Robert J. Gorlin

Foreword

I have always regarded the concurrence in 1964 of my first faculty appointment in Madison with the appearance of the first edition of Gorlin's magisterial *Syndromes of the Head and Neck* as an especially happy event. Since then I have never been far from one of the subsequent editions in office or clinic or any place else in the world where I have taught or consulted. "*The Syndromes*. . . .", as it is known throughout the world, has become the most useful book in clinical genetics, rivaled perhaps only by McKusick's *OMIM*. The number of contributors to this immensely useful volume is increasing with each edition; however, the judgment, experience, and weight of authority that guarantee the book's value still largely derive from Drs. Gorlin and Cohen, undisputed leaders in the field of oral genetics and oral pathology.

In this edition, they drew on the enthusiasm, experience, and energy of Dr. Raoul Hennekam from Amsterdam. Dr. Hennekam has a well-deserved world reputation as a clinical geneticist. He will assume the helm in future editions.

The millennial date of this fourth edition is a propitious historical landmark, the year 2000 marking also the 200th anniversary of the science of morphology, the 100th of the rediscovery of Mendel's "laws," and the completion of the human genome project. The shaping by Goethe (1796) and Burdach (1800) of morphology as the science of the form, formation, transformation, and malformation of living beings on the basis of historical and developmental considerations dramatically changed the world view of biologists early in the 19th century. It led to the essential, indeed crucial, distinction between structural analogy and homology. Homology became, in Darwin's view, "the most interesting department" of morphology and "may almost be said to be [the] very soul" of natural history. Thus, it was natural selection, not descent, that was the radical innovation in thought in *The Origin of Species*. . . . (1859). Let it be remembered that much, perhaps most of morphology of the 19th century (including modern embryology, the cell theory, pathology, cytology, the study of mitosis, meiosis and chromosomes, evolution, and heredity—the inheritance of form) was the creation of physicians who frequently performed their own autopsies and pathological studies (as do Drs. Gorlin and Cohen) and also studied a multitude of malformed animals and fetuses. Craniofacial anomalies early became a major concern of these physician morphologists who introduced terms still familiar to all of us, such as teratology, otocephaly, anencephaly, and holoprosencephaly. Thus, it is no surprise that Drs. Gorlin, Cohen, and Hennekam, continuing in this richly productive 200-year tradition of craniofacial morphology, have provided some of the most authoritative discussions of these anomalies in the pages of this book.

Mendel was a true child of his age, whose work was initially motivated by a search for the cause of form, i.e., the inherited causes of development. Contrary to the views of many who have not read his original paper of 1865 (1866), Mendel did have a word for what Johannsen later (1909) called "the gene," namely: ". . . .die bildungsfähigen Elemente. . . .," i.e., the form-giving or morphogenetic elements present in haploid form in germ cells. The fact that these elements segregated and freely recombined astounded and delighted him and led him far from his original goal of wanting to understand the causal nature of development and of evolution. It was not until the end of what in biological circles has sometimes been called the Mendelian century that Mendel's original goal was realized in the reunion of all of the branches of morphology through the intermediacy of molecular technology, which at last made it possible to determine the function of these segregating, form-giving elements under normal and abnormal circumstances. And while "*The Syndromes*. . . ." gives hundreds of examples of the abnormal pleiotropic function of genes, including molecular data on many craniofacial syndromes, it must be remembered that nothing can happen in development, whether normal or abnormal, that has

not been made possible by evolution, and that far beyond even the "invention" of the neural crest during the evolution of vertebrates, the beginnings of development are to be found in those pre-Cambrian times, over 600 million years ago, that allowed the emergence of all living metazoans.

This book, more than any other in clinical genetics over the last few decades, has shown us the best results and also the limitations of nosology based on phenotype analysis. During evolution development became severely constrained into a remarkably impoverished set of final morphogenetic outcomes which, if abnormal, must all be highly heterogenous given the ratio of tens of thousands of genes to only a handful of developmentally highly correlated parts of the craniofacial region. The fact of inductive molecular *parsimony*, whereby the same gene acts in different permutations with other transcription or growth factors at different times in several embryonic primordia and perhaps even in later histogenesis of several tissues, explains the phenomenon of pleiotropy that is ubiquitous in clinical morphology. This biologic fact or hypothesis has to be considered in every genetic disorder and is addressed masterfully in "*The Syndromes*. . . .," extending its value far beyond the head and neck into *all* parts of the human body.

The highly successful application of molecular methods to a causal analysis of development and the completion of the human genome sequencing project is expected to redress, at last, the half-century imbalance between genotype and phenotype research—not opposing but complementary scientific efforts—so as to give ever-increasing clarity to the phenomena of heterogeneity, variability, homology, penetrance, and expressivity, issues addressed with ever-increasing urgency in the successive editions of this book. The introduction of many new molecular insights in the Fourth Edition is a harbinger of the future of clinical morphology and a most valuable resource for all of its practitioners. For undertaking and continuing this labor of love, biomedicine owes Drs. Gorlin, Cohen, and Hennekam a profound debt of gratitude.

John M. Opitz, M.D.
Pediatrics (Medical Genetics), Human Genetics, Obstetrics and Gynecology, University of Utah, Salt Lake City Utah

Foreword to Third Edition (1990)

Syndromologists, medical geneticists, and (even more so) other health workers have found it increasingly difficult to keep up with the vigorous growth of knowledge about syndromes. The distinguished teratologist Josef Warkany wrote "with the increasing interest in congenital malformations a syndrome fever is spreading through many specialties, and it is difficult for editors of medical journals and readers to separate spurious from durable and meaningful syndromes." That was in 1971 (Congenital Malformations: Notes and Comments). Thus, there is a need for judicious sifting, organizing, and synthesis of the plethora of syndromic literature into meaningful patterns. The first edition of this volume was welcomed by those who were even then beginning to feel this need. Its breadth and depth reflected the encyclopedic knowledge and judgment of Robert Gorlin, an extraordinary phenomenon. And it was by no means limited to the head and neck! To keep up with the burgeoning growth of knowledge, the second edition added another extraordinary repository of syndromic lore, in the form of Michael Cohen. In the present edition, the breadth and depth of the syndrome data base have been further extended by the otolaryngologic knowledge of L. Stefan Levin and by specific chapters from no fewer than 18 collaborators. The result is a truly encyclopedic work, containing descriptions of the phenotypic spectrum, epidemiology, mode of inheritance, and pathogenesis of nearly 700 syndromes. McKusick's Catalogue has more entries, since it covers all Mendelian disorders, not just syndromes, but this volume includes non-Mendelian syndromes as well, and in far more depth. The several computer-aided syndrome-diagnosis systems now available are useful as diagnostic aids, but do not provide as exhaustive descriptions of phenotype or as critical analyses of the literature. This book will be welcomed as an essential component of the knowledge base for the clinical geneticist and others confronted with syndromes. It is an honor to be associated with it, even in this peripheral way. I am certainly

looking forward to having it on my bookshelf, and hope that I will be able to persuade my students to let me read it now and then!

F. Clarke Fraser, O.C., M.D., Ph.D., FRS(C)
Emeritus Professor of Medical Genetics
McGill Centre for Human Genetics, Montreal, Canada

Foreword to the Second Edition (1976)

The first edition of this book was the pioneering text for this segment of medicine. I vividly recall the excitement upon first reading the book in 1964. At last!—here was a cohesive authoritative text which portrayed the majority of syndromes which had been recognized at that time. Though entitled *Syndromes of the Head and Neck*, it covered all known features of each disorder in a nonspecialized and balanced manner, including the natural history, etiology, differential diagnosis, and pertinent references for each disorder. The field of syndromology has expanded since that time. The number of recognized disorders set forth in the book has more than doubled, and the knowledge has been updated on the original syndromes. A third person, M. Michael Cohen, Jr., has been added to the authorship of this expanded work on syndromes. Thus, this second edition is a most welcome addition for all those who work with, or are interested in, syndromes of malformation. Many children and their parents will be the indirect beneficiaries of this text. For our own patients, we sincerely thank the authors for this monumental work.

David W. Smith, M.D.*
Professor of Pediatrics, Dysmorphology Unit, Department of Pediatrics
University of Washington, School of Medicine, Seattle, Washington

Foreword to the First Edition (1964)

The authors of this monograph are keen observers and ardent students of disease in the best tradition of Jonathan Hutchinson, Parkes Weber, and other clinicians of an earlier generation. Many of the diseases on which they have concentrated their attention are rare, but for several reasons no less important. Although these diseases occur infrequently, they constitute in the aggregate a significant portion of medicine. Most of them are congenital malformations or disorders loosely called constitutional; many of them are genetic either in the classic Mendelian sense or as chromosomal aberrations. It is a truism that this body of diseases has come to represent a main challenge to medicine now that infectious and nutritional diseases are better understood and controlled. That the disorder from which he suffers is rare is no consolation to its victim. The first step in the understanding of these conditions must be an accurate and full clinical description.

The careful study of exceptional cases can contribute importantly to medicine and to biology in general. Bateson, a famous early geneticist, said "Treasure your exceptions!" In 1657 William Harvey, of blood circulation fame, eloquently expressed the usefulness of the study of rare diseases:

> Nature is nowhere accustomed more openly to display her secret mysteries than in cases where she shows traces of her workings apart from the beaten path; nor is there any better way to advance the proper practice of medicine than to give our minds to the discovery of the usual law of Nature by careful investigation of cases of rarer forms of disease. For it has been found, in almost all things, that what they contain of useful or applicable nature is hardly perceived unless we are deprived of them, or they become deranged in some way.

Professors Gorlin and Pindborg have done a valuable service to oral pathology and medicine in general by collating their extensive personal experiences and the widely scattered reports of the literature. With skill they have synthesized and interpreted. The fundamental relationship between disorders separately reported, usually under diverse labels, has been carefully explored and convincingly demonstrated in a number of instances. For this, all medicine is in debt of the authors. Their monograph is a particularly valuable addition to the English-language medical

*Deceased

literature because they have mined much ore previously not available. With their linguistic prowess they have been able to study in the original a considerable body of literature previously unknown to most of us. Specialists such as ophthalmologists, dermatologists, and dentists have always been in the enviable position of being able to study disease with simple clinical methods. Fortunately many of these specialists, appreciating the relationship of systemic and constitutional disorders to the manifestations which fall within their purview, have made worthwhile contributions to pathology. With this monograph, Gorlin and Pindborg have joined this company. Their work will be valued, not only by dentists, but by all the numerous medical specialists who are called on to care for patients with these disorders.

Victor A. McKusick, M.D.
William Osler Professor of Medicine
Johns Hopkins University, School of Medicine
Physician-in-Chief, Johns Hopkins Hospital
Baltimore, Maryland

Preface

A number of the chapters have been reviewed by individuals who have far greater expertise than any of the editors. To these individuals, generous with their time, we express our profound indebtedness. We truly appreciate the effort and expertise that they have lent to improve the text.

Alphabetically, they include: Mary Ahrens, Judith Allanson, Susan Berry, Beth Ann Bloom, David M. Brown, Suzanne G. Cassidy, Vazken Der Kaloustian, Charis Eng, Vickie Matthias Hagen, Judith G. Hall, Betsy Hirsch, Ioannis Koutlas, Bonnie LeRoy, Brian Michalowicz, Maximilian Muenke, John M. Opitz, Mary Ella Pierpont, Andrew Read, Nathaniel Robin, Karol Rubin, Heddie O. Sedano, Karel Vrticka, Matthew Warman, and Chester B. Whitley. We are profoundly indebted to the staff of the Biomedical Library of the University of Minnesota. Among these, Delbert Reed is the consummate librarian. He has never failed to exhibit unbridled enthusiasm for any literature search, however hopeless. In Amsterdam, the same job was done by Hannelore De Groot, who always succeeded in finding the publications immediately. We are honored that John Opitz has agreed to write the Foreword to this edition. For continuity with earlier editions, we are reprinting the Forewords from the first edition (Victor A. McKusick), the second edition (David W. Smith), and the third edition (F. Clarke Fraser).

This fourth edition of *Syndromes of the Head and Neck* was written at a point when each new weekly or monthly publication presented us with additional molecular information. It was also written at a time when a spate of new syndromes appeared each month. We tried to be as catholic in our approach as possible, the limiting factor being that the facies must be unusual—hence the title that is so well known that change of the name was not deemed wise. It took approximately five years of almost full-time labor to bring this edition to fruition. Based on our experience, it would have been better to have started the fourth edition upon completing the third, and it is our sincere hope, because of the burgeoning of material, that Raoul Hennekam who will assume the helm for further editions will be able to assign each chapter to a different author who will update the material monthly. We have added new material up to June 2001.

Although we have tried to group syndromes into useful categories, many conditions have facets that span several categories and assignment may appear arbitrary. We have added another chapter: Syndromes Involving the Eye, and have, in part, reassigned some entities to it.

An attempt was made in this edition to address the molecular aspects of the syndromes, if known. In many cases, gene mapping has been accomplished, but the nature of many of the genes has not yet been precisely determined.

Syndrome delineation has burgeoned. The 1964 edition contained 580 pages, the 1990 edition had about 1000 pages. The present edition has about 1275 pages. In 1972, we tabulated 72 syndromes of orofacial clefting. Within the confines of these pages, we have tallied over 350 such syndromes.

Our personal desire for a one-volume text was accomplished by altering typographic style, removing redundant illustrations, and deleting orthodontic measurements in the Appendix. Raoul Hennekam has vastly improved the index, and we have added sections on helpful web sites and computer database systems.

Production of this edition was made smooth by Jeffrey House, Nancy Wolitzer, and Susan Hannan of Oxford University Press. Their suggestions and respect for our opinions have made the task so much easier.

This edition and the second edition of *Hereditary Hearing Loss and Its Syndromes* were made possible by the unlimited generosity of Guilan Norouzi.

For the past one and one-half decades, one of us (RJG) has been fortunate to have the editorial assistance of Carol Bauer Rose. In part she was hired because of her experience in many aspects of book production. Very few know what it is like to devote five years of intense effort toward developing a text without major flaws—at least grammatical ones. Carol has agonized about semicolons and clear phraseology. The scientific errors are ours. We are also grateful to Ruth E. MacLean and Belinda Leeuwenhage for their editorial help on this text.

Syndromes of the Head and Neck

Chapter 1
Deformations and Disruptions

Craniofacial deformations

Congenital deformations of the head and neck are common, and most resolve spontaneously within the first few days of postnatal life. When they do not, further evaluation may be necessary to plan therapeutic interventions (1,2,4,5,9) that may prevent long-term consequences. The distinction between deformations and malformations and its implications are discussed elsewhere (6,8,9).

Approximately 2% of infants are born with extrinsically caused deformations that usually arise during late fetal life from intrauterine constraint. Approximately 30% of deformed infants have two or more deformations. Deformed infants tend to show catch-up growth toward their genetic potential during the first few postnatal months after release from the intrauterine constraining environment (8). Table 1–1 indicates some of the known causes, both extrinsic and intrinsic, of deformations. Deformations considered here include nasal, auricular, and mandibular deformities, torticollis, nonsynostotic plagiocephaly, craniosynostosis caused by intrauterine constraint, and abnormal fetal presentations, which may result in craniofacial deformation.

Table 1–1. Causes of deformations[a]

Extrinsic
Mechanical
Unstretched uterine and abdominal muscles
Small maternal size
Amnionic tear
Unusual implantation site
Uterine leiomyomas
Unicornuate uterus
Bicornuate uterus
Twin fetuses
Intrinsic
Malformational
Spina bifida
Other central nervous system malformations
Bilateral renal agenesis
Severe hypoplastic kidneys
Severe polycystic kidneys
Urethral atresia
Functional
Neurologic disturbances
Muscular disturbances
Connective tissue defects

[a] From MM Cohen Jr, The Child with Multiple Birth Defects, 2nd ed, Oxford University Press, New York, 1997.

Nasal deformation. Deformation of the nose may be associated with face presentation, transverse lie, oligohydramnios, or severe fetal crowding. In most instances, the nose will be compressed and/or deviated (Fig. 1–1), which may make it appear short. Occasionally the nasal cartilage is dislocated from the vomerine ridge, resulting in nasal asymmetry with slanting of the columella. The naris on the side toward the dislocated cartilaginous septum will appear small (9).

Auricular deformation. Overfolding of the superior rim of the helix and other alterations in the cartilaginous auricle are frequently caused by fetal constraint. The ear may be flattened against the head by oligohydramnios, and prolonged pressure against the auricle may result in overgrowth. Enlarged, flattened ears have frequently been associated with renal agenesis as part of *Potter sequence*. When one ear is exposed to more pressure than the other, they may be asymmetric. Occasionally, with prolonged breech presentation, particularly when associated with tilted head position in utero, the lower auricle may be lifted by pressure from the shoulder (2).

Mandibular deformation. Micrognathia may result from limitation of mandibular growth caused by late gestational constraint, which compresses the chin against the chest. With prolonged compression, there may be a pressure indentation on the superior aspect of the anterior thorax. Marked compression may also lead to pressure necrosis along the edges of the anterior neck creases (Fig. 1–2). Such necrosis may extend

Fig. 1–1. *Craniofacial deformations*. Compression of the face, particularly the nose, from prolonged transverse presentation with the head retroflexed and the face compressed against the lateral wall of the uterus. (From JM Graham Jr, Smith's Recognizable Patterns of Human Deformation, 2nd ed, W.B. Saunders, Philadelphia, 1988.)

A B C

Fig. 1–2. *Craniofacial deformations*. Extensive compression from persistent leakage of amnionic fluid documented by ultrasound from 17 weeks gestation to birth. (A) Marked mandibular deformity at 3 days of age. Note necrosis along neck creases (which healed with scarring). (B) Extensive mandibular deformation still evident at 3 weeks of age. (C) Partial resolution of mandibular deformity by 2.5 years of age. (From JM Graham Jr, Smith's Recognizable Patterns of Human Deformation, 2nd ed, W.B. Saunders, Philadelphia, 1988.)

deeply enough into the dermis to result in scarring. When micrognathia occurs on a deformational basis (rather than on a hypoplastic, malformational basis), there is usually catch-up growth postnatally once the fetus is no longer in the constraining intrauterine environment (6,9).

When mandibular compression is asymmetric, it can produce mandibular asymmetry. Most commonly, this results from the shoulder being thrust up under the mandible with prolonged breech or oblique presentations. A prominent sulcus impression may occur along the neck from shoulder compression (6,9).

Torticollis. Congenital torticollis usually occurs together with an obliquely shaped plagiocephalic head and mandibular asymmetry. Often this results from the head being caught askew prenatally. Muscular torticollis may result from constraint on one side of the neck causing ischemia to the central portion of the sternocleidomastoid muscle followed by secondary fibrosis. A fusiform fibrous mass may sometimes be palpable within the muscle, a sternocleidomastoid "knot" or "tumor." Asymmetric shortening of one sternocleidomastoid muscle may lead to aberrant head posture. With persistent torticollis and resultant head posture, craniofacial deformation may be progressive (4,5,9).

Torticollis-caused plagiocephaly. When persistent sternocleidomastoid torticollis or asymmetric cervical vertebral anomalies result in the head resting in an asymmetric position, oblique molding results in the head being rhomboid shaped, with frontal prominence on the preferred side together with contralateral prominence of the occiput (Fig. 1–3). With marked cranial distortion, the eyes and ears may be asymmetrically placed and the mandible may be asymmetrically deformed. If torticollis remains uncorrected, plagiocephaly may be progressive (4,5,9).

Deformation-induced craniosynostosis and plagiocephaly. Fetal head constraint has been implicated as an important cause for some instances of sagittal, coronal, and metopic craniostenosis. In such instances, craniosynostosis is not associated with other malformations and the condition is not familial. With deformational synostosis, fetal head constraint results in lack of growth stretch across the suture, enhancing liability toward synostosis (7,9,11–13,15). Experimental evidence for this interpretation was provided by Koskinen-Moffett (16), who produced prenatal synostosis of the coronal and squamosal sutures in mouse pups by closing the uterine cervix with a surgical clip to delay birth for several days, which crowded the fetuses.

Plagiocephaly is etiologically and pathogenetically heterogeneous. Well-known types include synostotic anterior plagiocephaly (unilateral coronal synostosis), synostotic posterior plagiocephaly (unilateral lambdoid synostosis), deformational anterior plagiocephaly, and deformational posterior plagiocephaly. Of these, deformational plagiocephaly is common and lambdoid synostosis is rare. Deformational posterior plagiocephaly has increased dramatically since the 1992 recommendation of the American Academy of Pediatrics for supine infant sleeping to reduce the risk of sudden infant death syndrome. Unfortunately, deformational posterior plagiocephaly has sometimes been diagnostically confused with lambdoid synostosis, resulting in unnecessary surgery when helmet

Fig. 1–3. *Craniofacial deformations*. Four and one-half month-old infant with persistent head turn to the left caused by cervical and thoracic vertebral anomalies. Note resultant marked plagiocephaly. (From JM Graham Jr, Smith's Recognizable Patterns of Human Deformation, 2nd ed, W.B. Saunders, Philadelphia, 1988.)

A B

Fig. 1–4. *Craniofacial deformations*. (A) Extensive vertex molding at birth. (B) Self-resolution by 2-3 months of age. (From JM Graham Jr, Smith's Recognizable Patterns of Human Deformation, 2nd ed, W.B. Saunders, Philadelphia, 1988.)

therapy would have been effective if introduced early enough. Surgery may be indicated in nonresponders to helmet therapy and in those who are still asymmetric after 1 year of age. Differentiation of deformational vs. synostotic plagiocephaly has been discussed extensively by Cohen and MacLean (7).

Abnormal fetal presentation. A vertex presentation is most common and transient molding of the head occurs in the birth canal. With prolonged engagement, normal vertex birth molding may be accentuated (Fig. 1–4). The prognosis for a complete return to normal form in such instances is excellent (9).

With prolonged pressure on the vertex region, particularly with a first-born infant, a large fetus, or a small mother, diminished mineralization of the cranium may result. Mild vertex craniotabes occurs in 2% of neonates, with more extensive cranial softening occurring less frequently (Fig. 1–5). The presence of normal cranial bone along the sides of the calvaria helps distinguish craniotabes from defective calvarial mineralization resulting from inherited metabolic or connective tissue disorders such as hypophosphatasia or osteogenesis imperfecta. Vertex craniotabes, resulting from late fetal head constraint, usually resolves spontaneously within the first few postnatal months (10).

Breech presentation is the most common abnormal fetal presentation, occurring in 6% of all pregnancies; one-third of all deformations occur in breech babies (3). In Dunn's series (8), 32% of all deformations in newborns were associated with breech presentation. Genu recurvatum (100%), hip dislocation (50%), postural scoliosis (42%), mandibular asymmetry (20%–25%), torticollis (20%–25%), and talipes equinovarus (20%–25%) are all related to breech presentation.

Prolonged breech presentation may give rise to unusual molding of the fetal head, resulting in dolichocephaly with a prominent occipital shelf (14) (Fig. 1–6). Vaginal delivery of a breech fetus with hyperextended head is associated with significant morbidity and mortality (1). Serious consequences include trauma to the spinal cord or brachial plexus, compression of the vertebral artery with cerebral ischemia, or severance of the pituitary stalk with consequent hypopituitarism. Thus, the current trend is toward cesarean delivery of fetuses with breech presentation.

Transverse lie is less frequent than breech presentation, occurring once in every 300–600 deliveries. It is more common in multiparous women, and it results in problems similar to those associated with breech presentation. Thus, unresolved transverse presentation is also an indication for cesarean delivery. Lateral constraint of the fetus may flatten the face, limit mandibular growth, and cause cephalic retroflexion and truncal scoliosis with positional foot deformities. Figure 1–1 demonstrates remarkable facial compression associated with prolonged transverse lie. Such compression is usually only temporary.

Face and brow presentations (Fig. 1–7) may also temporally compress the presenting part. Face presentations occur about once in 500 births and

Fig. 1–5. *Craniofacial deformations*. Prolonged vertex presentation at least 4 weeks prior to delivery. Large area of craniotabes represented by cross hatching. Self-resolution by 2 months of age. A B

brow presentations are even less common. Only anterior positions can be delivered vaginally because of the inability of the neck to further extend in the posterior position. Compression of the mandible may temporarily restrict its growth, and compression of the neck against the pubic ramus during vaginal delivery may cause fracture of the trachea or larynx. Thus, cesarean section should be given consideration in this situation. It should also be noted that 90% of babies born in face or brow presentation are infants with major malformations, with anencephaly being the most common. For otherwise normal infants with facial features such as those shown in Figure 1–7, the prognosis for complete return to normal form is excellent.

Potter sequence (oligohydramnios sequence)

Potter sequence is characterized by compression deformities of the face and limbs (Fig. 1–8A), pulmonary hypoplasia, wrinkled skin, and growth restriction resulting from any pathologic condition that leads to oligohydramnios (42,95,151), such as bilateral renal agenesis (110,113), cystic dysplasia (10), severe polycystic kidneys (43,60,103,114), urinary tract obstruction (4,79), or amnionic leakage (20,79,150). In addition to diverse renal pathology, more extensive malformations may occur in some instances (35), the severe caudal axis defect sirenomelia (Figs. 1–8B–D) being the most extreme example (15,29,37,52,77,80,103,122,143, 146,158). Several unusual experiments of nature have been recorded in which the extrarenal features of Potter sequence are not manifest (4,79, 94,150) (Fig. 1–9).

Originally described by Potter (113–116) in association with bilateral renal agenesis, Potter sequence is now known to be extremely heterogeneous, both etiologically and pathogenetically. The term "Potter sequence" or "oligohydramnios sequence" best describes the condition, with other terms, such as "Potter syndrome" (44,45,84,89,110,129, 165,167) (the condition is not a true syndrome sui generis, but may occur as a component part of many different syndromes or may occur nonsyndromically), "bilateral renal agenesis" (48,113–115,124,148) (too restrictive), and "renofacial dysplasia" (18,52,58,60,64,105,106,156) (not specific enough), now being obsolete.

A B C D

Fig. 1–8. *Potter sequence*. (A) Potter sequence with compressed facial appearance and limb positioning deformities. (B) Sirenomelia, a severe caudal axis malformation sequence in which kidneys and genitals are missing. Note Potter facies and upper limb deformities. (C, D) Another example of sirenomelia. (A from DW Smith, Recognizable Patterns of Human Malformation, 3rd ed, W.B. Saunders, Philadelphia, 1982. B courtesy of the Warren Anatomical Museum, Harvard University. Montage from MM Cohen Jr, The Child with Multiple Birth Defects, 2nd ed, Oxford University Press, New York, 1997.)

With Potter sequence, malformations of the genitourinary tract, lumbosacral spine, and lower intestinal tract are common (35) and constitute, in Opitz's terminology (107), a developmental field defect. Duncan et al (38) noted the frequent association of müllerian duct anomalies, renal agenesis, and cervical and thoracic vertebral anomalies, and coined the term "MURCS association."

Extensive reviews have been carried out by Curry et al (35), who analyzed 80 cases, Schmidt et al (140), who studied 23 families, and Roodhooft et al (126) and Al Saadi et al (3), who studied 41 and 21 families, respectively. Approximately 80% of Potter sequence cases are nonsyndromic (35), with the remaining 20% occurring in many different syndromes and associations. They may be chromosomal, autosomal dominant, autosomal recessive, X-linked, teratogenic, disruptive, or of unknown origin. They have been reviewed extensively by Gorlin et al (54) and Van Allen (155) and in many specific articles (2,9,11,12,13,21,25, 29–31,33–36,40,41,44,45,49,53,54,57,63,65,68–70,73,75,76,78,83–85, 88,93,98–101,111,112,118,128–130,133,134,138,141,142,145,147,153, 154,163–166) (Table 1–2).

The complex and variable renal pathology found with Potter sequence has been reviewed by Bernstein and associates (9–11). In 80 retrospectively ascertained cases, Curry et al (35) found bilateral renal agenesis in approximately 21%, cystic dysplasia in approximately 48%, obstructive uropathy in approximately 25%, and other forms of renal pathology in the remaining 6%.

The prevalence of bilateral renal agenesis has been reported to vary from 1 in 3000 to 1 in 9000 births, predominating in males by a ratio of 2:1 or 3:1. The prevalence of unilateral renal agenesis at necropsy varies from 1 in 600 to 1 in 1000 (4,27,47,77,110,116,157). Genetic evidence is accumulating to indicate that bilateral renal agenesis and cystic dysplasia should be nosologically grouped together. In several documented instances, bilateral renal agenesis has been observed in one sib and cystic dysplasia with or without unilateral renal agenesis has been found in the other sib (22,27,35,61). Affected sibs with either bilateral renal agenesis or cystic dysplasia have been observed on numerous occasions (7,20,22,23,32,61,89,94,96,97,102,109,124,126,127,132, 135–137,161,162). Autosomal dominant inheritance with reduced penetrance and variable expressivity is consistent with affected families in which a parent with unilateral renal agenesis has children with either unilateral or bilateral renal agenesis (12,16,20,23,59,82,103,134,168); Buchta et al (20) called the condition "hereditary renal adysplasia." In some of the affected families, second- and third-degree relatives as well as first-degree relatives of probands with bilateral renal agenesis had unilateral renal agenesis (12,23,67,82,97). Roodhooft et al (126) ultrasonically investigated the parents and siblings of 41 probands with bilateral renal agenesis and/or cystic dysplasia and found renal abnormalities in 9%. McPherson et al (97) suggested that hereditary renal adysplasia was more common than previously supposed and may account for most recurrences of bilateral renal agenesis, even when the parents are normal. They calculated penetrance to be between 50% and 90%. Offspring and affected or obligate heterozygotes have an empiric risk for bilateral severe involvement of 15%–20%. Other manifestations of the gene may include cryptorchidism in males and müllerian duct abnormalities in females (12,20,23,136).

Al Saadi et al (3) obtained family histories and performed renal ultrasonography on parents and sibs of 21 probands with renal dysplasia. Among the probands were 16 bilateral and 5 unilateral cases. Specifically excluded from this study were cases of bilateral renal agenesis and known syndromes, both chromosomal and nonchromosomal, with renal dysplasia. Empiric recurrence risk calculated from this family study was only 2.1%. Al Saadi et al (3) concluded that multicystic and aplastic types of renal dysplasia are usually sporadic and only rarely familial in contrast to other types of renal dysplasia identified in the literature as familial.

Obstructive uropathy as a cause of Potter sequence is also complex because of clinical and pathologic heterogeneity. Several possible sites for obstruction exist, particularly in the male. The marked male preponderance for obstructive uropathy is related to the more complex development of the male urethra (108). Clinical variation extends from early fetal lethality to survival with minimal morbidity. Recurrence of prune belly secondary to obstructive uropathy has most frequently involved affected brothers (19,51,56,82,123,159). Three affected sibs—two males and one female—have been reported in one instance (50). Affected male cousins (1,51) and three pairs of discordant monozygotic twins (71) have also been observed.

Family studies of probands with vesicoureteral reflux or duplication of the collecting system have shown that affected sibs have the same abnormality as the proband in 26%–34% of cases with reflux (39,72) and in 19% of cases with ureteral duplication (160). Twenty-three percent of parents with children who had ureteral duplication had similar findings (5,160). Finally, six pairs of twins and three pairs of sibs with posterior urethral valves were reviewed by Livne et al (87). Their data suggested that obstructive urinary tract abnormalities may result from an autosomal dominant gene with reduced penetrance.

Prenatal and perinatal factors. Amnion nodosum, breech presentation (40%), intrauterine death (25%), and antepartum hemorrhage (15%) have been found in a large series. Cesarean delivery is required in about 10% of cases. About half the infants are small for date of birth. Respiratory insufficiency is common (6,116,121).

Renal pathology. Renal pathology is quite variable. Bilateral renal agenesis is a valid diagnosis only when no renal tissue is found on gross

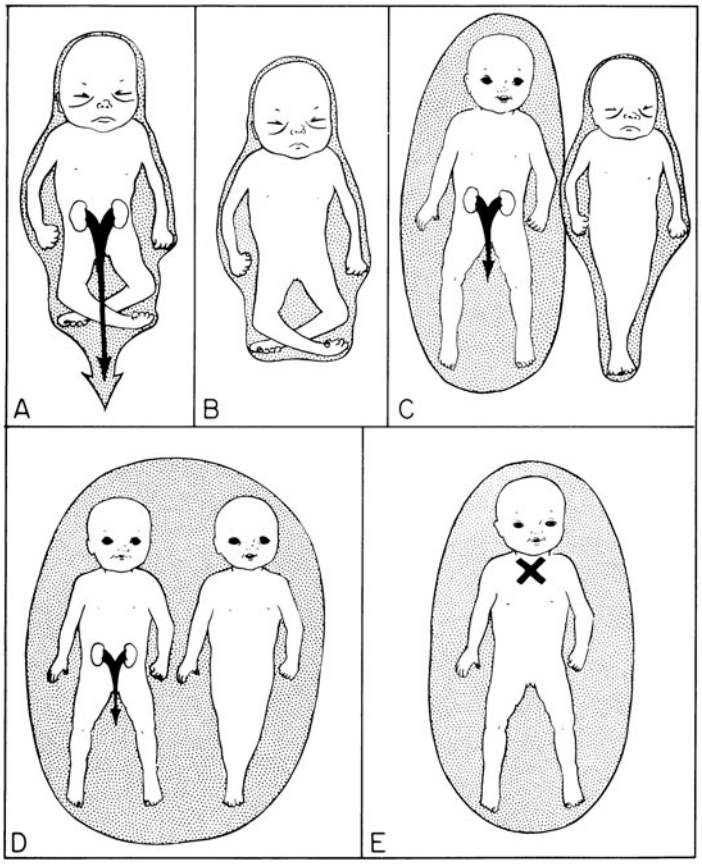

Fig. 1–9. *Potter sequence*. Oligohydramnios has different causes and, except under unusual circumstances, leads to facial and limb deformities of Potter sequence. Normally, small amounts of amnionic fluid cross the amnion as a transudate, but most amnionic fluid results from fetal urination. (A) Amnionic tear with chronic leakage of fluid leading to oligohydramnios, Potter facies, and limb positioning defects. Both kidneys are present and urination is normal. (B) Bilateral renal agenesis. (C) Monozygotic twins with separate amnions. Fetus on the left has kidneys, and enough fetal urine is contributed to amnionic fluid to protect fetus from deformities of Potter sequence. (D) Monozygotic twins sharing common amnionic sac. Note that although the fetus on the right has sirenomelia, Potter deformities are not present because the fetus on the left provides enough urine in amnionic fluid to protect the co-twin from deformities of Potter sequence. (E) Fetus has bilateral renal agenesis and therefore does not contribute fetal urine to amnionic fluid. Potter sequence based on neurologic swallowing deficit; amniotic fluid crossing the amnion remains external to the fetus, protecting it from extrinsic, deforming forces. (From MM Cohen Jr, The Child with Multiple Birth Defects, 2nd ed, Oxford University Press, New York, 2000.)

histopathologic examination. In such instances, the renal arteries and ureters are also absent and the bladder is hypoplastic, rudimentary, or absent (11).

In renal cystic dysplasia, abnormal renal organization may result from arrested development. Pathologic changes include primitive ducts, nests of cartilage, and primitive glomerular and tubular structures with aberrant relationships to one another. Kidneys may be enlarged, of normal size, or reduced in size. When involvement is unilateral, the other kidney is absent. Various abnormalities of the renal arteries, ureters, and bladder are common (10,11).

In infantile polycystic kidney disease, both kidneys are greatly enlarged with minute cysts on the surface. Medullary ductal dilatation is characteristic, and hepatic lesions with an increased number of portal bile ducts are observed (9).

Hypoplastic kidneys are distinguished from cystic dysplasia. The kidneys are extremely small but structurally normal with normal differentiation (35).

With intrauterine obstructive uropathy, the kidneys may be large and cystic, but may also be small, cystic, and dysplastic when destruction is a significant factor. Obstruction may occur in the distal urethra or the prostatic urethra. Atresia of the ureters is noted less commonly at the level of the bladder or the posterior urethral valves. Massive urinary ascites with distended abdomen may occur on occasion (35).

Medullary dysplasia is uncommon, but, when present, is reported to be accompanied by abnormalities of cortical tubular differentiation (35).

When Potter sequence results from amnionic leakage, both kidneys are normal (151).

Craniofacial features. A prominent semicircular skin fold extends from the inner canthus onto the cheek. When this fold is absent, some functioning kidney tissue may be present. Ocular hypertelorism has been observed. The nose may be blunted, with a turned-down nasal tip. A prominent crease is often present on the chin. The ears are low-set, posteriorly angulated, large, and floppy with cartilaginous deficiency. Micrognathia has been observed in most cases. Cleft lip and/or palate have been noted in a few instances (110,113–115).

Skin. The skin is very dry, loose, and wrinkled, giving a prematurely senile appearance (43,48,114). Markedly hypoplastic nails have been observed in some instances (35). Less commonly, neck webbing may be noted (35). Prune belly may be observed in some instances and does not necessarily correlate with the pathologic diagnosis of obstructive uropathy, nor does lack of abdominal wall distention exclude the presence of urinary tract obstruction. The wrinkled, prune-like appearance is found only in those without abdominal distention. Variable degrees of abdominal distention with abdominal muscle deficiency may be observed (35).

Skeletal and limb anomalies. Large fontanels and wide sutures have been observed in some instances (35). Flexion contractures at the knees and hips, spade-like hands, genu varum, and talipes equinovarus are common (106,114). Other findings are quite variable and may include hyperextensibility of the knees and other joints, camptodactyly, hypoplastic arm, hypoplastic leg, especially with obstructive uropathy, thoracic hemivertebrae, ischial and sacral aplasia or hypoplasia, other vertebral anomalies, and sirenomelia (1,4,24,35,46,55,66,86,104,106,108, 114–116,120,152).

Pathogenetic hypotheses about sirenomelia are particularly well reviewed by Stevenson et al (146). Their study indicated that sirenomelia and its commonly associated defects are produced by a vascular steal that diverts blood flow and nutrients from caudal structures of the embryo to the placenta. Arteries below the level of the steal vessel are underdeveloped and tissues dependent on them for nutrient supply fail to develop, become arrested in some incomplete stage of development, or are malformed. Thus, the single lower extremity in sirenomelia arises from failure of the lower limb bud field to be cleaved into two lateral masses by an intervening allantois.

Genital anomalies. Abnormalities may include cryptorchidism (33% of affected males and 100% of affected males with prune belly), gonadal hypoplasia, absent ductus deferens, absent seminal vesicles, rectovaginal fistula, absent uterus, bicornuate uterus, unicornuate uterus, blind-ended vagina, absent vagina, and masculinization of the external genitalia with 46,XX karyotype (4,12,20,26,35,91,115,116,124, 134,137).

Lungs. The lungs are hypoplastic with primitive or absent alveoli (67,114,116).

Gastrointestinal system. Imperforate anus, esophageal atresia, duodenal atresia, malrotation, Meckel diverticulum, and omphalocele have been observed (3,35,162).

Cardiovascular anomalies. Reported congenital heart defects include atrial septal defect, ventricular septal defect, patent ductus arteriosus, hypoplastic left ventricle, pulmonic stenosis, tetralogy of Fallot, pulmonary atresia, abnormal tricuspid valve, coarctation of the aorta, and single umbilical artery (3,35,162).

Table 1–2. Syndromes in which *Potter sequence* has been reported

Syndromes	Renal pathology	References
Chromosomal		
46, XX, −3, +der(3)t(3;11)(p25;ql3.2)mat	Hypoplastic kidney	Curry et al (35)
Deletion short arm 4	Bilateral renal agenesis	Mikelsaar et al (100)

EEC syndrome	Obstructive uropathy	Ivarrson et al (70)
Müllerian duct and renal anomalies	Renal agenesis	Biedel et al (12); Schimke and King (134)
Autosomal recessive		
Abnormal renal tubular differentiation, microcephaly, and joint hypermobility	Obstructive uropathy	Allanson et al (2)
Acrorenal mandibular syndrome	Bilateral renal agenesis	Halal et al (63)
Bilateral renal agenesis, lens prolapse, and cataracts	Bilateral renal agenesis	Biedner (13)
Cerebro-oculo-facio-skeletal syndrome	Bilateral renal agenesis	Preus et al (118)
Cryptophthalmos syndrome	Bilateral renal agenesis	Burn and Marwood (21); Codère et al (31); Kahler et al (75)
Cystic dysplasia, CNS malformations, and liver abnormalities	Cystic dysplasia, small kidneys	Miranda et al (101)
Elejalde syndrome	Cystic dysplasia, enlarged kidneys	Elejalde et al (41)
Familial renal tubular dysgenesis	Other	Saunders et al (133)
Glutaric aciduria, type II	Cystic dysplasia, enlarged or small kidneys	Kahler et al (76)
Infantile polycystic kidney disease	Other	Bernstein (9)
Meckel syndrome	Cystic dysplasia, enlarged kidneys	Mecke and Passarge (98)
Medullary dysplasia and cerebral dysgenesis	Other	Bernstein and Kissane (11)
Mesomelic dysplasia	Other	Rutledge et al (128)
Prune belly, pulmonic stenosis, retardation, and hearing deficit	Obstructive uropathy	Lockhart et al (88)
Renal cystic dysplasia and cerebellar dysgenesis	Cystic dysplasia, small kidneys	Kornguth et al (83)
Renal dysplasia and asplenia	Cystic dysplasia enlarged or small kidneys	Crawford (34)
Renal, genital, and middle ear anomalies	Bilateral renal agenesis	Schmidt et al (138); Winter et al (163)
Saldino-Noonan syndrome	Cystic dysplasia, enlarged kidneys	Spranger et al (145); Saldino and Noonan (130)
Smith-Lemli-Opitz syndrome, type II	Renal agenesis, cystic dysplasia	Curry et al (36)
Thymic aplasia, growth retardation, fetal death	Other	Shepard et al (141)
X-linked		
Lenz microphthalmia syndrome	Bilateral renal agenesis	Hoefnagel et al (68)
Teratogenic		
Diabetes mellitus	Bilateral renal agenesis or cystic dysplasia with small kidneys or obstructive uropathy	Grix et al (57)
Thalidomide	Bilateral renal agenesis or obstructive uropathy or other pathology	Pliess (112)
Disruptive		
Amnion rupture sequence	Normal kidneys	See amnion rupture sequence section
Unknown genesis		
Agnathia, tracheoesophageal fistula, duodenal atresia, and renal agenesis	Bilateral renal agenesis	Saito et al (129)
Congenital cystic adenomatoid malformation and bilateral renal agenesis	Bilateral renal agenesis	Krous et al (84)
Ear anomalies, cataracts, and cystic dysplasia	Cystic dysplasia, small kidneys	Wright et al (165)
Renal agenesis, cardiac anomalies, and skeletal defects	Bilateral renal agenesis	Holzgreve et al (69)
Renal dysplasia, mesomelia, and radiohumeral synostosis	Cystic dysplasia, small kidneys	Ulbright et al (155)
Renal dysplasia, pancreatic fibrosis, meconium ileus, and situs inversus	Cystic dysplasia, small kidneys	Yoshikawa et al (166)
Renal hypoplasia and ectrodactyly	Renal hypoplasia	Fitch and Lachance (45)
VATER association	Bilateral renal agenesis or cystic dysplasia with small kidneys or obstructive uropathy, or other pathology	Uehling et al (154)

Other findings. Other findings may include brain malformations, diaphragmatic hernia, asplenia, polysplenia, adrenal hypoplasia, and accessory adrenal glands (3,35).

Diagnosis, differential diagnosis, and laboratory aids. Because of the heterogeneous causes of Potter sequence, diagnosis and recurrence risk counseling should be based on (*a*) careful clinical examination, (*b*) complete autopsy with special attention to renal histopathology, (*c*) chromosome analysis, (*d*) family history, and (*e*) renal ultrasound examination for parents of infants with renal agenesis and/or cystic dysplasia and more distant relatives if indicated by history or by demonstrated parental involvement based on ultrasound. Prenatal ultrasonography has identified oligohydramnios (35), renal agenesis and/or cystic dysplasia (8,28,37,62,74,125,139,140), and obstructive uropathy (17,131,144).

Syndromes with Potter sequence are listed in Table 1–2. The association of ear anomalies with genitourinary defects independent of Potter sequence has been discussed by several authors (14,90,149,155).

Amnion rupture sequence

Amnion rupture sequence may result in limb reduction defects, amputations, ring constrictions, distal syndactyly, talipes equinovarus, short umbilical cord, craniofacial disruptions and clefts, neural tube defects, limb/body wall deficiency, gastroschisis, extrathoracic heart, scoliosis, growth restriction, and various other anomalies (Figs. 1–10 to 1–14). Severity of amnionic rupture sequence varies from a single ring constriction or amputation to such severe involvement that viability

Fig. 1–10. *Amnion rupture sequence*. (A) Agenesis of membranous skull bones with protrusion of cranial contents. Bilateral facial clefts extending through premaxilla, lips, lateral nose, medial orbits, and skull. (B) Variations in hand anomalies. Note circumferential creases, syndactyly. (C) Amputations of variable extent. (A from MS Granick et al, Plast Reconstr Surg 80:829, 1987).

is not possible. The condition has also been known as amnionic band syndrome, aberrant tissue band syndrome, amnionic band lesions, and ADAM complex (4,6,7,23,26,43,45,51,62). Large series have been reported by numerous authors (1,4,6,7,23,26,45,54,57–59). Craniofacial involvement has been emphasized in several publications (2,23,26, 28,37). A good review is that of Christianson et al (7a).

Amnionic rupture may lead to all three basic types of anomalies—disruptions, deformations, and malformations (60). Disruptions are caused by adhesions, by tearing, and by constriction by amnionic bands. Shepard et al (55) indicated that facial clefting, anteriorly located encephaloceles, and pseudoanencephaly might be caused by membranes adhering to the perforating buccopharyngeal membrane and lateral edges of the closing neural folds between 23 and 35 days of development. If bands are present during the embryonic period, they may interfere with normal embryogenesis, resulting in malformations. Deformations result from oligohydramnios, which leads to intrauterine crowding and tethering of fetal parts. Severe constraint leads to vascular engorgement, hemorrhage, edema, and tissue necrosis resulting in severe disruptions such as limb/body wall defects. Finally, some malformations that cannot be explained by bands, constraint, or compression may occur with amnionic rupture sequence anomalies. In such instances, disruptive and nondisruptive abnormalities may have a common primary etiology in some cases and may occur by chance in others (1,19,22,23,27,32,39,47,57–59). Herva and co-workers (17,18) suggested that many severe cases were based not on a single rupture of the amnion but by a defective early germinal disc.

Fig. 1–12. *Amnion rupture sequence*. Bizarre facial clefting and asymmetric encephaloceles. Note amputation of thumb and index finger. (From MM Cohen Jr, The Child with Multiple Birth Defects, 2nd ed, Oxford University Press, New York, 1997.)

Fig. 1–13. *Amnion rupture sequence*. Cloverleaf skull in infant with bilateral oblique facial clefts. Patient also had amputation of digits. (From A Schuch and HJ Pesch, Z Kinderheilkd 109:187, 1971.)

Fig. 1–14. *Fetal brain disruption sequence*. (A–D) Severe microcephaly, ridged and overriding sutures, collapse of skull, prominent occipital bone, and scalp rugae. (From LJ Russell et al, Am J Med Genet 17:509, 1984.)

Baker and Rudolph (1) estimated that congenital ring constrictions and amputations occurred with a frequency of 1 in 10,000 live births. Herva et al (18) noted a cluster of severe amnionic band cases (9 in 17 months) in Finland. Ossipoff and Hall (45) reported that 1 in 1300 pregnancies had amnionic rupture sequence, and Byrne et al (6) gave a frequency of one in 5000–15,000 births, but indicated that the condition was relatively common among abortuses. On the basis of ultrasound at 18 weeks in utero, Papp et al (48) reported amnionic bands without signs of amnionic rupture or other fetal malformations in 5 of 12,131 consecutive pregnancies. They suggested that "innocent bands" may exist. Kalousek and Bamforth (24) found that amnion rupture sequence was common in previable fetuses, the prevalence being 1 in 56.

The best epidemiologic study is that of Garza et al. (11). Using amputation or ring constriction as a minimal criterion, among 388,325 live births, the birth prevalence for amnionic rupture sequence was 1.17 per 10,000. The prevalence for males was 0.91 and for females was 1.44. Defects occurred 1.76 times more often among blacks than among whites. Infants of young, black multigravidas showed the highest rate (6.2), and infants of older black multigravidas showed the lowest rate (0.5). Maternal age effect was not observed in black primagravidas or in white mothers. Birth weight was below 2500g in 49% of amnionic rupture sequence cases compared with 6.8% among all live births in the Atlanta area. The known case fatality rate was 30%.

The overwhelming majority of cases are sporadic. However, a few examples have been familial (9,32,33). Although most reported identical twins have been discordant (8,25,31,45,57), concordant twins have also been noted (10,31,64). Gellis (12) reviewed two families in which father and son had ring constrictions on the terminal phalanges of the same fingers. Such cases are probably best understood on the basis of Streeter dysplasia of genetic origin. Amnionic disruption sequence has been associated with amniocentesis (41).

Limb defects. Limb defects are the most commonly observed abnormalities with amnionic rupture sequence (Fig. 1–10B,C). Findings may include ring constrictions, lymphedema below the ring constriction, congenital amputations of one or more limbs or digits, distal syndactyly, and talipes equinovarus (1,7,21,42,44,50,57). Less common and more unusual abnormalities have included absent limb, oligodactyly, arthrogryposis, single forearm bone, single lower leg bone, radial and ulnar hypoplasia, ectrodactyly, and preaxial polydactyly (13,58). Proximal syndactyly has also been noted (14). Hall (16) noted a transposed arm secondary to amnionic band disruption.

Craniofacial anomalies. With increasing severity of disruption, craniofacial anomalies may include severe microcephaly with deficiency of the anterior calvaria; asymmetric, usually anteriorly located, and sometimes multiple encephaloceles, bony orbital clefts, coloboma of eyelids, ectropion, lacrimal outflow obstruction, globe involvement, and microphthalmia; distortion and disruption of the palpebral fissures; various nasal disruptions; cleft lip, cleft palate, and bizarre facial clefts; and aberrant tissue bands about the face (Fig. 1–10A) (6a,29,30). Potter deformities (Fig. 1–11) and anencephaly have been observed. Various malformations have been reported including holoprosencephaly, Dandy-Walker malformation, septo-optic dysplasia, cloverleaf skull, hydrocephaly, ocular hypertelorism, uveal coloboma, choanal atresia, unilateral proboscis, Robin sequence, and other malformations (2–4,7,19,20,22,23,26,28,35,37,46, 51,53,58,59). Neurologic manifestations in survivors have been discussed by Chen and Gonzalez (7).

Thoracic, abdominal, and other defects. Body wall deficiency may include thoracoschisis, abdominoschisis, thoracoabdominoschisis, ectopia cordis, gastroschisis, omphalocele, and even extrophy of the bladder. Many other malformations have been reported including various cardiovascular anomalies, abnormal lung lobulation, absent or abnormal diaphragm, abnormalities of intestinal rotation, anal atresia, absent gonads, and anomalous external genitalia (19,22,23,39,47,56,58,59). Scoliosis may be observed (39). Low-frequency malformations have been tabulated by several authors (22,58,59). Placenta and membranes have been discussed by Van Allen and Myhre (58). Sachdev et al (52) reported a case of amnionic rupture sequence associated with an incompetent cervix.

Differential diagnosis. Amnionic band defects may mimic *frontonasal dysplasia*, ocular hypertelorism, branchial arch dysplasia, *Meckel syndrome, cryptophthalmos*, arthrogryposis, pterygium-related entities, scalp defect/limb reduction, and ectrodactyly (15). Genetic type ring constrictions of the terminal phalanges (12) may mimic amnionic band constrictions and amputations. Differences between amniogenic and genetic or teratogenic limb anomalies have been discussed by Baker and Rudolph (1). On occasion, postnatal hair strangulation of toes during infancy may mimic amnionic band ring constrictions or amputations of digits (40). Amnionic bands have been observed with severe *osteogenesis imperfecta* (62,63), *type IV Ehlers-Danlos syndrome* (63), and *epidermolysis bullosa* (36). One must exclude *oromandibular limb hypogenesis disorders*.

Laboratory aids. Elevated amnionic α-fetoprotein levels are often found (5). Prenatal diagnosis by ultrasonography is possible in patients with severe craniofacial defects (7,31,34,38,49,61).

Fetal brain disruption sequence

In 1984, Russell et al (3) reported three infants with severe microcephaly, overlapping sutures, prominence of the occipital bone, and scalp rugae. Four additional cases were reported by Moore et al (2).

The fetal brain disruption sequence is postulated to arise from partial brain disruption during the second or third trimester with subsequent skull collapse secondary to decreased intracranial pressure. Possible mechanisms include interruption of the blood supply to selected areas of the brain such as disruption secondary to co-twin demise, prenatal viral infection, and hyperthermia.

Severe microcephaly with severe to profound mental deficiency is characteristic. Diminished intracranial pressure leads to calvarial collapse with overlapping sutures, scalp rugae, and prominent occipital bone (Fig. 1–14).

Differential diagnosis. *Cutis verticis gyrata* occurs as a separate condition, typically having its onset after puberty; collapse of the calvaria does not occur, although microcephaly may be present. Associated endocrine problems are common. Scalp rugae have been observed with severe microcephaly and with hydranencephaly. The fetal brain disruption sequence differs from atelencephaly (1).

Chapter 2
Teratogenic Agents

Growth and development of the embryo can be adversely affected by a wide variety of environmental agents (*teratogens*). These include intrauterine infections, various chemical agents and medications, radiation, and maternal metabolic disorders. Prior to discussion of specific teratogens, it would be logical to familiarize the reader with some of the general principles of teratology.

The first two weeks of life, that is, the time prior to organogenesis, appear to be a relatively safe time for the embryo regarding teratogenic exposure. The next 45 days, however, are especially dangerous, for it is during this period that most organs develop. After an organ has developed, unless there is disruption, the teratogen cannot cause a malformation. Thus, most major malformations, such as amelia, cleft lip/palate, microtia, and congenital heart anomalies, arise during the first 60 days of embryonic development. One exception is deleterious defects due to alcohol consumption which can arise during the entire pregnancy. Craniosynostosis and hearing loss appear to develop after the first 60 days of conception. The same teratogen can cause different defects at different times of exposure. For example, exposure to thalidomide around the 33rd postconceptual day causes microtia and facial palsy; a bit later exposure results in aplasia of arm bones, and around the 55th day, thalidomide exposure makes the thumb look like a finger. Exposure to rubella after the 55th day causes hearing loss and retinopathy; earlier it induces cataracts and congenital heart anomalies. Isotretinoin exposure in the embryonic period causes epicanthic folds and microtia, but after fetal exposure, no anomalies of the pinnae are noted.

Most, but not all, teratogens have a threshold dose below which no identifiable effects or malformations can be detected. Beyond the threshold dose, some teratogens exhibit a dose–response effect, i.e., the higher the dose, the greater the response. However, in humans this may not be easily observed. Some agents, such as isotretinoin, have a narrow therapeutic dose range. Alcohol, by contrast, has teratogenic effects throughout pregnancy. Still other medications such as anticonvulsants have produced very inconsistent dose-effect responses.

Most teratogens produce a characteristic, that is, clinically recognizable, pattern of abnormalities. Apart from causing retarded growth, most cause specific malformations. Pathogenesis for most teratogens is unknown, but it is likely that a number of them act as ligands, binding cellular or nuclear receptors. Determination of which organs will be affected by which teratogens probably reflects the tissue- and time-specific distribution of matching receptors during the period of exposure. as demonstrated in the case of vitamin A congeners. Other agents probably interfere with cell migration division, differentiation, and death. Altered epithelial-mesenchymal interaction also appears to be a factor.

Teratogens are often species specific; what is teratogenic in mice is not necessarily teratogenic in humans or other animals. For example, cortisone produces cleft palate with high frequency in certain strains of mice but not in others, whereas rats and humans are not susceptible. Thalidomide is not teratogenic in mice, rats, dogs, cats, or guinea pigs, but exposure in rabbits produces injury. Higher apes and humans are highly susceptible.

Alcohol embryopathy

Of all teratogens, alcohol has surely received the greatest attention, for it is the most common recognizable cause of mental and growth retardation in children (43). Although it must be the most venerable of teratogens, its role was not recognized until 1968 by Lemoine et al (38), and Jones et al (31) first clinically defined fetal alcohol syndrome (FAS) in 1973. A less severe manifestation has been termed "fetal alcohol effect" (FAE), but because this is an imprecise term, we discourage its use (1). The structural and functional effects on the embryo are dose related, with up to one-half of affected infants being born to women who drink 2 oz. or more of absolute alcohol per day. It has been estimated that 1 in 30 pregnant women abuse alcohol and that about 6% of these women have children with clinically recognizable FAS (3,9,15). Moderate drinkers, i.e., those who drink from 1 to 2 oz. of absolute alcohol per day, have children with functional and growth disturbances without other morphologic changes (Table 2–1A). Furthermore, the risk of spontaneous abortion is increased for those who drink increased amounts of alcohol during pregnancy. Binge drinking during the first trimester may cause fetal death. Fetal alcohol syndrome has been estimated to occur in at least 2 per 1000 livebirths (53). In the United States this would amount to more than 7000 affected infants annually. There appears to be no safe period for excess alcoholic consumption during pregnancy (2,4,29,30). An excellent follow-up is that of Autti-Ramo et al (6a).

The risk of abortion is doubled if one oz. of alcohol is consumed twice a week (34). Clinical findings of FAS include pre- and postnatal growth retardation, central nervous system dysfunction, and characteristic facies. Birth weight is usually less than 2500 g and subsequent growth is deficient (7). Facial abnormalities include small head circumference, epicanthic folds, short palpebral fissures, ptosis, strabismus, optic nerve hypoplasia, short nose with anteverted nostrils, broad low nasal bridge, mild midfacial hypoplasia, indistinct philtrum, thin vermilion of upper lip, and small mandible (25a,27) (Fig. 2–1; Table 2–1B). Dentition is somewhat delayed. In some surveys, there appears to be an increase in the occurrence of cleft palate (as much as 15%); the heavier the consumption, the greater the frequency of cleft palate (56). Other studies have found an increase in cleft lip/palate but not in cleft palate (45a). Cephalometric study shows upper and midfacial asymmetry and a long face (21,23,27). These changes become evident only if maternal use exceeds four oz. of absolute alcohol per day (17,42). The characteristic facies tends to disappear with age (58,64).

Hypoplasia of the optic nerve head and increased tortuosity of retinal vessels are extremely common (65). Microphthalmia is rare (6). A tendency toward both conductive and sensorineural hearing loss has been noted (13).

Central nervous system problems are increased, and can take the form of hyperactivity, mild to moderate mental retardation, attention deficit, sleep disorders, motor and neuropsychological deficits, and brain malformations, which include microcephaly, hydrocephalus, lissencephaly, and neural tube defects (10,24,45,61,62). Abnormal neuronal migration results in neurological heterotopias, polymicrogyria, pachygyria, agenesis and hypoplasia of the corpus callosum, ventriculomegaly, small brain stem, and defects in the limbic system (16,28,32,46). Glial cell proliferation is increased (23a). Holoprosencephaly is increased in infants of mothers who drink heavily (42). Seizures are likely to occur with elevated frequency of alcohol consumption, as is maladaptive adult behavior. Handicaps range from mild to severe mental retardation, to fine motor dysfunction (tremulousness, poor eye–hand coordination, and various self-stimulating behaviors) (12,59). Hyperactivity is common. In the neonate, such signs as

Table 2–1A. Principal features of fetal alcohol syndrome observed in 245 persons affected

Feature	Manifestation
Central nervous system dysfunction	
Intellectual	Mild to moderate mental retardation[a]
Neurologic	Microcephaly[a]
	Poor coordination, hypotonia[b]
Behavioral	Irritability in infancy[a]
	Hyperactivity in childhood[b]
Growth deficiency	
Prenatal	<2 SD for length and weight[a]
Postnatal	<2 SD for length and weight[a]
	Disproportionately diminished adipose tissue[b]
Facial characteristics	
Eyes	Short palpebral fissures[a]
Nose	Short, upturned[b]
	Hypoplastic philtrum[a]
Maxilla	Hypoplastic[b]
Mouth	Thinned upper vermilion[a]
	Retrognathia in infancy[a]
	Micrognathia or relative prognathia in adolescence[b]

[a]Feature seen in >80% of patients.
[b]Feature seen in >50% of patients.
(From SK Clarren and DW Smith, N Engl J Med 298: 1063, 1978.)

Table 2–1B. Associated features of fetal alcohol syndrome observed in 245 persons affected

Area	Frequent[a]	Occasional[b]
Eyes	Ptosis, strabismus, epicanthal folds	Myopia, clinical microphthalmia, blepharophimosis
Ears	Posterior rotation	Poorly formed concha
Mouth	Prominent lateral palatine ridges	Cleft lip or cleft palate, small teeth with faulty enamel
Cardiac	Murmurs, especially in early childhood, usually atrial septal defect	Ventricular septal defect, great-vessel anomalies, tetralogy of Fallot
Renogenital	Labial hypoplasia	Hypospadias, small rotated kidneys, hydronephrosis
Cutaneous	Hemangiomas	Hirsutism in infancy
Skeletal	Aberrant palmar creases, pectus excavatum	Limited joint movements, especially fingers and elbows, nail hypoplasia, especially 5th, polydactyly, radioulnar synostosis, pectus carinatum, bifid xiphoid, Klippel-Feil anomaly, scoliosis
Muscular		Hernias of diaphragm, umbilicus or groin, diastasis recti

[a]Reported in between 26% and 50% of patients.
[b]Reported in between 1% and 25% of patients.
(From SK Clarren and DW Smith, N Engl J Med 298:1063, 1978.)

Table 2–2. Cardiovascular anomalies associated with selected teratogens

Agent	Anomalies reported
Alcohol	Frequent: VSD, ASD, tetralogy of Fallot, PDA Occasional: Pulmonic stenosis, subaortic stenosis, endocardial cushion defects, dextrocardia, double outlet right ventricle, coarctation of aorta, peripheral pulmonary stenosis, cardiomyopathy, patent foramen ovale, persistent left superior vena cava
Phenytoin	VSD, ASD, pulmonic stenosis, tetralogy of Fallot, valvular pulmonary stenosis, coarctation of aorta, endocardial cushion defects, aortic stenosis, superior vena cava duplex
Trimethadione	VSD, ASD, PDA, aortic stenosis, pulmonic stenosis, hypoplastic left heart, endocardial cushion defect, transposition of great vessels, tetralogy of Fallot
Valproic acid	VSD, PDA, coarctation of aorta, hypoplastic left heart, peripheral pulmonic stenosis, levocardia, right bundle branch block
Coumarin	PDA, peripheral pulmonic stenosis, transposition of great vessels, total anomalous pulmonary venous return

ASD, atrial septal defect; PDA, patent ductus arteriosus; VSD, ventricular septal defect.

poor sucking, abnormal muscle tone, irritability, and hyperacusis are frequently noted (52). Linguistic deficits, problems of socialization and memory, sleep disturbances, impulsiveness, and personality disorders are increased (26,45,49,60,62,63).

Cardiac anomalies include atrial and ventricular septal defects. In those infants with severe FAS, over 60% have congenital heart anomalies (30,50,54), and the occurrence of *DiGeorge syndrome* is increased (Table 2–2).

Skeletal anomalies include retarded bone age, copper-beaten skull, an increase in radioulnar and cervical vertebral fusions, radioulnar synostosis, hip dislocation, carpal fusion, pseudoepiphyses of metacarpals, hypoplastic distal phalanges, clinodactyly of V, and stippled epiphyses of the lower extremities (14,20,37,40,44,57).

Terminal transverse defects of the limbs occur more frequently (6,22,52), as does nail dysplasia (19). Palmar creases are altered. There is also an increase in embryonal tumors (8,11,18,25,33,55,68).

The pathophysiologic basis for alcohol embryopathy appears to be related to genetic polymorphisms for alcohol dehydrogenase, which converts alcohol to acetaldehyde, and for acetaldehyde dehydrogenase, which converts acetaldehyde to acetate. Technically, FAS may be an acetaldehyde embryopathy (36,41).

There is an excellent mouse model for alcohol embryopathy (66,67). Kotch and Sulik (35), through exposing pregnant mice to ethanol in vivo, noted excessive cell death in selected cell populations in 8-day embryos, especially those at the rim of the anterior neural plate (67). Exposure at day 7 resulted in holoprosencephaly and anencephaly, and at day

Angiotension-converting enzyme (ACE) inhibitor embryopathy

Captopril and similar compounds (Capoten, Monopril, Prinivil, Vasotec, Lotensin, Accupril, etc.) have been used in the United States and in Europe with and without the addition of diuretics for control of hypertension. They cross the placenta and are renally excreted. These angiotensin-converting enzyme (ACE) inhibitors have also been shown to impede diabetic nephropathy, both types 1 and 2.

There is some evidence that this group of drugs is fetotoxic; Pryde et al (7) summarized 31 examples in humans, and Barr and Cohen (2) reviewed the literature. The most common findings are second- and third-trimester onset of oligohydramnios and growth restriction followed by profound hypotension and anuria, pulmonary hypoplasia, and renal tubular dysgenesis. The calvaria is delayed in development (1–8).

Chorionic villus sampling embryopathy

Chorionic villus sampling (CVS), performed at about 56–66 days of gestation, has been carried out in about 150,000 women during the last decade. In 1991, several case reports were published which suggested that an increased number of infants with transverse limb deficiencies were born to mothers who had CVS (2,4,7). Most reports discussed absence of parts of the fingers or toes. Firth et al (4) and Chen et al (3) also noted associated defects of the tongue and lower jaw (*oromandibular-limb hypogenesis*). In a later report, the same group found this association in 19 of 75 cases (5). These reports engendered a large number of cohort and case–control studies that both supported and contradicted the association (1,4,6,8,9). Ultimately, the World Health Organization (12) suggested that CVS be delayed until weeks 9–12 since a temporal relationship had been indicated. In 1995, a U.S. population–based, multistate case–control study suggested that the odds ratio for all types of limb deficiency after CVS from 8 to 12 weeks gestation was 1.7, while for specific types, such as transverse deficiency, the odds ratio was 6.4. The absolute risk for this type of anomaly was 1 in 2900 births (0.03%)—i.e., a sixfold increase for transverse deficiency (9). Botto et al (1) found that the relative risks for any digital deficiency in two studies were 10.6 and 6.1, respectively. For severe transverse digital deficiencies, the relative risks were 30.5 and 10.7, respectively. Severe deficiencies were found in <25% of all digital deficiencies. The earlier the chorionic villus sampling, the more severe the deficiency.

Stoler et al (11) found an increased frequency of gastroschisis, club foot, and intestinal atresia. A similar body of literature regarding amniocentesis is available (10).

Cocaine embryopathy

Cocaine is used so often in conjunction with alcohol, cigarettes, marijuana, opiates, and illicit drugs that it has been difficult to separate its effects from those of other substances (8). An estimated 50% of cocaine users take only cocaine; the remainder take other drugs as well (18). Cocaine readily crosses the placental barrier.

Cocaine use is widespread. By 1985, approximately 25 million Americans had used cocaine, and about 5 million used it regularly. In 1986, it was estimated that 10% of pregnant women in Detroit used it (11). In 1992, 6% of babies born at a private suburban hospital had cocaine metabolites in the meconium (18). Similar data were evident in Boston (8). In mothers who use cocaine, preterm labor is increased (14).

Birth weight, length, and head circumference are generally below the 25th centile (2,10,12,17,19). Microcephaly is evident in about 30%, and about 25% have intrauterine growth retardation (2,11,14). In another study, no such effects were found (3). The facies is characterized by bitemporal narrowing, low hairline, horizontal supraorbital ridge, prominent glabella, short palpebral fissures, and short nose with anteverted nares (1,9,13,16).

Infants exposed prenatally to cocaine exhibit long-term depression of interactive behavior (3). Midline prosencephalic development and neuronal migration are also affected. Agenesis of the corpus callosum and septum pellucidum, septo-optic dysplasia, schizencephaly, and neuronal heterotopias have been described (6), as well as microphthalmia, optic hypoplasia, retinal dysgenesis, and retinal colobomas (7). Porencephaly and brain hemorrhage of various types have been reported (5,14).

The incidence of various major cardiac anomalies is increased (14,15), as are urinary tract anomalies (4). Limb reduction defects and intestinal atresias have been attributed to the vascular disruption effects of cocaine (1,13,16,18). Maternal hair tests have been employed to determine use during pregnancy (13a).

Cyclophosphamide (Cytoxan) embryopathy

Cytoxan, an alkylating agent used in treating cancer and autoimmune disease, has been cited as being teratogenic but not producing a specific phenotype (1–4). Variable findings have included growth deficiency and developmental delay, craniosynostosis, microcephaly, blepharophimosis, unusual pinnae, flat nasal bridge, and various extremity anomalies (hypoplastic radius and/or thumbs, hypoplastic middle phalanx of fifth fingers, absent fingers/toes).

Cytomegalovirus and toxoplasmosis embryopathies

Cytomegalovirus (CMV), which is contracted through transplacental transmission, is the most common cause of congenital infections, occurring in 0.5%–2.5% of all live births. It has been estimated that about 1 in every 3000 infants born in the United States suffers brain damage due to CMV exposure in utero. Conversely, when exposed early in pregnancy, the frequency of brain damage due to cytomegalic meningoencephalitis in the newborn has been estimated to be about 80%. In addition, intrauterine growth retardation (35%), pneumonitis (25%), hepatosplenomegaly (90%), thrombocytopenia (70%), jaundice (50%), and hemolytic anemia (50%) may be seen in the neonatal period.

Because the CMV causes cellular necrosis, infections such as necrotizing meningoencephalitis eventuate in microcephaly (40%), periventricular calcifications (25%), metaphysitis (25%), mental retardation, seizures, sensorineural hearing loss, and motor deficits (1,5,6). Obstuctive hydrocephalus may occur. Cytomegalovirus infections of the eye result in chorioretinitis and optic atrophy.

Similarly, about 6 in 1000 pregnancies in the United States are associated with primary maternal infection with toxoplasmosis. In about half the cases, the untreated mother gives birth to a congenitally infected infant, about 75% being asymptomatic, 10% being stillborn, and 10% being severely affected. It has been estimated that 70%–85% of women of childbearing age in the United States lack antibodies and are susceptible to primary infection. Prematurity occurs in 25% of infants exposed to CMV. Although malformations do not occur, hydrocephalus (5%) and microcephaly (5%) may result from chronic destructive meningoencephalitis and, as in the case of CMV, chorioretinitis may progress to loss of vision. Cerebral calcifications may be seen in about 10% of affected infants.

In those with severe toxoplasmic infections, about 80% have some degree of mental retardation, 70% have seizures or spasticity, and 50% have chorioretinitis. About 15% of this group will manifest sensorineural hearing loss (1–4,7). The mildest expression is chorioretinitis.

Severity of infection reflects time of infection—the earlier in pregnancy it occurs, the more severe the infection. Those who acquire the infection in the last trimester are often asymptomatic.

Diabetic embryopathy

It has been well demonstrated that children born to insulin-dependent diabetic mothers have a two- to threefold increased risk of congenital malformations and/or spontaneous abortion (7). One case–control study indicated a relative risk of about 8, with a relative risk of 15 for major central nervous system injury and 18 for cardiovascular system injury (2). Injuries to the fetus occur before the seventh week of gestation (8).

While the spectrum of injury is broad, the most frequently noted anomalies are those of the cardiovascular, genitourinary, and central nervous systems. In addition, infants with caudal regression developmental field defect and femoral hypoplasia–unusual facies syndrome are born to diabetic mothers with greater frequency. The term "axial mesodermal dysplasia" refers to a condition with signs of oculoauriculovertebral dysplasia (but without facial asymmetry) and caudal "regression" (12). Oculoauriculovertebral abnormalities are more common in children of diabetic mothers (4).

About 3% of these children have anomalies of the pinnae, heart, vertebrae, and central nervous system (5). Anomalies of the central nervous system include spina bifida and anencephaly. Ear anomalies, found in

2% of affected infants, include ear tags, microtia or anotia, and hirsutism (3,4,10). Caudal dysplasia is found in about 1%–2% (6,7,14,15). Conversely, about 15% of infants with caudal dysplasia are born to diabetic mothers. Malformations of the ribs and vertebral column occur with greater frequency (9,11). About 25% of those with femoral hypoplasia–unusual facies syndrome have diabetic mothers (5). Holoprosencephaly also occurs more frequently (1).

Cardiac anomalies include ventricular septal defect (VSD), transposition of great vessels, single umbilical artery, and situs inversus. Increased numbers of gastrointestinal anomalies include malrotation of bowel and anal or rectal atresia; and increased numbers of genitourinary abnormalities include renal agenesis, hypospadias, and cryptorchidism (14).

Sadler et al (13) have suggested that the pathogenesis involves a primary insult to developing somite mesoderm and associated neural crest cells.

Diethylstilbestrol embryopathy

Diethylstilbestrol (DES) was used to reduce spontaneous abortion and preterm delivery in at least 4 million pregnancies from 1948 to 1970 (8). Herbst et al (6) first pointed out in 1971 the tendency of female offspring exposed in utero to develop vaginal adenocarcinoma (mesonephroma). While vaginal adenosis is common, seen in possibly 75% of females exposed to DES before the ninth week of gestation, the frequency of adenocarcinoma of the vagina and cervix is very low—1 in 10,000. Another study estimates the risk to be 1 in 1000 (7).

Exposure to DES during the fourth to 12th week of gestation is teratogenic. In addition to being predisposed to vaginal adenosis, most female infants exposed prenatally to DES have persistence of müllerian mucosa over the upper vagina, cervix, and tubular walls. The uterus may be hypoplastic and T-shaped. The fallopian tubes are often short and narrow with absent fimbria (3). The vagina may show transverse ridges, and the cervix may be hooded or collared.

A follow-up study in 1977 of male and female offspring of mothers exposed to DES during pregnancy showed that 18% of female infants exposed to DES had oligomenorrhea compared to 10% of the control group (1), and fertility was diminished (18% vs. 33%). Circumferential or transverse ridges of the vagina and cervix were found in 40% of DES-exposed females in contrast to none in the control group. Adenosis was noted in 67% of the DES group and 3.5% in the control group. Dysplastic lesions of the vagina and cervix were noted in the exposed group, but not in the controls. Although the age range for adenocarcinoma has been 7–42 years, most cases have occurred in females between 15 and 27 years of age. Risk factors include DES taken before the 13th week of pregnancy and birth weight below 2500 g. Survival seems to be related to histologic pattern (women with a tubulocystic pattern fare better than those with a papillary pattern) and degree of nuclear atypia (2,5,6,9–13) (Fig. 2–2). Adenosis was greater in females exposed during the first two months (75%) than in those exposed during the 17th week or later (7%). Fertility does not appear to be decreased (8).

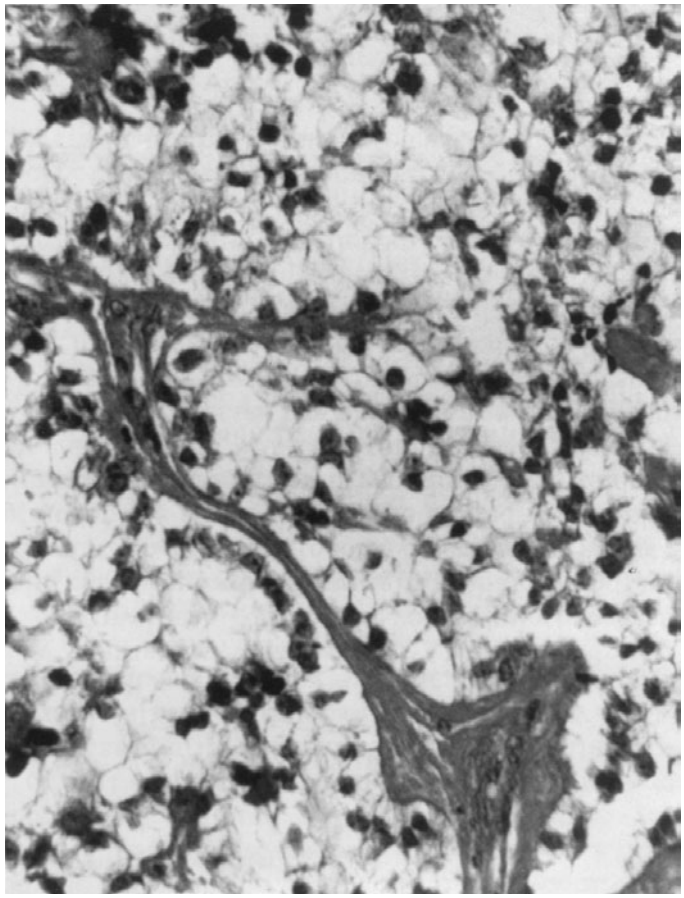

Fig. 2–2. *Diethylstilbestrol embryopathy.* Clear cell adenocarcinoma following DES therapy.

Male infants may have micropenis, hypospadias, cryptorchidism, small testes with indurated capsule, epididymal cysts, and impaired sperm production. About 13% of males have difficulty urinating compared to 2% of a control group (4). There was no increase in the incidence of cancer (8).

About 25% of males had epididymal cysts, hypotrophic testes, and capsular induration compared with 6% of control males. Furthermore, about 25% of the DES-exposed males had an ejaculate volume of <1.5 ml as opposed to 0% in the control group. Also lower were sperm density and total motile spermatozoa. Cancer was not observed in either group (1).

Fluconazole embryopathy

Fluconazole is a bis-triazole antibiotic effective against fungal pathogens. In 1992, Li et al (2) were the first to report an infant exposed in utero to fluconazole. The baby exhibited a pattern of malformations consistent with the *Antley-Bixler syndrome* of bony synostosis and characteristic craniofacial abnormalities. Similar cases have since been described (1,3). Findings in four cases included brachycephaly, depressed nasal bridge, dysplastic pinnae, midfacial hypoplasia, pear-shaped nose, proptosis, large anterior fontanel, and craniosynostosis. These patients also exhibited femoral bowing, radiohumeral synostosis, femoral fracture, long palms and fingers, rocker-bottom feet, cardiac defects, and early death. Patients with Antley-Bixler syndrome characteristically have frontal bossing, choanal atresia, and camptodactyly.

Folate antagonist (aminopterin, methotrexate) embryopathy

Folic acid antagonists have been recognized as having human teratogenic potential since the 1950s, when studies of aminopterin (4-aminopteroyl glutamic acid), which had been employed as an abortifacient, revealed serious congenital malformations (10,11,15,26,27). The embryopathy was first described by Thiersch (26) in 1950. The compounds aminopterin and its methylated derivative, methotrexate, are currently used as chemotherapeutic agents. Their action reduces DNA synthesis through competitive inhibition of folic acid reductase. Over 60 pregnancies have been documented in which there has been exposure to folate antagonists, but information is incomplete with regard to the frequency with which this exposure occurred (10,16,25). Nonetheless, increasing use of these agents for treatment of psoriasis and rheumatoid arthritis raises a legitimate concern for woman exposed to folate antagonists (4,6).

A somewhat similar pattern of anomalies (pseudo-aminopterin embryopathy) has been reported in several children for whom no prenatal antifolate exposure has been identified [7,20 (case 3),28]. The susceptible period appears to be during the eighth to ninth week of gestation (5,15,16,20,22). Specific attack rates associated with particular drug levels are not available.

Fig. 2–3. (A) *A folic acid antagonist-induced syndrome* caused by methotrexate, a methyl derivative of aminopterin. (B) Brachydactyly and soft tissue syndactyly involving digits 3 and 4 of the hands together with absence of toes. (From MM Cohen Jr, MacLean RE, Craniosynostosis: Diagnosis, Evaluation, and Management, 2nd ed, Oxford University Press, New York, 2000.)

Clinical findings. Findings from approximately 20 well-documented cases indicate that growth deficiency of prenatal onset may occur. Craniofacial abnormalities include hydrocephalus, abnormal calvaria with widely patent cranial sutures, craniolacunae, abnormal skull shape, and, sometimes, craniosynostosis (16). Less frequently, neural tube defects have been reported (26,27). Dysmorphic facial features include hypertelorism, dysmorphic pinnae, large nose, and striking micrognathia (3,9, 14,16,19,20,22–24) (Fig. 2–3). Cleft palate is increased in frequency (5).

Mental development has been extremely variable, ranging from normal intelligence to low IQ. Some patients have delayed speech development.

Other skeletal defects include short stature, absence or hypoplasia of digits, stenotic changes in long bones, and rib anomalies. Syndactyly and talipes equinovarus have also been reported (1,2,8,12,13,17,18,21) (Fig. 2–3).

Differential diagnosis. Differential diagnosis includes various genetic syndromes associated with *craniosynostosis* and other anomalies of the developing calvaria. Conditions causing micrognathia with cleft palate including the whole range of disorders associated with *Robin sequence* and skeletal defects should be considered. In cases with limb reduction defects and/or syndactyly, the *oromandibular limb-hypogenesis* group of disorders may be suggested.

Hydantoin embryopathy

As discussed elsewhere in this section, hydantoin (phenytoin, Dilantin), employed as an antileptic, is usually used in combination with other agents for control of seizures (7,27). The first suggestion that the hydantoins were teratogenic was made by Janz and Fuchs (17) in 1964. In 1976, Hanson et al (15) estimated that about 6000 babies were exposed annually.

When taken during pregnancy, hydantoin increases the risk for congenital malformations by two- to threefold—i.e., about 5%–10% of exposed fetuses manifest hydantoin embryopathy (12) while 30% exhibit some changes (16,18,28). Similar data were reported by Majewski et al (22).

The role of genetic factors in hydantoin embryopathy has been confusing (8); in some cases, the effects have been dissimilar. Affected sibs have been noted (5,10,12,29). Genetic susceptibility may be a factor as arene oxide metabolism has been linked to hydantoin embryopathy (9,24,26). Dean et al (7a) found that mothers of children with hydantoin or valproate embryopathy more often have mutations in the *MTHFR* gene.

Among those with features of the syndrome, the findings most often include prenatal and postnatal growth retardation (45%), microcephaly (30%), mental retardation (25%), sutural ridging (10%), cleft lip and/or palate (5%), small nose with low broad nasal bridge (20%), ptosis of eyelids (10%), epicanthic folds (15%), strabismus (15%), wide mouth, short neck with mild webbing, congenital heart disease (especially VSD) (10%), and digital anomalies (35%) (9a,22a). Renal malformation and hypospadias are not rare (11,13,23,30) (Fig. 2–4A,B).

The digital anomalies are characterized by nail hypoplasia and/or hypoplasia of distal phalanges (especially of digits 4 and 5) (15%) and digitalization of thumbs (10%) (Fig. 2–4C,D). An increased number of fingerprint arches has been found (14,31). The incidence of hernia, both umbilical and inguinal, is increased (25%), and about 30% have shawl scrotum.

Embryonal neoplasms include neuroblastoma, ependymoblastoma, ganglioneuroblastoma, melanotic neuroectodermal tumor of infancy, Hodgkin lymphoma, cystic hygroma, mesenchymoma, and Wilms tumor (1,2,3,6,19–21,25). Epoxide hydrolase deficiency is seen in those prone to have affected children (4).

Probably many cases are associated with subtle manifestations. Differential diagnosis includes *alcohol embryopathy* and embryopathy due to other anticonvulsant agents. *Coffin-Siris syndrome*, if indeed it exists, must be excluded.

Hyperthermic embryopathy

Hyperthermia, i.e., body temperature of at least 38.9°C, has been described as an antimitotic teratogen following exposure between weeks 4 and 16. While it has been clearly demonstrated that hyperthermia is teratogenic in many species of animals, producing anencephaly, exencephaly, holoprosencephaly, neuronal heterotopias, microcephaly, microphthalmia, cleft lip and/or palate, and arthrogryposis, its role in human teratogenesis is less than clear (1,2). This debate has been elegantly presented by Warkany (10). Most case reports have been related to infections or sauna bathing. Smith et al (7) described several retrospective examples of exposure from 4 to 6 weeks gestation, showing severe mental retardation, seizures, hypotonia, microphthalmia, midface hypoplasia, and mild distal abnormalities. When exposure occurred from the 7th to the 16th week, the infants had neurogenic arthrogryposis and, during the time of neural tube closure (21–28 days), neural tube defects (anencephaly, myelomeningocoele, occipital encephalocele) (3–6). During the latter half of gestation, anomalies were not increased. Superneau and Wertelecki (9) suggested that oromandibular-limb hypogenesis might be the result of hyperthermia.

Cell death is a major factor in heat-induced teratogenesis, mitotic cells being most susceptible (8).

One must exclude Native American (Lumbee) myopathy. This consists of developmental delay, short stature, ptosis, cleft palate, myopathic facies, scoliosis, congenital joint contractures, early death, and autosomal recessive inheritance (CM Powell, personal communication, 2000).

Maternal phenylketonuria embryopathy

Individuals with phenylketonuria, when placed on a phenylalanine-free diet, lead a reasonably normal life. However, females with this autosomal recessive metabolic disorder who are not diet protected during their pregnancy nearly always have infants with intrauterine and postnatal growth retardation, microcephaly, mental retardation, congenital heart anomalies, dislocated hips, and other problems (1–3,8,12,17). The infants of phenylketonuric mothers are heterozygotes and, because phenylketonuric heterozygotes are normal, the anomalies in the fetus have been attributed to the maternal metabolic disturbances. When maternal phenylalanine levels exceed 20 mg/deciliter, 95% of affected infants have mental retardation, 73% have microcephaly, 40% have intrauterine growth retardation, and 14% have cardiac anomalies (10–13,15,18). When blood levels are maintained at 120–360 μmol/liter prior to the eighth week, infants suffer no congenital heart disease and their intelligence is normal (7–9). Although 25% of pregnancies in women with phenylketonuria were reported to be spontaneously aborted in 1967 (16), a recent international collaborative study recorded a rate of 15% (5), a not unusual level. A 1997 collaborative study suggested that the mother begin the phenylalanine-free diet prior to conception and maintain it throughout pregnancy (16).

