sepsis, or intracranial pathologic lesion, the nature of partial seizures may be difficult to classify.

Status epilepticus is classified by a similar system that has been altered to match observable clinical phenomena (Table 53-3).[27] Generalized convulsive status epilepticus is the most common type encountered in the ICU and poses the greatest risk to the patient. It may either be primarily generalized, as in the drug-intoxicated patient, or secondarily generalized, as in the brain abscess patient who develops generalized convulsive status epilepticus. *Nonconvulsive status epilepticus* in the ICU frequently follows partially treated generalized convulsive status epilepticus. Some practitioners use the term for all cases of status epilepticus that involve altered consciousness without convulsive movements; this blurs the distinctions among absence status epilepticus, partially treated generalized convulsive status epilepticus, and complex partial status epilepticus, which have different causes and treatments. *Epilepsia partialis continua* (a special form of partial status epilepticus in which repetitive movements affect a small area of the body) sometimes continues for months or years.

The International League Against Epilepsy continues to work toward revising and updating the current classification system. The goal is a multi-axis diagnostic scheme that incorporates anatomic, etiologic, therapeutic, and prognostic implications. For the most recent information regarding this ongoing project, refer to *www.epilepsy.org*.[28]

PATHOGENESIS AND PATHOPHYSIOLOGY

The causes and effects of status epilepticus at the cellular, brain, and systemic levels are interrelated, but their individual analysis is useful for understanding them and their therapeutic implications. The ionic events of a seizure follow the opening of ion channels coupled to excitatory amino acid receptors. From the standpoint of the intensivist, three channels are particularly important because their activation may raise intracellular free calcium to toxic concentrations: alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), *N*-methyl-D-aspartate (NMDA), and metabotropic channels. These excitatory amino acid systems are crucial for learning and memory. Many drugs that block these systems are available but are too toxic for chronic use. Counter-regulatory ionic events are triggered by the epileptiform discharge as well, such as the activation of inhibitory interneurons, which suppress excited neurons via $GABA_A$ synapses.

The cellular effects of excessive excitatory amino acid channel activity include (1) the generation of toxic concentrations of intracellular free calcium; (2) activation of autolytic enzyme systems; (3) production of oxygen free radicals; (4) generation of nitric oxide, which both enhances subsequent excitation and serves as a toxin; (5) phosphorylation of enzyme and receptor systems, making seizures more likely; and (6) an increase in intracellular osmolality, which produces neuronal swelling. If adenosine triphosphate production fails, then membrane ion-exchange ceases and neurons swell further. These events produce the neuronal damage associated with status epilepticus. Longer status epilepticus duration produces more profound alterations and an increasing likelihood of permanence and of becoming refractory to treatment.[29] The processes involved in a single

seizure and the transition to status epilepticus have been reviewed.[30]

Many other biophysical and biochemical alterations occur during and after status epilepticus. The intense neuronal activity activates immediate-early genes and produces heat shock proteins, providing indications of the deleterious effects of status epilepticus and insight into the mechanisms of neuronal protection.[31] The mechanisms by which status epilepticus damages the nervous system have been reviewed.[32] Absence status epilepticus is an exception among these conditions; it consists of rhythmically increased inhibition and does not produce clinical or pathologic abnormalities.

The electrical phenomena of status epilepticus at the whole brain level, as seen in the scalp electroencephalogram (EEG), reflect the seizure type that initiates status epilepticus (e.g., absence status epilepticus begins with a 3-Hz wave-and-spike pattern). During status epilepticus, this rhythm slows, but the wave-and-spike characteristic remains. Generalized convulsive status epilepticus goes through a sequence of electrographic changes (Table 53-4).[33] The initial discharge becomes less well formed, implying that neuronal firing loses synchrony. The sustained depolarizations that characterize status epilepticus alter the extracellular milieu, most importantly by raising extracellular potassium. The excess potassium ejected during status epilepticus exceeds the buffering ability of astrocytes.

The increased cellular activity of status epilepticus elevates demand for oxygen and glucose, and cerebral blood flow initially increases. After approximately 20 minutes, however, energy supplies are exhausted, causing local catabolism to support ion pumps (in an attempt to restore the internal milieu); this is a major cause of epileptic brain damage. In addition to damaging the CNS, generalized convulsive status epilepticus produces life-threatening systemic effects.[34] Excess secretion of epinephrine and cortisol cause systemic and pulmonary arterial pressures to rise dramatically at seizure onset and also produce hyperglycemia. Muscular work raises blood lactate levels. Both airway obstruction and abnormal diaphragmatic contractions impair respiration. Carbon dioxide excretion falls while its production increases markedly. Muscular work accelerates heat production, raising core body temperature.

The combined respiratory and metabolic acidoses frequently reduce the arterial blood pH to 6.9 or lower. The acidemia may produce hyperkalemia; in addition to its deleterious effects on cardiac electrophysiology, the elevated extracellular potassium level helps propagate seizure activity. Coupled with hypoxemia and the elevation of circulating catecholamine concentrations, these conditions rarely can produce cardiac arrest. This sequence probably accounts for some cases of epileptic sudden death; neurogenic pulmonary edema is the likely cause of many others. The severity of the acidosis may prompt consideration of bicarbonate administration. When this is attempted, however, the likelihood of the occurrence of pulmonary edema is inordinately high. Rapid termination of seizure activity is the most appropriate treatment; the restitution of ventilation and the metabolism of lactate quickly restore a normal pH.

After approximately 30 minutes of continuous convulsions, motor activity may diminish while electrographic seizures persist. Hypotension and hyperthermia ensue, and gluconeogenesis can fail, resulting in hypoglycemia. Generalized convulsive status epilepticus patients often aspirate oral or gastric contents, producing chemical pneumonitis or bacterial pneumonia. Rhabdomyolysis is common and may lead to renal failure. Compression fractures, joint dislocations, and tendon avulsions are other serious sequelae.

The mechanisms that terminate seizure activity are poorly understood. The leading candidates are inhibitory mechanisms, primarily GABA-ergic interneurons and inhibitory thalamic neurons.

CLINICAL MANIFESTATIONS

Three problems complicate seizure recognition: (1) the occurrence of complex partial seizures in the setting of impaired awareness, (2) the occurrence of seizures in patients receiving pharmacologically induced paralysis and/or sedation, and (3) misinterpretation of other abnormal movements as seizures. ICU patients often have depressed consciousness in the absence of seizures owing to their disease, its complications (such as hepatic[35] or septic[36] encephalopathy), or drug administration. A further decline in alertness may reflect a seizure; an EEG is required to confirm that one has occurred.

Patients receiving neuromuscular junction blocking agents do not manifest the usual signs of seizures. Patients with increased intracranial pressure (ICP) from primary brain injury, hepatic encephalopathy, or other critical illnesses may be both paralyzed and sedated, making identification of seizures particularly challenging. Tachycardia, tachypnea, and hypertension are signs of seizure that can be misinterpreted as evidence of inadequate sedation. Continuous EEG monitoring is warranted in this population if seizures are suspected.

Patients with metabolic disturbances, anoxia, and other types of nervous system injury may demonstrate abnormal movements that can be confused with seizure. Asterixis is a brief asynchronous loss of tone at the wrist or hip joints that

TABLE 53–4. ELECTROGRAPHIC-CLINICAL CORRELATIONS IN GENERALIZED CONVULSIVE STATUS EPILEPTICUS

Stage	Typical Clinical Manifestations*	Electroencephalographic Features
1	Tonic-clonic convulsions; hypertension and hyperglycemia common	Discrete seizures with interictal slowing
2	Low or medium amplitude clonic activity, with rare convulsions	Waxing and waning of ictal discharges
3	Slight but frequent clonic activity, often confined to the eyes, face, or hands	Continuous ictal discharges
4	Rare episodes of slight clonic activity; hypotension and hypoglycemia become manifest	Continuous ictal discharges punctuated by flat periods
5	Coma without other manifestations of seizure activity	Periodic epileptiform discharges on a flat background

*The clinical manifestations may vary considerably, depending on the underlying neuropathophysiologic process (and its anatomy), systemic diseases, and medications. In particular, stages of the electrographic progression may be sufficiently brief to be overlooked. Partially treating status epilepticus may dissociate the clinical and electrographic features.

Data from Treiman DM: Generalized convulsive status epilepticus in the adult. Epilepsia 1993;34(Suppl 1):S2-S11.

can appear in the setting of hepatic dysfunction. Stimulus-sensitive massive myoclonus after anoxia can be dramatic but usually self-abates in a few days. Controversy exists as to the epileptic origin of this disorder, and post-anoxic myoclonus has been reported in the presence of almost total cortical suppression.[37] Brain-injured patients may manifest paroxysmal episodes of sympathetic hyperactivity and associated rigidity or decerebrate posturing. These "hypothalamic seizures" can sometimes be distinguished from epileptic seizures with observation. Patients with tetanus are awake during their spasms and flex rather than extend their arms as seizure patients do. Psychiatric disturbances in the ICU occasionally resemble complex partial seizures. If doubt about the nature of abnormal movements persists, an EEG should be obtained.

The manifestations of status epilepticus depend on the type and, for partial status epilepticus, the cortical area of abnormality. Table 53-3 presents the types of status epilepticus encountered and focuses on those seen most frequently in the ICU.

Primary generalized convulsive status epilepticus begins as tonic extension of the trunk and extremities without preceding focal activity. No aura is reported and consciousness is immediately lost. After several seconds of tonic extension, the extremities start to vibrate; clonic (rhythmic) extension of the extremities quickly follows. This phase wanes in intensity over a few minutes. The patient may then repeat the cycle of tonus followed by clonic movements, or continue to have intermittent bursts of clonic activity without recovery. *Myoclonic status epilepticus* (bursts of myoclonic jerks that increase in intensity and lead to a generalized convulsion) is a less common form of generalized convulsive status epilepticus that is usually associated with anoxic coma.

Secondarily generalized status epilepticus begins with a partial seizure and progresses to a convulsive activity. The initial focal clinical activity may be overlooked. This seizure type implies a structural lesion, so care must be taken to elicit evidence of lateralized movements.

Of the several forms of generalized nonconvulsive status epilepticus, the one of greatest importance to intensivists is nonconvulsive status epilepticus as a sequela of inadequately treated generalized convulsive status epilepticus. When a patient with generalized convulsive status epilepticus is treated with anticonvulsants in inadequate doses, visible convulsive activity may stop, but the electrochemical seizure continues. Patients begin to awaken within 15 to 20 minutes after the successful termination of status epilepticus; many regain consciousness much faster. Patients who do not start to awaken after 20 minutes should be assumed to have entered nonconvulsive status epilepticus. Careful observation may disclose slight clonic activity. Nonconvulsive status epilepticus is an extremely dangerous problem because the destructive effects of status epilepticus continue even without obvious motor activity. Nonconvulsive status epilepticus demands emergency treatment guided by EEG monitoring to prevent further cerebral damage since there are no clinical criteria to indicate whether therapy is effective.

Failure to recognize nonconvulsive status epilepticus is common in patients presenting with nonspecific neurobehavioral abnormalities, such as delirium, lethargy, bizarre behavior, cataplexy, or mutism.[38] Patients may present in nonconvulsive status epilepticus without an inciting episode of generalized convulsive status epilepticus. A high suspicion for this disorder should be maintained in patients with unexplained alteration in level of consciousness or cognition admitted to the ICU.

Partial status epilepticus in ICU patients often follows a stroke or occurs with the rapid expansion of brain masses. Clonic motor activity is most easily recognized, but the seizure takes on the characteristics of adjacent functional tissue. Therefore, somatosensory or special sensory manifestations occur, and the ICU patient may be unable to report such symptoms. *Aphasic status epilepticus* occurs when a seizure begins in a language area and may resemble a stroke. *Epilepsia partialis continua* involves repetitive movements confined to a small region of the body. It may be seen with nonketotic hyperglycemia[39] or with focal brain disease; anticonvulsant treatment is seldom useful. *Complex partial status epilepticus* manifests with diminished awareness. The diagnosis often comes as a surprise when an EEG is obtained.

DIAGNOSTIC APPROACH

When an ICU patient has a seizure, one has a natural tendency to try to stop the event. This leads to both diagnostic obscuration and iatrogenic complications. Beyond protecting the patient from harm, very little can be done rapidly to influence the course of the seizure. Padded tongue blades, or similar items, should not be placed in the mouth; they are more likely to obstruct the airway than to preserve it. The seizures of most patients stop before any medication can reach the brain in an effective concentration.

Observation is the most important activity to perform when a patient has a single seizure. This is the time to collect evidence of a partial onset to implicate structural brain disease. The postictal examination is similarly valuable; language, motor, sensory, or reflex abnormalities after an apparently generalized seizure are evidence of focal pathology.

Seizures in ICU patients have several potential causes that must be investigated. Drugs are a major cause of ICU seizures, especially in the setting of diminished renal or hepatic function or when the blood-brain barrier is breached. Theophylline frequently produces seizures or status epilepticus if it has been rapidly loaded or if high concentrations of the drug occur; occasionally, however, these complications arise at "therapeutic" levels. Imipenem-cilastatin[40] and fluoroquinolones[41] have substantial potential to lower the seizure threshold, especially in patients with renal dysfunction. They should be avoided if possible in patients already at risk for seizure. Other antibiotics, especially beta-lactams, are occasionally implicated.[42] Sevoflurane, a volatile anesthetic agent, is dose-dependently epileptogenic in patients with no predisposition to seizures.[43]

Recreational drugs are frequently overlooked offenders in patients presenting to the ICU. Acute cocaine or methamphetamine intoxication is characterized by a state of hypersympathetic activity followed by seizures.[44] Although ethanol withdrawal is a common cause of seizures, discontinuing any hypnosedative agent may prompt convulsions 1 to 3 days later. One report suggests that narcotic withdrawal may produce seizures in the critically ill.[10] In the absence of other clear causes for seizure, complete toxicologic screening should be performed.

Serum glucose, electrolyte concentrations, and serum osmolality should also be measured. Nonketotic hyperglycemia[45,46] and hyponatremia can precipitate both focal and generalized seizures. Seizure activity may infrequently

be the first presenting sign of diabetes mellitus. However, hypocalcemia rarely causes seizures beyond the neonatal period; its identification on analysis must *not* signal the end of the diagnostic work-up. Hypomagnesemia has an equally unwarranted reputation as the cause of seizures in malnourished alcoholic patients.

The physical examination should emphasize assessment for both global and focal abnormalities of the CNS. Evidence of cardiovascular disease or systemic infection should be sought and the skin and fundi examined closely.

The need for imaging studies in these patients has been an area of uncertainty. A prospective study of neurologic complications in medical ICU patients determined that 38 of 61 patients (62%) had a vascular, infectious, or neoplastic explanation for their seizures.[11] Hence, head computed tomography or magnetic resonance imaging should be performed on ICU patients with new seizures. With current technology, there are almost no patients who cannot undergo computed tomography scanning. Magnetic resonance imaging is particularly helpful in detecting evidence of acute ischemic stroke and encephalitis. Magnetic resonance imaging cannot be performed on patients with pacemakers. Many ICP monitor catheters are compatible with magnetic resonance imaging, provided the device is not coiled when it is secured to the scalp. Patients who need cerebrospinal fluid analysis always require imaging of the brain first. When CNS infection is suspected, empirical antibiotic treatment should be started while these studies are being performed.