A somewhat unusual facies includes epicanthic folds, wide outer canthus, hypoplastic maxilla, wide flat nasal bridge, anteverted nostrils, long smooth philtrum, and thin upper lip (16), reminiscent of that seen in fetal alcohol syndrome (11).

When the diet is essentially phenylalanine-free prior to and during pregnancy but supplemented with tyrosine, children are unaffected (4,6,14). This regimen, however, is extremely difficult to achieve and maintain. Fisch et al (4) have suggested that affected individuals use in vitro fertilization followed by embryonic transfer to a surrogate mother.

Pathogenesis is still unknown, but it may be related to inhibition by phenylalanine of large neutral amino acid transport across the placenta or by direct toxicity of phenylalanine to various organs. At least 250 mutations are known and almost all individuals are doubly heterozygous for the mutations (11).

Misoprostol embryopathy

Misoprostol, a synthetic analog of prostaglandin E_1, has been employed as an abortifacient in Brazil for about 15 years (1a,3,5–7,11,12). It increases the amplitude and frequency of uterine contractions and stimulates uterine bleeding. When taken during the second month of gestation, it can produce cranial nerve disorders in the fetus, principally affecting cranial nerves VI and VII, and can cause transverse amputations and talipes.

Misoprostol, which is bought over the counter, is used by 50%–75% of women who attempt abortion in Brazil. However, the drug is not very effective and 80% who use the agent continue to term. Fonseca et al (4) reported a localized defect of the cranium and overlying scalp in five babies. Collins and Mahoney (2) described a male baby with hydrocephalus, digital anomalies, and equinovarus deformities. Wood et al (15) found hydrocephalus and growth retardation. Gonzalez et al (5–7) and Pastuszak et al (12) have described 51 children exposed to misoprostol, 22 of whom had *Moebius sequence*, 11 had hydrocephalus, 11 had talipes equinovarus, and 7 had syndactyly of fingers. They posited that the uterine contractions cause vascular disruption, including brain stem ischemia. Some infants have Arnold-Chiari anomaly.

Lipson et al (9) found that rats with abdominal trauma and clamping of the uterine artery produced pups with changes similar to those of misoprostol embryopathy. There is good evidence that occlusion of the subclavian artery will produce Moebius sequence (1,8,10–14).

Primidone embryopathy

Primidone, a relative of phenobarbitol, was introduced in the early 1950s for prevention of generalized tonic–chronic seizures. The first example of embryopathy was reported by Seip (8) in 1976. About 35 examples have been reported to date (1–10). Patient 1 of Myhre and Williams (4) may have had Noonan syndrome (1); however, a similar phenotype was noted by Krauss et al (3).

The clinical features include pre- and postnatal growth delay, and abnormal facies characterized by metopic ridging, thick nasal root, anteverted nares, up-slanting palpebral fissures, thin vermilion, and micrognathia. Microcephaly, jitteriness, hirsutism, hypoplastic nails, and cardiac defects [coarctation of aorta, VSD, patent ductus arteriosus (PDA), pulmonary artery hypertension, mitral valve deformity, biventricular hypertrophy] were also found.

Radiation embryopathy

In utero radiation was known as early as the 1920s to be associated with microcephaly, mental retardation, and stunted growth, especially in infants exposed between the 8th and 15th week of gestation. In survivors of the atomic bombings of Hiroshima and Nagasaki, there has been a progressively increased frequency of malignant neoplasms, especially leukemias and lymphomas, but in subsequent pregnancies, there had been no increased rate of spontaneous abortions, stillbirths, or chromosomal abnormalities.

An estimated 0.1% rate of leukemia has been found in individuals who were within 1500 meters of the atomic bomb epicenter. Among 1600 offspring whose mothers were exposed to the bomb, the rate of mental retardation was about 2.5% at dose levels of 10–49 rads and 18% at 15–99 rads, the most critical period being between the 8th and 15th week following fertilization (5–7). Significant exposures between the second and fourth week usually resulted in spontaneous abortion. Doses of <5 rads are probably not teratogenic and an excess of 25 rads is required for evidence of obvious teratogenesis (3,4). Following exposures of 100 rads or more, infants are prone to microcephaly, hydrocephalus, microphthalmia, optic atrophy, retinal dysplasia, and cataracts (1,2a).

Data regarding the nuclear accident at Chernobyl are too confusing to assess (2).

Retinoid embryopathy

During embryogenesis, retinoids are involved in morphogenesis of many organs: brain, craniofacies, heart, limbs, and axial skeleton, functioning as ligands bound to nuclear receptors of the steroid–thyroid hormone receptor superfamily. These receptor complexes function in transcription factor activation involved in embryologic development.

Although intake of excess vitamin A has been reported to cause embryologic damage (17a,20,22), teratogenic exposure from ingestion of isotretinoin or etretinate concerns us here. The first reports of isotretinoin teratogenicity were those of Rosa (18) in 1983 and Braun et al (3) in 1984. Isotretinoin (13-*cis*-retinoic acid), an active congener and metabolite of vitamin A, is taken orally for treatment of severe cystic acne. Unlike retinyl esters, isotretinoin is not stored in adipose tissues; its elimination half-life is less than one day. During the first trimester, it is a rather powerful teratogen, although a precise critical period has not been established. It has been estimated that about 25% of affected pregnancies reaching 20 gestational weeks have a major malformation (23,25). A mouse model has been studied (9). As with other powerful teratogens, there is a significant increase in the rate of spontaneous abortion and premature delivery (20%–25%) (17).

Etretinate has been used for severe psoriasis. In contrast to isotretinoin, etretinate accumulates in the body with an elimination half-life of about 120 days. Pregnancy should not be attempted until 2 years post-treatment (8). Among 75 pregnancies in which exposure to etretinate occurred, 6 had one or more typical manifestations. Five of 14 induced aborted fetuses had the typical stigmata (8). Over 100 cases of isotretinoin embryopathy and over 20 examples of etretinate embryopathy have been reported, mostly from North America (11,27). Acitretin can also produce an embryopathy (6).

Clinical findings. Exposure of the embryo to retinoids during the first 10 weeks may result in malformations of the brain, craniofacies, heart and major arteries, and thymus. Brain anomalies (noted in 70%) have included hydrocephalus, microcephaly, ventriculomegaly, malformations of the cerebellum and brain stem, and various cranial nerve deficits (16). Intellectual deficits were found in a series of 5-year-olds, with over 50% being in the subnormal range (1).

The skull tends to be somewhat triangular, with narrowing of the frontal area and a large occiput. Hair whorls tend to be misplaced. Abnormalities of the pinnae, seen in 70% of affected infants, range from pretragal pits to anotia with imperforate auditory canals. Those parts of the pinna derived from the second branchial arch are more susceptible than those derived from the first arch (7). The pinnae are asymmetrically microtic (4) (Fig. 2–5). Occasionally, only a tragus and slit-like canal are present. The

Fig. 2–5. *Retinoid embryopathy.* Note abnormal ears. (Courtesy of L Van Maldergem, Loverval, Belgium.)

ossicles of the middle ear are less frequently affected, and the inner ear, only rarely. Facial nerve paralysis on the side of the more severely affected ear may be seen. The nasal bridge and midface are often depressed. Cleft palate is found in about 15% of affected individuals (12,14,15), and the mandible is small in 35% (19). The eyes are occasionally microphthalmic (20).

Cardiac anomalies include common truncus, transposition of great vessels, atrial septal defect (ASD), VSD, tetralogy of Fallot, and aortic arch malformations. Classic DiGeorge anomaly (conotruncal malformations, thymic and parathyroid hypoplasia / aplasia) are seen in over 35% of cases (13). Retinal or optic nerve abnormalities are found in 20%. Various thymic abnormalities, such as T-cell immunodeficiency and ectopic thymic tissue in the lateral neck, occur in about 35% of affected individuals (5,13).

The external ear, palatal, mandibular, and cerebellar abnormalities can be explained by excessive cell death in the rhomboencephalic neural folds prior to the time of their emigration into the first two arches. The thymic and conotruncal abnormalities could be similarly explained as the result of a deficiency of crest cells going to the third and fourth arches (2,10,14,24,26,28).

Rubella embryopathy

Rubella (German measles) was one of the first known teratogens, its effects having been demonstrated by the Australian ophthalmologist Gregg (3) in 1941. An excellent history of our understanding of rubella embryopathy is that of South and Sever (9). In a 1964 rubella epidemic of almost 2 million cases in the United States, an estimated 20,000–30,000 babies were damaged by the epidemic (7). Rubella contracted prior to the 11th week has a complication rate of close to 100% (principally sensorineural hearing loss and congenital heart disease), and about 35% of those infected during the 13th–16th week have complications (primarily hearing loss) (4–6,7,9,12). After 16 weeks, no stigmata attributable to rubella can be found (4). A superb survey of the teratogenic effects of rubella can be found in Webster (13).

Various studies have demonstrated that spontaneous abortion occurs in about 10% of affected pregnancies and stillbirth in about 5%, and most affected fetuses have intrauterine growth retardation (6). Approximately one-third of liveborn infants who also have thrombocytopenic purpura die during the first year of life. Major abnormalities, largely those of the eye, ear, and heart, occur in about 25% of infants exposed to rubella (1). The most commonly noted abnormalities are sensorineural hearing loss (unilateral or bilateral), mental retardation, various eye anomalies (cataract, microphthalmia, iris hypoplasia, strabismus, glaucoma, nystagmus, retinopathy, mesodermal dysgenesis), and cardiovascular anomalies (pulmonary artery stenosis, pulmonary valvular stenosis, aortic valvular stenosis, ventricular septal defect, and patent ductus arteriosus) (Table 2–3C). Diabetes mellitus develops in about 30% of adults who had rubella embryopathy. Progressive rubella panencephalitis, a "slow" virus presentation, is rare (9) (Fig. 2–6).

Cataract and glaucoma and cardiac malformations can occur in infants exposed through 12 weeks, with peripheral pulmonary stenosis occurring through 24 weeks and hearing loss through 28 weeks (9). When

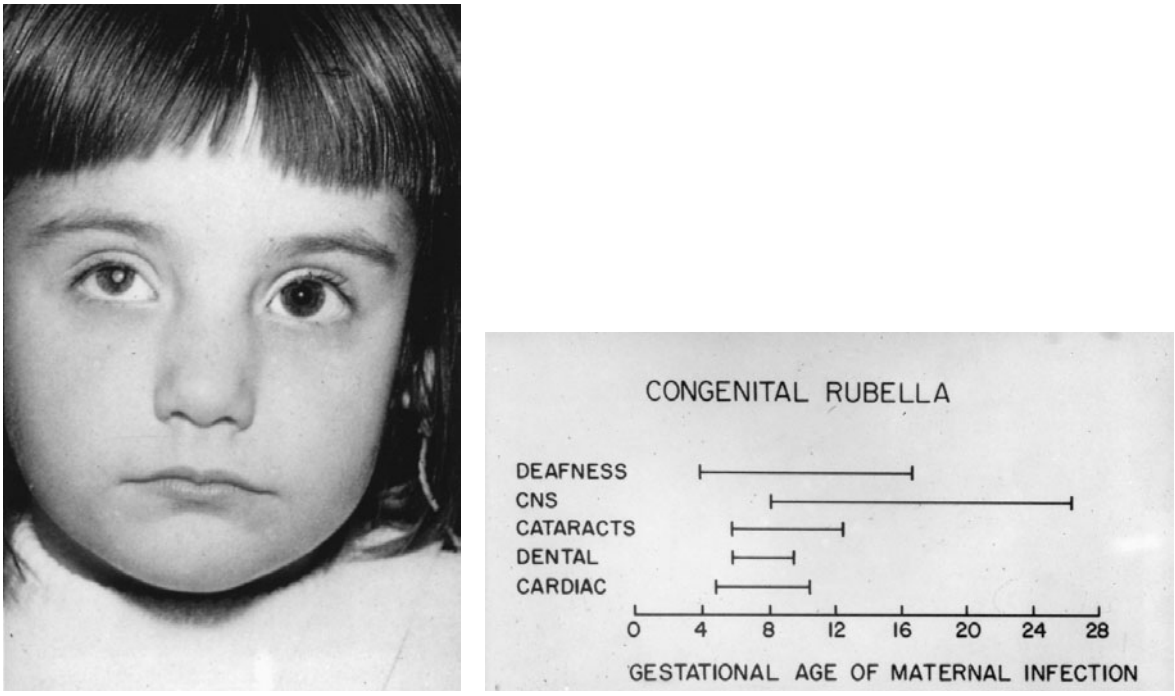

Fig. 2–6. *Rubella embryopathy.* (A) Congenital cataract. (B) Relationship of gestational age at time of maternal rubella infection to anomalies observed.

contracted during the last trimester of pregnancy, the brain is apparently not affected.

Enamel dysplasia of the primary teeth was found in 20% of infants (2).

Tetracycline embryopathy

Discoloration of the deciduous or permanent teeth may result from ingestion of tetracycline by the pregnant female or by the child. Chlortetracyclines were first introduced in 1949. Since then, many homologues have become available. These yellow antibiotics fluoresce yellow under ultraviolet light, and darken in color with oxidation. The affinity of tetracycline for bone and for teeth was first demonstrated in 1956 by Schwachman and Schuster (5).

The state of tooth development determines the location and distribution of the staining. Calcification of the deciduous teeth begins during the fourth month of gestation, and the crowns of the permanent dentition begin to calcify shortly before birth, with completion occurring by the eighth year of life. Discoloration depends upon dose, time, length of administration, and the homologue of the tetracycline employed; for example, oxytetracycline stains to a lesser degree than tetracycline (1). Anterior deciduous teeth (incisors and canines) are stained from four months in utero to nine months postpartum, and anterior permanent teeth are stained from 3 months postpartum to seven years of age. Dosages of 20–25 mg/kg or greater over a period of as little as three days can produce discoloration (4).

In the 1960s, the frequency of staining peaked at about 25% among children seen in pediatric practice. However, on microscopic examination at least 50% of extracted first permanent molars from children 7–15 years of age showed at least one deposit (6). The permanent teeth were especially stained if tetracycline therapy was continued for years, such as in cystic fibrosis. The dentin is more heavily stained than the enamel (11). Tetracycline forms an orthocalcium phosphate complex with dentin and enamel that is then oxidized by ultraviolet light (7).

Fig. 2–7. *Tetracycline embryopathy.* Note dark discoloration of anterior teeth.

The deciduous teeth present a yellow to brownish discoloration of the crown located primarily near the gingival third of the incisors, and the occlusal and incisal third of the molars and canines, respectively (Fig. 2–7). In premature infants, a larger surface is stained, and enamel hypoplasia is often found. The bright yellow color which is striking upon eruption of deciduous teeth becomes brown after exposure to light. As the teeth become brown, fluorescence under ultraviolet light progressively declines (2,3,6,8,10).

Ground sections reveal a zonal pattern of staining that forms bands in the dentin corresponding to the time of administration of tetracycline, the fluorescent bands running parallel to the dentinoenamel junction following the incremental lines of growth (9) (Fig. 2–8). Decalcified sections show an increase in interglobular spaces indicating hypomaturation.

Fig. 2–8. *Tetracycline embryopathy.* Ground section of premolar tooth under ultraviolet light showing periodic deposits. (From N Kotsanos, Br Dent J 152:91, 1982.)

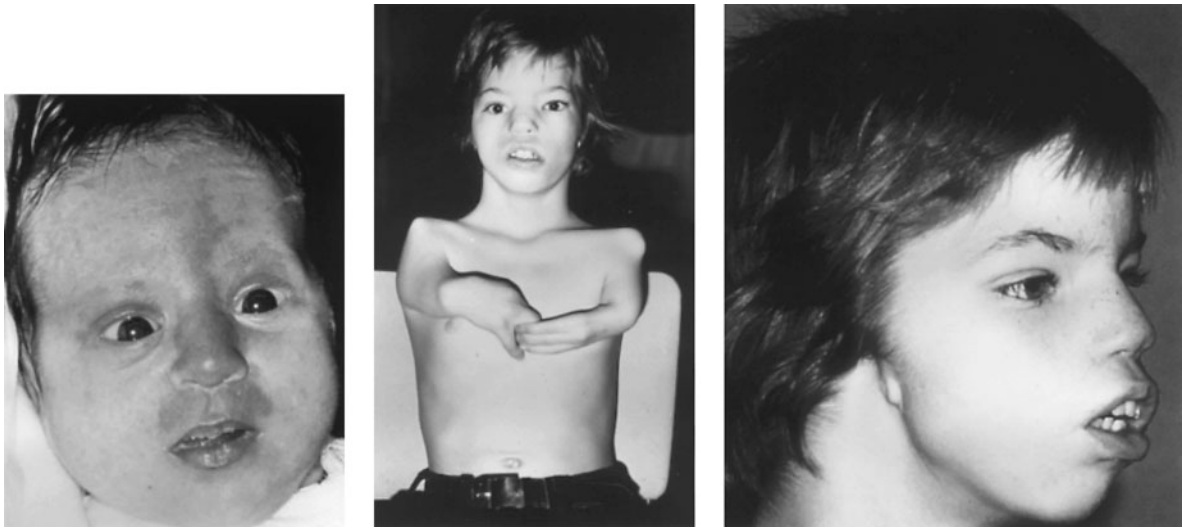
Thalidomide embryopathy

Thalidomide, used principally as a sedative for nausea during pregnancy, from 1958 to 1961 and mainly in Germany, The Netherlands, United Kingdom, Sweden, Brazil, and Japan, injured over 10,000 infants through prenatal exposure. In 1961, Wiedemann (15) noted an epidemic of limb malformations and Lenz (5) in Germany and McBride (9) in Australia attributed the cause of the malformations to thalidomide. The drug was not approved for use in the United States by the Food and Drug Administration. Frances Kelsey (4), who was in charge of the New Drug Branch, received reports that the drug caused peripheral neuritis, and had insufficient data to ensure safe use during pregnancy. The fascinating history of thalidomide embryopathy was further detailed in a series of papers published during the 25th year after recognition of the role of thalidomide in causing this epidemic (2,5,6,8). Because of its current use for leprosy, it is still a teratogenic threat in South America (3). Other recent uses are for aphthae, Behçet syndrome, lupus erythematosus, rheumatoid arthritis, diabetic retinopathy, and graft-versus-host disease (9a,14,16).

Clinical findings. The most findings have been limb defects, which range from triphalangeal thumb to phocomelia (principally of the upper limbs) (Fig. 2–9B). Aplasia of bones (thumb, radius, humerus, ulna, ulnar digits) is extremely variable, and preaxial polydactyly is not rare. The most critical period for occurrence of amelia is from days 39 to 44 following the last menstrual period or from the 27th to 30th day postconception. The peak period for occurrence of upper limb anomalies precedes that for lower limb abnormalities by a day or two. Triphalangeal thumb (digitalization) occurs most frequently if the drug is given during days 46 to 50 after the last menstrual period (2,6,7,10,11).

Facial anomalies include "stork bite" (forehead, nose, upper lip) hemangiomata, anotia, meatal microtia/atresia, stenosis, ear tags, facial palsy, external ophthalmoplegia, anophthalmia or microphthalmia, colobomata, cleft lip/palate, and choanal atresia (Fig. 2–9A,C). These anomalies are especially prominent when the thalidomide exposure is during days 20 to 29 postconception.

In addition to facial palsy, such unusual findings as jaw-winking and crocodile tear syndrome occur more frequently. Dental involvement



A B C

Fig. 2–9. *Thalidomide embryopathy.* (A) Midfacial hemangioma. (B,C) Phocomelia of both arms, absent ears. Patient also had ankylosis of temporomandibular joint, bifid uvula, and absence of one parotid gland. Mother had used thalidomide during the first three months of pregnancy. (A courtesy of H-R Wiedemann, Kiel, Germany. B,C courtesy of PJW Stoelinga, Arnhem, The Netherlands.)

consists of mild enamel dysplasia (50%) and agenesis of maxillary lateral incisors (8%), both deciduous and permanent (1).

Internal anomalies include esophageal and duodenal atresia, various cardiac defects, especially tetralogy of Fallot, PDA, ASD, VSD, pulmonary stenosis, and renal agenesis. Many of these anomalies contribute to the estimated 40% early mortality. Late involvement (46–50 days) is associated with anorectal stenosis.

The mechanism of action has never been firmly established; an excellent review of the various hypotheses is that of Stevens (12). Taken before or after the critical period, thalidomide apparently has no effect upon the embryo. In 2000, Stevens and Fillmore (13) suggested that thalidomide interfered with angiogenesis.

Toluene embryopathy

Toluene embryopathy, first described by Hudak and Ungvary (6) and Toutant and Lippman (9), is a consequence of solvent abuse (exposure to spray paint or lacquer, or glue sniffing). Paint or glue sniffing is especially common among teenagers, with some 3%–4% engaging in this activity on a regular basis. More than 50% are females in prime childbearing years (7). There is no evidence that exposure to organic solvents under normal laboratory conditions results in increased abortions or in malformed infants (2).

Toluene easily crosses the placenta, producing changes in infants that are very reminiscent of those seen in fetal alcohol embryopathy. Both toluene and alcohol probably effect a common insult to mesoderm ventral to the forebrain (7). At least 50 cases of toluene embryopathy have been reported (1–11).

Teratogenic timing and dosage have not been determined, but, as in the case of alcohol, it may be that there is no safe period. Neurogenesis is inhibited (3a).

Clinical findings. Prematurity (40%), pre- and postnatal growth deficiency (50%), prenatal microcephaly (33%), postnatal microcephaly (67%), and developmental delay (80%) occur. The facies is similar to that noted in *alcohol embryopathy*: micrognathia (65%), midfacial hypoplasia (65%), small palpebral fissures (65%), dysmorphic pinnae (60%), narrow bifrontal diameter (50%), abnormal scalp hair pattern (45%), thin upper lip and smooth philtrum (35%), small nose (35%), downturned corners of the mouth (33%), and large anterior fontanel (20%) (10) (Fig. 2–10). Nail hypoplasia (40%), altered palmar creases (35%), blunt fingertips (50%), clinodactyly (20%), hypotonia or hypertonia (35%), hemangiomata (30%), and hydronephrosis (25%) are additional findings (1,4,5,7,8,10,11). Similar findings have been noted in the offspring of mice and rats exposed to a variety of industrial solvents (3).

Findings more common in toluene embryopathy than in alcohol embryopathy include prematurity, micrognathia, ear abnormalities, narrow

Trimethadione embryopathy

As with other anti-epileptic drugs, it has been difficult to define distinct effects of trimethadione on growth and morphogenesis because so few epileptic women receive monotherapy. German et al (3) appear to be the first to have noted a teratogenic association with tridione in 1970. Spontaneous abortion or miscarriage occurs in about 25% of women taking trimethadione.

The most frequent features reported in association with taking paramethadione (Paradione) and trimethadione (Tridione), both oxazolidinediones, include a dysmorphic facies consisting of V-shaped eyebrows, low nasal bridge, anteverted nares, hypertelorism, occasional ptosis and/or epicanthic folds, mildly down-slanting palpebral fissures, and low-set, posteriorly rotated pinnae (Fig. 2–11). Cleft lip/palate was found in 25% of affected infants (6). About 5% had tracheoesophageal abnormalities (2). Mild mental delay was found in 50% with only intrauterine growth retardation and mild postnatal growth deficiency. About 50% of affected individuals have a mild reduction in head circumference. Speech is retarded in over 60% (1–8).

Congenital heart anomalies noted in 50% of affected infants have included PDA, pulmonic stenosis, tetralogy of Fallot, VSD, and coarctation of the aorta. Inguinal and/or umbilical hernia has been noted in 15%. Renal malformations and hypospadias were observed in 30% of cases.

Valproate embryopathy

Valproic acid (Depakene) was first marketed in Europe in 1967 and in the United States in 1978 for treatment of seizure disorders. Although it may be used as the only agent, polytherapy with phenytoin, phenobarbitol, and carbamazepine is relatively common. Valproate use probably increases the risk of abnormalities in the developing fetus by 2–3 times that of the general population. The earliest reports of valproate embryopathy are

A B

Fig. 2–11. *Fetal trimethadione syndrome.* (A) V-shaped eyebrows and (B) dysplastic ears. (Courtesy of JW Hanson, Iowa City, Iowa.)

those of Dalens et al (10) in 1980, Gomez (12) in 1981, and Bjerkedal et al (3) in 1982. Over 100 cases have been reported.

We feel that the facies of valproate embryopathy is not significantly different from that produced by use of hydantoin (phenytoin, Dilantin) or carbamazepine (Tegretol). Facial changes include midface hypoplasia (60%), short, upturned nose with broad or flat nasal bridge (50%), epicanthic folds, mild dysmorphic changes in the pinnae, long flat philtrum, thin vermilion, and small mandible (4,5,8,15,21,23) (Fig. 2–12). Occurrence of cleft lip and/or palate is apparently not increased (17). Prominent metopic ridge, outer orbital ridge deficiency, and bifrontal narrowing are more often seen in valproate embryopathy. Developmental delay and hypotonia were found in up to 90% of affected patients (1,2,11,14). The variable effect on sib pairs has been discussed by Chitayat et al (6) and Christianson et al (7). Other findings include lumbosacral meningomyelocoele or meningocoele (1%–5%) (5,16,19,20), talipes equinovarus, and tracheomalacia or stridor.

Genital anomalies, seen in 30% of affected individuals, include hypospadias and cryptorchidism in males and incomplete fusion of müllerian duct structures in females. Cardiac abnormalities, seen in 20%, include VSD, coarctation of the aorta, and PDA (22). Anomalous right pulmonary artery has also been described (18).

Limb anomalies, noted in 65%, are usually mild ones: clinodactyly of fifth fingers and distal phalangeal hypoplasia (20a). However, radial ray reduction has also been described (13). Rodriguez-Pinilla et al (20a) noted that 36% of cases have congenital limb defects. Joint laxity has been noted (17a).

Postnatal growth is normal. Although there is global developmental delay, expressive speech delay is greater than receptive speech delay. Gross motor delay is less marked (6). Hyperactivity, learning difficulties, autistic features, and fine motor delay are frequent (17a).

Myopia has been described in 35% (17a).

Experimental teratogenesis has been reviewed by Cotariu and Zaidman (9).

Varicella embryopathy

Infection with the varicella zoster virus during the first two trimesters of pregnancy causes fetal damage in 2.5% of the cases (4,9). Estimated incidence in the United Kingdom is 3/1000 (9), and in recent prospective studies, the rate of affected offspring has ranged from 0% to 9.1% (4,6,9,11). In 1947, Laforet and Lynch (8) first described multiple congenital defects following maternal varicella. A specific syndrome was postulated by Srabstein et al (13); at least 50 cases have been reported (4).

Findings in 10%–50% of reported cases include limb paralysis and various neurologic problems (hydrocephalus, microcephaly, cortical atrophy, mental retardation, weak cry, seizures, Horner syndrome, bulbar dysphagia, anal sphincter dysfunction, and phrenic nerve palsy) (5). Skeletal changes include talipes and hypoplastic scapulae, clavicles, ribs, fingers, or toes. Only rarely are gastrointestinal and genitourinary anomalies found (7). Cutaneous scars with dermatomal distribution are seen in over 50% of affected individuals. Eye anomalies include chorioretinitis, anisocoria, nystagmus, cataracts, and microphthalmia (1–3,8,10,12,14).

Asymptomatic fetal infection after maternal zoster infection is not uncommon but does give rise to varicella embryopathy.

Warfarin and vitamin K deficiency embryopathy

Warfarin (coumadin), employed as a blood thinner for those having artificial heart valve replacement or because of thromboembolic disease, crosses the placental barrier. In 1966, DiSaia (4) may have been the first to report Warfarin embryopathy. In addition to an increased rate of spontaneous abortions and stillbirths, Hall et al (6) found that about 15% of such pregnancies resulted in abnormal liveborn infants, 15% in abortion or stillbirth, and about 70% in normal births. Wong et al (33) noted that 60% were spontaneously aborted or were stillborn. Iturbe-Alessio et al (11) and Wong et al (33) found that 15%–30% of pregnancies exposed to coumadin during the first trimester showed signs of the embryopathy. A rat model has been created using large doses of Warfarin and vitamin K1 (8).

About 35% of infants exposed to coumadin anticoagulants during pregnancy die prenatally or suffer serious teratogenic consequences. Among those who survive, approximately 30% manifest prenatal growth deficiency. The most severe teratogenic damage occurs from 6 to 9 weeks postconception (3,12,19). After 9 weeks, ocular defects and central nervous system (CNS) malformations and hemorrhages are most characteristic. When taken after the first trimester, there is no effect on skeletal growth (30a).

Clinical findings. The most striking finding, although in itself rare (4%), is the hypoplastic nose (Fig. 2–13A). Exposure during the sixth-ninth week results in premature calcification of nasal cartilages (vide infra). The nose is small with upturned, narrowed nares. The nose often appears sunken into the face (1,2,5,7,20,24). Choanal narrowing or even choanal stenosis causes the breathing and/or feeding difficulties seen in about 70% during the first few months of life (15,29). In many cases, there is improvement both functionally and cosmetically with time.

When Warfarin is taken at any time during pregnancy, there is a 3% chance for CNS abnormalities (mental retardation, microcephaly, hydrocephaly, agenesis of the corpus callosum, Dandy-Walker malformation, seizures, and hearing loss) (12,13,22). Of those with Warfarin embryopathy, about 30% have mental retardation. Eye anomalies, which are also rare, include corneal opacities, cataract, optic atrophy, and microphthalmia (12,19,21,25).

Bone abnormalities of the axial and appendicular skeleton may be striking. The epiphyses of long bones (especially the femur), vertebrae, ribs, calcanei and cuboids, scapulae, terminal phalanges, and carpal and tarsal bones manifest a stippled radiographic appearance (10,26,28,32,34) (Fig. 2–13B). The paravertebral lumbosacral and cervical areas of the spine are especially affected. Brachydactyly is noted in 40%. The punctate features disappear with age by resorption or incorporation within bone. The laryngeal and nasal cartilages may appear calcified on X-ray. While short stature is seen in 35% (33), asymmetric growth is not observed.

Premature calcification occurs because Warfarin prevents the reduction in vitamin K, resulting in gamma carboxyglutamation of osteocalcins or

A B

Fig. 2–13. *Warfarin embryopathy.* (A) Hypoplastic nose with groove between alae and nasal tip. (B) Note stippling of calcaneus. (B courtesy of JG Hall, Vancouver, BC.)

other vitamin K–dependent bone proteins. Because osteocalcin binds less to calcium, it is deposited in the fetal cartilage (6,17,18). This mechanism of vitamin K deficiency also occurs in various forms of *chondrodysplasia punctata* and *Binder phenotype* (8,23). In the case of the former, there appears to be a mutation in arylsulfatase E (4a); in Warfarin embryopathy, it results from competitive inhibition by Warfarin (23). Thus, Warfarin embryopathy is a phenocopy for these disorders (30). Pauli et al (19) described the simultaneous occurrence of chondrodysplasia punctata and congenital deficiency of vitamin K–dependent coagulation factors in an infant and posited that there was a deficiency of vitamin K epoxide reductase.

If the mother is taken off Warfarin and given heparin, which does not cross the placenta, from the 6th to the 12th week of gestation, no signs of the embryopathy present. However, if she remains on Warfarin until the beginning of the eighth week, then about 25% of exposed infants have anomalies (12).

Differential diagnosis. Various forms of *chondrodysplasia punctata* and *Binder phenotype* must be excluded if, indeed, the latter is not a variant of the former or an expression of prenatal vitamin K deficiency (9,27). Various causes of stippled epiphyses include *Zellweger syndrome,* hypothyroidism, and genetic disorders of vitamin K metabolism (14,19). Malabsorption due to celiac disease, short bowel syndrome, and jejunalilial bypass will produce vitamin K deficiency and the associated syndrome in infants of pregnant mothers (16). Prenatal diagnosis of vitamin K deficiency embryopathy (31) has been made.

Table 2–3A. Other drug and chemical hazards to the fetus

Agent	Congenital abnormalities
Environmental chemicals	
Organic mercurials	Microcephaly, cerebral palsy, mental retardation
Polychlorinated biphenyls (PCBs)	"Cola-colored" babies, growth deficiency, natal teeth, exophthalmos
Prescription drugs	
Anticancer agents	
Alkylating agents (e.g., chlorambucil, nitrogen mustards)	Fetal death, growth and mental deficiency, ocular, genitourinary, and limb malformations, cleft palate
Antibiotics	
Tetracyclines	Brownish yellow teeth, hypoplastic enamel
Streptomycin	Hearing loss
Kanamycin	Hearing loss[a]
Aminoglycosides (e.g., gentamicin)	Hearing loss[a]
Chloroquine	Ocular defects,[a] hearing loss[a]
Anticonvulsants	
Barbiturates (and primidone)	Possible syndrome, present evidence inconclusive[a]
Diazepam	Low risk for facial clefts[a]
Psychotropic agents	
Meprobamate[b]	Brain, heart, palate, and limb defects[a]
Benzodiazepines[b]	Cleft palate[a]
Thalidomide[c]	Facial asymmetry, cranial nerve palsies, cochlear hypoplasia with deafness, hypoplastic teeth, low nasal bridge with broad nasal tip, choanal atresia, colobomas, microphthalmia, cataracts, microtia, facial capillary hemangiomas, phocomelic limb defects
Lithium	Ebstein anomaly
Methimazole	Aplasia cutis, choanal atresia, absent nipples

[a]Proposed association; magnitude of risk uncertain; more information needed.

[b]These drugs have not been clearly associated with congenital defects, and available information is insufficient to ascribe specific risk estimates. In each case, if the risk is increased at all, it is estimated to be very low.

[c]Though thalidomide is of major historical interest, its clinical significance has waned somewhat, except for continuing legal problems and the health management issues among affected person. Nonetheless, it is important to note that this drug continues to be used in some parts of the world for the treatment of epilepsy and major aphthae. Accordingly, new cases still appear sporadically.

Table 2–3B. Hazardous maternal metabolic and genetic factors for the fetus

Factor	Effects
Diabetes mellitus (insulin dependent)	Cardiovascular, renal, and neural tube defects, facial clefts, holoprosencephaly, caudal regression syndrome
Phenylketonuria	Mental retardation, growth deficiency, microcephaly, heart defects,[a] vertebral defects,[a] fetal death[a]
Myotonic dystrophy	Severe early-onset myotonic dystrophy, arthrogryposis, heart defects,[a] hernia,[a] hydrocephaly,[a] hydronephrosis,[a] facial clefts[a]

[a]Proposed association; magnitude of risk uncertain; more information needed.

Table 2–3C. Infectious teratogenic agents

Agent	Congenital abnormalities
Viruses	
Rubella	Ocular and cardiovascular anomalies, deafness, microcephaly, immune and endocrine disturbances, delayed skeletal development, growth deficiency, mental deficiency
Cytomegalovirus	Ocular and cardiovascular anomalies, deafness, microcephaly, hydrocephaly, gastrointestinal tract anomalies,[a] growth deficiency,[a] mental deficiency
Herpes simplex	Ocular anomalies, microcephaly, patent ductus arteriosus, hypoplastic distal phalanges, growth deficiency,[a] mental deficiency
Varicella zoster	Ocular anomalies, microcephaly, hypoplastic limbs, neurogenic muscular atrophy, cutaneous defects, growth deficiency, mental deficiency
Bacteria	
Treponema pallidum	Ocular, dental, and skeletal anomalies, hydrocephaly, microcephaly, cutaneous lesions, nerve palsies, nephrosis, growth deficiency, mental deficiency
Mycoplasmas	Neural tube defects,[a] aneuploidy,[a] growth deficiency,[a] mental deficiency[a]
Parasites	
Toxoplasma gondii	Ocular anomalies, microcephaly, hydrocephaly, deafness, growth deficiency, mental deficiency
Possibly hazardous agents	
Influenza viruses	Neural tube defects,[a] hydrocephaly[a]
Lymphocytic choriomeningitis virus	Hydrocephaly[a]
HTLV-III(AIDS virus)[b]	Growth deficiency, microcephaly, hypertelorism, prominent forehead, short nose with low nasal bridge, long, slanting palpebral fissures, blue sclerae, triangular philtrum, patulous lips
Pestiviruses	Microcephaly

[a]Proposed association; magnitude of risk uncertain; more information needed.

[b]Present evidence clearly indicates that HTLV-III can be passed to the fetus from an infected mother. However, the dysmorphic features reported in some infants with documented prenatal infection are still of uncertain significance. No data have yet established whether these reported findings are the consequence of prenatal disturbances of growth, or may represent postnatal changes; nor have susceptible prenatal periods been defined.

Table 2–3D. Physical hazards to the fetus

Agent	Effects
Radiation	
High levels	Microcephaly, ocular defects,[a] mutations, malignancy
Heat or fever	Neural tube defects, other CNS anomalies,[a] mental retardation[a]
Mechanical factors	
Oligohydramnios, multiple gestation, uterine malformation	Positional deformities, limb reduction defects,[a] mandibular hypoplasia[a]
Amniotic bands	Syndactyly, prenatal limb amputations, atypical facial clefts, exencephaly, encephalocele, thoracogastroschisis, ocular defects

[a]Proposed association; magnitude of risk uncertain; more information needed.

Other teratogenic agents

A number of other agents (1–29) have less dramatic or less well-characterized effects on craniofacial growth and development. These teratogens and their respective effects are summarized in Tables 2–3A–D. It can be anticipated that this list may be expanded substantially as further information becomes available.

Chapter 3
Chromosomal Syndromes: Common and/or Well-Known Syndromes

Trisomy 21 syndrome (Down syndrome)

Trisomy 21 is the most common and best known of all malformation syndromes. More than 100 different signs have been reported (160). The reader is referred to the following sources: comprehensive coverage (10,136,160), biology (6,124), anatomic aspects (11,48,169), pediatric aspects (35,76,175), central nervous system manifestations (10,39,160,187), growth charts (41), craniofacial aspects (97), craniofacial pattern profiles (3), oral manifestations (34), contribution of S. Langdon Down and other history (76a,125,182), cytogenetic considerations and recurrence risk counseling (2,14,23,35,51,54,70,74,79,84–86,94,96, 111,115,118,122,123,126,130,145,160,164–168,178,183), prenatal screening (4,91,171), epidemiology (110), life tables (9), frequency of malformations (95,176), associated tumors (146), presentations for parents of an affected child (87,159).

In 1866, Langdon Down (107) described a condition that he named "mongolian idiocy." A description of the syndrome also appeared in the works of Séguin (150), who called the condition "furfuraceous cretinism" as early as 1846. Lejeune (109) demonstrated in 1959 that the condition was associated with an extra G group chromosome; in 1960, Polani et al (133) reported translocation-type Down syndrome; and Clarke et al (28) observed mosaicism for an extra G group chromosome in 1961.

Prevalence. The birth prevalence of trisomy 21 syndrome is generally stated to be 1/650 live births, but it is known to vary in different populations from 1/600 to 1/2000 live births. Fifteen percent of patients institutionalized for mental retardation have trisomy 21 (77,110,160). It has been estimated that from 65% to 80% of trisomy 21 conceptions result in spontaneous abortions (160). The prevalence in Japan has been discussed by Hoshi et al (88).

Cytogenetics and recurrence risks. Approximately 95% of all cases of Down syndrome result from nondisjunction. Although the syndrome occurs in offspring of mothers of all ages, the risk increases with increasing maternal age. The birth prevalence is 0.9/1000 when the mother is less than 33 years of age, 2.8/1000 when the mother is 35 to 38 years old, and 38/1000 when the mother is 44 years old or older (74). The association of advanced maternal age and nondisjunction has been discussed by several authors (86,94,178). Nondisjunction may occur during the first or the second meiotic division in either the female or male parent (94,115,118) (Table 3–1). The possibility of paternal age effect has been discussed by several investigators (145,167). The occurrence of a genetic predisposition or nondisjunction gene has been debated, and although the risk of trisomy 21 in second and third degree relatives of an individual with nondisjunction-type Down syndrome has been shown to be no greater than the risk to the general population (2,54), the recurrence risk for free trisomy 21 in couples with one affected child is generally accepted to be 1% (168). Rarely, unusual recurrences of free trisomy 21 are reported, such as three affected first cousins (23). Approximately 1 in 200 patients with trisomy 21 syndrome has a double primary nondisjunction, the most frequent type being 48,XXY,+21(78).

Approximately 4.8% of Down syndrome cases are caused by an unbalanced translocation, either arising de novo or being transmitted from one of the parents (70). Information available about translocation-type Down syndrome appears in the following references and tables: frequency of different types of translocations (74,111,160) (Table 3–2), ratio of de novo to inherited translocations (111) (Table 3–3), frequency of maternal and paternal origins of inherited translocations (77,94,111) (Table 3–1), and recurrence risks for translocation-type Down syndrome when one parent is a carrier (51,77,111,165,166) (Table 3–4).

Detectable mosaicism is found in approximately 3% of trisomy 21 cases (79); the Down syndrome phenotype may not be fully expressed. Although it is frequently assumed that the extra chromosome 21 in mosaic Down syndrome arises from nondisjunction in a chromosomally normal zygote, evidence based on maternal ages suggests that a large proportion of such cases arise from meiotic nondisjunction followed by a "normalizing" mitotic error (126,140). Mosaic normal/trisomy 21 patients show a significantly decreasing percentage of trisomy 21 cells with age (130,183). If gonadal mosaicism occurs in a parent, it is possible to have a child with Down syndrome (77).

Fertility in female Down syndrome patients has been well documented. Not uncommonly, a male relative is the parent. In about 50% of cases, the offspring has Down syndrome. Fertility in male Down syndrome patients is probably severely reduced but documented examples of fatherhood have been published (12,156).

Screening. Different types of prenatal screening, detection rates, and false-positive rates have been discussed by Johnson and Summers (91). Assessment of risk by combining maternal age, fetal nuchal translucency, and invasive testing in 5% of the pregnant population with the highest risk would identify about 80% of trisomy 21 pregnancies (4). The predictive value of triple screening [maternal serum α-fetoprotein, (AFP), human chorionic gonadotropin (hCG), and unconjugated estriol (uE3)] has been discussed by Tahski et al (171).

Mortality. In spite of advances in health care of the retarded and a gradual increase in the life span of those affected with Down syndrome, the average life expectancy is still 35 years (172). The periods of highest mortality risk are in infancy when congenital heart disease, leukemia, and respiratory diseases play a role and late adulthood when Alzheimer's disease and declining immunological function are significant. Estimates during the 1960s and 1970s vary from a 12-fold to a 124-fold increase in mortality from pneumonia and other infectious diseases. Death due to congenital heart disease is highest during the first 2 years of life and only 40%–60% of Down syndrome children with congenital heart

Table 3–1. Origin of nondisjunctions and inherited translocations

	Maternal (%)	Paternal (%)
Overall origin of nondisjunction	80	20
Ratio of first-to-second meiotic nondisjunction	80/20	60/40
Origin of inherited D/G translocations	93	7
Origin of inherited G/G translocations	50	50

(Based on TJ Lister and O Frota-Pessoa, Hum Genet 55:203, 1980; RC Juberg and PN Mowrey, Am J Med Genet 16:111, 1983; and JL Hamerton, Human Cytogenetics, Academic Press, New York, 1971.)

Table 3–2. Frequencies of different types of translocations

Type	Percent
t(Dq21q)	54
t(14q21q)	(58)
t(13q21q)	(22)
t(15q21q)	(20)
t(21qGq)	41
t(21q21q)	(83)
t(21q22q)	(17)
t(21qOther[a])	5

[a] For example, chromosomes 1, 2, 6, 7, 12, and 19 (160).

(Based on J de Grouchy and C Turleau, Autosomal disorders. In: Principles and Practice of Medical Genetics, Churchill Livingtstone, Edinburgh, 1983; and TJ Lister and O Frota-Pessoa, Hum Genet 55:203, 1980.)

disease live to age 10. Recent life expectancy figures have been provided by Baird and Sadovnick (9). Neoplastic disease accounts for approximately twice the expected number of deaths, which are mostly attributable to leukemia, but lymphomas and other neoplasms such as testicular carcinoma, retinoblastoma, and central nervous system tumors have also been reported with Down syndrome (124,160,172).

Common clinical diagnostic features. Hall (76) noted 10 common signs in the newborn period: hypotonia, poor Moro reflex, hyperextensibility of joints, loose skin on the nape, flat facial profile, up-slanting palpebral fissures, short ears with overhanging helices, dysplastic pelvis, clinodactyly of fifth fingers, and single palmar creases. At least four of these abnormalities were present in all of his cases, and six or more were present in 89% (Table 3–5). Other common signs include short stature, mental retardation, brachycephaly, flat occiput, epicanthic folds, Brushfield spots, fine lens opacities, open mouth with protruding tongue (Fig. 3–1A–D), short neck, short broad hands, distally placed axial triradii, wide gap between the first and second toes, and tibial arch pattern (160). Common physical findings in children and adults are listed together with their respective frequencies in Table 3–6, which is based on the combined data of Øster (129) and Domino and Newman (47).

A number of diagnostic indices have been developed. Rex and Preus (139) developed an index of eight phenotypic features capable of clinically diagnosing 95% of patients suspected of having Down syndrome. Various dermatoglyphic indices have also been developed (vide infra).

Growth and skeletal abnormalities. Both prenatal and postnatal growth deficiency are evident in Down syndrome. The average length is 2–3 cm less and average weight is 400 g less than for normal infants. There is also a tendency toward premature birth, although prematurely born Down syndrome infants are smaller than their premature counterparts for gestational age. Postnatally, both height and weight are usually 2–4 SD below those of the general population. Bone age is normal to advanced at birth and thereafter slows down so that by 3 years of age, osseous maturation is significantly delayed. For final height attainment, males average approximately 151 cm and females average approximately 141 cm. Among the most characteristic skeletal findings are flaring of the iliac wings and brachymesophalangy of the fifth fingers (160). Radiographic criteria for the diagnosis of Down syndrome in stillborn infants has been discussed by Dasgupta et al (44). Hand development in Down syndrome fetuses has been studied by Kjaer et al (99).

Table 3–3. Translocations

Characteristic	Type of translocation	
	D/21 (%)	G/21 (%)
De novo	53	91
Inherited	47	9

(Based on TJ Lister and O Frota-Pessoa, Hum Genet 55:203, 1980.)

Table 3–4. Recurrence risks for translocation-type trisomy 21 syndrome when one parent is a carrier[a]

Type of translocation	Risk (%)
D/G maternal	10
D/G paternal	2–5
G/G (21/22)	4
G/G (21/22)	100[b]

[a] The theoretical risk is that one-third of the offspring of a translocation carrier will have Down syndrome, but the actual risk is much lower, being related, in part, to in utero loss of Down syndrome fetuses.

[b] t(21q21q) results in monosomic or trisomic zygotes. Since monosomy for chromosome 21 does not produce a viable zygote, all viable zygotes will have translocation type Down syndrome.

(Based on TJ Lister and O Frota-Pessoa, Hum Genet 55:203, 1980; J Stene, Ann Hum Genet 34:93, 1970 and Hum Genet 20:465, 1970; B Dutrillaux and J Lejeune, Ann Genet 12:77, 1969; and JL Hamerton, Human Cytogenetics, Academic Press, New York, 1971.)

Central nervous system and performance. Fetal brain growth is clearly delayed, so that infants commonly are microcephalic at birth (10,50). A decrease in total brain weight has been observed (127,161). Neuropathologic examination has demonstrated that the cerebellum and certain nuclei in the brain stem appear to be smaller than normal. Specific deficits have been documented in certain areas, such as auditory sequencing (46,137), color retention (158), short-term memory (114,137), articulation (46,55,102), visual–motor tasks (114,137), ability to differentiate between symbols (114,137), and language development.

Various other lesions of the brain have been observed, including anomalous structure of the peduncles of the cerebellar flocculi and fibrous gliosis of the white matter (121). Many pathologic findings have been reported in the brain and spinal cord by Benda (10). Pi et al (132) and Urioste et al (180) reported holoprosencephaly in association with trisomy 21 syndrome. Moyamoya disease occurs with somewhat increased frequency (43a).

Pathologic observations of the brain in older patients demonstrate the atrophic changes characteristic of Alzheimer's disease. Senile plaques, neurofibrillary tangles, and granulovacuolar changes have been observed with both light and electron microscopy. In some patients, dementia follows slowly progressive intellectual and emotional deterioration; others seem less obviously affected (17,52,61,74,101,116,128,161). Heston (81) and Heston and Mastri (82) reported that relatives of probands with classic Alzheimer's disease had an excessive frequency of trisomy 21 syndrome and myeloproliferative disorders. The gene for amyloid beta-A4 precursor protein, which is found deposited in the brains of patients with Alzheimer's disease as well as in older individuals with Down syndrome, maps to chromosome 21. The overexpression of the gene appears to be responsible for the Alzheimer-like histopathologic features of Down syndrome (5).

Neoplasms of the brain and retinoblastoma have been reported occasionally with Down syndrome, but far less frequently than leukemia (124).

Table 3–5. Hall's ten cardinal features of trisomy 21 syndrome in the newborn[a]

Feature	Percent
Hypotonia	80
Poor Moro reflex	85

Excess skin on back of neck	80
Flat facial profile	90
Slanted palpebral fissures	80
Anomalous auricles	60
Dysplasia of pelvis	70
Brachymesophalangy of fifth finger	60
Single palmar crease	45

[a] 100% have at least four features and 89% have six or more features.

(Based on B Hall, Acta Paediatr Scand (Suppl) 154:1, 1964.)

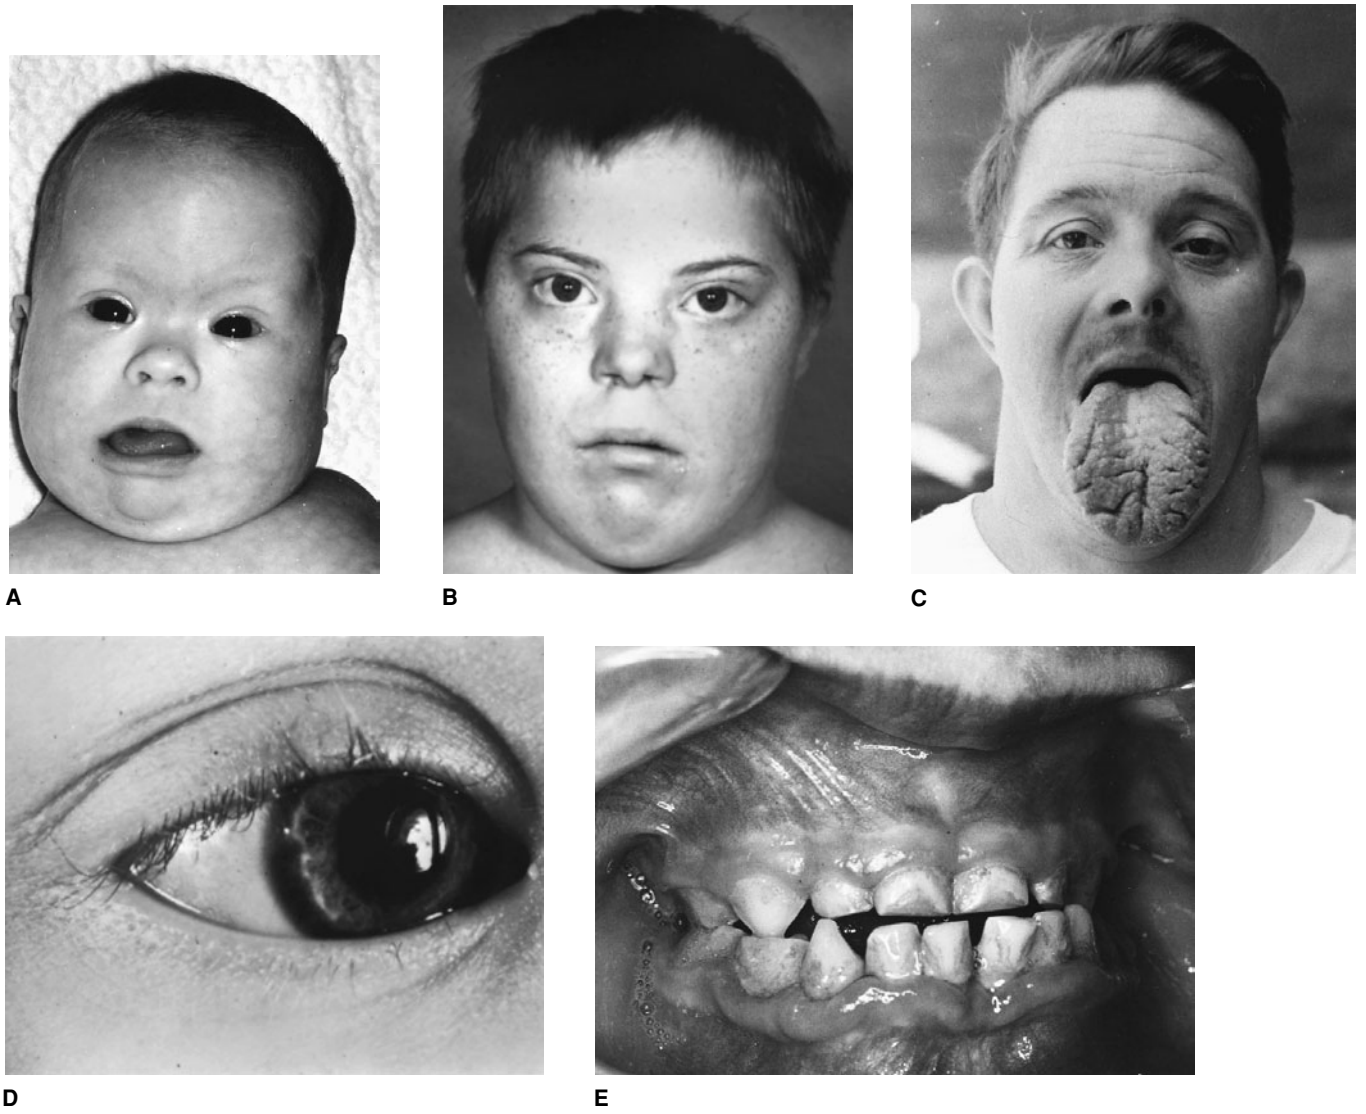

Fig. 3–1. *Trisomy 21 syndrome (Down syndrome).* (A) Typical facial appearance with up-slanting palpebral fissures, low nasal bridge, button-like nose, tendency of the mouth to be open with the tongue protruding. Note also overfolding of helix and cutis marmorata. (B) Compare facies to A and C. (C) Severe macroglossia. (D) Brushfield spots. (E) Primary dentition showing enamel hypoplasia, severe gingival and periodontal involvement with mobility and drifting of lower incisors. (A from MM Cohen Jr, The Child with Multiple Birth Defects, Raven Press, New York, 1982, p 20. B,D from B Russell, Gentofte, Denmark. C courtesy of J Cervenka, Minneapolis, Minnesota. E courtesy of MM Cohen Sr, Boston, Massachusetts.)

The most extensive EEG investigation was carried out by Ellingson et al (51a). They reported that 21% of Down syndrome cases had abnormalities including asymmetry and/or asynchrony, diffuse slow activity, and diffuse focal seizure activity. The frequency of epilepsy varies from $<1\%$ to nearly 10%. Epilepsy may be of the grand mal variety but other types, including myoclonic seizures and petit mal, may occur. In adults, epilepsy may sometimes be related to the cerebral changes of Alzheimer's disease (75,113,134,151,185).

Mental retardation is considered to be a hallmark of nonmosaic trisomy 21 syndrome. The degree of hypotonia is also important as it affects not only motor ability but language as well (38,64,113). In the study of Domino and Newman (47), no systematic relationship between IQ and various physical stigmata was found. Typically, the IQ is reported to vary between 30 and 50 (49,59). The IQ range for home-reared patients varies from 27.4 to 62.4 compared to a range of 17.4 to 37.4 for institutionalized patients (45). Furthermore, developmental milestones such as walking and talking are achieved at a much earlier age in affected children reared in the home (24,27,58,119,157,163,174). It is believed by some that the developmental potential of offspring with trisomy 21 syndrome is higher in families in which the parents have higher IQs (45,63). The study of Golden and Pashayan (71) showed that parental education is also a factor; the mean IQ of patients whose parents had graduated from high school was 50 (range 32–74), whereas the mean IQ was 35.6 (range 0–45) if the parents had completed grade school only.

The pattern of mental development usually demonstrates an early rise in IQ, which plateaus from ages 2 to 5 years, followed by a gradual decline (21,59,60,119). The social quotient tends to be substantially ahead of the mental age. The ability to make social adjustments sometimes makes Down syndrome individuals appear more intelligent than they are (37).

Investigation of the performance of individuals mosaic for trisomy 21 syndrome has shown that their mean performance level is above that of those with pure trisomy 21. Data suggest that the level of functioning tends to be higher in those with higher percentages of normal cells (59,60,62,140,144). Few mosaic individuals, however, test in the normal range. They often manifest milder physical stigmata than those with nonmosaic trisomy 21 (20,28,59,60,69). Kousseff (103) reported a Down syndrome patient with average intelligence. Chromosomal analysis of cultured peripheral lymphocytes showed trisomy 21 in all 62 mitoses counted.

Table 3–6. Physical findings in trisomy 21 children and adults but not newborns

Findings	Percent
Craniofacial	
Flat nasal bridge	61
Flat occiput	76
Eyes	
Up-slanting palpebral fissures	79
Epicanthic folds	48
Brushfield spots	53
Strabismus	22
Nystagmus	11
Ears	
Dysplastic	53
Absent lobules	70
Mouth	
Open mouth	61
Fissured lips	56
Protruding tongue	42
Macroglossia	43
Furrowing of tongue	61
Narrow palate[a]	67
Irregular alignment of teeth	71
Neck	
Broad, short	53
Chest	
Flat nipples	56
Pectus excavatum	10
Pectus carinatum	8
Dorsolumbar kyphosis	11
Abdomen	
Diastasis recti	82
Umbilical hernia	5
Genitalia	
Small penis	70
Cryptorchidism	21
Small scrotum	37
Hands	
Short broad hands	70
Brachydactyly	67
Single palmar crease	52
Clinodactyly	59
Short fifth finger	59
Single flexion crease on fifth finger	20
Feet	
Gap between hallux and second toe	50
Plantar furrow	31
Joints	
Hyperflexibility	62

[a]In trisomy 21 syndrome, the palate appears high because it is narrow. Palatal height, however, is no higher than that observed in the general population.

(Based on combined data of J Øster, Mongolism, Danish Science Press, Copenhagen; and G Domino and D Newman, Am J Ment Def 69:541, 1964.)

Although in older patients dementia may develop as a consequence of Alzheimer's disease, psychiatric problems are encountered in some children. In the study of Menolascino (120), 11 of 86 children were found to be emotionally disturbed, and absence of speech development was common.

Newborn infants are frequently described as being good babies because they are not easily disturbed and cause their mothers very little trouble. Such traits probably reflect reduced response to external stimuli and marked hypotonia. Later, children are often described as happy, cheerful, good tempered, and easily amused. They tend to mimic and may be mischievous. Langdon Down observed that they were humorous and had a lively sense of the ridiculous. Another common feature is obstinacy. Only a minority is judged to be aggressive or hostile or to display other varieties of maladaptive behavior (107,186).

The overwhelming majority have articulation defects; pronunciation is often slurred, making speech incomprehensible. Sibilants and affricates are more severely compromised than other consonants. More than one-third also have dysrhythmic or explosive speech, which is commonly identified with stuttering or inexact rapid speech leading to distortion of sound and phrasing. The voice is often hoarse, raucous, and low pitched.

Craniofacial manifestations. Brachycephaly and flat occiput result in a cephalic index that is usually >0.80 and may exceed 1.00 (normal, 0.75 to 0.80) (142). Head circumference in children has been studied by Palmer et al (131). Fontanels are large, and closure is late (160). In the study of Chemke and Robinson (25), a "third fontanel" was noted in all affected patients. Persistent metopic suture is found in 67% of males (normal, 8.8%) and in 42% of females (normal, 12.3%) (142). Frontal and sphenoidal sinuses are absent and maxillary sinuses are hypoplastic in over 90% of cases (90,142,143,162). Bony midface hypoplasia produces ocular hypotelorism, a small nose with flattening of the nasal bridge, and relative mandibular prognathism (15,68,73). The nasion-sella-basion angle is increased (18).

In an anthropometric study of craniofacial profile patterns, Allanson et al (3) showed a change in facial shape from rounded during infancy to oval in later life. Discriminant functional analysis identified three variables—ear length, maxillary arc, and upper facial depth—that would accurately classify more than 99% of a combined Down/non Down sample.

Upward slanting of palpebral fissures and epicanthic folds are common. Other ocular findings include Brushfield spots, fine lens opacities, convergent strabismus, nystagmus, keratoconus, and cataract (160).

The ears tend to be small (1). Overlapping of the superior rim of the helix and small or absent lobes are common (76,160).

Odontoid abnormalities are found in 16% of affected individuals, and atlantoaxial instability, a feature found in 10%–20% and sometimes found in association with occipitoatlantal instability, results from generalized congenital laxity of ligaments, which is especially noticeable at the craniocervical joint (40).

The lips are broad, irregular, fissured, and dry (19). An open mouth with a protruding tongue is observed. The tongue appears relatively large because of the small oral cavity. That the "large tongue" is relative was demonstrated by Ardran et al (7). Occasionally, true macroglossia may be present. A fissured tongue is common and geographic tongue has also been described (53) (Fig. 3–1C). Lingual papillae have been noted to be large even during infancy (34).

The palate is narrower and shorter but not higher than the mean (155). Radiographically, palatal length averages about 25 mm (normal, 31 ± 3 mm) in the newborn. Cleft of the lip and/or palate is present in 0.5% (72).

Parotid salivary flow rate is decreased. A significant rise in pH, sodium, calcium, bicarbonate, uric acid, and nonspecific esterase in pure parotid saliva has been reported (34,43,184).

Periodontal disease has been observed in over 90% of cases. Severe involvement even below the age of 6 years is particularly common in the mandibular anterior and maxillary molar regions (Fig. 3–1E). Exfoliation of the lower central incisors from periodontal bone loss occurs frequently. However, calculus formation is neither common nor severe. Necrotizing ulcerative gingivitis has been reported to occur in about 30% of patients (15,30,92,98,149,170). The prevalence of dental caries has been stated

to be low by several authors (15,34), although these findings have been challenged (105).

Eruption of both deciduous and permanent teeth is delayed in 75% of cases. An irregular sequence of eruption is common, deciduous first molars sometimes preceding incisors (90,106,108,141,170). Missing teeth have been reported in 23%–47% of patients. Third molars, second premolars, and lateral incisors are most frequently absent in the permanent dentition. In 12%–17% of patients, deciduous lateral incisors are absent. Peg-shaped maxillary lateral incisors have been observed in 10%. Extreme hypodontia and anodontia have been noted occasionally (34,146,153,173).

Crown-size asymmetry (66) and a gradient of reduction along a mesial-to-distal axis (31) have been reported. Fusion of a deciduous mandibular lateral incisor with a canine or, less commonly, with a central incisor is a low-frequency finding (19,34).

Morphologic crown alterations have been reported (16,33,34,67, 104,135,177). Almost 50% of patients have three or more dental irregularities (104). Enamel hypoplasia (Fig. 3–1E) and enamel hypocalcification have also been noted (29,34). Jaspers (89) indicated that taurodontism occurs with greater than expected frequency.

Irregular alignment of teeth is common. Posterior crossbite, mandibular overjet, mesiocclusion, anterior open bite, crowded teeth, and widely spaced teeth have been discussed by several authors (15,34,97).

Cardiovascular system. Cardiovascular anomalies occur in approximately 40% of cases and are a frequent cause (about 20%) of the recorded trisomy 21 syndrome deaths. Atrioventricular communis occurs in one-third of Down syndrome patients with congenital heart defects. In contrast, it is rare as an isolated defect in the general population. Another one-third of cardiac anomalies in Down syndrome are ventricular septal defects. Approximately one-fourth are either tetralogy of Fallot (7%), atrial septal defect (10%), or patent ductus arteriosus (3%). Transposition of the great vessels and coarctation of the aorta occur less frequently in Down syndrome patients than in the general population. Among patients with Eisenmenger complex, it has been noted that the proportion with trisomy 21 syndrome is higher than expected. It has also been reported that the highest mortality rate in Down syndrome patients with congenital heart defects occurred in those with right ventricular outflow tract obstruction or pulmonary vascular pressure at the systemic level, whereas the group with normal or slightly higher pulmonary vascular resistance did quite well (22,26,42,56,57,152,160).

Gastrointestinal system. Gastrointestinal malformations occur in 10%–18% of cases. Findings include tracheoesophageal fistula, pyloric stenosis, duodenal atresia, annular pancreas, Hirschsprung's disease, and imperforate anus (95,100). Knox and ten Bensel (100) reported that approximately 8% die from their gastrointestinal anomalies. Celiac disease is increased (187).

Skin. Dermatologic features include palmoplantar hyperkeratosis (40.8%), xerosis (9.8%), and seborrheic dermatitis (30.9%) (53). Cutis marmorata is common during infancy.

Dermatoglyphics. Many dermatoglyphic studies of trisomy 21 syndrome have been carried out, and several dermatoglyphic indices have been developed (13,83,112,138,160). Such indices have been particularly useful as a diagnostic aid in trisomy 21 syndrome. The Walker index allows discrimination of approximately 70% of affected individuals from controls. Borgaonkar et al (13) developed a method by which 88% of trisomy 21 syndrome patients could be discriminated from the control population. This method was simplified by Reed et al (138) as a nomogram that discriminated 81% of patients with trisomy 21 syndrome. Lu (112) devised a discriminant analysis that permits the identification of 89% of those with trisomy 21 syndrome.

Significant findings in Down syndrome include a hallucal tibial arch or small distal loop, distally placed axial triradius on the palm, single palmar creases, single flexion crease on the fifth finger, and an increased number of ulnar loops on the fingertips. An unusual finding of a radial loop on the fourth and fifth fingers is also increased in trisomy 21 syndrome. In Table 3–7, significant dermatoglyphic features are summarized as percentages in the Down syndrome population compared with percentages of such findings in the general population.

Table 3–7. Dermatoglyphic features of trisomy 21 syndrome

Dermatoglyphic pattern	Trisomy 21 syndrome (%)	Controls (%)
Hallucal tibial arch	72	$\simeq 0.5$
Hallucal small distal loop	32	11
Bilateral t″	82	3
Single crease, digit 5	17	<1
Bilateral single palmar crease	31	2
10 ulnar loops on fingers	31	7
Radial loop, digit 4 or 5	13	4
Bilateral I_3 pattern	46	26
Thenar pattern	4	11

(From M Preus and FC Fraser: Am J Dis Child 124:933, 1972.)

Other anomalies. A variety of low-frequency anomalies have been reported and these are extensively reviewed by several authors (57,160). It has been noted that there may be a greater association with anomalies such as polydactyly and omphalocele than that observed in the general population (95,117).

Hematologic system. Congenital hematologic disorders are common in Down syndrome and a benign natural history is common. Newborns frequently have polycythemia. A number of Down syndrome patients, usually newborns, have had transient, severe disorders of hematopoiesis simulating leukemia but with full recovery (vide infra). Down syndrome studies have also shown a preponderance of younger forms of polymorphonuclear leukocytes that may be explained by an increased turnover of granulocytes.

Tumors. Acute lymphoblastic leukemia occurs with increased frequency in Down syndrome and the peak in the leukemia mortality rate occurs at an earlier age than in childhood leukemia without Down syndrome (124,160).

A tumor profile of Down syndrome (148) shows a 20-fold excess of leukemias and some excess in lymphomas, gonadal and extragonadal germ cell tumors, and possibly retinoblastomas and pancreatic and bone tumors. Other solid tumors appear to be underrepresented when compared to the frequency in the general population.

Immune system. Immunodeficiency in Down syndrome is related to an increased susceptibility to infection, an increased risk for developing neoplasia, particularly leukemia, an increased frequency of autoantibodies, and early aging. Autoantibodies against thyroid antigen are frequently found during early life (175). An increased prevalence of hypothyroidism and, less commonly, hyperthyroidism has been reported (147). The disturbed immunoglobulin (Ig) balance increases with age; IgG and IgA rise after 5 years of age whereas IgM stays within normal limits. T-cell deficiency is observed from birth onward (175).

Differential diagnosis. The Down syndrome phenotype is distinctive. Conditions that are sometimes clinically confused with it include hypothyroidism, *XXXXY syndrome, penta-X syndrome* (65), and *Zellweger syndrome.*

Laboratory aids. Chromosome study is necessary to confirm all cases. Amniocentesis or chorionic villus biopsy can be offered to all mothers with a previous history of having a child with Down syndrome, to older mothers, and to translocation carriers. Pelvic radiograph is sometimes diagnostically useful in suspected cases. There are low levels of AFP in maternal serum and amniotic fluid in trisomy 21 and in other trisomies (8,180).

Trisomy 13 (Patau) syndrome

In 1960, Patau et al (22) first identified trisomy 13 in the laboratory, although the clinical description of the syndrome may date back as early as 1657 in the writings of Bartholin. Trisomy 13 syndrome is characterized by microcephaly, scalp defects, frequent holoprosencephaly, microphthalmia, orofacial clefting, congenital heart defects, polydactyly, severe developmental retardation, and early demise (Fig. 3–2). The reader is referred to the following sources for extensive coverage: general review (9,14,30,33), epidemiology (1,7,10,15,18,33), cytogenetic aspects (4,9,12,15,16), partial trisomy (26,27), anatomic studies (6,17,23), pathologic studies (19,20,30), holoprosencephaly (3,5,29), neoplasia (8,13), and long-term survival (25,28,33,35).

Birth prevalence for free trisomy 13 is approximately 1/12,000, that of Robertsonian translocations, 1/56,000 to 1/80,000, and that of familial cases, 1/33,000 to 1/42,000 (10,33). The rate of trisomy 13 spontaneous abortions is about 100-fold greater than the rate of live births. Trisomy 13 is seen in approximately 1% of all recognized spontaneous abortions (15). A slightly greater number of females than males are affected.

Free trisomy 13 occurs in approximately 75% of all cases and is associated with a maternal age effect (mean age, 31.6 years) (29). Free trisomy originates in nondisjunction. Ishikiriyama and Niikawa (16) have shown that in trisomy 13, the ratio of nondisjunction in maternal and paternal meiosis was 14:3. For maternal meiosis, nondisjunction occurred more frequently during the first than during the second meiotic division (9:4) (12). Approximately 20% result from translocations, mostly t(13q14q). The overwhelming majority arise de novo. Approximately 5% of the translocation type are transmitted by one of the parents, with the recurrence risk being 5% and the risk of spontaneous abortion being approximately 20%. In the unusual translocation t(13q13q), the risk of recurrence or abortion is 100%. About 5% of all cases are mosaic for trisomy 13 (27) with areas of hypomelanosis (11a). In such instances, the phenotype tends to be less severe (2). Distinct clinical syndromes involving a partial proximal or partial distal trisomy segment of chromosome 13 have been phenotypically defined (26,27). Different features of trisomy 13 syndrome are associated with these partial trisomic segments.

Mean life expectancy is 130 days. Approximately 45% die during the first month, 70% during the first 6 months, and 86% during the first year (27). Survival beyond 3 years is exceptional (25,28,33,34). Recurrent chronic cellulitis, affecting the parotid region, axilla, groin, and abdominal wall, with sinus formation and resistance to antibiotic treatment have been found as well as wasting of the distal limb muscles (28). Survival appears to be better with translocation cases than with free trisomy (15). Females appear to live longer than males, but this difference has not been statistically significant (15).

Trisomy 13 syndrome and trisomy 18 syndrome share a number of features in common; these are listed in Table 3–8. Features more common to trisomy 13 syndrome and features more common to trisomy 18 syndrome are also listed. Extensive clinical and pathological findings of

Fig. 3–2. *Trisomy 13 syndrome.* (A) Premaxillary agenesis type of holoprosencephaly with trisomy 13. Note hypotelorism, lack of nasal bones, and extra digits. (B) Bilateral cleft lip/palate, microphthalmia, ulnar hexadactyly, and superficial angioma over brow. (C) Skin defect at vertex of skull. (A from PE Conan, Am J Dis Child 111:236, 1966.)

trisomy 13 syndrome are noted in Table 3–9 together with approximate percentages.

Growth. Mean birth weight is 2600 g. Feeding difficulties and failure to thrive are characteristic (27). Crown-rump length is significantly decreased (29).

Central nervous system. Moderate microcephaly with sloping forehead and wide sagittal suture and fontanels are characteristic. Some degree of holoprosencephaly is common and is accompanied by apneic episodes and seizures. Severe developmental retardation is the rule and presumptive deafness is common. Hypotonia, hypertonia, and hydrocephaly have been encountered in some instances. Cerebellar hypoplasia and meningomyelocele are less commonly observed (3,14,30). Lipoma of corpus callosum has been noted (32).

Craniofacial features. Scalp ulceration is commonly observed at the vertex and may be variable in size. Sloping forehead and capillary hemangiomas, particularly in the glabellar region, are commonly observed. Accompanying variable degrees of holoprosencephaly are ocular hypotelorism and various associated features including, most commonly, lateral cleft lip, median cleft lip, and cebocephaly. Cyclopia occurs infrequently and ethmocephaly is rare. Ocular findings include microphthalmia, iris coloboma, and retinal dysplasia characterized by intraocular cartilage extending from the retrolental region to the sclera at the site of the iris coloboma. Cleft palate, micrognathia, and malformed ears, which may be low set in some instances, are also observed (Fig. 3–2). Inner ear anomalies are of the Mondini or Scheibe types (3,5,11,14,30).

Neck. The neck is short and loose skin on the nape may be seen (29,30). This nuchal translucency may be used in diagnosis (29). Fetal cystic hygroma has been reported (21).

Cardiovascular system. Cardiovascular anomalies are common and autopsy studies have shown that more than one type may be present in the same individual. Those most commonly observed are patent ductus arteriosus, infundibular ventricular septal defect, and atrial septal defect. Also reported are left superior vena cava, dextrocardia, aorta arising from the left ventricle, bicuspid aortic valve, bicuspid pulmonary valve, coarctation of the aorta, atretic pulmonary valve, hypoplastic pulmonary trunk, hypoplastic left atrium, hypoplastic left ventricle, and abnormal semilunar valves (19). Renal abnormalities are common and may include cystic dysplasia, renal hyperlobulation, hydronephrosis, hydroureters, double ureters, horseshoe kidney, and persistent nodular renal blastema (19).

Genitalia. Cryptorchidism and scrotal anomalies are present in males. Bicornuate uterus is found in females. Other findings have been reported including hypertrophy of the clitoris, double vagina, hypoplastic ovaries, gonadal dysgenesis, and hypospadias (9,30).

Limb anomalies. Postaxial polydactyly, flexion of the fingers, sometimes with overlapping, and hyperconvex nails are common (18a). Prominent calcaneus may be observed in some instances. Dermatoglyphic alterations include single palmar creases, distal palmar axial triradius, and fibular S-shaped hallucal pattern or hallucal loop tibial. Also frequent are thenar exit of the A mainline (80%) and radial loops on fingers other than the index finger (50%) (9,14,30).

Other findings. Other reported findings are single umbilical artery, inguinal hernia, umbilical hernia, thin posterior ribs with or without a missing rib, hypoplastic pelvis with shallow acetabular angle, retroflexible thumb, ulnar deviation at the wrist, talipes equinovarus, ectrodactyly, various malformations of the spine, as well as other abnormalities (9,14,30,31). Pancreatic dysplasia is a characteristic feature (19). An odd pigmentary disorder has been noted (24).

Hematologic findings. Polymorphonuclear leukocytes often have nuclear projections (25%–80%). Persistence in the newborn period of embryonic hemoglobin Gower-2 has been observed (9). Those with myelofibrosis do not do well (34).

Neoplasia. Leukemia has been noted in patients with trisomy 13 (13). The association of trisomy 13 syndrome and neuroblastoma in the same family has been reported (8). Wilms tumor has been documented on a few occasions (21a,29a).

Anatomic features. Autosomal trisomies are known to have rather specific constellations of muscle, peripheral nerve, and vascular variations that are not usually examined by either clinicians or pathologists. Trisomy 13 syndrome has the following characteristics: absence of

Table 3–8. Comparison of trisomy 13 and 18 syndromes

Features	Trisomy 13 syndrome (%) ($n = 19$)	Trisomy 18 syndrome (%) ($n = 29$)
Common to both syndromes		
Ear anomalies	87	100
Cardiac defects	94	93
Micrognathia	66	96
Overlapping fingers	73	100
Microcephaly	86	70
Prominent heels	62	87
Highly arched palate	72	87
Microphthalmia	88	82
Hypertonia	67	60
Umbilical hernia	83	67
Cryptorchidism	100	43
More common to trisomy 13		
Cleft palate	63	
Polydactyly	78	
Scalp defects	75	
Cleft lip	50	
Apneic episodes	100	
Capillary hemangiomas	88	
Dextrocardia	100	
Hypotelorism/hypertelorism	83	
Iris coloboma	67	
Sloping forehead	100	
Flat head	75	
Hypoplastic nipples	100	
Prominent nasal bridge	100	
Short neck	100	
More common to trisomy 18		
Prominent occiput		91
Hip dislocation		82
Hypoplastic nails		100
Clubfoot		89
Widely spaced nipples		90
Hypertrophic clitoris[a]		89
Hammertoes		89
Narrow palpebral fissures		80
Short sternum		100
Small mouth		86
Excess skin, neck		86
Seizures		62
Abnormal head		83
Hypoplastic labia		100

[a] Sex-adjusted percentage.
(Adapted from ME Hodes et al, J Med Genet 15:48, 1978.)

the palmaris longus, palmaris brevis, plantaris and peroneus tertius, presence of a pectorodorsalis muscle and unusual muscles from the central tendon of the diaphragm to the pericardium, and variations in extensor indicis, extensors carpi radialis longus and brevus, biceps brachii, and suprahyoid muscles (6,23).

Differential diagnosis. Many syndromes have *holoprosencephaly* as one feature. Pseudotrisomy 13, *Meckel syndrome,* and even *Pallister-Hall syndrome* can have holoprosencephaly and polydactyly concurrently (3). *Smith-Lemli-Opitz syndrome* and *hydrolethalus syndrome* have some individual features in common with trisomy 13, but the overall pattern of anomalies in each of these syndromes is distinctive.

Laboratory aids. Diagnosis is established by banded chromosome study.

Table 3–9. Features of trisomy 13 syndrome

Feature	Percent
Growth	
Failure to thrive	87
Central nervous system	
Microcephaly	86
Holoprosencephaly	70
Apneic episodes	58
Seizures	25
Hypotonia	48
Hypertonia	26
Severe developmental retardation	100
Presumptive deafness	50
Craniofacial features	
Scalp defects	75
Sloping forehead	100
Capillary hemangiomas	72
Ocular hypotelorism	83
Epicanthic folds	56
Microphthalmia	76
Iris coloboma	33
Other eye defects	88
Cleft lip	58
Cleft palate	69
Micrognathia	84
Malformed ears	80
Neck	
Short neck	79
Loose skin, nape	59
Cardiovascular anomalies	
Patent ductus arteriosus	(82)[a]
Ventricular septal defect	(73)
Atrial septal defect	(91)
Left superior vena cava	(14)
Dextrocardia	(24)
Aorta from right ventricle	(11)
Bicuspid aortic valve	(8)
Bicuspid pulmonary valve	(8)
Coarctation of aorta	(9)
Renal anomalies	30–60
Polycystic kidneys	(70)[b]
Renal hyperlobulation	(22)
Hydronephrosis	(25)
Hydroureters	(10)
Double ureters	(12)
Horseshoe kidney	(9)
Genitalia	
Cryptorchidism	(100)
Bicornuate uterus	(50)
Limb anomalies	
Polydactyly	76
Flexion of fingers, sometimes with overlapping	68
Hyperconvex nails	68
Single palmar crease	64
Distal axial triradius	74
Prominent calcaneus	28
Fibular S-shaped hallucal pattern	39
Other findings	
Inguinal/umbilical hernia	40

[a] Percentages in parentheses are from necropsy series that biases findings.

Trisomy 18 (Edwards) syndrome

In 1960, Edwards et al (14) described a new syndrome associated with the presence of an extra chromosome 18. Features included growth deficiency, developmental retardation, prominent occiput, low-set malformed ears, micrognathia, short sternum, congenital heart defects, overlapped flexed fingers, dorsiflexed halluces, and prominent calcaneus (13,43) (Fig. 3–3A–C). The reader is referred to the following sources for extensive coverage: general aspects (4,13,23,27,33), epidemiology (3,11,22,24,50), growth curves (4), cytogenetics (18,32,34,38,47), anatomic aspects (6,46), pathology (23,27,32,45), central nervous system anomalies (30), ophthalmological aspects (7), cardiovascular defects (9,32,36), renal anomalies (32,36), long-term survival (4,8,20,26,33), prenatal diagnosis and counseling (1,35), and neoplasia (2,12,20,26,40). A diagnostic scoring system has been developed (31).

Large surveys have indicated a prevalence of approximately 1/5000 to 1/7000 (8,20,41). Sex ratio shows an excess of affected females (4 F:1 M) (4,13). Trisomy 18 is associated with a maternal age effect, with the mean maternal age being 32.5 years (44).

The overwhelming majority of cases of trisomy 18 syndrome are due to de novo meiotic nondisjunction (13). About 85% of the examples come from the mother from either the first or second meiosis (15,37,49). Translocations may arise de novo or may be transmitted in a family. Mosaicism occurs in approximately 10% of cases (13). Classic trisomy 18 in two sibs was reported by Pauli et al (38). Translocation, isochromosome formation, partial trisomy 18, and mosaicism have been discussed by several authors (19,29,34,38,47). Double trisomies have been discussed. Sibling recurrence risk for trisomy 18 is about 0.5% (4).

Tetrasomy for 18p produces a distinct phenotype (16,39): moderate mental retardation, spasticity, lowset malformed pinnae, strabismus, upslanting palpebral fissures, flat nasal bridge, small pinched nose, long philtrum, small mouth, simian creases, and scoliosis.

Partial duplication 18q21.1–qter results in the phenotype of trisomy 18 (35).

The median life expectancy for liveborn infants with trisomy 18 is 4 days with a range of 1 hour to 18 months. Mean age at death is 48 days. In patients without accompanying cardiac defects or life-threatening gastrointestinal anomalies, median life expectancy is 40 days with a range of 4 hours to 18 months. Although females survive longer than males, the difference is trivial (8). About 45% survive 1 week, 3%–9% survive 6 months, and 0%–5% live more than 1 year (8,13,20,41,50). There are several reports of children surviving into the second decade (33).

Average duration of pregnancy is 42 weeks with low fetal activity, polyhydramnios, and small placenta. A single umbilical artery is common. Altered gestational timing may occur with premature delivery in some instances (13,43). About 50% are delivered by cesarean section because of fetal distress (4).

Clinical findings are summarized in Table 3–10 and internal malformations are listed in Table 3–11. The features of trisomy 18 and trisomy 13 are compared in Table 3–8.

Growth. Mean birth weight is 2240 g. Postnatally, there is failure to thrive. Characteristically, hypoplasia of skeletal muscle, subcutaneous tissue, and adipose tissue is encountered. Some examples of trisomy 18 mosaicism have been associated with asymmetry of the body and/or face, and anomalies that lateralize, such as limb defects, may occur on one side but not on the other (43).

Central nervous system. Mental deficiency is severe. Hypotonia during the neonatal period is followed by hypertonia. The cry is weak and there is diminished response to sound (43). Variable degrees of holoprosencephaly associated with apneic episodes, seizures, and poikilothermia

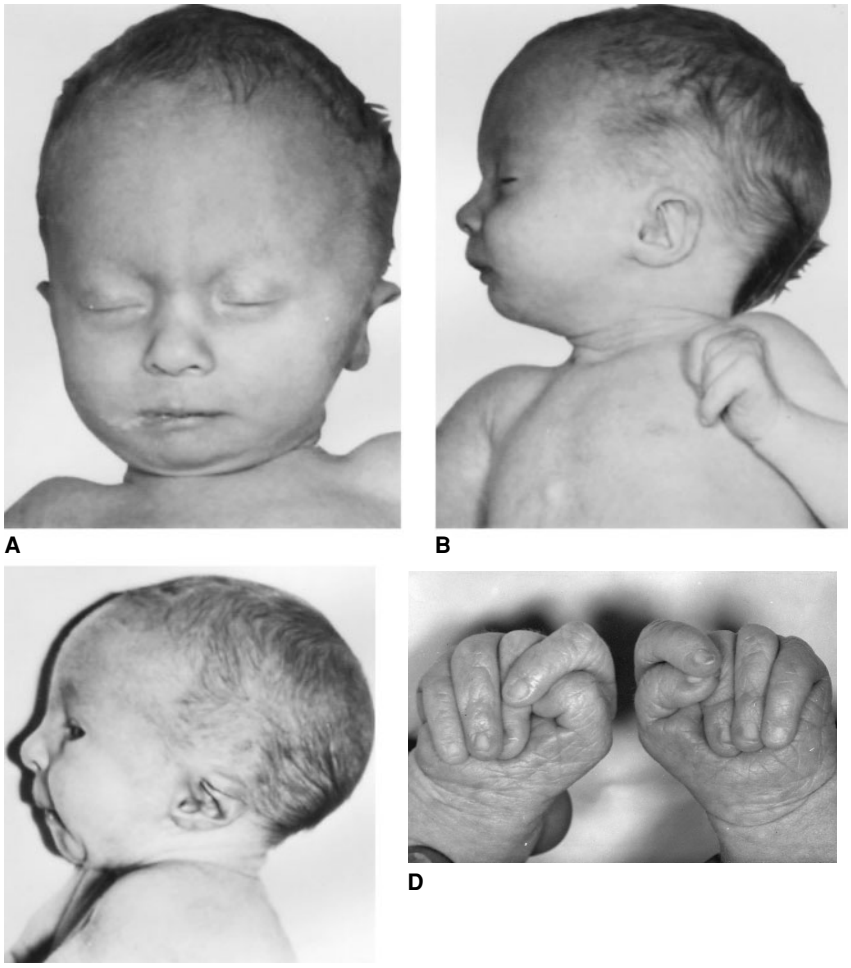

Fig. 3–3. *Trisomy 18 syndrome.* (A) Narrow bifrontal diameter and small lower jaw. (B) Prominent occiput, ptosis of the eyelid, low-set ears, and micrognathia. (C) Compare facies with patient in B. (D) Overlapping fingers. (A,B,C from P Paerregård, Acta Pathol Microbiol Scand 67:479, 1966.)

can be found on occasion (9,30). Psychomotor development has been discussed at length by Baty et al (5). With apparently somewhat higher frequency, simple absence of the corpus callosum has been noted. Rarely, hydrocephaly, anencephaly, meningomyelocele, and facial palsy may be observed (35,43). Paucity of myelinization, microgyria, cerebellar hypoplasia, absent geniculate body, absent occipital lobes, and occipital lobe hemorrhage have been recorded.

Heterotopias of well-formed neurons either with or without undifferentiated neuroblastic cells have been found in the periventricular areas of the brain, located most commonly above or lateral to the head of the caudate nucleus and/or in the roof and lateral wall of the inferior and posterior horns, within fibers converging on the internal capsule and around the optic radiation. Heterotopias appear to result from excessive formation of embryonic neuroblasts with focally arrested migration in the periventricular white matter without resulting in deficient neuronal composition of the cerebral cortex (7,45).

Craniofacial features. The head is dolichocephalic in shape. The bifrontal diameter is narrow and the occiput is prominent. The ears are malformed and low set. The mouth is small, the palate is narrow, and micrognathia is evident (43) (Fig. 3–3). Cleft lip is found in about 5%, cleft palate in another 5% (4).

Less frequently occurring craniofacial abnormalities include microcephaly, wide fontanels, hypoplasia of orbital ridges, Wormian bones, shallow elongated sella turcica (43), and various eye anomalies: globe (corneal opacities, corneal clouding, microphthalmia, iris colobomas, cataracts, persistent hyaloid artery, glaucoma, blue sclera, absent retinal pigment, persistent iridopupillary membrane), adnexa (slanted or narrow palpebral fissures, epicanthic folds, ptosis of the eyelids, congenital filiform ankyloblepharon, abnormally thick eyelids, abnormally long or sparse eyelashes, inability to close the eyelids, blepharophimosis), orbit (hypertelorism, hypotelorism), and neuroophthalmology (strabismus, lateral gaze, asynergy of extraocular movement, decreased response to visual stimuli, nystagmus, anisocoria) (17). Ocular histopathology has been reviewed extensively by Calderone et al (7).

Inner ear defects may include complete or partial absence of the auditory nerve, defects of the osseous spiral laminae and interscalar septa, abnormalities of the utriculoendolymphatic valve, atresia or absence of the semicircular ducts, and deformities of the organ of Corti (21,48).

Limbs. The hands are clenched with a tendency toward overlapping of the second finger over the third finger and the fifth finger over the fourth. The distal crease on the fifth finger may be absent with less frequently occurring absence of the distal creases on the third and fourth fingers (Fig. 3–3D). The nails are hypoplastic, particularly on the fifth finger and the toes (43).

Dermatoglyphic analysis shows an increased frequency of arched fingertip patterns on six or more fingers. Abnormalities of the feet include dorsiflexed halluces, prominent calcaneus, talipes equinovarus, rocker-bottom feet, and syndactyly of the second and third toes. Low-frequency anomalies include syndactyly of the third and fourth fingers, polydactyly, short fifth metacarpals, and limb reduction malformations (10,43).

Cardiovascular system. Cardiovascular anomalies occur in about 85% of cases and include polyvalvular disease, ventricular septal defect (VSD), high takeoff of the right coronary ostium, patent ductus arteriosus (PDA), and various other abnormalities (23,32,44). Cardiopulmonary abnormalities are the chief cause of death (4). These are listed in Table 3–11.

Table 3–10. Features of trisomy 18 syndrome

Feature	Percent
Growth	
Growth deficiency	96
Central nervous system	
Severe developmental retardation	96
Hypertonia	60
Craniofacial	
Microcephaly	70
Dolichocephaly	93
Prominent occiput	91
Narrow palpebral fissures	80
Small mouth	86
Micrognathia	96
Low-set, malformed ears	88
Neck	
Loose skin, nape	56
Thorax	
Short sternum	68
Widely spaced nipples	90
Cardiovascular anomalies	85
Abdominal wall	
Inguinal or umbilical hernia	67
Urogenital system	
Renal anomalies	30
Cryptorchidism	100
Prominent clitoris[a]	89
Pelvis and hips	
Small pelvis, limited hip abduction	68
Limbs	
Overlapped, flexible fingers	89
Hypoplastic nails	100
Arch fingertip patterns	96
Clubfoot	89
Prominent calcaneus	77
Rockerbottom feet	10–50
Dorsiflexed hallux	75
Syndactyly, second and third toes	10–50

[a] Sex-adjusted percentage.

(Adapted from ME Hodes et al, J Med Genet 15:48, 1978; and AI Taylor, J Med Genet 5:227, 1968.)

Urogenital system. Urogenital anomalies are common (Table 3–10) and may include cryptorchidism, prominent clitoris, cystic kidneys, horseshoe kidneys, gonadal dysgenesis, and other abnormalities (23,32,44) (Table 3–11).

Other anomalies. A variety of other abnormalities have been reported, including tracheoesophageal fistula, Meckel's diverticulum, incomplete fixation of the colon, ectopic pancreas, anal atresia, thyroglossal duct cyst, eventration of the diaphragm, diaphragmatic hernia, and skeletal anomalies (32) (Table 3–11).

Anatomical studies. Bersu and Ramirez-Castro (6) dissected eight infants and found hypoplastic occipitofrontalis, auricular, and nasal muscles. Extensive fusion of muscles occurred around the corners of the mouth, a supernumerary muscle band extending from the corner of the mouth to the occipital attachment of the trapezius muscle. The otomandibular region showed a variable spectrum of muscular, skeletal, arterial, and salivary gland variations. Absence of muscles, supernumerary muscles, and variations in musculature of the upper and lower limbs have been described by Urban and Bersu (46). Kjaer et al (28) described the following axial changes in the skeleton of trisomy 18 fetuses: notched basilar occiput, hypoplastic nasal bones, and malformations of thoracic or thoracolumbar vertebrae.

Table 3–11. Internal malformations in trisomy 18 syndrome

Finding	Frequency
Central nervous system	
Hypoplasia or absence of corpus callosum	3/15
Absent septum pellucidum	2/15
Short frontal lobe	2/15
Abnormal gyri	2/15
Persistent paraventricular nerve cells	3/15
Cardiovascular system	
Polyvalvular disease	15/15
Ventricular septal defect	13/15
High takeoff of the right coronary ostium	12/15
Patent ductus arteriosus	11/15
Common brachiocephalic trunk	7/15
Coarctation of aorta	3/15
Mitral atresia with hypoplastic left ventricle	1/15
Patent foramen ovale	14/15
Urogenital system	
Cystic kidneys	5/15
Horseshoe kidney	7/15
Ovarian cyst	1/15
Double ureter	2/15
Alimentary tract	
Esophageal atresia (TEF)	1/15
Meckel's diverticulum	8/15
Incomplete fixation of the colon	7/15
Ectopic pancreas	10/15
Anal atresia	2/15
Other	
Thyroglossal duct cyst	2/15
Eventration of diaphragm	2/15
Skeletal anomalies	5/15
Single umbilical artery	2/15
Diaphragmatic hernia	1/15

(Adapted from R Matsuoka et al, Am J Med Genet 14:657, 1983, autopsy cases.)

Neoplasia. Various neoplasms have been reported on occasion, including Wilms tumor (20,26), hepatoblastoma (12), neurogenic tumor (40), and benign congenital papillary tumor of the bicuspid valve (2).

Differential diagnosis. Differential diagnosis includes *Pena-Shokeir syndrome I* and *trisomy 13 syndrome.*

Laboratory aids. Diagnosis is established by banded chromosome study. Cases may be referred for ultrasonographic evaluation of polyhydramnios around the 30th week of gestation. Fluorescent in situ hybridization (FISH) studies may be used if the tissues are formalin-fixed or paraffin-embedded (24a).

del(4p) syndrome (Wolf-Hirschhorn syndrome)

Although the defect is due to deletion of the 4p16.3 band (5,8,16), the deletion may be submicroscopic. Milder expression has been called "Pitt-Rogers-Danks syndrome" (13,34). In most cases one-third to two-thirds of the short arm is deleted. The critical region is 4p16.3 (20a). The facial phenotype is not deletion size dependent (22). Translocation is responsible for 10%–15% of the cases (3,11,18,25,30); the rest are largely de novo, nearly always from the paternal chromosome (23,27,28). Polymerase chain reaction (PCR)-based screening (1) or fluorescence in situ hybridization (FISH) (33) can be used to detect this syndrome. Frequency appears to be about 1/50,000 births with a 2:1 female predilection. At least 35% of affected infants die during the first year of life due to heart defects, but some survive to adulthood (20). The phenotype is quite striking. In spite of normal gestation time, birth weight is usually reduced. Fetal activity is diminished and the child is characteristically hypotonic. In addition to very severe psychomotor and growth retardation (75%), mild microcephaly (90%), craniofacial asymmetry, high forehead, wide nasal bridge with prominent glabella (50%) and nasal beaking (65%), hypertelorism (75%), and epicanthal folds are seen (Fig. 3–4). About 10% have a midline scalp defect. The eyebrows are highly arched and somewhat sparse medially. About 50% exhibit ptosis, downward slanting palpebral fissures, facial angiomas, and divergent strabismus. The facies has been likened to that of a Greek helmet (6) (Fig. 3–4). About 25% have coloboma of the iris and corectopia (31). The ears are deep seated, poorly differentiated, and have lobeless pinnae (26) and narrow external canals. Most have a preauricular dimple or skin tag. Sensorineural hearing loss has been documented in 25%(15). The philtrum is short and deep and the mouth usually has downturned corners. Cleft lip with cleft palate (Fig. 3–4A) (10%), cleft palate (25%), and micrognathia (50%) have been documented (19). Hypodontia has been reported (4). The neck is long and thin. There are some changes with age (2a,2b).

Congenital heart malformations, most often ASD or VSD, are noted in about 45%. Seizures occur in about 50%. Cryptorchidism (40%) and, particularly, hypospadias (70%) are found in affected males; and absent uterus and streak gonads have been described along with disproportionately small kidneys including bilateral small kidneys with large glomeruli that are reduced in number and dilation of proximal renal tubules (oligomeganephronia) (9,16,21). Sacral dimple is an almost constant feature (32). The trunk is long and the limbs are thin. Talipes

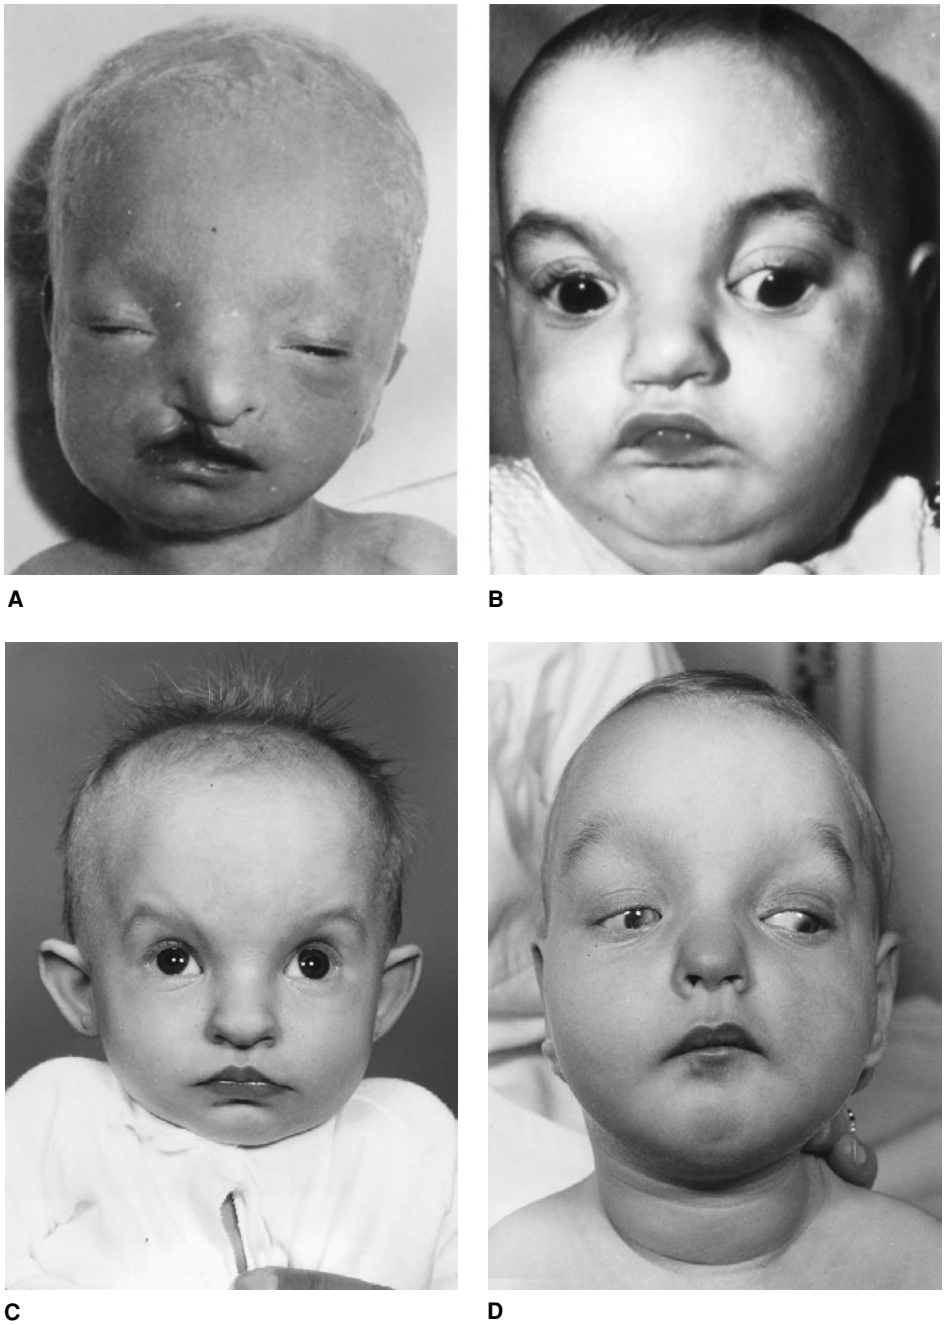

Fig. 3–4. *del(4p) syndrome (Wolf-Hirschhorn syndrome).* (A) Small head, hypertelorism, flat nose, cleft lip, short philtrum, down-turned mouth. (B) Microcephaly, cranial asymmetry, hypertelorism, strabismus, broad-based nose with asymmetric nares, short philtrum, and down-turned mouth. (C,D) Compare facies with patients A and B. (A from AI Taylor, J Med Genet 5:227, 1968. B from D Arias et al, J Pediatr 76:82, 1970. C,D from A Schinzel and W Schmid, Arch Genet 45:88, 1972.)

equinovarus is relatively common. Radiographically, proximal radioulnar synostosis, anterior fusion of vertebrae, fused ribs, dislocated hips, and talipes have been reported (17). The clavicle may look like a bottle opener (14). The pelvis and carpal bones are late in ossification and pseudoepiphyses are seen at the base of each metacarpal. The fingers may be long and tapering with ulnar deviation. Preaxial polydactyly, split hand, and other digital anomalies have been noted (2,10,24).

Proximal deletion of 4p produces a nonspecific phenotype (7,29). FISH detection is used for demonstration of the deletion (12,20a).

del(5p) syndrome (cri-du-chat syndrome)

The basic defect is due to a partial deletion, either terminal or interstitial, of 5p15.2–p15.3 (8,11). This may result from either a de novo deletion of the short arm (about 85%) or unbalanced translocation inherited from a carrier parent (about 15%) (1,4,6), the latter being more severely affected (16). In a large series of deletions of varying size, the high-pitched cry seemed to map to 5p15.3 whereas the rest of the phenotype mapped to 5p15.2 (11). The δ-catenin gene is deleted. More proximal deletions do not produce the phenotype (5,14). The greater the deletion, the lower the intelligence, height, and weight and the more severe the microcephaly (15). Growth charts are available (7a). The frequency has been estimated at about 1/50,000 births. There is usually reduced life span. The syndrome is seen in approximately 1% of institutionalized mentally retarded patients. A good study of cognitive function is that of Cornish et al (2a). The syndrome is characterized by a high, shrill cry during infancy. However, the cry is neither pathognomonic nor present in all patients. It appears to be central, not laryngeal (7). In addition to severe somatic and mental retardation (7b), the child exhibits microcephaly, increased inner canthal distance, and round face (3). Other features include downward-slanting palpebral fissures (60%), hypertelorism (75%), epicanthal folds, posteriorly rotated pinnae, preauricular tags (20%), and broad nasal bridge with prominent nasal root and micrognathia (Fig. 3–5). With time, the face becomes asymmetric and the plumpness disappears (1). Malocclusion is common, particularly overjet. The hair becomes prematurely gray. Cleft lip/palate occurs in 8%–15% (9,16). The hands are smaller than normal with clinodactyly (10). Various congenital defects of the heart (30%–50%) and frequent upper respiratory infections, otitis media, and feeding problems are common (15).

Musculoskeletal anomalies include talipes, dislocated hips, and inguinal hernia (16). Hypotonia, very marked in infancy, disappears and reflexes become hyperactive. The gait becomes shuffling. Malrotation of the bowel or megacolon is found in about 25% of the cases resulting from parental translocation (15). The reader is referred to the study by Van Buggenhout et al for the changing phenotype in older patients (13).

Prenatal diagnosis has been accomplished on uncultured amniocytes using a FISH probe in a case of balanced carrier mother (2,13).

Trisomy 8 (Warkany) syndrome

Trisomy 8 (15%), or far more frequently trisomy 8 mosaicism (85%) syndrome, is a relatively common autosomal chromosomal disorder. The estimated frequency is about 1/25,000 to 50,000 children, accounting for about 10% of autosomal trisomies. There is at least a 5:1 male predilection. Full trisomy 8 is rare postnatally but has been seen in 10% of spontaneous abortions (8). There is no significant difference in phenotype between so-called pure trisomy 8 and trisomy 8 mosaicism. Over 100 cases have been reported (1–19).

Life expectancy is essentially normal. Most infants have normal birth weight for gestational age. Mental retardation, usually of moderate degree (IQ 40–75), is a virtually constant feature, but occasionally near normal intelligence is noted (8). Agenesis of the corpus callosum is somewhat increased (13).

The forehead is usually high and prominent. The skull is often scaphocephalic. The face is elongated and the pinnae dysplastic. Mild hypertelorism and strabismus are evident in over 50% of the patients. Corneal opacities are frequent. The nose is broad based with an upturned tip in 60%. The mandible is small and retruded and the lower lip is commonly everted in about 40% of cases (Fig. 3–6A,B). Cleft palate has been reported (1). Beemer et al (2) reported a cephalometric study of three cases.

About 70% of affected individuals manifest contractures of fingers and toes, and generalized progressive joint restriction is common (Fig. 3–6C,D). About 35% of the patients have a long slender trunk with narrow chest and slender pelvis and about 65% have a spinal deformity, most often scoliosis. Broad ribs, extra ribs, first rib gap, spina bifida occulta, and butterfly vertebrae are common (1,10). Absent or hypoplastic patellae are frequent. Cardiac anomalies, found in 25% of patients, include VSD, PDA, pulmonary stenosis, coarctation of the aorta, total anomalous pulmonary venous connection, and truncus arteriosus. Hydronephrosis and/or hydroureter are relatively common. Cryptorchidism has been noted in about 50%, and hydronephrosis, hydroureter, or ureteral obstruction in 40% of patients (1,13). Wilms tumor and various types of leukemia have been described (12). Deep palmar and/or particularly plantar furrows are seen in about 75%. Other dermatoglyphic changes have been found (15). Recombinant 8 syndrome is associated with similar findings (19).

The abnormal cell line tends to disappear from the lymphocytes with age (11).

dup(9p) syndrome

Although less striking than 13 or 21 trisomy, the phenotype of dup(9p) nevertheless has classic craniofacial stigmata. There is a 2:1 female predilection. Over 125 cases have been reported (11).

The classic features involve short stature, characteristic facies, variable mental retardation, and hypoplasia and/or dysplasia of the terminal phalanges, particularly those of the second and fifth fingers (Fig. 3–7). The facies is characterized by microcephaly/brachycephaly, high, broad forehead, large fontanel and open metopic suture in childhood, mild microbrachycephaly, flat occiput, enophthalmus, mild hypertelorism, and divergent strabismus. The eyes appear relatively small and deeply set with mildly downward-slanting palpebral fissures. The nose has a large globular tip, broad nasal root, and short philtrum. The mouth is large with the angles turned down and the lower lip everted. The pinnae are large, low set, and outstanding with abnormal anthelix. The auditory canals are narrow. Cleft lip and/or palate has been found in 5% of patients. The neck is short and webbed with a low hairline (1,3–6,8,9,11,12).

Intelligence quotients have varied between 30 and 65. There may be mild finger contractures, brachydactyly, and mild syndactyly of the third and fourth fingers. The clinodactylous fifth fingers often have a single flexion crease. The nails are frequently hypoplastic and most have transverse palmar creases. Congenital heart disease is found in 15%–20%. Skeletal anomalies include hallux valgus, limited extension at the elbow, genua valga, kyphosis, and/or lumbar hyperlordosis.

Radiographically there is delayed bone age and retarded closure of anterior fontanel, thoracolumbar scoliosis, hypoplastic terminal and middle phalanges of fingers and toes, and proximal ossification centers of the metacarpals.

Among the several examples of tetrasomy for 9p, about one-third have cleft lip/palate, congenital heart disease, and hydrocephalus (2,7,10,11).

del(11)(p13) syndrome (aniridia-Wilms tumor syndrome, WAGR)

The syndrome of aniridia, mental retardation, and Wilms tumor (Fig. 3–8) is associated with deletion of the distal half of band 13 of the short arm of chromosome 11 (9,11). Maternal age appears to be advanced (10). The syndrome is generally sporadic. However, familial occurrence has been reported (7,13).

Fig. 3–7. *dup(9p) syndrome.* (A–C) Globular nasal tip, divergent strabismus, down-turned mouth, clinodactyly of fifth fingers, and small nails. (A from CE Blank et al, Clin Genet 7:261, 1975. B,C from P Balicek, Hum Genet 27:253, 1975.)

C

Fig. 3–8. *del(11)(p13) syndrome (aniridia-Wilms tumor syndrome).* (A) Bilateral aniridia. (B) Cataract developing in patient with aniridia. (C) Radiograph of bilateral Wilms tumor.

Craniofacial alterations include microcephaly with a prominent forehead, cranial asymmetry, long, narrow face, high nasal root, ptosis of eyelids, and low-set poorly lobulated pinnae.

Mental retardation is nearly always a constant feature as well as hypospadias and cryptorchidism in males. Hyperkinesis is common. About one-half of the children exhibit growth retardation.

Among children with Wilms tumor, the syndrome is seen in about 1%–2%. There is a definite male predilection, possibly as great as 3:1. In about 35% of the cases the Wilms tumor is bilateral, contrasting sharply with bilateral Wilms tumor not associated with the syndrome (2%–4%). In the syndrome, the tumor appears at a somewhat younger age (2–3 years) than in those with isolated Wilms tumor (4–5 years).

Rarely gonadoblastoma is found instead of Wilms tumor (1,11). The syndrome has been concordant in monozygotic twins with a variable degree of expression (e.g., Wilms tumor in only one twin), indicating that the event is postzygotic and that the deletion is not predisposing to the Wilms tumor (3,5). Although the interstitial deletion of 11p has varied from case to case, all have in common del(11)(p13). The gene for catalase is located in the same band. This has been demonstrated by its dosage effect in normal individuals, compared to the effect in those who are trisomic and monosomic for this region. Thus, catalase levels allow for differentiation of either isolated aniridia or isolated Wilms tumor from the syndrome, particularly since the syndrome is variably expressed (4,6). The genetic aspects of aniridia are discussed by Churchill and Booth (2).

Wilms tumor may also be found in association with *hemihyperplasia, Beckwith-Wiedemann syndrome, Simpson-Golabi-Behmel syndrome,* Perlman syndrome, Denys-Drash syndrome, *Sotos syndrome, Weaver syndrome,* and crossed renal ectopia (8).

del(13q) syndrome

Virtually constant features are reduced birth weight, psychomotor retardation, hypotonia, and microcephaly. Neural tube defects (NTDs), holoprosencephaly, and agenesis of the corpus callosum have also been noted (5). About one-half of the patients exhibit trigonocephaly. A critical region for producing this phenotype is 13q32 (2,10). The facies is characterized by frontal bossing, broad prominent nasal root, protruding maxilla and incisors, and large, prominent, malrotated ears with deep helical sulcus. Eye anomalies consist of ptosis, epicanthal folds, microphthalmia, and colobomas. Retinoblastoma occurs in approximately 15% of patients (3,4,6,7,13,14). Osteosarcoma and synovial sarcoma are found with increased frequency. The neck is short with redundant skin folds. Various congenital heart anomalies have been noted in approximately 35%. About 60% of the males have genital malformations including hypospadias, small or bifid scrotum, cryptorchidism, micropenis, and perineal fistula (Fig. 3–9). Anal atresia or ectopic anus has been noted in about 20% of all patients. Microcrania, hip dislocation, talipes equinovarus, delayed skeletal maturation, and metaphyseal undulations have increased frequency and thumbs are hypoplastic or absent in about 30% (4).

Most of the reported cases have involved loss of the distal two-thirds of the long arm. In some, this has resulted from deletion, in others, from translocation, and, in still others, from deletion and fusion, producing a ring chromosome (8). Deletion of bands 13q33–qter results in severe mental retardation, microcephaly, ocular hypertelorism, frontal bossing, protruding maxilla, large ears, and more NTDs. Those with additional deletion of bands 13q31–q32 exhibit mental retardation, microcephaly, trigonocephaly, hypoplastic or absent thumbs and metacarpals, and male

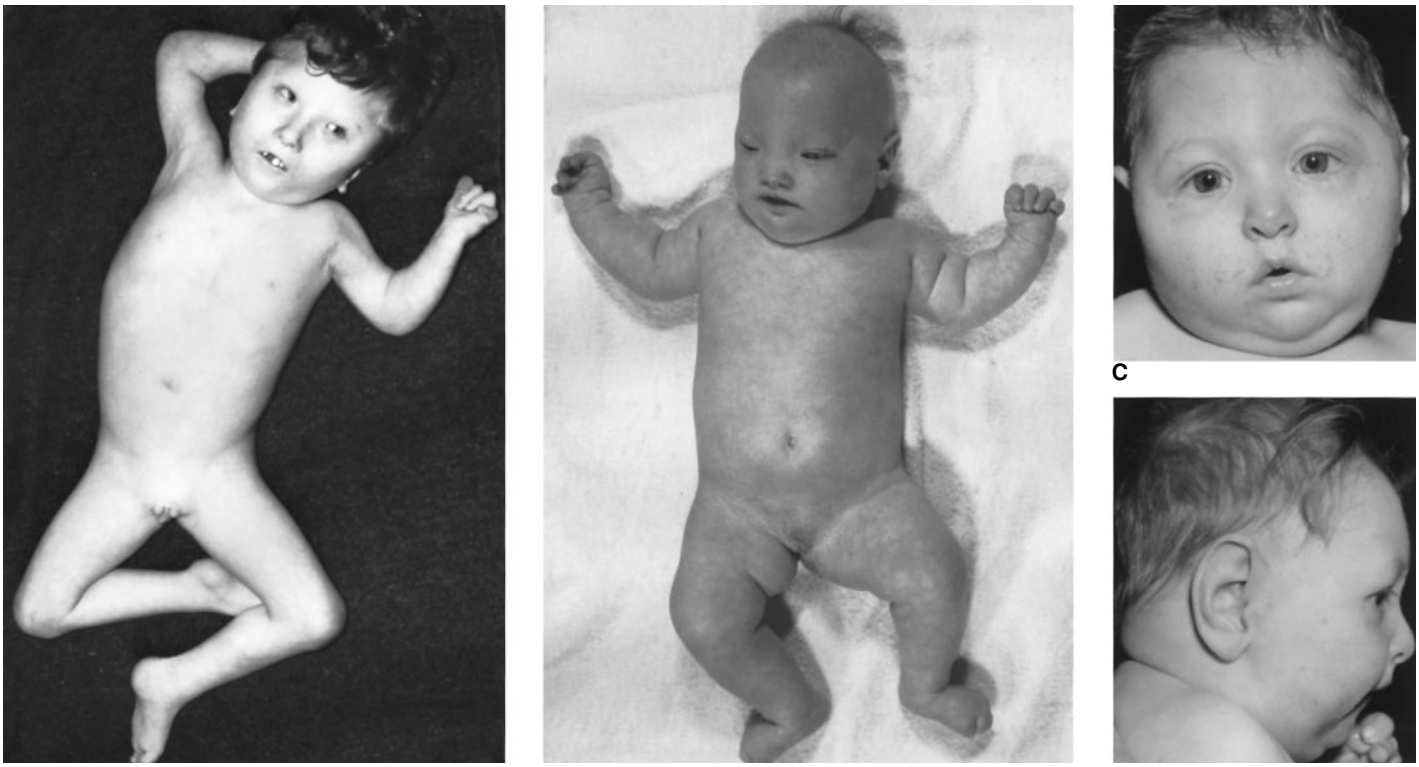

Fig. 3–9. *del(13q) syndrome.* (A) Absence of thumbs, micropenis, cleft scrotum in severely retarded child. (B) Broad-based nose, ptosis of eyelids, and absent thumbs. (C,D) Microcephaly, trigonocephaly, apparent hypertelorism, prominent nasal bridge, and short neck. (A from RS Sparkes et al, Am J Hum Genet 19:644, 1967. B from RC Juberg et al, J Med Genet 6:314, 1969. C,D from E Grace et al, J Med Genet 8:351, 1971.)

genital abnormalities. Retinoblastoma is associated with deletion of band 13q14, but only about 20% of those with that deletion have the tumor. With large deletions, holoprosencephaly may be found. Chromosome 13 deletion has also been seen with Waardenburg syndrome, type 2 (11). In a related way, Weigel et al (12) and Sparkes et al (9) described the combination of retinoblastoma and Hirschsprung disease in a patient with deletion of 13q13–q22. A child with von Voss-Cherstvoy syndrome (occipital encephalocele, radial ray defects, urogenital anomalies) had deletion of 13q (1). The gene for esterase D is proximate; thus it can be used for prenatal diagnosis and prediction for occurrence of retinoblastoma (3). J Fenyk (Minneapolis, 2000) has noted multiple areas of linear aplasia of the scalp in a newborn with ring 13.

del(18p) syndrome

At least 120 cases of del(18p) syndrome have been reported (1–12). There is a 3F:2M predilection. Mean parental age is increased (9). At least 85% arise de novo from translocation in 10% and rarely is familial (11). The extent of deletion of the short arm of chromosome 18 does not correlate with the clinical picture (4). In addition to the mental (100%) and somatic (75%) retardation, the phenotype is not striking unless associated with holoprosencephaly. Growth hormone deficiency has been reported (1,3). Microcephaly (50%), round face (40%), ocular hypertelorism (50%), ptosis (50%), strabismus (40%), epicanthus (40%), broad flat nose (80%), large outstanding ears (60%), carp mouth (65%), microretrognathia (45%), and short neck (45%) characterize the facies (Fig. 3–10) (7). Perhaps 25% exhibit pterygium colli. About 5% have cleft lip and 10% have cleft palate (10,11). As noted, about 10% exhibit semilobar or alobar holoprosencephaly (6,11). Single central incisor has been reported (2,3,5). No more than 5% have congenital heart anomalies. These are heterogeneous (VSD, coarctation of the aorta, AV canal, PDA, and transposition of large vessels) (10,11). About 50% of the males have micropenis and/or cryptorchidism. Dystonia has been noted in several patients (8).

del(18q) (de Grouchy) syndrome

In 1964, de Grouchy et al (4) reported partial deletion of the long arm of chromosome 18. The phenotype is distinctive, consisting of hypotonia, mental retardation, characteristic facial dysmorphism (Fig. 3–11), abnormal genitalia, and tapered fingers. More than 100 cases have been reported (1,5,6) and several extensive reviews are available (2,3,18). Wilson et al (22) and others (13) indicated that the typical syndrome with rare exception (20,21) had deletion in band 18q21 and identified a different clinical syndrome in association with a more proximal deletion within band 18q12. Most observers have found poor correlation between phenotype and size of deletion (17,20). However, Kline et al (12) found that low limb anomalies mapped to the most distal part of 18q with microcephaly and mental retardation to the more proximal part. In 80% of cases, the deletion occurs de novo; in 10%, the deletion results from parental pericentric inversion or translocation (15); and in 10%, the deletion is in the mosaic state, resulting in a less severe phenotype (3). There is a predilection for females, with a 2:3 male-to-female sex ratio. Mean birth weight is below 2700 g and, with growth and development, short stature below the fifth centile is observed in 78% (18,19). Growth hormone deficiency has been noted (8). Approximately 10% of affected infants die within the first few months of life (3) but, in general, most have a normal life expectancy (17). Hypotonia is a nearly constant feature but seizures are noted in only 10%. Mental retardation (100%) is profound, with few patients having an IQ over 30. The voice is often low pitched (18,19,22).

Microcephaly with head circumference below the second centile is observed in 68%. In some instances, fontanel closure is delayed. The midface is retruded (85%) and relative mandibular prognathism becomes evident with age. The eyes are deeply set. Other features may include epicanthic folds (42%), strabismus (34%), nystagmus (80%), coloboma of the iris (7%), pale optic discs (84%), prominent anthelix or antitragus (84%), stenotic ear canals (50%), impaired hearing (61%), broad nasal bridge (81%), carp-like mouth (87%), cleft lip (9%), and cleft palate (29%) (3,7,10,11,18,19,22). A small subcutaneous nodule may be evident at the site of cheek dimples (18).

The nipples are widely spaced (79%) and bilateral subacromial dimples are observed. Umbilical hernia is a feature in 16% of cases. Congenital heart defects occur in 35% (3,19,22), with atrial septal defect, pulmonary

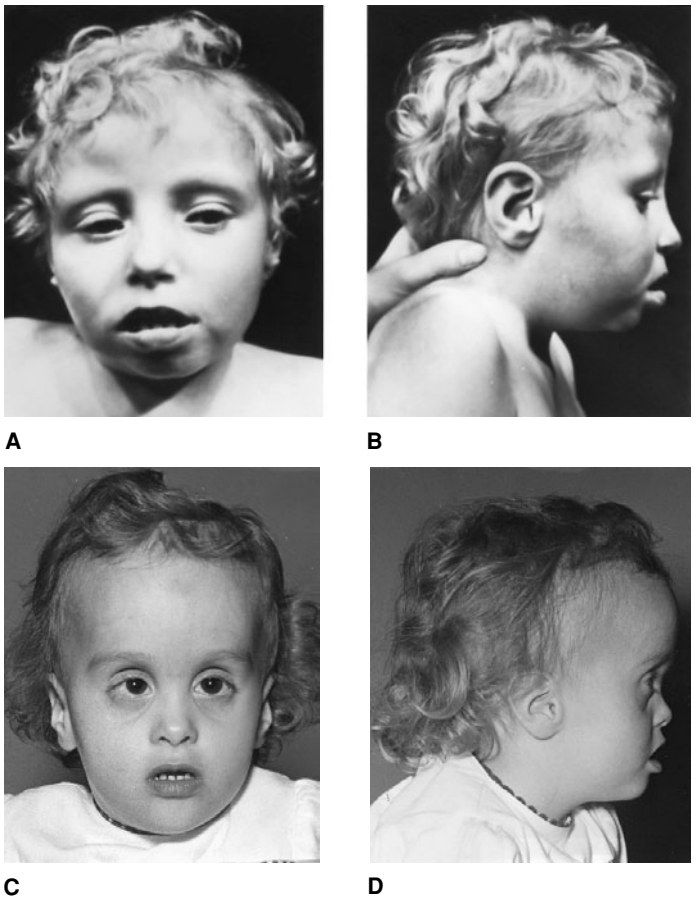

Fig. 3–11. *del(18q) syndrome.* (A,B) Midface hypoplasia, deeply set eyes, and prominent anthelix and antitragus in patient with 18r karyotype. (C,D) Compare facies of patient with that of patient in A,B. (A,B from JD Mürken et al, Z Kinderheilkd 109:1, 1970.)

stenosis, patent ductus arteriosus, and ventricular septal defect occurring in decreasing order of frequency.

The genitalia are abnormal in both sexes. Findings include cryptorchidism (52%), hypospadias, micropenis, and hypoplasia of the labia minora (47%) (3,18,19). Inguinal hernia occurs in 13% (19).

Dimples are present on the epitrochleal regions, over the knuckles, and on the lateral surfaces of the knees. The hands are long, thin, and tapered (90%). The thumbs are proximally placed in 90% and transverse palmar creases occur in 92% of cases. An excess number of fingertip whorl patterns and a high total finger ridge count are characteristic. Other findings include abnormal implantation of the second toes (84%) and talipes equinovarus (21%) (3,19).

Approximately half the cases are associated with osteoarticular anomalies, including supernumerary or hypoplastic ribs, costal synostoses, spina bifida occulta, and coxa valga (4).

IgA deficiency is found in approximately 30% (3,16,22). Diagnosis is based on banded chromosome study and FISH technique. Similar findings are noted in 18r syndrome (9,14).

Turner syndrome

In 1938, Turner (58) recognized the combination of sexual infantilism, webbed neck, and cubitus valgus as a distinct entity. In 1959, Ford et al (13) showed that patients with Turner syndrome were missing one sex chromosome (45,X). The syndrome consists of short stature, streak gonads, webbed neck, shield chest, peripheral lymphedema at birth, coarctation of the aorta, hypoplastic nails, short metacarpals, and multiple pigmented nevi (Fig. 3–12) (11). The reader is referred to the following sources for extensive coverage: general aspects (8,9,14), cytogenetics (5,6,10,11,19,26,27,38,39,52), growth and development (29,44), cognitive and psychosocial aspects (33,46,48,49), cardiovascular anomalies (24,32,35–37), craniofacial and oral aspects (12,15,16,34,55), renal anomalies (43), and neoplasia (2,42,54,61). The prevalence is 1/2500 female births (11,17).

Cytogenetics. Approximately 98%–99% of Turner syndrome fetuses are spontaneously aborted (19); maternal origin of the single X chromosome occurs much more commonly than an X chromosome of paternal origin (5). The clinical phenotype is identical (57a). About 20% of all spontaneously aborted fetuses have Turner syndrome (8,9,17). About one-third of patients are diagnosed in the newborn period, one-third during childhood, and one-third during the teenage years when failure to go through puberty becomes evident. Maternal origin of the single X chromosome is also more common in 45,X survivors than in those with an X chromosome of paternal origin (27). Minimal diagnostic criterion is an abnormal karyotype in which all or part of one of the X chromosomes is absent. The overwhelming majority of patients have gonadal dysgenesis and short stature.

Approximately one-half of patients with Turner syndrome have 45,X karyotypes. The frequencies of different karyotypes are listed in Table 3–12 and the most common nonmosaic and mosaic karyotypes are listed in Table 3–13. Unusual mosaic karyotypes are also known to occur (41). Cryptic Y mosaicism has been discussed by several authors (26,40). Magee et al (30) noted seven pregnancies in a 45,X woman who, following hysterectomy and oophorectomy, was found to have two alleles in ovarian tissue. Clinical diagnosis is based on the overall pattern of anomalies; there are no obligatory malformations and even phenotypic features such as amenorrhea and short stature may be absent (54). Patients mosaic for Turner syndrome tend to have fewer phenotypic features than patients with isochromosome of the long arm of the X chromosome or with pure 45,X Turner syndrome (Table 3–14). The clinical severity of Turner syndrome mosaics increases with the relative increase in the abnormal cell line population (50). Patients with isochromosome formation of the short arm of the X chromosome are frequently normal phenotypically (54). Mosaicism of the 45,X/46,XY type exhibits variable findings. Approximately 15% have features of Turner syndrome, about 80% have ambiguous genitalia, and about 5% have a male phenotype with bilateral cryptorchidism (8). Phenotypic features of pure 45,X Turner syndrome are listed together with percentages in Table 3–15.

Candidate genes. Zinn (63) and Zinn and Ross (64) have discussed candidate genes such as *SHOX, ZFX,* and *RPS4X.* Accumulating evidence indicates that the latter two genes with haploinsufficiency are not the causes of Turner syndrome. *SHOX,* in the pseudoautosomal region, may be responsible for short stature, but haploinsufficient mutations have been shown to cause Leri-Weill dyschondrosteosis and Langer mesomelic dwarfism.

Growth. Average birth length is 47 cm (8) and birth weight is lower than normal, 2933 ± 467 g. Ranke et al (44) studied growth in 150 patients from three German-American centers, observing that growth could be divided into four phases: (*a*) intrauterine growth retardation; (*b*) height development, which is normal up to a bone age of 2 year; (*c*) bone age of 2 to 11 years, when growth is markedly stunted; and (*d*) bone age after 11 years when the growth phase is prolonged but total height gain is below normal. Ranke et al (44) observed no difference in height between 45,X patients and other chromosomal variants. Lyon et al (29) provided growth data for four published series of European patients. Their results enable reasonable prediction of adult height in any patient with Turner syndrome. Lyon et al (29) also noted that estrogen treatment, although resulting in initial accelerated growth, had no significant effect on final height attainment. Lemli and Smith (23) and Brook et al (3) observed that familial height played a role in determining final height attainment in patients with Turner syndrome, with taller parents having taller daughters. Final height attainment is usually between

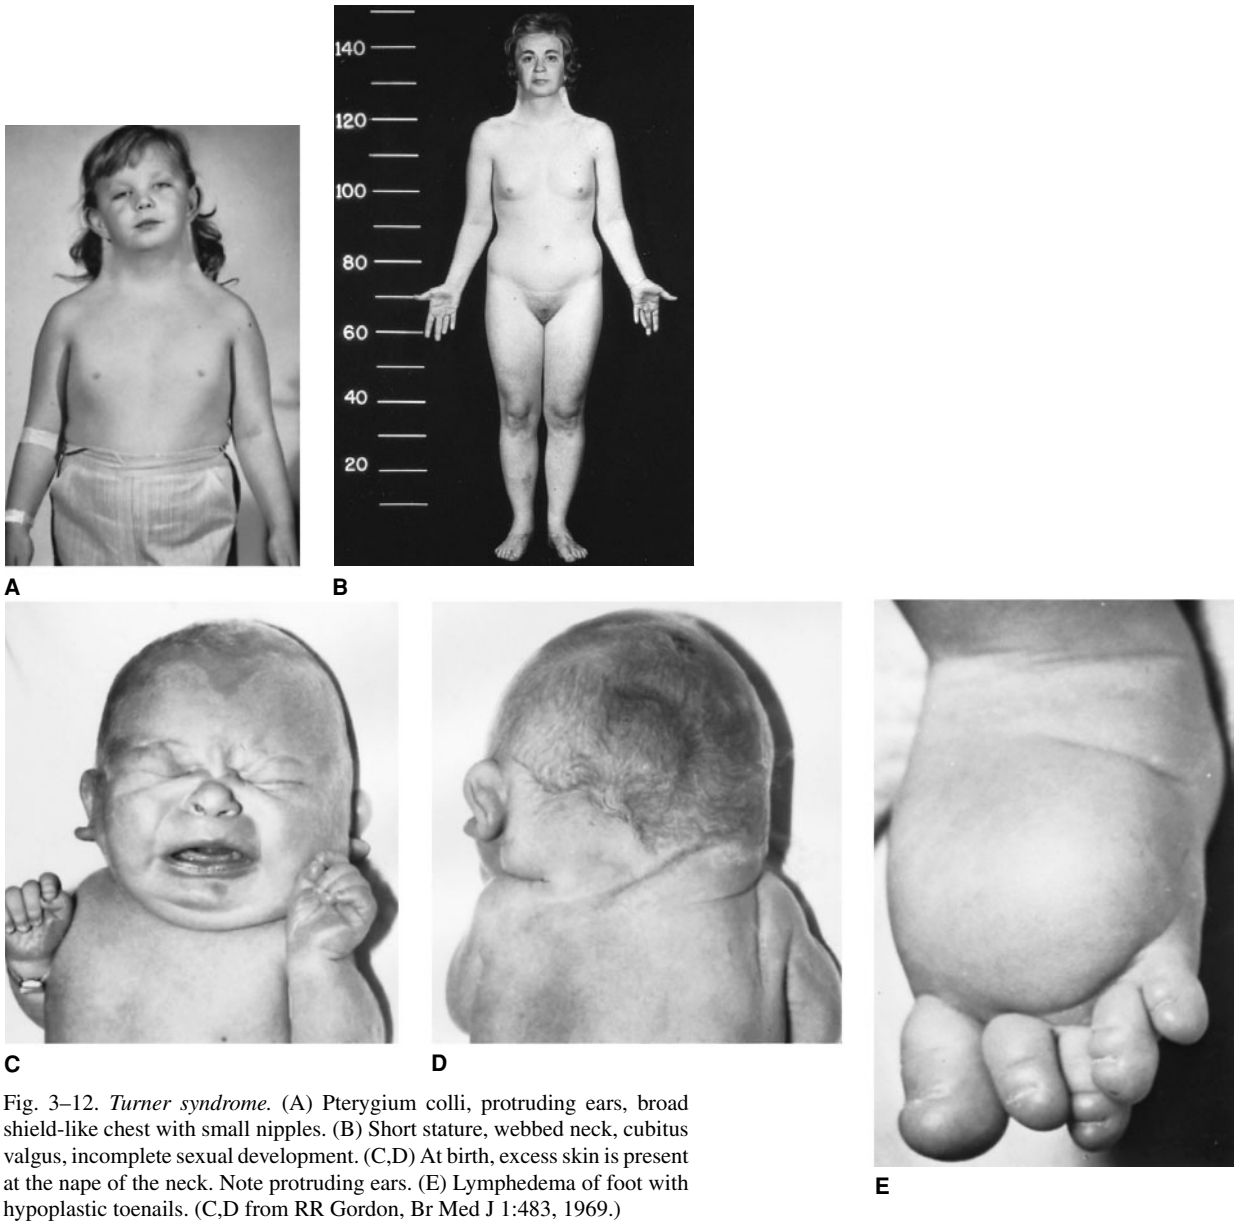

Fig. 3–12. *Turner syndrome.* (A) Pterygium colli, protruding ears, broad shield-like chest with small nipples. (B) Short stature, webbed neck, cubitus valgus, incomplete sexual development. (C,D) At birth, excess skin is present at the nape of the neck. Note protruding ears. (E) Lymphedema of foot with hypoplastic toenails. (C,D from RR Gordon, Br Med J 1:483, 1969.)

122 and 152 cm (11). Ranke et al (44) found a mean adult height attainment of 146.8 cm. Short legs make for the disproportionate short height (47).

Central nervous system. Studies of performance in Turner syndrome have been subject to methodological shortcomings, including (*a*) faulty reporting of mental retardation in some patients when, in fact, reduced performance IQ in the presence of a normal verbal IQ results from specific deficit in spatial ability rather than global reduction in

46,X,i(Xq)
46,X,del(Xp) or 46,XXp–
46,X,del(Xq) or 46,XXq–
46,X,r(X)
46,X,i(Xp)
46,X,i(Yq)
46,X,t(X;X) or 46,X,ter rea (X;X)
46,X,t(X;any autosome) or 46,X,t(X;Y)

Most common mosaic karyotypes

45,X/46,XX
45,X/47,XXX
45,X/46,XX/47,XXX
45,X/46,XY
45,X/any karyotype with a structurally abnormal X or Y

(Adapted from A de la Chapelle, Sex chromosome abnormalities. In: Principles and Practice of Medical Genetics, Emery EH, Rimoin DL (eds), Churchill Livingstone, Edinburgh, 1983, p 193.)

Table 3–14. Comparison of findings in pure Turner syndrome and Turner mosaicism

Finding	45,X (%) ($n = 59$)	Mosaic Turner (%) ($n = 41$)
Head and neck		
Epicanthic folds	37	12
Ptosis of the eyelids	14	7
Myopia	14	15
Abnormal ears	56	37
Low hairline	66	37
Webbed neck	51	27
Thorax		
Shield chest	66	39
Coarctation of aorta	12	5
Heart murmur	46	39
Limbs		
Lymphedema	53	12
Abnormal nails	53	20
Cubitus valgus	56	54
Renal abnormalities	32	20

(Modified from JG Hall et al, West J Med 137:32, 1982.)

intelligence; (*b*) ascertainment bias of patients by severe phenotypic stigmata instead of independently by karyotype; and (*c*) samples composed of pooled karyotypic subgroups instead of independent examination of each subgroup (1). Visual–spatial deficit has been related to reduced functioning in the right cerebral hemisphere, specifically the right parietal lobe (1). This has been shown to be due to deletion of the most distal area of the short arm of the X chromosome (49a). Bender et al (1b) found that 45,X Turner syndrome subjects were slightly delayed in walking, had a moderately decreased full-scale and performance IQ, and demonstrated striking deficit in perceptual organization and fine motor skills, but had average language skills. Linden et al (25) noted that features such as slow speech development, hyperactivity, learning disabilities, neuromotor deficits, and short stature could contribute to poor self-image and lowered self-esteem during adolescence. In a study of 99 Turner syndrome subjects, Romans et al (46) and Ross et al (49) found problems in spatial/perceptual skills, visual–motor integration, affect recognition, visual memory, attentional abilities, and executive function. Motor problems are not related to cognitive defects (36a).

Several psychiatric disturbances have been reported. A slight increase in the risk for anorexia nervosa has been noted (21). McCauley et al (33), studying 30 adult subjects, reported a significant subgroup with major psychiatric problems, especially depression with markedly low self-esteem.

Head and neck abnormalities. Epicanthic folds, ptosis of the eyelids, prominent ears, and micrognathia are common facial features. Visual abnormalities, particularly strabismus, are found in approximately 20% of patients. Chronic suppurative otitis with resultant hearing loss occurs in some cases (22,56). In infants, excess skin on the nape of the neck is common. During embryonic life, neck blebs or cystic hygromas are common (4). With age, the excess skin on the neck metamorphoses into pterygium colli. The ears are prominent and the posterior hairline is low (Fig. 3–12). The palate is highly arched in approximately 35% and cleft palate may occur with a somewhat higher than normal frequency. The teeth may erupt prematurely, the first permanent molars appearing between 1.5 and 4 years of age (12,15,16,34,55). There is increased molarization of premolars (60). Cusp height is reduced (31) as is crown size (55a).

The cranial base is short, so the face is retrognathic. The mandible is short, the maxilla being of normal length (1).

Chest. The chest is broad with seemingly wide-spaced, hypoplastic, and, at times, inverted nipples. Breast development is poor.

Table 3–15. Features of 45,X Turner syndrome

Feature	Percent or Finding
Growth	
Birth length	$\overline{X} = 47$ cm
Birth weight	$\overline{X} = 2933 \pm 467$ g
Final height attainment	122–152 cm
Performance	
Cognitive	Deficits[a]
Intelligence	Normal
Psychiatric	Slightly increased risk for anorexia nervosa[b]
Head and neck	
Epicanthic folds	25
Highly arched palate	36
Visual abnormalities, usually strabismus	22
Auditory problems	50
Webbed neck	46
Short, broad neck, low hairline	74
Chest	
Shield chest	53
Cardiovascular	
Coarctation of the aorta, ventricular septal defect	10–16
Renal	38
Horseshoe kidney	—
Duplicated or otherwise anomalous ureters	—
Unilateral renal aplasia or hypoplasia	—
Gastrointestinal	
Telangiectases	—
Skin and lymphatics	
Pigmented nevi	63
Lymphedema of hands and feet	38
Nails	
Hypoplasia	66
Skeletal	
Cubitus valgus	54
Short metacarpals, metatarsals (usually 4)	48
Deformed medial tibial condyle	65
Osteoporosis	50

(Adapted in part from JL Simpson, Disorders of Sexual Differentiation, Academic Press, New York, 1976; and A de la Chapelle, Sex Chromosome abnormalities. In: Principles and Practice of Medical Genetics, EH Emery, DL Rimoin (eds), Churchill Livingstone, Edinburgh, 1983, pp 193–215.)

Genitalia. Gonadal dysgenesis or streak gonads are characteristic. The histologic pattern consists of long streaks of white wavy connective tissue stroma without follicles. However, follicles are present in fetal and infantile ovaries of patients with Turner syndrome. Patients have primary amenorrhea and sterility. Exogenous hormone replacement is essential for establishing secondary sexual characteristics. Fertility is a rare possibility and has been recorded in a number of instances.

Cardiovascular abnormalities. In a study of 594 Turner syndrome patients, Mazzanti et al (32) found a prevalence of cardiac malformations of 23%; bicuspid aortic valve (12.5%), aortic coarctation 6.9%), and aortic valve disease (3.2%) were most common. Bastianon et al (1a) found 26% of patients with mitral valve prolapse and 15% with bicuspid aortic valve. Only 4% had aortic root dilatation. Coarctation of the aorta occurs with higher frequency with pure 45,X karyotype. Dissecting aortic aneurysm has also been reported (24). Coarctation of the aorta is the most common cause of hypertension and blood pressure often returns to normal following surgical repair. Adults have an increased frequency of hypertension (30%) even when coarctation of the aorta, renal parenchymal, and renal vascular disease have been eliminated as causes. Less common anomalies include ventricular septal defect, atrial septal defect, dextrocardia, bicuspid aortic valves, and hypoplastic left heart (37).

A variety of other vascular anomalies may be observed infrequently, including intestinal telangiectasias, vascular malformations, and lymphangiectasia. Gastrointestinal bleeding may indicate vascular malformations of the intestinal tract. Since the frequency of ulcerative colitis and Crohn's disease is higher in Turner syndrome than in the general population, gastrointestinal bleeding may also indicate primary bowel disease. Protein-losing enteropathy from gastrointestinal lymphatic malformations has also been recorded. Patients with Turner syndrome also have a higher frequency (90%) of increased numbers of renal arteries. Lymphedema occurs in approximately 80% of newborns. The hands and feet may appear puffy but lymphedema is usually transient, resolving in childhood. Recurrent lymphedema of the extremities may be observed in some patients and, rarely, severe lymphedema may be found in adulthood with chylous ascites (57). Lymphedema is almost always secondary to congenital hypoplasia of the lymphatic channels. Shepard et al (53) documented hypoalbuminemia in 45,X fetuses and suggested that lowered plasma albumin concentration could contribute to the edema by lowering osmotic pressure in the blood vessels.

Renal anomalies. Renal findings include horseshoe kidneys (20%), duplication of the collecting ducts (20%), and malrotation of the kidney (15%) (43). Potter sequence has been observed with Turner syndrome (28,62) and may result from cystic dysplasia, small kidneys, or obstructive uropathy (43). When the latter occurs, prune belly may be present (51). The various renal anomalies depend upon the karyotype (1c).

Skeletal abnormalities. Bone age remains within normal limits until 12–14 years of age when the adolescent growth spurt fails to take place. Bone age is generally 2–3 years behind (34). The homeobox *SHOX* is involved in skeletal abnormalities (4a). Without hormone therapy, epiphyses usually fail to fuse until patients reach their 20's. Common skeletal abnormalities include cubitus valgus (approximately 75%), short fourth metacarpals (about 65%), deformity of the medial tibial condyle (about 65%), cervical ribs (100%) (20), hypoplasia of the cervical vertebrae (about 80%), small carpal angle (45) and *relatively* longer hands (59). Some degree of osteoporosis is found in about 50%. However, bone radiolucency and coarse trabeculations can be observed in childhood. Common radiographic findings are listed in Table 3–16. Cohen (7) reviewed five cases with craniosynostosis.

Table 3–16. Common radiographic features of Turner syndrome

Hand

- Drumstick distal phalanges
- Short fourth metacarpals
- Carpal sign: change in angulation of carpal bones
- Shortening of all hand bones
- Madelung's deformity

Feet

- Similar to hands
- Pes cavus

Knees

- Lateral dislocation of patellae
- Hypoplastic patellae
- Irregularity of tibial metaphysis and epiphysis
- "Mushroom" projections, medial surface of proximal tibial metaphysis (medial tibial condyle)

Spine

- Scoliosis
- Lack of lumbar lordosis
- Schmorl's nodes (abnormalities of cartilaginous endplates)
- Hypoplasia of arch of atlas
- Shortening of anteroposterior diameter of vertebral bodies

Ribs

- Thin
- Developmental abnormalities

Pelvis

- Android configuration (50%)
- Occasional widening of symphysis pubis

Skull

- Midfacial hypoplasia
- Deepening of posterior cranial fossa
- Widely spaced mandibular rami

(Adapted from CG Brook et al, Ann Hum Biol 4:17, 1977; WD Risch et al, Am J Roentgenol 126:1302, 1976; and JG Hall et al, West J Med 137:32, 1982.)

Dermatologic features. Hypoplastic, deeply set nails, and multiple pigmented nevi are common. Kato (18) noted a patient with a combined nevus of the compound and Spitz types. Seborrhea, xerosis, hirsutism, and keloid formation occur with increased frequency. Dermatoglyphic findings include an increased total finger ridge count. Redundant folds of skin resulting in pterygium colli and low nuchal hairline have already been discussed.

Neoplasia. Patients who are mosaic for 45,X/46,XY have an increased risk of gonadoblastoma. Such neoplasia develops in a high percentage during early childhood, but there is also an increase around puberty (54). Wertelecki et al (61) studied 289 patients with Turner syndrome and found nongonadal neoplasia in 2.8%. Three tumors were of neural origin, three were gastrointestinal, and one case of leukemia and one of carcinoma of the thyroid were noted. Wertelecki et al (61) listed all other cases of nongonadal neoplasia, including, among others, two pituitary tumors, two adrenal tumors, and four brain tumors. Neuroblastoma and ganglioneuroblastoma have been reported (2). Simultaneous neuroblastoma and adrenocortical carcinoma were noted in a patient with a germline *p53* mutation (42).

Autoimmune disease. Hypothyroidism, diabetes mellitus, and inflammatory bowel disease occur more frequently in the Turner syndrome population than in the general population. Acute Hashimoto's thyroiditis occurs infrequently, but hypothyroidism on an autoimmune basis occurs in approximately 20% of adult women with Turner syndrome. Papendieck et al (39) reported that 55% of patients had thyroid disturbances (n = 49).

Differential diagnosis. Short stature can be observed with *Noonan syndrome,* familial short stature, dyschondrosteosis, type E brachydactyly, growth hormone deficiency, hypothyroidism, glucocorticoid excess, *multiple pterygium syndrome, Klippel-Feil anomaly,* and short stature due to chronic disease. Amenorrhea or failure to begin puberty occurs in pure gonadal dysgenesis, Stein-Leventhal syndrome, and primary or secondary amenorrhea. Lymphedema occurs as Milroy disease, lymphedema with distichiasis, *Hennekam syndrome,* lymphedema with recurrent cholestasis, and lymphedema with intestinal angiectasia. Fetal lymphaticovenous malformations may be seen in *fetal alcohol syndrome, trisomy 21, trisomy 18, del(13q), del(18p), trisomy 22 mosaicism,* and *Noonan syndrome.*

Laboratory aids. Banded chromosome studies should be carried out when a clinical diagnosis of Turner syndrome is suspected. Fifty cells should be counted to rule out mosaicism. If leukocyte studies are normal but clinical suspicion of Turner syndrome is strong, fibroblast cultures should be carried out. Buccal smears should no longer be used because patients with isochromosome X often show Barr body material, resulting in misdiagnosis.

Klinefelter syndrome and its variants

Klinefelter et al (28) reported postpubertal males with small testes and tubular hyalinization, normal numbers of Leydig cells, azospermia, gynecomastia, elevated urinary gonadotropins, and decreased urinary 17-ketosteroids. By 1956, such patients were shown to have Barr bodies (37). In 1959, Jacobs and Strong (25) described an XXY sex chromosome complement in chromatin-positive Klinefelter syndrome. The birth prevalence of chromatin-positive males is approximately 2/1000 and is composed of several X-aneuploidy variants: 47,XXY, 48,XXYY, 46,XY/47,XXY, 48,XXXY, and 49,XXXXY. Approximately 80% are 47,XXY, about 10% represent mosaics, and the remainder have more unusual karyotypes. The prevalence of "classic" Klinefelter syndrome (47,XXY) is approximately 1.18/1000 births. XXY Klinefelter syndrome is at least 20 times as common as other types of X-chromosome polysomy (27). At conception, mean maternal age has been advanced—31.3 years; mean paternal age is 35.5 years (12). Klinefelter syndrome occurs with a frequency of about 0.5%–1.0% in males institutionalized for mental retardation, seizures, or mental illness and in about 10% of males who have sterility. Double aneuploidy of Klinefelter syndrome and Down syndrome occurs with greater frequency than expected by chance (6). Mosaicism has been discussed by several authors (12,26,27,39). Except during screening, it is unusual for clinical diagnosis to be made during infancy or childhood, except for severe conditions such as 49,XXXXY. Classic Klinefelter syndrome is diagnosed most commonly at puberty, although rarely clinical clues may be evident in childhood (9). With increasing X-aneuploidy (47,XXY to 49,XXXXY) several clinical trends become evident: decrease in stature, increase in mental retardation, decrease in total finger ridge count, increase in varicosities, increase in hypostatic leg ulcerations, increased frequency of radioulnar synostosis, increased frequency of mandibular prognathism, and increased frequency of taurodontism (10,29). It should be emphasized that these are statistical trends and need not apply to individual cases (47,XXY).

Growth. Mean birth weight is 3048 g, which tends to be lower than in normal brothers of Klinefelter infants (39). Until 3 years of age, height distribution in a large series of Klinefelter children is unremarkable, but after 3 years of age, the distribution is skewed, with significantly fewer boys below the 25th centile than expected. Head circumference distribution during infancy is similar to that found in the general population. However, at about 4 years of age, head circumference distribution tends to be skewed to the lower half of the normal curve (39). In adulthood, typical Klinefelter individuals are of average or somewhat above-average height; in most populations, Klinefelter individuals are 2–5 cm taller than average normal males. Mean height of such individuals in northern Europe is 177.4 cm. Tall stature is primarily the result of increase in leg length, which is present before puberty but not particularly obvious. In approximately 60% of cases, arm span exceeds height by 3 cm or more (12,39).

Central nervous system and performance. Delayed speech is found in 50% of patients. Delays in emotional development are common (30%), and school maladjustment has been reported in 45%. Poor gross motor coordination is a feature in approximately 25%. During childhood, psychiatric problems do not occur more frequently than in normal individuals. Average IQ is approximately 90 with about 30% below 90. In general, Klinefelter individuals are usually neither highly intelligent nor severely retarded (12,16,39,40).

In adults, there may be disturbances of behavior, deviations in personality, as well as neurotic and psychotic reactions. Antisocial behavior, alcoholism, aggressiveness, depression, and periods of mania have been reported to occur commonly (12,39). Feelings of inadequacy and poor body image often accompany gynecomastia and testicular atrophy (30) (Fig. 3–13A). However, most Klinefelter individuals tend to lead a quiet, passive type of existence (12,39).

Psychosexual orientation is male. Erection, coitus, and ejaculation occur but libido is often subnormal. Many Klinefelter individuals lead normal married lives (12,39).

Genitalia. Penile size is normal or slightly reduced. Small testes are a constant feature, with adult size measuring 1–2 cm compared with 3.5–4.5 cm in normal males. In nearly all cases, the testes are descended. The scrotum is normal in size and in pigmentation. Approximately 50% have a female pubic escutcheon. The prostate is smaller than normal (39,45).

Prepubertal testes are of normal size and microscopic appearance, but during adolescence they fail to enlarge. The testes are small, soft, and often insensitive to pressure. The seminiferous tubules are usually shrunken, hyalinized, and irregularly arranged. Tubules that are not sclerotic are immature and lined exclusively with Sertoli cells. Elastic fibers are absent around the tunica propria of the tubules. Leydig cells are clumped. Rarely, spermatogenesis can be demonstrated. Generally, Klinefelter syndrome is associated with sterility, but in a number of instances, indisputable evidence of paternity has been found (12,39,45).

Secondary sexual characteristics. Typically, Klinefelter syndrome patients do not have female fat distribution, a high-pitched voice, or notably scanty body hair (Fig. 3–13A). However, these features may be present. Facial hair is sparse in 60%–90% and untreated Klinefelter individuals shave only once or twice per week. Gynecomastia develops after puberty in approximately 50% (12,39) (Fig. 3–13A).

Hormones. Leydig cells are defective; plasma testosterone is low in the presence of normal or high follicle-stimulating hormone (FSH) and leutinizing hormone (LH). Typically, patients have 50% or less of normal levels of plasma testosterone and a four-fold increase in urinary excretion of pituitary gonadotropin (12,39) (Fig. 3–13A).

Dermatologic findings. Varicose veins and hypostatic leg ulceration have been reported (10). There are no suggestive dermatoglyphic findings, although the total finger ridge count tends to be lower than average because of an increased number of arches (12).

Craniofacial features. Cephalometric investigation shows smaller calvarial size, smaller cranial base angle, and larger gonial angle than normal (5). Both maxillary and mandibular prognathism tend to occur (22). Alvesalo and Portin (2) found permanent tooth crowns to be larger in 47,XXY males than in control males. Taurodontism has been reported in some instances (14,29).

Congenital malformations. Major malformations are found in approximately 20%, but no clear patterns have emerged. Findings may include cleft palate, inguinal hernia, cryptorchidism, unilateral renal aplasia, microcephaly, corneal opacity, aortic stenosis, mitral valve prolapse, omphalocele, nerve deafness, hypospadias, pectus excavatum, or scoliosis. Minor anomalies are observed in 25% of patients, with clinodactyly being the most common (20%). Other findings may include ear anomalies, single palmar creases, strabismus, external rotation of legs, "third" fontanel, micropenis, down-slanting palpebral fissures, or genu recurvatum (12,39).

Other findings. Some evidence indicates an increase in pulmonary disorders (39) and, perhaps, lupus erythematosus (46). Autoimmune disorders, in general, are increased (2a). Diabetes mellitus is present in 8% of adult XXY patients.

A

B

Fig. 3–13. *Klinefelter syndrome.* (A) Note gynecomastia, female fat distribution, paucity of pubic hair; small testes in XXY male. (B) Male with XXYY karyotype. Note mild gynecomastia, knock-knees, female pubic escutcheon, stasis dermatitis of lower legs.

Neoplasia. An increased frequency of carcinoma of the breast has been noted, the risk being 66 times that in normal men and approaching the risk in normal women (24). Conversely, Klinefelter syndrome is found in 3.3% of men with breast cancer (19). Isurugi et al (23) reported seminoma of the testis.

48,XXYY. Birth prevalence is 0.04/1000 male births. At least 120 cases have been analyzed (13). The frequency is 50 to 100 times greater among males in mental institutions and prisons (12). Most likely, the disorder is caused by nondisjunction in both the first and second meiotic divisions during spermatogenesis, with the production of an XYY sperm. The less likely possibility of nondisjunction at the second meiotic division in both parents must be rare. Advanced parental age has not been observed (12,39).

In general, individuals with 48,XXYY karyotype tend to be approximately 4 cm taller, more aggressive with more truncal obesity, and more mentally retarded than those with 47,XXY karyotype. Characteristic features include small testes, eunuchoid habitus, sparse body hair, gynecomastia, varicose ulceration, and elevated gonadotropins (8,13,17) (Fig. 3–13B). Dermatoglyphic studies have shown that fingertip arch patterns are more common in 48,XXYY individuals. Thus, the total finger ridge count is low (12).

48,XXXY. This condition is rare and arises from successive nondisjunction in either maternal or paternal meiotic divisions (12,39).

Mental retardation is a constant finding. The penis is hypoplastic in 50% of cases and gynecomastia is observed in approximately 35%. Other findings include facial asymmetry, epicanthic folds (25%), ocular hypertelorism, protruding lips, mandibular prognathism, short neck, radioulnar synostosis (10%), clinodactyly of fifth finger (30%), coxa valga, and other abnormalities (12,39).

49,XXXXY. Over 100 cases of 49,XXXXY syndrome have been reported (7,31,49). A frequency of 1 in 85,000 births has been noted (36). Postzygotic nondisjunction during both meiosis I and meiosis II appears to cause the XXXXY state, all the X chromosomes being of maternal origin (21,48). Maternal age does not appear to be advanced (12,39). Sarto et al (41) suggested two hypotheses to best explain the abnormal phenotype that accompanies 49,XXXXY karyotype: (1) increased dosage of active genes that escape X inactivation and (2) asynchronous replication of the extra X chromosomes.

Average birth weight is approximately 2500 g. Height is often below the third centile and bone age is delayed in 90%. However, Borghgraef et al (7) reported infants small for their age who had significant catch-up growth, being at the 50th to 75th centiles after age 4 years. Variable mental retardation is found, with IQs ranging from 20 to 70. There is some evidence of decline in intellectual performance with age. Affected individuals may be extremely shy and timid (7,11,32,43). Language development is especially retarded (11,32). Hypotonia, joint laxity, or both are found in approximately 33% (12,39). Hypoplasia of the corpus callosum and growth hormone deficiency have been noted (18).

The phenotype is distinctive (Fig. 3–14). Hypogonadism is severe, with pea-sized testes, micropenis, and pronounced infantilism of secondary sex characteristics. The scrotum is usually hypoplastic (80%) and the testes may be cryptorchid (25%). Histologically, Leydig cells are hypoplastic and germ cells are absent (3,12,38).

Clinical features (Table 3–17) include mild microbrachycephaly, ocular hypertelorism (30%), up-slanting palpebral fissures (70%), epicanthic folds (85%), strabismus (60%), myopia (25%), low broad nasal bridge, sometimes with upturned nasal tip (95%), poorly modeled ears (80%), and short neck, sometimes with webbing (12,20,39).

During infancy, the face is rounded (36). With growth, the midface appears retruded with relative mandibular prognathism (50%).

Fig. 3–14. *49,XXXXY Klinefelter syndrome.* (A) Up-slanting palpebral fissures, small ears, hypogenitalism, and cubitus valgus. (B) Hypogenitalism. (C,D) Marked mandibular prognathism. (A from MC Joseph et al, J Med Genet 1:95, 1964. B from RA Pfeiffer, Z Kinderheilkd 87:356, 1962. C,D courtesy of H Schade, Münster, Germany.)

Taurodontism is a common finding (29). Cleft palate has been documented (47).

Skeletal anomalies (Table 3–17) occur in over half of the cases and include sclerotic cranial sutures (60%), thick sternum, radioulnar synostosis, cubitus valgus, elongation of distal ulna and proximal radius, wide proximal ulna, pseudoepiphyses of metacarpals and metatarsals, hypoplasia of middle phalanx of fifth digit with clinodactyly (95%), coxa valga (85%), genua valga (15%), and pes planus (55%). Other findings may include malformed cervical vertebrae, narrow chest, thoracic kyphosis, retarded bone age, and scoliosis (11,35,42,44).

Congenital heart defects, particularly patent ductus arteriosus, are present in approximately 20% of cases (11,27). Gynecomastia is not a feature of 49,XXXXY individuals, but the nipples may be widely spaced. Gonadotropins are not elevated (12,39). A low total finger ridge count with an increased number of fingertip arch patterns may be observed (12).

46,XX males. Suggested birth prevalence is 1/25,000 newborn males. Phenotypic features are very similar to those of 47,XXY Klinefelter syndrome, with two major differences. First, mean height attainment (168.2 cm) is below that of 47,XXY subjects (177.4 cm) (15). Second, disproportion between trunk and limbs found in 47,XXY is not found in 46,XX males. About 10%–15% of 46,XX males have some degree of hypospadias (33,34). Other differences are less striking; intelligence is normal (15). Gynecomastia occurs slightly less frequently than in classic Klinefelter syndrome (12). Measurements of permanent tooth size indicate that teeth in 46,XX males are smaller than those of normal males and are similar in size to those of normal females (1).

At present, no single hypothesis explains the 46,XX male condition, which may be etiologically heterogeneous. One possibility is undetected mosaicism involving a Y chromosome–containing cell line, although this has not been shown (33). A second possibility involves translocation of the testis-determining factor (*TDF*) gene from the short arm of the Y chromosome to the X chromosome or to an autosome during paternal meiosis. Most cases are due to Y-X interchange. This hypothesis is supported by observing an increased length in the short arm of one X chromosome in some 46,XX males, although short arm length of X chromosomes is normal in others. Finally, testes and maleness in 46,XX individuals might result from an X-linked *TDF* gene mutation, suggested by the small number of families with more than one 46,XX male (15,33,39).

Differential diagnosis. Differential diagnosis includes eunuchoidism, *homocystinuria*, and *47,XYY* syndrome. Patients with

(Modified from CL Levy et al, J Med Gent 15:301, 1978.)

49,XXXXY syndrome are distinctive clinically, but sometimes their features suggest *trisomy 21 syndrome* in fetuses (38) and newborns, although the overall pattern of anomalies is at variance with the latter.

Clinical clues leading to the detection of classic 47,XXY Klinefelter syndrome during childhood include dull mentality, school or behavioral problems, altered body habitus with relatively long legs and slim build, small testes, and inadequately developed phallus (9).

Laboratory aids. Banded chromosome study is essential when a clinical diagnosis of Klinefelter syndrome is suspected. Fifty cells should be counted to rule out mosaicism.

47,XYY males and other poly-Y conditions

The 47,XYY chromosomal constitution was first observed by Sandberg et al (27) in 1961; the subject was a man of normal intelligence who had, with two different women, numerous progeny, including an amenorrheic female, twins (one with trisomy 21, the other a "blue baby"), and two spontaneous abortions (13). The 47,XYY karyotype aroused considerable public attention because of the many reports of criminal behavior, most of which had a known ascertainment bias favoring behavioral disability (3,5,8,14,16,21). Birth prevalence is approximately 1/1000 male births (26,29). Sumner et al (32), using a fluorescent technique, showed that over 1% of sperm from normal males contained two Y chromosomes, implying marked selection against such sperm.

Growth. Tall stature in adult life is characteristic. Mean final height attainment varies from 180 to 186 cm (26). Leg length and trunk length are increased, but the leg/trunk ratio is normal (17). Birth weight and length are normal (26). In a study of 43 affected boys (26), overall distribution of growth centiles was not significantly different from normal, although one subset from Edinburgh (25) suggested a growth spurt between ages 2 and 6 years in approximately one-third of the cases. By 5 years, all boys were above the 50th centile for height and approximately 38% were above the 90th centile.

Central nervous system and performance. Approximately one-third of affected individuals have delayed speech or language development and there is some evidence of fine motor problems (26). Muscle weakness and poor coordination are commonly noted (9). In a study of 43 affected subjects (26), IQ scores ranged from 78 to 145. Approximately 38% showed IQs from 70 to 89. Thus, average IQ is lower than in normal males and verbal IQs tend to be more affected than performance IQs.

Males with 47,XYY chromosomal constitution probably blend into the general population as normal individuals. The most frequently observed stigmatizing features are excessive height for age, excessively impulsive behavior, and excessive temper tantrums in childhood. Stigmatization does not correlate with socioeconomic class (21). Psychological studies have shown that infantilism, lack of emotional control, increased impulsiveness after emotional stimulation, and weak sense of self are so characteristic of 47,XYY men that they can be recognized by psychological tests alone.

Even correcting for earlier biased ascertainment from mental institutions and prisons, it is now well established that among 47,XYY males, an excess degree of criminal behavior exists compared to 46,XY males. For example, Daly and Harley (8) karyotyped 3011 males from five Wisconsin state correctional institutions and found a 47,XYY frequency of 1%, which is five times greater than the newborn prevalence for 47,XYY males. Crimes are similar to those committed by 46,XY men. The preponderance of serious aggressive behavior against people has not been substantiated. Rather, theft, arson, and burglary are the crimes most often cited. The cause of antisocial behavior leading to conflict with the law is not entirely resolved and still much debated. None of the suggested causes, which include impaired intellectual function, abnormal electroencephalographic findings in a few instances, low socioeconomic status, or very tall stature, either separately or together, explains the increased risk of antisocial behavior (26).

Gonadal status and fertility. Gonadal development, testicular size, and testicular histology are normal (7,11,26). Many 47,XYY males have fathered offspring who are chromosomally normal. Pregnancies resulting from XYY individuals have ended in miscarriage or perinatal deaths, or have produced offspring with various chromosomal abnormalities (12). In rare instances, subjects have procreated 47,XYY sons (33). In a few instances, however, small testes, decreased spermatogenesis, subfertility, and sterility have been noted. Cryptorchidism, micropenis, or hypospadias are rarely observed (11).

Congenital malformations. In a study of 43 affected infants, Robinson and de la Chapelle (26) found the overwhelming majority to be completely normal in appearance. Major malformations were not increased, although approximately 20% had minor anomalies. Although no clear pattern of minor anomalies emerged, clinodactyly with single fifth finger crease, inguinal hernia, and abnormal ears were observed in two instances each. Other minor anomalies and subtle phenotypic alterations have been noted, including mild facial asymmetry, mild pectus carinatum or excavatum, mild winging of the scapula, glabellar mounding, long ears, highly arched palate, and bony chin point (4,9,26). A number of major abnormalities have also been noted, including urinary tract malformations (20) and radioulnar synostosis (6).

Dermatologic findings. Nodulocystic acne involving the face, chest, and back has been reported in association with 47,XYY subjects (36).

Dentition. Careful measurement of teeth has indicated that tooth size in 47,XYY males is larger than normal in both the deciduous and permanent dentitions (1,2). In a study of shovel-shaped maxillary incisors, affected central incisors were similar to those of normal controls, but lateral incisors were more shoveled and showed deeper lingual fossae in 47,XYY subjects than in control subjects (18).

Differential diagnosis. Differential diagnosis includes *Klinefelter syndrome* and *Marfan syndrome*. Males with 48,XXYY karyotype have features that combine Klinefelter syndrome with above-normal stature and frequent mental deficiency. Several poly-Y karyotypes have been reported, including 48,XYY (15,28,34) and 49,XYYYY (23,24,29–31,35). Townes et al (34) described a 48,XYYY patient with mild mental deficiency, inguinal hernia, cryptorchidism, valvular pulmonic stenosis, and single palmar creases. Das et al (10) reported a 49,XXYYY male with mild microcephaly, limited supination of elbows, delayed bone age, and mild mental retardation. Schoepflin and Centerwall (28) described a 48,XYY patient with mental retardation, impulsive aggressive behavior, single palmar creases, clinodactyly, delayed bone age, pseudoepiphyses at the bases of the metacarpals and metatarsals, and lack of patellar epiphyseal calcification. Hunter and Quaife (15) noted a 48,XYYY individual with no stigmata other than sterility. Sirota et al (30,31) reported a 49,XYYYY patient with trigonocephaly, up-slanting palpebral fissures, epicanthic folds, highly arched palate, micrognathia, low-set ears, limitation of motion at the elbows and knees, and an IQ of 50. Mosaic 45,X/49,XYYYY was documented by van den Berghe et al (35). Findings included mental retardation, facial asymmetry, cataracts, and clinodactyly.

Laboratory findings. Karyotypic findings are usually unrelated to the reason for testing. Whether discovery occurs prenatally, during childhood, or later, it is a formidable challenge to counselors and patients alike. The ethical controversies of XYY screening are discussed elsewhere (19).

47,XXX, 48,XXXX and 49,XXXXX syndromes

47,XXX. No specific phenotype is characteristic and no increase in major malformations has been observed. This syndrome has been found in about 1 in 1200 female newborns. The condition arises from maternal nondysjunction in meiosis I. The mothers of the probands tend to be older. In a study of 43 females with 47,XXX (15), the overwhelming majority of infants appeared normal at birth and no unusual karyotype would be suspected. Minor anomalies have been noted in some instances, and an increased frequency of epicanthic folds, minor ear anomalies, and clinodactyly was reported by Robinson and de la Chapelle (15). Judisch and Patil (10) described a case with bilateral retinoblastoma and pinealoma.

In general, birth weights tend to be low but within normal limits. Height percentiles increase with age (15,17), most being above the 50th percentile by age 6 years. The greater height affects the legs rather than the trunk. In contrast, head circumference tends to be between the 25th and 35th centiles. Frank microcephaly has been noted in an occasional instance (15).

Delay in both receptive and expressive language is common (7,9,11,15). Full-scale IQs tend to be significantly lower than normal (15). Fryns et al (4) found mental deficiency as the presenting symptom in over 25% of cases, but noted that his sample was biased. Deficit in gross motor skills and poor coordination have been reported (7). Also encountered have been emotional immaturity, social problems, passivity, learning disorders, and psychosis (4,7,9,11).

As a rule, sexual development is normal. However, there may be late-onset menarche, oligomenorrhea, or early-onset menopause. Fertility may range from normal to complete infertility with streak gonads (4). Some triple-X patients suffer from recurrent urinary tract infections (5). Most of their children have been chromosomally normal.

48,XXXX. More than 40 cases have been recorded to date (6,15,18). No specific phenotype is associated with tetra-X females, although mental deficiency appears to be an essentially constant feature, IQs averaging 55 with a range of 30–75. Speech and behavioral problems are frequently encountered. No increased frequency in congenital heart defects has been observed. Facial anomalies have included midface hypoplasia, mild hypertelorism, epicanthic folds, and mild micrognathia (6,18). On occasion, the face has been suggestive of trisomy 21 syndrome. A patient reported by Fryns et al (4) had features of Turner syndrome, although final height attainment was normal. Occasionally, clinodactyly of the fifth finger and radioulnar synostosis have been observed. The shoulder girdle may be narrow. Development of secondary sexual characteristics is incomplete with small breasts, scanty axillary and pubic hair, and frequently hypoplastic external genitalia. Menarche may occur spontaneously, but disturbances in the menstrual cycle have been noted in about 50% of cases. Ovarian tissue may be normal in some instances, although bilateral gonadal agenesis has also been reported (5).

49,XXXXX. Approximately 30 cases (at least 3 mosaic) of the penta-X syndrome have been described to date (1–5,12–14,16,19,20). Some patients are initially thought to have Down syndrome. Several reviews of clinical findings are available (5,19). Features of the penta-X syndrome appear in Table 3–18.

Growth deficiency of prenatal onset with failure to thrive and short stature are common (5). Delayed bone age has been reported. The head circumference is small in about 55% of cases, and moderate to severe mental or psychomotor retardation occurs in approximately 80% (5,13). Hypotonia has been reported (4,14).

The craniofacial appearance can be striking, with up-slanting palpebral fissures, flat nasal bridge, abnormal ears, and short neck (5). The hairline may be low. Ocular findings have included hypertelorism, epicanthic folds, ptosis of eyelids, and iris coloboma (4,5,13,16). Small ears and ear tags have been mentioned (5,13), as has hearing loss (13). Other features have occasionally been noted: everted, furrowed, or thick lips, cleft palate, and micrognathia. Dental abnormalities include malocclusion, hypodontia, and taurodontism (1,5,20).

The phenotypic appearance may be striking, with narrow shoulders and genua valga (Fig. 3–15) (1,2,16). Radioulnar synostosis occurs in about 45% of cases with joint hyperflexion or dislocations in approximately 35%. The patient reported by Dryer et al (3) had multiple dislocations suggestive of Larsen syndrome. Camptodactyly and/or clinodactyly are common, occurring in about 75%. Other reported findings have included micromelia, low total finger ridge count, clubfoot, metatarsus varus, and malposed toes (4,5).

Congenital heart defects occur in about 40% of patients, with PDA and VSD being particularly common (13,20). Small uterus and ovarian agenesis have been recorded in some cases. Delayed puberty has been noted (5,13,19). The kidneys are hypoplastic in some instances (5,19). In one

Table 3–18. Features of the penta-X syndrome

Feature	Percent ($n = 20$)[a]
Growth	
Low birth weight	55
Failure to thrive	35
Short stature	65
Delayed bone age	30
Small head circumference	55

Triploidy syndrome

Triploidy is a frequent cause of fetal wastage (20%) prior to and during the second trimester of intrauterine development (2,3). It should be suspected when ultrasound shows fetal malformations, specifically intrauterine growth retardation, and/or cystic placental changes. Most newborns with triploidy die within the first few days of life, but some survive into early infancy (4,24,27). About 60% are 69,XXY with the rest mostly 69,XXX. 69,XYY conceptions are rare, as they abort early and grow in culture poorly. A digynic infant with triploidy has survived for 46 days (15).