Electroencephalography is a vital diagnostic tool for evaluating the seizure patient. Partial seizures usually show EEG

FIGURE 53–1. Electroencephalographic recording during status epilepticus. The first panel illustrates the onset of the seizure; the subsequent panels show its evolution. Montage: longitudinal bipolar; channels 1-4, left temporal, and channels 5-8, left parasagittal. Calibration: vertical, 50 μv; horizontal, 1 sec.

D

FIGURE 53-1.—cont'd

abnormalities that begin in the area of cortex that produces seizures. Primary generalized seizures appear to start over the entire cortex simultaneously. Postictal slowing or depressed amplitude provides clues as to the focal cause of the seizures, and epileptiform activity helps to classify the type of seizure and to guide treatment. An emergency EEG is necessary to exclude nonconvulsive status epilepticus in those patients who do not begin to awaken soon after seizures have apparently been controlled (Fig. 53-1).

In contrast to the patient with a single or a few seizures, the status epilepticus patient requires concomitant diagnostic and therapeutic efforts. Although 30 minutes of continuous or recurrent seizure activity usually define status epilepticus, one should not stand by waiting for this period to pass to start treatment. Since most seizures in critically ill patients stop within 2 to 3 minutes, it is reasonable to start treatment after 5 minutes of continuous seizure activity or after the second or third seizure occurs without recovery between the spells.

Treatment for status epilepticus should not be delayed to obtain an EEG. However, a prospective evaluation of 164 patients demonstrated that nearly half manifested persistent electrographic seizures in the 24 hours after clinical control of convulsive status epilepticus.[47] These data suggest that EEG monitoring after control of convulsive status epilepticus can be essential in directing the course of treatment. A variety of findings may be present on the EEG, depending on the type of status epilepticus and its duration (see Table 53-4). Complex partial status epilepticus patients are often without such organized discharges of generalized convulsive status epilepticus; instead, they have waxing and waning rhythmic activity in one or several brain regions. A diagnostic trial of

intravenous benzodiazepine therapy is often necessary to diagnose complex partial status epilepticus. Patients developing refractory status epilepticus or having seizures during neuromuscular junction blockade require continuous EEG monitoring.

The availability of continuous paperless EEG monitoring allows for detection of seizure activity over a long period. Subclinical seizures have been observed to occur in patients receiving aggressive treatment for status epilepticus and even in patients treated with barbiturates to a burst-suppression EEG pattern. The clinical significance of these subclinical seizures, and their effect on prognosis, remains uncertain.

MANAGEMENT APPROACH

TREATING ISOLATED SEIZURES

Making the decision to administer anticonvulsants to an ICU patient who experiences one or a few seizures requires consideration of a provisional cause, estimation of the likelihood of recurrence, and recognition of the utility and limitations of anticonvulsants. For example, the occurrence of seizures during ethanol withdrawal does not indicate the need for chronic treatment, and giving phenytoin does not prevent further withdrawal convulsions. The patient may need prophylaxis against delirium tremens, but the few seizures themselves seldom require treatment. Patients with convulsions during barbiturate or benzodiazepine withdrawal, in contrast, should usually receive short-term treatment with lorazepam to prevent status epilepticus. Prolonged or frequent seizures caused by metabolic disturbances can be treated temporarily with benzodiazepines while the abnormality is being corrected. Seizures in these settings are notoriously resistant to treatment with phenytoin. In particular, treatment of patients with partial seizures related to nonketotic hyperglycemia should be directed at correction of the hyperglycemia and hypovolemia rather than anticonvulsant therapy.[46]

The ICU patient with CNS disease who has even one seizure should be given chronic anticonvulsant therapy, and this approach should be reviewed before the patient is discharged. Initiating this treatment after the first *unprovoked* seizure may help prevent subsequent epilepsy,[48] although there is considerable difference of opinion regarding this concept.[49] Starting therapy after the first seizure in a critically ill patient at risk for seizure recurrence may be even more important, especially if the patient's condition would be seriously complicated by a convulsion.

In the ICU setting, phenytoin is frequently selected owing to its ease of administration and lack of sedative effects. Hypotension and arrhythmias may complicate intravenous administration and can usually be prevented by slowing the infusion to less than 25 mg/min. Because of the rare occurrence of third-degree atrioventricular block, an external cardiac pacemaker should be available when patients with conduction abnormalities receive intravenous phenytoin. Propylene glycol in the parenteral formulation of phenytoin is the probable cause of these effects. Additionally, the parenteral formulation of phenytoin is alkaline, and this is thought to contribute to pain, burning, and redness at the injection site.

The phenytoin prodrug fosphenytoin is water soluble and its vehicle does not contain propylene glycol; adverse effects are less common with fosphenytoin than with intravenous administration of phenytoin.[50,51] Fosphenytoin is dosed by phenytoin equivalent units; therefore, no dosage adjustments are needed when converting patients from phenytoin to fosphenytoin. Fosphenytoin can be administered by intramuscular injection or by intravenous infusion at a rate of up to 150 mg phenytoin equivalents/min. Fosphenytoin is rapidly converted to phenytoin in vivo, and free phenytoin levels after fosphenytoin administration are not markedly different compared with phenytoin.

Whether phenytoin or fosphenytoin is used, the serum phenytoin concentration should be kept in the "therapeutic" range of 10 to 20 μg/mL (corresponding to an unbound or "free" concentration of 1 to 2 μg/mL), unless further seizures occur; the level can then be increased until signs of toxicity occur. Failure to prevent seizures at a concentration of 25 μg/mL is usually an indication to add phenobarbital to the regimen. When fosphenytoin is administered, phenytoin concentrations should not be measured until the biologic conversion to phenytoin is complete: 2 hours after an intravenous infusion or 4 hours after an intramuscular injection of fosphenytoin.

Phenytoin is approximately 90% protein bound in normal hosts. Patients with renal dysfunction have lower total phenytoin levels at a given dose because the drug is displaced from binding sites, but the unbound level is not affected. Thus, renal failure patients, and perhaps others who are receiving highly protein-bound drugs (which compete for binding), may benefit from determination of free phenytoin level. Only the free fraction is metabolized, so the dose is not altered with changes in renal function. The clearance half-time with normal liver function varies from about 12 to 20 hours (intravenous form) to more than 24 hours (extended-release capsules), so that a new steady-state serum concentration occurs in 3 to 6 days. Phenytoin need not be given more frequently than every 12 hours. Hepatic dysfunction mandates a decrease in the maintenance dose. Hypersensitivity is the major adverse effect of concern to the intensivist. This may manifest itself solely as fever but commonly includes rash and eosinophilia. Adverse reactions to phenytoin and other anticonvulsants have been reviewed elsewhere.[52]

Phenobarbital remains a useful anticonvulsant for patients who are intolerant to phenytoin or who have persistent seizures after adequate phenytoin administration. The target for phenobarbital in the ICU should be a serum concentration of 20 to 40 μg/mL. Hepatic and renal dysfunction alter phenobarbital metabolism. Since its usual clearance half-time is about 96 hours, maintenance doses of this agent should be given once a day. A steady-state level takes about 3 weeks to become established. Sedation is the major adverse effect; allergy to the drug occurs rarely.

Carbamazepine therapy is seldom started in the ICU because its insolubility precludes parenteral formulation. Oral loading in conscious patients may produce coma that lasts several days. This drug also causes hyponatremia in patients who receive it chronically.

TREATING STATUS EPILEPTICUS

Generalized convulsive status epilepticus obviously constitutes a medical emergency; however, nonconvulsive status epilepticus and complex partial status epilepticus are also emergencies but are more difficult to recognize. In each circumstance, one must act quickly to prevent additional cerebral damage.

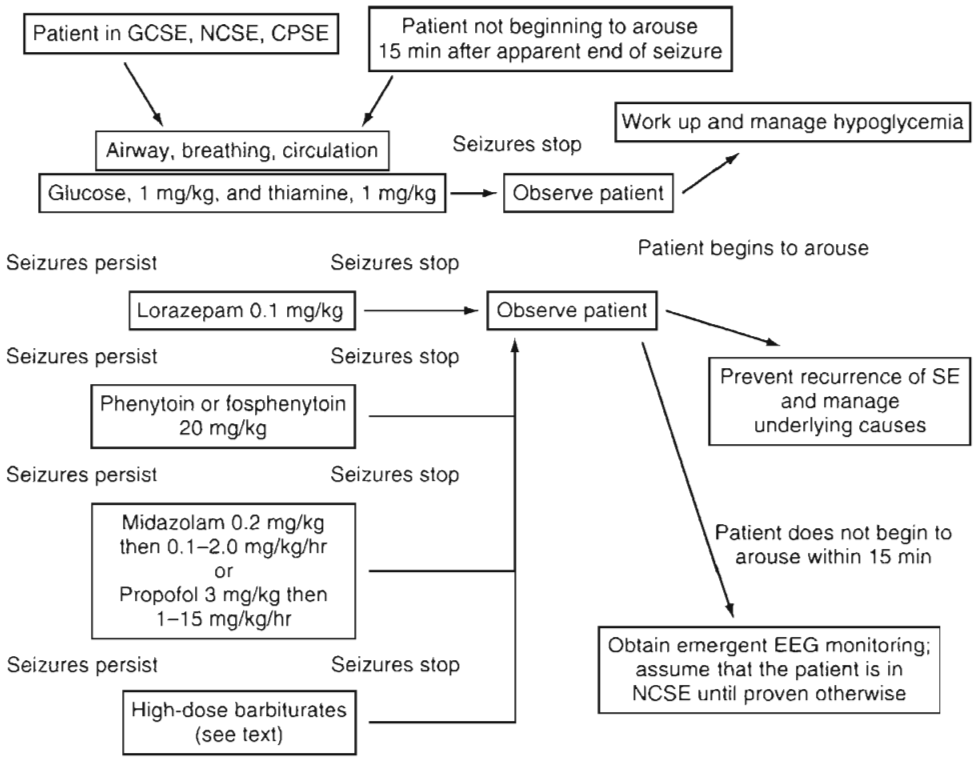

FIGURE 53–2. Management algorithm for status epilepticus. CPSE, complex partial status epilepticus; GSCE, generalized convulsive status epilepticus; NCSE, nonconvulsive status epilepticus; SE, status epilepticus.

Figure 53-2 shows a management algorithm for status epilepticus and Table 53-5 presents a sample management protocol for drug administration.[53] Patients with simple partial status epilepticus or epilepsia partialis continua are at less risk for the development of widespread cerebral damage and are also less likely to respond to the aggressive approach outlined in Table 53-5. In these patients, correcting underlying problems, such as nonketotic hyperosmolar hyperglycemia, is crucial. Errors in terminating status epilepticus include inadequate dosing of effective drugs and continued use of drugs that are ineffective in the patient being treated.

The conventional agents used in the first line of treatment of status epilepticus are the benzodiazepines (especially lorazepam, diazepam, and midazolam), phenytoin, and phenobarbital. Status epilepticus that is refractory to the traditional agents is treated with continuous infusions of the short-acting barbiturates, midazolam, or propofol. A recent multicenter clinical trial comparing lorazepam alone, phenytoin alone, diazepam followed by phenytoin, and phenobarbital alone as the initial drug treatment for generalized convulsive status epilepticus has been reported.[54] In this study, the highest rate of successful treatment of "overt" generalized convulsive status epilepticus was achieved with lorazepam. There was no demonstrable difference among these four drug regimens in the initial treatment of "subtle" generalized convulsive status epilepticus. Lorazepam has been our agent of first choice for terminating status epilepticus for many years and remains so with support from this study.

Advantages of lorazepam over diazepam are its duration of action against status epilepticus (4 to 14 hours as opposed to 20 minutes) and its higher initial response rate. European practitioners often use midazolam or clonazepam initially. In patients in whom intravenous access is difficult to attain, 0.2 mg/kg of midazolam administered intramuscularly will be rapidly and reliably absorbed. The use of midazolam in refractory status will be discussed later. Respiratory depression is the major adverse effect of the benzodiazepines, especially when they are given together with barbiturates or paraldehyde.

Phenytoin is an effective agent in the treatment of status epilepticus; however, the constraint on the rate of intravenous administration is of concern. Phenytoin has a long duration of action when an adequate dose is given (a 20 mg/kg dose produces a serum level above 20 μg/mL for 24 hours). Adding 5 mg/kg if the first 20 mg/kg load fails to stop status epilepticus may be useful. Fosphenytoin can be administered by a more rapid intravenous infusion and has fewer cardiovascular side- effects than phenytoin. Free phenytoin levels reach a therapeutic range 10 to 20 minutes after an infusion of fosphenytoin is started.[55,56] Intramuscular injection of fosphenytoin in patients with status epilepticus may be supported by the known pharmacokinetics of this route, but it should not be considered to be acceptable therapy for status epilepticus and should be reserved for only those rare circumstances in which intravenous access cannot be obtained.

Some practitioners advocate the use of phenobarbital as a first-line drug,[57] but it has typically been used as a third-line agent, after administration of a benzodiazepine and phenytoin.[58] Although this approach has been widely accepted by the neurologic community, we rarely use phenobarbital for two reasons. First, only a small percentage of patients who have failed treatment with two anticonvulsant drugs respond to a third conventional agent[59]; second, at least an additional 20 minutes are required to obtain control in the few patients who do respond. Phenobarbital remains an important drug in the management of simple partial status epilepticus and for those patients who are being weaned from high-dose midazolam or anesthetic barbiturates.

Pentobarbital and thiopental infusions are usually reserved for refractory status epilepticus.[55] Although these drugs are effective in sufficiently large doses, their side effects

TABLE 53–5. SUGGESTED PROTOCOL FOR TREATING STATUS EPILEPTICUS

I. Establish an airway, provide oxygen, and ensure ventilation. If neuromuscular junction blockade is required for intubation, use a short-acting agent (e.g., succinylcholine or vecuronium).

II. Determine blood pressure. If the patient is hypotensive, begin volume replacement or administration of vasoactive agents (or both), as indicated. Generalized convulsive status epilepticus patients who present with hypotension will usually require admission to a critical care unit. Hypertension should not be treated until status epilepticus is controlled, since terminating status epilepticus usually substantially corrects it, and many of the agents used to terminate status epilepticus can produce hypotension.

III. Unless the patient is known to be normo- or hyperglycemic, administer dextrose (1 g/kg) and thiamine (1 mg/kg).

IV. Terminate status epilepticus. The following sequence is recommended (see text for details); be cognizant of the potential of these drugs to eliminate the visible convulsive movements of generalized convulsive status epilepticus when leaving the patient in nonconvulsive status epilepticus. Patients who do not begin to respond to external stimuli 15 minutes after the apparent termination of generalized convulsive status epilepticus should be considered at risk for nonconvulsive status epilepticus and should undergo emergent EEG monitoring.

A. Give lorazepam, 0.1 mg/kg at a rate of 0.04 mg/kg per min. This drug should be diluted in an equal volume of the solution being used for intravenous infusion, as it is quite viscous. Most adult patients who respond do so by a total administered dose of 8 mg. The latency of effect is debated, but lack of response after 5 minutes should indicate failure.