Over 50 well-documented cases of newborns with true triploidy and 20 cases of diploid/triploid mosaicism have been reported. In general,

A

B

Fig. 3–16. *Triploidy phenotypes.* (A) Diandric fetus (type 1) with normal head and large cystic placenta. (B) Digynic fetus (type 2) with disproportionately large head and small placenta. (From DE McFadden and DK Kalousek, Am J Med Genet 38:535, 1991.)

the latter condition is less severe, more compatible with life, and harder to diagnose clinically, as peripheral lymphocyte cultures show a normal karyotype only (3). Fibroblast culture may be required to show the cell line with triploid complement.

The triploid fetus may show paternal genome dominance, being derived either from dispermy or from faulty meiotic division in the male. Errors in maternal meiosis produce triploid with maternal genome dominance or mitotic errors in female germ cell precursors (8,10,23,26,29,30). There has been recurrence in the same family (24a).

McFadden and Kalousek (17) showed two phenotypes of triploid fetuses: type 1 (diandric), in which the head is normal or somewhat small while the placenta is large and cystic (Fig. 3–16A) and type 2 (digynic), in which there is marked intrauterine growth retardation, the head is disproportionately large, and the placenta is small but noncystic, (Fig. 3–16B). The two different types are due to genomic imprinting (18) and reflect paternal or maternal genomic dominance. Microscopically, type 1 chorionic villi are hydropic and cystic (partial hydatidiform moles) (Fig. 3–17) whereas type 2 chorionic villi have fibrosis of the stromal core without trophoblastic hyperplasia. Zaragoza et al (31) found diandry to be predominant.

Miny et al (21) showed that maternal origin of the triploidy was often found in those fetuses that survived until late pregnancy.

Vertebral fusions were found in 6 of 15 triploid fetuses by Kjaer et al (15a). No correlation with genotype was found.

In true triploidy, polyhydramnios is common. Mosaic triploid pregnancy complications are unusual. About 70% exhibit birth weight below 1900 g. Pronounced asymmetry has been observed in about 50% with either pure or mosaic triploidy. This may lead to the misdiagnosis of *Silver-Russell syndrome* (19). The degree of asymmetry does not reflect the degree of mosaicism. Hypotonia has been documented in about 60%. Syndactyly of the third and fourth fingers (Fig. 3–18C) and variable syndactyly of toes, transverse palmar creases, and clubfoot have been noted in at least 60% of both true and mosaic triploids (3).

Fig. 3–17. *Triploidy syndrome.* Note both normal and hydropic and cystic villi. (Courtesy of S Walker, Liverpool, England.)

C

D

Fig. 3–18. *Triploidy syndrome.* (A,B) Frontal bossing, coloboma of iris, strabismus, and malformed ear. (C) Soft tissue syndactyly of third and fourth fingers. (D) Note talipes. (A–C from W Schmid and D Vischer, Cytogenetics 6:145, 1967. D courtesy of E Niebuhr, Copenhagen, Denmark.)

Camptodactyly of the fifth finger and an increased number of digital whorls have been reported (11,14). Mental deficiency has been noted in most true examples. Hydrocephalus (20%), absent corpus callosum (15%), dilated ventricles (35%), large posterior fontanel (90%), Dandy–Walker malformation, lumbosacral meningomyelocele (20%), and, frequently, Arnold–Chiari malformation and hydranencephaly have been reported. Holoprosencephaly has been noted (9). Microphthalmia, iris and choroid colobomas, and epicanthal folds are each seen in 25% of true triploidy (3). The ears are dysplastic and/or low set in 35%–50% (Fig. 3–18). Micrognathia is common. Isolated cleft palate (1,7,9) or cleft lip with or without cleft palate has been noted (1,27,29) in about 35%. Oral asymmetry, macroglossia, and smaller teeth on one side have been described (6,12,22,30).

The male genitalia in those with true 69,XXY are often abnormal (25). Hypospadias (40%), cryptorchidism (85%), micropenis (75%), and ambiguous genitalia (40%) are common. Scrotal abnormalities (60%) include bifidity and scrotal hypoplasia or agenesis. Leydig cell hyperplasia has been documented in 20% (3,13). Females (69,XXX) usually manifest gonadal dysgenesis. Kidney anomalies (cystic dysplasia, glomerulosclerosis, hydronephrosis), adrenal hypoplasia, and congenital heart defects, particularly ventricular septal defect, patent ductus arteriosus, and atrial septal defect, occur in 50% of those with complete triploidy but do not occur in the mosaic form (1,3,5,7). In true triploidy, abdominal wall defects such as omphalocele, gastroschisis, umbilical hernia, and diastasis recti are seen in 50% (3). Agenesis of the gallbladder has been reported.

Radiographic changes include harlequin orbits, small anterior fontanel, gracile ribs, upswept clavicles, diaphyseal overtubulation of long bones, vertical ilia, and proximal radioulnar synostosis (28). The posterior fontanel is always large at birth. Asymmetry of the occipitoparietal calvaria occurs in 50%.

Large placentas with molar changes (diandry) have generally been associated with increased maternal serum AFP (MSAFP) and high hCG levels; and those with digyry and small monocystic placentas have normal MSAFP and low hCG.

Fragile X syndrome (Martin-Bell syndrome, macro-orchidism-marker X syndrome)

X-linked mental retardation (XLMR) is close in frequency to that of Down syndrome and fetal alcohol syndrome. More than 125 XLMR syndromes have been identified (50,55), of which fragile X (FraX) is the most common, accounting for approximately 50% of cases. Fragile X, the most common inherited form of mental retardation, is the only XLMR syndrome we shall consider here for extensive discussion. Several historical reviews of FraX have been published, including those of Schinzel and Largo (64), Goldson and Hagerman (22), de Vries et al (12), Stevenson et al (74), and Laxova (43).

The frequency of FraX has been estimated at approximately 1/4000 males and 1/8000 females (54,83,89). Its prevalence among mentally retarded males has been estimated to be about 2%–6% (3).

The term "fragile X" refers to its cytogenetic manifestation: a gap or break disrupting the long arm of the involved X chromosome. This abnormality was first described by Lubs (49) in 1969, and a scanning electron microscopy (EM) study has been carried out (29). Disruption of the long arm occurs at a specific site referred to as a fragile site. For the fragile X syndrome described here, it occurs within band Xq27.3, designated FRAXA. Several other fragile sites on the distal long arm of X have been described, only one of which, FRAXE at Xq28, appears to be associated with phenotypic consequences as well (16).

FRAXA differs from other chromosome abnormalities in that (*a*) the abnormality is only detectable if cells are cultured under specific conditions of folate stress; and (*b*) the abnormality is only seen in a proportion of cells from an affected individual (generally 10%–60% for lymphocytes of an affected male and 5%–30% for an affected female) (75).

The gene *FMR1*, responsible for FraX, has been sequenced, and its gene product, the FMR protein (FMRP) has been characterized; for review, see Fang et al (14) and Kaufmann and Reiss (38). Affected status appears to be caused by silencing of *FMR1*, resulting in absence of FMRP. Monozygotic female twins exhibited postzygotic X inactivation in one but not the other (90a).

In most cases of FraX, transcriptional silencing of *FMR1* is related to the presence of a greatly expanded and methylated CGG trinucleotide sequence (Fig. 3–19). Silencing has also recently been associated with histone diacetylation (10) (complete silencing and affected status have, in a few exceptional cases, been caused by single base pair mutations within *FMR1* or deletions). The CGG repeat is located in the 5′ untranslated region of the gene. The CGG repeat tract can be interrupted by one or more AGG triplets (40). Normal values of CGG repeats generally range from 6 to 60, and are transmitted without change from one generation to the next. *FMR1* alleles with 60–200 repeats comprise the so-called premutation range, and alleles with greater than 200 repeats designate full mutations (40). It is the full mutation that is typically associated with cytogenetic and phenotypic expression of the fragile X syndrome. In contrast, individuals carrying premutation alleles are not expected to be affected (18,31,72,84) and do not manifest the cytogenetic abnormality. However, such premutation alleles, when transmitted by a female, are unstable from one generation to the next—that is, the trinucleotide repeat tract can expand from premutation to full mutation size when passed from a mother to a child. Premutations are more stable in male carriers, who from pedigree analyses have been called "transmitting males." Daughters of transmitting males inherit such premutation alleles with little or no change in repeat number. However, during transmission from these daughters to their offspring, the premutations can expand to full mutations. Thus, daughters of transmitting males do not manifest FraX, whereas the grandchildren of transmitting males are frequently affected. Selective expansion of the CGG repeats associated with female meiosis explains the so-called Sherman paradox of very low penetrance (<20%) in brothers of nontransmitting males and high penetrance (>80%) in brothers of affected males (21). The instability and expansion of the triplet repeats also explains the basis for the observed genetic anticipation of FraX, that is, an increase in disease severity through successive generations (15,30,39,76,79,86).

Fragile X syndrome has variable expression in the hemizygote male and especially in the female heterozygote (46), about 35% of whom have cognitive impairment (26). In females, affected status appears to be related to the pattern of X-chromosome inactivation, and, as in males, to the ultimate level of FMRP expression.

Birth weight may be elevated (3). Adult height is somewhat decreased (47,48). Head circumference is relatively increased (42a), and there is dolichocephaly (6). Hand and foot lengths are slightly reduced (53). In the postpubertal male, only about 60% exhibit the triad of typical facies, mental retardation, and macro-orchidism (8,18). Occasionally, hemizygotes appear entirely normal (84).

Facies. A long narrow face is present in roughly 70% of postpubertal hemizygotes. The forehead is high, large, and quadrangular with prominent supraorbital ridges. There may be puffiness around the eyes.

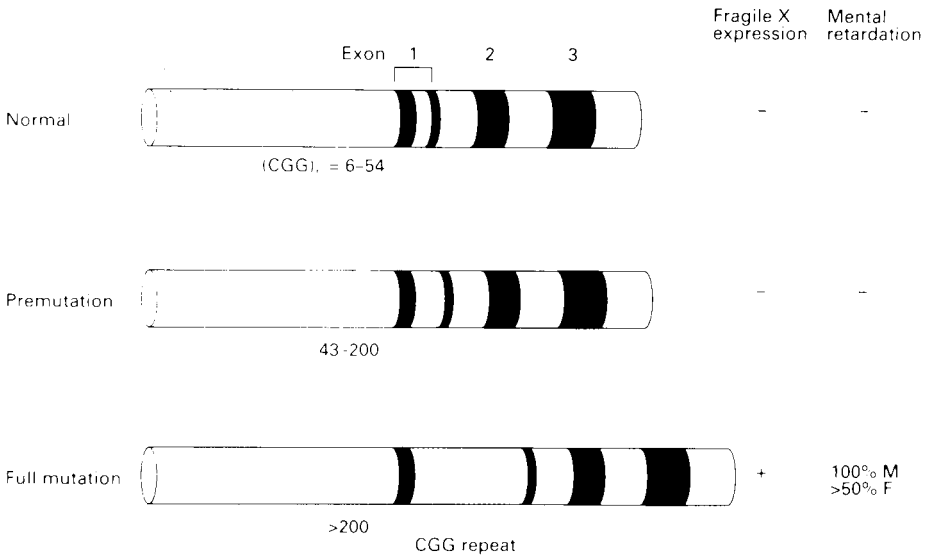

Fig. 3–19. *Fragile X syndrome.* Part of *FMR1* gene and its CGG related mutations in the first exon of the *FMR1* gene that contains the CGG repeat (gray). (From BBA de Vries et al, J Med Genet 35:579, 1998.)

D

Fig. 3–20. *Fragile X syndrome.* (A) Long, narrow face with large, quadrangular forehead, somewhat underdeveloped midface, broad-based nose, prominent chin, and prominent ears. (B) Compare facies to patient in A. (C) Macro-orchidism. (D) G–non-banded fragile X site. (A from A McDermott et al, J Med Genet 20:169, 1983.)

Palpebral length is increased and inter–inner canthal distance is decreased. Strabismus is noted in 10% and refractive errors in 25% of patients. The cheeks feel somewhat thickened (56). The chin becomes long and prominent during adolescence and there is some degree of midface retraction (77). The nose is usually broad based. The pinnae are very large (7 cm) in 70% of cases, and are somewhat soft, and outstanding or cupped with simple helices and absent lobes (5,25) (Fig. 3–20A,B). Otitis media occurs in 85%. Hull and Hagerman (34) have suggested that females with the premutation have outstanding ears. The palate is highly arched in 50% (3,18,53,80). Perhaps 25%–40% of carrier females, especially the more retarded ones, have the typical facies (long face, prognathism, large everted pinnae), are shy, and have poor eye contact (19,25,42a,45,81,87). In the newborn, relative macrocephaly and large fontanel may be noted, but not the long face. Ear infections are frequent (42a).

Central nervous system. Cognitive variability has been discussed by Theobald et al (78), Chudley and Hagerman (8), and Schapiro et al (62). Mental retardation in the hemizygote is moderately severe with IQs ranging from 20 to 69 (9,20). However, in over 75% of affected individuals, IQs are less than 39. Females with the full mutation have IQs of 50–107 (mean 81). Retardation seems to increase with age (91). Speech delay is constant. Those with a higher IQ exhibit cluttered speech (dysfluencies, stuttering). Often there is characteristic rhythmic intonation (litany speech). Those with low IQs are less verbal with short bursts of repetitive phrases. Patients exhibit delayed milestones (sitting, 10 months; walking, 21 months; speaking, 20 months), clumsiness, hyperactivity, mild hypotonia, increased deep tendon reflexes, emotional instability, and automutilation (especially handbiting). Approximately 25% exhibit autism (avoidance of eye contact, hand flapping or other stereotypic movements, perseverative speech, echolalia) (3,18,70,85). Hand biting is common. About 50% of patients manifest aggression. Seizures, noted in 20%, occur principally in those with the lowest intelligence. However, at least 50% of the adult males have abnormal EEG recordings. About 50%–75% of females who carry the full mutation have borderline to subnormal intelligence (IQs less than 85) (19,33,45,68) and another 15% have learning disability, especially in mathematics and reading. There is often a decrease in intelligence with age (33). Intelligence in female carriers appears to be inversely correlated with the expression of the fragile site. Higher functioning males have an incompletely methylated full mutation (27). Some female heterozygotes are psychotic (19). There is an overall enlarged brain with particular enlargement of hippocampus, caudate thalami, and ventricles with reduced size of vermis (58,66).

Connective tissues. Joint laxity, especially of the thumbs, metacarpals, fingers, knees, and ankles, is seen in 75% of children with FraX. The feet are flat in 70%. The skin feels velvety soft over the dorsum of the hand. It is somewhat lax, but hand calluses are seen in 30%. Single palmar creases are noted in 25%. Cutis verticis gyrata has been described (63). Mitral valve prolapse has been found in 80% of hemizygotes over 18 years, with mild aortic dilatation in about 15% (24,44). Younger children do not often have mitral prolapse (11).

Genitourinary. Macro-orchidism (Fig. 3–20C), unilateral or bilateral, first noted after 8 years and in only 40% prior to puberty, is found in about 75% of adult hemizygotes (8,41). The testes tend to be softer than normal. There is increased tubular length and interstitial edema (12,13). Hyperpigmentation of the scrotum and enlargement of the penis have been noted in over 50%. Carrier females exhibit high fertility, a higher frequency of twinning (19), premature ovarian failure, and an increased rate of miscarriages (33,45,65,67a). Premature ovarian failure is possibly due to paternal genomic imprinting (34a), but this was not confirmed by a subsequent study (85a).

Oral findings. The palate is high and narrow. Robin sequence has been reported (42). Crossbite and openbite are relatively common (67). Tooth crown diameter asymmetry is frequent (57). The lateral palatine ridges are prominent in 60% of patients (53).

Differential diagnosis. In the absence of a family history, one must exclude other forms of nonspecific mental retardation, especially Renpenning syndrome, which is characterized by relatively severe mental retardation without other central nervous system involvement, small head circumference, short stature, normal facies, normal ears, and normal or small testes. It should be emphasized, however, that fragile X syndrome, because of its variable expression, may be difficult to diagnose, especially before puberty. Several patients were initially thought to have *Sotos syndrome* or *Prader-Willi syndrome* (8,12,13). About 7%–15% of autistic males are positive for the fragile X chromosome (8). It should be emphasized that macro-orchidism is not an invariable finding in the fragile X syndrome. Conversely, one may find macro-orchidism in otherwise normal males.

There are an increasing number of X-linked mental retardation syndromes described that are beyond our attempt at coverage. Several are mentioned here because of orofacial involvement: Allan-Herndon syndrome [severe mental retardation, dysarthria, ataxia, athetoid movements, muscle hypoplasia ("limberneck") (73) , and spastic paraplegia with hyperreflexia], which maps to Xp21; macrocephaly with heterozygous expression (1,2,82); mental retardation, congenital heart anomalies, cleft palate, short stature, and unusual facies (28); microcephaly, growth delay, and hereditary bullous dystrophy, which maps to Xq24 (52); mental retardation and pseudoglioma (17); cleft lip/palate, broad nasal tip, and large hands mapping to Xp11.3–q21.3 (69); macrocephaly, macroorchidism, midface hypoplasia, triangular facies mapping to Xq12–q21 (37); hypertelorism, short nose, seizures, hearing loss, cardiomegaly, and early demise (at Xq28) (51); short stature, small hands and feet, seizures, cleft palate, and glaucoma mapping to Xq28 (65); unusual facies, hypogenitalism, congenital hypotonia, and pachygyria (93); unusual facies (35); unusual facies, epilepsy, ophthalmoplegia, and cerebellar atrophy, which maps to Xq24–q27 (7); and marfanoid habitus which maps to Xq22–q25 (19a,51a,57a). These and an inordinate number of other ones have been summarized in 1998 (50) and in 2000 (28a).

Laboratory tests. Although historically, cytogenetic assays were employed for detection of a fragile X chromosome and can still provide a reliable means of identifying affected males and females, molecular genetic assays now provide the methods of choice for diagnosis (36). The molecular methods are less labor intensive and, importantly, are the only means by which the premutation alleles can be identified and differentiated from normal alleles. Thus, the molecular methods can provide for identification not only of affected males but also of carrier females and transmitting males.

The molecular methods most commonly employed in laboratories include both PCR to amplify the CGG trinucleotide repeat segment within *FMR1*, and the Southern blot analysis, involving restriction enzyme digests and hybridization with a labeled nucleic acid probe complementary to the CGG repeat segment. The PCR methods provide the means for determining the number of repeats within premutation and normal *FMR1* alleles, while Southern blot analysis provides for the detection and characterization of the full mutations. (Classic PCR methods are generally unable to amplify reliably the very large repeats found within most full mutations.) A rapid antibody test for detection of the FMR1 protein has also been developed (90).

Although molecular methods are preferred for determining a diagnosis of FraX, cytogenetic analysis can provide a complementary test for ruling out the presence of other types of chromosome abnormalities that can be associated with similar developmental delays and mental retardation. As noted previously, differential diagnosis of FraX can be difficult, and most laboratories that perform parallel cytogenetic and molecular testing have found several-fold higher frequency of the "other" chromosomal abnormalities than FraX among their referrals (with the exception of those patients with a confirmed positive family history for fragile X) (59,61). Included among these other abnormalities are *47,XXY,* deletions of 17p11.2 (*Smith-Magenis syndrome*), deletions of 22q11.2 (*velocardiofacial syndrome*), various de novo balanced translocation, and others.

Testicular volume is usually measured by orchiometer and can be calculated by the formula $\pi/6 \times \text{length} \times \text{width}^2$. Testicular volume in the postpubescent male is significantly increased (25–127 ml) over

normal values (15–25 ml) (92). Prenatal diagnosis has been carried out on amniocytes, using molecular methods (23,32). Chorionic villus sampling, induction with at least two cytogenetic methods, and restriction fragment length polymorphism (RFLP) analysis have been advocated (66,88). Dermatoglyphic features of the hemizygote include increased radial loops, whorls, and arches on fingertips (especially the second and third fingers), abnormal palmar and plantar creases, absence of c-triradii on palms, dysplasia of papillary ridges, and low frequency of true patterns on soles. Female heterozygotes show some of the same changes (60,71). A metacarpal phalangeal index has been established for the syndrome (4).

Screening can be done by hair root analysis (79a).

Chapter 4
Chromosomal Syndromes: Unusual Variants

It is impossible to provide a totally comprehensive review of the unusual variants of chromosomal syndromes, as some variations are extremely complicated, involving complex translocations; others represent single reports. Our goal here is to summarize what is known about these variants, especially where generalizations can be made on the basis upon several cases of the apparently same deletions or duplications. If sufficient numbers of examples have been reported, we have attempted to present the approximate frequency of a finding.

del(1p) syndrome

Deletion of the terminal short arm of chromosome 1 (1p36.22–pter) is relatively common (1–10), although a few examples of ring 1 have been reported [see del(1q) syndrome]. It has been estimated that the frequency of this syndrome is at least 1 in 10,000 live births (7). Others have found it to be as common as 1 in 500 (2a). Only the rare interstitial deletion has been noted (4); about 20 examples of deletion have been documented. The deletions are de novo, with most of them being maternally derived (11). Interstitial deletions have been reviewed by Stockton et al (9).

Terminal 1p deletions result in mental and somatic retardation (90%), hypotonia (90%), seizures (75%), microcephaly (40%), large anterior fontanel (100%), low-set dysmorphic pinnae with thickened helices (50%), flat nose (35%), depressed nasal bridge (65%), deep-set eyes with small, almond-shaped palpebral fissures (50%), relative prognathism (45%), cleft lip/palate (10%), congenital heart defects (20%), clinodactyly of fifth fingers (65%), small hands and feet (20%), cardiomyopathy (40%), and cryptorchidism (30%) (8) (Fig. 4–1).

There may be some correlation between phenotype and size of deletion (11).

dup(1p) syndrome

The rarest of structural abnormalities involving chromosome 1, dup(1p) has been reported barely more than a dozen times.

In addition to growth and psychomotor retardation, most affected individuals had microcephaly, craniosynostosis, depressed nasal bridge, malformed pinnae, hypertelorism, cleft palate, brachydactyly, and cryptorchidism. Less constant features have included prominent pinnae, micrognathia, and clinodactyly of fifth fingers (1–9).

Some individuals with dup(1p) have shown facial resemblance to *Kabuki syndrome* (6).

del(1q) syndrome

About 70 reports of patients with variable deletion of the long arm of chromosome 1 have been published. We have grouped these deletions into three categories: interstitial proximal (1q21–q24), interstitial intermediate (1q24–q32), and distal (1q42–qter). Most cases have been de novo. Rarely have ring chromosomes been reported (9,23).

Proximal interstitial deletion. Patients with proximal interstitial deletion (1q21–q24) have growth and psychomotor retardation, microbrachycephaly, sparse fine hair, up-slanting palpebral fissures, unusual pinnae, cleft lip/palate, small hands and/or feet, hernia, transverse palmar crease, clinodactyly of V, convex dysplastic nails, short neck, and hypotonia (2–4,10–12,21,22,24). External genital anomalies and talipes equinovarus have also been noted.

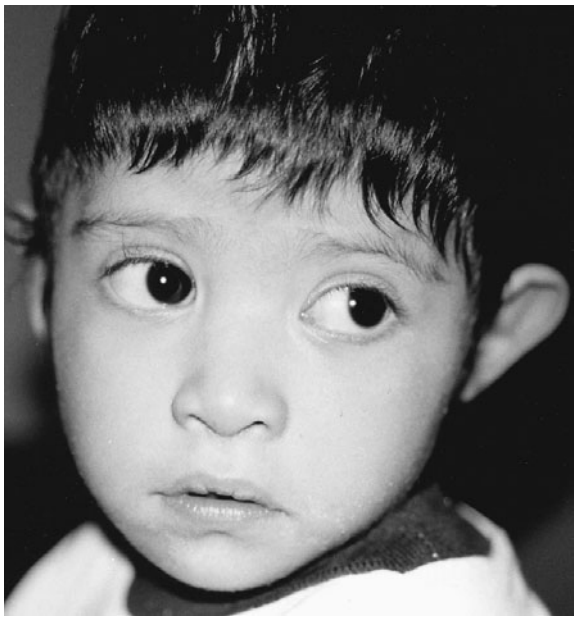

Fig. 4–1. *del(1p) syndrome*. Microcephaly, large anterior fontanel, dysmorphic pinnae, somewhat flattened nose. (Courtesy of SK Shapira and LG Shaffer, Houston, Texas.)

Intermediate interstitial deletions. Intermediate interstitial deletions (1q24–q42) are few in number. In addition to mental retardation, these infants have microdolichocephaly, prominent metopic suture, coarse scalp hair, preaxial hexadactyly, clinodactyly, hypospadias, cryptorchidism, and inguinal hernia (1,6,10,18,20).

Distal deletion. Patients with distal deletion (1q42–qter), the most common of the deletions, exhibit mental retardation, autism, hypotonia, seizures, microbrachycephaly, fine scalp hair, epicanthic folds, upslanting palpebral fissures, flat nasal bridge, downturned mouth, thin vermilion, long upper lip with smooth philtrum, congenital heart disease, broad nasal tip, cleft palate, micrognathia, short neck, weak or high-pitched cry, hypospadias, cryptorchidism, short fingers, and hypoplastic nails (5,7,8,13–17,19,25–27) (Fig. 4–2A). About 25% of cases have agenesis of the corpus callosum.

Fig. 4–2. (A) *del(1q) syndrome.* Microbrachycephaly, round flat face, upslanting palpebral fissures with apparent hypertelorism, epicanthal folds, heavy cheeks, malformed pinnae, short neck. (B) *dup(1q) syndrome.* Five-week-old infant presenting macrocephaly, craniofacial asymmetry, apparent hypertelorism, and anteverted nostrils. (A from M Andrle et al, Hum Genet 41:115, 1978. B from NL Chia et al, Clin Genet 34:224, 1988.)

dup(1q) syndrome

As in other duplications, examples of "pure" trisomy are rare. The clinical picture seems to reflect the size of the duplicated segment, and includes pre- and postnatal growth retardation and psychomotor retardation.

About 25 cases of trisomy for 1q42–qter have been reported, the phenotype consisting of relative macrocephaly (85%), large fontanels (60%), widely separated sutures in infancy (60%), prominent forehead (70%), hypertelorism (65%), flat nasal bridge, down-slanting narrow palpebral fissures (10%), low-set pinnae (55%), facial capillary nevi, and micrognathia (30%) (1). Various other anomalies have been found with lower frequency (2,3,5,7–10,13,16,17,21) (Fig. 4–2B). Cleft lip/palate

has been noted in about 15% of cases. Malformed fingers and toes are seen in 65%. Various forms of congenital heart anomalies have been found in about 40% of affected individuals (5).

In those cases with a longer duplicated segment, the above findings, especially cardiac abnormalities (60%) occur more frequently. Various digital anomalies (camptodactyly, syndactyly, brachydactyly, overlapping digits) have been noted in individuals with both small and marked duplications (4–7,11,12,14,15,18,19).

Schorry et al (20) have suggested that those with duplication for 1q31.1–q32.1 have pre- and postnatal growth retardation, narrow palpebral fissures, pituitary abnormalities, microphthalmia, and normal intelligence in some individuals.

del(2p) syndrome

Deletion of part of the short arm of chromosome 2 must be lethal as we were able to locate but few examples. Duca et al (1) and Fryns et al (2) reported interstitial deletion of the 2p13–p15 region.

Other than mental retardation, both children had severe speech retardation and mild dysmorphism: wide bossed forehead, low hair implantation, wide mouth, short neck, narrow chest, kyphosis, and long and broad halluces.

There are at least 10 examples of r(2) chromosomes. In addition to mental and somatic retardation, the more common findings have included microcephaly, epicanthic folds, micrognathia, low-set pinnae, short neck, widely spaced nipples, hypogenitalism, and clinodactyly (3).

dup(2p) syndrome

Approximately 30 cases of trisomy of the 2p21 or p23pter region have been described (1–14). In addition to being severely retarded, all patients show microcephaly. Other features include a high, prominent forehead with frontal upsweep of hair, hypertelorism, strabismus, dysmorphic pinnae, short nose with prominent tip, maxillary hypoplasia, broad nasal bridge, small mouth, cleft palate, broad alveolar ridges, and micrognathia (Fig. 4–3).

Pre- and postnatal growth retardation are constant findings. The body build is slender with hypotonia, and the toes are widely spaced (40%). Skeletal anomalies include long, tapering, hyperflexible fingers (60%), scoliosis (15%), pectus excavatum (33%), increased internipple distance, and limited hip movement. Congenital heart anomalies (35%) are inconsistent in type. Micropenis (60%), shawl scrotum (15%), hypospadias (15%), and cryptorchidism (10%) have been found.

Fig. 4–3. *dup(2p) syndrome*. Slender body, thin extremities, wide spaced toes, high prominent forehead, wide flat nasal bridge, ptosis, pointed chin. (From U Francke and KL Jones, Am J Dis Child 130:1244,1976.)

del(2q) syndrome

Interstitial deletion of bands 2q22.3–q23.3 has been associated with short neck and excess cervical skin. Deletion of the bands 2q23.3–q24.2 is seen with hypertrichosis and a high-pitched cry (11).

Children with deletion 2q21–q31 have somatic and mental retardation, relative macrocephaly, prominent nose, cataracts, microphthalmia, coloboma, ptosis, micrognathia, flexion deformity of fingers, syndactyly, ectrodactyly, and congenital heart anomalies (3,7,12,19) (Fig. 4–4). Several patients have cleft palate.

Most cases of del(2q) involve deletion 2q31–q33. In addition to mental and somatic retardation, these children exhibit the eye anomalies and finger deformities seen with del2q21–q31 (1,2,6,14–16,18). Blepharophimosis and microcephaly are common, and frequently there are seizures and brain anomalies. The midface is hypoplastic with a long philtrum. About 50% of affected individuals have cleft lip or cleft palate (1,2,3,6). Congenital heart anomalies are found in 50%.

Terminal deletion (2q35→qter) is associated with mental and somatic retardation, frontal bossing, macrocephaly, deep-set eyes, long eyelashes, down-slanting palpebral fissures, cleft palate, micrognathia, hypotonia, inverted nipples, and syndactyly (4,5,10,13,17,20,21).

There are at least 10 reported examples of r(2) chromosomes. In addition to mental and somatic retardation, the more common findings have included microcephaly, epicanthic folds, micrognathia, low-set pinnae, short neck, widely spaced nipples, hypogenitalism, and clinodactyly (9).

There is some evidence that an Albright hereditary osteodystrophy-like phenotype is associated with deletion of 2q (2a).

Fig. 4–4. *del(2q) syndrome*. Microphthalmia, strabismus, prominent nose, micrognathia, camptodactyly of fingers 3–5, hyperextensible index fingers, syndactyly of toes 2–5 in patient with interstitial deletion of 2(q31–q33). Cleft palate was also present. (From P Franceschini et al, Hum Genet 64:98, 1983.)

dup(2q) syndrome

Approximately 25 examples of various degrees of partial trisomy 2q have been analyzed by Kyllerman et al (3), Yu and Chen (8), and Siffroi et al (5). The phenotype seems to vary little with the degree of deletion q31→qter to q34→qter (2,3). Birth weight and length are usually normal. In addition to the constant mental retardation, frequent findings include frontal bossing, microbrachycephaly with temporal retraction, hypertelorism, short beaked nose, elongated philtrum, and abnormal pinnae (Fig. 4–5). Other eye findings include reduced vision, myopia, exotropia, glaucoma, nystagmus, iris defects, and fundus lesions (9). Some patients have thoracic kyphosis (1,6) and clinodactyly of the fifth finger. Visceral abnormalities have been extremely rare.

Cleft palate has been reported in several cases (1,4,7).

Chromosome 2 pericentric inversion of 2p12–q14

In 1995, Ramer et al (4) defined the syndrome of pericentric inversion of 2p12–q14. Findings included mental and growth retardation, lissencephaly, and trigonocephaly. The facies is characterized by ptosis, coloboma, epicanthic folds, hypertelorism, long philtrum, and large mouth. The pinnae are somewhat dysmorphic. About 50% of patients have sensorineural hearing loss.

del(3p) syndrome

About 25 cases of del(3p) syndrome have been reported with most involving loss of the 3p25 (terminal) band. The most common features include low birth weight (70%), severe postnatal growth retardation (100%), severe mental retardation (100%), microcephaly (80%), brachycephaly, unusual facies, and developmental delay with severe psychomotor retardation (1–12,14–16).

The face is somewhat triangular (40%) with a high prominent forehead (25%), arched bushy eyebrows (15%), flat nasal bridge, up-slanting palpebral fissures, synophrys (30%), blepharoptosis (80%), epicanthic

A B C

(C) Microcephaly, ptosis, inverse epicanthus, small nose with prominent bridge, narrow vermilion, and small mandible. (A,B from DR Witt et al, Clin Genet 27:402, 1985. C from MC Higginbottom et al, J Med Genet 19:71, 1982.)

folds (50%), broad nasal tip (50%), and low and dysmorphic pinnae (95%). The lips are thin (25%), the philtrum long (75%), the angles downturned (30%), and the mandible small (65%) (Fig. 4–6).

Supernumerary postaxial digits of hands and feet (50%), renal malformations (45%), sacral dimple (20%), cryptorchidism (45%), small penis (25%), congenital heart anomalies (25%), and rocker-bottom feet have each been reported in about 30% of cases (7). About 15% of patients suffer premature death.

About 8 examples of interstitial deletion of 3p14 have been described (13). There does not appear to be a distinct phenotype.

dup(3p) syndrome

Approximately 50 patients with partial trisomy for the short arm of chromosome 3 have been reviewed by Reiss et al (11). The size of the trisomic segment seems to have little effect on the phenotype (14).

Prenatal growth is retarded in only 15% of patients and postnatal growth is slowed in about 35%. About 50% of infants have died within the first 2 years of life. All exhibit psychomotor retardation. Hypospadias, micropenis, or cryptorchidism has been found in 75% of males. Congenital heart defect has been documented in 70% of patients, and excessive fingertip whorls were noted in about 85%.

Facial features include brachycephaly (75%), frontal bossing (85%), temporal indentation (85%), hypertelorism (80%), epicanthal folds and square-shaped face with full cheeks (80%), prominent philtrum, large mouth, microretrognathia (60%), and short neck (85%). About 25% have cleft lip with or without cleft palate (Fig. 4–7). The facies become less distinctive with age (1–15). Possibly 10% of cases have associated holoprosencephaly (1,5–7,9).

del(3q) syndrome

Approximately six cases of terminal deletion of the long arm of chromosome 3 have been reported (2–4,6,8), which have been sufficiently different so that no distinct syndrome can be discerned. However, two examples (2,4) seem somewhat similar, having hypoplastic supraorbital ridges, microphthalmia and broad nose with deep sulcus across the nasal bridge, short neck, and cardiac and limb anomalies.

Interstitial deletion (3q12–q25) results in microcephaly, blepharophimosis, ptosis, epicanthic folds, malformed large ears, talipes, joint contractures, and congenital heart anomalies in addition to short stature and mental retardation (1,5,7).

dup(3q) syndrome

Falek et al (2) first described the clinical features of dup(3q), reporting the condition as "familial de Lange syndrome." At least 40 examples have been reported, about 60% of these resulting from a familial translocation (9). The phenotype has been remarkably constant for dup3q21→qter. At least one-third of affected infants have died before the end of the first year of life as a result of heart malformation and infections (9). Mental retardation is severe, and underlying brain anomalies (polymicrogyria, hypoplastic olfactory bulbs) and seizures have been noted in at least 85% of cases. Craniofacial anomalies are remarkably constant. Hypertrichosis and synophrys are marked, and most infants have abnormal head shape due to craniosynostosis. Palpebral fissures are often up-slanting. There is a broad nasal root with anteverted nostrils, the upper lip is long, and the maxilla is prominent. The corners of the mouth are downturned. The pinnae are malformed, and approximately 80% have cleft palate. The neck is short and occasionally webbed (1–11) (Fig. 4–8).

Head anomalies include clinodactyly, camptodactyly, single palmar crease, and nail hypoplasia. In extreme cases, the hand may resemble that seen in trisomy 18. Talipes is present in at least 65% of cases.

Omphalocele occurs in about 25%. Various urogenital abnormalities (micropenis, hypospadias, cryptorchidism, ambiguous genitalia, absent scrotal folds) have been found in approximately 50% of patients, and

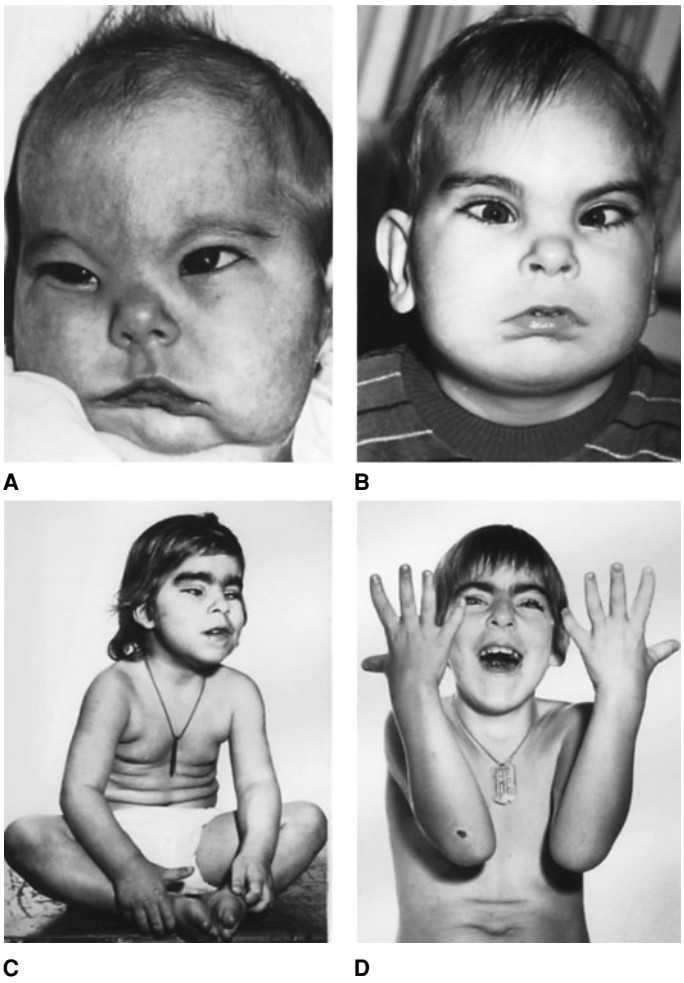

Fig. 4–8. *dup(3q) syndrome*. (A,B) Bushy eyebrows, synophrys, up-slanting palpebral fissures, broad nasal root, anteverted nostrils, long philtrum, downturned corners of mouth. (C,D) Similar phenotype in older children. (A from MT Mulcahy et al, Ann Genet 22:217, 1979. B from L Tranebjaerg et al, Clin Genet 32:137, 1987. C,D from A Falek et al, Pediatrics 37:92, 1966.)

cardiac defects [atrial septal defect (ASD), double outlet right ventricle, subaortic stenosis, aberrant right subclavian artery] have been noted in at least 75%.

The clinician should have little difficulty in differentiating dup(3q) syndrome from the *Brachmann-de Lange syndrome,* which far more frequently is marked by severe intrauterine growth retardation, prominent philtrum, oligodactyly, proximally placed thumbs, and syndactyly of the second and third toes. Also, craniosynostosis, cleft palate, and urinary tract anomalies occur far more frequently in dup(3q) syndrome.

Approximately 75% of the cases are derived from parental rearrangements involving a pericentric inversion of chromosome 3 or balanced translocation. Duplication of the 3q25→qter region is sufficient to generate the characteristic face, although a slightly more severe phenotype is produced by complete duplication of 3q.

dup(4p) syndrome

Patients having duplication of at least the distal two-thirds to the entire short arm have a distinct phenotype. Over 75 cases have been reported (9) with no sex predilection. About 75% of reported cases have arisen from a balanced parental translocation, the most common recipient being acrocentric, especially chromosome 22. About 10% arise de novo. Death has occurred during early infancy in about 35%.

In addition to mental retardation (IQ: 20–25), about 25% of affected infants have prenatal and 65% postnatal growth retardation. Flexion contractures (55%), hypotonia (40%), hypertonia (35%), and seizures (25%) are also seen.

The following constitute the phenotype: microcephaly (75%), frontal bossing (20%), prominent glabella (30%), hypertelorism (45%), strabismus (40%), down-slanting palpebral fissures (20%), microphthalmia (15%), nystagmus (20%), synophrys and long, bushy eyebrows (25%), depressed broad nasal bridge with bulbous tip (60%), microstomia (30%), thin lips (25%), low-set, posteriorly rotated pinnae (75%), prominent mandible (50%), short neck with low hairline (50%), wide-spaced nipples (40%), micropenis (50%), cryptorchidism (35%), hypospadias (25%), and abnormal digits of the hands or feet (65%) (1–13) (Figs. 4–9 and 4–10).

del(4q) syndrome

In about 10% of del(4q) cases, one of the parents is a balanced translocation carrier. The critical deletion segment is 4q31→qter. Over 30 patients have been described; a most comprehensive survey of this syndrome is that of Lin et al (9). About 70% die within the first two years of life from congenital heart disease or from aspiration pneumonia (1–17). Deletion of 4q34.2–4qter may be associated with a *velocardiofacial syndrome* phenotype (1,3,17).

Although birth weight is normal, mild postnatal growth retardation and mild to moderately severe mental retardation are common features. Craniofacial anomalies include microcephaly, low-set posteriorly angulated pinnae with malformed helices, short nose with a low nasal bridge and anteverted nostrils, and micrognathia. Cleft palate with or without cleft lip is common (75%), as are hypertelorism, epicanthal folds, and laterally displaced inner canthi (11,13,14) (Figs. 4–11 and 4–12A,B). Small, upward-slanting palpebral fissures, oropharyngeal hypotonia, cardiac defects (mostly ASD and VSD), limited extension at the elbows, clinodactyly and tapering of the fifth finger with a pointed or duplicated nail (which appears to highly suggestive of the syndrome), transverse

A B

Fig. 4–11. *del(4q) syndrome*. (A,B) Asymmetric forehead, up-slanting palpebral fissures, pointed helix, epicanthal folds, anteverted nostrils, cleft lip/palate. [From JL Frias et al, Birth Defects 14(6C):355, 1978.]

palmar crease, and overlapping toes also occur (Fig. 4–12C). Anomalies having a frequency of 25% or less include low-set posteriorly angulated pinnae and various skeletal anomalies (proximately implanted thumbs, camptodactyly, short distal phalanx of the fifth finger, absence of the fourth metacarpal, dislocated hips, and talipes equinovarus).

There is some evidence that del4q33–qter is associated with absorptive hypercalciuria (8).

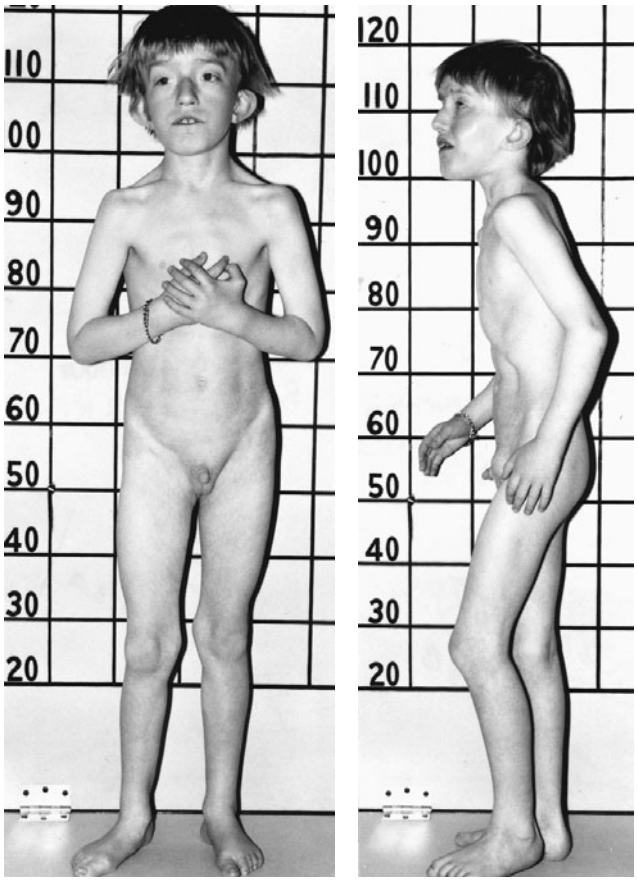
dup(4q) syndrome

In 90% of dup(4q) cases, one of the parents has a balanced translocation, which can range from 4q21→qter to 4q32→qter. At least 60 patients have been reviewed (3a). Poor correlation with clinical findings is noted (1–10). There is no sex predilection.

Neonatal mortality is about 30%, largely in those infants with more severe cardiac or renal anomalies. In addition to severe psychomotor retardation, cardiac and genitourinary anomalies are frequent. Birth weight is low in about half the cases.

The craniofacies is often characterized by microcephaly with sloping forehead (75%), epicanthal folds (40%), hypertelorism (75%), narrow down-slanting palpebral fissures (35%), large or prominent nasal bridge (40%), straight nasofrontal angle, short philtrum with protruding lateral margins (25%), downturned corners of mouth (35%), low-set, posteriorly angulated or malformed pinnae with prominent anthelix and hypoplastic tragus (90%), pointed chin, micrognathia (30%), and short neck (60%) (Figs. 4–13 and 4–14). Hyper- or hypotonia has been noted in over 60%



A B

of cases and umbilical or inguinal hernia in about 30%. About half the patients have cardiovascular anomalies, including tetralogy of Fallot and various venous-return anomalies, and about 30% exhibit genitourinary abnormalities (horseshoe kidney, renal hypoplasia, urethrovesicular reflux with or without hydronephrosis). In males, cryptorchidism is a constant feature. The fingers are tapered, and the feet are edematous in 30% of patients.

dup(5p) syndrome

In addition to severe psychomotor retardation, the main features of this disorder are postnatal growth retardation, hypotonia, seizures, slender extremities with long fingers, short first toes, and club feet. Craniofacial findings include macrodolichocephaly, hypertelorism, up-slanting palpebral fissures, narrow palpebral fissures, epicanthic folds, low nasal bridge, bulbous nose, low-set pinnae, jowly appearance, long philtrum, full lips, cleft palate, and macroglossia (Fig. 4–15). Dermatologlyphic changes include excess ulnar loops and arch tibial patterns in the hallucal area (2,3).

An extensive review of this syndrome is that of Kleczkowska et al (6); about 50 cases have been reported (1–14). Duplications of segment 5p13 have more severe phenotypic changes (6,10) whereas duplication of 5p14→pter results in milder manifestations (4). Mosaic tetrasomic examples of 5p are associated with areas of skin hyperpigmentation (8,11), but otherwise the phenotype is similar.

del(5q) syndrome

The effect of various deletions of the long arm of chromosome 5 has been well studied (2–5,7,9,10). Mental retardation is severe, but growth retardation has not been evident.

Micro- or macrocephaly; high, protruding forehead; telecanthus; epicanthic folds; anteverted nostrils; wide, flat nasal bridge; dysmorphic pinnae; long deep philtrum; microretrognathia; and short neck with redundant folds characterize the craniofacies (Fig. 4–16). Cleft palate has been noted in a few cases (6,8).

Various heart anomalies include ASD, VSD, and patent ductus arteriosus (PDA). Bilateral pes adductus, diastasis recti, short fingers, and inguinal hernias have been observed. Single palmar creases have also been described.

Megalokaryocytes may be abnormal (1).

dup(5q) syndrome

About 30 examples of various duplications have been reported. Trisomy for 5q31→5qter results in severe psychomotor retardation, low birth weight, microcephaly, high forehead, hypertelorism, downward slanting palpebral fissures, epicanthal folds, strabismus, large outstanding pinnae, prominent nasal bridge, long philtrum, large upper lip, and micrognathia. Musculoskeletal anomalies include brachydactyly, clinodactyly, preaxial polydactyly, and hernia (2–11). Various congenital heart defects, mostly VSD and ASD, are found in about one-half the cases.

In cases of trisomy 5q13→q22, the children have a high forehead, bulbous nose, short philtrum, large, protruding pinnae, and micrognathia (5). A smaller deletion, that of 5q34→qter, results in failure to thrive and strabismus (1,5).

del(6p) syndrome

Most examples of this syndrome have involved a break point near 6p23 (2–7), but there are others (8,9). No sex predilection has been found. Involvement of ring chromosome 6 has also been discussed (2).

Mental retardation has been a constant feature of del(6p) syndrome. Most patients have microcephaly and abnormal cranial sutures. A broad, flat nasal bridge, eye anomalies (blepharophimosis, iris coloboma, strabismus, Peters anomaly, megalocornea), low-set dysmorphic pinnae with atresia of the canal, short neck with excessive skin folds, and micrognathia characterize the facies. About 35% of patients have cleft lip/palate. In reviewing the published cases, we have not been able to identify a common facies.

Pectus excavatum, hypoplastic nipples, and congenital heart anomalies (ASD, VSD, PDA, anomalous valves) are essentially constant features. Variable camptodactyly and minor genital hypoplasia occur frequently.

We have recently seen an infant with agenesis of the corpus callosum, Dandy-Walker cyst, diffuse cloudy corneae, and VSD.

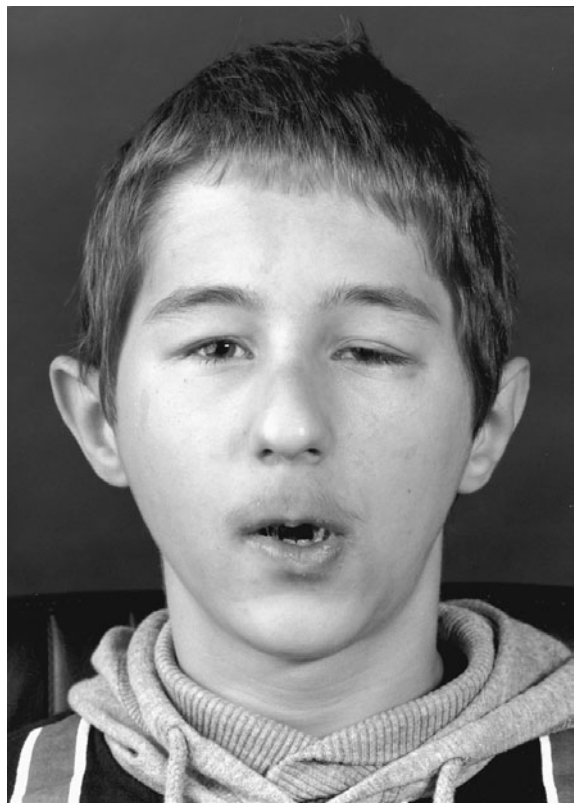
dup(6p) syndrome

About 40 cases of this partial trisomy have resulted from parental translocation or inversion duplication. Low birth weight has occurred in 95% of cases, and all survivors have had short stature. Most patients have died during infancy from respiratory or feeding problems (1–11). Developmental delay is a constant feature.

The facies is characterized by microcephaly (90%), high, prominent forehead (95%), craniosynostosis, flat occiput, wide fontanel, blepharophimosis/ptosis (90%), cataracts, microcornea (100%), strabismus, epicanthic folds, flat nasal root, very short nose, long philtrum (80%), thin lips, small mouth with cupid's bow, large, simple, low-set pinnae with poorly developed lobes (95%), and small pointed chin (80%) (Fig. 4–17).

Congenital cardiac abnormalities (ASD, VSD, PDA) are found in 65% of cases. Renal anomalies have included hydronephrosis and hypoplastic

Fig. 4–17. *dup(6p) syndrome.* Note high forehead, blepharophimosis, and microstomia. (From B Röthlisberger et al, Am J Med Genet 85:389, 1999.)



kidney (85%). Musculoskeletal abnormalities have involved umbilical or inguinal hernia and talipes equinovarus.

del(6q) syndrome

About 60% of del(6q) cases have involved interstitial deletion and 40% have involved terminal deletion (3). At least 60 examples have been reported (1–16); these examples have been analyzed by Evers et al (1) and Hopkin et al (3). The latter authors have divided the cases into three groups; those with proximal deletions (6q11–q16), those with intermediate deletions (6q15–q25), and those with terminal deletions (6q25–qter). In all groups, mental retardation was a constant finding. Considerable overlap was evident among the groups. However, some findings were more often found in each group.

del(6)(q11–q16). This group was marked by growth failure (85%), ear anomalies (85%), epicanthic folds (65%), up-slanting palpebral fissures (85%), flat nasal bridge (50%), thin lips (55%), hypotonia (90%), hernia (70%), and limb anomalies (80%).

del(6)(q15–q25). This group was characterized by growth failure (65%), hypertelorism (60%), microcephaly (75%), broad nasal tip (65%), micrognathia (60%), ear anomalies (100%), limb anomalies (65%), and hypotonia (75%).

del(6)(q25–qter). Patients in this group had growth retardation (70%), microcephaly (80%), eye anomalies (50%), ear anomalies (90%), prominent nasal bridge (70%), long philtrum (55%), short neck (60%), and limb anomalies (70%).

A Prader-Willi-like phenotype has been noted (2).

dup(6q) syndrome

About 25 cases of this syndrome are known, all arising from balanced parental translocation or inversion (1–13).

The facies is striking and recognizable, characterized by microbrachycephaly or turricephaly, prominent forehead, flat face and occiput, prominent, almond-shaped eyes, microphthalmia, hypertelorism, downslanting palpebral fissures, broad flat nasal bridge, bow-shaped mouth with thin lips, short nose, short philtrum, micrognathia, short, webbed neck, and low-set ears with thickened earlobes. The lower lip may have a median indentation (Fig. 4–18). Cleft lip/palate or bifid uvula has also been reported (5,6).

In addition to severe somatic and mental retardation, there are joint contractures, flexed or deviated fingers and wrists, club feet, scoliosis, and single palmar crease. In the absence of congenital heart defects, survival is normal. Genital anomalies include hypoplastic labia, penis, and/or scrotum.

del(7p) syndrome

This syndrome is characterized by variable craniosynostosis [turricephaly, microcephaly, flat occiput, prominent forehead, craniosynostosis (40%), trigonocephaly, cranial asymmetry] (3,5,6,9). The precise region involved in craniosynostosis has not been determined. Intelligence has varied from severe retardation to normal. Facial nevus flammeus, hypotelorism, downward-slanting palpebral fissures, ptosis, epicanthal folds, saddle nose, small, low-set dysplastic pinnae, and transverse palmar creases are frequent (1–14) (Fig. 4–19). Congenital heart disease and urogenital malformations are found in 50% of patients (12). Cleft palate has been described in association with this syndrome (3,9,10).

A B

dup(7p) syndrome

Patients with duplication of 7p15→pter exhibit a syndrome comparable to those with larger deletions. The most common break points are 7p11,7p15 and 7p21. The critical segment appears to be 7p21→pter (1). The principal features, in addition to mental retardation, include asymmetric skull, wide anterior fontanel, brain malformations, high, large forehead, hypertelorism, choanal atresia, cleft palate, abnormal pinnae, congenital heart anomalies, joint dislocation or contractions, and broad digits (1–14) (Fig. 4–20).

del(7q) syndrome

Among 25 examples of proximal interstitial deletions involving 7q21–7q32, no recognizable clinical syndrome was evident (6,12,16). However, findings among 30 examples of deletion of 7q32–qter included pre-and postnatal growth retardation (85%), feeding problems (35%), severe mental retardation (95%), microcephaly (90%) with prominent forehead (40%), broad nasal bridge with bulbous tip, hypertelorism (30%), hypotelorism (20%), epicanthus (25%), up-slanting palpebral fissures (20%), various other eye anomalies (50%), large dysplastic pinnae (40%), large, downturned mouth (35%), midface hypoplasia (35%), micrognathia (40%), and short neck (9,10,13,14) (Figs. 4–21 and 4–22). Cleft lip with or without cleft palate has been noted in 30% of cases (1,8,14,15). Clefting of the midline and single central incisor have been noted in those patients with variant holoprosencephaly (vide infra). Early death occurred in 25%.

Various congenital heart defects (15%), distal limb anomalies (30%), inguinal hernia (30%), hypospadias and small penis (60%), and abnormal palmar creases (50%) occur frequently. Typical holoprosencephaly may be seen in 30% of those with 7q32–qter deletions (2–5,7,11). Some have only a single central incisor (5).

Sacral dysgenesis has been noted with terminal 7q deletion (14a).

dup(7q) syndrome

About 50 patients with this syndrome have been documented; an excellent analysis is that of Johnson et al (8). For purposes of simpler presentation, two rather than six subgroups will be briefly described here. All patients exhibited mental and somatic retardation, with low-set abnormal pinnae and apparent hypertelorism (11a).

Patients with dup(7q31→7qter) have large fontanels; square, prominent forehead; short, down-slanting palpebral fissures; long eyelashes; short nose; long philtrum; thin vermilion; down-curved upper lip; and micrognathia. Most had cleft palate (Fig. 4–23A). Anomalies seen in a few cases include ventricular dilatation and severe hypospadias. Death is early (1,2,4,6,8,14,18).

Among 25 cases, those with dup(7q32–7qter) had no cleft palate. These patients also exhibited hypotonia, high forehead, depressed nasal bridge, macrocephaly with frontal bossing, large fontanelle, and hydrocephaly (3,5–13,15,18,20).

Total dup(7q) has been described in only a few cases (11a,19,21), but full trisomy 7 has been associated with Potter sequence (13,21). Renal anomalies have been seen in association with mosaicism for trisomy 7 (12,18,19).

r(7) syndrome

About a dozen examples of ring chromosome 7 have been reported. Nearly all patients with r(7) have had skin lesions; among them vascular lesions (80%), large pigmented congenital nevi (50%), café-au-lait spots (30%), and achromic spots (10%) (1–9). Melanoma has been found in one case (3,7).

Intelligence has ranged from retarded (7,9) to normal (2–5). Microcephaly was noted in about 80% of patients (1,2,5–9). Short stature is a common feature, but major malformations are apparently rare. There is resemblance to *Silver-Russell syndrome* (8).

del(8p) syndrome

At least 40 patients have been described with deletion of the distal portion of the short arm of chromosome 8. Intrauterine growth retardation (65%), abnormal facial appearance, and congenital heart defects (65%) have been observed in most patients, and genital anomalies have been found in males. Postnatal growth deficiency, mental retardation, seizures, developmental delay, microcephaly, dolichocephaly, and some lessening of facial changes become evident later in life.

The most prominent facial alterations during the first year of life include microcephaly (50%), a high forehead, wide low nasal bridge, epicanthic folds, short, broad nose (25%), malformed or malpositioned ears (70%), prominent alveolar ridges, microstomia (50%), and micrognathia and short neck (50%). Virtually all facial changes except epicanthal folds disappear with increasing age. Minor hand anomalies are present in about 50% of cases, taking the form of single transverse palmar crease, prominent palmar creases, clinodactyly, and puffy hands and feet (1–13). Various congenital heart anomalies have also been reported (9).

A variety of congenital heart anomalies (VSD, PS, ASD, transposition of great arteries), seen in 75% of patients, have been associated with a break point proximal to 8p23.1 (8,8a). Genitourinary abnormalities seen in 50% have included cryptorchidism, hypospadias, and hypogonadism (11). The nipples are widely set in most patients (6).

The use of FISH with 8p-specific telomeric probes may be used for detecting minor deletions (12).

dup(8p) syndrome

Approximately 35 cases of this syndrome which are either spontaneous or result from a parental translocation have been described. Mosaic tetrasomy 8p has also been reported in at least 10 patients (6,9).

dup(8p) results in a high forehead with frontal and parietal bossing, but with temple retraction, full cheeks, round face, low nasal bridge, anteverted nostrils, wide mouth, cleft palate and/or bifid uvula, everted lower lip with carp mouth, large earlobes, and a short neck with redundant skin folds. Severe mental retardation and absence of the corpus callosum have been reported as have various congenital heart malformations (1–8). An excellent phenotype–segment duplication correlation study is that of Walker and Bocian (8).

The trunk and extremities are long and contractures may restrict movement. Micropenis and cryptorchidism are frequent findings.

9. Winters J et al: Mosaic "tetrasomy" 8p. Case report and review of the literature. Clin Genet 48:195–198, 1995.

Mosaic tetraploidy (8p) syndrome

Mosaic tetraploidy for the short arm of chromosome 8 has been reported several times (1–5). Associated features included prominent expressive language and motor delay, facial anomalies were very mild. The ventricles were dilated and the corpus callosum absent. Congenital heart anomalies (ASD, VSD, PDA) were evident in most patients.

Radiographically there were thoracolumbar hemivertebrae, fused vertebrae, and extra ribs or flail ribs.

dup(8q) syndrome

Approximately 50 cases of dup(8q) have been reported (8). Among those with trisomy for 8q23–pter, apart from mental retardation (IQ, 20–70), phenotypic changes have been very inconstant: low birth weight (35%), prominent forehead and flat occiput (65%), triangular face (50%), upslanting palpebral fissures (50%), strabismus (60%), short nose with broad base (40%), and low-set pinnae (65%) (1–9) (Fig. 4–23B,C). Cleft palate has been reported 1,5,9). Excellent phenotype–segment duplication analyses are those of Walker and Bocian (9) and Stengel-Rutkowski et al (7).

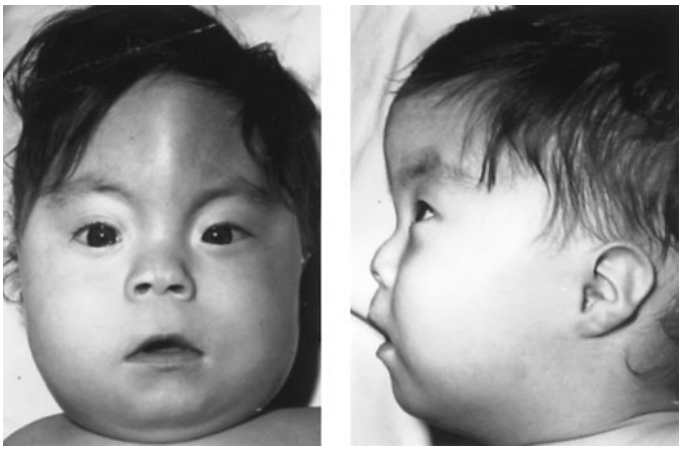
del(9p) syndrome

Approximately 100 cases of del(9p) have been described (1–13). In about 85%, the deletion occurs de novo at most often at 9p22, and has been shown to be of paternal origin in nine cases and of maternal origin in four cases (4). Several r(9) examples have been documented, most having the phenotype of del(9p) (7). In 15% of cases the disorder results from a parental translocation. Clinical findings include mental and somatic retardation but normal birth weight (100%), trigonocephaly (90%), flat occiput (70%), hypertelorism and upward-slanting, small palpebral fissures (75%), epicanthal folds, broad flat nasal bridge (90%), anteverted nostrils (100%), low-set malformed pinnae with abnormal lobules (85%), low hairline, long philtrum (95%), small mouth and protruding lips (75%), micrognathia (85%), short, somewhat webbed neck (95%), pterygium colli (75%), wide-set nipples (100%), congenital heart disease (VSD, PDA, PS) (65%), and omphalocele or umbilical hernia (65%). Scoliosis, inguinal hernia, long fingers or toes because of dolichomesophalangy, relative shortness of the metacarpals, square hyperconvex nails, and increased number of fingertip whorls (90%) (2,13) have also been reported (Figs. 4–24, 4–25, and 4–26). Infections, particularly those of sinus and middle ear, are common, as are genitourinary and gastrointestinal reflux. Muscle tone is low. Seizures may develop in mid-childhood. Many of these findings change with age (4). Among 30 cases, three had cleft palate or bifid uvula (11,13). Some patients developed leukemia or lymphoma (1,3).

Fig. 4–24. *del(9p) syndrome.* (A,B) Prominent forehead with trigonocephaly, mild up-slanting palpebral fissures, apparent hypertelorism, wide nasal bridge, anteverted nostrils, long philtrum, short neck. (From OS Alfi, Ann Genet 16:17, 1973.)



A B

Fig. 4–25. *del (9p) syndrome.* Trigonocephaly, down-slanting palpebral fissures. (From RS Young, Am J Med Genet 14:751, 1983.)

Because of the upward-slanting palpebral fissures, at birth a child may be mistaken for having *Down syndrome.*

A dozen examples of r(9) have been reported (10). The features of r(9) resemble those of del(9p) syndrome: microcephaly, a facies similar to that of del(9p), flexion of major joints, ambiguous genitalia, hypospadias, inguinal hernia, and various cardiac defects (10).

Sex reversal has been reported (1a).

Fig. 4–26. *del(9p) syndrome.* (A,B) Trigonocephaly, up-slanting palpebral fissures, strabismus, broad flat nasal bridge, malformed pinna, long philtrum, short neck. (From FJ Rutten et al, Ann Genet 21:51, 1978.)

Tetrasomy (9p) syndrome

Tetrasomy (9p) is rare, having been first reported by Ghymers et al (7) in 1973, with less than three dozen reports having been written on this condition (1–18). It is very similar to *dup(9p) syndrome* (Fig. 4–27).

Fig. 4–27. *Teltrasomy 9p syndrome.* Note similarity to dup(9p). Infant also manifests Dandy-Walker cyst and Hirschsprung disease. (From MI Melaragno et al, Ann Genet 35:79, 1992.)

In addition to psychomotor and somatic retardation, the following have been found in 50% or more of cases: hypotonia, microbrachycephaly, hydrocephaly, wide sutures and fontanels, wide forehead, hypertelorism, enophthalmos, down-slanting palpebral fissures, epicanthal folds, strabismus, bulbous-beaked nose, low-set malformed pinnae, down-slanting mouth, retromicrognathia, and short neck. Approximately half the patients have cleft lip/palate (9a). Various congenital heart and urogenital anomalies have been reported in more than 80% of cases. Dysplastic finger nails, single palmar creases, and clinodactyly V are found in about 50%. Sacral dimple and redundant skin are common (14). The nipples are widely spaced.

del(9q) syndrome

Because only a few more than a dozen examples with various deletions of the long arm of chromosome 9 have been reported thus far, investigators have had difficulty in recognizing a distinct syndrome. Perhaps this situation will be resolved with the publication of more examples (1–4,7). The interstitial deletion reported by Ying et al (7) is unique.

Characteristics of del(9q) include frontal bossing with hypoplasia of supraorbital ridges, down-slanting palpebral fissures, epicanthic folds, and a short, flat nose. In addition to growth and mental retardation, hypotoniais frequent.

A dozen examples of r(9) have been reported, the features of which resemble those of *del(9p) syndrome:* mcrocephaly, a facies similar to that

of del(9p), flexion of major joints, ambiguous genitalia, hypospadias, inguinal hernia, and various cardiac defects.

Deletions of 9q have been noted in *Gorlin syndrome* (5).

dup(9q) syndrome

Approximately 30 patients are known to have partial trisomy for various segments of the long arm of chromosome 9 (1–7). Mental retardation is severe in these patients, the relatively constant features being microdolichocephaly, deep-set eyes, prominent beaked nose, relatively large pinnae, overlapping upper lip, and microretrognathia (Fig. 4–28). Approximately 35% of those with tetrasomy for 9pter→q21–32 have cleft lip/palate.

The fingers and toes tend to be long. Flexion of fingers and/or limitation of joint mobility, dislocated hips, talipes equinovarus, hypoplastic genitalia, and congenital heart disease have also been found.

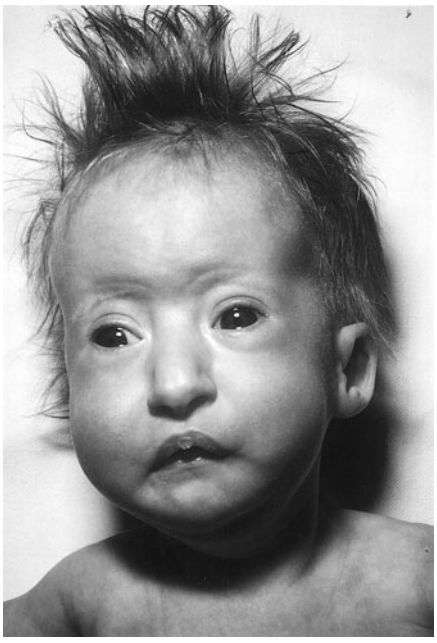
Fig. 4–28. *dup (9q) syndrome.* Microdolichocephaly, up-slanting small palpebral fissures, prominent beaked nose, short philtrum, microretrognathia. (From SF Aftimos et al, Am J Dis Child 134:848, 1980.)



Trisomy 9 syndrome

Trisomy 9 and trisomy 9 mosaicism do not appreciably differ in phenotype. All patients have psychomotor retardation. Most patients have low birth weight and/or failure to thrive and neurologic impairment, and most die before the fourth month of life (1–26); those with full trisomy 9 are not very viable. About 30 cases of trisomy 9 syndrome or trisomy 9 mosaicism have been reported. We suspect that one patient really had trisomy 8 (5).

Approximately 65% of patients exhibit microcephaly with narrow temples. The palpebral fissures are short in 75%. Microphthalmia and deep-set eyes are noted in 50% (8). In 70%, the nose is bulbous and prominent. Cleft lip/palate has been seen in 25% of patients (12–15,17,19,21,25). The ears are low set and/or malformed, the chin small, and the neck short or webbed (Fig. 4–29). Arhinia has also been found (8).

Musculoskeletal abnormalities are common: congenital dislocation of the hips or other joints, scoliosis, joint limitations or dysplastic hands and/or feet, rocker-bottom feet, and talipes. Congenital heart anomalies, seen in 60% of patients, include ASD, VSD, PDA, double-outlet right ventricle, and persistent left superior vena cava (6,9,13). Brain malformations have been noted in 65% of patients (18), with Dandy-Walker malformation constituting about one-quarter of these cases (24,26).

Urogenital abnormalities, noted in 65% of cases, include hydronephrosis, duplication of collecting system, cryptorchidism, micropenis, and hypospadias. The external genitalia of females are normal. Deep palmar and/or plantar creases occur frequently.

Fig. 4–29. *Trisomy 9 syndrome.* Microcephaly, dolichocephaly, and high forehead. Eyes are deeply sunken into the sockets. Palpebral fissures are up-slanting. Pinnae are dysmorphic.

del(10p) syndrome

Less than 30 cases of this syndrome are known, about 75% of them being male (1–23). Several break points have been determined, most at 10p13, yielding various phenotypes. Nearly all have been de novo cases. Mental retardation is severe in all patients, and seizures occur in 20%. Postnatal growth retardation is a constant feature. About 40% of patients have died in infancy. The more constant facial features include microcephaly; frontal bossing; hypertelorism; short, down-slanting palpebral fissures; epicanthus; ptosis; strabismus; low nasal root with anteverted nostrils; small, low-set pinnae; prominent upper lip; micrognathia; and short neck (Fig. 4–30A). Cleft lip/palate has been reported in about 60% of cases (17,21,23).

The nipples are widely spaced in 60%. Various congenital heart anomalies have been found in about 60% of patients. Cryptorchidism, hernia, and renal abnormalities are noted in over 60%. Hypoplasia or aplasia of olfactory bulb and tracts have been found in those individuals with more proximal deletions (6). Various anomalies of the extremities have been noted in over 80%. Sensorineural hearing loss has been found in several patients (9,20). *DiGeorge anomaly* has also been noted (6,8,13–19,24). However, the facial features are different from those seen in 22q11 deletion. The nasal bridge is broad with very narrow palpebral fissures (15). There are two non-overlapping regions, the DiGeorge critical region II at 10p13–p14 and the hypoparathyroidism, sensorineural hearing loss, renal (HDR) region which is more telomeric at 10p14-pter. The GATA3 gene codes for a zinc finger transcript factor which is involved in vertebral skeletal development (24,25).

Ring chromosome 10 has no distinct phenotype.

dup(10p) syndrome

Most examples of dup(10p) result from familial reciprocal translocation. Approximately 50 cases have been reported (1–11) with early death occurring in 25% of these patients. This syndrome is marked by severe mental and motor retardation with little or no speech. Birth weight is usually normal. Infants are often dolichocephalic (30%) with a high prominent forehead and wide open sutures and anterior fontanel (30%). Palpebral fissures have a slightly downward slant. The eyebrows are highly arched (30%), and hypertelorism is present in about 50% of patients. The maxilla tends to protrude. The nasal root, initially broad, becomes prominent in older patients and the mouth becomes triangular with a thin inverted upper lip (45%) (Fig. 4–30B). Cleft lip/palate has been noted in over 30%. The ears are often low set and somewhat angulated (75%). Elbows, wrists, and fingers are often hyperextensible (35%). Flexion deformities of fingers and toes and clubfeet are common (20%). The kidneys tend to be cystic. For various other anomalies, see Stengel-Rutkowski et al (10), Lurie et al (6), and Kozma and Meck (4).

del(10q) syndrome

About 30 cases of terminal deletion have been reported (1–19), of whom about 25% died in the neonatal period. More females than males may be affected. In addition to severe mental and growth retardation, there are a few relatively nonspecific facial features of del(10q): microcephaly, brachycephaly, prominent beaked nose, apparent hypertelorism, down-slanting palpebral fissures, strabismus, deep-set eyes, malformed pinnae, bow-shaped upper lip, and short neck. Cleft lip has been noted (9).

In about a dozen cases of interstitial deletion, in addition to psychomotor retardation and hypotonia, unusual pinnae, hypertelorism, and VSD occurred (7).

A Prader-Willi-like phenotype (hypotonia, typical facies, hypogenitalism) may be seen in infancy with hyperactive behavioral pattern adolescence (7a). There is no obesity and no hyperphagia.

dup(10q) syndrome

Over 90% of cases of dup(10q) have resulted from a balanced translocation in a parent. A significant majority are male. The prognosis is poor with death occurring prior to the age of 4 years in approximately half the cases, largely because of cardiac, renal, or respiratory complications. Those who survive are severely retarded (12).

Duplication of 10q11–q22 produces a distinct phenotype: mental and somatic retardation, microcephaly, deep-set eyes, strabismus, small

A B

Fig. 4–31. *dup (10q) syndrome*. (A,B) Large forehead, round face, arched eyebrows, small palpebral fissures, hypertelorism, and bow-shaped mouth. (A courtesy of S Cho, Wichita, Kansas. B from S Kröyer and E Niebuhr, Ann Genet 18:50, 1975.)

upturned nose, short prominent philtrum, bowed mouth, and thick ear helix (2,4,11).

Trisomy (10q25→qter) produces a rather distinctive clinical picture: severe mental retardation, pre- and postnatal growth retardation, marked hypotonia, microcephaly, large, high forehead, somewhat flattened round face, fine arched eyebrows, narrow palpebral fissures, epicanthus, microphthalmia, flat nasal bridge, small short nose with anteverted nostrils, prominent cheek bones, bow-shaped mouth with prominent upper lip, small mandible, and low-set malformed pinnae (Fig. 4–31). About 35 cases have been reported (1,2a,3,5–10,12).

About 50% of patients exhibit ptosis, cleft palate, and long philtrum. Bilateral epicanthal folds create an illusion of hypertelorism, whereas reduced corneal diameter may simulate microphthalmia.

Anomalies of the hands and feet include camptodactyly, proximally implanted thumbs and/or great toes with a wide space between the hallux and second toe, overlapping and/or fusiform fingers, and rocker-bottom feet. Deep plantar furrows have been noted in over one-third of patients. At least half of the males exhibit cryptorchidism. Various congenital heart defects have been found. Delayed bone age, scoliosis, and thin ribs are noted in about one-third of patients. Various kidney abnormalities include hypoplasia, cystic alterations, hydronephrosis, and hydroureter.

Unbalanced 11/22 translocation

This disorder, caused by unbalanced segregation of a translocation rcp(11;22)(q23;q11), is the most frequent non-Robertsonian balanced rearrangement in humans.

Mental deficiency is severe to profound. Survival is reduced, with at least 50% of liveborn patients not surviving the first 3 years. There is a tendency toward stereotypic movement, seizures, and autistic behavior (1,3,5). Causes of early death include cardiac failure, brain malformations, seizures, and infections. The clinical features overlap partly with those of *cat eye syndrome* [tetrasomy for (22)(pter→q11)] and (mosaic) trisomy 22. The facies is characterized by a broad and flat nose, long and well-marked philtrum, marked micrognathia, and abnormal pinnae. Preauricular pits, tags, or both, long narrow dysmorphic pinnae, and, less commonly, severe microtia with atresia or absence of the external canals are seen (Fig. 4–32). Severe conductive hearing loss or sensorineural hearing loss are common. Male genital hypoplasia with micropenis, small scrotum, and cryptorchidism is also found. Other malformations include cleft palate (>50%), heart defects (at least 50%), anal atresia with fistula, renal malformations, hypoplasia of diaphragm, intestinal malrotation, 13 pairs of ribs, bipartite clavicles, and cerebral malformations. In contrast to *cat-eye syndrome* and *trisomy 22,* coloboma of the iris does not occur in this disorder.

Karyotypes reveal an extra marker chromosome smaller than a 22 and with different staining qualities of the distal long arm. One parent, nearly always the mother, has an identical marker replacing a 22 and an abnormal 11 with an elongated long arm. The translocation is reciprocal, with break points probably at 11q23 and 22q11, and thus the unbalanced products are trisomic for a segment of 11(q23→qter) and a centromere-containing segment of 22(pter→q11). Unbalanced 2:2 segregations obviously do not survive in utero. The translocation is frequent and occurs in all populations and races. Family studies following the detection of a chromosomally unbalanced patient usually show multiple balanced carriers in several generations. There is also an excess of reproductive loss in these families.

del(11p) syndrome (Potocki-Shaffer syndrome)

Shaffer et al (4) reported that proximal deletions at 11p11.2p12 produce a phenotype that includes multiple cartilaginous exostoses, mental retardation, brachycephaly, biparietal foramina, large fontanels, craniosynostosis, and minor facial anomalies (ptosis, epicanthic folds, short philtrum, downturned upper lip) (1–4). This deletion involves EXT2 and appears to be contiguous. Loss of functional mutations of the homeobox gene *ALX4* is responsible for the syndrome (2).

For a more complete description of this syndrome, see *enlarged parietal foramina, craniofacial anomalies, mental retardation, and multiple exostoses (Potocki-Shaffer syndrome, del11p11.2p12 syndrome)* in Chapter 25.

del(11q) syndrome (Jacobsen syndrome)

Patients with the most common del(11)(q23→qter) have exhibited mental retardation. This deletion is of a folate-sensitive site. Most 11q deletions are de novo deletions of paternal origin (11). At least 75 cases of del(11q) have been reported. Other deletions have been reviewed by Herz et al (7). A few individuals have been small for gestational age, but nearly all have poor postnatal growth. About 60% of patients have exhibited postnatal somatic retardation. Most have manifest frequent respiratory infections. About 25% die before 2 years of age, usually from congenital heart disease (1–18).

The facies is characterized by trigonocephaly (85%), hypertelorism (80%), microcephaly (60%), flat occiput (40%), deep-set short nose (100%), abnormally modeled pinnae (95%), carp mouth (95%), and micrognathia (90%). Eye anomalies have included intermittent strabismus, up-slanting palpebral fissures (75%), ptosis (85%), epicanthus (75%), hypertelorism (80%), and coloboma of iris (35%) (11,16) (Fig. 4–33).

Various congenital heart anomalies (VSD, single ventricle, ASD) (65%), joint contractures (camptodactyly, hammer toes) and/or minor digital anomalies (70%), and single flexion creases (65%) have been found. Systemic anomalies are unusual (17). About 40% of patients have exhibited isoimmune thrombocytopenia and recurrent infections (13). Some have giant platelet alpha granules (1). For unusual findings, see Hustinx et al (8).

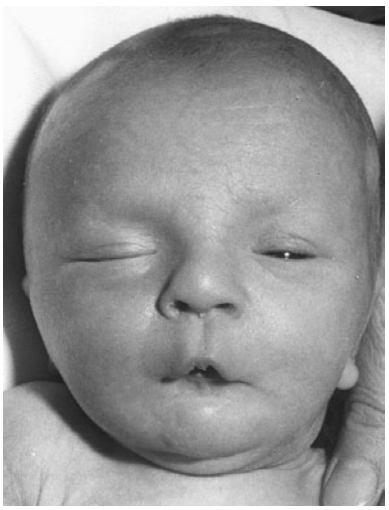
dup(11q) syndrome

In most cases, dup(11q) is associated with 11q/22q translocation, and is inherited in nearly all cases through the carrier mother and has a recurrent risk of 2%–6% (3,7). The frequency of this disorder appears to be far higher than estimated. There is also a group of cases representing dup(11q), most often 11q23→11qter (1,2,4–6,8–10). Although the first group may include trisomy for a small portion of 22q, the phenotypic overlap with the second group is marked.

Reduced birth weight and postnatal growth are nearly constant features. Mental retardation, ranging from low normal to moderate, is present in all cases. Hypertonia is found in about 50%.

Craniofacial asymmetry and microcephaly are present in 35% of affected individuals. Inconstant features include hypertelorism, epicanthal folds, and down-slanting palpebral fissures. The nose is short with a long philtrum. About 85% have low-set pinnae and preauricular (usually bilateral) ear tags or pits. The lower lip is usually retracted and the mandible small. Cleft palate has been found in 60% of patients (2–5) (Figs. 4–34 and 4–35). The neck may be short.

Fig. 4–35. *dup(11q) syndrome.* Hypertelorism, broad flat nasal bridge, small mouth, retracted lower lip, micrognathia, and short neck. (From HD Rott et al, Humangenetik 14:300, 1972.)



Genitourinary anomalies include imperforate anus or anal atresia (15%), associated with a fistula into the bladder, vestibule, or perineum. Cryptorchidism occurs in 35% of patients with micropenis occurring in 85%.

Musculoskeletal anomalies include bipartite clavicular defect and dislocation or dysplasia of the hips (30%). Inguinal or umbilical hernia has been described in 30%. Congenital heart anomalies, found in 60% of patients, are variable and nonspecific.

Pallister-Killian syndrome (mosaic tetrasomy 12p, isochromosome 12p syndrome)

Pallister et al (13) in 1977 and Killian et al (8) in 1983 independently described a syndrome consisting of profound mental retardation, coarse facies, localized alopecia, pigmentary skin anomalies, supernumerary nipples, diaphragmatic hernia, and cardiovascular anomalies. It is caused by isochromosome, i.e., tetrasomy 12p. The isochromosome is usually of maternal origin (27,30). Hexasomy produces the same phenotype (31). It should be pointed out that tetrasomy 12p ranges from classic Pallister-Killian syndrome to mild learning disability with pigmentary skin changes (23).

Although peripheral lymphocytes are usually normal, cultured fibroblasts, direct bone marrow analysis, and other soft tissues (33) will show the chromosome marker, but it may be lost in long-term culture (16) and with age (18,33). It may be diagnosed in amniocytes (16,25,28) or on chorionic villus sampling (3). Buccal smear of patients by means of FISH is effective in diagnosis (9a,12). A phenocopy has been reported (22). Mothers of affected infants tend to be older (34).

Birth weight is normal. Polyhydramnios is not rare (21,34,37). In infancy, the hair is sparse and fine, particularly in the frontal and temporal areas, extending to the vertex. With age, hair distribution becomes normal. Hypopigmented areas of the skin have been noted, reflecting mosaicism. The facies is coarse at birth and becomes more markedly so with age. The forehead is high and the metopic skin and eyelids are puffy (6). Eyebrows and eyelashes are sparse medially. Mosaic retinal pigmentation has been noted (14). Ptosis, strabismus, and hypertelorism also occur. The nose is short with a flat nasal bridge and anteverted nostrils, and the pinnae are fleshy. Hearing loss has been documented in nearly all patients. The philtrum is long and prominent; the mouth is large and downturned. The upper lip is thin and has a cupid-bow shape, and the lower lip protrudes. Clefting of the lip or palate is rare (10,11,24). The mandible is small and dental eruption is delayed. The neck is very short and often webbed with excess nuchal skin (Figs. 4–36 and 4–37). There is some phenotypic overlap with *Fryns syndrome* (11,21). The adult phenotype is one of severe retardation, epilepsy, coarse, flat facies, mandibular prognathism, macroglossia, hypertonia, and contractures (5,18).

A B

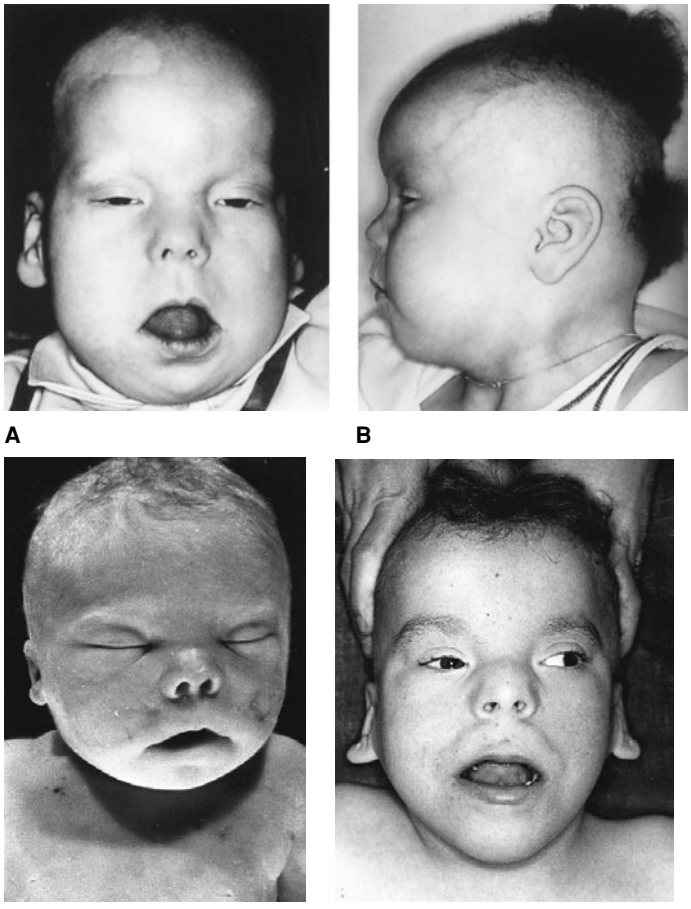
Fig. 4–36. *Pallister-Killian syndrome.* Tetrasomy i(12p). (A) Note altered body proportions and multiple depigmented areas. (B) Short depressed nasal bridge, prominent premaxilla, and large mouth. (From L Shivashankar et al, Prenatal Diagn 8:85, 1988.)