B. If status epilepticus persists after lorazepam administration, consider phenytoin at up to 50 mg/min or fosphenytoin 20 mg/kg at up to 150 mg/min (dosed by phenytoin equivalent). Many investigators believe that an additional 5 mg/kg dose of phenytoin equivalent should be administered before the next line of therapy is attempted. However, this step may have more value for the prevention of status epilepticus recurrence than for its initial control.

C. If status epilepticus persists, administer midazolam 0.2 mg/kg as a bolus, followed by an infusion of 0.1-2.0 mg/kg per hour to achieve seizure control (as determined by EEG monitoring). Intubate the patient at this stage if this has not already been accomplished. A patient reaching this stage should be treated in a critical care unit.

E. Should the patient's condition not be controlled with midazolam, administer propofol or pentobarbital. Propofol is given as a continuous infusion at a rate of 1-15 mg/kg per hour to achieve seizure control (as determined by EEG monitoring). A bolus dose of propofol (3.0 mg/kg) is often given but may increase the occurrence of hypotension. Pentobarbital is given as a bolus dose of 12 mg/kg at a rate of 0.2-0.4 mg/kg per minute as tolerated, followed by an infusion of 0.25-2.0 mg/kg per hour, as determined by EEG monitoring (with an initial goal of burst-suppression; in some cases, an isoelectric electroencephalogram may be required to eliminate all electrical seizures). Most patients require systemic and pulmonary arterial catheterization, with fluid and vasoactive drug therapy as indicated to maintain blood pressure. Other complications of this treatment are discussed in the text.

V. Prevent recurrence of status epilepticus. The choice of drugs depends greatly on the cause of status epilepticus and the patient's medical and social situation. In general, patients not previously receiving anticonvulsants whose status epilepticus is easily controlled often respond well to chronic treatment with phenytoin or carbamazepine. In contrast, others (e.g., patients with acute encephalitis) will require two or three anticonvulsants at 'toxic' levels (e.g., phenobarbital at greater than 100 μg/mL) to be weaned from midazolam or pentobarbital and may still have occasional seizures.

VI. Treat complications.

A. Rhabdomyolysis should be treated with a vigorous saline diuresis to prevent acute renal failure; urinary alkalinization may be a useful adjunct. If definitive treatment of generalized convulsive status epilepticus takes longer than expected because of hypotension or arrhythmias, neuromuscular junction blockade under EEG monitoring might be considered.

B. Hyperthermia usually remits rapidly after termination of status epilepticus. External cooling usually suffices if the core temperature remains elevated. In rare instances, cool peritoneal lavage or extracorporeal blood cooling may be required. High-dose pentobarbital generally produces poikilothermia.

C. The treatment of cerebral edema occurring secondary to status epilepticus has not been well studied. When substantial edema is present, one should suspect that status epilepticus and cerebral edema are both manifestations of the same underlying condition. Mannitol and mild hyperventilation may be valuable if edema is life threatening. If substantial cerebral edema is present, ICP monitoring should be strongly considered. Edema due to status epilepticus is vasogenic in origin; thus, steroids may be useful as well, but they have not been studied in this setting.

can limit their use and may be fatal.[60] However, they are important when other modalities have failed (see Table 53-5). Endotracheal intubation and mechanical ventilation are mandatory when high-dose barbiturates are used, and both continuous EEG and invasive hemodynamic monitoring are highly recommended. Severe hypotension is the most frequent side effect of pentobarbital therapy, and its occurrence is associated with increased mortality.[61] An increased occurrence of nosocomial respiratory tract infection has been reported in patients treated with pentobarbital infusion.[62] An inhibitory effect on leukocyte chemotaxis and paralysis of respiratory cilia by the barbiturates have been postulated. Despite these side-effects, barbiturate anesthesia should not be rapidly discontinued if it is successful in terminating refractory status epilepticus; rather, continuing therapy for at least 48 hours, gradual tapering of the infusion dose, and the administration of phenobarbital during the drug taper are recommended.[63]

Midazolam is a water soluble benzodiazepine that has demonstrated high efficacy in refractory status in adults and children.[64,65] At our institution, this agent is used as a second-line drug, after lorazepam has failed to control status epilepticus. Clinically significant hypotension is rare even at very high doses that are often required to address tachyphylaxis. Respiratory depression is uncommon after a loading dose, but should be anticipated with infusions of any duration. Sedation is quickly reversed after short-term infusions are discontinued. However, terminal half-lives of three to eight times normal have been reported with extended administration.[66] In addition, prolonged elimination times have been associated with critical illness and hepatorenal dysfunction. Others have recently discussed its use in this setting.[67]

Although intravenous paraldehyde has been abandoned, this agent is still useful. The current formulation is licensed only for enteral use. It can be given every 3 hours through a Teflon-coated nasogastric tube or rectally via a rubber catheter. The enteral form can be filtered for intramuscular injection; it should be given deeply into the lateral gluteal muscles, with special care taken to avoid the sciatic nerves. This route of administration should be confined to a few doses, when rectal or oral treatment is not feasible.

Isoflurane, an inhaled anesthetic, controls refractory status epilepticus; however, it is difficult to deliver such a gas outside of the operating suite or the recovery area. It has no

known advantage over intravenous anticonvulsants and can raise ICP.

Propofol has been reported to be effective in the treatment of refractory status epilepticus, but direct comparisons with other agents have shown mixed results.[68,69] It may offer a lower risk of ventilatory depression and promote more rapid awakening compared with other drugs when it is discontinued. Early fears of a possible proconvulsant effect appear to be unfounded, although withdrawal convulsions may occur if the drug is abruptly terminated. A dosage range of 1 to 15 mg/kg/hr has been studied,[70] although the actual upper limit is not known. Acidosis and oxygenation difficulties have been reported in children.[71] Mortality with its use appears to be greater than with midazolam.[72] Careful monitoring of creatine kinase and oxygen saturation would be prudent.[73]

The role of the newer anticonvulsant agents has yet to be determined. Intravenous valproate may emerge as an important drug for the treatment of several forms of status epilepticus.[74] Topiramate may also be useful for refractory status epilepticus,[75] especially when an intravenous form becomes available.

ACKNOWLEDGMENT

The authors would like to recognize the contributions of Christopher Dunatov, MD, to the previous edition of this chapter.

Fountain NB, Adams RE: Midazolam treatment of acute and refractory status epilepticus. Clin Neuropharmacol 1999;22:261-267.

This thorough review discusses both the pharmacology of and the data supporting midazolam use in patients with status epilepticus. Practical clinical hints are conveyed regarding specific advantages and potential disadvantages of midazolam.

Lothman E: The biochemical basis and pathophysiology of status epilepticus. Neurology 1990;40(suppl 2):13-23.

A classic, comprehensive summary of clinical and experimental evidence explaining the alterations in systemic physiology and brain metabolism that occur during prolonged seizures.

Shneker BF, Fountain NB: Assessment of acute morbidity and mortality in nonconvulsive status epilepticus. Neurology 1996;47:83-89.

A retrospective review of 100 patients with nonconvulsive status epilepticus found a mortality rate of 18% that correlated with the underlying cause, severe impairment of mental status, and development of acute complications. Generalized spike-and-wave discharges did not correlate with mortality. This is the largest series to date.

Towne AR, Waterhouse EJ, Boggs JG, et al: Prevalence of nonconvulsive status epilepticus in comatose patients. Neurology 2000;54:340-345.

A retrospective review of the EEG recordings of 236 comatose ICU patients without clinical signs of status epilepticus found that nonconvulsive status epilepticus occurred in 18%. These findings suggest that EEG is an essential part of the coma evaluation.

Treiman DM, Meyers PD, Walton NY, et al: A comparison of four treatments for generalized convulsive status epilepticus. N Engl J Med 1998;339:792-798.

This 5-year randomized, double-blind, multicenter trial of four intravenous regimens in the first-line treatment of generalized convulsive status epilepticus demonstrated that lorazepam is more effective than phenytoin. Although lorazepam was not found to be more efficacious than phenobarbital or diazepam and phenytoin, it was easier to use and therefore recommended for initial intravenous treatment. There were no significant differences in side effects among the four treatment groups.

Chapter 54

NEUROMUSCULAR DISORDERS IN THE ICU

Vern C. Juel • Thomas P. Bleck

KEY POINTS

1. Respiratory dysfunction due to neuromuscular disease typically presents with a combination of **upper airway dysfunction and diminished tidal volume** (V_T).
2. Along with vital capacity, **trended measurement of the maximum inspiratory pressure** (PImax or negative inspiratory force [NIF]) is a useful index of ventilatory capacity. Inability to maintain a PImax greater than 20 to 25 cm H_2O usually indicates a need for mechanical ventilatory assistance.
3. **Autonomic failure and pulmonary embolism** are now the major causes of mortality in Guillain-Barré syndrome.
4. **Evidence-based guidelines for Guillain-Barré syndrome immunotherapy** have been published by the Quality Standards Subcommittee of the American Academy of Neurology. Plasma exchange is recommended for adult patients who cannot walk within 4 weeks of symptom onset. Intravenous immune globulin (IVIg) is recommended in these patients within 2 or possibly 4 weeks of symptom onset. Plasma exchange and IVIg are considered equivalent in efficacy, and no additional benefit is conferred by combining these treatments. In light of the therapeutic equivalence, the decision whether to employ plasma exchange or IVIg in treating acute Guillain-Barré syndrome may be determined by resource availability and by avoiding potential side effects related to a patient's medical comorbidities.
5. **In the initial North American outbreak of West Nile virus,** about 10% of infected patients experienced flaccid weakness with clinical features resembling Guillain-Barré syndrome.
6. Approximately 20% of patients with myasthenia gravis develop myasthenic crisis with **respiratory failure requiring mechanical ventilation.**
7. **Critical illness polyneuropathy** is a widespread axonal peripheral neuropathy that develops in the context of multiple organ failure and sepsis. Critical illness polyneuropathy is possibly the most common neuromuscular cause of prolonged ventilator dependency in patients without prior known neuromuscular disease.
8. **Acute quadriplegic myopathy** has developed most frequently in the setting of severe pulmonary disorders, in which neuromuscular blockade is used to facilitate mechanical ventilation and high-dose corticosteroids are concurrently administered. Given the growing recognition of acute quadriplegic myopathy, the use of high-dose corticosteroids should be avoided, if possible, when neuromuscular blockade is required.

Abnormal neuromuscular function may precipitate a patient's admission to an ICU or may develop as a consequence of another critical illness and its treatment. This chapter focuses primarily on respiratory failure as a consequence of neuromuscular disease but also addresses autonomic dysfunction occurring in this setting. To facilitate understanding of the concepts involved, a brief review of the motor unit and its physiology is provided and specific muscles critical to ventilation are identified.

THE MOTOR UNIT AND ITS PHYSIOLOGY

Central nervous system activity designated for motor output is ultimately conducted to lower motor neurons, also known as alpha motor neurons. A motor unit is composed of a lower motor neuron and its distal ramifications, its neuromuscular junctions, and the muscle fibers it innervates. The cell bodies of the lower motor neurons are located in the brainstem for cranial musculature and in the anterior horn of the spinal cord for somatic muscles. At the level of the brainstem or spinal cord, the motor neurons receive various excitatory and inhibitory inputs. Motor axons project through the subarachnoid space and penetrate the dura mater as nerve roots. They may join with other motor axons and with sensory and autonomic fibers in a plexus and then travel in peripheral nerves to the muscles they innervate. Alpha motor neurons are myelinated, a feature that accelerates nerve impulse propagation. The multiple terminal ramifications of the motor neuron synapse on individual muscle fibers.

The motor axon communicates with muscle via a specialized area termed the neuromuscular junction. On the presynaptic side of the neuromuscular junction the neurotransmitter acetylcholine is synthesized, packaged in vesicles, and stored for release. Depolarization of the axon opens presynaptic voltage-gated calcium channels, which activate the molecular machinery responsible for drawing the vesicles

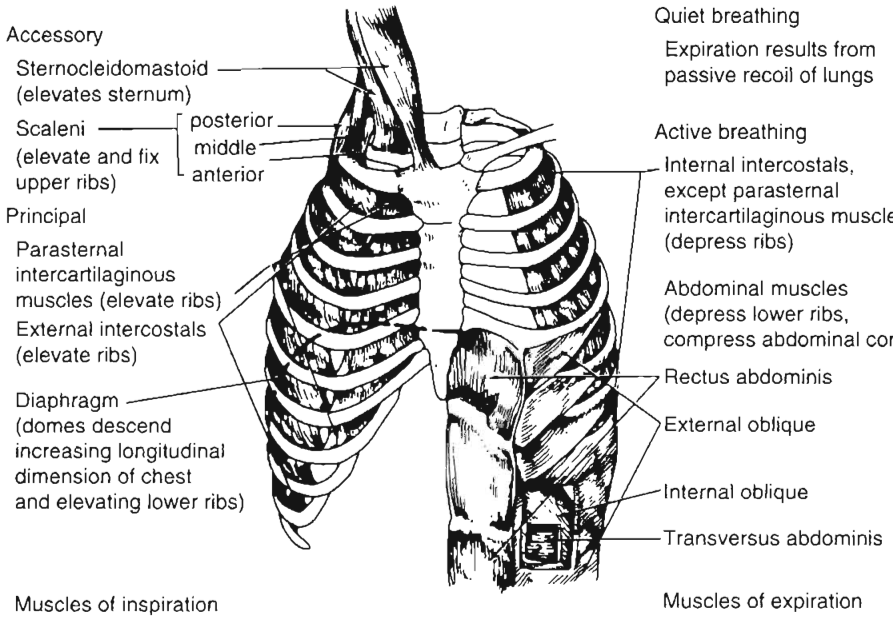

FIGURE 54–1. Major respiratory muscles. Inspiratory muscles are indicated on the left and expiratory muscles are indicated on the right. (From Garrity ER: Respiratory failure due to disorders of the chest wall and respiratory muscles. In MacDonnell KF, Fahey PJ, Segal MS [eds]: Respiratory Intensive Care. Boston, Little, Brown, 1987, p 313.)

to the presynaptic membrane. The vesicles then fuse with the membrane and release acetylcholine into the synaptic cleft. Acetylcholine molecules bind to receptors on the postsynaptic membrane and cause an influx of sodium, which in turn increases the muscle end-plate potential. When the end-plate potential exceeds the threshold level, the muscle membrane becomes depolarized. This depolarization releases calcium ions from the sarcoplasmic reticulum, and muscle contraction occurs through a process known as excitation-contraction coupling. After activating the acetylcholine receptor complex, the acetylcholine molecule is degraded by cholinesterase; the choline released by this reaction is then recycled by the presynaptic neuron.