Developmental retardation is profound; speech is not attained. Neonatal asphyxia and death are frequent. Bone age is retarded. Postnatal growth deficiency and natal gigantism have been reported (20). Pineal tumor has been documented (9b). Marked hypotonia, hypermobile joints, and areflexia have been noted in infancy, but these improve with age (20). Pineal tumor has been documented (9b). Talipes has also been observed (4). Supernumerary nipples are a common finding.

Several children have had unexplained fever. Increased height of the vertebral bodies, mild thoracic scoliosis, and atlanto-occipital fusion have been documented (21,29,36). Cardiovascular anomalies, most frequently VSD, are found in about 25% of patients. Diaphragmatic hernia, which may be lethal, has been reported (15,21,32,36). Imperforate anus, anal atresia, or anteriorly displaced anus has been reported in several infants (4,24). The limbs and fingers tend to be short and there is often a sacral dimple (15,32–34). The thumb may be proximally inserted and the hallux may be large (7). Hexadactyly has been noted (14).

FISH has been used to confirm the identity of the chromosome (25,26). Fibroblast analysis is the best means of diagnosis, since the isochromosome tends to disappear with age (17,33). Maternal age effect is a factor in development of Pallister-Killian syndrome (34). Partial duplication of 12p is associated with a much milder phenotype (1,2,19).

Prenatal diagnosis has been made on nuchal translucency (8a).



A B C D

Fig. 4–37. *Pallister-Killian syndrome.* (A,B) Fine, sparse hair, particularly on frontal and temporal areas. Facies coarse. Note hypopigmented area of scalp, high forehead, eyebrows, medially sparse eyelashes, short nose with flat bridge and anteverted nostrils, downturned mouth, and thin upper lip. (C) Note similarity in facies to that of Fryns syndrome. (D) Observe microcephaly, ptosis, strabismus, flat wide nasal bridge, short upturned nose, prominent philtrum, dysplastic pinnae with upturned lobes. (A,B,D from W Killian et al, J Clin Dysmorphol 1(3):6, 1983. C from J Rodriguez, Am J Med Genet 53:176, 1994.)

del(14q) syndrome

Most cases of del(14q) have ring chromosomes. Break points at 14q32 are most common. About 50 examples have been reported. There is a 2:1 female predilection. The main features include microcephaly with flat occiput, high forehead with lateral hypertrichosis, epicanthic folds, downward-slanting palpebral fissures, narrow elongated face, short, narrow palpebral fissures, flat nasal bridge, large, low-set pinnae, micrognathia, and short neck (Fig. 4–38A). Retinal dystrophy, seen in about 50% of cases, may be specific (hyperpigmentation and yellow-white spots of the macula) (1–12).

Mental retardation, hypotonia, and seizures are severe as are prenatal and postnatal growth retardation. The lateral ventricles are moderately enlarged. Ring 14 syndrome is compatible with extended survival but recurrent respiratory infections are common. Lymphedema of the hands and feet is not rare (2) (Fig. 4–38B).

dup(14q) syndrome

In addition to mental retardation and pre- and postnatal growth retardation, this syndrome is characterized by a large face, chubby cheeks, facial asymmetry, hypertelorism, broad nose, short prominent philtrum, carp mouth, posteriorly rotated pinnae with prominent antitragus, and micrognathia (1–10). Cleft palate has been found in at least 50% of cases (1,3,4,9) (Fig. 4–39A)

The nipples are high and widely spaced. Males exhibit hypogenitalism. Brain, lung, and congenital heart defects are common.

Trisomy 14 mosaicism syndrome

Although trisomy 14 has been reported in abortuses, all living examples have been mosaic. About 20 examples have been reported. Polyhydramnios is frequent. Although weight is normal, postnatal growth and psychomotor development are severely retarded.

Prominent forehead, hypertelorism, wide nasal bridge and broad nose, narrow palpebral fissures, prominent maxilla, long philtrum, large mouth, thick lips, dysmorphic low-set pinnae, micrognathia, and short neck are characteristic. A number of patients have cleft palate (1–4,7,9,10,12) (Fig. 4–39B). This syndrome is similar in features to *dup(14q) syndrome.* Several patients have exhibited reticular hyperpigmentation of the skin, reflecting mosaicism. Body and facial asymmetry have been seen in about one-third of patients. Congenital heart anomaly, particularly tetralogy of Fallot, is found in nearly all examples (5,11,13). Micropenis and cryptorchidism are constant features in males (3).

Uniparental disomy 14

There have been only a few examples of this very rare condition. Paternal and maternal uniparental disomy 14 differ in clinical findings.

Paternal disomy 14. In three of four examples of paternal isodisomy 14, polyhydramnios was observed. The facies was characterized by hirsute forehead, blepharophimosis, protruding philtrum, puckered lips, small pinnae, and small mandible. A webbed neck was seen in two of four examples. The thorax tended to be small with abnormal ribs. Other findings included ventral wall hernia, short extremities, and digital contractures (2,5,9,10).

Maternal disomy 14. Maternal uniparental disomy 14 is characterized by a phenotype of variable severity, including short stature, arrested hydrocephalus, small hands, scoliosis, mild developmental delay, and precocious puberty (1,3,4,6–8).

There is no evidence that uniparental disomy 14 is a cause of intrauterine growth retardation (4a).

del(15q) syndrome

Deletion of the long arm of chromosome 15 usually results in a ring. At least 30 patients have been described (1–15).

In the young patient, the most characteristic findings include prenatal growth retardation (100%), short stature (100%), variable mental retardation (95%), microcephaly (85%), hypertelorism (45%), a triangular face resembling that of *Silver-Russell syndrome* (40%) (12), and limb anomalies including delayed bone age (75%), brachymesophalangy (45%), clinodactyly of the fifth fingers, and thumb hypoplasia. About 30% of patients have congenital heart anomalies. Café-au-lait spots are found in 30% of patients (Fig. 4–40).

During the adult years, severe mental and somatic retardation become evident. The forehead is bossed (35%), the face triangular (40%), and the pinnae anomalous (30%); the nose has a high bridge. Males are hypogonadal.

dup(15q) syndrome

Most examples of dup(15q) have resulted from unbalanced translocation (1–13). About 30 cases have been described.

Microdolichocephaly, occasionally hydrocephaly, narrow or short and downward-slanting palpebral fissures, bulbous nose, malformed pinnae, long philtrum, cleft palate, and micrognathia characterize the facies of trisomy for the proximal long arm of chromosome 15 (1,8,9,13) (Fig. 4–41). Other investigators deny any predictable phenotype (2,7).

Those individuals with distal 15q trisomy exhibit microcephaly with sloping forehead, facial asymmetry, down-slanting and short or narrow palpebral fissures, ptosis, prominent nose with broad bridge, long philtrum, downturned mouth, highly arched palate, midline crease of the lower lip, puffy cheeks, micrognathia, and short neck (10,11) (Fig. 4–42). Postnatal growth deficiency, scoliosis, pectus excavatum, cryptorchidism, arachnodactyly, camptodactyly, hyperextensible thumbs, and cardiovascular anomalies are relatively common. Severe mental retardation is constant and hypotonia is frequent. Seizures are noted in 30% of patients.

An example of complete trisomy 15 has been described (4).

Trisomy and tetrasomy 15 mosaicism syndromes

An extremely rare and essentially lethal condition, trisomy 15 mosaicism is characterized by symmetrical growth retardation, distinct craniofacies, congenital heart anomalies, severe hypotonia, and minor skeletal anomalies (1,3–8). The facies has a low hair line, hypertelorism, broad nasal bridge, short bulbous nose, long philtrum, small mouth, dysmorphic pinnae, small mandible, and short neck.

Fig. 4–41. *dup(15q) syndrome.* Duplication of proximal chromosome 15. Patient has mental retardation, microcephaly, flat nasal bridge, cleft palate, small mouth, and micrognathia. (From G Annerén and KH Gustavson, Clin Genet 22:16, 1982.)

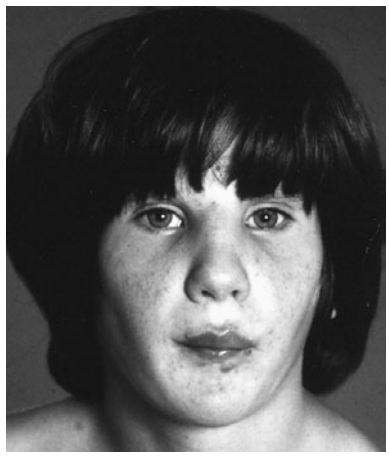

Fig. 4–42. *dup(15q) syndrome. Duplication of distal chromosome 15.* (A–H) Note facial asymmetry, narrow down-slanting palpebral fissures, ptosis, prominent nose, long philtrum, downturned mouth, and puffy cheeks in eight reported patients. (From P Schnatterly et al, Am J Hum Genet 36:444, 1984.)

Mosaic tetrasomy 15, usually the result of isochromosome formation, is even rarer than mosaic trisomy 15 (2,9).

inv dup(15) syndrome

The inv dup(15) syndrome is caused by an extra marker chromosome, which is cytogenetically defined as inv dup(15)(pter→q12–13→pter) and, by FISH analysis, includes the Prader-Willi and Angelman syndromes' critical regions. The extra chromosome is maternally derived (8). When the critical region is included, there appears to be an abnormal phenotype.

In addition to developmental delay and moderate to severe mental retardation, features of this syndrome include seizures, diffuse hypotonia, and peculiar behavior such as lack of social interaction, absent or poor echolalic language, and nonfunctional use of objects (1–7). Affected individuals also have down-slanting palpebral fissures, epicanthic folds, low-set pinnae, coarse face, and multiple hypopigmented areas of the skin (1–7).

dup(16p) syndrome

Although trisomy 16 is the most frequent chromosome anomaly found in abortuses, the anomalies are quite lethal, and only a few examples of trisomy 16p are known (1–8). Anomalies include severe developmental delay, round face, prominent glabella, hypertelorism, narrow palpebral fissures, scant brows and lashes, broad, depressed nasal bridge, anteverted nares, long philtrum, thin vermilion of upper lip, cleft palate, micrognathia, severe mental retardation, and growth delay (1–8). Congenital heart anomalies were found in 50% of patients (1,2). The skin is loose in about 50% of patients (5). The thumbs are abnormally placed.

del(16q) syndrome

Over 25 examples of interstitial and terminal deletions of the long arm of chromosome 16 have been reported (1–15). It has been shown that 16q21 must be deleted for the typical syndrome changes to occur (12).

The phenotype is characterized by mental retardation (100%), low birth weight (50%), delayed growth and development (90%), feeble suck (100%), and hypotonia (100%). The distinct craniofacies includes microcephaly (70%), high forehead (70%), prominent metopic suture (65%), large anterior fontanel with or without wide cranial sutures (100%), short, up-slanting palpebral fissures (40%), hypertelorism (60%), small, upturned nose with flat bridge (70%), low-set folded helices (100%), micrognathia (65%), and short neck (65%). Cleft palate has been described (11), as well as natal teeth (4) (Fig. 4–43A,C).

Diverse musculoskeletal anomalies [narrow thorax (50%), small hands and feet (50%), talipes, umbilical hernia, polydactyly, flexed fingers, broad halluces (80%)] have been reported (Fig. 4–43B). Cardiac anomalies [coarctation of aorta, VSD (40%)], renal anomalies [cystic dysplasia (35%)], and intestinal anomalies [ectopic anus, malrotation (35%)] anomalies have also been described.

dup(16q) syndrome

Trisomy 16 is the most common trisomy among spontaneous abortions during the first trimester, thus there are only a few known liveborn examples (2,4,9,10).

In addition to low birth weight and severe psychomotor and mental retardation, common features of dup(16q) include round face, high forehead, frontal bossing, prominent glabella, hypertelorism, depressed nasal bridge, round nasal tip with anteverted nostrils, low-set small pinnae, prominent maxilla, asymmetric skull, small palpebral fissures, hypertelorism, malformed long philtrum, hypertrichosis, flexion contractures, cryptorchidism, VSD, and foot deformities (1,3,5–7). Breast asymmetry has been noted (8). Early death is common.

Trisomy 16 and partial trisomy 16

Trisomy 16 is the most common trisomy among spontaneous abortions during the first trimester, but there are relatively few liveborn examples (2–4,8,9).

In trisomy 16p, in addition to low birth weight and severe psychomotor and mental retardation, common features include dolichocephaly, round face, frontal bossing, prominent glabella, hypertelorism, depressed nasal bridge, round nasal tip with anteverted nostrils, low-set pinnae, high palate, prominent maxilla, micrognathia, and short neck. Atrial septal defects and tetralogy of Fallot have also been observed. Various other features include scoliosis, talipes, clinodactyly, and camptodactyly.

In trisomy 16q, common features include low birth weight, psychomotor retardation, low-set small pinnae, asymmetric skull, high forehead, small palpebral fissures, hypertelorism, flat nasal bridge, malformed long philtrum, high palate, hypertrichosis, flexion contractures, hypospadias, cryptorchidism, ASD, VSD, PDA, and foot deformities (1,2,5–7). Sacral dimple has been noted. Early death is common.

Single umbilical artery and umbilical hernia have been noted in both trisomy 16p and 16q.

Smith-Magenis syndrome [del(17p11.2)]

Smith-Magenis syndrome, or interstitial del(17p11.2), is characterized by growth retardation, mental deficiency, typical behavior abnormalities, and a relatively nonspecific combination of congenital minor or, occasionally, major anomalies. At least 100 patients with this syndrome have been described (16). Incidence has been estimated at 1 in 25,000 births (8).

The face is distinctive, even in the young child (1): there is brachycephaly (85%), a broad, square face with frontal bossing, flat midface, prominent chin, synophrys and lateral extension of eyebrows, telecanthus, epicanthic folds, up-slanting palpebral fissures, deep-set eyes, strabismus, Brushfield spots, myopia, retinal detachment, depressed nasal root, broad nasal base, full nasal tip, wide mouth with downturned corners, full lips, short philtrum with tenting, prominent lower jaw, and midface hypoplasia (2–4,6,7,12,13,15–17) (Fig. 4–44). Cleft lip/palate is found in 10% of patients. The external ears are misshapen and posteriorly angulated. Large ears, small ears, prominent ears, asymmetric ears, or thick helices have been noted. At least 65% of affected individuals have conductive hearing loss, and about 35% have sensorineural loss (7). Repeated middle ear infections are frequently reported. An excellent facial anthropometric study is that of Allanson et al (1).

The hands are broad with short fingers and fifth finger clinodactyly. Fingertip pads are often present (11). A characteristic metacarpophalangeal pattern has been discerned (11). The feet are flat with syndactyly between toes 2 and 4. Scoliosis, seen in 65% of patients, increases with age. Heart anomalies and renal malformations, especially duplication of collecting system, are found in about 35% (9).

Mental deficiency varies from moderate to, more often, severe. Speech is disproportionately delayed (95%), and the voice is hoarse or deep in 80% of cases. A constant pattern of behavioral abnormalities is characterized by low tolerance of frustration, sudden changes of mood, hyperactivity, distractibility, self-injury, irritability, sleep disturbance, impulsive, violent, and aggressive behavior, bruxism, reduced REM

Fig. 4–44. *Smith-Magenis [del(17p11.2)] syndrome*. (A–C) Facies in individuals of different ages. Overall shape is broad and square, brows are heavy with lateral extension of eyebrows, upslanting palpebral fissures, deep set nose with scooped bridge, short nose with broad tip. Mouth is wide with full lips. Central part of upper lip is fleshy and everted, producing a tented appearance. Increased mandibular width and prognathism. (From J Allanson et al, J Med Genet 36:394, 1999.)

A B C

sleep, and self-mutilation. Peripheral neuropathy is seen in 75% of patients, and about 25% have seizures of no predominant type. Ventriculomegaly is found in over 50%.

The diagnosis is based on prometaphase chromosome examination, which is usually prompted by the characteristic physical and behavioral abnormalities. The deletion is not easily detected in routine karyotypes unless the examiner pays special attention to 17p. FISH probes aid in diagnosis (10), although fibroblast study is preferable. All deletions have occurred de novo. Smith-Magenis syndrome has been detected prenatally (5,18). Molecular studies have shown that both paternal and maternal origin may occur, without any differences in clinical presentation (8).

Potocki et al (14) have described dup17p11.2, the reciprocal of Smith-Magenis syndrome.

dup(17p) syndrome

Severe mental and somatic retardation, microcephaly, narrow, downslanting palpebral fissures, midface hypoplasia, hypertelorism, broad nasal bridge, dysplastic low-set ears, smooth philtrum, chronic open mouth, micrognathia, and short, webbed neck are characteristic of this syndrome (2,3,5,7). Some patients have mild to severe retardation (6).

Flexion abnormalities of the first four digits with extension of the fifth finger are common. The fingers tend to be long and tapered. Inguinal hernia has also been noted. A transverse palmar crease has been found in most patients. The male genitalia are hypoplastic (1–10).

del(17q) syndrome

Deletion of the long arm of chromosome 17 is essentially lethal. Only a few examples of interstitial deletion of 17q21–q24 can be cited (1,3). Clinical findings have encompassed prominent glabella, hypertelorism, up-slanting palpebral fissures, anteverted nares, long philtrum, cleft palate, proximally placed thumbs, symphalangism, tracheoesophageal fistula, and cerebral abnormalities. Ring 17 is also rare. Growth retardation, seizures, café-au-lait spots, microcephaly, and broad nasal bridge with anteversion of nostrils are common features (2).

3. Park JP et al: A unique de novo interstitial deletion del(17) (q23.13q23) in a phenotypically abnormal infant. Clin Genet 41:54–56, 1992.

dup(17q) syndrome

Duplication of the distal portion of 17q is quite rare. Most cases have involved bands q21, q22, or q23–qter (1–10).

The phenotypic alterations appear to be remarkably similar. Stature is short and psychomotor retardation is profound. Most patients exhibit microcephaly, plagiocephaly, frontal bossing, temporal retraction, facial asymmetry, and widow's peak. Several patients have manifested downward slanting palpebral fissures, hypertelorism, and epicanthal folds with a flat nasal bridge. The mouth is often wide with a thin upper lip and downturned corners. Over half of patients have either cleft lip or cleft palate (1,2). The pinnae are often low set, posteriorly angulated, and malformed. The neck is short and broad and may occasionally be webbed with low posterior hairline (Fig. 4–45). Postaxial polydactyly of the hands and/or feet has been reported in several patients, as have hyperlaxity of limb joints and brachyrhizomelia (6). Serious congenital heart anomalies have been present in about 50% of patients. Central nervous system abnormalities have been a constant feature; renal anomalies (hydronephrosis, cystic kidneys) are also common. All males have exhibited cryptorchidism.

Examples of liveborn mosaic trisomy 17 have been reported, in whom mental and somatic retardation, seizures, autism, microcephaly, and hearing loss were found (6,9). An extra ring 17 results in severe retardation, microstomia, eye coloboma, unusual pinnae, polydactyly, contractures, and hearing loss.

dup(19q) syndrome and mosaic trisomy 19

Less than a dozen cases of trisomy for the distal third of the long arm of chromosome 19 are known (1–3,4,6–9). There is no sex predilection. In addition to mental retardation, the phenotype includes low birth weight and length, marked postnatal growth retardation, microbrachycephaly, widely open sutures, downward-slanting palpebral fissures, hypertelorism, ptosis, prominent glabella, short nose, short philtrum, downturned mouth, cleft lip and/or palate, and short neck with redundant skin (Fig. 4–46). The thorax is barrel shaped. Musculoskeletal disorders include hypotonia, diastasis recti, kyphosis, duplicated thumb, valgus deformity of feet, and laterally curved halluces. Survival into late childhood has been reported. FISH probes have been used for diagnosis of distal trisomy 19q (3).

Mosaic trisomy 19 has been described (2,5) with features in one case including hydrops, hypertelorism, flat nasal bridge, short nose, small mouth, dysmorphic pinnae, narrow meati, short neck, and talipes. Another case showed a pointed nose, short upper lip, up-slanting palpebral fissures, and laryngeal stridor.

del(20p) syndrome

Among a dozen cases of del(20p), the following clinical features have been noted: psychomotor and growth retardation, frontal bossing, hypertelorism, prominent nasal root, flat nasal bridge, anteverted nares, long philtrum, malformed helices with variable hearing loss, micrognathia, short neck with redundant skin, cardiovascular anomalies, chronic cholestasis, vertebral defect, and single palmar creases. Many of the features are those of *Alagille syndrome* (1,3–7).

Ring 20 cases, analyzed by Brandt et al (2), have, in addition to mental retardation and seizures, few clinical features: behavioral abnormalities, variable microcephaly, and facial dysmorphism.

dup(20p) syndrome

The clinical picture of patients trisomic for the short arm of chromosome 20 is quite variable. Approximately 35 cases have been analyzed, about 90% of which originated from parental translocation, more often in the female parent (1–14).

Clinical features of dup(20p) syndrome uniformly include mild to severe, but usually moderate, psychomotor retardation, poor motor coordination, and rudimentary, delayed speech. Also found are flat occiput (80%); coarse hair; round face; full cheeks; sloping forehead; deep widely set eyes with up-slanting palpebral fissures; strabismus (40%), short nose with large, upturned nostrils (50%); low-set, large, and posteriorly angulated pinnae; microretrognathia; and positional abnormalities of the feet, fingers, and toes (11) (Fig. 4–47). Various vertebral abnormalities resulting in scoliosis have also been noted. Cardiac anomalies have been found in about 35% of patients, most frequently VSD and tetralogy of Fallot.

Trisomy 20 mosaicism, a not uncommon finding in amniotic fluid cell cultures, has no clinical significance.

dup(20q) syndrome

Trisomy for the long arm of chromosome 20 is extremely rare as is trisomy for complete trisomy 20. Features include brachycephaly, low hairline, frontal bossing, epicanthic folds, microphthalmia, alar hypoplasia, cleft lip and/or palate, large pinnae, chin dimple, and congenital heart anomalies (1–4).

Monosomy 21 and del(21q) syndrome

Cases of del(21q) are usually due to maternal translocation. Because of the difficulty in differentiating chromosomes 21 and 22 prior to chromosome banding, we have carried out critical analysis of cases published since 1973. A good review of 25 cases is that of Huret et al (12).

The infant is small at birth and fails to thrive, often succumbing within the first year of life. Head circumference measures between the 3rd and 10th centiles. The occiput is prominent and the hairline is low. The facies is characterized by down-slanting small palpebral fissures, thick eyebrows, hypertelorism, broad nasal base with large tip,

A B

Fig. 4–48. *Monosomy 21 syndrome*. (A,B) Down-slanting palpebral fissures, broad nasal base, large nose, large dysmorphic pinna, micrognathia, and short neck. (From M Mikkelsen and S Vestermark, J Med Genet 11:389, 1974.)

no alar furrows, anteverted nostrils, low-set large pinnae with prominent anthelix and large lobes, large carp mouth, long philtrum, thin vermilion, micrognathia, and short neck (Fig. 4–48). Most have cleft lip and/or cleft palate (4,7,10). Skeletal anomalies include overlapping and/or flexed fingers and toes, kyphoscoliosis, pseudoarthrosis of clavicles, short thorax, and narrow pelvis (1,11,19). Inconstant features include wide-set nipples, ambiguous genitalia or micropenis, cryptorchidism, and imperforate anus (17).

Cardiac anomalies have included preductal coarctation and patent ductus arteriosus. Thrombocytopenia has been described in about 20% of cases, most of which were hypertonic.

Tetrasomy 22pter→q11 or cat eye syndrome

Cat eye syndrome is defined as the combination of an extra small chromosome (an inverted duplicated 22 with a break at 22q11) with a particular pattern of congenital anomalies. The clinical phenotype may have been first recognized in 1978 (4). Highly unusual for an autosomal chromosome duplication, mental development is often normal or only mildly to moderately impaired. Less than 50% of patients show growth retardation, and a minority are microcephalic. Hypertelorism, down-slanting palpebral fissures, and uni- or bilateral, total or partial, inferior coloboma of iris, choroid and retina (rarely microphthalmia) are found. The external ears usually exhibit preauricular pits, tags, or both (Fig. 4–49). This is the most consistent finding in the syndrome. Occasionally, the pinnae are malformed, rarely with severe reduction or even absence, with atretic or absent canals and severe conductive hearing loss (1–15). Moderate to severe sensorineural hearing loss has also been found.

Congenital heart malformations occur in about 35% of patients. Especially characteristic is false pulmonary venous return. About 50% exhibit various renal anomalies, most often horseshoe kidneys, congenital hydronephrosis, or unilateral agenesis/hypoplasia. Less than 35% of patients have anal atresia, always with a fistula into the bladder, vagina, perineum, or urethra. Some patients have a covered anus or anteriorly displaced anus. Males may have cryptorchidism (2,3).

Diagnosis is based on the finding of an extra 21–22-like chromosome that is usually shorter than a 21 chromosome and has a different morphology. The chromosome may be unstable and thus present in a mosaic state. It varies in form within families (5). It is often bisatellited, showing short and long arm association with other acrocentrics. Centromere staining unmasks a second centromere. The marker represents a rearranged chromosome derived from one or two 22 chromosomes with break(s) at the proximal long arm followed by reunion that results in an isodicentric, inv dup(22)(pter→q11) (3). This finding was proved by a molecular study with a polymorphic marker on 22q11, which revealed a quadruple dosage in patients with cat eye syndrome (15). The FISH technique may be used to identify partial or complete cat eye syndrome (1,6).

The cat eye chromosome, which by definition is an inv dup (22)(pter→q11) chromosome, cannot be secondary to a familial balanced rearrangement. However, partial trisomy (and not tetrasomy) of the analogous segment can and does result in a quite similar, but milder, clinical picture and can be transmitted to the offspring of an affected patient (5).

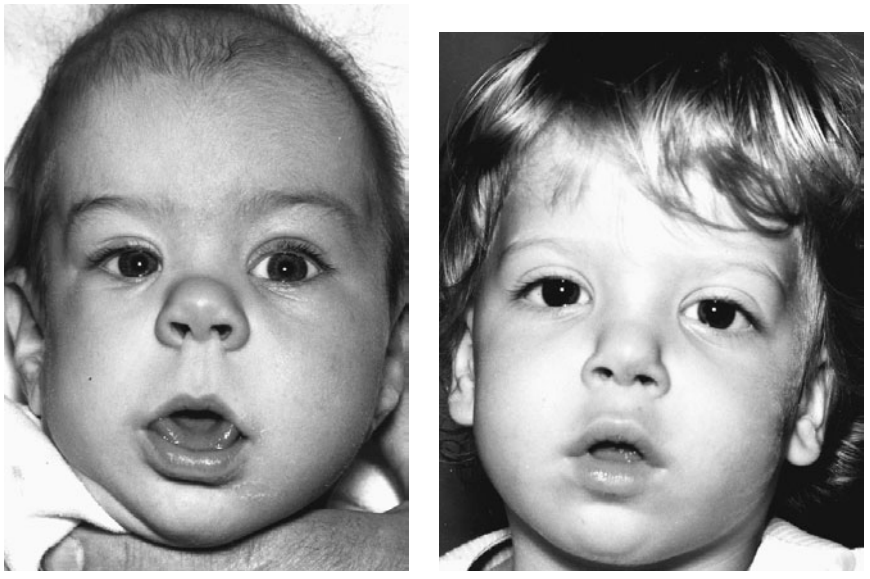
del(22q) syndrome

Loss of the distal portion of the long arm of chromosome 22 usually results in a ring. Approximately 40 patients with this syndrome have been described (1,5,8,13). The phenotype is not striking (1a). The head circumference is reduced in about 65% of patients. The face tends to be round in young children, with horizontal and wide, almond-shaped palpebral fissures. Epicanthic folds are frequent. Ptosis is present in approximately 35%. The eyebrows tend to be full, the nose has a bulbous tip in infancy, and the pinnae are often large (6,7,10,11,16,17) (Fig. 4–50). Mental retardation is usually severe and becomes even more pronounced with age. Hypotonia is constant, with poor motor coordination.



A B

Fig. 4–50. *del(22q) syndrome.* (A) Epicanthal folds, ptosis, broad upturned nose and long philtrum. (B) Compare facies with that of older child. (A courtesy of D Hoefnagel, Dartmouth, New Hampshire. B courtesy of R Warren, Miami Florida.)

Deletion of 22q11 has been found in about 75% of those with *velocardiofacial syndrome,* in the autosomal dominant form of *Opitz BBB/G syndrome,* and in almost 90% of infants with *DiGeorge sequence* (thymic aplasia, congenital heart anomaly, hypoparathyroidism) (4). In some cases, the chromosome abnormality has resulted from de novo rearrangements and, in others, from unbalanced transmission of familial translocations.

DiGeorge sequence, a developmental field defect, involves failure of the thymus and parathyroids to develop, resulting from disturbances of the third and fourth pharyngeal pouches (2,14). This sequence is usually isolated but may be seen in *CHARGE association.* Occasionally, DiGeorge sequence may be transmitted by autosomal recessive or dominant inheritance (9,12,15). Some of these examples may represent chromosome translocation. However, in several cases, no chromosome change has been detected with high-resolution cytogenetics (15).

Congenital heart anomalies, mostly conotruncal abnormalities, vary from VSD (most common) to interrupted aortic arch, right aortic arch, truncus arteriosus, tetralogy of Fallot, PDA, and single ventricle (3).

Cleft lip and/or palate have been noted. The pinnae may be malformed or posteriorly rotated. Hypertelorism, short palpebral fissures, prominent nose, short philtrum, and micrognathia are frequent features.

A B

Trisomy 22 (dup22q) syndrome

Trisomy 22 is the second most common anomaly seen in embryos lost spontaneously during the first trimester. However, it is rare in liveborn babies. Some of the early cases represented undetected unbalanced 11/22 translocations or were composed of part of chromosome 22 and material from other chromosomes (17). However, there are numerous examples of true trisomy 22 that have been demonstrated by chromosomal banding and FISH analysis (4,9,10,18,21–24). Examples of trisomy 22 mosaicism (5) have been described, with origin being shown in paternal nondisjunction at the second meiosis shown (7). Parental age is advanced. Early cases of trisomy 22 were tabulated by Cervenka et al (4) in 1977. It has been described with *holoprosencephaly* (8) and with *Fryns syndrome* phenotype (12).

Life expectancy is limited for patients with pure trisomy, but the mosaic state is compatible with prolonged survival. Intrauterine growth retardation is seen in almost all cases. The head is microcephalic. Hypertelorism, epicanthic folds, and down-slanting palpebral fissures are noted in over 90% of patients. Coloboma has been described (1,4). The nasal bridge is flat and the nasal tip is often flat as a result of a short septum. About 65% have preauricular tags or sinuses. Complete atresia of the external auditory canal has been reported (2). The pinnae are low set with prominent anthelix. Cleft lip and/or palate are present in about 50% of patients (7,9,11,14–16,18,19). The mandible is small in 85% and many patients have been classified as having *Robin sequence* (Fig. 4–51). Webbed neck or redundant skin has been noted in over 80%.

The fingers have hypoplastic nails and distal phalanges in 90% of cases. The thumbs are digitalized in 50% (3). Clinodactyly is not rare. About 40% exhibit hip dysplasia and/or luxation. Hypotonia has been noted in about 50% of cases.

Abnormal external genitalia described in about 90% of males include micropenis, bifid scrotum, and cryptorchidism (12). Anal atresia is found in 30% of patients (3), and various renal malformations have been noted in 50% (6).

Congenital heart anomalies, present in 85%, have included a diverse group of abnormalities without an obvious pattern: pulmonary stenosis (PS), VSD, ASD of secundum type, PDA, tricuspid valve atresia, hypoplastic right ventricle, aberrant subclavian artery, coarctation of aorta, left superior vena cava, and bicuspid aortic valve (9,13,17,20). An excellent survey of congenital heart anomalies seen in this syndrome is that of Lin et al (13).

Those individuals with mosaicism have failure to thrive, mental retardation, ptosis, hearing loss, low posterior hair line, syndactyly, hemihypoplasia, streaky pigmentation, and ovarian failure (5).

Tetraploidy and tetraploid/diploid mosaicism syndrome

Although relatively common (2%–3%) in embryos lost spontaneously during the first trimester, tetraploidy or tetraploid–diploid mosaicism (mixoploidy) in liveborn infants is so rare (not more than a dozen examples of tetraploidy having been recorded) that few generalizations can be made (8). Some cases have been 92,XXYY and others 92,XXXX. They arise either from post-fertilization mitotic cleavage error or trispermic fertilization of a haploid egg (2). Trispermy causes molar changes. The origin of mixoploidy may be failure of cytokinesis at some time after the first mitotic division, resulting in mosaicism. In at least one case, AFP was low while hCG was elevated (2). Tetraploidy is not uncommon as an artifact in amniotic cell cultures. Most true examples abort spontaneously in early gestation. Of embryos lost in the first trimester, about 5%–6% have tetraploidy (5,8).

All living examples have exhibited severe mental retardation, low birth weight, hypotonia, and most have microcephaly. The majority have died within the first year. The forehead is narrow and prominent, the nose beaked, and the philtrum short. The pinnae are often low set and often lack cartilage (4,12,15). Some infants have microphthalmia or anophthalmia and short palpebral fissures (4,10,15,16), whereas others have corneal opacity, colobomas, aphakia, and retinal detachment (10,11). The nose appears pinched and the mouth, small (Fig. 4–52). Cleft lip and/or cleft palate has been found in a few cases (9–11).

Anomalies of the extremities are common: positional limb defects, arachnodactyly (11,12,15,16), syndactyly of toes (15), talipes (12,15), and single palmar creases (4,12,15). About 35% of patients have major congenital heart anomalies (8,11,15).

Among 13 examples of tetraploid–diploid mosaicism (1,3,6,7,10, 13,14,17–21), the phenotype was very similar to that described above for tetraploidy but milder. The hands and feet are slender with long tapering digits, and growth deficiency is often asymmetric. Skin pigmentation changes reflect the mosaicism.

Nijmegen breakage syndrome (Seemanová syndrome)

Nijmegen breakage syndrome is a chromosomal instability disorder characterized by pre- and postnatal growth retardation, microcephaly, "bird-like" facies, and recurrent infections (16). It has been called "ataxia-telangiectasia variant," sharing with it cellular, immunological, and chromosomal but not clinical findings.

Severe microcephaly becomes evident after a few months of life. The forehead is often low and receding. The palpebral fissures have an upward slant. The eyes may be prominent (1). The face is triangular and narrow with a rather long, straight nose and a high nasal bridge. The philtrum is smooth and the chin small (10) (Fig. 4–53).

An immunodeficiency is characterized by low immunoglobulin levels and cellular immune defect. Various infections, especially sinopulmonary, are extremely common. Urinary and gastrointestinal infections have been noted in 15% of patients. Death has resulted from bronchopneumonia (15%) and lymphoid malignancy (20%) (12).

Chromosomal rearrangements involving chromosomes 7 and 14 are seen in 15%–35% of patients; these rearrangements are very similar to those noted in ataxia telangiectasia. The sites most frequently involved are 7p13, 7q34, and 14q11 (10) (Fig. 4–54). There is increased sensitivity to ionizing radiation and bleomycin (7,9,11). Malignancies seen in 30% of cases have included acute lymphoblastic leukemia, malignant lymphoma, neuroblastoma, glioma, medulloblastoma, and rhabdomyosarcoma (3,4,9,13). Most affected individuals have normal intelligence, but some have mental retardation (12).

The syndrome is caused by an autosomal recessive radiosensitivity gene (8,13) that has been mapped to 8q21–24 (2,6,8). Mutation in nibrin, a protein involved in double strand break repair, has been shown (5a,14). Heterogeneity has not been found (5), but allelic mutations have been noted (11).

Clinical and cytogenetic (chromosomal rearrangement) similarities are seen not only in *ataxia telangiectasia* but in *Bloom syndrome* and Fanconi anemia. Other features such as growth retardation, immunodeficiency, and a high incidence of malignancy are also shared. However, patients with Nijmegen breakage syndrome have microcephaly and do not have ataxia, oculocutaneous telangiectasia, or progeric skin change (5). Also, there is no elevation in serum AFP levels. Complementation analyses have shown that Nijmegen breakage syndrome and ataxia telangiectasia are different disorders (16), but both may be part of the same protein complex or pathway (8,18).

A new autosomal dominant chromosomal instability syndrome characterized by less breakage than in ataxia-telangiectasia and Nijmegen breakage has been reported. Anticipation was observed (4a). Stature

Immune deficiency with centromeric instability of chromosomes 1, 9, and 16 (ICF syndrome)

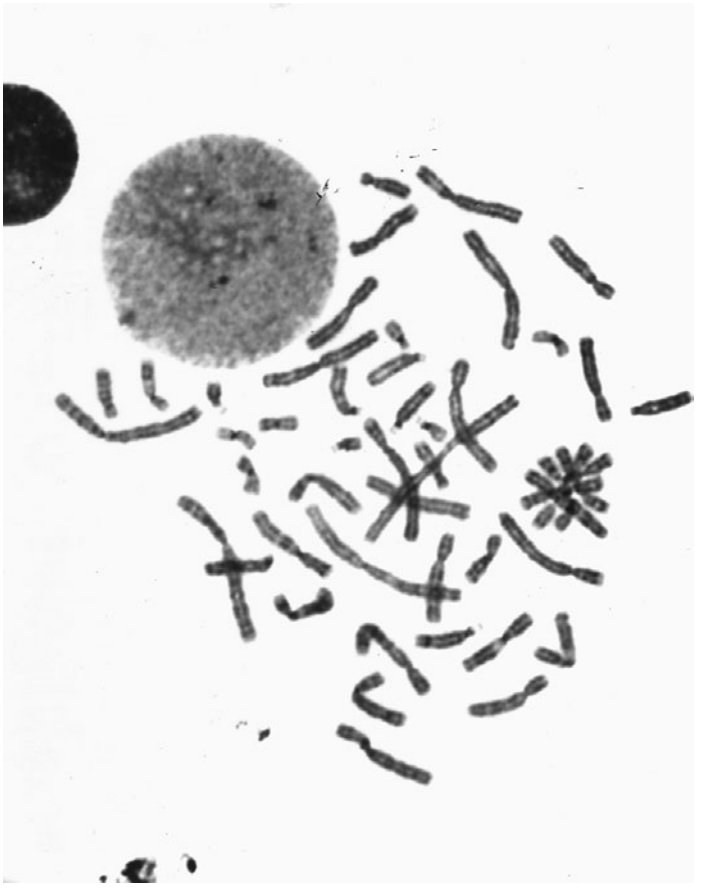
This syndrome, first reported in 1978 by Tiepolo et al (19) and briefly by Hultén (9), has been described in about 20 patients (1–22), including sibs (4,7,20,22). Parental consanguinity has been noted on a few occasions (2,4). There is no sex predilection. Autosomal recessive inheritance has been shown (21); the gene maps to 20q11–q13 (22). It has been characterized (24), but there may be genetic heterogeneity (23). The name ICF is an acronym for *I*mmunodeficiency, *C*entromeric heterochromatin instability, and *F*acial anomalies (14).

Facial changes. The facies is characterized by frontal bossing, hypertelorism, flat nasal bridge, small, upturned nose, epicanthic folds, and micrognathia. Protruding tongue has been a variable feature (6,7,11,14,17,21) (Fig. 4–55A). Cleft palate has also been found (8).

Growth and mental retardation. Mental retardation varies from mild (2,8) to severe (4). Most authors have indicated that growth has been below the 3rd centile.

Immune deficiency. Recurrent skin and chronic respiratory infections include bronchitis, bronchiectasis, pneumonia, sinusitis, and otitis media (3). Variable immune deficiency associated with at least two depressed immunoglobulin levels is a constant feature (7,13). Some patients suffer from persistent diarrhea (3,7,14,17). Others have defective cell-mediated immunity (3,4,9,20,22). Death from pneumonia has occurred in infancy or childhood in a number of children (4,9,22).

A



B

Fig. 4–55. *ICF syndrome.* (A) Facies characterized by frontal bossing, flat nasal bridge, small upturned nose, micrognathia, protruding tongue. (B) Multibranched configuration involving chromosomes 1, 9, and 16. (Courtesy of H Hinkel, Dresden, Germany.)

Other findings. Miscellaneous findings have included hydrocephalus (22), short stature (9), macrocornea (4), sparse, dry hair (2), hyperpigmented skin spots (3,5), bipartite nipples (5), umbilical hernia (22), shawl scrotum (5,8), and hypospadias (5,11).

Laboratory findings. In all cases there has been instability of paracentromeric heterochromatin of chromosomes 1, 9, and 16 (12). This has been manifest by despiralization, chromosome and chromatid breaks, triradials, somatic pairing and interchanges between homologous and nonhomologous chromosomes seen in variable numbers of peripheral blood lymphocytes. These appear as multiple branched configurations. Abnormalities can be seen in interphase nuclei using in situ hybridization with a probe specific for pericentromeric regions of chromosomes 1, 9, and 16 (12,15,18)(Fig. 4–55B). Fibroblast chromosomes appear to be essentially normal (12). Undermethylation of satellite DNA has been shown (10,16).

Chapter 5
Metabolic Disorders

Mucopolysaccharidoses

As in the last edition of this book, coverage of the mucopolysaccharidoses is essentially limited to those metabolic disorders that cause alteration in the facies of patients.

The mucopolysaccharidoses (MPS) are a family of inherited metabolic diseases that result from the deficiency of lysosomal enzymes involved in the degradation of the glycosaminoglycans (mucopolysaccharides; also designated MPS). These glycosaminoglycans (GAGs) include dermatan sulfate (DS), heparan sulfate (HS), and keratan sulfate (KS). Chondroitin sulfate (CS) may also be involved (11).

On the basis of clinical and biochemical studies, these disorders have been designated MPS I through MPS VII (11) (Table 5–1). Extensive reviews on various aspects of the MPS have been published (6,7,14,18). A deficiency of a specific lysosomal enzyme has been demonstrated in each of the MPS disorders. Each has autosomal recessive inheritance with the exception of Hunter disease (MPS II), which is X-linked recessive. Considerable progress has been made in the field of molecular genetics toward understanding these disorders (11) (Table 5–2).

Although the clinical phenotypes of these disorders are very heterogeneous, they share many features and permit provisional clinical diagnoses. For example, all of the disorders have characteristic skeletal abnormalities (termed "dysostosis multiplex"), with the exception of Morquio disease (MPS IV), which has quite different skeletal changes (15). Hearing, vision, and cardiovascular function may be affected (19). Joints are often stiff and marked short stature is observed, except in Scheie disease (MPS I-S). In addition, unusual hair, corneal clouding, hepatosplenomegaly, hearing loss, arteriosclerosis, and stiffening of the thoracic cage are common findings (16,17).

There is clinical similarity among different enzyme deficiencies and, conversely, a remarkable clinical heterogeneity within each of these diseases. For example, patients with MPS I-H, MPS I-S, and MPS I H/S have in common deficiency of α-L-iduronidase, an enzyme activity required to degrade DS and HS. The genes appear to be allelic (11). Patients with MPS I-H have severe dysostosis multiplex, short stature, and mental retardation and expire in childhood, whereas patients with MPS I-S have mild skeletal abnormalities, normal height, and normal intelligence and survive into adulthood. Patients with MPS I-H/S have an intermediate phenotype. The genes appeared to be allelic (10). Molecular genetic studies will make genotype–phenotype correlations possible (12). There have been several reports on the relative frequencies of the various types of MPS (8).

The suspected clinical diagnosis of patients with MPS is confirmed by the demonstration of the specific enzymatic defect in isolated leukocytes, cultured skin fibroblasts, or serum. Prenatal diagnosis following amniocentesis or chorionic villus biopsy is possible for all MPS (11). Identification of heterozygotes is becoming more definitive as specific mutations are identified.

Progressive deterioration generally leads to death in childhood, with the exception of MPS I-S, MPS IV, and the mild form of MPS VI; patients with these disorders survive into adulthood. Animal models that have facilitated the development of therapeutic strategies by supplying enzyme exogenously (3) have been described for MPS I (9,13), MPS VI (4), and MPS VII (5). The partial therapeutic success of bone marrow transplantation (BMT) has shown that cells of donor hematopoietic origin can assist in the removal of GAGs stored in various tissues of the host. But allogenic BMT is a high-risk procedure, thus development of somatic gene therapy, using retroviral vectors to introduce cDNA encoding the missing lysosomal enzyme into the patient's own bone marrow cells (11), has been encouraged.

Retrovirally transduced cDNA encoding α-L-iduronidase can restore normal GAG metabolism in deficient fibroblasts (1). Neither enzyme replacement nor retroviral vector-mediated gene therapy is thought likely to affect the central nervous system (11). However, MPS I patients with normal IQ scores before BMT maintained normal scores from 2 to 7 years post-transplantation (18). After BMT, cardiac function, e.g., left ventricular restriction, may be ameliorated (2,6).

The relative frequency of the mucopolysaccharidoses has been addressed and reviewed by Poorthuis (11a).

Table 5–1. Classification of the mucopolysaccharidoses

Type	Synonym	Clinical dysmorphism	Skeletal dysplasia	Corneal opacities	Mental retardation	Excessive urinary AMPS	Defective enzyme	Genetic transmission
I-H	Hurler	Severe	Severe	Yes	Yes	DS and HS	α-L-Iduronidase	AR
I-H/S	Hurler/Scheie	Intermediate	Moderate	Yes	No	DS and HS	α-L-Iduronidase	AR
I-S[a]	Scheie	Mild	Mild	Yes	No	DS and HS	α-L-Iduronidase	AR
II-A	Hunter A	Late (moderate)	Moderate	No	No	HS and DS	Iduronate sulfate-sulfatase	XR
II-B	Hunter B	Early (moderate)	Moderate	No	Yes	DS and HS	Iduronate sulfate-sulfatase	XR
III-A	Sanfilippo A	Mild	Minimal	No	Yes	HS	Heparan-*N*-sulfatase	AR
III-B	Sanfilippo B	Mild	Minimal	No	Yes	HS	α-*N*-acetyl glucosaminidase	AR
III-C	Sanfilippo C	Mild	Minimal	No	Yes	HS	Acetyl CoA:α-glucosaminide-*N*-acetyltransferase	AR
III-D	Sanfilippo D	Mild	Minimal	No	Yes	HS	α-*N*-acetylglucosaminide-6-sulfatase	AR
IV-A	Morquio A	Severe	Severe	Yes	No	KS	Galactosamine-6-sulfate-sulfatase	AR
IV-B	Morquio B	Severe	Severe	Yes	No	KS	β-galactosidase	AR
VI-A	Maroteaux-Lamy A	Mild to moderate	Moderate	Yes	No	DS	Arylsulfatase B	AR
VI-B	Maroteaux-Lamy B	Severe	Severe	Yes	Mild	DS	Arylsulfatase B	AR
VII	Sly	Severe	Severe	None	Late	DS and HS	β-glucuronidase	AR

[a]Formerly classified as type V.
AMPS, acid mucopolysaccharide; DS, dermatan sulfate; HS, heparan sulfate; KS, keratan sulfate.

Mucopolysaccharidosis I-H (Hurler syndrome). Mucopolysaccharidosis I-H (MPS I-H) was first described in 1919 by Hurler (20) at the suggestion of Von Pfaundler who was from the same clinic. It is the classic prototype of the MPS, having the following cardinal features: growth failure after infancy, marked mental retardation, characteristic craniofacial dysmorphism and physical habitus, dysostosis multiplex, corneal clouding, histochemical and biochemical evidence of intracellular lysosomal storage of GAGs, and excessive urinary excretion of DS and HS.

The onset of symptoms is in the first year of life (8). During the first months of life there are a few relatively nonspecific findings, such as hernias, macrocephaly, limited hip abduction, and recurrent respiratory infections.

Skeletal abnormalities become apparent at around the age of 6 months. Acute cardiomyopathy associated with endocardial fibroelastosis has been a presenting feature in several infants with MPS I less than 1 year of age (4,12). The full clinical picture usually develops in the second year of life (Figs. 5–1 to 5–5). Death most often occurs before 10 years of age from pneumonia and cardiac failure. Intrafamilial variability in Hurler syndrome has been reported in a limited number of families in which sibs with comparable deficiencies of α-L-iduronidase in vitro showed a divergence in clinical severity and disease progression (25).

The frequency of mucopolysaccharidosis I-H is approximately 1/144,000 births (23). Similar data stem from the Netherlands (33a). More recent data from Northern Ireland revealed an incidence of approximately 1/76,000 live births (29). The specific enzymatic defect is

Table 5–2. Chromosomal assignment of structural genes for lysosomal enzymes that degrade glycosaminoglycans

Mucopolysaccharidosis	Enzyme	Chromosome region
MPS I	α-L-iduronidase	4p16.3
MPS II	Iduronate 2 sulfatase	Xq28
MPS III-A	Heparan-*N*-sulfate	17q25.3
MPS III-B	α-*N*-acetylglucosaminidase	17q21
MPS III-C	Acetyl CoA:α-glucosaminide-*N*-acetyltransferase	14(?)
MPS III-D	α-*N*-acetylglucosamine-6-sulfate sulfatase	12q14
MPS IV-A	Galactosamine 6-sulfate sulfatase	16q24.3
MPS IV-B	β-galactosidase	3p21-p14.2
MPS VI	Arylsulphatase B (*N*-acetylgalactosamine-4-sulfatase)	5q13
MPS VII	β-glucuronidase	7q21.11

Fig. 5–1. *Hurler syndrome*. (A–D) Characteristic facies with large head, prominent forehead, coarse features, hypertelorism, heavy lids, low nasal bridge, snub nose, long philtrum, and open mouth. (A,D courtesy of RJ Desnick, New York, New York. C courtesy of E Passarge, Hamburg, Germany.)

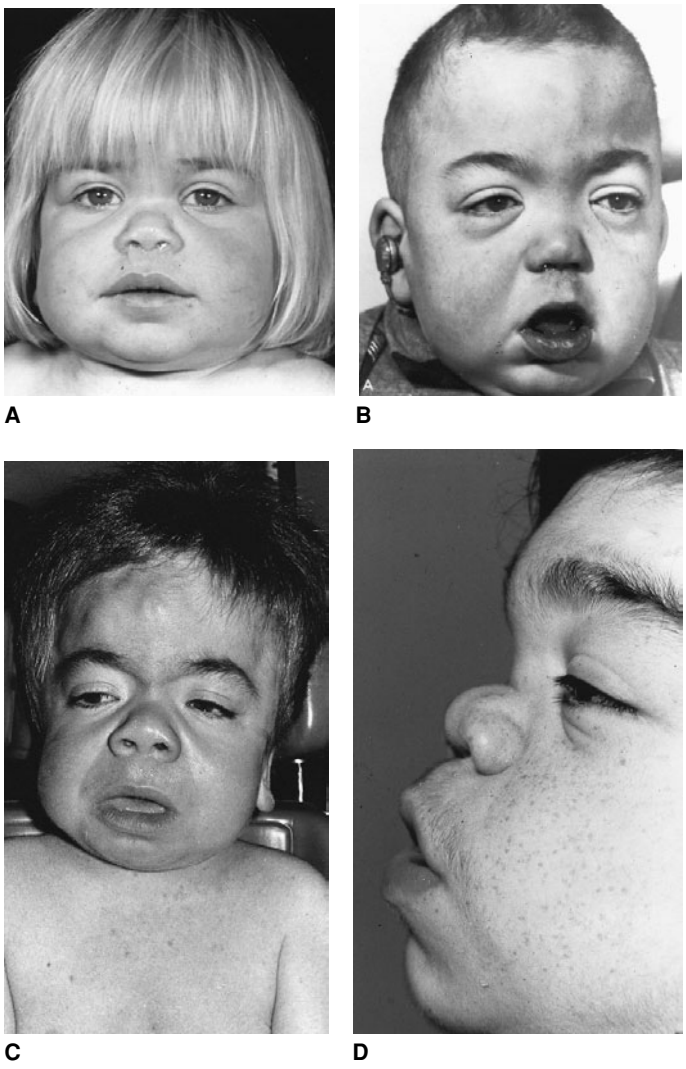

Fig. 5–2. *Hurler syndrome*. Two-year-old girl. Note characteristic facies and gibbus.

deficiency of α-L-iduronidase (IDUA) activity, lack of which precludes intralysosomal degradation of the α-L-iduronide-containing GAGs, DS, and HS. IDUA has been localized to chromosome 4p16.3 by in situ hybridization and confirmed by Southern blot analysis (35,36). In MPS I, molecular heterogeneity has been reported (7). It has been treated by bone marrow transplantation (13,18).

Facies. A slight coarsening of facial features at 3–6 months of age is usually the first abnormality noted. The head is large, and the frontal bones bulge. Premature closure of the sagittal and metopic sutures and hyperostosis in this area frequently lead to scaphocephaly. Hirsutism is represented on the face only as synophrys. The nasal bridge is depressed, the tip of the nose is broad, and the nostrils are wide and anteverted. The interpupillary distance is greater than normal. Generally, corneal clouding appears during the third year of life. Glaucoma may be an early complication (31). The lower eyelids and nasolabial folds are prominent, and the cheeks are full. The earlobes are thick. The lips are enlarged and patulous, and the mouth is usually held open, particularly after the age of 3 years. Chronic nasal discharge is usually marked, even between the frequent bouts of upper respiratory infection (Fig. 5–1). Nasal congestion with stertorous breathing through the mouth is severe, as it is related to hyperplastic adenoid tissue and a deep cranial fossa that narrows the airway between the sphenoid bone and the hard palate. Gag and swallowing reflexes become progressively diminished (22).

Musculoskeletal system. Length at birth is not below the norm. Most MPS I-H patients between the ages of 6 and 12 months are at or above the 87th centile for total body length. Some remain among the tallest infants until 18 months, but growth ceases in all patients before 2 years of age. By age 3 years, all MPS I-H patients are below the third centile for stature. The neck is short; a serious complication is subluxation of C1–C2 (3,45). Both pectus carinatum and excavatum occur, and usually there is lumbodorsal kyphosis or gibbus (Fig. 5–2). Range of motion is limited in all joints; in the hands, the so- called clawhand deformity (Fig. 5–3) results.

Fig. 5–3. *Hurler syndrome*. Clawhand deformity.

Radiographically, in infancy, bone trabeculation is coarse. In late infancy and early childhood, a pattern of skeletal changes called "dysostosis multiplex" emerges: the skull becomes large and deformed, the sphenoidal plane is depressed, and the sella is J-shaped, possibly from arachnoid cysts (Fig. 5–4A). The sagittal and lambdoid sutures close prematurely. The cranial base and orbital roofs are particularly thick and dense. The orbits are shallow. Communicating hydrocephalus, which is usually associated with increased intracranial pressure, is often present. The stylohyoid ligament is almost always calcified (normal, 25%) and thicker than normal (32). The ribs are wide in their lateral and ventral portions, with overconstriction at their paravertebral ends (Fig. 5–4B). The vertebral bodies are dysplastic, with biconvex endplates and hook-shaped configuration of the lower thoracic and upper lumbar bodies, after 12–18 months of age (Fig. 5–4C). The basilar portions of the ilia are underdeveloped, with flaring of the iliac wings (Fig. 5–4D). The long tubular bones show marked diaphyseal widening and distortion, with small and deformed epiphyses. The shafts of the short tubular bones are underconstricted, with bullet-shaped phalanges and proximal pointing of the second to fifth metacarpals (Fig. 5–4E) (42).

The abdomen protrudes because of hepatic and splenic enlargement, deformity of chest, shortness of spine, and laxity of abdominal wall. These changes are noted during the second year of life. Hepatomegaly may be detected as early as 1 month of age.

Inguinal hernia, present at birth or developing within the first 3 months of life, is a constant feature in boys. The hernias tend not to recur following surgery; they are a classic part of the patient's history before diagnosis is established but are not common during the subsequent course of the disorder. Umbilical hernias, usually small at birth in both sexes, gradually reach major proportions.

Other findings. The skin is pale, coarse, and dry and is covered with fine, lanugo-like fuzz, particularly on the back and extremities. Mental retardation is conspicuous and progressive. Moderate cardiomegaly, as a result of deposition of acid mucopolysaccharide (AMPS) in the myocardium and valves, is usually present (43). Echocardiographic mitral valve deformity has been demonstrated (21). Hypertension is a frequent finding in older patients (44).

Oral manifestations. Oral changes (Fig. 5–5) have been reviewed by Gardner (15). The lips are enlarged and patulous, with flattened philtrum, and the upper lip is particularly long. The mouth is usually held open, with protruding tongue, from about 3 years of age. Lip and tongue enlargement becomes marked after the age of 5 years (22).

The teeth are widely spaced, often exhibiting severe attrition. The incisors may exhibit some degree of conical crown form but are otherwise normal structurally. Because of macroglossia, there may be anterior open bite. Eruption is probably delayed in at least half of the patients (6), particularly in areas of bone destruction. The second primary molars or first and second permanent molars are often distoangularly positioned, with the distal surface of the crown being situated more deeply than the mesial. In some cases, there is dilaceration of the distal roots (48). These changes occur more frequently in the mandible.

Extremely common are localized areas of bone destruction that have been designated "dentigerous cysts." These are often present by 3 years of age and more often involve the second primary molars and first and second permanent mandibular molars. The margins of the radiolucencies are usually smooth and clearly defined (6,14,19). We believe that the cysts represent pooling of dermatan sulfate in hyperplastic dental follicles, since they also occur in MPS I-S and MPS VI but not in MPS III. However, the material in the follicles in MPS VI has been shown to be hyaluronic acid (vide infra).

The alveolar ridges are nearly always hyperplastic, resulting in spacing of the teeth. Some patients exhibit hyperplastic gingivitis, because of poor oral hygiene and mouth breathing. Rarely, there is true hyperplastic

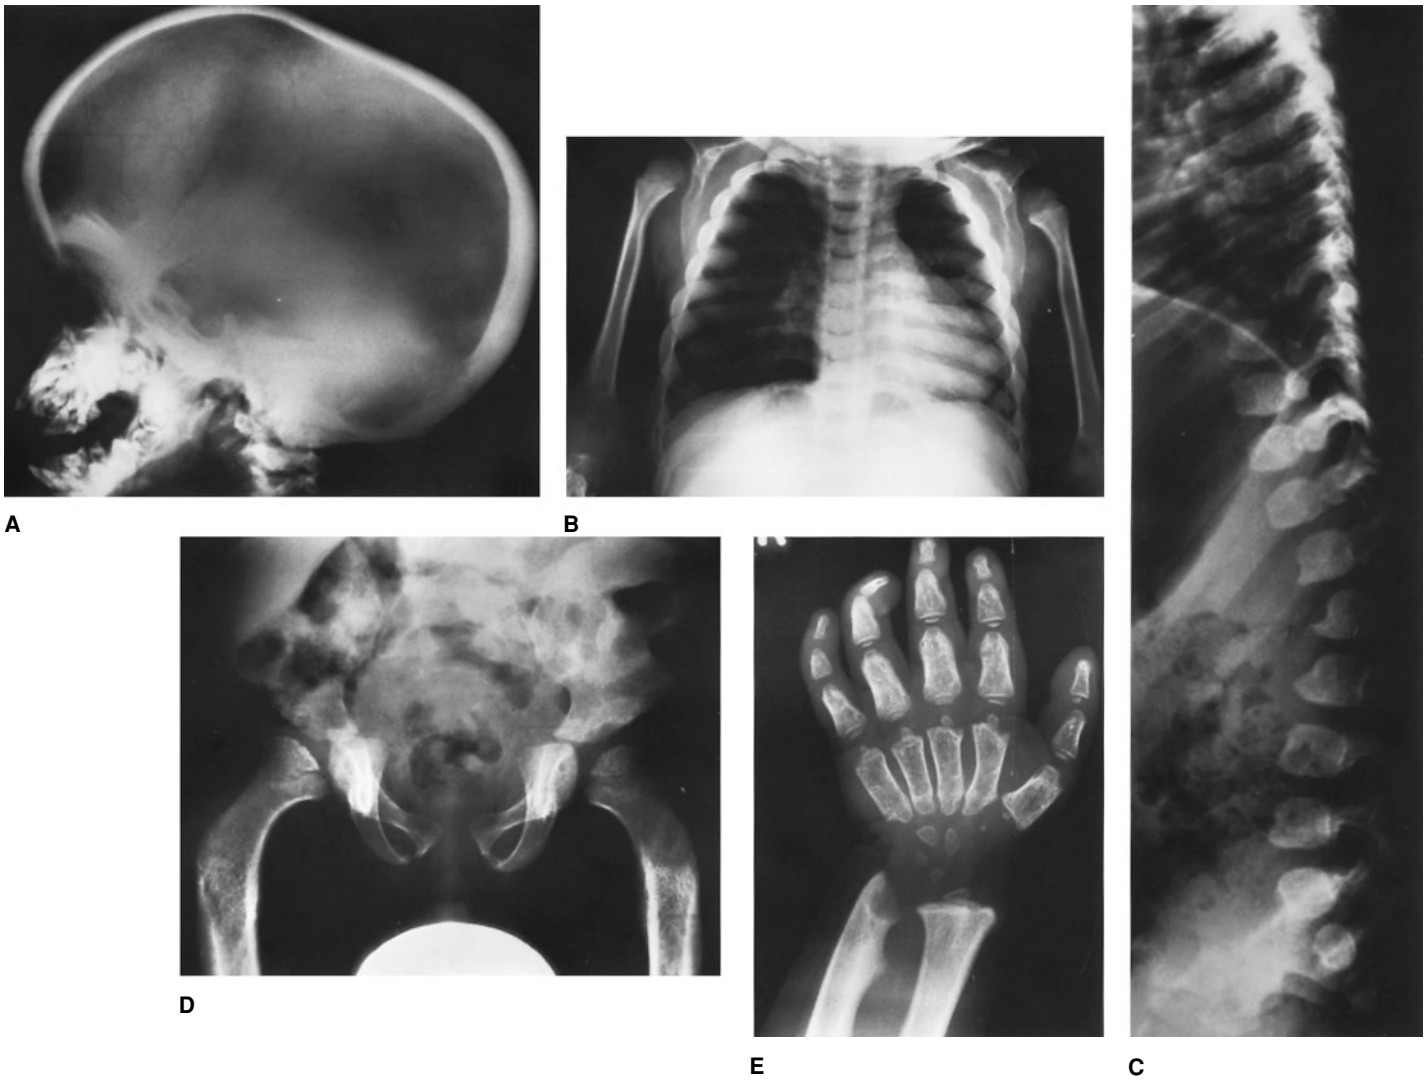

Fig. 5–4. *Hurler syndrome*. Radiographs. (A) Skull of 8-year-old patient with macrocephaly, dolichocephaly, thickened calvaria, and wide sella. (B) Chest of same patient, showing wide, oar-shaped ribs, expanded medial portion of clavicle, valgus deformity of humeral neck, submetaphyseal overconstriction of proximal humerus, and expansion of distal shaft of humerus. (C) Spine of 4-year-old patient with flattening and biconvex endplates of vertebral bodies, and hooked-shaped configuration of first two-thirds of the lumbar vertebrae. (D) Pelvis of 8-year-old patient, showing hypoplasia of basilar portion of ilia, flared iliac crest, long femoral neck, and coxa valga. (E) Hand of 6-year-old patient, with expanded shafts of short tubular bones, bullet-shaped phalanges, proximal pointing of second to fifth metacarpals, small carpal bones, and tilted distal ends of radius and ulna.

gingiva with eruption cysts (14). Histochemical study of the gingiva has demonstrated metachromatic cells (14).

The mandible is short and broad, with a wide bigonial distance (48). The rami are short and narrow, and the condyle is replaced by a flat, inclined surface or cup-shaped excavation (24). The mandibular notch is irregular or cleft. The temporomandibular joint may exhibit limited motion. Airway obstruction and sleep apnea have been reported (28,41).

Diagnosis. The earliest diagnostic tests for the MPS syndromes were based on the urinary excretion of GAGs. A great number of methods have been devised, ranging from semiquantitative spot tests to precise qualitative and quantitative measurements (33). Spot tests are quick and inexpensive but have the disadvantage of both false-positive and false-negative results (11).

Although the reported ratios vary significantly, there is generally more DS than HS found in MPS I-H. It is generally more efficient to omit extensive analysis of urinary GAGs and to proceed to the enzyme assay directly. In MPS I-H, the deficiency of α-L-iduronidase can easily be detected in isolated leukocytes or cultured fibroblasts (17), using artificial (fluorogenic, chromogenic, or radioactive) substrates. Heterozygote testing has been complicated by the marked overlap of normal and carrier groups (47), but presently DNA analysis can be used to give unambiguous information on the carrier state. Prior to undertaking carrier testing in a family, it is necessary to identify the mutant allele in that particular family, because there is a marked genetic heterogeneity in MPS-I, leading to a broad range of clinical phenotypes (35,40). Prenatal diagnosis is possible on cultured amniotic fluid cells, but because of the long waiting time for culturing and testing, rapid enzyme testing in chorionic villus biopsies has been developed. Diagnosis of MPS I on the enzyme level may present some difficulties because normal villi may have low activity (50). When the specific mutation in a given family is known, DNA analysis can be used for prenatal diagnosis, giving the most reliable results.

Laboratory aids. α-L-iduronidase, the 653 amino acid enzyme protein deficient in the MPS-I disorders, has been purified to homogeneity from a number of human sources and has been extensively characterized (9,10). The enzyme is a monomer that is proteolytically processed within the lysosome to a number of unique peptide species, which have been shown to form catalytically active aggregates (9).

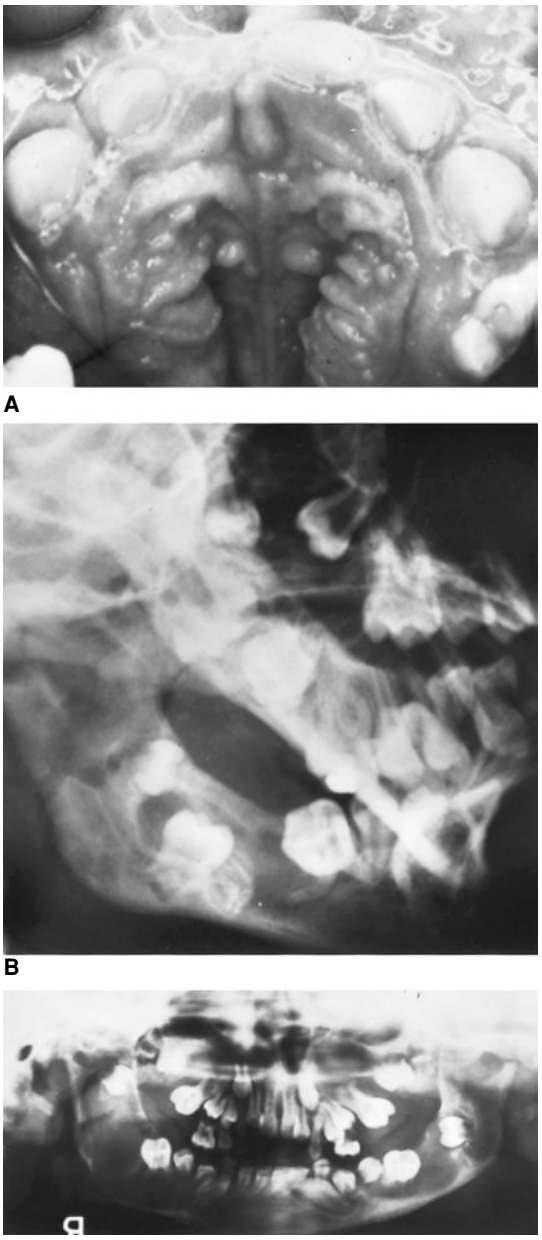

Fig. 5–5. *Hurler syndrome*. (A) Widened alveolar processes. (B) Note distoangular mandibular first molar with dilaceration of distal root, cystic bone destruction around first and second mandibular molars, partially inverted mandibular third molars in ramus, and clearly discernible cleft in mandibular notch. Condyle is hypoplastic. (C) More extensive alterations in a 9-year-old male with mucopolysaccharidosis. (A courtesy of Maj J Fay, US Army. B from HM Worth, Oral Surg 22:21, 1966. C from MA Germann, Dtsch Zahn Mund Kieferheilkd 59:59, 1972.)

Individuals with MPS-IH have from 0.0% to about 1% of normal enzymatic activity, depending on the substrate and assay conditions used. The milder forms of MPS I, Scheie and Hurler-Scheie syndromes, are likely to have at least one mutant allele that permits some residual activity (30).

The gene encoding α-L-iduronidase (*IDUA*) has been mapped to chromosome 4p16.3 (36). It consists of 14 exons spanning a distance of 19 kb, and contains a large intron (13 kb) that separates the second from the third exon (38). In the canine *IDUA* gene, a similar architecture has been found (26). There is also a murine counterpart (34).

Scott et al (37,39) found *W402X, Q70X* and *P533R* to account for over half the MPS mutations in a population of European origin. In a group of 27 Italian patients, the two most common mutations in northern Europeans (*W402X* and *Q70X*) (4) accounted for 11% and 13% of the alleles, respectively (16). In Caucasians, homozygosity or compound heterozygosity for the nonsense mutations *W402X* and *Q70X* are the common causes of MPS-I with a severe form of Hurler syndrome while the presence of *R89Q* may lead to a milder phenotype (49). In contrast, the 704ins5 and the *R89Q* mutations were the two most common MPS-I mutations in Japanese populations (49). Additional studies in a Libyan/Jewish patient (27) and in Druze and Muslim Arab patients in Israel (2) have indicated that there is marked genetic heterogeneity of MPS I-H alleles both between and within ethnic groups (5,46).

α-L-iduronidase pseudodeficiency has also been described, the proband showing clinical features of MPS I and II (1). The proband, his sister, and his father were found to be heterozygous for the common *W402X IDUA* mutation. The novel *IDUA* mutation *A300T* was identified in the proband, his sister, and his mother, which accounted for reduced IDUA activity in these individuals. They also had the *R468W* mutation, common in iduronate-2-sulfatase deficiency, which leads to the Hunter syndrome (1).

Mucopolysaccharidosis I-S (Scheie syndrome). Sibs with mucopolysaccharidosis I-S (MPS I-S) were described in 1962 by Scheie et al (8). Patients referred to in the older European literature as having "late Hurler disease" may have had the same condition (9,10).

The disease is rarely recognized in childhood. It is characterized by normal stature, corneal opacities, deformity of the hands (clawhands), involvement of the aortic valve, normal intelligence, and biochemical evidence of lysosomal storage of HS and DS and their excessive urinary excretion.

The disorder has autosomal recessive inheritance. Its frequency has been estimated at 1/500,000 (5) to 1/600,000 (4) live births. Abnormal intracellular accumulation of DS and HS results from the deficient activity of α-L-iduronidase, the same enzyme deficiency responsible for MPS I-H (1). It is now clear that MPS I-H and I-S are caused by allelic mutations (6). The milder forms of MPS I, the Scheie and Hurler-Scheie syndromes, are likely to have at least one mutant allele that permits some residual enzyme activity. In MPS I-S, various mutations have been described (12,13).

Facies. No major abnormalities are noted in early childhood: symptoms usually become apparent by 5–15 years of age. In adults, the face is somewhat coarse, but not Hurler-like. It is broad with increased midfacial height and with mandibular prognathism. In most cases, the corners of the mouth are turned downward. Macroglossia may be present. Occasionally, the nose is broad and the nares are wide. Corneal clouding starts in early life and is initially peripheral, but by the third or fourth decade the corneal dystrophy can severely curtail vision (Fig. 5–6).

Skeletal system. Patients are normal or near-normal in height. The neck may be short. In some, the trunk is relatively shorter than the extremities. Hands and feet are broad and short, and fingers and toes are fixed in a clawlike position (Fig. 5–7). The range of mobility is limited in all joints. Genua valga and pes cavus are common (3).

The most prominent radiographic changes are small carpal bones and claw deformity of the fingers. Cystic changes are frequent in the carpals and metacarpals.

The carpal tunnel syndrome, complicated by median nerve entrapment, is common. In addition, there are widened ribs and sometimes mild hypoplasia of the basilar portion of the iliac bones.

Other findings. Intelligence is usually normal. Liver and spleen may be enlarged. Rarely, peripheral corneal clouding has been found (11). Inguinal and/or umbilical hernias are frequently present. Most adult patients show signs of aortic stenosis and/or regurgitation. The murmurs are detected in childhood, but are not clinically significant until maturity. Valve replacement has been reported, although experience is limited (2). Compression of the cervical cord by thickened dura, pachymeningitis cervicalis, with resulting myelopathy can occur in MPS I-S, though less commonly than in MPS I-H/S (7). Life span is normal or may be reduced because of cardiac disease.

Oral manifestations. The oral changes are similar to those seen in MPS I-H, MPS II, and MPS VI—i.e., cystic changes around unerupted first permanent molars. The mandibular condyles are underdeveloped.

Laboratory aids. As is true in MPS I-H, diagnosis may be readily accomplished by direct assay for α-L-iduronidase activity in isolated leukocytes or cultured skin fibroblasts (7). In childhood and late adolescence, pseudo-Hurler polydystrophy should be excluded, since the body habitus of young patients with this condition may be similar to that in MPS I-S. However, in pseudo-Hurler polydystrophy the GAG excretion is normal, the corneae are usually clear, and there is mental retardation.

Mucopolysaccharidosis I-H/S (Hurler-Scheie syndrome). McKusick et al (7) described a third disorder having a phenotype intermediate between Hurler syndrome and Scheie syndrome, designated Hurler-Scheie disease (MPS IH/S). This disorder is also caused by a deficiency of α-L-iduronidase that results in lysosomal accumulation of DS and HS. The fact that MPS I-H/S patients have milder phenotypes than MPS I-H individuals and more severe manifestations than MPS I-S patients suggests that MPS I-H/S patients have the genetic compound of MPS I-H and I-S alleles (3,7,8). Earlier reports of MPS I-H/S patients from consanguineous parents indicated that these patients did represent the expression of other mutant alleles at the α-L-iduronidase locus (4). Molecular genetic studies have supported this supposition and have provided additional information for genotype-phenotype correlations (17). The incidence in Northern Ireland has been estimated at 1/280,000 (9).

Clinical manifestations of the disease are usually evident between 3 and 8 years of age (1,5,10) and survival to adulthood is common. Affected individuals have certain features in common with MPS I-H patients, including marked short stature, dysostosis multiplex, hepatosplenomegaly, umbilical and/or inguinal hernias, and corneal clouding (Fig. 5–8) (1,13,16,19). However, the symptoms present later and are milder than those seen in MPS I-H patients at the same age. The disease is progressive, particularly with regard to cardiopulmonary disease, and death usually occurs by age 25 years (18) due to cardiac involvement and upper airway obstruction. Nearly all patients are mentally normal (1). Psychotic symptoms have been observed in older patients (2). Other anomalies include hearing loss (12%), thickened skin (25%), hirsutism (20%), and carpal tunnel syndrome (10%) (1). In a 5-year-old boy with MPS I-H/S, diffuse thickening of the skin and clustered, skin-colored papules on the upper portions of thighs, scapular area, and sides of the arms were reported (14). Earlier, these papules were supposed to be unique findings in MPS II (12). Pachymeningitis cervicalis, compression of the cervical cord due to mucopolysaccharide accumulation in the dura, occurs in MPS I-H/S, but communicating hydrocephalus appears to be uncommon in patients with normal intelligence (10). Severe nasal polyps have been documented (6).

Oral findings. Oral findings are similar to those found in MPS I-H patients. Some patients with MPS I-H/S have micrognathism that creates a characteristic facies (10). Particular care must be taken in the induction of anesthesia (11). Airway obstruction and sleep apnea have been reported, as in both Hurler and Hunter syndromes.

Laboratory aids. The diagnosis of MPS IH/S can be confirmed by demonstration of deficient α-L-iduronidase activity in isolated leukocytes or cultured fibroblasts, or by the massive urinary excretion of DS and HS. Residual α-L-iduronidase activity has been detected in all three MPS I subtypes. By characterization of the allelic mutations at the molecular level, classification of patients with MPS I-H, I-S, and I-H/S has become possible (15,17). Finally, it is anticipated that the explanation for the

presence of severe neurologic manifestations in MPS I-H and I-H/S and their absence in MPS I-S patients will provide further insight into the pathogenesis of α-L-iduronidase deficiency.

Mucopolysaccharidosis II (Hunter syndrome). The first patients manifesting the X-linked form of MPS were reported by Hunter in 1917 (18). These two brothers were mildly affected at ages 8 and 10 years, respectively, with clear corneas and apparently normal intelligence. Although they died at 11 and 16 years, they probably suffered from the mild form of the disease (MPS II–mild), which is compatible with survival to adulthood (41,49,55). In the severe form (MPS II–severe), which occurs three to four times more frequently than the mild form, rapid motor deterioration and progression of physical deformities may be observed after the third year of life, with death usually occurring between 4 and 14 years of age (41,56).

A deficiency of the enzyme iduronate-2-sulfatase (IDS) is the cause of both forms of Hunter syndrome (MPS II) (1), resulting in progressive accumulation of DS and HS. Approximately 20% of the patients have deletions of the whole gene or major structural alterations (7,16,21,29). An IDS-related region (IDS2) has been found which is located on the telomeric side of the *IDS* gene at Xq28 within 80 kb (4).

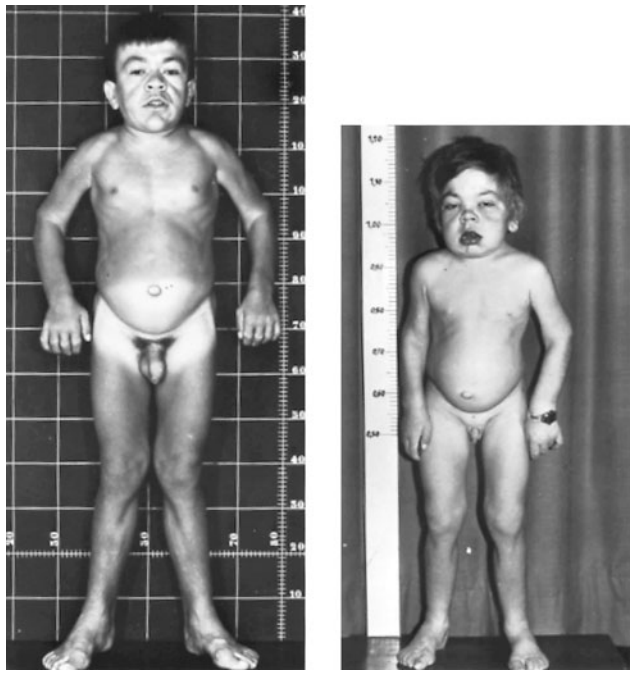
In patients with the severe Hunter syndrome, molecular and phenotypic variation is great (47,51). Missense or nonsense point mutations as well as deletions of various numbers of base pairs have been described (6,17a,19,20a,21a,22,44). Mutation "hot spots" have been noted (31). In two patients with Hunter syndrome who had a complete deletion of the *IDS* gene, features were seen that were uncommon in this syndrome (53)—e.g., early onset of seizures and ptosis. Contiguous gene syndromes were postulated (53). Truncation of the last 108 amino acids of iduronate sulfatase permitted an intermediate clinical phenotype of Hunter syndrome and a trace of residual enzyme activity (43). Recently, it was demonstrated in a patient with features of moderate to severe Hunter syndrome that a complete lack of expression of IDS is consistent with the moderate to severe phenotype (48). There is certainly molecular and phenotypic variation (47).

Incidence of MPS II has been estimated at 1/78,000 to 1/111,000 male births in British Columbia (23). In Northern Ireland, the incidence has been estimated 1/72,000 male live births (26). It may be more common among Jews (34,57).

Data about the number of new mutations vary from 25% (8) to 100% (20). MPS II in female patients is a rare occurrence that requires nonfunctionality of the *IDS* gene on both X chromosomes (27). Interestingly, full expression of the MPS phenotype has been observed in two females, one with an X/5 translocation breakpoint presumably involving the region Xq26 (33), the other with a small X chromosome deletion involving band Xq25 (5). Tools for the genetic analysis of similar patients have been developed (12). Hunter syndrome has also been reported in karyotypically normal females (9,45).

Facies. Macrocephaly is present, with all measurements being enlarged. The facies, although similar to that observed in MPS I-H, is sufficiently different as to be distinguishable. Although all MPS I-H facies are very similar as a whole, the facies of any MPS II patient bears a coarse resemblance to the facies of family members. The facies of patients with the more common MPS II–severe form is usually more striking than that of the milder form (41,55) (Figs. 5–9 and 5–10).

Skeletal system. The neck is short, the chest is broad, and the abdomen protrudes with umbilical hernias. Moderate thoracolumbar kyphosis may be present. The trunk is relatively shorter than the extremities. Joint mobility is restricted, with clawlike deformities of the fingers. The gait is stiff, with the trunk bent forward. Typically, there is shortness of stature only from about 3 years of age; however some patients are not dwarfed until 5 or 6 years of age. Patients with the severe form of MPS II grow as fast or faster than healthy children during the first 2–3 years of life. Adults with a mild type reach a height of between 120 and 140 cm (55), whereas patients with the severe form reach a height of between 105 and 115 cm.



A B

Fig. 5–9. *Hunter syndrome*. (A) Sixteen-year-old male with mild MPS II. He has mild coarseness of facies with broad face, low nasal bridge, joint contractures, and genua valga, as well as mixed hearing loss and normal intelligence. (B) Thirteen-year-old patient with severe MPS II. Growth retardation is evident, and he has abundant and coarse scalp hair, coarse facies, low nasal bridge, and open mouth. (A from UN Wiesmann and S Rampini, Helv Paediatr Acta 29:73, 1974).

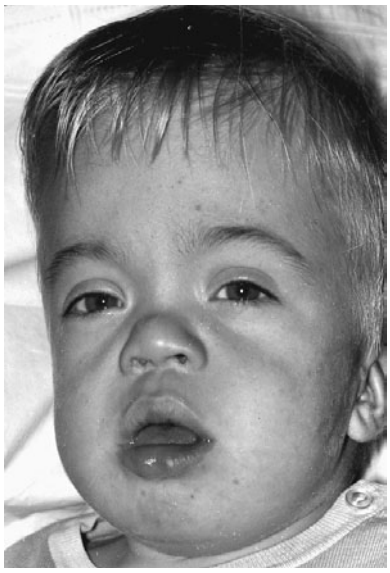
Radiographic changes are qualitatively similar to, but quantitatively less pronounced than, those observed in MPS I-H when compared at identical ages (41).

Other findings. Intelligence is only slightly impaired in the mild form. In the severe type, there is progressive loss of intellectual function after the age of 2–3 years. In retrospect, it can be seen that intellectual function of these patients never was normal. At 3 years of age, patients may be brought to a physician because of lack of speech. Patients become restless, hyperactive, and destructive (2,56). Diarrhea due to autonomic nervous system involvement and perhaps also to mucosal dysfunction is common (56). Hepatosplenomegaly, inguinal, and/or umbilical hernia, and cardiovascular defects are often found (32).

Eye findings. Corneal clouding does not occur in either the mild or severe forms with rare exception (42). Optic nerve head swelling and optic atrophy have been described (10). Vision may be impaired because of retinitis pigmentosa or chronic papilledema associated with chronic hydrocephalus. Two brothers were reported with bilateral epiretinal membranes (25).

Central nervous system. The central nervous system deterioration is probably exacerbated by moderate to severe communicating hydrocephalus with increased intracranial pressure after the age of 7 to 10 years (27,39). In a 44-year-old Japanese male with a mild type of Hunter syndrome, cranial magnetic resonance imaging (MRI) revealed patchy areas of increased and decreased signals in the thalamus and basal ganglia giving rise to a honey comb–like appearance as a whole (40). Thickening of soft tissue posterior to the odontoid peg was present with associated canal stenosis in five cases studied, resulting in compression of the cervical cord in four (28).

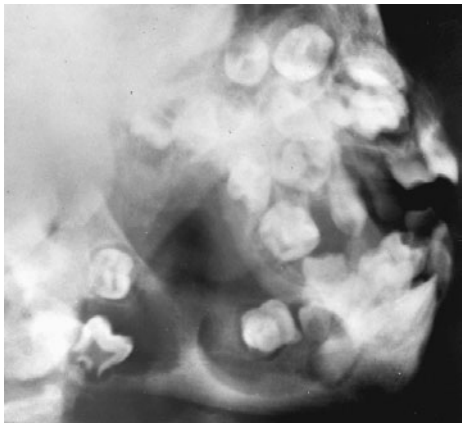
In both forms of the disease, progressive hearing loss occurs in most patients. It is often of the mixed type but may be predominantly conductive or sensorineural (35).



A

B

C



D

Fig. 5–10. *Hunter syndrome*. (A) Coarse facies, low nasal bridge, and open mouth. (B) Compare facies with patient in A. (C) Clawhands. (D) Radiograph showing cysts around crowns of malaligned teeth. (B,C from E Passarge et al, Dtsch Med Wochenschr 99:144, 1974. D from HM Worth, Oral Surg 22:21, 1966.)