MUSCLES OF RESPIRATION

Three muscle groups may be defined based on their importance for respiration, as follows (Fig. 54-1):[1]

1. *Upper airway muscles:* palatal, pharyngeal, laryngeal, and lingual
2. *Inspiratory muscles:* sternomastoid, diaphragm, scalenes, and parasternal intercostals
3. *Expiratory muscles:* internal intercostal muscles (except for parasternals) and abdominal muscles

The upper airway muscles receive their innervation from the lower cranial nerves. Sternomastoid innervation arrives predominantly from cranial nerve XI, with a small contribution from C2. The phrenic nerve originates from cell bodies located between C3 and C5, with a maximum contribution from C4, and innervates the diaphragm. Innervation to the scalenes arises from C4 to C8, whereas that of the parasternal intercostals is from T1 to T7. The intercostal muscles receive innervation from T1 to T12, and the abdominal musculature receive it from T7 to L1. Reference to this innervation scheme is important in understanding the effects of spinal cord and nerve root injuries on respiration and for the differential diagnosis of disorders producing apparently diffuse weakness.

CLINICAL PRESENTATION OF NEUROMUSCULAR RESPIRATORY FAILURE

Patients experiencing respiratory dysfunction due to neuromuscular disease typically present with a combination of upper airway dysfunction and diminished tidal volume (V_T). Difficulty with swallowing liquids, including respiratory secretions, is the most typical presentation of pharyngeal weakness, although some patients have an equal or greater degree of difficulty with solid food. A hoarse or nasal voice may also signal problems with the upper airway. These conditions are noted in patients who are at risk for aspiration and present with difficulty with attempts at negative-pressure ventilation (cuirass or iron lung), because the weakened muscles may not be able to keep the airway open as the pressure falls.[2] Paradoxical abdominal movement (inward movement of the abdomen during inspiration) is an important sign of diaphragmatic weakness.[3]

Loss of V_T occurs most dramatically with diaphragmatic weakness but also follows insults that affect the ability of the parasternal intercostals to keep the chest wall expanded against negative intrapleural pressure. This is most apparent in lower cervical spinal cord injuries where atelectasis commonly develops despite preserved phrenic nerve function. This problem usually diminishes over weeks as the parasternal intercostal muscles develop spasticity.

Patients with progressive generalized weakness (e.g., with Guillain-Barré syndrome) commonly begin to lose V_T before developing upper airway weakness. To maintain minute ventilation, and therefore carbon dioxide excretion, a patient's respiratory rate increases. Respiratory rate is thus one of the most important clinical parameters to monitor. As the vital capacity falls from the norm of about 65 to 30 mL/kg, a patient's cough weakens and clearing secretions becomes difficult. A further decrease of vital capacity to 20 to 25 mL/kg results in an impaired ability to sigh with progressive atelectasis. At this point hypoxemia may be present because of ventilation-perfusion mismatching and because an increasing percentage of V_T is used to ventilate dead space. Before the vital capacity reaches 15 mL/kg, a patient should

be in an ICU because respiratory failure is imminent and endotracheal intubation should be considered. The precise point at which mechanical ventilation is necessary varies with the patient, the underlying condition, and especially with the likelihood of a rapid response to treatment.

Regardless of the vital capacity, however, indications for intubation and mechanical ventilation include evidence of fatigue, hypoxemia despite supplemental oxygen administration, difficulty with secretions, and a rising $PaCO_2$. In the absence of hypercapnia, occasional patients (e.g., those with myasthenia gravis) can be managed under very close observation in an ICU with less invasive techniques (e.g., bilevel positive airway pressure [BiPAP]).[4]

In addition to vital capacity, trended measurements of the maximum inspiratory pressure (PImax, more typically recorded as negative inspiratory force [NIF]) are useful indicators of ventilatory capacity. Inability to maintain a PImax greater than 20 to 25 cm H_2O usually indicates a need for mechanical ventilation. Although the maximum expiratory pressure (PEmax) is a more sensitive indicator of weakness,[5] it has not proved to be as useful as an indicator of the need for mechanical ventilation. A more detailed discussion of these variables and their use may be found elsewhere.[6,7]

Because a patient with neuromuscular respiratory failure has intact ventilatory drive,[8] the fall in V_T is initially matched by an increase in respiratory rate, keeping the $PaCO_2$ normal or low until the vital capacity becomes dangerously reduced. Many patients initially maintain their $PaCO_2$ in the range of 35 mm Hg because of either (1) a subjective sense of dyspnea at low V_T or (2) hypoxia from atelectasis and increasing dead space. When the $PaCO_2$ begins to rise in this circumstance, abrupt respiratory failure may be imminent.

The modest degree of hypoxia in most of these patients worsens when the $PaCO_2$ begins to rise, displacing more oxygen from the alveolar gas. However, aspiration pneumonia and pulmonary embolism are also frequent causes of hypoxemia in these patients. To determine the relative contributions of these conditions to a patient's hypoxemia, one can use a simplified version of the alveolar gas equation as follows (derived elsewhere)[6,7]:

$$P_AO_2 = P_IO_2 - (PaCO_2/R)$$

where P_AO_2 is the alveolar partial pressure of oxygen, P_IO_2 is the partial pressure of inspired oxygen (in room air, 150 mm Hg), and R is the respiratory quotient (on most diets, about 0.8). This allows estimation of the alveolar-arterial oxygen difference ($P_AO_2 - PaO_2$). Under ideal circumstances in young people breathing room air this value is about 10 mm Hg, but it rises to about 100 mm Hg when the fraction of inspired oxygen (F_IO_2) is 1.0. The alveolar air equation allows one to factor out the contribution of hypercarbia to the decrease in arterial partial pressure of oxygen (PaO_2); it should be used to determine whether there is a cause of significant hypoxemia in addition to the displacement of oxygen by carbon dioxide.

Patients with orbicularis oris weakness may have artifactually low vital capacity and NIF measurements because they cannot form a tight seal around the spirometer mouthpiece. The need for nursing and respiratory therapy personnel who are experienced in the care of these patients is thus underscored. It is also important for physicians to observe these patients directly rather than relying solely on reported measurements. The physical findings associated with neuromuscular respiratory failure are reviewed elsewhere.[6,7] Among the most important findings are rapid, shallow breathing,[9] the recruitment of accessory muscles, and paradoxical movement of the abdomen during the respiratory cycle. Fluoroscopy of the diaphragm is occasionally valuable for the diagnosis of diaphragmatic dysfunction.[10]

Autonomic dysfunction commonly accompanies some of the neuromuscular disorders requiring critical care, such as Guillain-Barré syndrome, botulism, and porphyria (Table 54-1). In Guillain-Barré syndrome (discussed later) dysautonomia is common and may arise in parallel with weakness or may follow the onset of the motor disorder after a week or more.

NEUROMUSCULAR DISORDERS

Many chronic neuromuscular disorders and other central nervous system conditions affecting the suprasegmental innervation and control of respiratory muscles eventually compromise ventilation. In this chapter, however, we emphasize the more common acute and subacute neuromuscular disorders that precipitate or prolong critical illness due to ventilatory failure and autonomic dysfunction. A more complete listing of neuromuscular diseases appears in Table 54-1; reviews of this subject[11,12] or the references listed in Table 54-1 may be consulted for details of the more rare disorders. Some of the diseases listed (e.g., Lambert-Eaton myasthenic syndrome) rarely cause respiratory failure in isolation but may be contributing causes in the presence of other conditions,[13] such as neuromuscular junction blockade intended only for the duration of a surgical procedure.[14]

NEUROMUSCULAR DISEASES PRECIPITATING CRITICAL ILLNESS

Guillain-Barré Syndrome

Guillain-Barré syndrome, or acute inflammatory demyelinating polyradiculoneuropathy, is typically a motor greater than sensory peripheral neuropathy with subacute onset, monophasic course, and nadir within 4 weeks. Although the precise etiology is unknown, Guillain-Barré syndrome is immune mediated and related to antibodies directed against peripheral nerve components. Approximately 1.7 cases occur per 100,000 population per year.[28] Most patients suffer a demyelinating neuropathy, but in about 5% of cases the condition is a primary axonopathy.[29] Numerous antecedents have been implicated[30]; the more frequent ones are listed in Table 54-2. The association with antecedent infections suggests that certain agents may elicit immune responses involving antibodies that cross-react with peripheral nerve gangliosides. In particular, the development of ganglioside antibodies has been observed in Guillain-Barré syndrome after *Campylobacter jejuni* infections, such as GM_1 antibodies in axonal forms of Guillain-Barré syndrome[31] and GQ_{1b} antibodies in the Miller-Fisher variant of Guillain-Barré syndrome.[32]

The initial findings of patients with Guillain-Barré syndrome are subacute and progressive weakness, usually most marked in the legs, associated with sensory complaints but without objective signs of sensory dysfunction.[33] Deep tendon reflexes are often significantly reduced or absent at presentation, though this finding may take several days to develop.

TABLE 54–1. NEUROMUSCULAR CAUSES OF ACUTE RESPIRATORY FAILURE

Location	Disorder	Associated Autonomic Dysfunction?
Spinal cord	Tetanus[15]	Frequent
Anterior horn cell	Amyotrophic lateral sclerosis[16]	No
	Poliomyelitis	No
	Rabies	Frequent
	West Nile virus flaccid paralysis	No
Peripheral nerve	Guillain-Barré syndrome	Frequent
	Critical illness polyneuropathy	No
	Diphtheria	No, but cardiomyopathy and arrhythmias may occur
	Porphyria	Occasional
	Ciguatoxin (ciguatera poisoning)	Occasional
	Saxitoxin (paralytic shellfish poisoning)	No
	Tetrodotoxin (pufferfish poisoning)	No
	Thallium intoxication	No
	Arsenic intoxication[17,18]	No
	Lead intoxication	No
	Buckthorn neuropathy	No
Neuromuscular junction	Myasthenia gravis	No
	Botulism[19]	Frequent
	Lambert-Eaton myasthenic syndrome[20]	Yes, frequent dry mouth and postural hypotension
	Hypermagnesemia[21]	No
	Organophosphate poisoning	No
	Tick paralysis	No
	Snake bite	No
Muscle	Polymyositis/dermatomyositis	No
	Acute quadriplegic myopathy	No
	Eosinophilia-myalgia syndrome[22]	No
	Muscular dystrophies[23]	No, but cardiac rhythm disturbances may occur
	Carnitine palmitoyl transferase deficiency	No
	Nemaline myopathy[24]	No
	Acid maltase deficiency[25]	No
	Mitochondrial myopathy[26]	No
	Acute hypokalemic paralysis	No
	Stonefish myotoxin poisoning	No
	Rhabdomyolysis	No
	Hypophosphatemia[27]	No

The cerebrospinal fluid (CSF) typically reveals an albuminocytologic dissociation or elevated protein content without pleocytosis; this may not evolve until the second week of illness. The major reason to examine the CSF is to preclude other diagnoses. Although mild CSF lymphocytic pleocytosis (10 to 20 cells/mm^3) may suggest the possibility of associated human immunodeficiency virus (HIV) infection, in most patients, the nucleated cell count is less than 10 cells/mm^3.[34] Although they may be normal initially, results of electrodiagnostic studies (motor and sensory nerve conduction studies and needle electromyography) often reflect segmental nerve demyelination with multifocal conduction blocks, temporally dispersed compound muscle action potentials, slowed conduction velocity, and prolonged or absent F waves.[35] Differential diagnostic considerations for patients with suspected Guillain-Barré syndrome are primarily those listed in the "Peripheral Nerve" section of Table 54-1.

The components of treatment for patients with Guillain-Barré syndrome are as follows:

- Management of ventilatory failure
- Management of autonomic dysfunction
- Meticulous nursing care
- Psychologic support
- Physical and occupational therapy
- Prevention of deep venous thrombosis
- Nutritional support
- Early planning for rehabilitation
- Immunotherapy for the underlying autoimmune process

Patients with Guillain-Barré syndrome with evolving respiratory failure should generally be intubated when the vital capacity falls to about 15 mL/kg or when difficulty with secretions begins because the response to treatment is slow. If a patient has been immobile for several days before intubation and neuromuscular junction blockade is needed, a nondepolarizing agent should be used to avoid transient hyperkalemia. Oral intubation is again being viewed as preferable to the nasal route, because the endotracheal tube is frequently required for a week or longer, raising the risk of sinusitis with nasal intubation.

Many patients are too weak to trigger the ventilator; in such cases, the assist/control or intermittent mandatory ventilation mode is initiated. Weaning patients with Guillain-Barré syndrome from mechanical ventilation must wait for adequate improvement in strength. We usually shift to pressure support ventilation for weaning, although evidence of its superiority over intermittent mandatory ventilation or synchronized intermittent mandatory ventilation modes is only anecdotal. Although the majority of patients require mechanical ventilation for less than 4 weeks, as many as one fifth need 2 or more months of support before they can breathe without assistance. Improvement in vital capacity to greater than 15 mL/kg and in NIF to greater than 25 cm H_2O suggests that a patient has improved enough to begin

TABLE 54–2. MAJOR ANTECEDENTS OF GUILLAIN-BARRÉ SYNDROME

Frequent
Upper respiratory tract infections
Campylobacter jejuni enteritis
Cytomegalovirus (CMV) infection
Epstein-Barr virus (EBV) infection
Hepatitis A infection
Hepatitis B infection
Hepatitis C infection
HIV infection
Infrequent
Mycoplasma pneumoniae infection
Haemophilus influenzae infection
Leptospira icterohaemorrhagiae infection
Salmonellosis
Rabies vaccine
Tetanus toxoid
Bacille Calmette-Guérin immunization
Sarcoidosis
Systemic lupus erythematosus
Lymphoma
Trauma
Surgery
Questionable
Hepatitis B vaccine
Influenza vaccine
Hyperthermia
Epidural anesthesia

weaning from the ventilator. A formula using a combination of ventilatory and gas exchange variables may allow more accurate determination of a patient's ability to be weaned.[36]

Autonomic dysfunction related to Guillain-Barré syndrome most typically presents as a hypersympathetic state and is often heralded by unexplained sinus tachycardia. The blood pressure may fluctuate wildly. Patients may rarely experience bradycardic episodes, which may require temporary pacing. Autonomic surges during tracheal suctioning or due to a distended viscus may be very dramatic and should be minimized. Autonomic failure and pulmonary embolism are now the major causes of mortality in Guillain-Barré syndrome.

Nursing care for patients with Guillain-Barré syndrome is similar to that for other paralyzed and mechanically ventilated patients, but special care must be taken to remember that patients with Guillain-Barré syndrome are completely lucid. In addition to explaining any procedures carefully, arranging for distractions during the daytime (e.g., television, movies, conversation, visitors) and adequate sleep at right is very important. For the most severely affected patients, sedation should be considered. In concert with physical and occupational therapists, passive exercise should be performed frequently throughout the day.

Deep venous thrombosis is a significant danger for patients with Guillain-Barré syndrome. Episodic arterial desaturation is a common event, presumably owing to transient mucus plugging; submassive pulmonary emboli may therefore be overlooked. Adjusted-dose heparin (to slightly prolong the partial thromboplastin time) should be given, and sequential compression devices should be used on the legs; therapeutic anticoagulation may be considered. The risk of fatal pulmonary embolism extends through the initial period of improvement until patients are ambulatory.

Nutritional support should begin as soon as a patient is admitted, with appropriate concern for the risk of aspiration.[37] Most mechanically ventilated patients with Guillain-Barré syndrome can be fed via soft, small-caliber feeding tubes; autonomic dysfunction affecting the gut occasionally requires total parenteral nutrition.