Skin findings. Skin changes, present in a minority of patients, consist of hard, nontender, irregularly shaped papules (pebbling of skin) varying in size from a few millimeters to a centimeter in diameter located over the scapulae and deltoid areas (30,46). These papules are also found in MPS I-H/S (36).

Oral findings. Oral characteristics are the same as those in Hurler syndrome (14).

Complications. Patients with the severe form usually die by 15 years of age; death is preceded by complications of progressive neurologic deterioration. Cardiopulmonary disease, primarily resulting from infiltrative valvular disease, is a common cause of death. In contrast, patients with the mild form typically live into the sixth and seventh decades of life. Disease complications in these adult patients include carpal tunnel syndrome with medial nerve entrapment, degenerative disease of the hips, compromised respiratory function, and sleep apnea (38).

Laboratory findings. Most patients with MPS II excrete approximately equal amounts of DS and HS in the urine, which is readily determined by routine screening tests. Alder-Reilly granules may be present in peripheral granulocytes and bone marrow cells. Lymphocytes show metachromatic granules within vacuoles following toluidine blue staining. Ultrastructural studies show single membrane-bound structures that are even evident on conjunctival biopsy (24).

Hemizygotes with both forms of MPS II can be enzymatically diagnosed by the demonstration of iduronate sulfatase deficiency in serum, isolated leukocytes, and cultured fibroblasts (13,50). Carrier detection is more difficult because of random X-inactivation, but has been accomplished by enzymatic and DNA techniques (3,37,52,54). Germline mosaicism has been reported in MPS II (3,17). Prenatal diagnosis has been carried out in hemizygotic males and heterozygous female fetuses as well (11,15).

Mucopolysaccharidosis III (Sanfilippo A, B, C and D syndrome). Mucopolysaccharidosis III (MPS III) was first recognized in 1958 by Meyer et al (23) and later described by Meyer et al (24) and Sanfilippo (30). The disease is characterized by severe mental and neurologic degeneration associated with relatively mild MPS features resulting from the progressive lysosomal accumulation of HS (7).

Four enzymatic steps are required for the normal degradation of HS, and deficiency of each enzyme in the pathway has been found in patients with MPS III (see Table 5–1). MPS IIIA results from deficient heparan-*N*-sulfate activity (22,33), MPS IIIB from defective α-*N*-acetylglucosaminidase activity (28,40), MPS IIIC from deficient α-*N*-acetyltransferase activity (16), and MPS IIID from deficient α-*N*-acetylglucosamine-6-sulfate sulfatase activity (5). An animal model of MPS IIID has been reported (36). Most notably, all four enzymatic defects result in the lysosomal accumulation of HS and cannot be differentiated phenotypically. All four subtypes have autosomal recessive inheritance. Taken together, the MPS III subtypes represent the most common type of mucopolysaccharide disorders, their frequency having been estimated at about 1/24,000 in The Netherlands (28a,38) and 1/280,000 in Northern Ireland (25). Because of the mild somatic phenotype of MPS III subtypes, the frequency estimate may be lower than the actual incidence of the disease. MPS IIIA is found most often in the United States and the United Kingdom while MPS IIIB is more common in Greece (2,37).

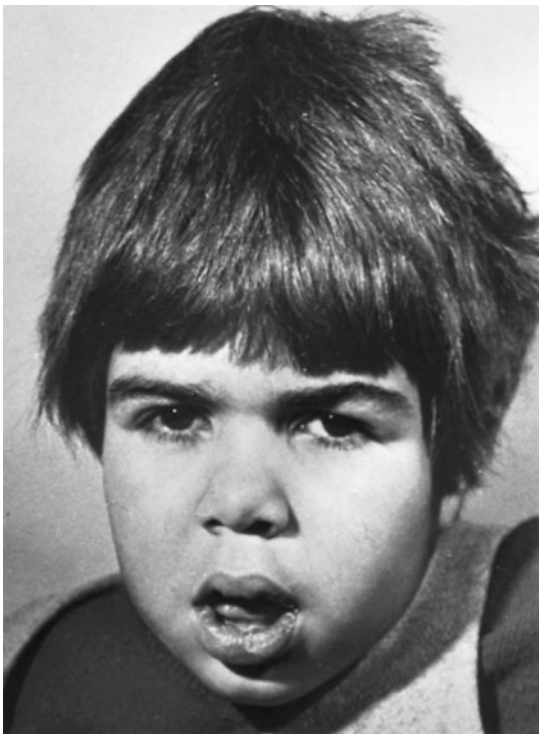

Fig. 5–11. *Sanfilippo syndrome*. Seven-year-old girl with MPS III. Note coarse features and thick abundant scalp hair. (From E Passarge et al, Dtsch Med Wochenschr 99:144, 1974.)

The isolation, sequence, and expression of cDNA clones encoding the enzyme deficient in MPS IIIA has been reported. The gene has been mapped to 17q25.3 (14,33). Mutational analyses have been reported from various ethnic groups, thus facilitating molecular diagnosis of MPS IIIA and allowing heterozygote testing in these populations (3,4). A late onset type has been described (1b).

The gene for α-*N*-acetylglucosaminidase, the enzyme involved in MPS IIIB, has been cloned, mapped to 17q21, and symbolized as *NAGLU* (43,44). Subtype IIIC has been mapped to chromosome 14 and IIID to 12q14. Additional mutations have been reported (32) and attempts at genotype–phenotype correlation have been made (1a,40a,45).

Facies. No abnormalities are noted in the young child. Older children may develop mild facial coarsening resembling that of patients with the MPS I-H phenotype, but the facial features never become as strikingly abnormal as in MPS I-H. Approximately 80% of children with MPS III have a dull appearance with a slightly sunken nasal bridge and abundant, coarse scalp hair (29). The latter finding is the most consistent clinical feature even in children without other morphologic alterations. Hairs have been described as triangular (6) or as having marked variability in shape and pigment in cross section (35). Corneal clouding is absent (Fig. 5–11).

Skeletal system. Height may be slightly reduced or normal. Joint mobility may be mildly restricted in elbows and knees. Radiographically, thickening of the posterior calvaria, sclerotic mastoids, ovoid-shaped vertebral bodies, and minimal hypoplasia of the supra-acetabular portions of the ilia are the most consistent abnormalities (10,18) (Fig. 5–12). Otherwise, dysostosis multiplex develops slowly and is very mild. For example, the hands in MPS III are normal.

Other findings. Early development is usually normal. In the second to fifth year of life, development ceases, and behavioral problems, such as restlessness, aggressiveness, diminished attention span, and sleep disturbances, become manifest. Aggressive hyperactivity is frequently the parents' reason for seeking medical help. Subsequent to this hyperactivity

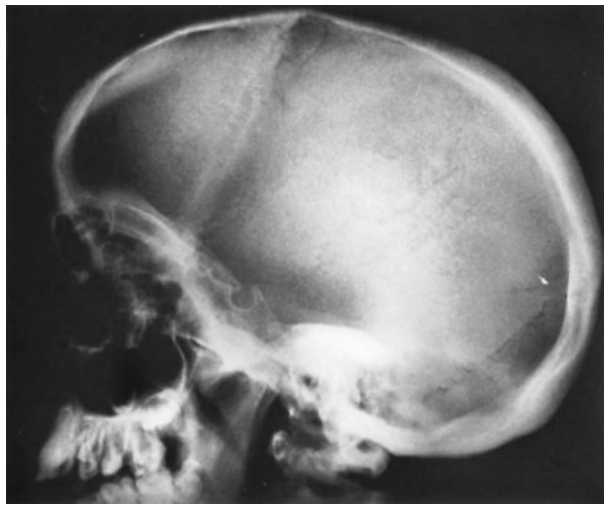

Fig. 5–12. *Sanfilippo syndrome*. Thickening of parietal and occipital portions of cranial vault in 11-year-old girl with MPS III.

is a progressive loss of mental and motor skills. Loss of environmental contact is evident prior to a "vegetative" state, with spastic diplegia and death occurring between the ages of 10 and 20 years (26). A comparison of the clinical course of patients with MPS IIIA, B and C indicates that patients with MPS IIIA are generally more severely affected than those with B or C subtypes (1,19,38,39,42). Subtype A has earlier onset, is more marked, and results in earlier death. In addition, intrafamilial variation in the clinical expression of each of the subtypes has been noted (22,38), consistent with different allelic mutations causing genetic heterogeneity in each subtype. The clinical manifestations of only 10 patients with MPS IIID have been reported to date (13).

Pathologic study of the brain has revealed marked deposition of HS as well as ceramide polyhexoside and G_{M1} ganglioside in the cerebrum (11,17). Hearing loss is frequently suspected but difficult to prove. Hepatosplenomegaly is present in more than 80% of patients. Histochemical and ultrastructural studies of MPS III have been reported (8,12,34).

Oral manifestations. There seem to be no remarkable oral manifestations, but tooth abscesses are of major concern during the late stage of the disorder. Obliteration of pulp chambers has been reported in one child (41). The tongue is not large but may protrude later in the disorder.

Laboratory findings. Clusters of coarse granulations are seen in the cytoplasm of about 35% of peripheral lymphocytes and in plasmacellular and reticulohistiocytic cells of the bone marrow. The granulations are frequently surrounded by areas of diminished stainability. The inclusions stain metachromatically with toluidine blue. Excessive amounts of HS (in the absence of DS) are excreted in the urine. It should be noted that the diagnosis of this disorder by demonstration of increased urinary excretion of HS may be missed by using certain procedures, such as the toluidine blue filter paper test.

Definitive diagnosis of each of the subtypes of MPS III, carrier detection, and prenatal diagnosis in chorionic villi or cultured amniocytes are feasible by demonstration of deficient enzyme activity (9,15,21,27,37).

A dog model was reported by Aronovich et al (1).

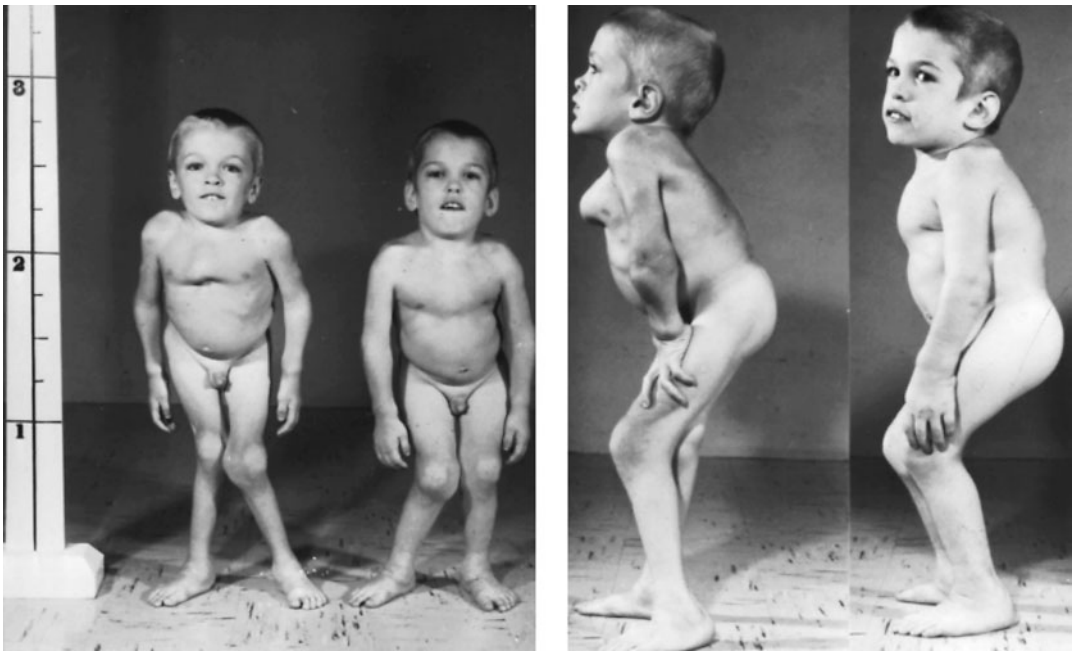
Mucopolysaccharidosis IVA and IVB (Morquio syndrome). In 1929, Morquio (29) and Brailsford (4) independently reported cases of a disorder characterized by short trunk dwarfism, progressive spinal deformity, short neck, pectus carinatum, genua valga, pes planus, odontoid hypoplasia, and normal intelligence (Figs. 5–13 to 5–15). Clinical and, later, biochemical and molecular heterogeneity was demonstrated by Dale (8) as early as 1931 and later by others (15,16,34). About 1960, the disorder was recognized as a MPS, caused by lysosomal accumulation and urinary excretion of the glycosaminoglycan KS.

Matalon et al (27) discovered the more common severe form (MPS IVA), caused by a deficiency of galactosamine-6-sulfate sulfatase, an enzyme that degrades KS (41). Arbisser et al (1) described a patient with normal *N*-acetylgalactosamine-6-sulfate sulfatase but deficient lysosomal β-galactosidase. This generally milder condition, known as MPS IVB, has been reported in several patients (1,12,13,17,21,46). However, not all examples have been mild (17,48). That β-galactosidase was indeed the primary defect was indicated by the absence of an endogenous inhibitor and by the intermediate enzyme levels in the parents (13,42). Maroteaux et al (26) described two patients with a clinical picture consistent with Morquio syndrome, but with normal *N*-acetylgalactosamine-6-sulfate sulfatase and β-galactosidase activities. Through fluorescence in situ hybridization, galactosamine-6-sulfate sulfatase was mapped to chromosome 16q24.3 (2,44).

MPS IVA has subsequently been shown to have severe, intermediate and even mild forms (7,16,32–34,46), implying different alleles. Difference in severity may also be explained by the associated finding of reduced neuraminidase activity in some cases (12). On the molecular level, allelic heterogeneity was proved and appeared to be marked (5,43a,45). A great number of different mutations (e.g., missense, nonsense, splice site alteration, cryptic site alteration, premature termination) have been reported from different populations (19,23,45). All forms of Morquio syndrome have autosomal recessive inheritance. The frequency of MPS IVA has been estimated to be about 1 in 76,000 (31) to 1 in 216,400 (25). The frequency of MPS IVB has not been estimated, but it is rarer than MPS IVA.



A B

Fig. 5–13. *Morquio syndrome*. (A,B) Brothers, ages 10 1/2 and 9 1/2 with dwarfism, kyphosis, genua valga, flexed knees, abnormally short neck, sternal protrusion, and large joints. (From H Zellweger et al, J Pediatr 59:549, 1961.)

MPS IVA. Type IVA has three grades of severity, and dental findings are present in all grades (11,32–34).

Facies. The facies is not specific, but the lower half of the face is often outstanding because of shortness and hyperextension of the neck.

Musculoskeletal system. There is reduced height because of shortened neck and trunk and, to a lesser extent, shortened extremities. Adult height rarely exceeds 100 cm (range 80–120 cm). The head is essentially normal, but mild scaphocephaly may be present because of premature closure of sutures. The head seems to rest directly on the shoulders. The neck is greatly shortened, with exaggerated cervical curvature and restricted movement (8,39,43).

Cervical myelopathy is an important complication (28,36). Cervical MRI studies have shown that the degree of cord compression may be more marked than that suggested by symptoms and signs (20). After the second year of life, the thorax exhibits marked kyphosis or kyphoscoliosis, with general flattening of vertebrae and a characteristic pectus carinatum, the sternum extending almost horizontally from its clavicular junction, then angling downward in midsection. The lumbar region of the spine frequently exhibits a gibbus-like kyphosis or, less often, lordosis in the region of the first lumbar vertebra (Fig. 5–13). Spinal cord compression may occur in the upper cervical segment as a complication from either atlantoaxial dislocation or subluxation at the thoracolumbar gibbus (3) and may result in death.

Extremities appear disproportionately long. There may be excessive joint mobility, and the wrists are usually enlarged. Genua valga, thickened knee joints, and pes planus are nearly constant findings (Fig. 5–13). The stance is semi-crouching. Usually there is a prominent potbelly.

Radiographically, generalized platyspondyly with hypoplasia of the last thoracic and first lumbar vertebrae, coxa valga, flared ilia, and progressive femoral head flattening and fragmentation are found. In the young child, the vertebral bodies are ovoid and the superior acetabulae are deficiently ossified. The odontoid process is hypoplastic or absent. The bases of the second to fifth metacarpals are conical, but their shafts are normally constricted (24), (Fig. 5–14). The distal ends of the radius and ulna are inclined toward each other. All the bones become markedly osteoporotic.

Other findings. The corneas become slowly but diffusely opacified in the form of a filmy haze; this is rarely obvious to the unaided eye before the tenth year of life. Glaucoma may develop (6,48), as well as cataracts (38). Progressive hearing loss usually begins in adolescence.

Intelligence is nearly always normal. Mitral and aortic regurgitation have been reported (49).

MPS IVB. In contrast to patients with MPS IVA, affected individuals with MPS IVB have a significantly milder phenotype. They have normal intelligence, milder dysostosis multiplex, mild pectus carinatum, corneal clouding, odontoid hypoplasia, moderate lumbar kyphosis, and minimal genua valga. Radiographs show platyspondyly and tongue-like protrusions of the lumbar spine. C2–C3 subluxation has been noted. Typically, the patients have normal hearing and no cardiac murmurs. Corneal clouding may be obvious or a slit- lamp examination may be required to observe fine corneal deposits. Often the clinical onset of the disease is characterized by an unstable, waddling gait.

Oral manifestations. In patients with MPS IVA, both the deciduous and permanent teeth have dull, gray crowns with pitted enamel that is very thin and has a tendency to flake off, causing small diastemas between the teeth (32,39a). The cusps are small, flattened, and poorly formed, and caries is frequent (11,40) (Fig. 5–15). The mandibular condyles may be flat or concave (39a). In contrast, in MPS IVB, the enamel appears normal and provides a means through which to clinically distinguish between the two types. Patients with MPS IVB tend to have a wide palate and widely spaced teeth.

Differential diagnosis. Practically all types of short-spine dwarfism have been confused with Morquio syndrome. In contrast to Morquio syndrome, *achondroplasia* is usually apparent at birth, with skeletal changes entirely different from those in MPS IVA. *MPS I-H* has radiographic similarities to Morquio syndrome during the first few years of life, but mentality is reduced and the gross physical appearance is strikingly characteristic. Although corneal clouding and hearing loss were thought to be the distinguishing factors, they are also features of Morquio syndrome (48). Multiple epiphyseal dysplasia, a dominantly inherited disorder, may also simulate Morquio syndrome, but spinal involvement, if present, is of a lesser degree.

Fig. 5–14. *Morquio syndrome*. (A) Platyspondyly of thoracolumbar vertebrae. (B) Deficiently ossified acetabula, dysplasia of femoral heads, and coxa valga. (C) Long bones of upper extremity are more severely involved than those of lower extremity. The humerus, radius, ulna, and metacarpals are short, coarse, curved, and irregularly tubulated, with irregular epiphyseal plates. Also note deficiency of carpal ossification centers. (From H Zellweger et al, J Pediatr 59:549, 1961.)

Diastrophic dysplasia is characterized by progressive kyphoscoliosis, but normal vertebral body height, micromelia, clubfoot, widening of metaphyses and epiphyses of long bones, some limitation of joint motion, and thickened pinnae easily distinguish Morquio syndrome.

Children with metatropic dysplasia at first exhibit a long-trunked and later a short-trunked dwarfism. The disorder is characterized by progressive kyphoscoliosis and anisospondyly without hypoplasia of the last thoracic and first lumbar vertebral bodies.

Spondyloepiphyseal dysplasia congenita, a type II collagen defect, inherited as a dominant trait, is a short-trunk dwarfism. There is platyspondyly but little or no involvement of the hands and feet, no corneal clouding, and no keratansulfaturia. Myopia is often severe. Rickets and *hypophosphatasia* should also be considered.

Individuals with *Dyggve-Melchior-Clausen syndrome* somewhat resemble those with Morquio disease in skeletal alterations but do not have corneal clouding, do not excrete KS in the urine, and are usually mentally retarded. They do not have enamel deficiency. Pointing of the proximal metacarpals does not occur. There is neither hypoplasia of the odontoid process nor of the inferior thoracic and lumbar vertebrae. The iliac crest has a lacy border. The disorder has autosomal recessive inheritance. Since several patients have had normal intelligence (Smith-McCort dysplasia), this disorder has genetic heterogeneity (30).

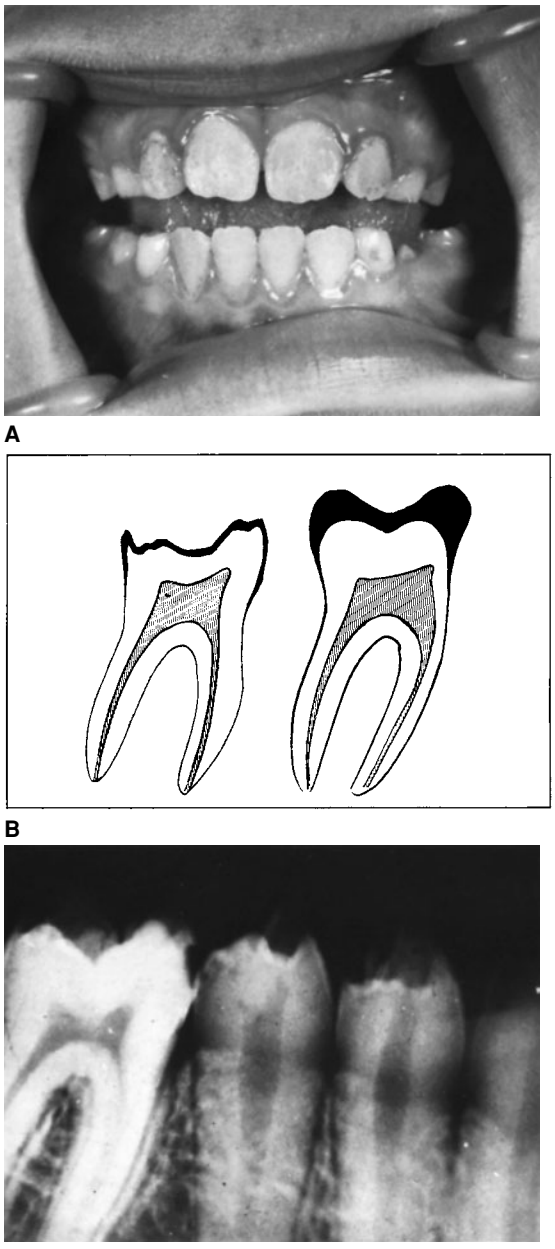


Fig. 5–15. *Morquio syndrome*. (A) Hypoplasia of enamel. (B) Diagram of lower molar showing reduced thickness of enamel layer in affected tooth (left) compared with corresponding tooth in normal sibling. (C) Dental radiograph showing reduced enamel thickness. (B,C from SM Garn and VO Hurme, Br Dent J 93:210, 1952.)

Congenital dysplasia of the odontoid process with atlantoaxial dislocation can be seen in a number of disorders: Morquio syndrome, *Aarskog syndrome, Dyggve-Melchior-Clausen syndrome,* pseudoachondroplasia, *cartilage-hair hypoplasia, spondyloepiphyseal dysplasia congenita*, and spondylometaphyseal dysplasia.

Laboratory findings. Marked excretion of KS in the urine in childhood is a constant feature but excretion diminishes markedly by the teenage years in MPS IVA. Some younger patients with MPS IVB do not excrete KS (10,22,35). *N*-acetylgalactosamine-6-sulfatase may be determined in cultured fibroblasts, isolated leukocytes, cultured amniotic cells, and chorionic villi (50). The same applies to mutational analyses (18,37,47), postnatally as well as prenatally. β-Galactosidase may be assayed using a *p*-nitrophenyl or 4-methylumbelliferyl β-galactoside (1).

Marked excretion of KS in the urine, in childhood, is a constant feature of MPS type IVA (12). It slowly decreases, reaching normal levels in adults. Usually coarse granular inclusions may be found in peripheral neutrophilic granulocytes and fibroblasts exhibit metachromasia. Ultrastructural studies of epiphyseal plates (22) and brain (23) have been described. Prenatal diagnosis has been carried out (23a,51).

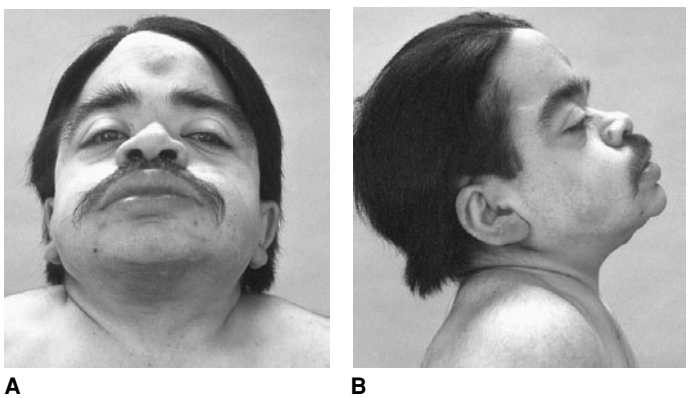
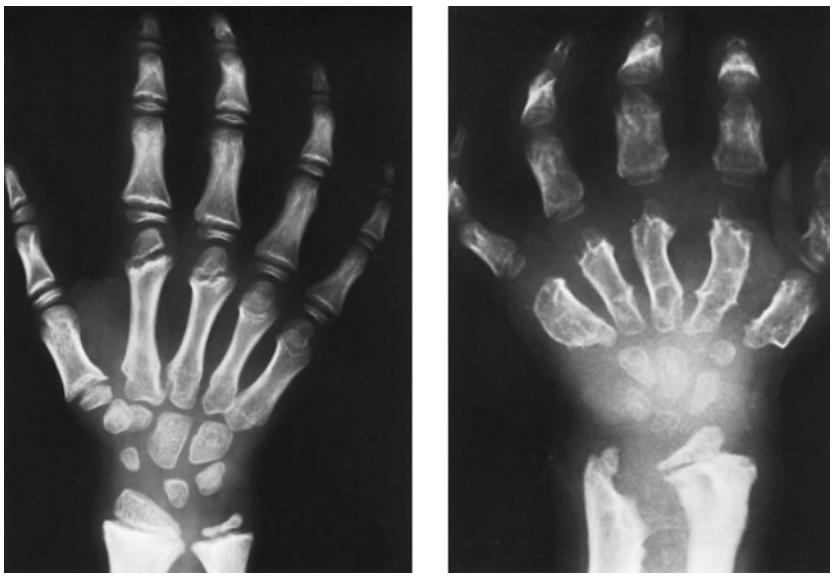
Mucopolysaccharidosis VI (Maroteaux-Lamy syndrome). In 1963, Maroteaux et al (16) described a patient with a moderately severe Hurler-like phenotype but normal intelligence and high urinary excretion of DS.

Three forms of mucopolysaccharidosis VI (MPS VI) exist: mild type (21,24), intermediate type, and severe type (25,32,33). There may even be a very mild form (29). Mutational studies in variable phenotypes have been performed (6). Children with the mild type develop reasonably well until about 6 years of age when short stature, corneal clouding and spinal deformities are noted. Legg-Perthes–like disease of the hips and aortic stenosis become apparent. The patients usually survive to adulthood (21). In patients with severe type, morphologic changes are noted in early childhood and the disease progresses more rapidly to a state of severe disability with strikingly short stature, coarse facial appearance, hyperextended head, musculoskeletal abnormalities, severe corneal clouding, markedly reduced hearing, and prominent cardiac defects that frequently lead to death in adolescence (Figs. 5–16 and 5–17).

MPS VI has autosomal recessive inheritance, the three types being the results of allelic mutations in the structural gene encoding arylsulfatase B. The gene has been mapped to chromosome 5q13–q14 (12) by in situ hybridization. The Maroteaux-Lamy syndrome was found to occur in

Fig. 5–17. *Maroteaux-Lamy syndrome*. (A,B) Severe form. Note head hyperextension. (Courtesy of S Rampini, Zürich, Switzerland.)





A B

Fig. 5–18. *Maroteaux-Lamy syndrome*. Radiographs. (A) Mild involvement of short tubular bones in 11-year-old. (B) Severe shortening and distortion of short tubular bones with marked epiphyseal and metaphyseal dysplasia in 14-year-old.

1/216,000 births in British Columbia (14). An animal model of MPS VI in Siamese and other cats has been extensively described and characterized (2,8,18). The clinical and biochemical features are caused by abnormal intracellular accumulation of DS in mesenchymal cells and, secondarily, in parenchymal cells of internal organs, such as the liver. Although *N*-acetylgalactosamine-4-sulfate residues are also present in chondroitin-4-sulfate, there is no evidence for the accumulation of this GAG in MPS VI individuals.

Facies. A prominent forehead may be noted at birth. The facies, similar to that in Hurler syndrome, with apparent hypertelorism, depressed nasal bridge, full cheek and lips, relatively broad jaws, large cranium, and abundant eyebrows and scalp hair, becomes evident at the sixth year of life, occasionally earlier (33,36). Marked corneal opacity is present in some patients (20) as well as glaucoma (1) (Figs. 5–16 and 5–17).

Musculoskeletal system. Adult height is usually 110–140 cm but those having the mild form may near 168 cm (23). The chest is deformed, with a prominent sternum. Multiple joint contractures and clawhand deformity secondary to flexion contractures of the fingers begin after the first year of life.

Genua valga, lumbar kyphosis, and sternal protrusion are common. The radiographic changes in the severe type are similar to those of MPS I-H and are striking examples of dysostosis multiplex (20). Ossification of the superior portion of the femoral capital epiphysis may be markedly defective. In the mild type, there are cranial changes, wide ribs, and pelvic dysplasia but few changes in spine and tubular bones (33) (Fig. 5–18). Hernias are common in the severe form.

Other findings. Hepatomegaly is almost invariably present in the severe form. The spleen is enlarged in about half of the cases. Cardiovascular involvement is common, with aortic stenosis, mitral valve regurgitation, cardiomyopathy (as a presenting feature), endocardial fibroelastosis, and narrowing of the coronary and other arteries (3,5,17,30,34).

Hearing defects, both conductive and sensorineural, may be detected audiometrically. Mentation is nearly always normal, with rare exception (35,38); when there is mental retardation, it is not always clear that it was caused by the MPS. However, impaired vision and hearing, restricted mobility, and secondary psychologic reaction may impede intellectual performance (32,33). Neurologic deficits most frequently include hydrocephalus, peripheral nerve compression (e.g., carpal tunnel syndrome), or hypoplasia of the odontoid process associated with atlantoaxial subluxation. Myelopathy and radiculopathy have also been reported (4,22,26). Marked tracheal stenosis has been documented (26).

Oral manifestations. The tongue becomes large with the full development of all clinical features. The teeth are frequently widely spaced. Eruption of primary and permanent dentition is retarded (19,31). Some are deeply buried, being angulated in the mandible, and are surrounded by radiolucent bony defects that presumably represent the accumulation of dermatan sulfate in hyperplastic follicles as seen in MPS I-H, MPS I-H/S, and in MPS II-B. The follicular fluid in MPS VI is composed of hyaluronic acid (27). The mandibular condyle is hypoplastic.

Differential diagnosis. For differential diagnosis of MPS VI, see Table 5–1.

Laboratory findings. There is an abundance of coarse, dense inclusions in granulocytes and monocytes and in a large proportion of lymphocytes in peripheral blood smears. Bone marrow preparations exhibit coarse inclusions in reticulohistiocytes, granulocytes, and their precursors (15). Biopsy may be easily done on the conjunctiva (11). Electron microscopic studies have shown numerous electrolucent vacuoles in cells from brain, liver, lung, and skin (10,11). Large quantities of DS are excreted in the urine, but the level decreases with age. Heterozygote testing has been difficult through enzymatic methods, but a method has been reported in which ratios of arylsulfatase B to another lysosomal sulfatase, arylsulfatase A, are used to minimize the overlap between normal and heterozygote populations.

The condition has been diagnosed prenatally (37). Diagnosis from chorionic villi through enzyme determination may not be accurate (28). Through molecular genetic studies, progress has been made toward determining various mutations in the arylsulfatase B gene, providing molecular evidence for genetic heterogeneity (7,9). Attempts to relate molecular findings and clinical phenotype have been made (13). In several patients with an intermediate form of MPS VI, novel mutant alleles have been found (39,40).

Mucopolysaccharidosis VII (Sly syndrome, β-glucuronidase deficiency). Mucopolysaccharidosis VII (MPS VII) which results from β-glucuronidase deficiency, was first described by Sly et al (20) in 1973. The disease is characterized by short stature, hepatosplenomegaly, progressive dysostosis multiplex, and progressive mental retardation after the age of 2 years. Clinical heterogeneity exists in the approximately 25 patients described so far (10,18): there are rather severely affected patients, and others who are moderately or mildly affected (2). There may also be a chronic variant (5). The severe type has its onset at birth or even prenatally. The severe neonatal form of β-glucuronidase deficiency is one of the few lysosomal storage diseases that may be recognized in utero or at birth (14,24,25). The milder types have symptoms from 3 to 4 years of age on, or sometimes at adolescence (Figs. 5–19 and 5–20). Inheritance is autosomal recessive for each type. The gene for MPS VII, at 7q21.1–q22 (1), encodes β-glucuronidase (GUSB), is 21 kb long, and is subdivided into 12 exons (12). The architecture is the same in the mouse gene (4). The human gene includes multiple unprocessed pseudogenes and/or closely related genes (21).

Murine (3), canine (7), and feline (6) models have been described. Deficiency of lysosomal β-glucuronidase activity in fibroblasts, leukocytes, and most tissues leads to an inability to degrade DS and HS, the predominant GAGs containing β-linked glucuronic acid residues, and results in their lysosomal accumulation and urinary excretion. Autopsy findings in a 19-year-old man (26) included dysostosis multiplex and extensive cardiovascular lesions, including arterial stenosis and marked fibrous thickening of the atrioventricular and aortic valves. In the brain, storage was localized to specific regions, primarily intraneuronal ones, and appeared ultrastructurally as delicate whorled filamentous accumulations in lysosomes.

Facies. In the severe form, the disorder may present a nonimmune hydrops fetalis (9,13,22,25). The severe type and, to some degree, the

Fig. 5–19. *Sly syndrome*, *β-glucuronidase deficiency*. (A,B) Coarse facies, pot belly, gibbus. (From WS Sly et al, J Pediatr 82:249, 1973.)

A B

Fig. 5–20. *Sly syndrome*, *β-glucuronidase deficiency*. (A,B) Six-year-old showing disproportionate growth retardation. There is right-sided sternal protrusion with resultant pectus excavatum, and mild kyphoscoliosis. (From AC Sewell et al, Clin Genet 21:366, 1982).

moderate type have moderate Hurler-like changes, with hypertelorism, depressed nasal bridge, prominent alveolar processes, and anteverted nostrils (2,8). The corneas appear cloudy in the severe type, but are clear in the milder types (5).

Skeletal system. In the severe type and, to some degree, in the milder type, short stature becomes apparent in the second year of life, with height falling below the third centile. The head is large, with frontal prominence and premature closure of the sagittal and lambdoidal sutures. Pectus excavatum or carinatum and thoracolumbar gibbus, already noted in infancy, increase with age in the severe and milder types (5). Talipes and hernia also occur.

Radiographically, in both severe and mild types there are moderately severe changes of dysostosis multiplex with premature closure of cranial sutures, J-shaped sella, oar-shaped ribs, hook-like deformities of the lower thoracic and upper lumbar vertebrae, underdevelopment of the basilar portions of the ilia, aseptic necrosis of femoral heads, shortening of tubular bones, and proximal pointing of metacarpals II–V.

Other findings. Hepatosplenomegaly, inguinal and/or umbilical hernia, and developmental retardation are present after the age of 2 years, but psychomotor retardation is evident only in the severe-type patients. Recurrent pulmonary infections are common.

Oral manifestations. Widened alveolar ridges have been described.

Differential diagnosis. For differential diagnosis of MPS VII, see Table 5–1.

Laboratory findings. Coarse metachromatic inclusions are present in peripheral granulocytes, granulocyte precursors in bone marrow, and in cultured fibroblasts. Ultrastructurally, there are clear vacuoles and granular inclusions in nearly all granulocytes and mononuclear cells in MPS VII (15).

The definitive diagnosis can be made by demonstration of markedly deficient β-glucuronidase activity in serum, leukocytes, and cultured skin fibroblasts. Prenatal diagnosis can be accomplished by demonstrating β-glucuronidase deficiency in chorionic villi or cultured amniocytes (11). Increased nuchal translucency has been reported as well (5a). Molecular analyses will become available in the near future for pre- and postnatal diagnosis (23,25,27). Studies on gene therapy are ongoing; however these are mainly in animal models (16,17,19).

Mucopolysaccharidosis IX. Triggs-Raine et al (1) recently reported mucopolysaccharidosis IX (MPS IX). The patient exhibited a deficiency of serum hyaluronidase and a surprisingly mild clinical phenotype, including notable periarticular soft tissue masses, mild short stature, and absence of neurological and visceral involvement and histological and ultrastructural evidence of a lysosomal storage disease. MPS IX maps to 3p21.3.

Oligosaccharidoses and related disorders

This section deals with various oligosaccharidoses and related conditions.

G_{M1} gangliosidosis, type 1. G_{M1} gangliosidosis is an oligosaccharidosis caused by the lysosomal accumulation of G_{M1} ganglioside, asialo-G_{M1} ganglioside, and galactose-containing oligosaccharides (16,21). The disease was first recognized in 1964 by Landing et al (11). There are three major forms of G_{M1} gangliosidosis: infantile (type 1), late infantile/juvenile (type 2), and chronic/adult (type 3). Since mainly the infantile form is dysmorphic, the latter two types will not be discussed here.

The infantile form is manifest at or shortly after birth. In its full expression, it is characterized by progressive cerebral deterioration, with death usually occurring between 6 months and 2 years of age from bronchopneumonia. The other clinical and radiographic features resemble either I-cell disease or MPS I-H. Neonatal ascites (23) and transient hydrops fetalis (7) have been described as a presenting symptoms in the infantile form. Cardiomyopathy at 4 months of age leading to heart failure was described in a child that deteriorated neurologically and died at the age of 9 months (4). There were no bony changes, and β-galactosidase was almost undetectable.

G_{M1} gangliosidosis of all types is the consequence of the homozygous state of the mutant gene that produces a functionally deficient acid β-D-galactosidase. The β-galactosidase gene is located in the 3p21-3pter region (*GLB1*) (24). A second beta-galactosidase locus (*GLB2*) has been assigned to 20q13.1 and codes for protective protein (14,21). A mouse model has been reported (13).

Gene mutations in G_{M1} gangliosidosis have been found to be heterogeneous among Japanese patients with infantile G_{M1} gangliosidosis (17,20). The disorder is seen mostly in compound heterozygotes without parental consanguinity (21). The number of reports on Caucasian patients is relatively small (3,15)

Inheritance is autosomal recessive. Patients of various ethnic origins have been reported (21), and the incidence is high in the Maltese Islands (12).

Facies. The facial features are coarse at birth, in contrast to the face in MPS I-H, which is normal for the first 6 months of life. Mild macrocephaly with frontal bossing is found in about 60% of patients. The nasal bridge is depressed, the philtrum is prominent, the cheeks are full, and the eyelids puffy (Fig. 5–21). In mild cases, these facial changes are present only in later infancy. Corneal opacities are rarely found, but cherry-red macular spots are detected in most cases (8).

Fig. 5–21. *G_{M1} gangliosidosis, type I.* Coarse facial features, widened alveolar processes, and large ears. Wrist and ankle deformities were apparent at 2 weeks of age. (From CR Scott et al, J Pediatr 71:357, 1967).

Skeletal system. Kyphoscoliosis is an early finding. The hands are short and stubby. There are multiple flexion contractures of the joints.

The radiographic changes are those of dysostosis multiplex which appear earlier and are more severe than in MPS I-H. The ribs are wide, and the vertebral bodies are short in their anteroposterior diameter, with convex endplates and hook-shaped deformities at the thoracolumbar junction.

The basilar portions of the ilia are hypoplastic. In young infants, there is periosteal cloaking of the shafts of the long tubular bones. This is not observed in MPS I-H, but is a well-known early finding in patients with I-cell disease. In older infants and in young children, the shafts of the long bones are overtubulated, with irregular contours. The short tubular bones appear swollen, with proximal pointing of the second to fourth metacarpals. Bone trabeculation is coarse (5,9).

Central nervous system. The infants are hypotonic. They suck and swallow poorly, fail to thrive, and never learn to crawl or sit. In addition to gross motor delay, they exhibit seizures, blindness, hearing loss, and often spastic quadriplegia within the first year after birth. Cranial computed tomography (CT) and MRI show diffuse atrophy of the central nervous system in early-onset patients, generalized cortical atrophy, enlargement of the ventricular system, and features of myelin loss in the cerebral white matter (6,7a,10,21). A CT scan revealed increasing white matter involvement in one case (13), with generalized areas of reduced density early in the course of the disease.

Other findings. Hepatosplenomegaly is present; hydrocele is frequent (5). Ectopic mongolian spots when present may aid in diagnosis (22).

Oral manifestations. The tongue and alveolar processes are enlarged (Fig. 5–22) (11).

Differential diagnosis. Cherry-red macular spots can also be found in Tay-Sachs disease, Sandhoff disease (AB variant), metachromatic leukodystrophy, infantile Niemann-Pick disease, the *sialidoses*, and Farber lipogranulomatosis. Similar, but not typical, changes have been described in cases of other lysosomal diseases such as metachromatic leukodystrophy, globoid-cell leukodystrophy, and Gaucher disease.

Fig. 5–22. *G_{M1} gangliosidosis, type I.* Gingival enlargement. (Courtesy of CR Scott, Seattle, Washington.)

Marked dysostosis multiplex-like skeletal anomalies in an infant are more compatible with G_{M1} gangliosidosis or I-cell disease than with a mucopolysaccharidosis.

Laboratory findings. Between 10% and 80% of peripheral lymphocytes are vacuolated. Foam cells are found in the bone marrow and in the viscera. Glomerular epithelial cells are vacuolated. The neurons of the central nervous system and retina have a granular appearance because of G_{M1} ganglioside–loaded lysosomes. Under electron microscopy these appear as whorled and striped "zebra bodies," identical to those seen in Tay-Sachs disease (19). Urinary excretion of GAGs is usually normal, although galactose-containing oligosaccharides are markedly elevated. The activity of acid β-galactosidase is deficient in tissues and body fluids, including lymphocytes and cultured fibroblasts; assay of urine is not recommended anymore (21). It is also important to determine other enzyme activities including neuraminidase for differential diagnosis of disorders with secondary β-galactosidase deficiency, such as *galactosialidosis, I-cell disease*, *mucolipidosis III*, and MPS other than *Morquio B disease* (21). Prenatal and heterozygote detection are possible, either with enzymatic or with molecular genetic techniques.

Animal models of G_{M1} gangliosidosis have been reported for cats (2), dogs (1), and sheep (18).

Fucosidosis. Fucosidosis is an oligosaccharidosis caused by a deficiency of α-L-fucosidase, leading to accumulation and excretion of glycoproteins, glycolipids, and oligosaccharides containing fucoside moieties (20). It was first described by Durand et al (4) in 1966.

Fucosidosis has autosomal recessive inheritance. It appears to be more common in Southern Italians and in people from the southwestern part of the United States—e.g., New Mexican Spanish-Americans, and Navajo (5,23). In a review (23), 40% of the 45 families reported were consanguineous.

Through in situ hybridization studies, the α-fucosidase 1 gene (*FUCA1*) was assigned to chromosome 1p34 (7). Using similar techniques, a pseudogene, *FUCA1P*, has been mapped to 2q31–q32 (2). The gene structure for human fucosidase includes eight exons spanning 23 kb, and the sequence of the pseudogene is 80% identical to the cDNA (10). Most mutations have been found in isolated families, suggesting that fucosidosis is due to a large number of different mutations (16,17,21,24).

Traditionally, two phenotypes have been identified: a more severe infantile form referred to as type I, and a milder form, described as type II. In a review of 77 cases (23), it was suggested that this is an arbitrary separation of a continuum of severity (20). In addition, mild and severe cases occur within sibships (22) and among patients who are homozygous for the common Gln to stop mutation at codon 422 (Q422X) (4). The major distinguishing features of the milder phenotype are the presence of angiokeratomas, longer survival, and a more normal sodium chloride content of sweat, as compared with the severe form (20).

Facies. Patients with a more severe phenotype typically have a progressively coarse facies in the first year of life with large lips, periorbital puffiness, and frontal bossing. There is some resemblance to patients with MPS III. The hair, however, is not as coarse. The tongue may be large. The corneas are clear and the fundi are unremarkable.

Skeletal system. Patients exhibit growth retardation and dysostosis multiplex. The vertebral bodies are initially ovoid with subsequent flattening, marginal irregularity, and beaking in lateral projection (1,11,15). There is mild hypoplasia of the supraacetabular portions of the ilia. Bone trabeculation is coarse.

Central nervous system. Progressive neurologic deterioration has been reported (15). Cranial CT and MRI have shown density and signal

Fig. 5–23. *Fucosidosis*. Telangiectatic lesions of gingiva. (From DE Prindiville and D Stern, J Oral Surg 34:603, 1967.)

abnormalities within the globus pallidus, internal capsules, and periventricular white matter (15,19). Spasticity, hyperreflexia, and dystonia may be present (9).

Other findings. Psychomotor retardation, hepatosplenomegaly, cardiomegaly, seizures, and respiratory infections occur frequently but are variable. Tortuous conjunctival vessels and bull's eye retinopathy have been reported (18). Kivlin (*Peters plus*) syndrome has been diagnosed in a single patient (18). Angiokeratomas may be present (6,9). Hernias have also been reported.

Oral findings. Gingival and labial telangiectasias (Fig. 5–23) have been reported (14).

Laboratory findings. Peripheral lymphocytes are vacuolated. Skin biopsy shows deposits of homogeneous eosinophilic material between the dermis and epidermis. Electron microscopic studies reveal numerous membrane-bound vacuoles in all tissues (8). Urinary excretion of MPS is normal, but there is excess excretion of fucosyl-containing oligosaccharides. There is a suggestion that fucosidosis types I and II can be distinguished by the pattern of urinary excretion (12). There is deficient activity of the lysosomal enzyme, α-L-fucosidase in tissues, cultured fibroblasts, leukocytes, serum, and urine (3). Sweat chlorides are markedly increased in the severe form and to a lesser extent in the milder form.

Prenatal diagnosis has been accomplished (13). If the molecular lesion in a specific family has been identified, prenatal diagnosis through DNA analysis can be considered.

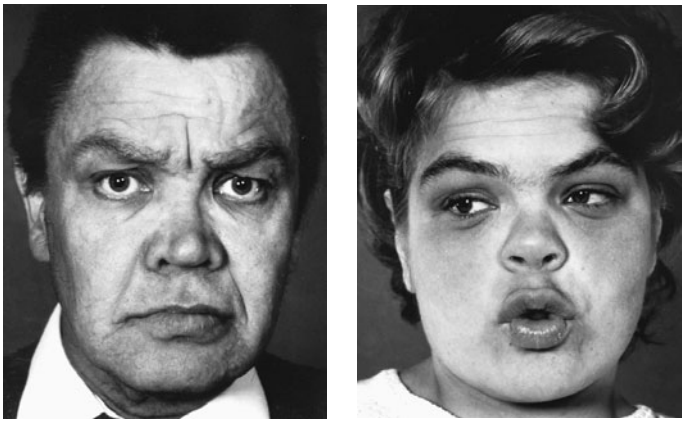
Aspartylglucosaminuria. Aspartylglucosaminuria, an oligosaccharidosis in which glycoprotein-derived aspartylglucosamine accumulates in various tissues and fluids, was first identified in England by Jenner and Pollit (20). Most of the identified patients have come from Finland (7,9,10). Aspartylglucosaminuria is in Finland what phenylketonuria (PKU) is in many other populations. Its frequency was estimated at 1/26,000 in Finland (11), but recalculated to be at least 1/18,500 (1). Mononen et al (22) found a frequency of 1 in 3643 in a study of children in eastern Finland. Aspartylglucosaminuria has also been observed in Finns living in Norway (26). A few cases have been reported from other ethnic groups, e.g., Puerto Rican (13), Italian (15), Dutch (14), Mauritian (23), Palestinian Arabs (27), and others.

Inheritance is autosomal recessive. The basic defect is deficiency of aspartylglucosaminidase (1-aspartamido-α-*N*-acetylglucosaminine amidohydrolase). Heterozygotes may be identified (16,22) and prenatal diagnosis is possible (8). The gene is located at 4q32–q33 (6) and consists of 9 exons spanning a total of 13 kb. A high degree of homogeneity in disease alleles is suggested in the Finnish population. In 115 aspartylglucosaminuria patients from 109 families, not only were the *C163S* and *R161Q* mutations always associated, but they were found in 98% of the aspartylglucosaminuria chromosomes analyzed (25). Moreover, the two mutations were not found in 120 unrelated control individuals. Aspartylglucosaminuria outside Finland appears to result from a large variety of mutations of the gene (18). A mouse model has been reported (19).

Infancy and childhood are usually characterized by recurrent diarrhea, umbilical and inguinal hernia, and frequent respiratory and ear infections, all of which diminish after six years of age (1). Early onset of splenomegaly occurs with abdominal protrusion. Lifespan is usually under 45 years.

Facies. A remarkable resemblance is noted among affected individuals. The skull is frequently asymmetric. The features gradually become coarse during childhood; the nasal bridge is broad and low. The nostrils are anteverted and the lips thickened. Mild hypertelorism, epicanthic folds, and crystal-like lens opacities have been present in about half the cases. The facial skin, particularly that of the eyelids and cheeks, has a tendency to sag with age (Fig. 5–24). Seborrheic and erythematous facial skin begins in adolescence (4). Acne, particularly of the face, has been noted in several patients (25).



A B

Fig. 5–24. *Aspartylglucosaminuria*. (A,B) Remarkable resemblance between affected individuals. Coarse facial features include furrowed brow, broad low nasal bridge, mild hypertelorism, epicanthal folds, sagging of facial skin, and thick lips. (Courtesy of S Autio, Helsinki, Finland.)

Skeletal manifestations. Inguinal and/or, more often, umbilical hernia has been found in over one-third of patients before the age of 3 months. Muscular hypotonia has been present in about 20% of patients, and genua valga is seen in at least 75%. Clubfoot needing surgical treatment has been reported. The long bones, metacarpals, and phalanges have thin cortices. Spondylolisthesis and spondylolysis have been described (13). Kyphosis or scoliosis and protuberant abdomen have also been frequently reported. There is excessive infantile growth and an early pubertal growth spurt (5). Growth retardation is seen only after 15 years of age.

The calvaria are characteristically thickened and brachycephalic. The frontal and maxillary sinuses are absent or poorly developed (Fig. 5–25A). Mild dysostosis multiplex in the spine is common. The ulna is somewhat shortened (24).

Nervous system. Progressive mental retardation to an IQ value of 40 or less in the second decade is a constant feature. It usually first becomes evident around 5 years of age. Speech is severely delayed. In about one-third of patients, the voice becomes raspy in adult life. Periodic hyperactivity, hyperirritability, and/or aggressive reactions have been noted in about 50% of patients.

Mild to moderate hearing loss has been found in about 20% of adults with this disorder. Clumsy gait and poor coordination of the hands are noted early in life. In 12 patients, MRI studies (11) showed that aspartylglucosaminuria is primarily a gray-matter disease, also affecting white matter by delaying myelination.

Skin. About 20% of affected individuals have angiokeratomata of the face (24).

Other findings. Macroorchidism has been documented (13). Amenorrhea and oligomenorrhea in females and scant beard and pubic hair have been noted (9).

Oral manifestations. The teeth have often been noted to be spaced. Tooth crown size and crown shape are normal, but dental malocclusions are common. In a study of 81 cases, an abnormally large tongue was reported in almost all cases (2), causing anterior openbite. Fibroepithelial hyperplasia of the gingiva and leukedema of the buccal mucosa are common (4). Diagnosis has been made on gingival biopsy (12).

Laboratory findings. From 5% to 20% of the blood lymphocytes are vacuolated in 75% of the patients (Fig. 5–25B) and about one-half of patients exhibit mild neutropenia and decreased prothrombin time.

The definitive diagnosis is made by finding large amounts of aspartylglucosamine in the urine by thin-layer chromatography, paper chromatography, or electrophoresis (25). Final diagnosis of aspartylglucosaminuria is usually based on the measurement of aspartylglucosaminidase activity in white blood cells or fibroblasts. Prenatal diagnosis using cultured amniotic cells or direct chorionic villi biopsy material has been accomplished (8).

α-Mannosidosis. α-Mannosidosis, a type of oligosaccharidosis, was first characterized in 1967 by Öckermann (17). At least 60 cases have been reported to date (2,3). Inheritance is autosomal recessive with parental consanguinity in 25% (22). Genetic heterogeneity is evidenced by a more severe infantile form (type I) and a milder juvenile–adult form (type II) (6), and there may be considerable variability among affected family members (14,15). The gene encoding acid α-mannosidase is located at chromosome 19p13.2–q12 (12). The lysosomal α-mannosidase cDNA has been cloned and many mutations have been reported (5,10,16).

Affected children are essentially normal for the first months to 1 year of life but about 60% exhibit a propensity toward recurrent respiratory infections (6,13a). Expression has varied from death in childhood to few clinical signs (3,4). Adults have stunted growth (3).

Facies. The coarse facies (prominent supraorbital ridges, hypertelorism, broad based nose, prominent jaw) noted after the first few years of life becomes progressive but not to the degree noted in MPS I-H or as early as in I-cell disease (15). The nasal bridge tends to be depressed; the forehead and mandible are prominent. The neck is somewhat short (Fig. 5–26A,B).

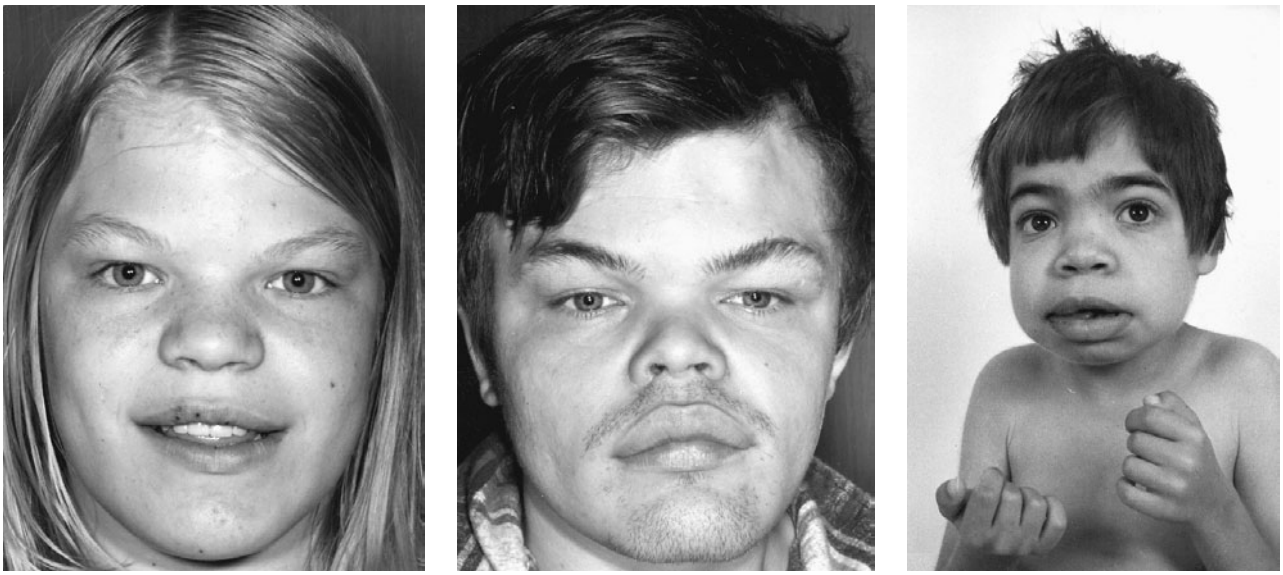
Central nervous system. There is delayed early motor development, which manifests as clumsy motor function and ataxia. Mental retardation is present in both type I and type II patients, but there is rapid progression of mental deterioration in type I patients. Speech is delayed. Tendon reflexes are brisk. In three patients, MRI findings in the head showed bony changes, verticalization of the chiasmatic sulcus, cerebellar atrophy, and white-matter signal changes (7).

Eyes and ears. Spoke-wheel posterior lenticular or superficial corneal opacities have been noted in 25% of cases (1,13); cherry-red spots have also been reported. Severe high-frequency sensorineural hearing loss is a common, if not constant, feature of type II patients (16).

Musculoskeletal system. There is general mild hypotonia, and the abdomen is protuberant. Umbilical hernia is found in 60% of cases.

All affected individuals have mild dysostosis multiplex, which becomes more severe in some and improves in others (5a,8,20,24).

Fig. 5–26. (A,B) *α-Mannosidosis*. Note gradual coarsening of features with age in 11-year-old and 18-year-old sibs. (C) *β-Mannosidosis*. Severely mentally retarded female with coarse facies and short neck. (C courtesy of E Seemanová, Prague, Czechslovakia.)



A B C

The calvaria is thick with hypoplastic to absent paranasal sinuses in at least 60% of cases. The long bones are osteoporotic. The ulna and radius are broad with curved diaphyses and a thin cortex. Joint mobility is remarkably variable in severity (22). The vertebrae are ovoid, flattened, and beaked in some cases, with gibbus formation (15,25). Mild bony deformity at the hip is common.

Other findings. Hepatosplenomegaly has been noted in 50% of patients (22) but this may disappear in childhood.

Oral findings. Macroglossia and widely spaced teeth have been noted (17). Transmission electron microscopy studies in gingival and oral hyperplastic mucosa have revealed histiocytic cells containing storage vacuoles with fine reticulogranular material (11).

Laboratory aids. The peripheral and bone marrow lymphocytes are vacuolated in as many as 90% of the cells counted (3). Coarse dark granules are present in the neutrophils, and there is a defect in neutrophil chemotaxis. Pancytopenia has been found (19), and decreased serum IgG has been noted. The condition is diagnosed by finding markedly reduced acid α-D-mannosidase in leukocytes and cultured fibroblasts (21). Mannose-rich oligosaccharides can be readily detected in the urine of affected individuals. Heterozygote detection is possible and prenatal diagnosis can be accomplished by finding acid α-D-mannosidase deficiency in chorionic villi (18). α-Mannosidase activity, however, has been found to be less than one-third of that found in cultured amniotic fluid cells (9); this finding emphasizes the need for good control data.

Bone marrow therapy (BMT) in cats with α-mannosidosis has been reported (23). The disease in cats shows clinical, morphologic, and biochemical features that closely resemble those of human disease. The BMT-treated animals showed little or no progression of neurologic signs 1 to 2 years after BMT, whereas untreated cats became severely impaired.

β-Mannosidosis. Deficiency of β-mannosidase was well known in goats and cattle (6) as a severe neurologic disease associated with dysmyelination of the central nervous system and early death before the first human patient was reported in 1986 (3). The first mutation associated with human β-mannosidosis was reported in a study (1) of 2 sibs with different manifestations of β-mannosidosis described by Kleijer et al (7). The gene for β-mannosidase was mapped to 4q22–q25 by study of a panel of rodent/human somatic cell hybrid lines (1). There appears to be homozygosity for an A-to-G transition 2 bp upstream of a splice acceptor site. Lysosomal β-mannosidase has been cloned (2). Inheritance of β-mannosidosis is autosomal recessive; the frequency is not yet known. Patients of different ethnic backgrounds have been reported— e.g., Hindu (3) and Turkish (5) patients. A goat model has been described (6).

Upper and lower respiratory tract infections are frequent.

Facies. There is a coarsening of facial features (Fig. 5–26C).

Central nervous system. Most patients are normal in the first few months of life; eventually all have mental retardation. In the most severe phenotype, status epilepticus at age 12 months with quadriplegia and death at 15 months have been reported (4). Speech is impaired (10). Aggressive or unstable behavior has been described. Brain atrophy has been demonstrated by CT scan in a severely affected patient (4).

Peripheral neuropathy has been documented in a number of patients (9).

Eyes and ear. Hearing loss and ear infections are common.

Musculoskeletal system. Skeletal abnormalities occur but are not usual (7).

Other findings. Hepatosplenomegaly has not been described, but angiokeratomas have been reported (3,11).

Laboratory aids. Cytoplasmic vacuoles have been noted on skin biopsy but not in lymphocytes or bone marrow cells. Slight vacuolization and granulation of bone marrow cells were reported in another patient (4).

A disaccharidase containing mannose and *N*-acetylglucosamine is the major abnormal component found in the urine of β-mannosidosis patients (12). Definitive diagnosis of β-mannosidosis is made by measuring the activity of β-mannosidase in leukocytes or cultured fibroblasts (12). Prenatal diagnosis can be carried out (8).

Sialidosis (neuraminidase/sialidase deficiency). Delineation of the clinical features of the various forms of sialidosis is complicated by the existence of both an isolated neuraminidase deficiency ("sialidosis") and a combined neuraminidase and β-galactosidase deficiency (galactosialidosis) (14). Patients with type I, the normosomatic sialidosis, present with symptoms between 8 and 25 years of age, have normal stature and intelligence, severe myoclonus, and macular cherry-red spots with visual loss. Since the facies is normal and there is no dysostosis multiplex, this type is not discussed further here. The reader is referred to reviews by Spranger (13), O'Brien (8), and Young et al (16).

Type II sialidosis consists of three forms with dysmorphic phenotype and more or less coarse facies (Figs. 5–27 to 5–29): (*a*) a congenital lethal variety, presenting with hydrops fetalis; (*b*) an infantile form (nephrosialidosis) initially presenting from birth to the end of the first year of life; and (*c*) a juvenile form, with onset at between 8 and 20 years that becomes progressively worse.

Fig. 5–27. *Sialidosis*. Note prominent scalp veins, mildly coarse features with broad hypoplastic nasal bridge, abdominal distension and large hydroceles. (From AS Aylsworth et al, J Pediatr 96:662, 1980.)

All types have autosomal recessive inheritance. Although the genetic relationships of the various clinical forms of the sialidosis remain uncertain, ethnic predilections of at least some forms appear to differ (14). Most reported type I patients have been Italian. The expression of the glycoprotein-specific neuraminidase, absent in sialidosis patients, requires the presence of at least two genes for normal expression (7). The lysosomal sialidase gene was mapped to 6p21.3, which is consistent with the previous chromosomal assignment of this gene in proximity to the HLA locus (10). The neuraminidase deficiency in a sialidosis type II patient is caused by a mutation in a structural protein encoded by a gene at 10pter–q23 (7). In contrast, the neuraminidase deficiency found in a galactosialidosis patient was shown to be caused by a mutation in a gene located at 20q13.1 (7). These findings indicate that sialidosis patients and individuals with the combined deficiencies suffer from two distinct and separate genetic disorders (14). The specific mutation affects the severity (1a).

Of those individuals with type II, the juvenile form has the mildest course, the life span usually being somewhat reduced, but most patients have survived to the fourth and fifth decades. There is variable coarsening of features ranging from thick lips, flat nasal bridge, and mild hypertelorism to a facies resembling MPS I-H, short trunk, relatively long limbs, and moderately severe dysostosis multiplex. Myoclonus, similar to that in the normosomatic type, is noted in 75% of patients. Neuromuscular findings have commonly included ataxic gait, tremor, myoclonic jerks, generalized seizures, impaired hearing, hypotonia, wasting, and peripheral neuropathy. Mental function is essentially normal until adolescence, when it tapers off to an IQ of 60–70. Eye findings include progressive visual loss, cherry-red macular spots, punctate lenticular opacities, and occasional corneal opacities (Fig. 5–30). Angiokeratomas similar to those found in Fabry disease and fucosidosis have been reported (6).

The infantile form (nephrosialidosis) is characterized by more severe dysostosis multiplex, hepatosplenomegaly, glomerular nephropathy, hearing loss, seizures, pyramidal tract signs, and severe mental retardation (1,5). Survival to the second decade is frequent. As in the juvenile form, visual loss, cherry-red spots, myoclonus, and ataxia are seen in older children (15,16).

In the so-called congenital or fetal form, infants are frequently stillborn with hydrops fetalis. Those not stillborn usually die within a few months. In addition to ascites with pericardial effusion, corneal opacities, hepatosplenomegaly, inguinal hernia, stippled epiphyses, and periosteal cloaking of long bones are seen (Fig. 5–28). Renal involvement with proteinuria also occurs in the congenital form (1,4,12) (Fig. 5–27).

A strain of mice (SM/J) has been shown to have a deficiency of neuraminidase in some tissues (9).

Differential diagnosis. Neuraminidase deficiency with β-galactosidase deficiency has been classified as a separate entity (see Galactosialidosis, below).

Laboratory findings. Vacuolated lymphocytes and bone marrow and placental foam cells are lacking in the normosomatic form but are prominent in the other types. Other findings include tissue storage of sialyloligosaccharides, increased urinary excretion of oligosaccharides, and sialylglycopeptides derived from glycoproteins. The definitive diagnosis of sialidosis is based on the direct measurement of sialidase activity in isolated leukocytes, fibroblasts, or cultured amniotic fluid cells (14). Prenatal diagnosis has been reported (3), using cultured amniotic fluid cells or chorionic villi samples (2). Recently, a point mutation in the neu-1 locus has been identified (11).

Hydrops fetalis may occur (13a).

Galactosialidosis. Galactosialidosis, an oligosaccharidosis, was originally described by Okada and O'Brien in 1968 (8). The disorder occurs in three clinical forms: (*a*) early infantile, (*b*) late infantile, and (*c*) juvenile/adult. Most of the patients belong to the juvenile/adult group and are mainly of Japanese origin.

The disorder has autosomal recessive inheritance. Galactosialidosis is associated with a combined deficiency of β-galactosidase and neuraminidase, secondary to a defect of another lysosomal protein, the protective protein (1). The gene encoding human protective protein (PPBG) is located at 20q13.1 (18). The protective protein forms a complex with β-galactosidase and neuraminidase and protects these enzymes against excessive proteolytic degradation (1). The human protective protein appears to be identical to lysosomal cathepsin A and has catalytic and protective functions as well (1,4,6). Its deamidase/carboxypeptidase activity has been found to be deficient in all patients with galactosidosis (11). Studies of the relation between protective protein/cathepsin A mutations and clinical severity (10,20) have shown that the main factor determining the clinical course in galactosialidosis patients is the lysosomal level of mutant *PPCA* (20). A mouse model has been reported (19).

Early-infantile type. The severe infantile form presents between birth and 3 months of age with fetal hydrops (7,9), neonatal edema, kidney involvement, coarse facies, inguinal hernias, and telangiectasias (9,16), the latter symptom being rare in the late-infantile and juvenile/adult types (1). Patients develop visceromegaly, psychomotor delay, and skeletal abnormalities, though to a lesser degree than in the other two types (1). Optic disc abnormalities and cherry-red spot have been described, as have cardiomegaly, thickened septum, and cardiac failure (16).

Late-infantile type. In this form, coarse facies develops in the first months of life, as well as hepatosplenomegaly and dysostosis multiplex, especially of the spine (13) (Fig. 5–31A). Cherry-red spots, cloudy corneas, and retinal and optic nerve abnormalities may be present (17). Mild or very mild mental retardation may be a feature (13). Mitral and aortic heart valve disease is a common feature, as well as conductive or mixed type hearing loss (13).

Fig. 5–31. *Galactosialidosis*. (A) Mild coarseness of facial features and muscular upper body. (B) Mild irregularities in vertebral bodies. (From D Chitayat et al, Am J Med Genet 31:887, 1988.)

A B

Juvenile/adult type. The clinical course is variable and there is a broad spectrum of severity and age of onset (2,14,15). Coarse facies is a constant finding, though less marked than in other lysosomal storage diseases (1). Visceromegaly is absent. Platyspondyly of thoracic and lumbar vertebrae is common (Fig. 5–31B). Major neurologic findings include myoclonus, cerebellar ataxia, generalized seizures, and mental retardation with deterioration (1). Cherry-red spots, corneal clouding and lens opacities have been reported. Angiokeratoma is present in this type of galactosialidosis only (3,16).

Laboratory findings. In all types of galactosialidosis, foam cells in the bone marrow and vacuolated lymphocytes in blood smears are seen. Excessive amounts of sialyloligosaccharides are excreted in the urine. Combined deficiencies of β-galactosidase and neuraminidase in white blood cells or cultured skin fibroblasts are found. Demonstration of a cathepsin A deficiency, the primary defect, may aid in diagnosis (6). However, the catalytic activity of the protein is distinct from its protective function (1). Prenatal diagnosis is possible by enzyme analysis in cultured amniotic fluid cells or chorionic villus tissue (5,7).

I-cell disease (mucolipidosis II). I-cell disease, formerly known as mucolipidosis II, was originally described in 1967 by Leroy and DeMars

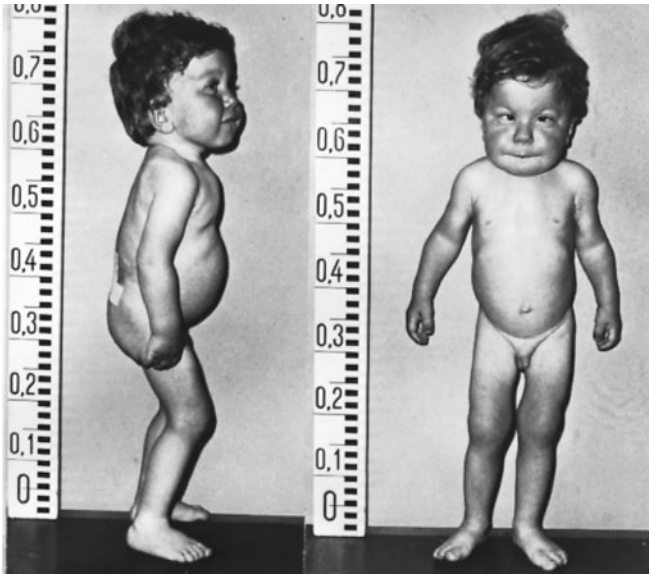

Fig. 5–32. *I-cell disease*. Hurleroid features are evident from early infancy. (From U Wiesmann et al, Acta Paediatr Scand 63:9, 1974.)

(6,12–15). It is characterized by severe psychomotor retardation, marked shortness of stature, facial features reminiscent of MPS I-H, impressive gingival enlargement, a rapid deteriorating course, and death from heart failure (hypertrophic cardiomyopathy), bronchopneumonia, or pulmonary atelectasis, usually by the age of 5 years (1,10) (Figs. 5–32 to 5–34). However, survival of patients with I-cell disease into their teens has been described (20). In a French-Canadian population, a prevalence at birth of 1/6184, has been found for mucolipidosis II, giving a carrier frequency of 1/39 (5). This disorder, like Hurler polydystrophy, is the result of a deficiency in recognition marker phosphotransferase. Inheritance is autosomal recessive, and consanguinity is high (20). The disease may be somewhat more frequent in Japan and there is probably genetic heterogeneity (19,24). The gene locus has been identified at 4q21–q23 (18). Important negative signs and symptoms are absent splenomegaly, equivocal or absent corneal cloudiness, and normal urinary excretion of MPS (7,25).

This disorder received the name of I-cell disease because of the numerous granular inclusions in the cytoplasm of cultured fibroblasts and amniotic fluid cells observed under phase-contrast microscopy (6,13). The inclusions are large lysosomes containing heterogeneous undegraded material (7).

At birth, the infants are small (<10th centile) and have coarse facies, muscular hypotonia, and dislocated hips. Inguinal hernias occur in males, and both genders may have tight and thickened skin that becomes more pliable with age (1,4,22) (Fig. 5–33). Hirsutism has been noted in about 60% of cases. During the first year, infants have a history of recurrent upper respiratory tract infections (rhinitis, otitis media), failure to thrive, and marked lack of psychomotor development. The full clinical picture is reached by 1 year of age (1). There is severe shortness of stature, with most never reaching the average height of a 1-year-old child and growth ceasing by the third year. This phenomenon differs markedly from MPS I-H, where excessive growth from 6 to 18 months of age has been frequently documented.

Motor retardation is more severe than mental retardation. Many patients do not accomplish unaided ambulation, but several older patients can walk without support. Most patients over 4 years of age can speak two-word sentences and are toilet trained.

Facies. Some patients have exhibited premature lightening of hair color. Head circumference remains normal with respect to stature. The facies is reminiscent of that in MPS I-H patients, with small orbits, flat supraorbital ridges, puffy eyelids, a slight degree of exophthalmos, and a pattern of tortuous veins around the orbits and temporal areas (1)

A B

Fig. 5–33. *I-cell disease*. (A,B) Characteristic facial appearance. (A courtesy of CI Scott, Wilmington, Delaware. B from NS Gordon, Postgrad Med J 49:359, 1973.)

(Fig. 5–33). The cheeks are full and pink, partly because of multiple fine telangiectasias. The gingiva shows marked enlargement (Fig. 5–34).

Intermittent copious nasal discharge has been noted, but to a lesser degree than in MPS I-H patients. Hearing impairment has been reported (9).

Mild corneal clouding has been documented as a late sign in about 40% of cases, but vision is not impaired. However, on slit lamp examination, all patients have some degree of corneal opacification. Glaucoma and megalocornea have been occasionally noted (16).

Musculoskeletal system. Shortness of the neck and a deformed thoracic cage are common. Umbilical and/or inguinal hernias are found in up to 75% of cases. Despite hypotonia, there is considerable restriction of joint mobility, particularly in the shoulders and wrists. The hands and fingers are stubby and the wrists broadened. Restriction of motion is less impaired in the lower limbs, which appear hypotrophic. Thoracolumbar kyphosis with gibbus formation may be present, but is not observed in any patient who can stand upright. The costochondral junctions are knob-like. Pes valgus has been noted in 25% of neonates.

Radiographically, generalized demineralization, a coarse trabecular pattern, and extensive periosteal cloaking of all long bones are seen in early infancy (21). This phenomenon is also observed in newborns with G_{M1} gangliosidosis type I and the disorders cannot be differentiated radiographically at this stage. Congenital fractures have been reported (17). Periosteal new bone formation can be observed until 4–6 months of age. Subsequently, this overgrowth becomes confluent with the underlying cortex and disappears entirely at between 8 and 12 months of age. From that point on, dysostosis multiplex is observed as in MPS I-H, the bony abnormalities being more severe in I-cell disease patients than in MPS-I-H patients at comparable ages. Other differences are minor involvement of the calvaria and minor to moderate diaphyseal widening in long bones, particularly of the lower limbs in I-cell disease (4,26).

Stippled epiphyses, particularly of the calcaneus and knees, and pathologic fractures have been documented (11,12), as have dysharmonic epiphyseal ossification and butterfly vertebral bodies (8). Premature synostosis of skull sutures has also been reported (27). No lamina dura is found around the teeth. The metacarpals are proximally pointed, with the distal phalanges being poorly modeled (11).

Other findings. Minimal to moderate hepatomegaly, evident at birth, occurs in 40% of cases.

Oral manifestations. Enlargement of the gingiva and anterior alveolar process is present as early as 4 months of age and is slowly progressive.

Fig. 5–34. *I-cell disease*. (A,B) Marked thickening of gingiva. Note anterior open bite in A. (A from D Galili et al, Oral Surg 37:533, 1974. B from DT Whelan et al, Clin Genet 24:90, 1983.)

A

B

In some patients, it reaches grotesque proportions (14) and together with a thick tongue prevents proper closure of the mouth (Fig. 5–34). Usually the teeth are deeply buried in the hypertrophic tissue or do not erupt at all. Radiographic examination of the teeth reveals that the enamel is quite hypocalcified and that there is accumulation of storage material about the crowns of unerupted first molar teeth.

Laboratory findings. Peripheral lymphocytes contain large lysosomal cytoplasmic inclusions. The urinary excretion of GAGs is normal. All cultured fibroblasts contain an abundance of coarse cytoplasmic inclusions (hence I-cell disease), with a characteristic inclusion-free perinuclear zone (13).

Most lysosomal acid hydrolase activities, such as hexosaminidase, iduronate sulfatase, and arylsulfatase A, are considerably increased (up to 10- to 20-fold) in the serum but are decreased (10% to 20% of normal) in cultured fibroblasts. The ratio of extracellular to intracellular enzyme activities can also be used (15).

The enzymatic defect is UDP-*N*-acetylglucosamine:lysosomal enzyme *N*-acetylglucosamine-1-phosphotransferase (10). This enzyme is defective in both mucolipidosis II and III. The enzyme catalyzes the first step in the synthesis of the recognition marker, necessary for targeting the lysosomal enzymes to lysosomes (10). Heterozygotes have intermediate levels of phosphotransferase activity in cultured fibroblasts and isolated white blood cells (10). Measuring the activity of acid hydrolases in amniotic fluid and cultured amniotic cells is reliable for prenatal diagnosis (3,23). This has also been accomplished by assay of *N*-acetylglucosamine-1-phosphotransferase assay of chorionic villi (2).

Mucolipidosis III (pseudo-Hurler polydystrophy). Reported initially by Maroteaux and Lamy (8) in 1966, pseudo-Hurler polydystrophy is characterized by mild mental retardation or learning disabilities in about 50%, early restriction of joint mobility, dysostosis multiplex, and normal mucopolysaccharidurıa. At least 90 patients have been described (Figs. 5–35 to 5–37) (1,3,5,17).

Like I-cell disease, pseudo-Hurler polydystrophy results from a deficiency in recognition marker phosphotransferase (6). The disorder has autosomal recessive inheritance. The gene for *N*-acetylglucosaminyl phosphotransferase has been mapped to 4q21–q23 (10), and there is genetic heterogeneity (4,11a).

Typically, in the second or third year of life, restricted joint mobility, small stature, short neck, tight indurated skin, scoliosis, and hip dysplasia, often leading to a waddling gait, are noted. Mild nonprogressive mental retardation (IQ 65–85) has been found in most patients (5,12). A relatively benign clinical course has been reported in at least three adult patients (16).

Fig. 5–35. *Pseudo-Hurler polydystrophy*. Mildly Hurleroid facies.

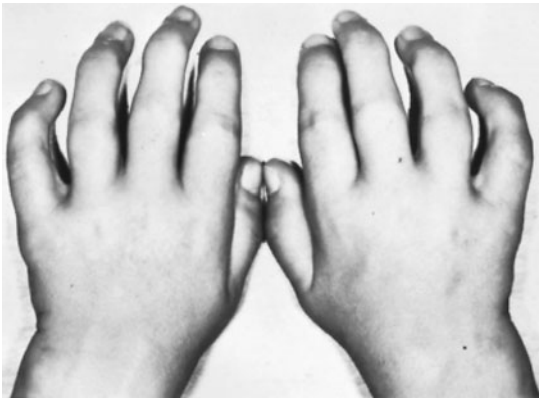

Fig. 5–36. *Pseudo-Hurler polydystrophy*. Fingers cannot be flexed or extended. (Courtesy of J Sensenbrenner, Baltimore, Maryland.)

Facies. The facies has been variable, but most patients exhibit some coarsening of features (Fig. 5–35). The mandible becomes progressively prognathic.

Eyes. Under slit-lamp examination nearly all patients have corneal clouding, often occurring together with mild retinopathy and hyperopic astigmatism (5,15).

Musculoskeletal system. Short stature, decreased upper-to-lower segment ratio, and shortened arm span are present in all patients. Joint stiffness, suggestive of rheumatoid arthritis, begins about the age of 3 years (2) and progresses slowly until puberty (Fig. 5–36).

Premature closure of cranial sutures is frequent, but the skull is normal in shape. The foramen magnum is small. The clavicles are short and thick, with the midportions bowed superiorly. Vertebral body alterations seen within the first year of life are quite variable but generally are mild (1,11). There is flaring of the iliac wings with constriction of the iliac bones and prominent anterior superior iliac spines. The acetabula are shallow with oblique roofs. Progressive destruction of the capital femoral epiphyses is a striking feature in most patients (Fig. 5–37B). The metacarpals are pointed proximally. The carpal bones are small and irregular. Bone age is considerably retarded (Fig. 5–37A) (1,7,9).

Skin findings. A huge connective tissue nevus of the skin of the back has been described in an adult male patient (13).

Laboratory findings. Peripheral leukocytes are normal. Vacuolated plasma cells are often found in the bone marrow. Finely granulated intracytoplasmic material with staining characteristics of MPS has been found in bone marrow cells. Ultrastructural studies of cultured fibroblasts reveal lysosomal vacuoles containing abnormally accumulated lipids, glycoproteins, and MPS storage (14). Urinary excretion of MPS is normal but that of sialyloligosaccharides is excessive. The activities of most lysosomal enzymes are low in fibroblasts, but high levels (5–50 times normal) are found in serum, findings similar to those demonstrated in I-cell disease (6).

The enzymatic defect is UDP-*N*-acetylglucosamine-1-phosphotransferase (6), the same as that found in I-cell disease. Heterozygotes can be identified by measuring the activity of phosphotransferase in cultured fibroblasts or isolated white blood cells (6). Obligate heterozygotes also have somewhat elevated levels of serum β-hexosaminidase (6).

Sialic acid storage diseases (includes Salla disease). The sialic acid storage disorders include Salla disease and the more severe infantile free sialic acid storage disease (ISSD). Intermediate forms may also exist. Salla disease and ISSD are most likely allelic disorders (18). Salla disease, characterized by early onset of developmental delay, ataxia, and minor dysmorphic features without signs of visceral or ocular involvement (1), was named after the geographical area in which the original Finnish kindred was found. Among the 92 cases reported so far, 87 come from Finland. It may be genuinely rare outside Finland or underdiagnosed (17,21). Infantile free sialic acid storage disease is more severe, is rare (less than 30 cases), and has no ethnic or geographic predilection. The mode of inheritance of Salla disease and ISSD is autosomal recessive. Both disorders are allelic and map to chromosome 6q14–q15 (10). The gene is involved in anion transport (23). There is some genotype-phenotype correlation (1a).

The clinical picture may vary (7) from the hypotonic, nephrotic syndrome or neonatal ascites (60%) of a newborn baby to the severely disabled adult with a nearly normal life span (4,6,11,15). Somatic growth is often retarded (6). Death ensues in early infancy (mean age at death, 13 months).

Facies. The facial features are usually normal in Salla disease but are often abnormal in ISSD. They may be coarse at later stages of the disease but to a much lesser extent than in other lysosomal storage disorders (6). Gingival enlargement at birth is common (25).

Eye findings. Ocular horizontal nystagmus may be an early presenting sign, even before muscular hypotonia and ataxia. Eye findings such as those found in other lysosomal storage disorders, e.g., corneal clouding, are absent in Salla disease (6).

Organomegaly. In Salla disease, there is no organomegaly. In ISSD, nephrosis has been reported (22), cardiomegaly was found in 9 of 21 cases, and hepatosplenomegaly and ascites with inguinal hernia in the first months of life are seen in roughly 60% (3,9). Especially good reviews of the pathology are those of Hale et al (8) and Lemyre et al (9).

Neurologic findings. A low-voltage-type electroencephalographic recording is a constant finding in Salla disease patients over 10 years of age. Cranial CT has revealed cortical and basal atrophy which is more pronounced in older than in younger patients (6). Brain atrophy has also been reported in MRI studies of ISSD (12). Neuropathological findings in Salla disease include reduction of cerebral white matter and degenerative features in the cerebellum (2,22a).

Differential diagnosis. There are four clinical entities (a-d) that present with intracellular accumulation and urinary excretion of sialic acid. Distinction between Salla disease and (*a*) ISSD is easy in typical cases, as a relatively severe phenotype points to the latter disorder. Hydrops/ascites (65%), prematurity (60%), psychomotor retardation (100%), failure to thrive (100%), visceromegaly (100%), dysmorphic features (100%), and hypopigmentation of the skin(100%) also characterize ISSD (6,9). Sialuria (*b*), originally described in 1968, is a rare disorder of free sialic acid metabolism (5,24). It is probably allelic to Salla disease and is due to mutations in UDP-*N*-acetylglucosamine 2-epimerase (20). The clinical presentation is characterized by varying degrees of developmental delay, hepatosplenomegaly, and coarse facies (6). The accumulation of sialic acid is in the cytosol and not in the lysosomal fraction as in Salla disease and ISSD. In patients with (*c*) sialidosis caused by a deficiency of neuraminidase, lysosomal accumulation of storage material is found in the urine, but not free sialic acid (6). The clinical findings in (*d*) galactosialidosis may look similar to those of ISSD but can be differentiated by assaying urinary oligosaccharides and enzyme activities in leukocytes.

Laboratory findings. There is increased urinary excretion of free sialic acid in Salla disease and ISSD (14). Vacuolated lymphocytes or enlarged lysosomes on electron microscopic examination of skin or on conjunctival biopsy can be found (16). Prenatal diagnosis has been accomplished (13,14) and is now possible by using markers linked to chromosome 6q (19) and mutational analysis. Heterozygote detection is also possible by analysis of markers linked to 6q (10).

Mucolipidosis IV (Berman syndrome). Berman et al (5) first described in 1974 a rare lysosomal storage disease characterized by bilateral corneal opacities in infancy, full facial features with puffy eyelids, hypotonia, and progressive psychomotor retardation (7,10). Storage of intralysosomal phospholipids and glycoconjugates in tissues occurs as a result of deficiency of soluble ganglioside sialidase (2,3). Electron microscopic studies of skin biopsies can be used as a diagnostic tool (18).