Immunotherapy for Guillain-Barré syndrome includes removal of autoantibodies with plasma exchange or immune modulation with high-dose IVIg. The efficacy of plasma exchange has been evaluated in a Cochrane systematic review of six class II trials comparing plasma exchange alone with supportive care.[38] Most of the trials employed up to five plasma exchanges of 50 mL/kg over 2 weeks. In a large North American trial,[39] the time needed to improve one clinical grade (being weaned from the ventilator or being able to walk) was reduced by 50% in the plasma exchange group by comparison with the control group. There was no significant benefit when plasma exchange was begun later than 2 weeks after symptom onset. A meta-analysis demonstrated more rapid recovery in ventilated patients treated with plasma exchange within 4 weeks of onset.[38] The optimal number of plasma exchanges has been assessed in patients with mild (unable to run), moderate (unable to stand without assistance), and severe (requiring mechanical ventilation) Guillain-Barré syndrome by the French Cooperative Group.[40] On the basis of this trial, two exchanges are better than none in mild Guillain-Barré syndrome; four are better than two in moderate Guillain-Barré syndrome; and six are no better than four in severe Guillain-Barré syndrome. Albumin is the preferred replacement solution.[41] Treatment with IVIg for Guillain-Barré syndrome has also been examined in a Cochrane systematic review. Three randomized controlled trials demonstrated class I evidence that IVIg (2 g/kg over 2 to 5 days) is as effective as plasma exchange in Guillain-Barré syndrome patients with impaired walking.[42] Complication rates were somewhat higher in the plasma exchange groups. A large, international, multicenter, randomized trial compared plasma exchange (50 mL/kg × 5 exchanges over 8 to 13 days), IVIg (0.4 g/kg × 5 days), and plasma exchange followed by IVIg.[43] No significant outcome differences between these therapies were found with respect to functional improvement at 4 weeks or at 48 weeks.

Evidence-based guidelines for Guillain-Barré syndrome immunotherapy have been published by the Quality Standards Subcommittee of the American Academy of Neurology.[44] Plasma exchange is recommended for adult patients who cannot walk within 4 weeks of symptom onset. IVIg is recommended in these patients within 2 or possibly 4 weeks of symptom onset. Both treatments are deemed equivalent in efficacy, and no additional benefit is conferred by combining treatment with plasma exchange and IVIg. In light of their therapeutic equivalence, the decision whether to employ plasma exchange or IVIg in treating acute Guillain-Barré syndrome may be determined by resource availability and by avoiding potential side effects related to a patient's medical comorbidities. Patients with heart disease, renal insufficiency or failure, hyperviscosity, or IgA deficiency may be more susceptible to complications of treatment with IVIg, whereas plasma exchange may be complicated in patients with labile blood pressure, septicemia, and significant venous access problems.

Despite the autoimmune pathophysiology of Guillain-Barré syndrome and the efficacy of corticosteroids in more chronic forms of inflammatory neuropathy, corticosteroids

have not demonstrated effectiveness in Guillain-Barré syndrome and are therefore not recommended for Guillain-Barré syndrome treatment.[44] A large, multicenter trial failed to demonstrate efficacy of high-dose intravenous methylprednisolone,[45] and another large, multicenter trial demonstrated no added clinical benefit in combined treatment with IVIg and methylprednisolone.[46]

West Nile Virus Acute Flaccid Paralysis Syndrome

The large outbreak of West Nile virus encephalitis in the summer of 1999 in New York City marked the emergence of a relatively new cause for neuromuscular weakness with the potential for neuromuscular respiratory compromise. West Nile virus is a flavivirus transmitted between birds and mosquitoes. Humans may acquire West Nile virus from the bite of an infected *Culex* species mosquito, and a corresponding peak in human disease occurs in the late summer and fall. West Nile virus may also be transmitted to humans by organ transplantation,[47] blood and blood product transfusion,[48] transplacental exposure,[49] breast feeding,[50] and percutaneous laboratory injuries.[51] About 20% of humans experience a mild flulike illness lasting 3 to 6 days, and about 1 in 150 develop central nervous system disease, which usually presents as meningoencephalitis.[52]

In the initial North American outbreak of West Nile virus, about 10% of infected patients experienced flaccid weakness with clinical features resembling Guillain-Barré syndrome.[53] In one report from the original outbreak, a patient developed electromyographic evidence for segmental demyelination compatible with Guillain-Barré syndrome.[54] Although patients with West Nile virus infection exhibit a spectrum of clinical weakness,[55] the most prominent and distinctive syndrome documented in several subsequent reports of West Nile virus infection is an acute "poliomyelitis-like" or acute flaccid paralysis syndrome with pathology localizing to the ventral horns of the spinal cord and/or ventral roots.[56-62] These patients developed acute, asymmetrical, flaccid weakness in the absence of sensory abnormalities, diffuse areflexia, or bowel/bladder dysfunction. Some of the patients experienced concurrent meningoencephalitis, and a few required mechanical ventilation.[57,58] West Nile virus acute flaccid paralysis syndrome may occur in the absence of overt encephalitic signs (e.g., fever, confusion) or meningismus. Although the risk for West Nile virus encephalitis is significantly increased with age,[63] West Nile virus acute flaccid paralysis syndrome occurs in relatively younger patients.[56-62]

Electrodiagnostic studies in patients with West Nile virus acute flaccid paralysis syndrome demonstrate normal sensory potentials, the absence of findings suggesting segmental demyelination (e.g., motor conduction block, reduced conduction velocities, prolonged distal and F-wave latencies), low amplitude compound muscle action potentials in affected regions, and marked denervation changes in affected limb and in corresponding paraspinal muscles on needle electromyography. Corresponding MRI findings are sometimes observed and include abnormal signal in the spinal cord on T2-weighted images[60,61] and abnormal enhancement of the nerve roots and cauda equina.[59,60] CSF analysis usually demonstrates mild pleocytosis with lymphocytic predominance, mild to moderate protein elevation, and normal glucose.[64] Prognosis for recovery of strength in these patients appears poor.[65]

West Nile virus infection may be diagnosed by demonstrating West Nile virus RNA in serum, CSF, or other tissues by reverse-transcriptase polymerase chain reaction, although this is insensitive.[66] More commonly, a diagnosis is made by demonstration of West Nile virus IgM in CSF or serum by antibody-capture enzyme-linked immunosorbent assay. When serum West Nile virus IgM is present, diagnosis is confirmed by a fourfold increase in West Nile virus IgG titers between acute and convalescent sera obtained 4 weeks apart. Positive IgM and IgG antibody titers should be confirmed by plaque-reduction viral neutralization assay to exclude false-positive results related to other flaviviral infections such as St. Louis encephalitis. Serology may not become positive until 8 days after symptom onset.[52]

Particularly in the absence of a more typical encephalitic presentation of West Nile virus infection, a high index of clinical suspicion is needed to make a diagnosis of West Nile virus acute flaccid paralysis syndrome and to distinguish such cases from Guillain-Barré syndrome in patients presenting with acute weakness in the late summer or fall. Electrodiagnostic studies may help localize the pathology to the ventral horns of the spinal cord or ventral roots in West Nile virus cases and to exclude findings of segmental demyelination suggesting Guillain-Barré syndrome. CSF should also be evaluated to help discriminate between the albuminocytologic dissociation of Guillain-Barré syndrome and the lymphocytic pleocytosis observed in West Nile virus infection.

Although there is currently no specific treatment for West Nile virus acute flaccid paralysis syndrome, a multicenter study to evaluate the efficacy of Israeli IVIg in patients with West Nile virus meningoencephalitis or weakness began in the summer of 2003. The IVIg for this study contains high levels of West Nile virus antibodies because it was prepared from sera obtained after an Israeli West Nile virus epidemic in 2000.[67] Two candidate vaccines against West Nile virus are also being evaluated.[64]

Myasthenia Gravis

Myasthenia gravis is a consequence of autoimmune attack on the acetylcholine receptor complex at the postsynaptic membrane of the neuromuscular junction. This process results in clinical weakness with a fluctuating pattern that is most marked after prolonged muscle exertion. Myasthenia gravis occurs at a higher rate in early adulthood in women, but in later life the incidence rates for men and women become nearly equal. The reported prevalence is 14.2 cases per 100,000 population.[68] Myasthenia gravis typically involves ocular muscle weakness producing ptosis and diplopia, as well as bulbar muscle weakness resulting in dysphagia and dysarthria. This diagnosis should be considered in patients who have acute respiratory failure with these cranial nerve findings. A clinical diagnosis of myasthenia gravis may be supported by edrophonium testing, by electrophysiologic studies including repetitive nerve stimulation studies and single-fiber electromyography, and by acetylcholine receptor and muscle-specific receptor tyrosine kinase (MuSK) antibody testing.

Approximately 20% of patients with myasthenia gravis develop myasthenic crisis with respiratory failure requiring mechanical ventilation.[69] Intensivists may also encounter myasthenic patients for management of complications of immunomodulating treatment or for postoperative care after thymectomy. The most common precipitating factors for myasthenic crisis include bronchopulmonary infections

(29%) and aspiration (10%).[70] Other precipitating factors include sepsis, surgical procedures, rapid tapering of immune modulation, beginning treatment with corticosteroids, pregnancy, and exposure to drugs that may increase myasthenic weakness (Table 54-3).[71] Patients with myasthenia gravis are exceptionally sensitive to nondepolarizing neuromuscular blocking agents, but are resistant to depolarizing agents.[72] Thymomas are associated with more fulminant disease and have been identified in about one third of patients in myasthenic crisis.[70]

Although sometimes less appreciated than respiratory muscle weakness, upper airway muscle weakness is a common mechanism leading to myasthenic crisis.[73] Oropharyngeal and laryngeal muscle weakness may result in upper airway collapse with obstruction, along with inability to swallow secretions that may also obstruct the airway and become aspirated. Because direct assessment of oropharyngeal muscle strength is impractical, a focused history and examination to assess surrogate muscles in the head and neck region is important. Findings of bulbar myasthenia associated with upper airway compromise include flaccid dysarthria with hypernasal, staccato, or hoarse speech, dysphagia sometimes associated with nasal regurgitation, and chewing fatigue. Patients may exhibit facial weakness with difficulty holding air within the cheeks. Jaw closure is often weak and cannot be maintained against resistance. Patients with myasthenic tongue weakness may be unable to protrude the tongue into either cheek. Although neck flexors are often weaker, a dropped head syndrome due to neck extensor weakness may occur. Vocal cord abductor paralysis may produce laryngeal obstruction with associated stridor.[74,75]

Patients with features of impending myasthenic crisis including severe bulbar weakness, marginal vital capacity (less than 20 to 25 mL/kg), weak cough with difficulty clearing secretions from the airway, or paradoxical breathing while supine should be admitted to an ICU and made NPO to prevent aspiration.[76] Serial vital capacity and NIF measurements may be used to monitor ventilatory function in impending myasthenic crisis. However, with significant bulbar weakness, these measurements are often inaccurate, owing to difficulty sealing the lips around the spirometer mouthpiece and to inability to seal the nasopharynx. Vital capacity measurements may not reliably predict respiratory failure in myasthenia gravis, due to the fluctuating nature of myasthenic weakness.[77] The criteria for intubation and mechanical ventilation are similar to those discussed earlier for Guillain-Barré syndrome. If the upper airway is competent and there is no difficulty handling secretions or gross hypercapnia ($PaCO_2 > 50$ mm Hg), intermittent nasal BiPAP may be a useful temporizing measure.[4] The majority of patients who develop hypercapnia in myasthenic crisis require intubation, as do those who are becoming fatigued.

Plasma exchange is an effective short-term immunomodulating treatment for myasthenic crisis and for surgical preparation in symptomatic myasthenic patients. Significant strength improvement in myasthenic crisis is well documented in several series,[78-82] although there have been no controlled clinical trials. We perform a series of five to six exchanges of 2 to 3 L every other day. Onset of improved strength is variable but generally occurs after two to three exchanges.

IVIg may represent an alternative short-term treatment for myasthenic exacerbations or crises in patients who are poor candidates for plasma exchange owing to difficult vascular access or septicemia. Comparable efficacy for plasma exchange and IVIg was demonstrated in myasthenic exacerbations and crises in a relatively small randomized, controlled trial of IVIg at 1.2 and 2.0 g/kg over 2 to 5 days.[83] However, in a retrospective multicenter study of myasthenic crisis, plasma exchange proved more effective than IVIg in ability to extubate at 2 weeks and in 1-month functional outcome.[82] Treatment failures to IVIg subsequently responding to plasma exchange have also been reported.[84] Recent experience with preoperative IVIg for thymectomy in myasthenia gravis suggests that the time course of maximal response may be considerably delayed in some patients.[85]

Corticosteroids (e.g., prednisone, 1 mg/kg/day) are occasionally used in prolonged myasthenic crises that fail to respond to treatment with plasma exchange or IVIg. If begun early in the course of myasthenic crisis, the transient increase in myasthenic weakness associated with initiating corticosteroids may prolong mechanical ventilation. When preceded by unequivocal improvement in strength after plasma exchange or IVIg treatment, long-term treatment with corticosteroids may begin with reduced risk for corticosteroid-related exacerbations.

In the context of myasthenic crisis, excessive dosing of cholinesterase inhibitors may superimpose a cholinergic crisis owing to depolarization blockade and result in increased weakness. Other symptoms of cholinergic crisis include muscle fasciculations and prominent muscarinic symptoms, including miosis, excessive lacrimation and salivation, abdominal cramping, nausea, vomiting, diarrhea, thick bronchial secretions, diaphoresis, and bradycardia. Cholinergic crisis is rare in contemporary series of myasthenic crisis,[70] and it is now common practice to avoid repeated dose escalations of cholinesterase inhibitors in impending myasthenic crisis and to discontinue the use of cholinesterase inhibitors after intubation to reduce muscarinic complications. When there is a question of cholinergic excess contributing to respiratory insufficiency, it is most prudent to discontinue all cholinesterase inhibitors, protect the airway, and support respiration as necessary.

Thymectomy may result in long-term improvement in patients with a suspected thymoma or with a life expectancy of more than 10 years. However, a patient in acute respiratory failure is generally considered a poor operative risk, and thymectomy is generally delayed until the patient's condition has improved.[86] Post-thymectomy pain control and ventilatory function may be improved by postoperative administration of epidural morphine.[87]

TABLE 54–3. DRUGS THAT MAY INCREASE WEAKNESS IN MYASTHENIA GRAVIS

- Neuromuscular blocking agents
- Selected antibiotics
  - Aminoglycosides, particularly gentamycin
  - Macrolides, particularly erythromycin and azithromycin
- Selected cardiovascular agents
  - Beta-blockers
  - Calcium channel blockers
  - Procainamide
  - Quinidine
- Quinine
- Corticosteroids
- Magnesium salts
  - Antacids, laxatives, intravenous tocolytics
- Iodinated contrast agents
- D-Penicillamine

NEUROMUSCULAR DISEASES SECONDARY TO CRITICAL ILLNESS AND ITS TREATMENT

Critical Illness Polyneuropathy

Critical illness polyneuropathy is a widespread axonal peripheral neuropathy that develops in the context of multiple organ failure and sepsis. This entity was recognized by several investigators in 1983[88-90] and has been further characterized in large part by Bolton and colleagues.[91,92] In a prospective series of 43 consecutive patients with sepsis and multiorgan failure, 70% developed electrophysiologic evidence of a sensorimotor axonal neuropathy and 15 patients developed difficulty weaning from mechanical ventilation as a consequence of the neuropathy.[93] Critical illness polyneuropathy is possibly the most common neuromuscular cause of prolonged ventilator dependency in patients without prior known neuromuscular disease.[94] Given the limitations to detailed clinical motor and sensory examinations in the setting of critical illness, the clinical features of critical illness polyneuropathy (extremity muscle weakness and wasting, distal sensory loss, and paresthesias) may not be recognized. Deep tendon reflexes are generally reduced or absent. In the setting of superimposed central nervous system insult with pyramidal tract dysfunction, however, deep tendon reflexes may be normal or increased.[95]

Electrodiagnostic studies are important in establishing a diagnosis of critical illness polyneuropathy, because the clinical findings may be unobtainable or indeterminate in this setting.[95] Nerve conduction findings include normal or near-normal conduction velocity and latency values and significantly reduced compound muscle action potential and sensory nerve action potential amplitudes. Needle electrode examination reveals denervation changes that are most marked in distal muscles, including fibrillation potentials, positive sharp waves, and reduced recruitment of motor unit potentials.[96] With recovery over time, the denervation potentials abate and the motor unit potentials become polyphasic and enlarged. Peripheral nerve histopathology has revealed widespread, primary axonal degeneration in distal motor and sensory fibers, and skeletal muscle has exhibited fiber-type grouping.[92]

Although the clinical history is usually adequate to distinguish between critical illness polyneuropathy and Guillain-Barré syndrome, the latter has developed in the context of recent surgery complicated by infection.[97] In some such instances, it may be necessary to differentiate between these two peripheral neuropathic disorders in a patient with extremity weakness and inability to wean from mechanical ventilation. Although only a few severe cases of critical illness polyneuropathy have been associated with facial weakness,[98] facial and oropharyngeal weakness are common in Guillain-Barré syndrome.[97] Dysautonomia and, occasionally, external ophthalmoplegia are also observed in Guillain-Barré syndrome but have virtually never been attributed to critical illness polyneuropathy.[98]

Electrophysiologic findings are also helpful in distinguishing these two disorders. Features of segmental demyelination may be observed in Guillain-Barré syndrome on nerve conduction studies (e.g., reduced conduction velocity, prolonged distal and F-wave latencies, conduction block, and temporal dispersion of compound muscle action potentials); these findings are not observed in critical illness polyneuropathy. Needle electromyographic findings may differ in that relatively less spontaneous activity is observed in clinically weak muscles within the first few days in Guillain-Barré syndrome.[96] Although electrophysiologic studies are quite helpful in demonstrating the classic, demyelinating form of Guillain-Barré syndrome, an electrophysiologic distinction between axonal forms of Guillain-Barré syndrome and critical illness polyneuropathy may not be reliable. The mean CSF protein level in Guillain-Barré syndrome is significantly higher than in critical illness polyneuropathy, although there is overlap between these populations.[96] Peripheral nerve histopathology may also distinguish between these two groups, because segmental demyelination and inflammatory changes may be observed in Guillain-Barré syndrome and are not seen in critical illness polyneuropathy.[92]

Although overall prognosis in critical illness polyneuropathy is dependent on recovery from the underlying critical illness, most patients who survive experience a functional recovery from the neuropathy within several months.[92] Critical illness polyneuropathy may prolong ventilator dependence, but it does not worsen long-term prognosis.[95] Proper positioning and padding are important to prevent compression neuropathies, because prognosis from superimposed compression neuropathies in the context of critical illness polyneuropathy is less favorable.[95]

The pathophysiology of critical illness polyneuropathy is unknown. No clear metabolic, drug, nutritional, or toxic factors have been identified,[92] although the severity of critical illness polyneuropathy has been correlated with the amount of time in the ICU, the number of invasive procedures, an increased glucose level, a reduced albumin level,[93] and the severity of multiple organ failure.[99] Given the common antecedents of multiple organ failure and sepsis in which significant release of various cytokines occurs, increased microvascular permeability has been postulated to ultimately result in axonal hypoxia and degeneration as a consequence of endoneurial edema.[100]

Prolonged Effects of Neuromuscular Blocking Agents

Prolonged neuromuscular blockade may occur with nondepolarizing agents, particularly when hepatic or renal function is impaired. In one study, administration of vecuronium for 2 or more consecutive days resulted in prolonged neuromuscular blockade and paralysis lasting from 6 hours to 7 days.[101] Although vecuronium is hepatically metabolized, patients with renal failure were susceptible to prolonged effects due to delayed excretion of the active 3-desacetyl metabolite. Acidosis and elevated serum magnesium levels were also associated with prolonged paralytic effects of vecuronium. A peripheral nerve stimulator may be used to monitor muscle twitch responses to a train of four stimuli during use of neuromuscular blocking agents. Drug dosage should be titrated to preserve one or two twitches to avoid overdosing. Two- to 3-hertz repetitive nerve stimulation studies may also be used to confirm neuromuscular blockade when it is suspected.

ACUTE QUADRIPLEGIC MYOPATHY

The syndrome known as acute quadriplegic myopathy[102] or acute myopathy of intensive care[103] was originally described in 1977 in a young woman who developed severe myopathy after treatment of status asthmaticus with high doses of corticosteroids and pancuronium.[104] Subsequent to that report, there have been numerous citations of an acute myopathy

developing in critically ill patients without preexisting neuromuscular disease. Acute quadriplegic myopathy has developed most frequently in the setting of severe pulmonary disorders, in which neuromuscular blockade is used to facilitate mechanical ventilation and high doses of corticosteroids are concurrently administered. In a majority of reported cases, myopathy developed when nondepolarizing neuromuscular blocking agents were used for more than 2 days.[102-112] The development of acute, necrotizing myopathy with myosin loss also occurs in patients receiving high doses of corticosteroids and hypnotic doses of propofol and benzodiazepines to induce paralysis.[113] This observation highlights the significance of high-dose corticosteroid exposure in the development of this syndrome and suggests that paralyzed muscles may be generally susceptible to the toxic effects of corticosteroids. The occurrence of acute quadriplegic myopathy after organ transplantation may be caused by the use of high doses of corticosteroids to prevent graft rejection along with perioperative exposure to neuromuscular blocking agents.[114] Although most cases of acute quadriplegic myopathy have been associated with critical illness, high doses of corticosteroids, and paralytic agents, acute quadriplegic myopathy has developed after isolated corticosteroid exposure,[102,115-118] isolated nondepolarizing neuromuscular blocking agent use,[112,116,119] or neither.[120] Factors that may impair neuromuscular transmission (e.g., hypermagnesemia, aminoglycoside exposure), factors that may slow the elimination of nondepolarizing neuromuscular blocking agents (e.g., hepatic or renal failure), and factors associated with critical illness (e.g., sepsis and acidosis) have also been associated with acute quadriplegic myopathy.[105]

In typical cases, a diffuse, flaccid quadriparesis with involvement of respiratory muscles and muscle wasting evolves after several days of induced paralysis. External ophthalmoparesis has rarely been noted.[121] Sensation remains intact, but deep tendon reflexes are reduced or absent. The creatine kinase level is commonly elevated, but this may not be observed if creatine kinase is measured well after the myopathy has developed. Although the paralysis may be quite severe and may necessitate or prolong mechanical ventilation, the prognosis from the myopathy itself is good, with functional recovery over several weeks to months.[107] Electromyographic findings include reduced amplitude of compound motor action potentials with normal sensory nerve action potentials and normal nerve conduction velocities. M-wave amplitude improvement accompanies clinical recovery.[112] Repetitive nerve stimulation studies may yield significant decremental responses while residual effects of nondepolarizing neuromuscular blocking agents or their active metabolites persist.[105,112] Needle electromyography often reveals small, low-amplitude, polyphasic motor unit potentials exhibiting early recruitment, sometimes along with positive sharp waves and fibrillation potentials.

A spectrum of muscle histologic changes may be observed, ranging from type II fiber atrophy and loss of adenosine triphosphatase (ATPase) reactivity in atrophic fibers to fiber necrosis in severe cases. However, the distinctive finding in most cases of acute quadriplegic myopathy is an extensive loss of thick filaments corresponding to myosin loss.[102,106,111,115,120] This finding may be demonstrated with immunohistochemical staining or electron microscopy. The increased expression of steroid receptors in denervated and immobilized muscle[122] may render these muscles susceptible to toxic catabolic effects of steroids.[102] Given the growing recognition of acute quadriplegic myopathy, the use of high doses of corticosteroids should be avoided, if possible, when neuromuscular blockade or induced paralysis is required.

Chapter 55
TRAUMATIC BRAIN INJURY

Steven M. Cohen • Donald W. Marion

KEY POINTS

1. **Severe traumatic brain injuries** are the leading cause of morbidity and mortality for Americans between the ages of 1 and 45 years.
2. **Outcome following traumatic brain injury** is determined not only by the primary injury, such as skull fracture and subdural hematoma, but also by secondary injuries initiated by post-traumatic ischemia.
3. **Secondary brain injuries** are primarily responsible for the development of delayed intracranial hypertension.
4. The **goal of critical care management** of patients with severe traumatic brain injury is to enhance cerebral perfusion and avoid therapy that may cause regional cerebral ischemia.
5. **Early assessment and triage** of patients with severe traumatic brain injury should use the advanced trauma life support protocol prescribed by the American College of Surgeons Committee on Trauma.
6. **Patients with severe traumatic brain injury** are best managed at a level I trauma center with immediate neurosurgical availability.
7. **All patients with contusions or hematomas** visible on head computed tomography scans and Glasgow coma scale scores of 8 or less will benefit from intracranial pressure monitoring.
8. **A ventricular catheter coupled to an external strain-gauge transducer** is the optimal means of monitoring intracranial pressure because it provides accurate measurements and allows for CSF drainage—the most benign way of treating elevated intracranial pressure.
9. **Prophylactic hyperventilation therapy**, particularly when the intracranial pressure is less than 20 mm Hg, should be avoided.
10. **Patients with subdural hematomas or contusions** benefit from anticonvulsive prophylaxis for 7 days after injury.
11. **Early evaluation of brain-injured patients** by a physical therapist and rehabilitation specialist is highly recommended and allows for their rapid mobility.
12. **Patients with mild or moderate brain injuries**, particularly those with sports-related concussions, benefit from careful neuropsychological evaluation before returning to contact sports.
13. **Athletes who have persistent headaches and focal neurologic deficits** should not be allowed to return to play until these symptoms have subsided.

An estimated 5.3 million people in the United States currently live with permanent disabilities due to traumatic brain injury (TBI). In addition to the personal toll, the direct and indirect costs of these disabilities are estimated to exceed $4 billion annually.[1] Americans sustain an estimated 1.6 million TBIs each year. Approximately 270,000 require hospitalization; 52,000 die of their injuries, and 80,000 are left with severe neurologic impairments.[2] Another 760,000 are treated and released, and an additional 400,000 mild or moderate TBIs are thought to occur but never come to medical attention.[3]

TBI is the leading cause of morbidity and mortality for Americans between the ages of 1 and 45 years. Teenagers and the elderly are most at risk, although the primary causes vary demographically. Motor vehicle crashes are the main cause of head injuries in those 5 to 64 years old, whereas falls are most common in people aged 65 years and older. The primary cause of penetrating head injury is gunshot wounds. Males have twice the risk of TBI as females across all age groups.

TBI death rates in the United States fell 22% from 1979 to 1992, according to one study.[4] A substantial decline in motor vehicle–related fatalities was primarily responsible. At the same time, however, the incidence of gunshot wounds to the head rose, and in 1990, firearms surpassed motor vehicle crashes as the single largest cause of death due to TBI in some urban areas.

PATHOPHYSIOLOGY

Trauma to the head causes primary injury, such as skull fracture, cerebral contusion, and hemorrhage, that is a direct physical consequence of the impact. Hours or days after the traumatic incident, secondary injury usually occurs and may be a major determinant of the patient's ultimate neurologic outcome.

PRIMARY INJURY

Injury to the brain is caused by external forces to the head that strain the tissue beyond its structural tolerance.[5] These forces

FIGURE 55–1. Right frontal depressed skull fracture caused by an assault with a hammer (axial CT scan, bone window).

FIGURE 55–2. Basilar skull fractures through the anterior skull base typically cause cerebrospinal fluid rhinorrhea and tears in the adjacent dura. CT scans through the base of the skull may not show the fracture itself but often show fluid in the sphenoid sinus or the other paranasal sinuses (axial CT scan, bone window).

can be classified as contact or inertial.[6] Contact forces typically produce focal injuries such as skull fractures, contusions, and epidural or subdural hematomas. Inertial forces result from the brain undergoing acceleration or deceleration (translational, rotational, or both) and can occur without head impact. Inertial forces can cause focal or diffuse brain injuries: pure translational acceleration leads to focal injuries such as contrecoup contusions, intracerebral hematomas, and subdural hematomas, whereas rotational or angular acceleration, common with high-speed motor vehicle crashes, usually causes diffuse injuries. Although external signs of head injury, such as scalp abrasions, lacerations, and hematomas, are common with blunt-force trauma, the brain can also be severely injured solely by inertial forces, without accompanying scalp injuries.

Skull fracture results from a contact force to the head that is usually severe enough to cause at least brief loss of consciousness. Linear fractures are the most common type of skull fracture and typically occur over the lateral convexities of the skull. Most often, they are nondisplaced cracks in the skull, but a particularly intense impact can cause a gap (diastasis) between the edges of the fracture. A depressed skull fracture, in which skull fragments are pushed into the cranial vault, usually results from blunt force by an object with a relatively small surface area, such as a hammer (Fig. 55-1). The base of the skull can be fractured by severe blunt trauma to the forehead or the occiput. Basilar skull fractures are most common in the anterior skull base and often involve the cribriform plate, disrupting the olfactory nerves (Fig. 55-2). Posterior basilar skull fractures may extend through the petrous bone and internal auditory canal, thereby damaging the acoustic and the facial nerves.

Skull fractures per se are less detrimental than the associated damage to underlying tissues or vessels. For example, linear skull fractures that involve the squamous portion of the temporal bone are frequently accompanied by a tear of the middle meningeal artery, causing an epidural hematoma. Depressed skull fractures are often associated with contusions of the underlying brain tissue, and a scalp laceration overlying a depressed skull fragment can contaminate the fragment with bacteria from the scalp and hair. With a basilar skull fracture, the dura underlying the fracture is often disrupted, resulting in a cerebrospinal fluid fistula and leakage of cerebrospinal fluid from the nose or ear. Such fistulas allow bacteria to enter the intracranial space from the normally colonized nose, paranasal sinuses, or external auditory canal.