Mucolipidosis IV has autosomal recessive inheritance, with about 80% of the patients being Jews of Ashkenazi origin, probably from Poland-Lithuania (18a,20). There may be genetic heterogeneity in this disorder (6,9). The gene mapped to 19p13.2-p13.3 has been linked to mucolipidosis IV (3,21). The gene encodes a novel membrane protein, mucolipidin (3).

Facies. The face is full, but unlike that of other mucolipidoses, it is not truly coarse. Some patients have a somewhat bulbous nose and full lower lip (7,8,15).

Eyes. Strabismus, amblyopia, myopia, photophobia, increased lacrimation, and bilateral moderate to severe corneal clouding are seen in infancy (5,14,15,20). Corneal involvement is congenital in about one-half of the cases (1). The latter improves with time but tapetoretinal changes and marked pallor of the optic discs become enhanced in older children (20). Recurrent episodes of severe ocular pain have been reported (16).

Organomegaly. Organomegaly is absent.

Skeletal anomalies. No skeletal changes or restricted joint movements are observed.

Neurologic. Mild to severe mental and motor retardation appears during the first year of life. Initially, hypotonia with normal or decreased reflexes is followed in time by athetosis and spasticity with hyperreflexia and clonus (15,22).

Differential diagnosis. The severely affected corneal epithelium with an intact Bowman's membrane distinguishes mucolipidosis IV from MPS and G_{M1} *gangliosidosis*. Lack of identifiable enzyme changes in serum and tissues rules out *sialidosis, I-cell disease*, and *pseudo-Hurler polydystrophy*.

Laboratory findings. There is no increase in urinary MPS. Phase contrast examination reveals numerous 1×2 mm inclusions in cultured fibroblasts similar to those in I-cell disease.

Diagnosis is confirmed by electron microscopic observation of characteristic storage bodies (single membrane, limited vesicles), filled with fibrillogranular material (MPS) and lamellar cytoplasmic bodies (phospholipids) in biopsied tissues (cornea, conjunctiva, skin, fibroblasts) (9,11,18). Fibroblasts have reduced (but not absent) ganglioside β-neuraminidase levels (4). The disorder has been diagnosed prenatally by ultrastructural examination of cultured amniotic fluid cells and chorionic villi for inclusions (12,17). Prenatal diagnosis is now possible with molecular markers (21).

Mucosulfatidosis (Austin syndrome, multiple sulfatase deficiency). The clinical features of mucosulfatidosis, a disorder described by Austin (3) in 1973, are those found in (*a*) steroid sulfatase deficiency (ichthyosis); (*b*) mucopolysaccharidoses [dysostosis multiplex, psychomotor delay, coarse facial features (Fig. 5–38), stiff joints, hearing loss, hepatosplenomegaly]; and (*c*) late infantile metachromatic leukodystrophy (motor weakness, psychomotor delay, demyelinization, and gliosis of white matter of the brain) (5). Corneal opacification does not occur. Oral changes are similar to those of MPS I-H, MPS II, and MPS VI. More than 50 cases have been reported (1,3,4,6,7,8,12,14,15). The eye findings have included skew deviation, optic atrophy, retinal degeneration, and cherry-red macula (7,9).

Children presenting with symptoms during the first 2 years of life then gradually lapse into a vegetative state and succumb during the late first or early second decade. Speech and locomotion are not achieved. However, survival into the third decade has occurred (9). Cervical cord compression and severe hydrocephalus have been reported (10).

Fig. 5–38. *Mucosulfatidosis*. Coarse facial features. (Courtesy of RD Burck, New York, New York.)

The decrease in arylsulfatase A, B, and C activities is caused either by impaired enzyme production or excessive degradation. Mucopolysaccharidurias and sulfatiduria occur. Schmidt et al (13) showed that a conserved cysteine residue in sulfatases is replaced by a 2-amino-3-oxopropionic acid residue normally, but not in sulfatases derived from multiple sulfatase deficiency cells. It has been proposed that this defect in post-translational conversion is the basic defect in mucosulfatidosis.

Inheritance is autosomal recessive. Prenatal diagnosis using chorionic villi is possible (11).

There is a Saudi variant (1,2) that differs from classic multiple sulfatase deficiency by the presence of macrocephaly, corneal cloudiness, severe dysostosis multiplex, and gibbus and the absence of ichthyosis, retinal degeneration, severe deafness, severe mental retardation, and dementia. The chief neurologic presentation is cervical cord compression due to axis abnormalities.

Laboratory findings. An increase in cerebrospinal fluid protein has been demonstrated. Nerve conduction velocity is slowed. Alder-Reilly granules are found in bone marrow and peripheral blood leukocytes. Besides the arylsulfatase A deficiency, there is a loss of activity of arylsulfatases B and C and four other sulfatases that help to degrade mucopolysaccharides (3).

The disorder is most often confused with *MPS II (Hunter syndrome)*.

Other metabolic disorders with dysmorphic features

Fabry syndrome (angiokeratoma corporis diffusum universale). The clinical syndrome was described independently in 1898 by two dermatologists, Anderson (2) in England and Fabry (25) in Germany. The characteristic cutaneous lesions led Fabry to call this disease "angiokeratoma corporis diffusum universale." The disorder results from the deficient activity of α-galactosidase A (9,19), a lysosomal enzyme encoded by a gene located at Xq22 and containing seven exons (14,17,23,24,45). The enzymatic defect leads to the systemic accumulation of the glycolipid globotriaosylceramide, particularly in the lysosomes of endothelial, perithelial, and smooth muscle cells of blood vessels and, to a lesser degree, in histiocytic and reticular cells of connective tissue (21). The progressive endothelial glycolipid deposition in affected males results in ischemia and infarction, and leads to the major clinical manifestations (16,56). The disease is inherited as an X-linked recessive trait with complete penetrance and variable clinical expressivity in hemizygous males (34,41,42,53). Disease expression in most heterozygous females is limited to keratopathy; however, a few have been described with manifestations as severe as those of affected males (6,10)

Onset of the disease in affected males usually occurs during childhood or adolescence. Early manifestations include periodic crises of severe pain in the extremities (acroparesthesias), the appearance of angiokeratomas, hypohidrosis, and characteristic corneal and lenticular opacities (21,48). With advancing age, progressive vascular involvement causes ischemia and infarction leading to cardiac, cerebral, and renal vascular disease with death typically occurring in the fourth or fifth decade of life (32,35,40,56). Affected individuals who are blood group B or AB have a more severe course since the blood group B substance also accumulates due to the deficient α-galactosidase A activity (21).

There is no pathognomonic facies; however, frontal bossing and prominent lower jaw and lips have been reported in several male patients. Many patients appear young for their chronological age (55).

Skin. The cutaneous vascular lesions (angiokeratomas) are telangiectases, which usually appear as clusters of individual punctate, dark red to blue angiectases in the superficial layers of the skin. The lesions may be flat or slightly raised and do not blanch with pressure (54). There may be a slight hyperkeratosis over these lesions. They usually appear during childhood and, with age, progressively increase in size and number. Characteristically, these lesions are most dense between the umbilicus and the knees (over the iliosacral area, scrotum, posterior thorax, thighs, buttocks, and umbilicus) and have a tendency toward bilateral symmetry (21) (Fig. 5–39). The face, with the exception of the submental area, may be involved.

Variants, without the characteristic skin lesions, have been described (1,4,53). Hypohidrosis is a common symptom, and atrophic or sparse sweat and sebaceous glands have been reported (50,52). Males shave infrequently and body hair may be slight.

Eyes. Ocular manifestations include aneurysmal dilatation and tortuosity of conjunctival and retinal vessels as well as characteristic corneal and lenticular changes (50). The conjunctival and retinal vascular lesions are common and part of the diffuse systemic vascular involvement. The keratopathy is characterized by diffuse haziness and whorled streaks extending from a central vortex in the corneal epithelium. The corneal

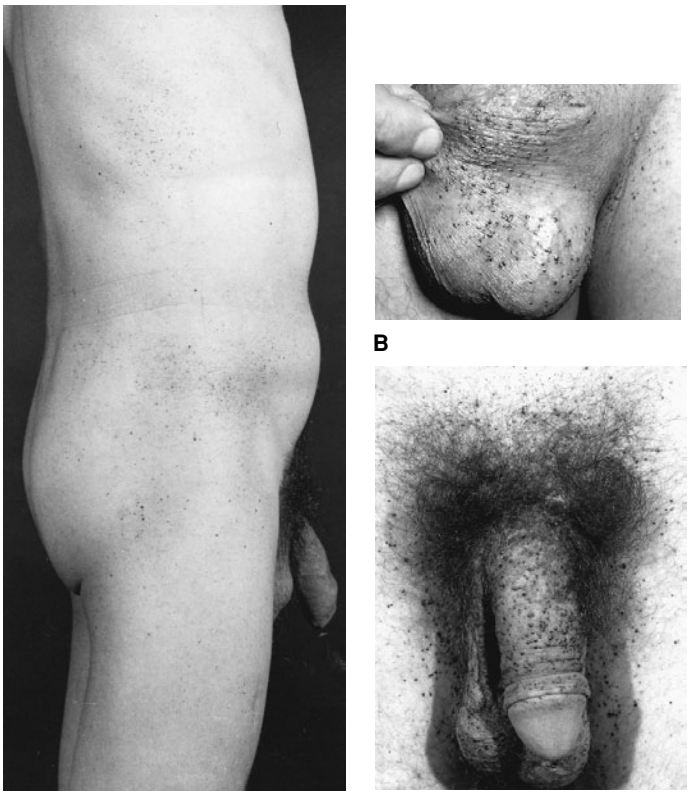

Fig. 5–39. *Fabry syndrome*. (A) Note distribution of skin lesions in 27-year-old man. (B,C) Small, somewhat raised, vascular lesions on scrotum and penis of patients. (A,B from A Rahmen, Trans Assoc Am Physician 75:371, 1961.)

lesions resemble the changes seen in chloroquine intoxication and must be observed by slit lamp microscopy (21). They occur in all hemizygous males and in about 80% of heterozygous females (38,50). The lenticular changes include a granular anterior capsular or subcapsular deposit seen in about 30% of males and a unique linear opacity (termed the "Fabry cataract") in hemizygous males and some heterozygous females that is best observed by retroillumination. The opacity appears as a whitish, spoke-like deposit of fine granular material near the posterior capsule (50). These lesions do not impair vision.

Cardiac, cerebral, and renal vascular manifestations. With increasing age, the major morbid symptoms result from the progressive involvement of the vascular system. Early in the course of the disease, casts, red cells, and lipid inclusions with characteristic birefringent "Maltese crosses" appear in the urinary sediment. Proteinuria, isosthenuria, and gradual deterioration of renal function and development of azotemia occur in the second to fourth decades of life (21). Cardiovascular findings may include hypertension, left ventricular hypertrophy, anginal chest pain, myocardial ischemia or infarction, cardiomyopathy, and congestive heart failure (10,14,20,22,29,35,57). Mitral insufficiency is the most common valvular lesion (20,47). Abnormal electrocardiographic and echocardiographic findings are common (28,57). Cerebrovascular manifestations result primarily from multifocal small vessel involvement. Death most often eventuates from uremia or vascular disease of the heart or brain (39).

Microscopic examination of various tissues demonstrates the accumulation of the glycolipid, predominantly in endothelial, perithelial, and smooth muscle cells of blood vessels, epithelial cells of the cornea and of glomeruli and tubules of the kidney, muscle fibers of the heart, ganglion cells of the autonomic nervous system, and peripheral Schwann cells and dermal nerves (12,30,32). Foamy, lipid-laden macrophages are seen in the bone marrow and lymph nodes.

Fig. 5–40. *Fabry syndrome*. Extensively swollen lower legs.

Acroparesthesias. The single most debilitating symptom of this disease is pain. Typically, affected males experience episodic crises of excruciating burning pain in fingers and toes in childhood that may become more frequent and severe in adolescence (49). These painful acroparesthesias may last several days to a week and are associated with low-grade fever and elevation of the erythrocyte sedimentation rate; these symptoms have led to the misdiagnosis of rheumatic fever. During the second and third decades of life, these recurrent, painful episodes may occur only infrequently, usually associated with a fever. However, in some patients, they may become progressively more frequent and severe, and the pain may radiate to proximal extremities and occasionally persist for 1–2 weeks. Affected individuals may be incapacitated for prolonged periods of time with pain that is so unrelenting that suicide has been attempted. It has been suggested that the etiology of the acroparesthesias may be due to impaired autonomic function (13) and involvement of the peripheral nervous system (44). The frequency and severity of these episodes are decreased by use of phenylhydantoin and carbamazepine (36,37).

Other clinical findings. Nausea, vomiting, diarrhea, and abdominal or flank pain are common gastrointestinal symptoms (26,27,43). Other less frequent features include massive lymphedema of the legs (Fig. 5–40) and dyspnea (11,46). Musculoskeletal findings have included a permanent deformity of distal interphalangeal joints of the fingers and avascular necrosis of the head of the femur and talus. Mild normochromic, normocytic anemia, presumably caused by decreased red cell survival, has been observed. Many hemizygotes appear to have growth retardation or delayed puberty.

Oral manifestations. Most patients have symmetric, pinpoint, macular, purplish spots (angiokeratomas) on the lips, particularly on the lower lip near the skin-mucosal junction, on either side of the midline (55) (Fig. 5–41). The lesions are smaller than those on the skin. The buccal mucosa appears to be involved to a lesser degree (21,55). The gingiva, soft palate and uvula are only rarely involved (48,55). The tongue is not affected. Involvement of the nasal mucosa with resultant epistaxis has been reported (55). Hearing loss has been noted (48). Glycosphingolipid accumulation has been demonstrated in dental pulp from hemizygous males (18).

Differential diagnosis. The condition can be diagnosed in hemizygous males by determining a history of acroparesthesias, the presence of characteristic skin lesions, and corneal and/or lenticular changes. Heterozygotes usually are asymptomatic; however, about 80% of patients have corneal lesions that can be observed by slit-lamp microscopy.

The skin lesions are so characteristic in distribution that need for differential diagnosis is extremely limited. The lesions of *hereditary hemorrhagic telangiectasia* are larger, do not involve the lower trunk and

Fig. 5–41. *Fabry syndrome*. Pinpoint lesions on lower lip. Oral lesions are generally limited to the lips and do not involve the tongue.

thighs, and are less numerous and more irregular. The Fordyce type of angiokeratoma is usually limited to the scrotum, and the Mibelli type forms warty lesions on the extremities or ears (21,54).

Angiokeratomas are also found in *aspartylglycosaminuria*, *β-mannosidosis, fucosidosis*, and *galactosialidosis*.

Laboratory aids. Histological and ultrastructural examination of biopsied skin, kidney, or other tissues will show birefringent lipid inclusions and lamellar inclusions in lysosomes, respectively (21). All suspect cases should be confirmed enzymatically by demonstration of deficient α-galactosidase A activity in plasma, isolated leukocytes, tears, or cultured fibroblasts or lymphoblasts (19,21,51). Prenatal detection can be accomplished by demonstration of deficient α-galactosidase A activity in chorionic villi obtained in the first trimester or in cultured amniocytes retrieved by amniocentesis in the second trimester of pregnancy (33). If the causative mutation is known (v.i.), prenatal diagnosis can be achieved using molecular methods. Detection of female carriers is carried out by mutational analysis (3).

The cloning of the cDNA encoding α-galactosidase A (7) has allowed further characterization of the molecular nature of the mutations that led to the enzymatic defect (5,8,15,23). At-risk females can be examined clinically, biochemically, immunofluorescentally, and molecular genetically for heterozygote identification (31).

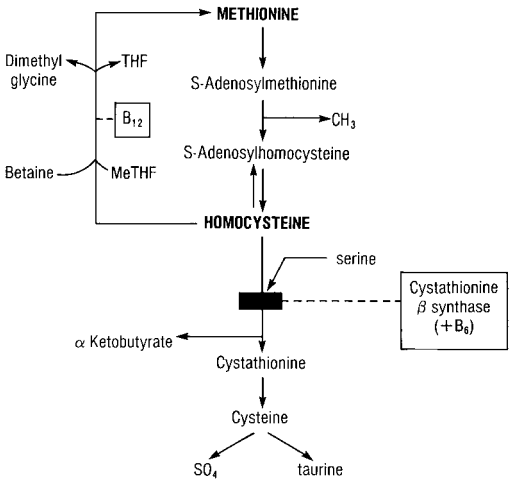
Homocystinuria (cystathionine synthase deficiency). Homocystinuria (cystathionine β-synthase deficiency) is accompanied by a distinctive clinical syndrome that includes ectopia lentis, arteriovenous thromboembolic episodes, dolichostenomelia, mental retardation, and osteoporosis (Figs. 5–42 to 5–45). It was first clearly distinguished from Marfan syndrome by Carson and Neill (6) and by Gerritsen and Waisman (21). Delineation of the biochemical defect followed soon after (19,20,39). The natural history of this condition has been expanded by a remarkable international survey of Mudd and others (42), who compiled the clinical findings for 629 affected individuals. Other excellent reviews are those by Przyrembel (47) and Fowler (16). A wide clinical spectrum of homocystinuria has been reported (12).

Fig. 5–42. *Homocystinuria*. Transsulfuration pathway. Cystathionine β-synthase is the key enzyme for conversion of sulfur-containing enzyme methionine to cysteine.



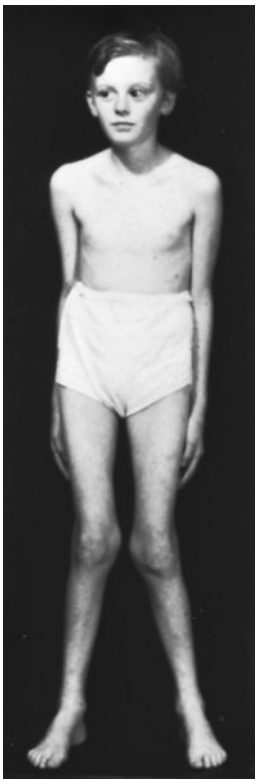


Fig. 5–43. *Homocystinuria*. Marfanoid habitus and genua valga.

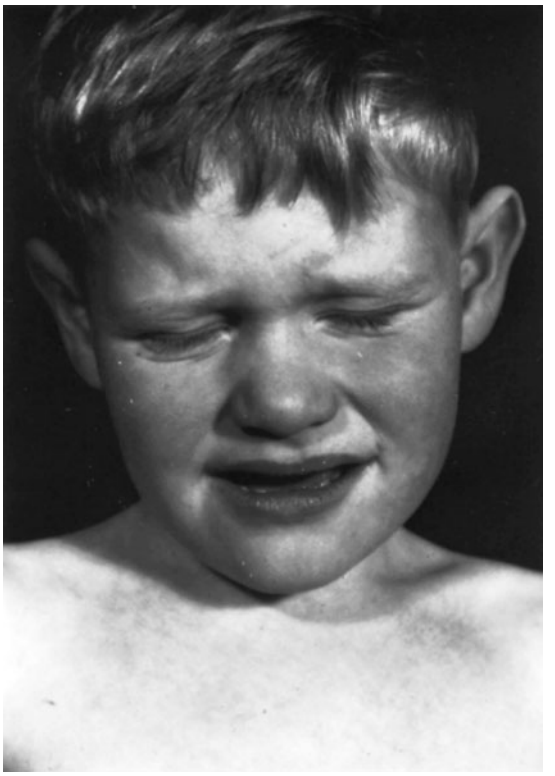
Fig. 5–44. *Homocystinuria*. Note malar flushing. (From NAJ Carson and G Gaull, New York, New York.)



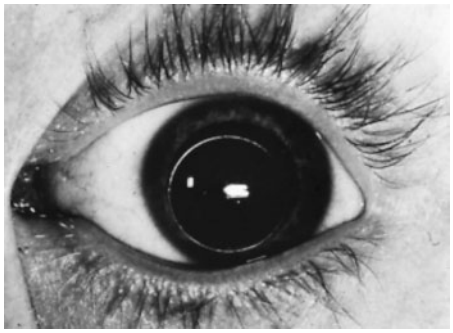


Fig. 5–45. *Homocystinuria*. Inferior dislocation of lens associated with acute glaucoma. (From MC Carey, Am J Med 45:7, 1968.)

Among 34 consecutively detected homocystinuria patients, the mean age at diagnosis was 24 years (range 1–61) (10). Cystathionine β-synthase is a heterodimeric enzyme whose size varies with the tissue of origin (43,55). Both subunits arise from the same parent polypeptide having a molecular weight of 63,000, but they are cleaved to fragments of 48,000 molecular weight in the process of enzyme activation. Thus, the size of the molecule and its activity are probably a function of tissue-specific proteolytic enzymes (55). The fetus probably directs a relatively larger proportion of available homocysteine through the 5-methyltetrahydrofolate-dependent methylation pathway than in the direction of cystathionine synthesis, with concomitant increases in methylneogenesis and conservation of the homocysteine moiety (43). Because fetal tissues and placenta lack γ-cystathionase activity, it has been suggested that cysteine may be an essential amino acid at this stage of life (60).

Cystathionine β-synthase is a key enzyme in the transsulfuration pathway that is responsible for the conversion of the sulfur-containing amino acid methionine to cysteine before it can be ultimately catabolized to its component parts—carbon dioxide, urea, and inorganic sulfate (Fig. 5–42). The enzyme normally requires pyridoxal-5′-phosphate, an active form of vitamin B6, as a cofactor and catalyses the replacement of the β-hydroxyl group of serine (another amino acid) by homocysteine to form cystathionine. In an important salvage pathway, homocysteine can also acquire a methyl group from an appropriate methyl donor, such as methylenetetrahydrofolate (MeH4F) or betaine (trimethylglycine), to regenerate methionine. A form of vitamin B12 known as methylcobalamin (MeCbl) is essential to this remethylation reaction (43). Homocysteine is the sum of the thio-containing amino acid homocysteine and the homocystinyl moiety of the disulfides cysteine-homocysteine, whether free or bound to proteins.

Cystathionine β-synthase deficiency is an autosomal recessive disorder with an estimated birth prevalence of about 1/200,000 to 1/335,000 (43). These figures are partly based on data from newborn screening programs that probably fail to recognize all patients. The much higher prevalence estimates in certain local surveys [e.g., New South Wales, Australia, (1/65,000–1/75,000); Northern Ireland (1/24,000)] further indicate an underestimate of the true frequency in populations with largely Irish ancestry (43,68). In contrast, the incidence is very low in other areas, e.g., Japan, where the rate is 1/900,000 (72).

In cystathionine β-synthase deficiency, both methionine and homocystine accumulate in various tissues, as well as in blood and urine. The deficiency has been studied in detail through the culture and biochemical or immunological characterization of mutant fibroblasts. There is a high concordance between the severity of the clinical syndrome and the extent of the enzyme defect (53).

The cDNA for human cystathionine β-synthase has been cloned and sequenced; alternative splicing during the formation of its mRNA and its expression in cultured cells have been reported (31).

Cystathionine β-synthase has been encoded by a gene located at 21q22.3 (36). There are two relatively common mutations, *I278T* and *G307S*, the former accounting for 15% and the latter for 58% of cases (51). To date, 16 different mutations have been identified (28,30), and a number of publications discuss the relation between genotype and phenotype (11,30,52,56). This allelic heterogeneity has clinical implications. Those individuals with no enzyme activity are essentially unresponsive to treatment with any amount of vitamin B6; those with residual activity in vitro are, as a rule, B6-responsive in proportion to that activity (24, 32,41,70,71). The degree of residual activity is relatively constant among family members, as are the clinical manifestations. There are also individuals, allelic compound heterozygotes, i.e., individuals with two different mutations for the cystathionine β-synthase gene, who may manifest a syndrome indistinguishable from that in apparently homozygous mutants.

Pathophysiology. Homocysteine, an amino acid with an active sulfhydryl side chain, readily forms disulfide bonds in place of its physiologic analog, cysteine. The proteins most susceptible to these abnormal reactions appear to be the collagens, although other structural peptides such as elastin may also be affected. Used as a drug, penicillamine is another sulfhydryl compound that can produce changes similar to those associated with cystathionine β-synthase deficiency via the same mechanism. The end result is weakened fibrous tissue, leading to altered bone formation, rupture of the ligaments of the lens, and abnormalities in joints, skin, and blood vessels (33,43).

Previously, the neurologic abnormalities were thought to arise from a deficiency of the enzyme product, cystathionine, which is a putative central nervous system neurotransmitter. Later, the mental deficit was attributed to high concentrations of a potentially toxic precursor, *S*-adenosylhomocysteine (Fig. 5–42). Adenosine itself is a known neurotoxin in vivo and *S*-adenosylmethionine accumulation leads to significant cytotoxic changes in cell culture. A third view—that the neurological changes are the result of multiple subclinic thromboembolic events—is not supported by autopsy examinations of the brain (43).

The relationship of homocystinuria to thrombosis and atherosclerosis has fascinated investigators since the disorder was first described (17,22,29). Much attention has been focused on abnormalities of platelet function, but the etiology of the thrombotic tendency associated with hyperhomocysteinemia has not been elucidated (57,69). Thromboxane biosynthesis was found to be enhanced in homocystinuria (14). This was thought to reflect, at least in part, in vivo platelet activation.

However, there are quite distinctive changes in the structure of the walls of large and small arteries, and vascular endothelial cell dysfunction has been described (17). Focal intimal and medial fibrosis together with perivascular connective tissue proliferation and widening of the internal elastic lamina have been linked to vascular damage initiated by high homocysteine concentrations. These lesions are also observed in animal studies with homocysteine loading and in homocystinuria as a result of 5,10-methylenetetrahydrofolate reductase (MTHFR) deficiency (Table 5–3) (29).

Clinical manifestations. Individuals with cystathionine β-synthase deficiency are normal at birth. Although the disorder is usually identified in childhood, more than 90% of patients reach their 16th birthday and more than 75% survive to the fifth decade (42).

Eyes. Ectopia lentis (Fig. 5–45) is a hallmark, being mentioned in 86% of the 472 case reports that gave an initial presenting sign (42). Dislocation results from disruption of the suspensory ligaments and occurs downward in most cases but may dislocate in any direction. Common secondary features include iridodonesis (particularly evident when the head is moved), marked myopia, and astigmatism. Anterior dislocation may cause pupillary block, glaucoma, and acute ocular pain (5). Cataract is usually the result of lens trauma (43).

Lens dislocation has occurred in more than 50% of patients by age 8 and in more than 90% by age 25 (42). Although B6 responders are less likely to dislocate regardless of treatment, early treatment appears to offer added protection to this group. Other reported ocular findings are optic atrophy, cystic degeneration of the retina, central retinal artery occlusion, and retinal detachment (5,9,20,65).

Musculoskeletal system. Affected individuals are tall and thin as children. True arachnodactyly and Marfanoid habitus with radiographic evidence of excessively long, thin bones (dolichostenomelia) are seen

Table 5–3. Causes of homocystinuria/hyperhomocyst(e)inemia

Underutilization of homocysteine due to impaired activity of CBS deficiency
Genetic CBS deficiency
6-azauridine triacetate administration
Isonicotinic acid hydrazide administration
Underutilization of homocysteine due to impaired activity of 5 methyl-tetrahydrofolate-homocysteine methyltransferase
Genetic MTHFR deficiency
Genetically determined failure to absorb vitamin B12—Immerslund syndrome
Failure of cellular uptake of B12—transcobalamin II deficiency
Failure to release B12 from lysosomes—cobalamin F disease
Failure to convert B12 to methyl- or adenosyl-B12—cobalamin C disease
Failure to convert B12 to methyl- or adenosyl-B12—cobalamin D disease
Failure to convert B12 to methyl-B12—cobalamin E disease
Failure to convert B12 to methyl-B12—cobalamin G disease
Methotrexate inhibition of dihydrofolate reductase
Nutritional B12 deficiency
Nutritional folate deficiency
Nitrous/oxide oxidation of methylcobalamin
Impaired excretion
Renal insufficiency
Artifactual
Bacterial metabolism of cystathionine to homocyst(e)ine
Mechanism uncertain
Colestipol plus niacin therapy

CBS, cystathione β-synthase; MTHFR, 5,10-methylenetetrahydrofolate reductase.

in one-third of cases (43). Other somatic manifestations include joint contractures, joint laxity, pes planus, pes cavus, pectus carinatum, pectus excavatum, kyphoscoliosis, widened metaphyses and epiphyses (most recognizable at the knee), genua valga, and increased carrying angle at the elbow (Fig. 5–43). Associated radiographic features include tibial growth arrest lines, metaphyseal spicules, enlarged carpal bones, short fourth metacarpals, elongated talus, and retarded calcification of the lunate bone in the hand (4,50,61). Of all the radiographic features, osteoporosis is the most frequent finding. Although present in less than 5% of patients under 4 years of age, it affects 70% of individuals over 20 (42). It appears to be less severe in the B6-responsive group. It is most often identified in the spine and is associated with biconcavity of the vertebral bodies. Some investigators have suggested that the latter finding is not a feature of osteoporosis per se but is of vascular origin, as the biconcavity is posteriorly placed—a feature typical of the osteopenia associated with chronic hemolytic diseases such as sickle cell anemia (43). However, vertebral wedging, kyphoscoliosis, and pathological fractures that heal slowly are all directly attributable to loss of bone mass (43). Although the progression of osteoporosis is less rapid in the B6 responders, the effect of B6 treatment is not clear (18,42).

Thromboembolic events. Thrombosis and embolism are life-threatening complications in this disorder. Large or small arteries and veins may be affected, and vascular occlusions can occur at any age (22,34,43). In an international survey of 629 patients, 253 events were reported in 29% of patients (42). Of these, 32% were cerebrovascular accidents, 51% involved peripheral veins (including 13% pulmonary embolism), 4% produced myocardial infarction, and 11% affected peripheral arteries or damaged major organs. In spite of a 4-year, event-free period in early infancy, there was a very sharp increase in thromboembolic events at puberty. By the age of 30, half of the reported patients had experienced at least one event. B6 responders were only marginally better off than nonresponders and the beneficial effect of B6 therapy was not clearly demonstrable. Surgery poses a significantly increased risk for thromboembolism (42). Many reports deal with the potential benefit for cardiovascular problems of a relatively low plasma homocysteine level (58,67). High plasma homocysteine is a risk factor for deep-vein thrombosis in the general population (22). Patients with a concurrent homocystinuria due to deficiency of cystathionine-β-synthase have an increased risk of thrombosis when they also have the factor V Leiden mutation (35). The growth-promoting effect of homocysteine on vascular smooth muscle cells, together with its inhibitory effect on endothelial cell growth, may explain homocysteine-induced atherosclerosis (63). It has been calculated that approximately 10% of the population's risk for coronary artery disease is attributable to elevated homocysteine levels (38).

Central nervous system. The degree of mental retardation associated with homocystinuria varies widely. Both profound retardation (IQ <30) and normal intelligence are described. In the international survey, the median IQ for B6 responders was 86 but for nonresponders was 64, a highly significant difference (42).

Seizures are characteristic, being reported at an earlier age in B6-nonresponsive patients. The great majority are of the grand mal type and affect about 20% of all patients (42). Also reported are nonspecific EEG changes (13,27), psychiatric disturbances (including schizophrenia) (1,25), dystonia (26), spasticity, and hyperreflexia (43). In some case, these latter two signs are related to a cerebrovascular thromboembolic event, but in others, they have been attributed to the disorder itself (8,42). In homocystinuria due to MTHFR reductase deficiency, stroke may occur (66).

Other findings. Other connective tissue findings include bilateral malar flush (Fig. 5–44) (50%), recurrent spontaneous pneumothorax (3), and livedo reticularis. Hepatomegaly caused by fatty liver is observed occasionally, and electromyographic abnormalities have been found in those patients with clinical myopathy. There is an increased incidence of bilateral inguinal hernia, and omphalocele has been described (43). Hypopigmentation is a feature of homocystinuria and can be shown to be reversible in patients with pyridoxine-responsive homocystinuria (48). Darkening of newly growing hair has been observed after initiation of pyridoxine therapy, creating a clear demarcation between the old, blond and the new, dark hair (48). Probably, DL-homocysteine inhibits tyrosinase by interaction with copper at the active site of tyrosinase. Recurrent early spontaneous abortion has been shown to be linked to hyperhomocystinemia (46,59,72). Homocysteine metabolism may play a role in the prevention by folic acid of neural tube defects (37).

Oral findings. The palate is often narrow and highly arched. The teeth have been reported to be crowded and irregularly aligned. Mandibular prognathism has been noted (42).

Diagnosis and laboratory aids. Mass neonatal screening programs detect some of the patients with homocystinuria (43,44). They are more likely to miss those with milder disease who, in turn, are more likely to respond effectively to pyridoxine (43). Infants and children at risk are usually screened by the cyanide-nitroprusside spot test for urine, but other disorders of sulfur amino metabolism will also produce a positive test (62). Moreover, false negatives have known to occur. Other investigators (2) recommend measuring plasma total homocysteine as the most reliable method for diagnosis. Diagnostic proof, particularly in individuals without clinical findings, rests with the demonstration of enzyme deficiency in fibroblast culture (53,54). Prenatal diagnosis is possible using this assay on cultured amniocytes (15).

The human cystathionine β-synthase gene spans over 30 kb and consists of 19 exons (7). At least 17 mutations in the cystathionine β-synthase gene have been identified on the basis of clinical homocystinuria (64). The most prevalent mutations are the gly307ser and ile278thr mutations.

Differential diagnosis. Other causes of homocystinuria are listed in Table 5–3. Inborn errors affecting the remethylation pathway from homocysteine to methionine (Fig. 5–42) constitute the majority of these.

Inherited deficiency of the MTHFR enzyme is an autosomal recessive condition characterized by mental retardation and sometimes early death (43). Enzyme activity is impaired if the B12 cofactor is deficient, a situation that can arise if there is dietary B12 deficiency, a B12 malabsorption syndrome, or defect in the conversion of B12 to the methylcobalamin form used by the remethylation enzyme (5,23,45,49). Because these patients are unable to resynthesize methionine, they have low plasma methionine, clearly distinguishing them from patients with cystathionine β-synthase deficiency. They may also have other abnormalities associated

with disturbed B12 mechanism, such as methylmalonic aciduria and/or megaloblastic anemia, but they do not have a Marfanoid somatotype or associated clinical features (40,49).

Lens subluxation is a feature of other disorders of sulfur amino acid metabolism, as well as Marfan syndrome and related disorders (43). The Marfanoid habitus is found in *Marfan syndrome*, congenital contractural arachnodactyly, *XXY syndrome*, *XYY syndrome*, sickle cell anemia, *nevoid basal cell carcinoma syndrome*, and *multiple endocrine neoplasia, type 2b*.

Hypophosphatasia. Hypophosphatasia is an inherited disorder of bone mineralization characterized by rhachitic changes in childhood or osteomalacia in adult life, absence of tooth cementum and premature loss of teeth, and decreased alkaline phosphatase enzyme activity (Figs. 5–46 to 5–50). Hypophosphatasia was first identified as a separate entity by

Fig. 5–46. *Hypophosphatasia*. Severe lethal hypophosphatasia. Note short limbs.

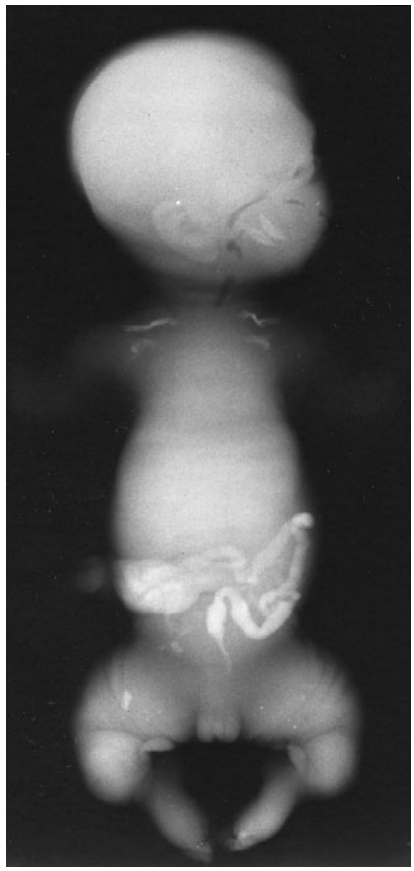

Fig. 5–47. *Hypophosphatasia*. Note markedly impaired mineralization and short extremities.

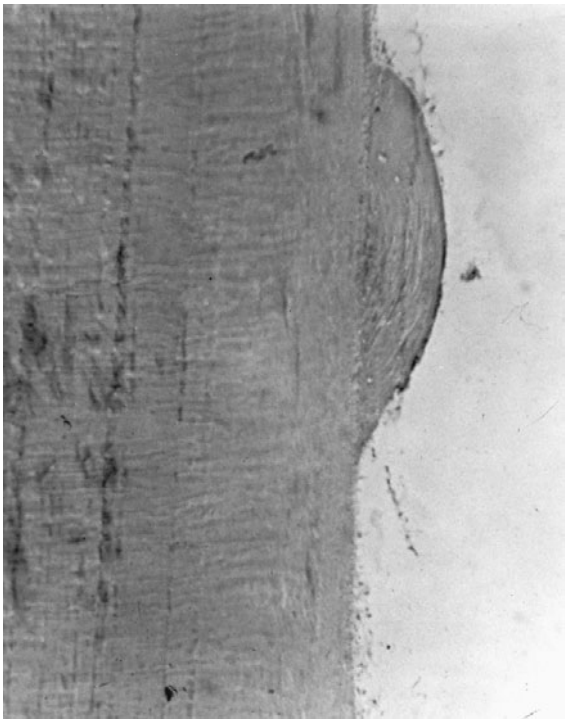
Fig. 5–48. *Hypophosphatasia*. Note large midmetaphyseal ossification defects and angulated tibias.

Fig. 5–49. *Hypophosphatasia*. Premature loss of deciduous teeth, most commonly affecting the anterior region.

Rathbun (43) in 1948, although there are earlier case reports (42). A wide range of presentations are described, but all patients have some deficit in serum and tissue alkaline phosphatase. From a clinical perspective, most individuals can be classified as having the perinatal (lethal), infantile, childhood, or adult form of the disorder (14,42). People who have only dental manifestations are regarded as having "odontohypophosphatasia." A very rare variant is called "pseudohypophosphatasia" (45) and resembles infantile hypophosphatasia, except that serum alkaline phosphatase activity is not reduced. A mild autosomal dominant form has been delineated. Prenatally it looks severe but has a benign course (32,40). Not all patients can be classified clinically. Some authors classify patients with hypophosphatasia into only two types: severe and mild (12,28,29). Others state that the levels of bone alkaline phosphatase immunoreactivity in serum reflect disease severity (65).

Fig. 5–50. *Hypophosphatasia*. Section of tooth in hypophosphatasia. Note almost complete absence of cementum.



Genetics and biochemistry. The human alkaline phosphatases share the property of hydrolyzing artificial phosphoester substrates at alkaline pH. They constitute a system of multiple molecular forms that originate from at least three different genes and multiple tissue-specific post-translational modifications (33). In hypophosphatasia, both the tissue-specific placental and intestinal isoenzymes localize to chromosome 2q34–37 (7) and are largely intact, but the so-called tissue-nonspecific or liver/kidney/bone group of isoenzymes is usually markedly deficient (33,52). A single gene localized to chromosome 1p34–p36 (17) codes for the protein precursor that is then modified to produce at least three electrophoretically and biochemically distinct isoenzymes found in bone, liver, and kidney, respectively (16,23). There are many mutations (50a). These isoenzymes are antigenically similar but have different developmental sequences (33,48). The bone isoenzyme is believed to play an important role in calcification, and its production varies with the rate of bone mineralization (44). Possible functions may include the supply of inorganic phosphate through phosphoester hydrolysis for mineralization, the clearing of pyrophosphate, a calcification inhibitor, and the binding and storage of inorganic phosphate (39,57).

Although pathologically similar to vitamin D-deficiency rickets, hypophosphatasia is clearly differentiated as a disorder of bone matrix rather than bone mineral, as secondary mineralization is intact (14,42). Moreover, vitamin D metabolism is normal in this disorder (60). Acid phosphatase activity, a marker of osteoclastic function, is also normal (14).

The deficit in the tissue alkaline phosphatase is reflected in decreased total serum activity, a composite of the various isoenzyme fractions (33). In serum, too, it is the tissue-nonspecific enzyme that is very low, but intestinal enzymes may also be depressed (57). Neutrophils and cultured skin fibroblasts are also deficient in alkaline phosphatase activity (7,49,52,55).

The birth prevalence of the severe form of hypophosphatasia in Toronto, Canada, has been estimated to be 1/100,000 live births (15). The disorder is especially prevalent in inbred Mennonite families from Manitoba, Canada, where 1 in 2500 newborns manifests severe disease and about 1 in 25 individuals is a carrier (18,57). Both recessive and dominant modes of inheritance have been observed in different hypophosphatasia kindreds (21,24,31,59). The frequency of consanguinity and the recurrence rates for infantile hypophosphatasia are clearly indicative of a recessive mode (18,30), but the suggestion that hypophosphatasia is an autosomal dominant condition with homozygous or compound heterozygous lethality is in keeping with the data on the adult form of the disorder (12,14,21,58). Subjects with childhood or adult hypophosphatasia can also be compound heterozygotes for tissue-nonspecific alkaline phosphatase missense mutations (57). It has now been demonstrated that all clinical forms of hypophosphatasia, with the possible exception of pseudohypophosphatasia, can result from tissue-nonspecific alkaline phosphatase missense mutations or, rarely, frameshift mutations (37). However, the precise genetic basis for most cases remains to be solved (57).

Clinical features. In the perinatal (lethal) form of hypophosphatasia, markedly impaired mineralization occurs in utero. The extremities are shortened, the long bones are deformed, and the cranial vault fails to mineralize (craniotabes) (Figs. 5–46 and 5–47). Polyhydramnios has been observed more frequently in hypophosphatasia pregnancies (46). Premature stillbirth deliveries are not uncommon (4,28). Radiographs show small, sclerotic bones at the base of the skull as well as a membranous calvaria. The ribs are small, thin, and deformed. The vertebrae are spottily involved; some are unossified, some dense, some rounded, and some flattened. Sclerotic patches are also observed in the ribs and other tubular bones. In some infants, almost no bone is formed. In others, the metaphyses are cupped and camptomelic changes are noted. The midshaft of the ulna and fibula may protrude through the skin. Spikes may be present at the elbows and knees (16b,35,47,51a,68). The clavicle is the least affected bone. In live births, the outcome depends on the extent of pulmonary and neurological compromise, but demise usually occurs within a few days (14,26).

Infantile. Those individuals with the infantile form commonly present some time after birth because of failure to thrive (14,57). This form is apparently difficult to recognize with radiographs; most newborns do well for a short period and then experience a wide variety of problems related to impaired bone growth. Hypercalcemia may be marked, explaining a history of irritability, poor feeding, anorexia, vomiting, hypotonia, polydipsia, polyuria, dehydration, and constipation. Episodes of unexplained fever, tender bones, and respiratory distress are also described. Renal function may be impaired by hypercalciuria and nephrocalcinosis. Traumatic fractures are frequently found (1,14,26). Mortality may be as high as 40% (50,51,67).

The anterior fontanel is often enlarged and may bulge. The membranous cranial sutures are also frequently widened, and some degree of ocular prominence resulting from shallow orbits may be apparent within the first few months of life. Head circumference also increases more slowly than expected as premature suture fusion sets in. Radiographs show widespread demineralization and rhachitic changes in the metaphyses (Fig. 5–48), but usually with less diaphyseal bowing than would be expected with severe metaphyseal disease (26). A rhachitic "rosary" is common. In infants who survive, there is often spontaneous improvement in mineralization and remission of clinical problems other than craniostenosis (64). Although the sutures appear widened and membranous, intense mineralization activity may be detectable by nuclear scintigraphy (50). Moderate short stature in adulthood and premature loss of deciduous teeth are also common. Skin dimples have been described (56). Carriers of the infantile form are stated to have less dense bones (8).

Childhood. Childhood hypophosphatasia is a milder condition that often presents as "rickets" in the second and third year of life (26). Signs of intracranial hypertension or failure to thrive are typical (14,26,57). Some long bone deformity is not unusual but tends to recede with time. The most serious treatable complication in this group is craniosynostosis. All sutures appear to be involved, but ocular prominence resulting from shallow orbits can be quite characteristic. Other ocular signs include keratopathy and conjunctival calcification caused by hypercalcemia (3). Spontaneous remission of bone disease is common. In at least one case, this has been accompanied by an increase in serum alkaline phosphatase activity (64).

Adult. The adult form is mild, but osteomalacia may produce significant pseudofractures, severe bone pain, and increased susceptibility to traumatic fracture (14,25,54,57,59). The proximal femur is a frequent site of pseudofractures that extend to complete transverse fractures and loss of mobility (9). In this group, a bone scan can be helpful in identifying and clarifying the sources of pain. There is also a predilection for chondrocalcinosis and marked osteoarthropathy later in life (61).

Oral manifestations. Delayed dentition, premature loss of deciduous teeth, and spontaneous loss of permanent teeth are characteristic of hypophosphatasia (Fig. 5–49) (2,6,13,36,41). These features may be the only clinical signs of disease, thus giving rise to the term "odontohypophosphatasia" for this variant condition (20,41). The anterior deciduous teeth are more likely to be affected and the most frequent loss involves the incisors. The process is that of relatively painless extrusion and does not invoke periodontal inflammation (2). Dental X-rays show reduced alveolar bone, enlarged pulp chambers and root canals, decreased cementum, but normal enamel (2,41). Findings in the permanent dentition may include large coronal pulp chambers, abnormal root cementum, and disturbances of the mineralization of the coronal dentin (36).

Pathology. In the infant, bone histomorphometry reveals a marked excess of osteoid volume and a osteomalacic pattern of tetracycline labeling in dynamic studies (14). Bone alkaline phosphatase is usually undetectable and electron microscopy shows otherwise normal subcellular architecture of osteoblasts and their associated matrix vesicles (14,39). Iliac crest biopsies in adults show less dramatic and more variable changes. The severity of the osteomalacia, as measured by relative osteoid volume, is inversely correlated with the amount of detectable alkaline phosphatase and with the concentration of serum alkaline phosphatase activity (12). In shed teeth, marked deficiency or absence of cementum (Fig. 5–50) is a striking characteristic, accounting for the ready loss of teeth (2,41,57). This appears to be the result of aplasia, since the resorption of cementum has never been observed. Dentin formation is delayed, thus less is formed. Interglobular dentin and osteodentin have also been seen (2,5,41).

Diagnosis and laboratory aids. Hypophosphatasia can be diagnosed on clinical grounds alone, but low serum concentrations of alkaline phosphatase will often help to rule out other disorders with similar findings. In general, the more severe the disease the lower the serum alkaline phosphatase activity level appropriate for age (57). In forms of rickets or osteomalacia other than hypophosphatasia, serum alkaline phosphatase activity is typically increased (57). In most cases, the detection of increased urinary phosphoethanolamine or pyrophosphate will serve to confirm the diagnosis, but is not pathognomonic (27). Measurements of the B6 vitamin pyridoxal-5′-phosphate in serum is a more sensitive test, as levels tend to be abnormally low in other bone diseases characterized by increased alkaline phosphatase activity (57). It may also be helpful in identifying mildly affected patients or detecting variants such as pseudohypophosphatasia (10,11). Alkaline phosphatase is also characteristically low in cultured fibroblasts from hypophosphatasia (60,62) but shows poor correlation with the severity of the disorder (60).

Neonatal hypophosphatasia can be distinguished from *osteogenesis imperfecta*, *achondrogenesis* of various types, *campomelic dysplasia*, and other congenital osteochondrodysplasias by radiographic and biochemical findings. Childhood and adult hypophosphatasia should be differentiated from treatable forms of rickets and osteomalacia and from other metaphyseal chondrodysplasias.

In the severe neonatal and infantile forms, prenatal diagnosis has been achieved using ultrasonic detection of the bony malformations (66). Monoclonal antibody testing of chorionic villus samples has been used successfully for first-trimester prenatal diagnosis (4,53). Successful prenatal diagnosis has also been reported with use of molecular techniques in chorionic villi samples, (22,34,38). High values of pyridoxal-5' phosphate have been found, and Gehring et al (16a) have suggested that during rapid growth, heterozygotes may be distinguished.

Pseudohypoparathyroidism (Albright hereditary osteodystrophy, pseudopseudohypoparathyroidism)

Albright et al (2) first described pseudohypoparathyroidism (PHP), a hypocalcemic syndrome similar to hypoparathyroidism but with renal and skeletal resistance to parathyroid hormone (PTH). Ten years later, Albright and associates (3) defined a normocalcemic variant of PHP, calling it "pseudo-pseudohypoparathyroidism" (PPHP). Most authors now accept that PHP and PPHP are variants of the same condition. Clinical and biological heterogeneity in PHP may be great (18,33). Chase et al (8) delineated two different types of PHP on the basis of the biochemical response to exogenous PTH. An excellent minibiography is that of Kruse (26a).

In the more common type I defect, neither cAMP nor phosphate are increased in urinary excretion in response to PHT. In the type II defect, there is a cAMP response to PTH, but no phosphate diuresis (Table 5–4). A decade later, Farfel et al (17) and Levine et al (31) reported that a GTP-binding protein was defective in erythrocytes of some PHP type-I patients. This protein, called "stimulatory guanine nucleotide-binding protein" (Gs), is responsible for coupling the cellular receptor that binds PTH—an external cell membrane event—with the formation and release

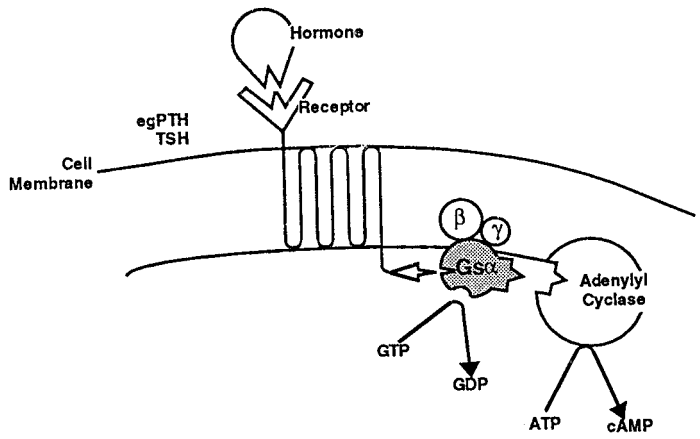
Table 5–4. Pseudohypoparathyroidism

Form	Ca^{2+}	Parathormone	cAMP response	G protein	S
Type Ia	↓	↑	↓	Lack	+
Type Ib	↓	↑	↓	Normal	−
Type II	↓	↑	Normal	Normal	−
PPHP	Normal	Normal	Normal	Lack	+

PPHP, pseudo-pseudohypoparathyroidism.

of cAMP on the internal membrane surface (Fig. 5–51). In signal transduction, a variety of G proteins is present (51). Distinct mutations in the gene encoding the Gs-α subunit, mapping to chromosome 20q13.2 (20), have been identified in affected individuals with PHP type Ia (31,34,50,61,64). In several unrelated patients with PHP, del(2)(q37) was found, perhaps pointing to a second disease locus (40,62). Some deletions were visible, whereas others required detection by fluorescence in situ hybridization (FISH) (62). These patients also exhibited brachymetaphalangy and mental retardation, and they have shown normal levels of Gs-α protein. Because the vasoactive intestinal peptide receptor (RDCI) has also been mapped to 2q37, this may be a candidate gene (42). Patients with PHP type Ia may show clinical signs of endocrinopathies, other than hypoparathyroidism, which are presumably due to generalized hormone resistance (28,30,53). Patients with PHP type Ia have a round face, are obese, and have short bones in the fingers, especially the fourth and fifth metacarpals, and subcutaneous calcification (2). Both PHP type Ia and PPHP can occur in the same family. Both are associated with mutations in the α unit of the G protein (Gs-α) and with a 50% reduction in Gs-α protein. In patients with PHP type Ib, physical appearance is normal, skeletal features are missing, and hormone resistance is limited to PTH. The defect is located proximal to cAMP formation, but unlike PHP type Ia, the defect is likely to involve a specific signal transduction component such as the PTH receptor (53). In PHP type Ib, the Gs-α-protein level is at 100%. A further subtype of PHP (type Ic) is characterized by low cAMP and phosphate responses to PTH, abnormal skeletal features, and 100% Gs-α protein levels. A defect more distal to PTH-stimulated cAMP production is involved in PHP type II (53), which was originally described in a child of normal appearance who was hypocalcemic and hyperphosphatemic, showed elevated serum PTH concentration, and had normal renal function—all of which are consistent with normal PTH-resistant hypoparathyroidism (14). This disorder may be an acquired disease; only a single instance of familial PHP type II has been reported (53).

Fig. 5–51. *Hormone receptor-Gs-adenylyl cyclase pathway*. Parathormone (PTH), like thyroid-stimulating hormone (TSH) and several other hormones, exerts its effects by stimulating adenyl cyclase to produce a second messenger cAMP. The receptor is coupled to adenyl cyclase by a signal transducing protein, Gs, one of a large family of heterotrimeric GTP-binding G proteins. Note that Gs is composed of α, β, and γ subunits, the subunit determining both effector and receptor specificity. (From LC Wilson and RC Trembath, J Med Genet 31:779, 1994.)



Genetics. The previously held concept of X-linked dominant inheritance for PHP (19) is no longer valid; autosomal dominant inheritance has been accepted. However, autosomal recessive examples have been reported (7). Reasons for the dispute were that relatively few instances of male-to-male transmission had been described (54,57) and females are affected twice as often as males. However, hemizygous males are not more severely affected than heterozygous females (32). When defects were identified in the G protein, autosomal dominant inheritance became clear (38,39). Johnson (25) suggested an inheritance pattern that is neither dominant nor recessive: one that results from metabolic interference, similar to that seen in *craniofrontonasal dysplasia*. Metabolic interference may occur when two allelic genes code for different subunits of a multisubunit enzyme or structural protein. Examples of possible metabolic interference in interspecies hybrids have been found (25). Evidence has been presented for genomic imprinting (6,11): an excess of maternal transmission results in the full syndrome and partial expression of the disease is associated with paternal transmission. It has been suggested that paternal transmission results in the PPHP phenotype (60). However, both paternal and maternal transmission of the PHP type Ia phenotype has been described within the same family (49). In another family with PHP type Ia, only maternal transmission of the Gs-α gene mutation was found (35), indicating that a maternal factor determines full expression of Gs-α dysfunction as PHP type Ia. In yet another family, the father had type Ib PPHP whereas at least three children had type II PHP (41).

Newborns with PHP are of normal length, but growth usually lags during childhood and about 60% of patients are less than the third centile for height at maturity (19). Birth weight may be slightly greater than normal; obesity characterizes 65% of patients under 18 years of age (19) (Fig. 5–52). Patients with PPHP tend to be taller and less obese.

Mental retardation is found in 70% of hypocalcemic PHP patients but in only 30% of normocalcemic PPHP patients (19). Farfel and Friedman (16) found that 65% of type Ia and none of type Ib patients were mentally retarded. Personalities are generally affable and pleasant. Seizures unrelated to hypocalcemia have been described. It is not clear whether seizures are secondary to earlier insult, such as hypothyroidism or intracranial calcifications, or whether they are primary (24).

In PHP type Ia, decreased olfactory ability supports the hypothesis that Gs-α (the deficient α chain of the stimulatory guanine nucleotide-binding protein) plays a major role in olfactory transduction (13). Patients with PHP type Ib appear to have olfactory dysfunction relative to matched controls (13). Patients with PPHP have relative normal olfactory function. So, in PHP, there is no direct causal relationship between generalized Gs-α protein deficiency and olfactory dysfunction. Other mechanisms must be responsible.

Craniofacial findings. The face is characteristically rounded with full cheeks, low nasal bridge, and short neck (Fig. 5–53); these features are more prevalent in PHP than in PPHP. With PHP, cataracts may be found in 25% in patients, but with PPHP, cataracts occur in less than 10% (19,28). Enamel hypoplasia, widened root canals, shortened roots with open apices, thickened lamina dura, and delayed eruption have been noted in over one-third of PHP patients (46,60). The second molars are often impacted (60).

Musculoskeletal changes. Most distinctive are short metacarpals and metatarsals, particularly of the fourth and fifth digits. Short metacarpals are manifest by absent knuckles when the patient makes a fist (Figs. 5–54 to 5–56). Also characteristic is a short distal thumb phalanx associated with a wide thumbnail (19,43). Such changes may not be evident until later childhood. Brachycephaly and premature suture closure have been reported. Hyperostosis of the cranial vault is seen in about one-third of patients. Long bone findings such as curvature of radius, bowing of tibia, and genua valga have also been noted.

Generalized osteopenia may be observed, and trabecular coarsening is a feature of PHP with skeletal resistance. In PHP with bone responsiveness, manifestations of hyperparathyroidism may be seen, including

Fig. 5–52. *Pseudohypoparathyroidism*. Short stature and obesity.

Fig. 5–53. *Pseudohypoparathyroidism*. Facies is rounded with low nasal bridge.

subperiosteal bone resorption, bone cysts, and focal osteosclerosis (4,26).

Calcifications. Propensity for soft tissue calcification is well known. Subcutaneous deposits, often osteomas, are found in the scalp and along the extremities, particular the periarticular areas of the hands and feet (12,24,44). Calcifications may also be found in the brain, particularly the basal ganglia and choroid plexus (52). As a rule, deposits are not present in muscle, viscera, or cartilage (19).

Endocrine findings. Disturbances of other endocrine systems are present in some but not all PHP patients (19,27). Hypogonadism and hypothyroidism are frequently found in PHP and tend to show high concordance with deficiencies in Gs protein activity (28,48). Growth hormone–releasing factor deficiency has been reported (55). Other deficits include altered prolactin response to thyroid-releasing hormone (28,31) and a deficient metabolic response to glucagon (28). Such changes are predictable on the basis of the widespread abnormality in receptor-coupling protein, but syndromic variability and inconsistency in the biochemical findings in type Ia patients have not been satisfactorily explained (30). Reproductive dysfunction and oligomenorrhea are common, probably representing partial resistance to gonadotropins (21,37).

Differential diagnosis. In idiopathic hypoparathyroidism, tetanic and epileptiform convulsions, increased thickness of the skull, hypoplastic enamel, and cataracts may be present, but other features of Albright hereditary osteodystrophy are absent. Hypoparathyroidism may occur with *Kenny syndrome*, in which short stature is associated with internal cortical thickening and medullary stenosis of the tubular bones (15). Short metacarpals occur in 10% of the general population and in a variety of conditions (4,21), including type E brachydactyly, peripheral dysostosis, Bilginturan syndrome (brachydactyly, short stature, hypertension) (9), *Turner syndrome*, and *nevoid basal cell carcinoma syndrome*. A metacarpal index for normal children is by Rand et al (45); one for normal white adults is by Parish (37); and one for normal Jamaican children and adults is by Walker and Ashcroft (59). *Acrodysostosis*, once thought part of the spectrum of pseudohypoparathyroidism on the basis of peripheral dysostosis of all metapodial bones and phalanges of hands and feet, nasal hypoplasia, short stature, and mental retardation, was shown not to be part of the spectrum of PHP (1,5,10,22,47,54,56,58). Acrodysostosis is not caused by mutations in the *GNAS1* gene (63). Individuals with deletions of 2q37 can have short fourth and fifth metacarpals and have features that resemble those of PPHP (40,62).

Laboratory aids. In PHP, routine laboratory tests show hypocalcemia, hyperphosphatemia, and increased immunoreactive PTH. Type I PHP may be differentiated from type II by observing no elevation in urinary excretion of cAMP and phosphate after exogenous stimulation by PTH. Type II PHP patients exhibit a rise in cAMP but not in phosphate excretion. Overlap often makes it necessary to examine the renal response to exogenous hormone (53). Measurement of Gs receptor–coupling protein can be used to detect the type Ia subgroup; this finding may be clinically significant, as these PHP patients are at greatest risk for related endocrine disturbances. Infants with PHP should be carefully tested for hypothyroidism as this is a treatable cause of mental deficiency (24,29).

Zellweger syndrome (cerebrohepatorenal syndrome)

De Lange and Janssen (15) probably reported the first case of Zellweger syndrome in 1949. In 1964, Bowen et al (7) and, in 1965, Smith and co-workers (75) described a syndrome consisting of hypotonia, high forehead and other craniofacial anomalies, hepatomegaly, liver dysfunction, and renal cortical cysts (Figs. 5–57 to 5–60). In 1973, Goldfischer et al (22) reported that liver and kidney in affected individuals lacked peroxisomes. Other generalized disorders of peroxisomal function that are less severe than Zellweger syndrome have been studied and include the neonatal form of adrenoleukodystrophy (not to be confused with X-linked adrenoleukodystrophy), the infantile form of Refsum disease, hyperpipecolic acidemia, and rhizomelic chondrodysplasia punctata. The reader may wish to consult several reviews of peroxisomal disorders and their clinical manifestations (8,9,40,45,47,54,71,78,80,87,89,92). An extensive compilation of older Zellweger syndrome references has been published (50), and milder variants of the syndrome have been reported (18).

Zellweger syndrome has autosomal recessive inheritance. Two or more sibs were affected in 17 of 90 families studied, and parental consanguinity was noted in 17% of the 78 cases in which data were available (30,41). The frequency of the disorder has been estimated to be 1/100,000 live births (13), but identification of milder variants and atypical cases by biochemical means has shown a higher frequency of 1/25,000 to 1/50,000 (93). Among Karaites in Israel, Zellweger syndrome is very frequent (94). Cases with pericentric inversion and deletion suggest tentative gene assignment to 7q11 (48,49). A point mutation in both alleles of the peroxisome assembly factor-1 gene (*PAF-1; PMP35; PXMP3*) has been reported in at least two cases (73,74). The *PXMP3* gene has been mapped to 8q21.1 (42), and mutation in the 70K peroxisomal membrane protein (PMP70) has been mapped to chromosome 1p22–1p21 in two patients (19). PEX3 gene mutations are responsible for Zellweger syndrome, complement G (20a,47a). This gene is involved in peroxisomal membrane assembly. The gene product is called double cortin (62a). There is some genotype-phenotype correlation (90a).

Disorders of peroxisome biogenesis fall into 4 phenotypic classes. Three of these—Zellweger syndrome, neonatal adrenoleukodystrophy, and infantile Refsum disease—form a spectrum of overlapping features, with the most severe being Zellweger syndrome and the least severe being infantile Refsum disease. This continuum is referred to as the "Zellweger syndrome spectrum" and includes patients from at least 16 complementation groups (46).

Fig. 5–57. *Zellweger syndrome*. (A) High forehead and up-slanting palpebral fissures in severely hypotonic female infant. (B) Extreme hypotonia. (A from JE Jan et al, Am J Dis Child 119:274, 1970. B from E Passarge and AJ McAdams, J Pediatr 71:691, 1967.)

Cell complementation studies indicate that neonatal adrenoleukodystrophy and rhizomelic chondrodysplasia punctata are biochemically distinct entities (Table 5–5) (10,43,55). Fibroblasts from patients with infantile Refsum disease and hyperpipecolic acidemia do not complement those from patients with Zellweger syndrome (20,44,57,78,81,83).

Peroxisomes can be identified by electron microscopy but can be more reliably differentiated from other organelles by histochemical techniques, immunofluorescence microscopy, or immunocytochemical procedures using antibodies against peroxisomal enzymes (22,67). In classic Zellweger syndrome, recognizable peroxisomes are essentially absent from liver and kidney and are greatly decreased in cultured skin fibroblasts (22,66,71).

Similarities between adrenoleukodystrophy and Zellweger syndrome led Brown and co-workers (9) to the discovery that both share a common defect in the catabolism of very long-chain fatty acids (VLCFAs) by a specific β-oxidation enzyme pathway (71). These distinctive lipids are readily quantitated in plasma, stored blood spots, cultured fibroblasts, brain, amniocytes, amniotic fluid, or chorionic villus tissue and therefore serve as useful markers for pre- and postnatal diagnosis (35,36,63,71,72,84).

Similarly, the peroxisomal localization of the biosynthetic pathway for plasmalogens, a minor species of either phospholipids, led to the identification of plasmalogen deficiency as another characteristic of Zellweger syndrome (14). The first enzyme in the pathway, acyl-CoA:dihydroxyacetone-phosphate acyltransferase (DHAP-AT), is also readily assayed in a variety of tissues and has been used for pre- and postnatal diagnosis (31,32,39,70,71,85).

Phytanic acid accumulation also occurs in Zellweger syndrome, as it does in other peroxisomal disorders, notably infantile Refsum disease (57,58,90).

Gestation and delivery are usually uneventful, but the neonate is small and the complications of cerebral and hepatic disease commonly manifest shortly after birth (8). Failure to thrive and delayed development are characteristic (65). Although demise in the first year of life is common, survival into later childhood has occurred (6,24); milder variants may not present in the newborn period (2,3).

Craniofacial features. The forehead is high and the skull may be pear shaped or show some degree of turribrachycephaly. The occiput is sometimes flattened, particularly the supraorbital ridges (51,52). Puffy eyelids, ocular hypertelorism, mild downward slanting of palpebral fissures, and epicanthic folds may be observed. The cheeks are full and the nostrils anteverted (Figs. 5–57A and 5–58). Micrognathia may be found and there is redundant skin on the nape. The ears may be posteriorly angulated and the helices abnormal (51,75). Narrow, highly arched palate

Fig. 5–58. *Zellweger syndrome*. Characteristic craniofacies. Compare with facies shown in Figure 5–57A. (From E Passarge and AJ McAdams, J Pediatr 71:691, 1967.)

Fig. 5–59. *Zellweger syndrome*. Gross pathologic specimens. (A) Crosssection of cerebrum showing macrogyria, flattening of cortical surface, and thickened cortical gray matter. (B) Kidney showing large cortical cysts. (A,B from A Poznanski et al, AJR Am J Roentgenol 109:313, 1970.)

and protruding tongue have been reported (92). In the infantile form, the teeth were described as being yellow-orange (1a).

Brushfield spots, cloudy corneas, and cataracts are common. The cortical cataracts do not appear to progress; a prominent lenticular Y-suture may also be found (34,38). Funduscopic examination may reveal optic disc pallor or retinal pigment changes that resemble other forms of retinitis pigmentosa (16,56). Visual impairment is progressive and is accompanied by nystagmus and electroretinographic changes.

Central nervous system. Macrocephaly and large anterior fontanel are often noted. Profound hypotonia is almost universal (Fig. 5–57); mental retardation and seizures (oculogyric fits) are also characteristic.

	2	4	ZS, NALD	+	*PEX 5*	12p13.3
	3		ZS	+	*PEX 12*	
	6		NALD	+		
R	11	1	RCDP		*PEX7*	6q22–24

[a] The numbering listed under KKI (Kennedy Krieger Institute, Baltimore, MD and AMC (Amsterdam Medical Center) is based on the study by AB Moser et al, J Pediatr 127:13, 1995.
[b] NALD, neonatal adrenoleukodystrophy; IRD, infantile Refsum disease; RCDP, recessive chondrodysplasia punctata; ZS, Zellweger syndrome.
[c] A plus sign (+) indicates presence, and a minus sign (−) indicates absence. Modified from N Shimozawa et al, Am J Hum Genet 63:1899, 1998.

Neonatal reflexes are sometimes absent but electromyography may be normal. Ventricular dilatation is frequently detected on CT scan and the EEG is abnormal (9,24,25). At autopsy, distinctive maldevelopmental and degenerative changes are found (Fig. 5–59A), including micropachygyria (67%), lissencephaly and hypoplastic or absent corpus callosum (20%), dysplasia of olivary nucleus, olfactory tracts, and cerebellum (27%), ependymal abnormalities and heterotopias of the cerebrum and cerebellum (48%) (60). Microscopic changes include sudanophilic leukoencephalomyelopathy (26%), increased glycogen storage, and gliosis (35%) (7,59,61,62,68,92). Periventricular germinolytic cysts or pseudocysts can be detected by ultrasound and may be of diagnostic value (64).

Liver. An enlarged liver is rarely encountered at birth but is a common finding in the first year (92). Prolonged neonatal jaundice may be observed and abnormal liver function can be biochemically documented early in life. Histopathologic changes suggest a progression from hepatic giant cell transformation through periportal fibrosis to cirrhosis without widespread inflammatory disease or necrosis (21,39). In some patients, this sequence is completed within a few months time but in older children, hepatic liver function may stabilize (24) and hepatic fibrosis predominates (21). Increased hepatic iron content has been frequently reported (13,21,38,39) but the finding is not without exception (13,53). Hemosiderin deposits appear to be unrelated to progression of hepatic disease (21,38,39). Serum iron, iron saturation, and transferrin concentrations are also elevated in about 65% of patients, but values vary widely and are not necessarily correlated with the degree of tissue iron storage (13,21,36,38). Biliary dysgenesis and intrahepatic cholestasis have also been described (21,38).

Related gastrointestinal findings include islet cell hyperplasia and hypoglycemia (21,53), pyloric hypertrophy, malrotation of colon (7,59), intestinal lymphangiectasis (17), and pancreatic fibrosis (13,16).

Kidney. The kidneys are variable in size and sometimes studded with multiple macroscopic cortical cysts (Fig. 5–59B). Glomerular and tubular microcystic disease is almost always found. Horseshoe kidneys, foci of renal dysgenesis, and interstitial fibrosis have also been described (21,39,59). Proteinuria and generalized aminoaciduria are often found (13,39,59).

Pulmonary and cardiovascular findings. Focal pneumonia may be noted and pulmonary hypoplasia is frequent. Cardiovascular malformations, including PDA, VSD, and aortic arch anomalies, are also common (21,38,92).

Skeletal findings. Bone age is often retarded and hypomineralization and wormian bones have been noted (53,91). Calcific stippling (Fig. 5–60) has been observed, particularly in the acetabular cartilages and along the inferior medial margin of the patellae. Stippled epiphyses are present in long bones in about 70% of cases (53,92). Calcification of the hyoid bone and thyroid cartilage has also been noted. Metaphyseal radiolucencies have been reported (13,53,91).

Other findings. Other features include camptodactyly, single palmar creases, ulnar deviation of hands, cubitus valgus, flexion at knees and hips, talipes equinovarus, metatarsus adductus, rocker-bottom feet, and dorsiflexion of fourth toes. Other anomalies are widely spaced nipples, deep sacral dimple, hypoplastic dermal ridges, small penis, hypospadias, cryptorchidism, prominent clitoris, umbilical hernia, and diastasis recti (13,51,53,59).

Differential diagnosis. Zellweger syndrome may be confused on occasion with *trisomy 21*. Differential diagnosis also includes hyperpipecolic acidemia (20,39,71,83), neonatal adrenoleukodystrophy (39), infantile Refsum disease (41,55), Leber disease (16), and *rhizomelic chondrodysplasia punctata* (33). Biochemical overlap and genetic distinctions between these entities are discussed elsewhere (78,79). Pseudo-Zellweger syndrome and milder variants of Zellweger syndrome have also been discussed (3,23,65). Beemer and co-workers (4,5) reported a new peroxisomal disorder in sibs that was characterized by lethality, hydrocephalus, unusual facies, dense bones, and sex reversal. A 32-year-old man was reported with profound mental retardation, mild facial dysmorphism, retinal pigmentary degeneration, seizures, and sensorineural hearing loss with multiple peroxisomal enzyme deficiencies with preserved peroxisomes (11).

Laboratory aids. Elevated pipecolic acid concentrations in urine and plasma, detected by routine amino acid chromatography, are helpful but not diagnostic (12,13,20,24,26,39,44,81,83). Very long chain fatty acids can be quantified from plasma, cultured fibroblasts, amniocytes, and amniotic fluid (28,41,47,70,71,76). Dihydroxyacetone-phosphate acyl transferase is readily assayed from various tissues and can be used for pre- and postnatal diagnosis (28,32,39,41,70,71,92). Abnormal bile acid and low levels of plasmalogens can also be used in diagnosis (27,29,37,38,43). Trihydroxycoprostanic acid levels are decreased in amniotic fluid (77). An algorithm has been suggested by FitzPatrick et al (18) (Fig. 5–61). Nuchal translucency has been noted (11a).

Carbohydrate-deficient glycoprotein syndromes (congenital disorders of glycosylation)

The carbohydrate-deficient glycoprotein (CDG) syndromes are a newly recognized family of diseases. The basic defects are probably in the glycosylation pathway (endoplasmic reticulum, Golgi or post-Golgi apparatus). The central nervous system is always severely affected but nearly all organs are involved to variable degrees. Jaeken and co-workers (15) reported the first cases of CDG syndrome, later called type I or classical type. By 1998, more than 250 patients were known on a worldwide basis (14,19). The CDG syndrome is characterized by a partial deficiency of the N-linked glycans of secretory glycoproteins, lysosomal enzymes, and probably also membranous glycoproteins (15). Four clinical and biochemical types have now been identified. Type I (Jaeken syndrome), the first described, and best known, seems to affect early neuronal development, while types II and III may be associated with dysmyelination or hypomyelination (32). Types III and IV exhibit severe encephalopathy including resistant epilepsy (14). All types have variable manifestations outside the nervous system (3a,9,10,16,31,32,42).

The CDG syndromes have autosomal recessive inheritance. The frequency in Sweden is estimated to be 1/50,000 births (2). There is a paucity of reports from North America despite the large population of European descendants. The disorder may still be underrecognized and the true frequency unknown (37). It has been described in Latin America (4).

The diagnosis of CDG syndrome type I (Jaeken syndrome) is usually made by isoelectric focusing and immunofixation of serum transferrin (37). The basic defect in CDG syndrome type I is phosphomannomutase deficiency (PMM) (19,37). There are types that do not fit known forms (1).

The phosphomannomutase 1 gene has been mapped to chromosome 22q13 (27); a second phosphomannomutase gene had been located at 16p13 (24). Data from 44 families in the western part of Sweden suggested a founder effect (2). Twenty different missense mutations have been identified in fifty patients from different geographical origins (26). Type II CDG syndrome is caused by a deficiency of Golgi-localized *N*-acetylglucosaminyltransferase II (GnT-II) (17). This deficiency has been demonstrated in fibroblasts and mononuclear blood cells (17,18), and its gene has been mapped to 14q21 and has been cloned (35). In two patients, different point mutations were found in the catalytic domain of the gene (36,37).

Patients with any of the CDG syndromes have, to a certain extent, different presentations, according to age (Fig. 5–62) (12). In infancy, the striking, essentially constant, characteristics are neurological abnormalities, e.g., axial hypotonia, psychomotor retardation, alternating squint, abnormal ocular movements, and variable dysmorphic features. The most typical dysmorphic feature is abnormal adipose tissue distribution such as fat pads (Fig. 5–62C), "peau d'orange" skin, and inverted nipples (13). These infants also have feeding difficulties with failure to thrive. After infancy, neurological involvement becomes predominant. Mental retardation is present in all known patients (13). Strabismus is a constant feature while cerebellar ataxia is variable. Other features include peripheral neuropathy and increasing atrophy and contractures of limbs, particularly in the legs. Retinal pigment degeneration is noted in 75%-100% of patients. Symptoms of hypogonadism are noted in 100% of females (13). The mortality rate is about 20%; death occurs almost exclusively before the age of 6 years.

Approximately 20% of the patients with phosphomannomutase deficiency (CDGI) die during the first years of life due to liver failure, severe infection, cardiac insufficiency, nephrotic syndrome, or in status epilepticus (6,12,14,38). Postmortem findings include olivopontocerebellar hypoplasia, loss of neurons, and gliosis in the cerebral cortex, basal ganglia, thalamus, and spinal cord (14). The peripheral nerves show decreased myelin and multivacuolar inclusions in Schwann cells. Liver pathology is characterized by fibrosis, steatosis, and glycogen storage; electron microscopy shows myelin-like inclusions in the lysosomes of hepatocytes, but not in Kupffer cells (16).

A mild facial dysmorphism is characteristic, with large, somewhat dysplastic ears, high forehead, long eyelashes, prominent base of nose, beaked nose, upturned alae nasi, protruding upper incisors, and receding chin (Fig. 5–62) (14,19).

Retinitis pigmentosa may occur after infancy (3). Abnormal, slow-rolling vertical or horizontal eye movements are combined with slow head movements in the neonatal period, and alternating strabismus (14).

Axial hypotonia and hyporeflexia have been reported (14). Marked psychomotor retardation develops, and ataxia is present as is, at times, epilepsy (14,19). Only rarely are patients able to walk without support. Neuroradiological investigations show pronounced cerebellar atrophy with early-onset Dandy-Walker malformation, atrophy of pons, brain stem, and olives, supratentorial frontotemporal cortical atrophy, small corpus callosum, and small cysts in the white matter (1,16,20). Proton magnetic resonance spectroscopy shows a reduction of *N*-acetylaspartate and an increase in glutamine and γ-aminobutyrate in white matter (29).

Retracted nipples are often found, as well as abnormal subcutaneous adipose tissue distribution in the form of fat pads and "orange peel" skin. Skeletal abnormalities include wide ribs, squared iliac wings, horizontal acetabular roofs, widening and modeling abnormalities of ischial and pubic bones, dorsolumbar kyphosis, and slight, hook-like dysplasia of the first lumbar vertebrae (30). Dystrophic extremities, mild to moderate hepatomegaly, hypogonadism, and proteinuria are found. Some infants develop pericardial effusion and/or cardiomyopathy (13,14,23,32). There is a great variability in clinical expression even in siblings (14,30). Renal cysts, fibrosis of the testes, and lymph node abnormalities have been observed (14).

Clinical findings in the two published cases of CDG type II patients are similar to those in CDG type I syndrome: facial dysmorphism with high forehead, beaked nose, large dysplastic ears, short neck, hollowed chest, increased internipple distance, and irregular implantation of toes. Tongue thrusting and hand washing movements are evident. Psychomotor retardation is severe.

Laboratory investigation showed lowered serum values for a number of glycoproteins, in part the same as in PMM deficiency. In particular, there is also a marked factor XI deficiency (17). The cerebrospinal fluid protein level was not increased in all patients. In one patient, MRI studies of the brain revealed white matter abnormalities fronto-occipitally.

Types III and IV of CDG syndrome have been reported in a very limited number of patients (31,33); the basic defect remains unknown. Three siblings from a consanguineous mating suffered from cyclic vomiting and congenital hepatic fibrosis. They exhibited a glycosylation disorder that was biochemically similar to CDG syndrome type I. However, normal phosphomannomutase activity was found in all three siblings (21). Phosphomannose isomerase was deficient in leukocytes, fibroblasts, and liver. An extremely mild form (type Ia) has cognitive dysfunction, cerebellar hypoplasia, and coagulation disturbances (40).

Laboratory findings. A large number of serum glycoproteins are abnormal, including transport proteins, glycoprotein hormones, complement factors, lysosomal and other enzymes, and enzyme inhibitors (14). A coagulopathy is also present with marked factor XI and antithrombin III deficiency as well as endocrinological abnormalities (5,7,14,22,39). Glycoprotein concentrations or enzyme activities in serum are decreased. Isoelectric focusing of these glycoproteins shows a cathodal shift due to partial deficiency of sialic acid (14,19,37). In addition, decreased serum levels of copper, iron, zinc, cholesterol, cortisol, and thyroid hormones are found due to decreased levels of the corresponding transport proteins (14). Partial thyroxine binding globulin deficiency is detected

in some patients through neonatal screening for congenital hypothyroidism using T4 measurement (19). Cerebrospinal fluid protein is often increased, as are some amino acids (14,34). Decreased phosphomannomutase activity in leukocytes or fibroblasts confirms the diagnosis for type I CDG; this finding should be confirmed by mutational analysis. Heterozygote detection is possible; prenatal diagnosis has been performed (28) by measuring PMM activity in either cultured amniocytes or trophoblast tissue. Decreased activity of phosphomannomutase cannot be demonstrated in fibroblasts of all patients with CDG type I, confirming earlier suggestions of heterogeneity for CDG type I (25).

Differential diagnosis. Transferrin changes similar to those found in CDG syndrome can be found in chronic alcoholism, galactosemia, and fructosemia (19).

Molybdenum cofactor deficiency

Molybdenum cofactor deficiency was first described in 1978 by Duran and co-workers (8). The molybdenum cofactor is a low-molecular-weight prosthetic group in which the metal is complexed to a unique pterin species termed "molybdopterin" (12). Its biosynthetic pathway has yet to be fully elucidated. Affected individuals exhibit a combined deficiency of sulfite oxidase, xanthine dehydrogenase, and aldehyde oxidase with symptoms that include severe neurologic abnormalities, dislocated eye lenses, and severe mental retardation (8,9,12).

The first patients were diagnosed in Europe (8); subsequent patients were reported from various ethnic groups from all over the world (6,12,15,16). Phenotypic variability has been reported, as well as late onset of the disease (11). Inheritance is autosomal recessive. Obligate heterozygotes do not exhibit clinical symptoms; heterozygosity cannot be established biochemically (5). By using homozygosity mapping in consanguineous affected kindreds, a gene for molybdenum cofactor deficiency has been localized at 6p21.3 (24). The results of this study provide tools for carrier detection and for prenatal diagnosis with microsatellite markers as well. Through fibroblast studies, molybdenum cofactor-deficient patients have been shown to comprise two complementation groups (12). The gene for the neurotransmitter receptor-clustering protein gephyrin causes a novel form of molybdenum cofactor disorder (20,20a).

Clinical symptoms of molybdenum cofactor deficiency include severe neonatal seizures, growth delay, severe psychomotor retardation, lens luxation, and death in the first decade (6,12). The similarity of the CT appearances in molybdenum cofactor deficiency and postanoxic encephalopathy has been noted (1). Pathological studies have shown a severe multicystic leukencephalopathy with marked neuronal loss, particularly in all layers of the isocortex (3). There was demyelination of white matter, accompanied by gliosis and diffuse spongiosis (12,25). These abnormalities may be caused by the toxicity of sulfite and/or inadequate amounts of inorganic sulfate available for the formation of sulfated compounds present in the brain (23).

Isolated sulfite oxidase deficiency is rarely reported; only 8 patients with this deficiency are known (22). It causes a clinical picture that is indistinguishable clinically and neuropathologically from that of the molybdenum cofactor deficiency (17,22). In isolated sulfite oxidase deficiency, molybdenum cofactor and xanthine dehydrogenase functions are unaffected. The inheritance pattern is autosomal recessive; consanguinity was apparent in five of the eight families reported (22).

Facial features include a long face, narrow bifrontal diameter, enophthalmos, telecanthus, elongated palpebral fissures, puffy cheeks ("cherubic"), thick lips, long philtrum and small nose (Fig. 5–63) (4,7,12). Enophthalmos, nystagmus, and unresponsiveness to light have also been

Fig. 5–63. *Molybdenum cofactor deficiency*. Note long face, narrow bifrontal diameter, telecanthus, enophthalmus, elongated palpebral fissures, long philtrum, and small nose.

reported. Lens dislocation is usually found in all patients who survive the neonatal period (12,14). Spherophakia has been reported in at least one patient (18). Severe seizures which occur in both molybdenum cofactor deficiency and in isolated sulfite oxidase deficiency are refractory to treatment and difficult to suppress. The seizures are tonic-clonic with axial hypotonia and peripheral hypertonicity. Other neurologic symptoms such as myoclonus, pyramidal syndrome, opisthotonus, spastic tetraplegia, hemiplegia, dilatation of ventricles, Dandy-Walker malformation, and hydrocephalus have been described (12,16,19,22). The MRI changes in two children include progressive widening of sulci, ventricles, and cisterna magna and a cessation of myelination at 31 months and 16 weeks of age, respectively (1). In some studies, an abnormal shape of the frontal horns of the dilated ventricles was found; this was caused by a severe volume loss of the basal ganglia, especially of the caudate nucleus and of the corpus callosum (24). Head circumference is generally normal at birth; microcephaly developed in a number of cases (7).

Laboratory findings. Plasma uric acid levels are very low; the excretion in the urine of sulfite, thiosulfate, *S*-sulfocysteine, taurine, xanthine, and hypoxanthine is elevated. There is no urothione, a molybdenum cofactor metabolite, demonstrable in the urine (2). The diagnosis can be suspected using a simple sulfite dip strip test on a fresh urine sample, although false-positive and false-negative results do occur. Prenatal diagnosis is possible by assay of sulfite oxidase activity in a chorionic villus sample (10,13). Prenatal diagnosis has been achieved molecularly (26).

Chapter 6
Syndromes Affecting Bone: The Osteogenesis Imperfectas

The osteogenesis imperfectas

Osteogenesis imperfecta is a heterogeneous group of heritable disorders of type I collagen metabolism characterized by bone fragility. Associated features in some affected individuals include blue sclerae, opalescent teeth with characteristic radiologic features, hearing loss, deformity of long bones and spine, and joint hyperextensibility. The first reported case was probably an Egyptian, whose remains, dating from 1000 BCE, are in the British Museum (81). Credit is usually given to Ekman (65) for performing the first comprehensive study of the syndrome in 1978 and discussing its inheritance. In the early nineteenth century, Lobstein (111) and Vrolik (207) described the disease in the adult and the newborn, respectively. Spurway (177) and Eddowes (63) described blue sclerae, and in the early 1900s, Van der Hoeve and de Kleijn (200) mentioned deafness as part of the syndrome. Preiswerk (153) may have been the first to describe the dental abnormalities. The basis for the current clinical classification is the study by Sillence et al (169). A monograph on the disorder has been written by Smith et al (175).

The severity of the disorder varies widely between and even within families; some individuals have minimum involvement of the skeleton and may never have a fracture, whereas others have very severe involvement and many fractures. Clinical and genetic studies delineate four major syndrome groups (Table 6–1) (169), although all of these syndromes are likely heterogeneous at the clinical, radiographic, and molecular levels (4,29,33,50,90,105,168,170,171).