Common post-traumatic intracranial lesions are hemorrhage (epidural, subdural, and intraparenchymal), contusion, and diffuse brain injury. Subdural hematomas are seen in 20% to 25% of all comatose victims of TBI (Fig. 55-3). They develop between the surface of the brain and the inner surface of the dura and are believed to result from the tearing of bridging veins over the cortical surface or from disruption of major venous sinuses or their tributaries. The hematoma typically spreads over most of the cerebral convexity; the dural reflections of the falx cerebri prevent expansion to the contralateral hemisphere. Swelling of the cerebral hemisphere is common in those with subdural hematomas, given the associated damage to underlying brain tissue. Underlying cerebral contusions were found in 67% of patients with subdural hematomas in one series.[7] Subdural hematomas are classified as acute, subacute, or chronic, each having a characteristic appearance on computed tomography (CT): acute hematomas are bright white, subacute lesions are isodense with brain tissue and are therefore often overlooked, and chronic hematomas are hypodense relative to the brain.

Epidural hematomas develop between the inner table of the skull and the dura, usually when the middle meningeal artery or one of its branches is torn by a skull fracture. They occur in 8% to 10% of those rendered comatose by TBI.[8,9] The majority of epidural hematomas are located in the temporal or parietal regions, but they can also occur over the frontal or occipital lobes and, rarely, in the posterior fossa. They appear as hyperdense mass lesions on CT. Unlike subdural hematomas, their spread is limited by the suture lines of the skull, where the dura is very adherent. Because an

FIGURE 55–3. Acute subdural hematomas typically spread over the entire surface of the hemisphere.

epidural space normally does not exist, the clot must strip the dura from the inner table of the skull as it enlarges, resulting in its classic biconvex or lenticular shape (Fig. 55-4). Epidural hematomas are uncommon in infants and toddlers, presumably because their skulls are more deformable and less likely to fracture, and in TBI victims older than 60 years, because the dura is extremely adherent to the skull.

An intraparenchymal hematoma is a hemorrhage within the brain substance that occurs after a very severe TBI. It is usually associated with contusions of the surrounding tissue. Duret's hemorrhage, or hemorrhage into the base of the pons or midbrain, is thought to result from disruption of the perforating arteries at the time of uncal herniation. Such brainstem hemorrhage almost always leads to death or vegetative survival.

Though common after severe TBI, subarachnoid hemorrhage does not produce a hematoma or mass effect.[10] However, it may be associated with an increased risk for post-traumatic vasospasm.[11]

Contusions are heterogeneous lesions comprising punctate hemorrhage, edema, and necrosis and are often associated with other intracranial lesions. One or more contusions occur in 20% to 25% of patients with severe TBI. Because they evolve over time, contusions may not be evident on the initial CT scan or may appear as small areas of punctate hyperdensities (hemorrhages) with surrounding hypodensity (edema) (Fig. 55-5). Local neuronal damage and hemorrhage lead to edema that may expand over the next 24 to 48 hours. With time, contusions may coalesce and look more like intracerebral hematomas. Depending on their size and location, they may cause significant mass effect, resulting in midline shift, subfalcine herniation, or transtentorial herniation. Contusions are most common in the inferior frontal cortex and the anterior temporal lobes,[12] where the surface of the inner table of the skull is very irregular; they result from shifting of the brain over this irregular surface at the time of impact. Direct blunt-force trauma to the head can produce a contusion in the tissue underlying the point of impact (coup contusion). If the head was in motion upon collision with a rigid surface, a contusion may occur in the brain contralateral to the point of impact (contrecoup contusion).

Diffuse axonal injury refers to lacerations or punctate contusions at the interface between the gray and white matter. Such punctate contusions are thought to result from the disparate densities of the gray and white matter and the

FIGURE 55–4. Epidural hematomas have a lens shape and a smooth inner border because they strip the dura from the inner table of the skull as they enlarge (axial CT scan).

FIGURE 55–5. Contusions are most common in the inferior temporal and frontal lobes. In the first few hours after injury, they appear only as areas of hemorrhage mixed with edematous brain. Within 24 to 48 hours after injury, further hemorrhage may occur, causing significant enlargement of the contusion and hematoma (axial CT scan).

consequent difference in centripetal force associated with a rotational vector of injury.[13] Thus, diffuse axonal injury most often occurs after a high-speed motor vehicle crash, during which severe angular and rotational forces are applied to the head. Diffuse axonal injury was once thought to result solely from mechanical disruption at the time of impact; however, more recent research has identified cases in which the histologic footprints of diffuse axonal injury, such as fragmentation of axons and axonal swelling, do not appear until 24 to 48 hours after the incident, suggesting that some cases are a secondary manifestation of trauma.[14,15] Diffuse axonal injury is present in almost half of all patients with severe TBI and in one third of those who die, and it is a common cause of persistent vegetative state or prolonged coma.

Post-traumatic intracranial lesions cause neurologic dysfunction via direct and, in some cases, indirect mechanisms. By destroying brain tissue, contusions and intraparenchymal hemorrhage cause deficits directly related to the function of the damaged tissue. Uncal herniation is also an important mechanism of temporary or permanent neurologic deficits.[16,17] Semirigid dural reflections divide the intracranial contents into compartments. The tentorium cerebelli separates the anterior and middle cranial fossae from the posterior cranial fossa. The brainstem, specifically the midbrain, traverses an opening, the tentorial foramen, in the anterior central portion of this partition. The medial portion of the temporal lobe, the uncus, lies on both sides of the tentorial foramen. Because the most common TBIs, such as hematomas and contusions, are usually located over the lateral surfaces of the brain, and because the brain's extreme lateral surface is the rigid skull, such lesions tend to depress the brain medially. Therefore, a subdural hematoma over the surface of the temporal lobe or a hemorrhagic contusion of the temporal lobe itself is likely to displace the medial portion of the temporal lobe (uncus) into the tentorial foramen (i.e., uncal herniation). Such displacement compresses the midbrain, which contains neurons that are part of the reticular activating system. At the base of the midbrain is the crus cerebri, which contains pyramidal fibers from the cortex, and the third cranial nerve, which exits the midbrain through the interpeduncular cistern. Midbrain compression due to uncal herniation damages the reticular activating system, causing loss of consciousness; stretches the third cranial nerve and its associated parasympathetic fibers, causing pupil dilatation and loss of the light reflex; and injures the pyramidal fibers in the crus cerebri, causing abnormal posturing responses in the contralateral arm and leg.

Medial displacement of a cerebral hemisphere resulting from hemispheric swelling or a subdural or epidural hematoma also can cause herniation of the cingulate gyrus under the falx cerebri. Permanent neurologic dysfunction usually does not result, however.

Intracranial hypertension is a major cause of post-traumatic neurologic morbidity and mortality.[18] The intracranial pressure (ICP) is defined by the volume of cerebrospinal fluid, blood, and brain tissue in the cranial vault. The volume of these components is dynamic, and the brain can accommodate moderate changes in any of the three. For example, the blood volume can rise or fall by as much as 30% to 40%; cerebrospinal fluid absorption can increase to reduce the size of the ventricles by up to 90%; and brain tissue itself is compressible. Thus, the intracranial volume can gain 100 to 150 mL, equivalent to a moderate-sized subdural hematoma, without the ICP increasing significantly. When these buffering mechanisms have been exhausted, however, even a small increase in the size of a hematoma will cause a rapid rise in ICP. If appropriate treatment is delayed, the ICP may approach the mean arterial pressure (MAP), causing a hydrostatic block of blood flow to the brain and brain death. Intracranial hypertension, particularly if refractory to medical or surgical treatment, is the most common cause of death after severe TBI.

SECONDARY INJURY

Post-traumatic ischemia initiates a cascade of metabolic events that lead to the surplus production of oxygen free radicals,[19-21] excitatory amino acids,[22,23] cytokines,[24,25] and other inflammatory agents.[26] Glutamate and aspartate are the excitatory amino acids most commonly implicated in excitotoxic injury,[27] which is mediated by activation of *N*-methyl-D-aspartate, α-amino-3-hydroxy-5-methylisoazole-4-proprionic acid, or kainic acid receptors.[23] Overactivation of these receptors causes an excessive influx of ionized calcium into the cytosol, and elevated amounts of ionized intracellular calcium play a key role in neurodegeneration after injury to the central nervous system (CNS).[28,29] In addition, post-traumatic nonischemic events, such as an increase in intracellular free Ca^{++} via receptor-gated or voltage-dependent ion channels, induce the release of oxygen free radicals from mitochondria.[30] Excessive levels of highly reactive oxygen free radicals cause lipid peroxidation of cell membranes, oxidation of intracellular proteins and nucleic acids, and activation of phospholipases A_2 and C, which hydrolyze membrane phospholipids, thereby releasing arachidonic acid. The liberation of arachidonic acid triggers the generation of free fatty acids, leukotrienes, and thromboxane B_2, all of which are associated with neurodegeneration and poor outcome after experimental TBI.[31-33] Inflammatory cytokines, particularly interleukin (IL)-1, IL-6, and tumor necrosis factor, also are overproduced after TBI.[34-36] In animal models, post-traumatic activation of microglia is a principal source of these cytokines.[25] IL-1 and IL-6 provoke an exuberant cellular inflammatory response believed to be responsible for astrogliosis, edema, and tissue destruction.[26,37]

TBI also increases extracellular potassium levels,[38] leading to an imbalance of intracellular and extracellular K^+, disruption of the Na^+,K^+-ATPase cell membrane regulatory mechanisms, and subsequent cell swelling.[39,40] Astrocyte swelling has been attributed to the clearance of excessive extracellular K^+.[41] High levels of extracellular K^+ have also been implicated as the cause of widespread neuronal depolarization and spreading depression seen after experimental TBI.[27,38,42] Moreover, potassium stimulates increased oxygen uptake in glial cells, potentially depriving adjacent neurons of oxygen.[43,44] Severe TBI also causes a substantial decrease in extracellular magnesium (Mg^{++}) levels, thereby impairing normal glycolysis, cellular respiration, oxidative phosphorylation, and the biosyntheses of DNA, RNA, and protein.[45-47] Because Mg^{++} competes with Ca^{++} at voltage-gated cell membrane–associated Ca^{++} channels, reduced levels of Mg^{++} will result in an abnormal influx of Ca^{++} into the cell.

PREHOSPITAL CARE

The acutely injured brain is vulnerable to further damage from systemic hypotension, cerebral hypoperfusion, hypercarbia,

hypoxemia, and elevated ICP. Preventing these physiologic insults is crucial to limiting secondary brain injury. Care of the TBI victim always should begin with evaluating and securing a patent airway and restoring normal breathing and circulation. Early endotracheal intubation usually benefits comatose patients. Securing and maintaining an airway are essential to optimal oxygenation and ventilation, and early intubation has been found to reduce mortality after severe TBI.[48]

The airway is usually most easily and safely secured by orotracheal intubation, a method in which most emergency medical personnel are trained and experienced. Patients with severe maxillofacial trauma may require nasotracheal intubation, but this is less desirable because it is a relatively blind procedure; the nasal passageways can be irritated, causing blood pressure and ICP to surge; and, in those with severe anterior skull base fractures, the tube can inadvertently be passed into the brain. A third alternative for securing the airway is the laryngeal mask airway, an easily learned and rapidly applied device that has undergone successful field trials.[49] However, it does not protect against aspiration and cannot be used to achieve high airway pressures. A surgical airway (cricothyroidotomy) should be performed only after other attempts to secure an airway have failed, and only by an experienced provider.

The patient should be sedated and pharmacologically paralyzed before intubation, because irritation of the oropharynx typically causes transient hypertension, tachycardia, increased ICP, and agitation that can interfere with the procedure. Fentanyl, a short-acting opioid agonist that produces analgesia and sedation, is the most commonly used sedative. The usual dose is 3 to 5 μg/kg body weight, administered intravenously 3 minutes before intubation. Etomidate, an alternative to opioids, provides adequate sedation and is less likely to cause hypotension. Some prefer thiopental because it is an ultra-short-acting barbiturate and is thus less likely to conceal the neurologic status when the patient reaches the trauma center; however, it is more likely than other agents to cause hypotension. Neuromuscular blocking agents commonly used for endotracheal intubation include succinylcholine (1.5 mg/kg i.v.), which has the advantages of rapid onset, complete reliability, and very short duration of action. This last attribute is particularly important in the prehospital setting, where attempts at intubation sometimes fail. Vecuronium (0.01 mg/kg i.v.), an alternative paralytic agent, offers the theoretical advantage of being a nondepolarizing muscle relaxant. Because it has a relatively long duration of action (1 to 2 hours), however, it is less forgiving of failed intubation attempts. Table 55-1 shows a recommended rapid-sequence intubation pathway.

TABLE 55–1. RECOMMENDED RAPID-SEQUENCE INDUCTION FOR SEVERELY HEAD-INJURED PATIENTS

1. Preoxygenation
   100% oxygen for 5 min or four vital capacity breaths
2. Pretreatment
   Fentanyl (3 to 5 μg/kg i.v.)
3. Wait 2 to 3 min if possible
   Continue preoxygenation
4. Paralysis and sedation
   Succinylcholine (1.5 mg/kg i.v.)
5. Intubation with in-line cervical spine immobilization
6. Positive-pressure ventilation and possibly reparalysis with vecuronium if prolonged transport time is anticipated

Supplemental oxygen should be provided before and immediately after intubation. Ventilatory rates of 10 to 12 breaths per minute for adults, 20 breaths per minute for children, and 25 breaths per minute for infants should supply adequate oxygenation.[2] Therapeutic hyperventilation is inadvisable unless neurologic deterioration is clearly evident during evaluation and transport. Aggressive hyperventilation can cause cerebral vasoconstriction, reducing already low cerebral blood flow (CBF) and potentially causing or exacerbating cerebral ischemia.

Rapid fluid resuscitation and restoration of a normal blood pressure are critical in the prehospital setting, because hypotension has been associated with doubling of the mortality rate after severe TBI.[50] The most likely cause of hypotension is hemorrhage, usually in the abdomen or chest; therefore, hypovolemia should be assumed. Lactated Ringer's or normal saline solutions should be infused through a large-bore intravenous catheter as quickly as possible until normotension is achieved. Although preclinical studies suggest that hypertonic saline may be more effective than isotonic solutions for rapid volume resuscitation,[51,52] results of several small clinical trials have not been convincing.[53,54]

In all cases of severe TBI, defined as a Glasgow coma scale (GCS) score of 3 to 8 and an inability to follow commands, patients should be treated as if they have a spinal fracture until an adequate examination of the spine proves otherwise. Among those who survive long enough to reach the emergency department, the likelihood of a cervical spine fracture is 2% to 6%. More troubling, however, is that an estimated 10% to 25% of all post-traumatic spinal cord injuries are iatrogenic, occurring during transport to the hospital.[55] After respiratory and hemodynamic stabilization, the patient should be placed in a neutral position on a flat, hard surface. If the patient requires immediate endotracheal intubation, it should be performed while another person provides in-line cervical spine immobilization. A rigid cervical spine collar should be placed as soon as possible. Next, the patient should be placed on a backboard; the cervical spine can then be further immobilized with a buttress of foam or towels placed on both sides of the head. To prevent any movement during transport, the patient should be strapped to the board in several locations.

The organization of emergency medical services and regional trauma programs has improved outcomes for victims of trauma, particularly those with severe TBI.[56] Designation as a level I or II trauma center by the American College of Surgeons Committee on Trauma or a state health department ensures the availability of immediate neurosurgical care when the patient arrives. Therefore, every effort should be made to transport severely injured patients directly to a designated trauma center. Nonetheless, if an adequate airway or venous access cannot be obtained in the field, some patients may need to undergo respiratory or hemodynamic stabilization at a nearby emergency department en route to the trauma center.

EMERGENCY DEPARTMENT CARE

Upon arrival at the trauma center, the emergency medical personnel should concisely report their prehospital assessment and management, including mechanism of injury, stabilizing maneuvers, medications given, initial vital signs, GCS score, and hemodynamic stability during transport. A thorough physical and radiographic examination to identify all

life-threatening injuries should then be performed. Most trauma centers follow the Advanced Trauma Life Support protocol, a comprehensive routine that has proved successful in quickly detecting all major injuries.[57] First, the airway is reassessed, and the need for endotracheal intubation is carefully reconsidered. For patients intubated in the field, proper placement of the endotracheal tube is verified both clinically and radiographically. When the airway is secure and adequate oxygenation is confirmed using a percutaneous oxygen saturation monitor or arterial blood gas analysis, two large-bore intravenous catheters are inserted to provide sufficient venous access for high-volume fluid resuscitation. An isotonic saline solution is infused to continue volume replacement, which probably began at the scene. Any life-threatening injuries, such as overt hemorrhage, tension pneumothorax, or cardiac tamponade, should be treated immediately upon discovery. A brief neurologic examination is performed, including assessment of the GCS score (Table 55-2), pupillary size and reaction to light, and symmetry and extent of extremity movements. The head is palpated to detect fractures, lacerations, or penetrating wounds, and lacerations are probed gently to ascertain the presence of a depressed skull fracture or foreign body. Large lacerations are compressed with pressure dressings or temporarily sutured to prevent further hemorrhage. Careful inspection of the head should reveal hemotympanum, periorbital or mastoid ecchymosis, and cerebrospinal fluid rhinorrhea or otorrhea.

Oxygen saturation is monitored continually, and blood pressure is measured frequently during this primary examination. A Foley catheter is placed to help monitor the fluid status, and an orogastric tube is inserted and connected to suction to decompress the stomach. Blood specimens are obtained and analyzed for glucose, electrolytes, complete blood count, platelets, prothrombin and partial thromboplastin times, and International Normalized Ratio. Type and crossmatch of a blood specimen should be considered, and an arterial blood gas obtained. Serum and urine toxicology screens are advisable if alcohol or substance abuse is suspected, and women of childbearing age should undergo a pregnancy test.

TABLE 55–2. GLASGOW COMA SCALE

Speech	Points
Alert, oriented, and conversant	5
Confused, disoriented, but conversant	4
Intelligible words, not conversant	3
Unintelligible sounds	2
No verbalization, even with painful stimulus	1
Eye Opening	
Spontaneous	4
To verbal stimuli	3
To painful stimuli	2
None, even with painful stimuli	1
Motor	
Follows commands	6
Localizes painful stimulus	5
Withdraws from painful stimulus	4
Flexor posturing with central pain	3
Extensor posturing with central pain	2
No response to painful stimulus	1

From Teasdale G, Jennett B: Assessment of coma and impaired consciousness: A practical scale. Lancet 1974;2:81-84.

The initial x-ray evaluation is usually performed in the trauma bay during the primary survey and includes chest, pelvis, and lateral cervical spine films. If the lower cervical spine is not visible on the lateral cervical spine film, a swimmer's view can be obtained, or this area can be imaged with axial CT.

After all life-threatening injuries have been identified and stabilized, the immediate concern is whether the patient requires a craniotomy to evacuate an intracranial mass lesion. A CT scan of the head should be performed, at intervals of 10 mm or less, from the C2 vertebra to the vertex. In addition to post-traumatic intracranial lesions, the scan should be examined for brain swelling, patency of the basal cisterns, and other characteristics that will guide subsequent treatment. If no surgical intracranial mass lesion is evident on the scan of the head, CT scans of the chest and abdomen can be performed to detect occult hemorrhage in these cavities. If a surgical mass lesion is seen on the head CT scan, however, it should be evacuated immediately, postponing any other imaging studies. Diagnostic peritoneal lavage is often performed during the craniotomy to detect abdominal bleeding. Conversely, if hemodynamic instability necessitates an emergent laparotomy or thoracotomy before a head CT scan can be obtained, several diagnostic procedures can be performed in the operating room to confirm a suspected intracranial injury. These procedures include an air ventriculogram or diagnostic burr holes and are most appropriate if the patient has lateralizing neurologic deficits, particularly a unilateral fixed and dilated pupil.

An air ventriculogram can detect most large hematomas. With the patient in the supine position, a right coronal ventriculostomy is inserted, and an anteroposterior radiograph of the skull is obtained. Just before the x-ray is performed, 3 mL of air is injected into the ventricles. The air outlines the ventricles on the film; a distorted or shifted outline suggests the presence and location of a hematoma.

An alternative to air ventriculography is the placement of diagnostic burr holes. The first burr hole should be placed over the temporal lobe ipsilateral to the dilated pupil. If no clot is detected, burr holes can be placed over the frontal and parietal lobes. If a hematoma is encountered, the burr hole is enlarged to a craniotomy, and the clot is evacuated.

DEFINITIVE TREATMENT

Critical to determining the severity of the brain injury and the appropriate treatment are CT findings combined with a reliable post-resuscitation GCS score and assessment of pupil size and reactivity. In the case of an acute subdural hematoma, for example, a patient with a moderate-sized lesion who has normal pupil size and reactivity and is able to follow commands might safely be treated nonoperatively. Conversely, surgery is unlikely to benefit an elderly patient with fixed and dilated pupils and a GCS score of 3 or 4, regardless of the CT findings. Other determining factors include the size and location of the hematoma, the presence and extent of an underlying contusion or brain swelling, and the results of the neurologic examination. Neurologic deterioration, particularly a decline in mental status, suggests enlargement of the hematoma, and a new CT scan should be obtained promptly. Hematomas less than 10 mm thick that cause a midline shift of less than 5 mm can usually be observed, especially if they do not involve the middle cranial fossa.[58] If nonoperative management is chosen for an intracranial hematoma, the

patient should be monitored with frequent neurologic assessments in the ICU. If the patient cannot follow commands, ICP monitoring is recommended.

The classic presentation of a patient with an epidural hematoma is a period of unconsciousness immediately after impact to the head, followed by a so-called lucid interval in which consciousness returns for a few minutes to an hour or more before the patient lapses into a coma. This lucid interval actually occurs in less than one third of patients with epidural hematomas, however; most either remain conscious after the injury (smaller clots) or remain comatose.

A hematoma that compresses the temporal lobe is particularly ominous and can rapidly cause uncal herniation with minimal enlargement. Thus, such lesions warrant a lower threshold for evacuation compared with hematomas in other locations. If the clot is small enough not to require evacuation, it should be monitored with frequent CT scans during the first several days after injury. Enlarging middle fossa hematomas, even those large enough to cause herniation, do not always cause an increase in the ICP; therefore, ICP monitoring should not be relied on to follow their status.

The initial signs and symptoms of contusions vary greatly, depending on their size and location and the presence of other associated lesions. A small contusion may cause only a headache or no symptoms at all. If located in an eloquent area of the brain, such as the speech or motor areas, it may cause focal neurologic symptoms. Larger contusions, especially those involving the frontal lobes, typically cause elevated ICP and coma. Patients with small or deep-seated contusions without mass effect initially can be managed nonoperatively. The contusion should be followed closely with serial CT scans, however, because there is a 20% to 30% risk that the contusion will enlarge during the next 24 to 48 hours. The ICP should be monitored if the patient cannot follow commands. As with hematomas in the middle cranial fossa, contusions of the temporal lobes should be closely watched with CT scans. A temporal contusion can enlarge to the point of uncal herniation without a significant rise in ICP; thus, the threshold for evacuation of these lesions should be low (Fig. 55-6). Unilateral frontal or temporal lobectomies are usually well tolerated, do not cause measurable neurologic deficits, and provide space for further brain swelling.

In the ICU, the primary goal is to prevent cerebral ischemia and thereby limit secondary brain injury. The most common preventable causes of cerebral ischemia are hypotension, hypoxia, and intracranial hypertension. Thus, comprehensive physiologic monitoring should be performed so that these physiologic insults can be detected and treated promptly.

PHYSIOLOGIC MONITORING

Continual monitoring of the end-tidal partial pressure of carbon dioxide (PCO_2) and frequent analyses of arterial blood gases enable the early detection of deteriorating ventilatory status, which should prompt appropriate ventilator adjustments. Oxygen saturation should also be monitored continually with pulse oximetry. Blood pressure monitoring is best accomplished with an indwelling arterial catheter coupled to a pressure transducer. The catheter is usually inserted into the radial artery and can also be used to obtain arterial blood samples for blood gas analysis. Hypovolemia is a common cause of post-traumatic hypotension. It can result from overt hemorrhage, which is usually detected soon after injury; from occult hemorrhage, which may not be recognized for several hours or days; or from soft tissue inflammation and swelling. Consequently, central venous pressure monitoring should be considered for patients with severe TBI, particularly those with significant non-CNS injuries. Indwelling subclavian or internal jugular venous catheters are used, coupled to pressure transducers. In elderly patients or those with severe pulmonary contusions, intravascular volume may be more accurately assessed by pulmonary artery catheterization with a Swan-Ganz catheter. Monitoring urine output with an indwelling Foley catheter is essential for determining the patient's fluid status.

FIGURE 55–6. Temporal lobe contusions must be monitored closely, because even a slight enlargement can cause uncal herniation, often without an increase in intracranial pressure (axial CT scan).

Continuous ICP monitoring is essential for all patients who have severe TBI and abnormal CT findings, because intracranial hypertension develops in 53% to 63% of such patients.[59] ICP monitoring is also recommended for comatose patients who are older than 40 years and have unilateral or bilateral motor posturing or a systolic blood pressure less than 90 mm Hg, even if no abnormalities are seen on the initial CT scan.[60] The gold standard for ICP monitors is the ventricular catheter, coupled to an external strain-gauge transducer.[61] It is accurate, reliable, and far less expensive than newer self-contained pressure-sensing devices. In addition, ventricular pressure is considered more reflective of global ICP than is subdural, subarachnoid, or epidural pressure. Catheters placed in these extracerebral spaces are more prone to occlusion and, owing to the effects of compartmentalization, typically record a pressure that is lower than the global ICP. Other advantages of the ventriculostomy method of ICP monitoring are that the system can be rezeroed after insertion, which is not possible with most of the newer self-contained devices, and cerebrospinal fluid can be withdrawn to treat intracranial hypertension. The overall complication rate for ventricular ICP monitoring is 7.7% (infection, 6.3%; hemorrhage, 1.4%),[59] and some studies

indicate that the infection rate increases significantly when a catheter remains in place for more than 5 days.[62]

Alternatives to the ventriculostomy technique have been developed that provide relatively accurate measurements of global ICP, are easier to insert, and may cause fewer complications. They include devices that contain a pressure-sensing transducer (either strain-gauge or fiber-optic technology) within the tip of the catheter.[61] These pressure sensors provide reliable ICP measurements even if they are inserted into the white matter and are often used when a ventricular catheter is difficult to insert because of small or collapsed ventricles. The primary disadvantage is that cerebrospinal fluid drainage is not possible. In addition, these devices can be calibrated only once, before insertion, and with some of them, measurement drift is as much as 1 to 2 mm Hg per day.

The cerebral perfusion pressure (CPP), defined as the difference between MAP and ICP, is a calculated physiologic measurement that is used to describe actual cerebral perfusion. Some have suggested that maintaining the CPP above a certain threshold is more important than any particular MAP or ICP.[63]

Devices that monitor the oxygen partial pressure (PO_2) of brain tissue can be used to determine whether cerebral oxygenation is adequate. These monitors continually measure the tissue PO_2 in the small region of brain into which they are inserted. The probes have been found to be very sensitive to changes in arterial PO_2 and PCO_2, as well as to medically induced or physiologic changes that may cause focal cerebral ischemia.[64] Although no methods are available for continuously monitoring global CBF, transcranial Doppler insonation of the middle cerebral arteries can provide indirect information. Positron emission tomography or CBF measurements with xenon, either as a radiolabeled agent or as a CT contrast medium, can provide periodic snapshots of the blood flow.

MEDICAL TREATMENT

Hypoxia is best avoided with the use of endotracheal intubation and mechanical ventilation. The fraction of inspired oxygen should be titrated to provide an arterial PO_2 of 100 mm Hg. Maintaining an arterial PCO_2 of approximately 35 mm Hg is advised to avoid the cerebral vasoconstriction associated with aggressive hyperventilation. A form of acute respiratory distress syndrome (ARDS) can develop in patients with severe chest injuries. In such cases, adequate oxygenation requires the use of positive end-expiratory pressure (PEEP). Concern has been raised that the use of PEEP in patients with TBI may increase the ICP. However, clinical studies have shown that, in the presence of ARDS, up to 14 to 15 cm H_2O of PEEP can be used without measurable changes in ICP, most likely because ARDS significantly reduces pulmonary compliance.

Hypotension, defined as a MAP of less than 90 mm Hg, should be treated aggressively. Normovolemia should be restored by infusing isotonic saline as needed to achieve a central venous pressure of 7 to 12 cm H_2O. Hypotonic intravenous solutions can exacerbate cerebral edema and should be avoided. If the patient is anemic, packed red blood cells should be transfused to restore the hematocrit to at least 30%. If hypotension is refractory to volume resuscitation, the patient should be given a continuous intravenous infusion of a vasopressor medication, with the dose titrated to raise the MAP above 90 mm Hg. Dopamine and norepinephrine are the preferred vasopressor agents.

Although some advocate the used of induced hypertension to raise the CPP above 70 mm Hg, particularly if the ICP is elevated and difficult to reduce,[65] others do not support this practice. A prospective, randomized clinical trial of patients with TBI compared a group whose CPP was kept above 70 mm Hg via induced hypertension with a group whose CPP was allowed to drift to 60 mm Hg.[66] Six-month clinical outcomes did not differ between the two groups. Moreover, the group whose CPP was kept above 70 mm Hg required more vasopressor agents and had a significantly higher incidence of ARDS and other pulmonary complications. Others have found that the brain tissue PO_2 in patients with TBI typically does not fall until the CPP drops below 60 mm Hg.[67] Based on these findings, the current recommendation is to maintain a CPP above 60 mm Hg.

Intracranial hypertension is defined as sustained ICP greater than 20 mm Hg. Several clinical studies have found that mortality and morbidity increase significantly when the ICP persistently remains above this threshold.[68] Based on this association and the widely accepted premise that elevated ICP can compromise cerebral perfusion and cause ischemia, the aggressive treatment of intracranial hypertension is almost uniformly endorsed. Before beginning therapy for intracranial hypertension, however, medical or physiologic conditions that can increase ICP should be considered and, if present, treated. These include seizures, fever, jugular venous outflow obstruction (e.g., poorly fitting cervical collars), and agitation.