Nomenclature classifying patients into congenital and tarda forms is not useful, as individuals with any osteogenesis imperfecta syndrome can be born with fractures; in addition, this feature cannot be consistently correlated with inheritance pattern, prognosis, or recurrence risk (168,169,194).

Classification into broad-boned and thin-boned types is also unsatisfactory, as change from one shape to another can occur with age. There appears to be little benefit in classification based on severity of long bone deformity (10), as severe deformity can occur in many osteogenesis imperfecta syndromes; in addition, this method of classification does not take into account the pattern of inheritance or other clinical findings (169,176,194).

Until recently, the phenotypes of patients with the syndrome, as well as the inheritance patterns, have not always been completely delineated. Thus, it is difficult to interpret much of the large body of literature on the disorder in view of the current classification. The estimated prevalence of all types combined is about 0.5/10,000 births (183).

Molecular pathology. The different forms of osteogenesis imperfecta are caused by mutations in the two genes that encode the chains of type I collagen—i.e., *COL1A1*, located on chromosome 17, and *COL1A2*, located on chromosome 7. They encode for the pro-α1 (I) and pro-α2 (I) chains of type I procollagen. Two pro-α1 (I) chains and one pro-α2 (I) chain together form one heterotrimer. This procollagen is secreted by fibroblasts, after which the aminopropeptides on each of the three pro-α chains are cleaved off by a protease, and the carboxy-propeptides are cleaved off by another protease. Thereafter, the collagen molecule self-assembles spontaneously to form fibril structures. The formation of fibrils depends heavily on the uniformity of the collagen molecules, and abnormal molecules have a deleterious effect on fibril structures. A more detailed review of the collagen biosynthesis and gene structure can be found elsewhere (3,33,50,154,155).

Each of the collagen genes contain more than 50 exons that contain the coding sequence for proteins of about 1400 amino acids. The primary sequence consists of a repeating tripeptide unit which can be written (Gly-X-Y). The amino acid glycine is in every third position, allowing for the tight helical structure because it is small and contains no side chains. Hydroxyproline is found only in the Y position, which it occupies in about a third of the triplets, often preceded by proline. The first exons encode the signal sequence, followed by the protease cleavage site. The final exons encode an additional protease cleavage site and the globular carboxyl-terminal domain. The stability of the triple helix is provided by interchain hydrogen bonds.

Patients with osteogenesis imperfecta type I show approximately 50% reduction in synthesis of type I procollagen. The causative mutations effect decreased synthesis; secretion and post-translational modification as well as rate of molecular assembly appear normal, in contrast with other types of osteogenesis imperfecta. Linkage studies show segregation with both the *COL1A1* gene and *COL1A2* gene (69,125,189,191,192,197,208,211). A variety of mutations has been described: promotor mutations, enhancer mutations, or those causing premature termination of transcription of one allele (33,209,214,215). The last may be the most common mechanism (215). Promotor mutations do not play a significant role (216).

In osteogenesis imperfecta type II, point mutations resulting in the substitution of glycine residues in the triple helix domain of the α1 (I) or α2 (I) chain are the most frequently found mutations (8,31,32,43,45,50,130,149,152–154,195,213). Such mutations disrupt the triple helix formation by a dominant-negative mechanism. A delayed triple helical assembly results in overmodification of type I collagen, which can be recognized electrophoretically. The phenotypic consequences are most severe if the mutation occurs near the carboxyl-terminal end and more mild toward the amino-terminal end (33,188). Exon skipping mutations are the more common mutations (50). There are no major mutational hot spots in the *COL1A1* or *COL1A2* genes. Most mutations are de novo, but there are reports of patients with type II in which the parents are mosaics (30,52,103,114). The parent may be normal or mildly affected. Until now, no molecular proof exists for an autosomal recessive form of type II (33,44,50). The phenotype in type II may be modified by the background of other components of connective tissue, such as decorin (62).

In osteogenesis type III, molecular studies have shown different mutations in *COL1A1* and *COL1A2*, resulting in substitution of glycine in the triple helix for another amino acid (128,150,209). Recurrence from unaffected parents could be explained by parental gonadal mosaicism (44), but homozygosity by descent for a *COL1A2* mutation has been described, thus proving autosomal recessive inheritance (59). In a group of South African families with type III, no linkage with the loci for *COL1A1* or *COL1A2* was found, indicating that probably other loci were involved that influence type I collagen processing (209).

Most patients with osteogenesis imperfecta type IV are linked with or have mutations in the pro-α2 (I) collagen chain (210,211), but linkage and mutations with *COL1A1* have also been found (33). The pathogenic pathway causes reduction in the amount of type I collagen by 50%, as in type I.

Table 6–1. Major osteogenesis imperfecta syndromes

Type	Salient features	Inheritance	Most common molecular background
I	Mild to moderately severe bone fragility Hearing loss (50%)	AD (common)	Nonfunctional COL1A1 gene (null allele)
IA	Normal teeth		
IB	Opalescent teeth		
II	Very severe bone fragility Blue sclerae	AD (common)	Point mutations resulting in substitution of Gly residues in triple helix domain of α1(I)/α2(I)
	Stillborn or death shortly after birth	AR (doubtful)	
III	Moderately severe to severe bone fragility	AD (common)	Point mutations in *COL1A1* and *COL1A2* genes
	Blue sclerae (in infancy) Generally not lethal in infancy, but death in first decades is not uncommon	AR (infrequent)	Deletions in *COL1A1* gene causing frame-shift
IV	Mild to moderately severe bone fragility Normal sclerae, but may be pale blue in early infancy Hearing loss	AD	Point mutations in *COL1A2* gene
IVA	Normal teeth		
IVB	Opalescent teeth		

Fig. 6–1. *Osteogenesis imperfecta, type I.* Both father and son had intensively blue sclerae, numerous fractures, and mild shortening of stature. (From DO Sillence, Symposium of Heritable Disorders of Connective Tissue, C.V. Mosby, St. Louis, 1982.)

Type I

General features. This disorder is characterized by autosomal dominant inheritance (169) (Fig. 6–1). Carothers et al (36) analyzed a heterogeneous group of patients with osteogenesis imperfecta type I and type IV, presumed to have resulted from new mutations. These investigators demonstrated that the mean paternal age at birth was significantly higher than that of controls and that paternal age effect in new mutation osteogenesis imperfecta type IA, when analyzed alone, was also significantly increased. The effect of paternal age on the mutation rate, however, was smaller than in other dominant disorders, such as achondroplasia. Sillence et al (169), Byers et al (30), and Orioli et al (131) found hardly any increase in paternal age.

Facies. Apart from the blue-gray sclera, we do not believe that there is a facies. The maxilla may be hypoplastic with a relative mandibular prognathism (49).

Ophthalmologic abnormalities. A hallmark of this syndrome is blue sclerae. It was noted early (10) that the severity of osteogenesis imperfecta was different depending on the presence or absence of blue sclerae. Scleral color appears to be consistent within families, although the degree of blueness varies from one family to another (173). Scleral blueness is believed to arise from disordered molecular organization (174). Sclerae are of normal thickness, but there is evidence for increased noncollagenous matrix (64). Low ocular rigidity in a heterogeneous group of patients with osteogenesis imperfecta has been found (95); some had blue sclerae, and thus may have had osteogenesis imperfecta type I. Lanting et al (104) found reduced optical scattering properties in the sclerae of two patients with this syndrome, findings they attributed, in part, to reduction in collagen fiber thickness and decreased variability of fiber diameter.

The cornea may appear thinner than usual by slit-lamp examination (175). Embryotoxon has also been noted (37). It is unknown whether this abnormality is the result of chance association of hypercholesterolemia or whether it is one of the pleiotropic effects of the syndrome, at least in some families. Rarely, retinal detachment occurs (118).

Otolaryngologic abnormalities. Hearing loss, rarely detected before 10 years of age, usually begins with a conductive deficit in the late second or early third decade (159). With age, mixed and sensorineural hearing losses are observed (53,159,164), the sensorineural component being the major one (74). Riedner et al (159) and Garretsen and Cremers (74) noted that by the fifth decade, half of all patients had hearing loss, whereas by the seventh decade, all individuals had hearing loss, although the number of older individuals tested was small. Cox and Simmons (53) reported similar findings. Shapiro et al (166) reported audiologic abnormalities in a heterogeneous group of patients: half of the patients younger than 30 years of age and 95% of the patients over 30 had hearing loss. Half of all patients examined had sensorineural loss. Conductive loss in this syndrome has been attributed to ossicular immobility at the stapes footplate (144,159). Fracture of the stapedial crura and atrophy of the stapes may also contribute to loss of hearing acuity (159). Results from ear surgery are available (73).

Neurologic manifestations. Results of computed tomography (CT) scans of the head have been normal in the few patients tested (198), and ventricles are normal in size. In the three-member family with osteogenesis imperfecta type I and dental abnormalities reported by Pozo et al (152), advanced basilar impression (platybasia) resulted in ventricular dilatation, multiple neurological disturbances of the foramen magnum compression syndrome, and death from acute brain stem compression; these findings, however, are likely rare in other patients with this syndrome. These investigators noted that all patients reported with osteogenesis imperfecta and basilar impression had mild skeletal disease. Rarely, radicular compression (40), trigeminal neuralgia (157), and communicating hydrocephaly (40) occur. Half the 56 patients with osteogenesis imperfecta studied by Reite and Solomons (158) had abnormal electroencephalograms; however, their patients were a heterogeneous group and were not classified.

Cardiovascular involvement. The frequency of symptomatic cardiovascular anomalies is low. Hortop et al (91) reported nonprogressive aortic root dilatation in about 12% of affected patients. In one study of dominant osteogenesis imperfecta, 9% of males and females had asymptomatic mitral valve prolapse; 24% of males but only 4% of females had asymptomatic aortic root dilatation (156). Aortic regurgitation has been observed in patients after the third decade, as has mitral regurgitation (1,156,178). Aortic aneurysm and dissection do not occur, although left atrial rupture has been reported in one patient (160). Vetter et al (203) reported 1 of 18 patient with valvular aortic stenosis. Mitral valve leaflets were thin in half the patients reported by White et al (212). They may cause mitral valve prolapse and regurgitation (91). Microscopic findings in the valves include myxoid degeneration and atrophy and, in the aorta, cystic medial necrosis (1).

Joint abnormalities. Joint hypermobility and joint dislocation are found (139). Separate entities with either a phenotype resembling *Ehlers-Danlos syndrome* (103,205) or with rigid joints or contractures (Bruck syndrome) (19a,25,25a,104a,123,206) exist.

Skeletal manifestations. Macrocephaly has been reported (169, 198). Head size is usually large for height: the median of the distribution of head sizes is above the 50th centile (169). Wormian bones may be present (169). Platybasia and occipitalization of the upper cervical vertebrae may produce a "tam o'shanter" appearance (93,139,152).

Multiple fractures usually occur, although about 10% of patients may not have fractures (169). There is considerable variability within and between families in age of onset and frequency of fractures. During infancy and childhood, fracture frequency remains constant, but reduction in fracture frequency at puberty has been noted, followed by an increase in fracture frequency in women after menopause (140) or after the sixth decade in men. Long bone deformity consists of bowing and angulation (169); however, it is not as severe in type I osteogenesis imperfecta as it can be in other forms. About 20% of adults have kyphosis or scoliosis, which may be progressive (85,169). Trunk shortening has also been described (16). Osteopenia may be minimal and undetectable on skeletal radiographs. In fact, radiography may fail to show any anomaly if pictures are taken during a period without a fracture. The ability to walk depends upon the type of osteogenesis imperfecta (68).

Paterson et al (138) found a significantly higher fracture rate in 5- to 20-year-old patients with type I osteogenesis imperfecta and opalescent teeth (type IB) than in those with type I who had normal teeth (type IA). They also found that individuals with type IB were more likely to have had a fracture at birth, to have a higher fracture frequency, and to have a height below the second centile. Patients with normal teeth were more likely than patients with opalescent teeth to have prolonged fracture-free periods during childhood. These two groups, however, were similar in frequency of joint hyperextensibility, bruising, hearing impairment, and joint dislocations.

Birth weights and birth lengths are generally normal. Short stature is of postnatal onset and usually mild; by adulthood, half the affected patients are less than the third centile for height (169). Given the (usual) absence of significant skeletal deformity, the shortness of stature appears to be constitutional. However, individuals with the disorder whose height exceeds 6 feet have been noted.

Gillerot et al (77) reported a family with osteogenesis imperfecta type I in which a newborn infant had features of type II. Heyes et al (88) reported a kindred with osteogenesis imperfecta type I and opalescent teeth; a stillborn had sustained multiple fractures in utero and had a membranous cranium, resembling that of osteogenesis imperfecta type II; no radiographs were depicted.

Oral manifestations. Dental abnormalities have been described in many individuals with osteogenesis imperfecta; unfortunately, in many of these reports, the complete phenotype and inheritance pattern have not been described, and interpretation in view of current classification is not possible. Heterogeneity based on the presence or absence of dental abnormalities has been noted (105,138,163). Paterson et al (138) recognized that two groups of families with osteogenesis imperfecta type I can be distinguished: a group with normal teeth (type IA) and a group with specific dental abnormalities (type IB). In patients with dental abnormalities, deciduous and permanent teeth are opalescent, and amber or blue–gray on eruption (107) (Fig. 6–2).

On radiographic examination, there is increased constriction at the coronal–radicular junctions, and pulps become obliterated with secondary dentin. However, pulps may be wider than normal during early development (107). Roots are thinner and shorter than normal (163). There is little variation in expression within the deciduous dentition, and these teeth may wear rapidly; on the other hand, there may be considerable variability in color within an individual's permanent dentition. Dental radiographs may be necessary to establish the diagnosis where tooth discoloration is mild. When dental abnormalities are present, they may be helpful in making the diagnosis of osteogenesis imperfecta when the presence of other abnormalities is equivocal.

Lukinmaa et al (112), Paterson et al (139), and Lund et al (114) noted that opalescent teeth were rarer in families with type I (8%) osteogenesis imperfecta than in those with type IV (37%). Malocclusion has been described and may be more common in individuals with opalescent teeth than in those with normal teeth (163).

Lukinmaa et al (113) described "thistle-tube" or flame-shaped pulps in several patients with osteogenesis imperfecta, one of whom may have had type I, although scleral color was not stated. These dental findings are similar to those found in dentin dysplasia type II (76). Levin et al (110) found similar abnormalities in the permanent dentitions of five members of a family with osteogenesis imperfecta type I.

There are few systematic studies of the histopathology of the teeth in what is unequivocally osteogenesis imperfecta type I. In general, however, the dentin–enamel junction has been reported by some investigators to be flatter than normal and to lack normal scalloping (161,217). However, on scanning electron microscopy (106) and light microscopy (112), others described a normal junction. On light microscopic examination, laminated dentin, tubules of abnormal size and shape, and structures resembling entrapped blood vessels have been described (147,161,216). Enamel surface and prism organization were found to be normal in osteogenesis imperfecta type IB (106). However, dentinal tubules were short, narrow, and tortuous compared with those of normal teeth from other osteogenesis imperfecta families and controls. Gage et al (72) studied teeth from a group of patients with a variety of osteogenesis imperfecta syndromes. They concluded that the majority of teeth from these patients were biochemically abnormal even if dental abnormalities were not present; however, the criteria for determining whether clinical abnormalities of the dentition existed in the patients studied were not presented.

Other abnormalities. Easy bruisability has been found in about 75% of affected patients (139). Angiomatosis (60), hernias, and excessive sweating have also been reported (139). Nephrolithiasis has been described (203).

Type II

General features. This clinically and biochemically heterogeneous group of osteogenesis imperfecta syndromes is characterized by extreme bone fragility consistently leading to intrauterine or early infant death (31,50,121,169,194). Sillence et al (171) subclassified this form into three subtypes (groups A, B, and C) distinguished from one another on the basis of radiographic features. Subtype IIA is the most common subtype, IIC the most infrequent. The distinction between the three subtypes is not always clear, as the radiographic findings represent a continuum. In general, the better the bone morphology and mineralization at birth, the longer the survival of the newborns (194).

At birth, newborns in group A are small for gestational age and usually premature. Twenty percent are stillborn and the remainder die within hours or days of birth; 90% are no longer living by 4 weeks of age. Breech delivery occurs in 15%. General connective tissue fragility is present and the head or a limb may be torn off during delivery (169). Infants in group B have a mean gestational age of 37.6 weeks; mean survival is about 14 hours (194). Length of gestation and survival of individuals in group C have not been described in detail because few

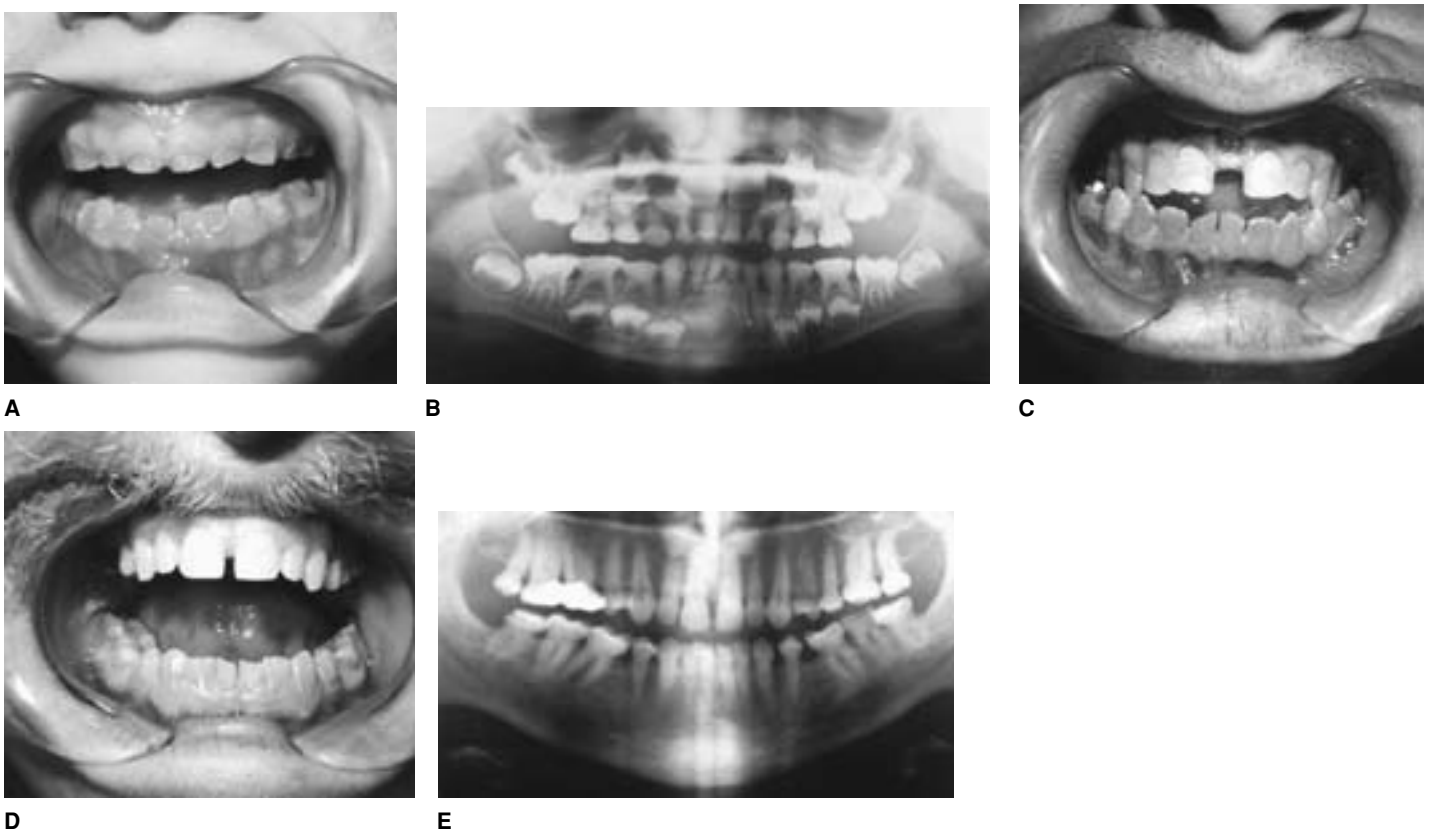

Fig. 6–2. *Osteogenesis imperfecta, type I.* (A) Opalescent deciduous teeth in a 5.5-year-old with type IB. Marked incisal wear is evident. (B) Radiographs of deciduous and developing permanent dentition in a 5.5-year-old with type IB. Pulp chambers and root canals of the deciduous teeth are almost completely obliterated, and greater constriction than normal is present at the crown-root junctions of these teeth. Pulp chambers and root canals are wider than normal in the permanent first molars. (C) Permanent dentition in type IB. All teeth are clinically opalescent. (D) Permanent dentition in type IB. Only mandibular teeth are opalescent. (E) Radiograph of permanent dentition in type IB. The root canals of some teeth, however, are patent. (B from LS Levin, Clin Orthop Rel Res 159:64, 1981.)

examples have been reported; however, two cases reported by Thompson et al (194) were stillborn at 28 and 30 weeks, respectively. Since most, if not all, cases of osteogenesis imperfecta type II have been ascertained through early death, the true average length of survival is unknown (30).

Although instances of familial recurrence and parental consanguinity have been observed in group A (171,194), the majority are sporadic examples. It was originally thought that most cases have autosomal recessive inheritance (135,148,171). However, from a study of 30 cases, Young et al (218) concluded that most cases of osteogenesis imperfecta type IIA were the result of new dominant mutations; no sib pairs were ascertained, 25 were born to nonconsanguineous couples, and increased paternal age effect was observed. This was later also confirmed by molecular studies (33,44,50). The sibling recurrence in type IIA can be explained by germline and somatic mosaicism in parents, which has been confirmed by molecular studies (31,52,103,115). Thompson et al (194) calculated an empirical recurrence risk of 7.7% for type IIB; no increase in parental age over the general population was found. It seems probable that a proportion of cases arises from de novo autosomal dominant mutations, and another part arises from autosomal recessive inheritance. Type IIC may follow autosomal recessive inheritance, although too few cases are available for analysis (171,194). The empiric overall recurrence risk of type II, irrespective of the subtype, is approximately 6% (31).

Facies. The face and cranium are molded and soft and the cranium often appears disproportionately large for the face (Fig. 6–3). Commonly, mild micrognathia and a small narrow nose are noted (50,171).

Ophthalmologic findings. Deep blue–gray sclerae are present in virtually all affected infants. On examination of the cornea of an infant who

Fig. 6–3. *Osteogenesis imperfecta, type II.* Perinatal death with frontal and temporal bossing, limb shortening with external rotation, and abduction of the thighs and angulation of the legs (From DO Sillence, Am J Med Genet 17:407, 1984.)

died at 17 days of age with presumed osteogenesis imperfecta type II, collagen fiber diameter was reduced, normal cross-striations were not seen, and collagen fibers were more densely packed than normal (21).

Cardiovascular system. Information about the cardiovascular system in osteogenesis imperfecta type II has been derived from autopsy studies. Abnormalities include thickening of the valve leaflets, myxoid degeneration of valves, calcification of pulmonary, cerebral, or peripheral arteries, intimal proliferation and medial calcification of the pulmonary artery, thickening of the media and adventitia in small and medium-sized pulmonary arteries, and atherosclerotic changes in the aorta. Microscopic calcification throughout the aorta and endocardium has also been noted (171).

Skeletal manifestations. In type IIA, there is marked reduction in ossification of the facial bones and cranial vault (Fig. 6–4), and numerous wormian bones are present. The chest is small. Ribs are slightly short, thick, and continuously beaded. The humeri and femora are crumpled (accordion-shaped), short, and broad. Thighs are held in abduction at right angle to the body. Tibias are broad, accordion-shaped, and angulated. Vertebrae are flattened, the ilia are broad and round, and the ischia and pubic bones are broad and without form (50,171,194).

Few cases of osteogenesis imperfecta types IIB and IIC have been studied. In type IIB, the skull exhibits spotty mineralization and the ribs are thin and wavy without beading, but ribs exhibit only occasional beading and are not uniformly thick (171). Femurs are short, broad, and crumpled, and tibias are thickened and angulated. In type IIB there are more well-modeled humeri with wide metaphyses, and there is more normal vertebral body height than type IIA. In type IIC, the face is not remarkably abnormal. The arms are longer than in type IIA, but the legs are similarly bent inward. Marked underossification of the skull and slender but not so uniformly beaded ribs as in type IIA have been noted. Long bones are slender and shafts are inadequately modeled. Angulation deformities of the shafts of all long bones and multiple fractures are seen. Heights of vertebral bodies are near normal (50,171,194).

Oral abnormalities. Dental abnormalities have been reported. Dean and Hiramato (56) noted argyrophilic fiber-like structures in the dentin, absence of predentin, irregular pulpal–dentin junction, paucity of argyrophilic granules in the odontoblast cytoplasm, abundance of argyrophilic fibers in the coronal pulp, and dilated capillaries in the coronal pulp. No abnormalities were found in the enamel organ or in the morphology of developing teeth. Calonius et al (34) reported the dental findings in an infant who died 8 days after birth: the dentin was thinner than normal, interglobular dentin extended to the cemento-enamel junction, dentin tubules in the circumpulpal dentin were few and wide, and degenerated osteoblasts were found entrapped in the dentin. Mantle dentin was normal and irregular at the enamel–dentin interface; the dental papilla and pulp were normal. Similar findings have been reported elsewhere (9,12,13,94). Haebara et al (83), however, reported normal teeth in a newborn with presumed osteogenesis imperfecta type II who died shortly after birth, suggesting heterogeneity, and Levin et al (108) also reported normal dentition in an infant with a lethal osteogenesis imperfecta syndrome of unknown type who survived for 10 months. Although other studies have reported dental abnormalities in patients with lethal osteogenesis imperfecta, phenotypes have not been sufficiently characterized; thus, it cannot be determined whether they had osteogenesis imperfecta type II or another lethal osteogenesis imperfecta syndrome (79,86,201).

Type III

General features. This osteogenesis imperfecta syndrome, characterized as progressively deforming with normal sclerae, is usually not lethal, at least in the newborn period (169).

Beighton and Versfeld (15) and Viljoen and Beighton (204) have reported a high prevalence of an autosomal recessive form among the black population in South Africa.

The diagnosis in sporadic cases with an osteogenesis imperfecta type III phenotype is confounded by clinical and radiographic heterogeneity, and by clinical similarity to other patients with severe osteogenesis imperfecta (171,194). The extent of this heterogeneity is unknown; Hanscom and Bloom (84) recognized four subtypes. In a recent study (172), approximately one-third of patients survived long term, reflecting not only the severity of the disorder but also heterogeneity within the group. Of 17 patients with this disorder, 4 died in the first year and 5 in the second and third decades. Death usually results from complications of severe bone fragility, skeletal deformity including kyphoscoliosis, pulmonary hypertension, and cardiopulmonary failure.

Thompson et al (194) calculated an empirical recurrence risk of 7% for families of children who have severe osteogenesis imperfecta but who survive the perinatal period. They concluded that about 75% represented new autosomal dominant mutations, whereas 25% were autosomal recessive. In a black population originating from South Africa, the chance for an autosomal recessive form was much higher (209). Both autosomal

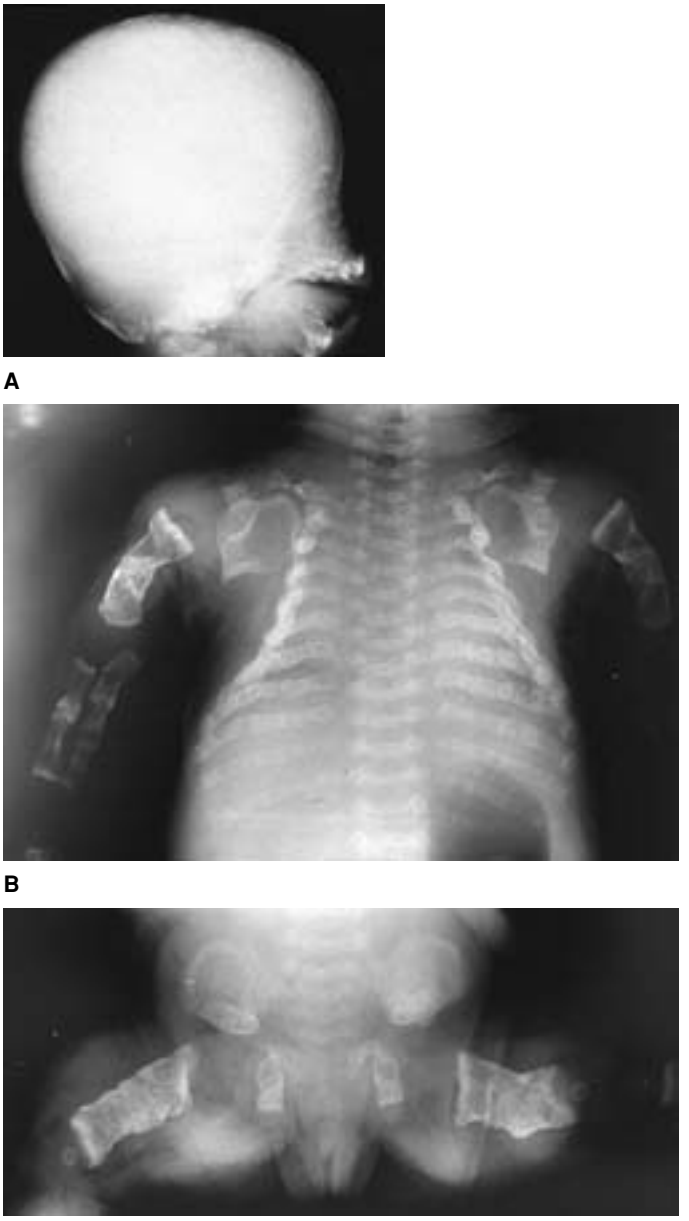

Fig. 6–4. *Osteogenesis imperfecta, type II.* (A) Lateral radiograph of skull and face showing extreme osteopenia and multiple bone islands (wormian bones) in frontal bone and vertex. (B) Chest radiograph showing continuously beaded ribs and short, broad, dysplastic humeri. (C) Femora showing crumpled and dysplastic (concertina-like) appearance. Pelvis showing osteopenia and dysplastic changes. (From DO Sillence, Am J Med Genet 17:407, 1984.)

recessive inheritance (59) and gonadal mosaicism for type III (44) have been demonstrated molecularly. Clinical, genetic, and radiologic findings have been reviewed by Sillence et al (169–172), Thompson et al (194), and Hanscom and Bloom (84).

Ophthalmologic abnormalities. Although blue sclerae are observed in infancy, the blueness fades by 1 year of age, so that older patients have pale blue or white sclerae (169).

Otolaryngologic abnormalities. Although hearing loss has been said to occur infrequently (169), audiologic findings have not been well documented in patients with unequivocal osteogenesis imperfecta type III.

Neurologic abnormalities. On head CT scans, diffuse ventricular dilatation and diffuse cortical atrophy have been described (198). There is one report of a child with osteogenesis imperfecta type III and an arachnoid cyst (51). No associated increase in intracranial pressure, cranial nerve dysfunction, or herniation syndrome was noted.

Cardiovascular system. Significant cardiac or vascular lesions have not been described, but asymptomatic mitral valve prolapse and type II atrial septal defects have been found (203).

Joint abnormalities. Ligamentous laxity is marked in children but is less severe in adults (169).

Skeletal findings. Infants with this syndrome are usually born at or near term with normal birth weight; birth length is usually normal, but some have marked deformity (169) (Fig. 6–5). With age, all fall well below the third centile in height for age and sex (171,194).

Head size is disproportionately large compared to the rest of the body. The ossification defect in the skull is not as severe as in osteogenesis imperfecta type II. Frontal and temporal bossing contribute to the triangular facies. The anterior fontanel, sutures, and posterior fontanel are wide, and wormian bones or bone islands may be palpable along the posterior sutures (169).

Fractures are present at birth in half or more of these infants; all have numerous fractures by 1 or 2 years of age (172). Although multiple rib fractures occur, continuous beading as seen in osteogenesis imperfecta type II is not found. Long bones are also subject to multiple fractures and bowing and, in some cases, there is metaphyseal flaring. The lower extremities are often already bowed at birth. The limbs are not as short or as deformed as in osteogenesis imperfecta type II. Some femora are normal, whereas others are short and broad (169). Femurs and tibias may be markedly angulated. In some patients, neonatal radiographs demonstrate broad metaphyses with centrally overmodeled diaphyses and angulation deformities; during the first year of life, diaphyses broaden (172). Sillence et al (169) demonstrated in a longitudinal study that many patients had marked thickening of the femoral shafts during the first few years of life; this morphology makes it difficult to distinguish these patients from those with osteogenesis imperfecta type IIB. With time, however, progressive narrowing occurs, so that in older patients, femurs are thin. Protrusio acetabulum is often severe.

In the first few years, metaphyses develop increasing density and irregularity, which progress so that by the end of the first decade, metaphyses and epiphyseal zones are replaced by whorls of radiodensity, giving a cystic appearance. Progressive and marked vertebral flattening with "cod-fish" changes are also observed (172). Trunk shortening is common (16). Severe kyphoscoliosis also develops (169).

Most patients become markedly handicapped (169,185). Bowing and angulation deformities are likely to be progressive.

Oral abnormalities. Dental abnormalities similar to those found in the other osteogenesis imperfecta syndromes may be present, but complete radiographic and morphologic evaluation of the teeth has been reported for few patients. The patient described by Nicholls et al (128) and Pope et al (151) had normal teeth. Within families, some patients have normal teeth, whereas others have teeth that are opalescent. Lund et al (114), using in vitro protein-chemical features and molecular mutations for classification, found that 81% of type III patients had dentinogenesis imperfecta.

Type IV

General features. Paterson et al (139,141) have provided the most complete clinical description of this disorder, although Sillence et al (169) first proposed this condition as a separate syndrome. Segregation in more than two generations and male-to-male transmission have been reported (139,169). Evidence thus favors autosomal dominant inheritance. The condition may be less common than type I. Beighton et al (16) have proposed that this disorder is heterogeneous.

Paterson et al (139) determined that, in addition to differences in scleral color compared to osteogenesis imperfecta type I, patients with osteogenesis imperfecta type IV more commonly have fractures at birth and opalescent teeth. Bruising and nosebleeds were found to be less common in osteogenesis imperfecta type IV than in type I.

Facies. Facial appearance is similar to that of osteogenesis imperfecta type I (Fig. 6–6).

Fig. 6–5. *Osteogenesis imperfecta, type III*. Seven-month-old with many healing fractures and limb deformity but relatively normal sclerae. (From DO Sillence, Symposium on Heritable Disorders of Connective Tissue, C.V. Mosby, St. Louis, 1982.)

Fig. 6–6. *Osteogenesis imperfecta, type IV*. Boy age 18 months with macrocephaly and mild frontal and temporal bossing.

Ophthalmologic abnormalities. Sclerae are usually normal, although they may be pale blue in early childhood. Paterson et al (139) noted that no adolescents or adults with the condition had abnormal sclerae.

Otolaryngologic findings. In type IV patients over 30 years old, the frequency of hearing impairment (30%) is significantly less than that in osteogenesis imperfecta type I.

Neurologic manifestations. Basilar impression resulted in neurologic signs and symptoms in the family with dominant osteogenesis imperfecta, opalescent teeth, and wormian bones reported by Hurwitz and McSwiney (93); scleral color, however, was not mentioned.

Cardiovascular system. A few reports describe a tendency to aortic root dilatation (156).

Joint abnormalities. A frequency of joint hypermobility, joint dislocations, and hernias similar to that found in osteogenesis imperfecta type I is noted in type IV.

Skeletal abnormalities. About 25% of patients have fractures at birth (139). There is wide variation in the total number of fractures. However, fracture frequency is maximal during childhood but decreases markedly after puberty. Some individuals with this syndrome may never have fractures (169). Sillence et al (169) proposed that some patients have a progressively deforming phenotype; thus, it might be difficult in some cases to distinguish this syndrome from osteogenesis imperfecta type III.

Although radiographs taken at the time of first fracture may show no osteoporosis, with repeated fractures, osteoporosis and cystic changes are found (139). Stature is generally significantly decreased: 40% of newborns have a length below the tenth centile, and the height of 95% of affected adults is below the third centile (139). The frequency and average number of wormian bones in the skull in this syndrome are unknown.

Oral findings. Dental findings are similar to those found in osteogenesis imperfecta type I. Dentinogenesis imperfecta was reported to be either consistently present or consistently absent in a family (105,106,139). Dental abnormalities are significantly more common in type IV (37%) than in type I (8%) (114). It was also noted that these abnormalities, when present, were the one consistent marker within a family, although other clinical features might vary (139). Thus, specific dental abnormalities, when present in a family, may be very helpful for diagnosis when other clinical abnormalities are mild.

Other features. A tendency toward bruising, hernias, and excessive sweating has been noted (139).

Differential diagnosis. There are numerous entities with an increased fracture frequency (Table 6–2), as well as a relatively large number of syndromes that can be classified as osteogenesis imperfecta but are distinguishable from the major groups by their associated features (Table 6–3).

Levin et al (109) described three kindreds in which multiple radiolucent-radiopaque lesions in the jaws, as well as fractures and other skeletal abnormalities, were found; teeth were normal and inheritance was autosomal dominant.

Cole and Carpenter (47) recognized a previously unreported form of osteogenesis imperfecta in which metaphyseal fractures were most prominent during the first 4 months of life, followed by diaphyseal fractures and bowing deformities as weight bearing increased. This is now known as *Cole-Carpenter syndrome*. Other distinctive features included craniosynostosis, proptosis, hydrocephaly, and distinctive facial appearance. Also noted were blue sclerae, micrognathia, and high-pitched voice. One patient had dentinogenesis imperfecta (Figs. 6–7 and 6–8). Both patients were males born to unrelated parents and both represented essentially sporadic occurrences in their respective families. A similarly affected child was reported by Amor et al (3a). Other as-yet unreported cases are known to MM Cohen Jr and RJ Gorlin.

Table 6–2. Other entities with increased fracture frequency

Antley-Bixler syndrome
Calvarial doughnut lesions
Camurati-Engelmann syndrome
Child abuse
Cutis laxa (different types)
Dermatosparaxis
Dysosteosclerosis
Ehlers-Danlos syndrome + osteogenesis imperfecta
Epidermal nevus syndrome
Gaucher disease
Gerodermia osteodysplastica
Hajdu-Cheney syndrome
Hyperparathyroidism (neonatal type)
Hyperphosphatasia
(Pseudo)*hypophosphatasia*
Jaffe-Campanacci syndrome
Lipodystrophy type Nasu-Hakola
Maffucci syndrome
Metaphyseal dysplasia Jansen type
Megepiphyseal dysplasia (*OSMED*)
Nemaline myopathy
Ollier enchondromatosis
Osteofibrous dysplasia
Osteopetrosis
Osteoporosis-pseudoglioma-mental retardation
Pena-Shokeir syndrome
Pyknodysostosis
Pyle disease
Rubinstein-Taybi syndrome
Schwartz syndrome
Yunis-Varón syndrome

Several sets of sibs have been described (3,87,146) with severe osteoporosis, fractures, dislocated hips, macrocephaly, wormian bones, frontal bossing, persistent anterior fontanel, brachytelephalangy, hyperextensible joints, congenital retinitis pigmentosa with blindness, and severe mental retardation (Figs. 6–9 and 6–10). Bone age was retarded, and there was severe dental malocclusion. Inheritance is probably autosomal recessive (3). A somewhat similar case was described by Blechmann and Crommer (20).

Beighton (14) described a kindred with dentinogenesis imperfecta, blue sclerae, multiple wormian bones, generalized moderate osteoporosis, mild femoral bowing, and mild vertebral flattening. One person had multiple fractures with mild trauma. Stature and intelligence

Fig. 6–7. *Cole-Carpenter syndrome*. (A,B) Compare facies. Note bulging forehead, striking proptosis, midfacial deficiency, and micrognathia. (From DEC Cole and TO Carpenter, J Pediatr 110:76, 1987.)

A **B**

Table 6–3. Other osteogenesis imperfecta syndromes in which multiple fractures are common

Salient features	Inheritance pattern	Reference
Normal sclerae Multiple radiolucent-radiopaque jaw lesions Normal teeth	AD	Levin et al
Generalized osteoporosis Destructive generalized joint disease	Unknown	Pentinnen et al
Osteoporosis Sclerotic skull lesions Normal teeth?	Unknown	Colavita et al
Area of rarefaction in pelvis and long bones Normal sclerae Normal hearing	AD	Keats and Anast
Bowed long bones Premature loss of teeth Hearing loss	AD	Osterberg et al Hughes et al
Wormian bones Short arms Radiolucencies in long bones	Unknown	Suarez and Stickler
Blue sclerae Wormian bones Generalized moderate osteoporosis Dentinogenesis imperfecta	AD	Beighton ?Crawfurd and Winter
Blue sclerae Wormian bones Mandibular hypoplasia Joint laxity Easy bruisability	Dominant	McLean et al
Joint hypermobility Wrinkled skin Blue sclerae Other osseous abnormalities	Unknown	Biering and Ivesen
Osteoporosis Wormian bones Frontal bossing Hyperextensible joints Retinitis pigmentosa	AR	Pfeiffer et al Heide Blechmann and Crommer Al Gazali et al
Contractures Spinal muscular atrophy	?AR	Borochowitz et al
Contractures in knees/elbows Pterygia Kyphoscoliosis	AR	Brady and Patton Viljoen et al McPherson and Clemens
Campomelia Ankyloglossia superior Cleft palate	Unknown	Stevenson
Ocular proptosis Craniosynostosis Hydrocephaly Distinctive facies	Unknown	Cole and Carpenter
Congenital cataract Microcephaly Thin calvaria Blue sclerae	AR	Buyse and Bull
Cataract Narrow thorax Distinctive facies	?AR	Dennis et al
Myopathy Cataract Hypogonadism Mental retardation	AR	Lundberg
Hearing loss Dystonia Choroidal-areolar dystrophy Mental retardation	XLR	Tranebjaerg et al
Marfanoid habitus Slight basilar impression Wormian bones Other osseous abnormalities	?Recessive	Meigel et al
Thin ribs/long bones Undermineralization of skull Short stature	Unknown	Bonaventure et al
Micromelia Posterior encephalocele Polysyndactyly Duplication of tibia	Unknown	Carpenter and Hunter
Excessive callus formation Short limbs Bowing forearms	Unknown	Feingold et al
Short limb dwarfism Craniosynostosis Brachydactyly	Unknown	Kozlowski and Kan
Short limb dwarfism Dense skull/vertebrae	Unknown	Muller et al
Bone cyst Rhizomelic short arms Scoliosis Delayed tooth eruption	Unknown	Schinzel
Osteoporosis Transverse bone interruptions Hydrops Monosomy X	X-linked recessive	Azouz et al
Osteoporosis White matter degeneration Mental retardation	AR	Neimann et al
Myelofibrosis Osteopenia Pigmented spots Distinctive face	Unknown	Cole et al
Osteopetrosis Hydrocephaly Neuronal loss	AR	El Khazen et al
Radial ray anomalies Bowing tibia Mental retardation	AR	Chitty et al
Blue sclerae Sparse hair Mental retardation	AR	Kaler et al
Skeletal hemangiomas Extraskeletal hemangiomas	Unknown	Devaney et al
Midface hypoplasia Micromelic short stature Wormian bones	Dominant	Nishimura et al

were normal. Crawfurd and Winter (54) reported a patient similar to the one reported by Beighton (14) who lacked femoral bowing and vertebral flattening, but who had frontal bossing, joint laxity, and easy bruisability. McLean et al (122) reported a father and daughter with wormian bones, blue sclerae, mandibular hypoplasia, loose joints with dislocations, and femoral and tibial bowing; dentition was normal and there were no fractured bones.

Buyse and Bull (28) described three sibs with congenital cataracts, microcephaly, thin calvaria, prenatal fractures, and blue sclerae. The brain had a smooth cortex without convolutions, sulci, or gyri. These sibs were stillborn or died shortly after birth. The parents were normal.

A B

Fig. 6–8. *Cole-Carpenter syndrome*. (A) At age 4 months, distinctive metaphyseal lucencies or compression fractures were apparent in all long bones. (B) By age 8 months, cortical thinning and demineralization had progressed. Diaphyseal fractures subsequently healed, but deformities and bowing were already well advanced. (A,B from DEC Cole and TO Carpenter, J Pediatr 110:76, 1987.)

Fig. 6–9. *Osteoporosis, fractures, macrocephaly, blindness, and severe mental retardation*. Two sibs with macrocephaly, frontal bossing, and congenital blindness. (Courtesy of W Lenz, Münster, West Germany.)

Fig. 6–10. *Osteoporosis, fractures, macrocephaly, blindness, and severe mental retardation*. Radiograph showing severe osteoporosis and leg length disparity due to dislocated hips. (Courtesy of W Lenz, Münster, Germany.)

Pentinnen et al (145) described a 14-year-old girl who had two fractures, generalized osteoporosis, and destructive generalized joint disease resembling juvenile rheumatoid arthritis; on biochemical investigations, an increased ratio of type III collagen to type I collagen was found. It should be pointed out that rarely a mutation in type I collagen may be found in type I Ehlers-Danlos syndrome (130a). *Campomelic dysplasia* should also be considered in the differential diagnosis.

Colavita et al (46) reported a 21-year-old male with fractures, bumps on the head, osteoporosis, and multiple sclerotic lesions of the skull; although the patient was said to have dentinogenesis imperfecta, radiographs showed normal teeth. See section on *calvarial doughnut lesions, osteoporosis, and dentigerous cysts* for further details on differential diagnosis. Osteogenesis imperfecta has been found with congenital joint contractures in an autosomal recessive condition called "Bruck syndrome" (25,25a,104a,123,206). In addition to multiple joint contractures, these patients exhibit club feet, pterygia, multiple fractures leading to deformed extremities, short stature, and progressive kyphoscoliosis. All have had normal hearing and normal intelligence, and white sclerae in childhood or later on.

Keats and Anast (97) reported a three-generation kindred with normal sclerae, normal hearing, multiple bone fractures, and circumscribed areas of rarefaction in the pelvis and long bones. It is also of note that a premature, stillborn infant with short, bowed lower extremities as well as fractures was born to this kindred. Meigel et al (124) described a 10-year-old male born to a consanguineous couple. The boy had multiple fractures, marfanoid habitus, narrow thorax, thin extremities and mild arachnodactyly, lumbar lordosis, genua valga, moderate muscular hypotonia, and mildly hyperextensible joints. Radiographs showed slight basilar impression, wormian bones, flattened vertebral bodies, and bowing of long bones; cystic irregularities in the bones were noted. Biering and Ivesen (18) described a 5-month-old male with blue sclerae, wrinkled, loose, and pale skin with a conspicuous venous network, excessive joint laxity, hypotonia, bilateral hip dislocation, multiple spontaneous fractures of vertebrae and femurs, thoracic kyphosis, severe generalized osteoporosis, and slender long bones.

Greenfield et al (82) reported a family with blue sclerae, keratoconus, childhood onset of otosclerotic-like hearing loss, and spondylolisthesis, but no fractures. Inheritance was autosomal recessive. We suspect a form of Ehlers-Danlos syndrome. Carey et al (35) described three children with bone fractures, blue sclerae, embryotoxon, gradual hearing loss beginning in the second decade of life, arachnodactyly, tall stature, dolichostenomelia, pectus excavatum, joint hypermobility, and scoliosis but no ectopia lentis. The proband had marked dilatation of the ascending aorta and severe aortic incompetence; he died suddenly at age 32. The father was a member of a large kindred with dominantly inherited osteogenesis imperfecta; the mother had scoliosis, pectus excavatum, clinodactyly and camptodactyly of the fifth fingers and toes, ligamentous laxity, and flat feet.

Osterberg et al (132) described a huge Northern Irish family in whom 40 individuals were affected with hearing loss in early childhood, bone pain at puberty or shortly thereafter, and early loss of dentition. Radiographically, the long bones showed abnormal modeling, disordered trabecular pattern, and gradually expanding areas of translucency leading to cortical thinning and an increase of fractures. The responsible gene was located at 18q21–q22 (92).

Suarez and Stickler (186) described a single girl with short arms, short fifth fingers and fourth and fifth toes, and radiolucent defects with cortical thinning in the humeri, forearms, and lower legs. Multiple wormian bones were seen in the skull. Borochowitz et al (24) described two male sibs with infantile spinal muscular atrophy who had spontaneous fractures shortly after birth. One had an unilateral preauricular tag. The sclerae were not blue. The parents were first cousins.

Stevenson (181) reported an infant with bowed femora, radii, and ulnae, a poorly ossified cranium, and fractures of the ribs. There were also cleft palate, adhesion of the tongue to the palate, hypertelorism, high nasal bridge, and small mandible. Two sibs were reported by Dennis et al (58) who had cataract, microphthalmia, thin beaked nose, short philtrum, and micrognathia. The facies resembled that of *Hallermann-Streiff syndrome* (Fig. 6–11). In addition, the thorax was narrow, and the fingers were tapered with small nails. Radiologically, the ribs, clavicles, and long bones were very thin and showed many fractures.

Lundberg (116) described a brother and two sisters with cataract, proximal myopathy involving the face, eyes, and swallowing, ataxia, and hypogonadotrophic hypogonadism. Development was delayed. Inheritance is probably autosomal recessive. Tranebjaerg et al (196) reported the mapping to chromosome Xq22 of an entity that showed progressive hearing loss, as well as ataxia and dystonia, starting in childhood, and progressive visual disturbances starting in puberty and manifesting as photophobia and central scotoma. Some affected males had psychiatric disorders and peripheral neuropathy. Several affected individuals had developmental delay and increased frequency of hip fractures. Three unrelated infants described by Bonaventure et al (23) had low birth weight, undermineralization of the skull but no wormian bones, and very thin ribs and long bones with multiple fractures. Biochemically, collagen type V was increased.

Fig. 6–11. *Dennis syndrome*. (A,B) Note microphthalmia, thin beaked nose, and micrognathia. (From NR Dennis et al, Am J Med Genet 59:517, 1995.)

A B

Carpenter and Hunter (37) described an infant with severe short-limbed dwarfism, posterior encephalocele, microphthalmia, absent external nares, cleft palate, postaxial polydactyly of hands and feet, duplication of right tibia, and multiple fractures of long bones. Autopsy showed pachygyria, absent olfactory bulbs, and atrial septal defect.

Moog et al (124a) reported male and female sibs with bilateral wave-like defects of the cortex of the tibia with alternate hyperostosis and thinning. Also noted were wormian bone, dentinogenesis imperfecta, hypertelorism, and periorbital fullness.

Feingold et al (70) reported a child with rhizomelic shortening of limbs, contractures of elbows, bowed forearms, and multiple fractures. In early childhood, radiographs showed marked osteoporosis and excessive callus formation. The skin broke down over these areas. Biochemically, the callus showed PAS-positive deposits. Osteocraniostenosis was first described by Kozlowski and Kan (102) and is characterized by short-limb dwarfism, craniosynostosis (often mild cloverleaf skull), hypomineralization of the skull, thin and sclerosed long bones, multiple fractures, brachydactyly, sometimes with absent distal phalanges, and poorly developed nails.

Muller et al (126) reported a stillborn girl with short-limb dwarfism and hydrops. Radiographically the skeleton was undermineralized except for the base of the skull, face, and spine. Shortening of the limbs was rhizomelic with wide metaphyses and fractures.

A pubertal boy described by Schinzel (162) showed rhizomelic shortening of arms, bone cysts, increased fractures, and delayed tooth eruption. He had short stature, severe scoliosis, and hypermobile small joints. Azouz et al (7) described a fetus with monosomy X and hydrops. Multiple fractures, osteoporosis, bent bones, and symmetric submetaphyseal transverse bone interruptions or pseudofractures were noted.

Neimann et al (127) reported four sibs and an isolated patient with white-matter degeneration, quadriplegia, amyotrophy, peripheral neuropathy, subluxation of hips, osteoporosis, and multiple fractures. They had severe developmental delay. Several patients have been described with widespread fibrous bone dysplasia, fractures of the femora, some bowing of long bones, myelofibrosis, and pigmented skin spots (48). They had hypertelorism, synophrys, saddle nose, anteverted nostrils, large mouth, and highly arched palate. The disorder is possibly caused by increased adenylate cyclase activity. El Khazen et al (67) described two sibs with increased bone density, multiple fractures, and hydrocephaly. Autopsy showed extensive loss of neurons and gliosis.

Chitty et al (42) reported two sibs with brachydactyly, variable radial ray anomalies, bowed tibiae, and, in one, bowed femora, osteopenia, and multiple fractures. The sibs had a square, flat face. Development was delayed. The parents were consanguineous. Two sibs with consanguineous parents, reported by Kaler et al (96), had sparse hair, macrocephaly, prominent forehead, hypertelorism, and joint hypermobility. Development was delayed. They had multiple fractures, osteopenic skeleton, and white sclerae.

Nishimura et al (129) reported a new brittle bone disorder consisting of dolichocephaly with frontal bossing, midfacial hypoplasia, postpubertal prognathism, micromelic short stature, coarse bony trabeculi, and bone fragility of variable degrees. Mild alteration in the vertebral bodies and iliac hypoplasia were other hallmarks. Multiple wormian bones were seen in the calvaria. There were progressive bowing of the legs and forearms and pseudofractures of the long bones with metaphyseal narrowing. Inheritance is either autosomal or X-linked dominant.

There are several reports of the occurrence of multiple hemangiomas of the skin, mouth, conjunctiva, various viscera, and bones; Devaney et al (60) provide a good review. Radiographs show widespread multiple lytic lesions. The origin of the disorder is unknown.

Wormian bones are found in *cleidocranial dysplasia, pycnodysostosis, progeria, mandibuloacral dysplasia, acroosteolysis,* and *Menkes disease.* Fractures can also be the result of child abuse (11,127,136,142,167). Opalescent teeth with radiologic abnormalities similar to those found in some patients with osteogenesis imperfecta are also seen in dentinogenesis imperfecta, a disorder affecting the dentition only. This disorder, sometimes called "hereditary opalescent dentin," has autosomal dominant inheritance (19,55,76).

Laboratory aids. Sonography has been used as a method of prenatal diagnosis for individuals at risk for osteogenesis imperfecta type I. Preimplantation diagnosis has been reported (60a). Hobbins et al (89) reported a displaced femoral fracture in a fetus of 19 weeks at risk for osteogenesis imperfecta. Chervenak et al (41) reported another fetus that was normal at 20 weeks of gestation; however, at 24 weeks, both femurs were markedly bowed, and at 32 and 38 weeks, long bone demineralization was suggested; no fractures were found. As only a limited number of newborns with osteogenesis imperfecta type I are born with fractures [8% in the series of Sillence et al (169)], and often no skeletal deformity is evident at that time, it is likely that many cases at risk will be missed. Prenatal diagnosis by molecular studies using linkage studies (117,198) or mutation analysis (198) has been accomplished. The same holds for osteogenesis imperfecta type IV.

Many authors have reported the prenatal diagnosis of osteogenesis imperfecta type II by ultrasound (61,66,75,134,165,180,193,194,217). Thompson (193) summarized the findings in 30 cases, many of which were diagnosed from 20 weeks of gestation to as early as 13.5 weeks of gestation (180). Both cases at risk and sporadic cases in which scans were made for other reasons have been reported. The most important findings have been reduced echogenicity, especially of the calvaria, marked reduction of long bone length (mainly femur), multiple fractures, and deformity of long bones, ribs, and skull. No false-negative diagnoses have yet been reported (193). Thompson (193) suggested serial scans from 14 weeks gestation in pregnancies at risk, and stated that osteogenesis imperfecta type II should be diagnosable at 17 weeks gestation. With intravaginal transducers, diagnosis may even be made earlier. Prenatal diagnosis by molecular methods is also possible (50).

The number of cases in which osteogenesis imperfecta type III was diagnosed prenatally by ultrasound is low (6,193,194). Three dimensional ultrasonography is better than two dimensional (72a). In several cases, early ultrasound scans at 14 or 15 weeks gestation were found to be normal. Abnormalities were found only at 19 to 20 weeks gestation. The findings were the same as those in type II, but were more mildly expressed (193). No false-negative results have been published, but the number of reports is still low.

An animal model of osteogenesis imperfecta with opalescent teeth has been described in Friesian calves (57), and a transgenic mouse model has been reported for mild dominant osteogenesis imperfecta (22).

Chapter 7
Syndromes Affecting Bone: Chondrodysplasias and Chondrodystrophies

We cannot emphasize strongly enough the need for radiographic examination of lethal bone dysplasias. The minimum number of radiographic views that should be taken include anterior–posterior (AP) and lateral views of the whole body (babygram), lateral skull, and hand and foot views. At autopsy, views of the trachea, vertebrae, costochondral junction, and the head of the humerus and femur should be obtained (3,9). Chromosomes may be cultured from human cartilage within seven days following death (7).

Osteodysplasias include disorders of osteopenia or osteosclerosis, while chondrodysplasias result in either short trunk or short limb. From 1960 to 1980, there was such a radiographic proliferation of disorders that a biennial meeting was held to classify the disorders of cartilage and bone into families. This culminated in the International Nomenclature and Classification of the Osteochondrodysplasias (4). Within recent years, the use of linkage, positional cloning, and positional candidate gene analyses have revealed basic genetic defects underlying several of these conditions (2,5,6). We refer the reader to an article by Wynne-Davies and Gormley (8) for a discussion of relative frequency. An excellent review of ossification and the molecular aspects of bone formation is that of Cohen (1).

Understanding the roles of the various collagens, the parts played by glycosaminoglycans and various enzymes involved in the degradation of bone, and especially new information regarding signaling between cell surface receptors, their ligands, signal transduction to the nucleus, and transcription factors has allowed for reclassification of many of the disorders on a molecular basis (1a).

Space limits us to those disorders that also involve the cranium and facial skeleton.

Achondrogenesis

Achondrogenesis, separated in 1936 by Parenti et al (41) from achondroplasia, is a type of lethal chondrodysplasia characterized by short trunk, severe micromelia, normal size head, and specific skeletal changes. There are, however, earlier examples (12). The term "achondrogenesis," first coined by Fraccaro (15) in 1952, represents a heterogeneity of at least three types (Figs. 7–1 to 7–4) (29,55). There has been considerable confusion regarding terminology. Camera et al (8) have suggested that type 1 with dense bones be designated "pycnochondrogenesis," citing earlier examples (50). Borochowitz et al (5) indicated further heterogeneity of type 1 with two distinct subgroups. We suggest that the reader peruse Whitley and Gorlin (61), Borochowitz et al (4), Yang et al (65), Chen et al (10), and Superti-Furga (55) for discussion of nomenclature. Over 200 cases have been recorded in aggregate, and several large series have

Fig. 7–1. *Achondrogenesis.* Phenotype of lethal dwarfism with disproportionately large head, disproportionately short limbs, and pot belly.

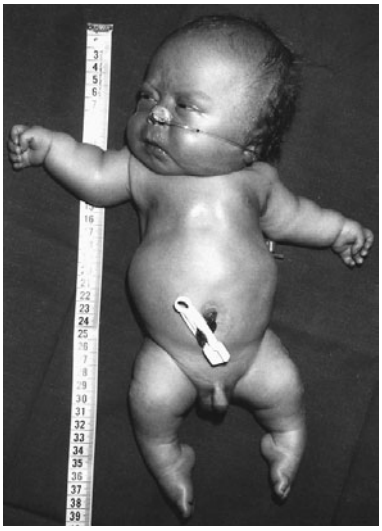

Fig. 7–2. *Achondrogenesis, type IV.* Hypochondrogenesis. (From G Hendrickx et al, Eur J Pediatr 140:278, 1983.)

been analyzed (48,66). The frequency has been estimated at 1/40,000 births (3,53).

We will use the classification of Table 7–1 (55). Type 1B has autosomal recessive inheritance. For type 1A, inheritance remains unproven. All patients with type 2 have been isolated examples (37), and probably represent new autosomal dominant mutations (18,19). The milder form of type 2 is also called "hypochondrogenesis." Affected sibs with achondrogenesis have been of the same type within the classification.

Achondrogenesis type 1B was proven to be caused by mutations in the gene for a sulfate transporter (*DTDST*), which is also the causative gene for diastrophic dysplasia (54,56). Impaired activity of the sulphate transporter in chondrocytes and fibroblasts results in synthesis of insufficiently sulfated proteoglycans, which in turn has a pronounced effect on the composition of the extracellular matrix (55). Genotype–phenotype correlations indicate that the amount of residual activity of *DTDST* modulates the phenotype, from lethal conditions such as atelosteogenesis type 2 and achondrogenesis type 1B, to nonlethal diastrophic dysplasia (7,57). Achondrogenesis type 2 is caused by mutations in the $\alpha(1)$II chain of type II collagen (14,15,18,19,28a,40,41). Mutations in *COL2A1* give rise to a spectrum of clinical phenotypes, the so-called type II collagenopathies (52), which in addition to achondrogenesis type 2 includes

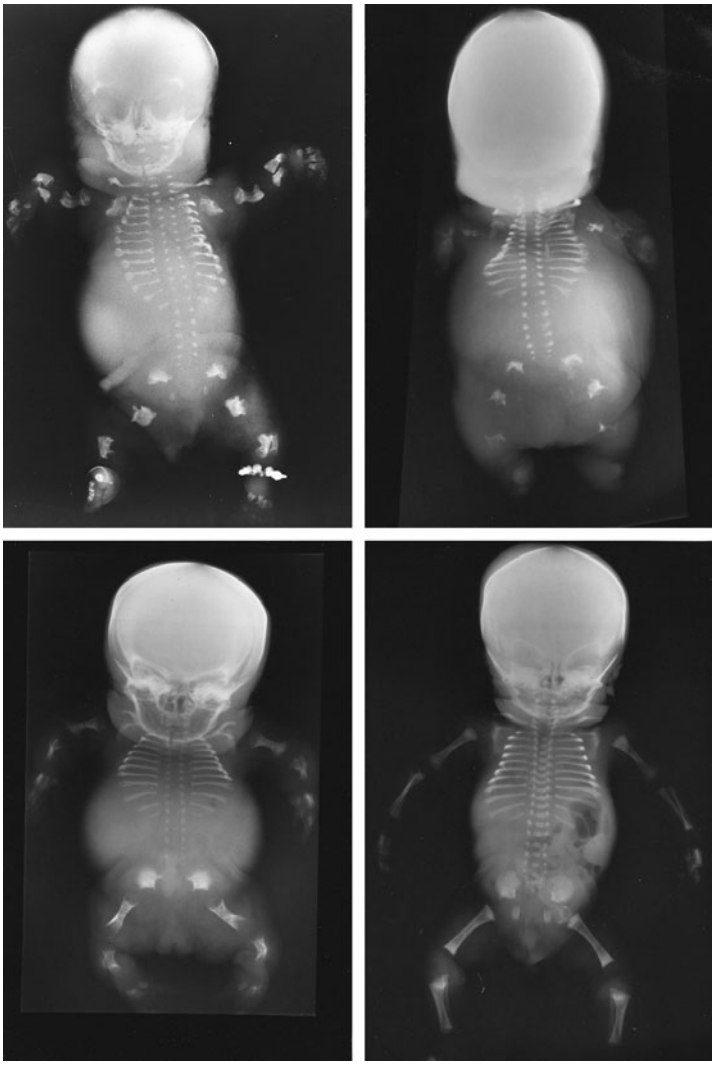

Fig. 7–3. *Achondrogenesis.* Radiographs of the four different types of achondrogenesis. Top left: Type I (Houston-Harris) with severe limb and multiple rib fractures. See also Figure 7–4, top left. Top right: Type II (Fraccaro), with severe limb reduction and no rib fractures. See also Figure 7–4, top right. Bottom left: Type III (Langer-Saldino), with mushroom-stem femora, intermediate limb reduction, and halberd ilia. See also Figure 7–4, bottom left. Bottom right: Type IV (hypochondrogenesis), with the least severe limb reduction. See also Figure 7–4, bottom right. (From CB Whitley and RJ Gorlin, Radiology 148:693, 1983. Top left courtesy of R Wapner and LG Jackson, Philadelphia, Pennsylvania. Top right courtesy of RM Saldino, San Diego, California. Bottom left courtesy of PE Andersen, Odense, Denmark. Bottom right courtesy of K Kozlowski, Sydney, Australia.)

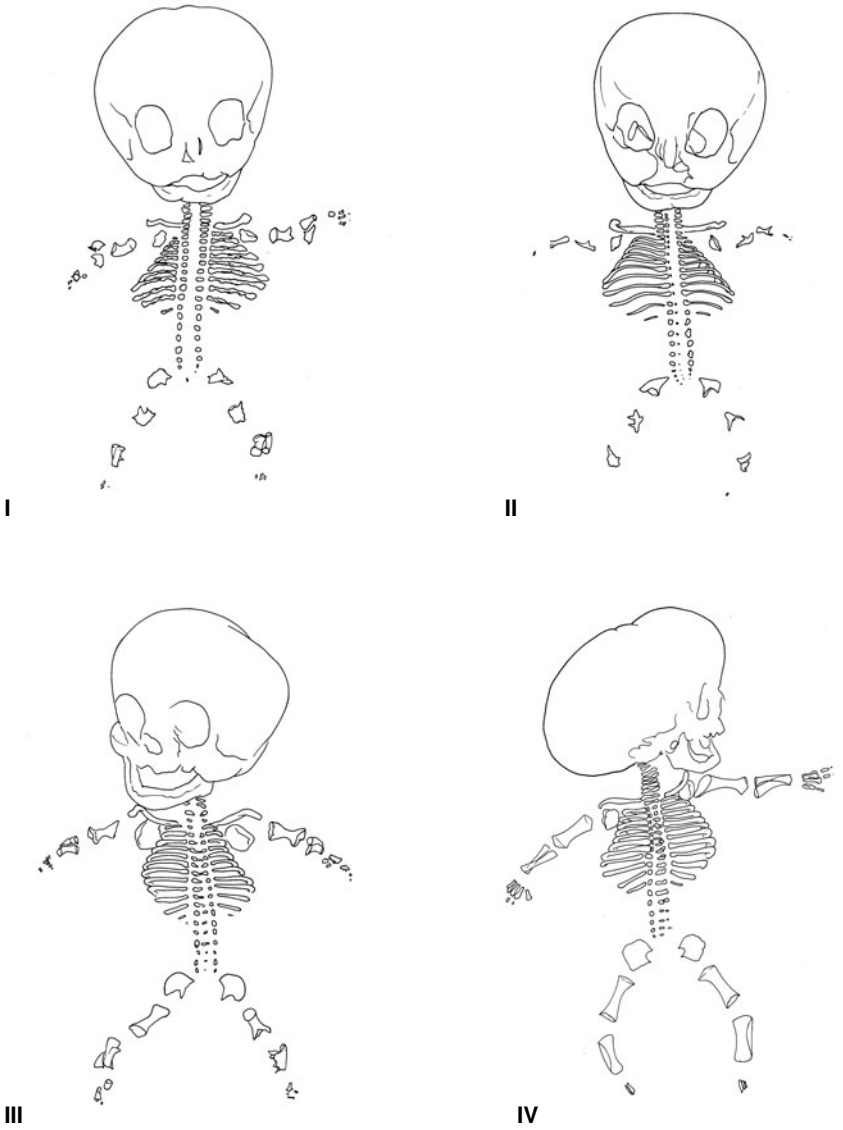

Fig. 7–4. *Achondrogenesis.* Diagrammatic sketches of the four types of achondrogenesis. Top left: Type I (Houston-Harris). Top right: Type II (Fraccaro). Bottom left: Type III (Langer-Saldino). Bottom right: Type IV (hypochondrogenesis). (From CB Whitley and RJ Gorlin, Radiology 148:693, 1983.)

congenital spondyloepiphyseal dysplasia, *Kniest dysplasia*, *Stickler syndrome*, *type 1*, spondyloperipheral dysplasia, and *spondyloepimetaphyseal dysplasia*, *Strudwick type* (17). The nature of the mutations and their localizations within the protein seem to explain this diversity in manifestations, although further modulating factors may be involved as well.

Achondrogenesis type 1 is incompatible with life, with half of the infants being stillborn and the rest succumbing within the first few hours. Mean weight for type 1A patients is about 1200 g, whereas type 1B infants average 2100 g. Infants with the mildest form of type 2 (hypochondrogenesis) have survived for as long as a few months, but no long-term survivors have been reported (4,22,36,37). There is a history of polyhydramnios in over 50% of type 1 patients (48). Gestation is about 30 weeks in type 1A and 35 weeks in type 1B. Fetal hydrops is common, although this appearance may also be caused by the abundance of soft tissue relative to the short skeleton.

Table 7–1. Classification of achondrogenesis

Name	Former types	Gene
Achondrogenesis type 1A	Houston-Harris	Unknown
Achondrogenesis type 1B	Fraccaro	*DTDST* (5q32)
Achondrogenesis type 2	Langer-Saldino	*COL2A1* (12q13)

Facies. The (usually normocephalic) head is disproportionately large relative to reduced neck, trunk, and limb length, causing the infant to be erroneously considered to have hydrocephaly. The head is often greater than 40% of body length and appears to sit on the chest. In type 1A, the forehead slopes and the face appears puffy. The nose is small with anteverted nares and long philtrum, and there is retrognathia with double chin. Type 1B and 2 infants have a large prominent forehead, flat face, depressed nose with marked anteversion of nostrils, normal philtrum, and more normal chin. The neck is short in all types. The face is not remarkable in the mild form of type 2.

Skeletal alterations. The extremities are bowed, rarely exceeding 10 cm in length, and have been compared to flippers (55). The fingers and toes are similarly short and stubby. In type 2, polydactyly may be found (45). Total body length is seldom greater than 36 cm at term (range 22–40 cm). The belly is greatly enlarged, partly from the short chest cavity and partly from hydrops. The genitalia are normal.

General radiographic characteristics shared by the severe types consist of marked underossification of vertebral bodies, sternum, ilia, ischia,

Table 7–2. Achondrogeneses

	Type 1A	Type 1B
Skull	Poorly ossified	Mild ossification disturbance
Vertebral column	Bodies unossified	Body minimally ossified
	Pedicles ossified	Arches ossified only in cervical and upper thoracic region
Ribs	Short with multiple fractures, cupped ends	Short without fractures, flared cupped ends
Clavicles	Short, wide	Mildly elongated
Scapulae	Irregularities, hypoplastic	Distal radial dichotomy, hypoplastic
Pelvis	Ilia crenated; ischia poorly ossified, widely spaced, low; pubic bones ossified	Ilia crenated, ischia and pubic bones unossified
Humerus	Short, stellate	Short, stellate
Radius/ulna	Short, metaphyseal irregularities	Short, poorly ossified,
Femur	Proximal metaphyseal spike, clubbing	Crenated, distal flare
Tibia/fibula	Short, wide, irregular metaphyses	Short, stellate, fibula unossified
Hands/feet	Unossified	Unossified
	Type 2	**Mild type 2 (hypochondrogenesis)**
Skull	Normally ossified, occipital defect	Normally ossified, occipital defect
Vertebral column	Bodies poorly ossified, arches ossified	Bodies flattened, but ossified
Ribs	Short, not flared	Short, not flared
Clavicles	Normal	Normal
Scapulae	Almost normal	Almost normal
Pelvis	Ilia small; halberd-shaped ischia; pubic bones unossified	Ilia better modeled, ischia ossified, pubic bones unossified
Humerus	Short, flared, cupped	Short, rounded ends
Radius/ulna	Short, flared, cupped	Short, rounded ends
Femur	Short, flared cupped	Short, rounded ends
Tibia/fibula	Short, flared at both ends, cupped	Short, rounded ends
Hands/feet	Short, talus and calcaneus unossified	Short, talus and calcaneus unossified

pubic bones, talus, and calcaneus. The ribs are short and cupped with flared ends. Since failure of endochondral bone growth, which manifests as reduced linear growth of long bones, appears to be a major defect in achondrogenesis, a ratio between length and width of the femora (the femoral cylinder index) has been used (61). A boneless variant has been reported (26). The specific characteristics of each type are summarized in Table 7–2 and will be discussed briefly.

Type 1A (Houston-Harris). In this form, the calvaria is very poorly mineralized. There is marked limb shortening and striking multiple rib fractures. The long bones are very short. The vertebral bodies are so inadequately mineralized that they may appear to be absent, particularly in the lower thoracic and lumbar spine (38,43,62,64). Multiple affected sibs have been reported (2,21,24,32,42,50,59,60).

Type 1B (Fraccaro). In this form, there are crenated ilia and stellate long bones. The vertebral bodies exhibit minimal ossification; the pedicles are ossified. There are no, or only one or two, rib fractures (6,55) (Table 7–1). Clinically, the limbs are shorter than those in type 1A and the calvaria is ossified. However, the degree of ossification is age dependent, and caution is needed in comparing radiographs from patients with different gestational ages. The distinction between type 1A and type 1B on radiographs is not always possible (55). Multiple affected sibs have been described (47,60,62).

Type 2 (Langer-Saldino). Infants have well-ossified calvaria and exhibit better developed mushroom-stem femora and almost triangular halberd-shaped ilia (Table 7–1). Ossification of the spine is variable. Ischial and pubic bones are unossified. Multiple affected sibs have been reported (11).

Mild type 2 (hypochondrogenesis). By radiographic criteria, the same pattern of chondrodysplasia is observed, but to a relatively mild degree (Table 7–1). Thoracolumbar vertebral bodies are only slightly ossified and manifest as thin lamellae. Ossification is incomplete in the cervical, upper thoracic, and lower lumbar regions. The sternum is very short. The ilia are hypoplastic but more sculptured. Ischial ossification is variably present but pubic ossification is never observed. The sacrum is deficient. Limb bones are thick and short with metaphyseal widening and irregularity. There are no epiphyseal centers. The distinction between type 2 and hypochondrogenesis has been challenged on the basis of the apparent continuity of clinical, radiographic, and histopathologic changes in a large series of patients (4,37).

Pathologic findings. Histopathologic studies have demonstrated different patterns of morphologic abnormalities in the most severe types (4). In type 1A, the cartilage is hypercellular with clustered chondrocytes within a diffuse matrix. The resting chondrocytes contain PAS-positive, diastase-resistant, round to oval intracytoplasmic inclusions. The lacunae are dilated. There is defective column formation. Type 1B has more randomly dispersed chondrocytes (16). Their cytoplasm is vacuolated but there are no inclusions. The lacunae are not dilated. As in type 1A, there is no columnization. In type 2, the chondrocytes are densely packed with dilated lacunae (49,60,66).

Other findings. Other than hypoplastic lungs, the viscera are usually normal (3). Patent ductus arteriosus (PDA) (11,32,47,62), cardiac septal defects (44), hydronephrosis (28,32), cryptorchidism (28,32,62), and inguinal hernia (27) have been noted. In type 1A, occipital encephalocele has been described (9,39).

Oral manifestations. Cleft palate has been observed in type 2 cases (62,63), and in one-half of hypochondrogenesis cases (4,37).

Differential diagnosis. The clinical appearance alone would allow the clinician to separate this disorder from *thanatophoric dysplasia*, homozygous *achondroplasia*, *atelosteogenesis type II*, *hypophosphatasia*, and *fibrochondrogenesis*. Multiple rib fractures in achondrogenesis type 1B may suggest *osteogenesis imperfecta*. Differentiation from *Schneckenbecken dysplasia* is more difficult but can be made on the basis of the characteristic "snail back" iliac silhouette in the latter. Another unique disorder in the achondrogenesis spectrum has been identified (30) but is

distinguished by more delicate and curved clavicles and other long bones. Mild type 2 (hypochondrogenesis) greatly resembles *spondyloepiphyseal dysplasia congenita*.

Laboratory aids. Prenatal diagnosis has been made sonographically in the first trimester (51) or early in the second trimester by several investigators (2,11,20,24,47,50,58,60,62a). Findings include polyhydramnios, hydrops, extremely short limbs, short trunk, prominent abdomen, cervical hygroma, and underossification of spine.

Achondroplasia

The term "achondroplasia" was first used by Parrot (68) in 1878 to describe a rhizomelic form of short-limbed dwarfism associated with enlarged head, depressed nasal bridge, short stubby trident hands, lordotic lumbar spine, prominent buttocks, and protuberant abdomen (Figs. 7–5 to 7–7). Achondroplasia is a misleading term because cartilage is, in fact, formed in the disorder; however, the term is well established. Until recently, a variety of chondrodysplasias were frequently confused with achondroplasia (42,65,88). The Egyptian gods, Bes and Ka, are depicted as having the disorder (84). Aesop also presumably had the disorder (26). The reader is referred to an excellent report on the 1986 International Symposium on Human Achondroplasia (64), and the series of papers by Hunter (36–38).

More than 80% of recorded cases of achondroplasia are sporadic, representing new mutations. Increased paternal age at time of conception is associated with sporadic cases (60,66,96). Among the familial cases, autosomal dominant inheritance can be demonstrated (60). The recurrence risk, in the case of normal parents, is 0.02% (53a).

The frequency of achondroplasia has been estimated as ranging between 1/16,000 and 1/35,000 live births (3,21,50,60,64,94), making it one of the most common of the nonlethal bone dysplasias. Earlier ascertainments of frequency (55,92) were probably overestimates because other chondrodysplasias, in addition to achondroplasia, were undoubtedly included in these surveys.

Affected individuals are heterozygous for the causative gene. Presumed homozygosity has been reported in a few instances in which both parents had achondroplasia (4,69,82,110). Homozygous achondroplastic infants are more severely affected, clinically and radiologically, than are infants heterozygous for the disorder, and the condition is lethal during infancy (69), although aggressive respiratory and surgical measures kept one infant alive for several years (57). Death appears to result from brain stem compression (29). Deaths attributable to cardiovascular causes are increased in patients between 25 and 54 years of age (30). The homozygous state resembles thanatophoric dysplasia in many respects but is still distinguishable.

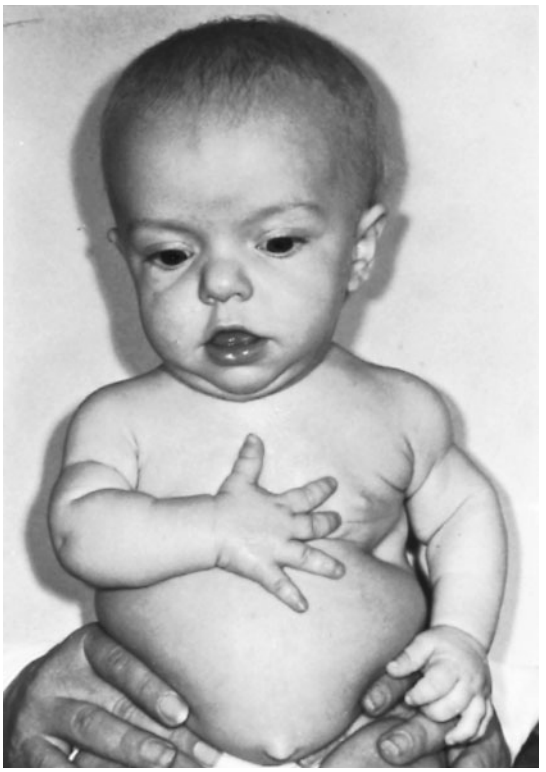

Fig. 7–5. *Achondroplasia.* Note enlarged head with frontal bossing and low nasal bridge. Rhizomelia and short hands with trident deformity of fingers are evident.

Presumed examples of an autosomal recessive achondroplasia describe either a recessively inherited chondrodysplasia misdiagnosed as achondroplasia or are insufficiently documented to establish the diagnosis with certainty (49). Instances of affected sibs with normal parents

Fig. 7–6. *Achondroplasia.* (A–C) Before and after leg straightening, and pronounced lordosis. (Courtesy of J Hall, Vancouver, BC.)

Fig. 7–7. *Achondroplasia.* Small hands with short fingers. Note trident hand deformity.

can probably be explained by gonadal mosaicism (10,17,20,78). Cases of achondroplasia within the same kindred that seemingly do not show complete penetrance have been reported on rare occasions (65,77,102). Probably, these cases can be explained by coincidence of two independent mutations due to the high mutation rate in achondroplasia. Examples of gonadal mosaicism have been reviewed (32a). Mosaic achondroplasia has been reported by Rimoin and McKusick (80) and Henderson et al (32a). Achondroplasia and hypochondroplasia can be allelic, although hypochondroplasia not linked to chromosome 4p has been reported. Cases of achondroplasia–hypochondroplasia compound have been reported (12,35,53,89). The outcome is poor (12). Examples of achondroplasia–pseudoachondroplasia compound (44,108) and achondroplasia–spondyloepiphyseal dysplasia congenita compound (111) have been documented. The clinical and radiologic abnormalities were intermediate between those of heterozygous and homozygous achondroplasia and mental retardation was marked.

Molecular and histological findings. The basic defect is a mutation in fibroblast growth factor receptor 3 (*FGFR3*). Linkage to 4p16.3 was established in 1994 (45,99), within months followed by discovery of mutations in *FGFR3* (14a,83,85).

The fibroblast growth factor receptor gene family encodes four structurally related receptors of the tyrosine kinase subclass IV type. Each is composed of an extracellular ligand-binding domain, a connecting or transmembrane region, and an intracellular kinase domain that is responsible for receptor dimerization and cell signaling. The ligands are the fibroblast growth factors (FGFs), a family of nine heparin-binding polypeptides. The intracellular kinase domain is activated if one of the FGFs binds to both heparan sulfate and FGFR, forming a trimolecular complex. The reader is referred to several excellent reviews for further background (14,22,51,59,67).

In achondroplasia, 98% of the patients have the same amino acid substitution: glycine to arginine at codon 380, almost always caused by a G-to-A transition at nucleotide 1138 within the transmembrane domain, the remaining cases having a G-to-C transition at the same nucleotide, resulting in the same amino acid substitution (9,83,85). It is the single most frequent mutation known in humans. Two patients have been described with a Gly375Cys transition, who showed a few unusual signs (63,95). The *FGFR* mutations cannot be loss-of-function mutations, as a deletion of the short arm of chromosome 4 results in the Wolf-Hirschhorn phenotype that does not have resemblance to achondroplasia. Indeed, Naski et al (61) have shown that mutations activate the receptor. In studying 40 sporadic cases, Wilkin et al (107) found that the mutation always occurred on the paternal chromosome, indicating the predisposition to the achondroplasia mutation through influences of DNA replication or repair during spermatogenesis and not during oogenesis.

Early histologic studies, which suggested gross disorganization of endochondral ossification, have been misleading because they described patients with thanatophoric dysplasia, metatropic dysplasia, or achondrogenesis, rather than true achondroplasia (81). Rimoin and associates (81) found well-organized endochondral ossification with longitudinal columns of cartilage cells at chondroosseous rib junctions. Iliac crest cartilage was normal. These findings suggest an abnormal rate of cartilage growth. However, Stanescu (91) found clusters of proliferative cells in biopsies of tibial growth plate, rather than columns. The clusters were separated by wide septa of fibrous material. Maynard et al (52) and Ponseti (74) also found abnormalities in the growth plates of the fibula, whereas the iliac crest cartilage and growth plate were nearly normal. Histologic, histochemical, ultrastructural, and biochemical studies of growth plates from different anatomic locations (including both weight-bearing and non–weight-bearing areas) in different age-groups are necessary to resolve further the pathogenesis of achondroplasia.

Defective oxidative energy formation with decreased phosphorylation at the NADH dehydrogenase region of the terminal respiratory system has been demonstrated in achondroplastic muscle (46). Absent oxidative phosphorylation has been observed in homozygous achondroplasia (47). A defect in peripheral glucose utilization has also been shown (16).

Growth and development. Mean birth length is 47.7 cm for males and 47.2 cm for females. Mean birth weight is 3500 g for males and 3150 g for females. Growth curves have been described by Horton et al (33). Mean adult height is 130 cm for males and 123 cm for females. Mean adult weight is 55 kg for males and 46 kg for females. Several studies of the effects of growth hormone therapy are available (34,90,106). The data suggest that, in some children, the therapy modestly increases short-term overall growth velocity, mainly in the children with low growth velocity prior to treatment. There is a tendency toward obesity (31). Hunter et al (36) established weight-for-height curves specific for achondroplasia.

Motor milestones are slow, possibly because acquisition of motor skills is influenced by the large head and short extremities (13,97). Head control may not occur until 3 to 4 months and affected children may not walk until 24 to 36 months. Ultimately, however, development falls within the population-based normal range and most individuals with achondroplasia are able to lead an independent and productive life. In a study of the cognitive skills of 30 children with achondroplasia, verbal comprehension was found to be significantly impaired (11). It was suggested that this impairment was related to frequent middle ear infections, and possibly also to delayed oropharyngeal muscle coordination and an altered response of parents and others to the changed body scheme. A practical guide for health supervision is available (2).

Reproductive fitness is considerably reduced among those with achondroplasia because of social difficulties in finding mates and because of obstetrical problems of achondroplastic women (prematurity and the necessity for cesarean deliveries due to cephalopelvic disproportion) (1,98). Furthermore, premature menopause and an increased incidence of leiomyomata have been reported (1).

Facies and skull. The head is enlarged, with frontal bossing and low nasal bridge (Fig. 7–8). Occasionally, these features are not present at birth, but disproportionate growth of the head occurs during the first year of life and then parallels the normal curve (13,18,43,62). Cephalometric analysis has been performed by Cohen et al (15) and Pederson (72).

Central nervous system. Mild ventricular dilatation has been reported by several authors (13,19,27,40,58). Gross mechanical block caused by obliteration of the basal cisterns, obliteration at the level of the foramen magnum, or kinking of the cerebral aqueduct has not been demonstrated in most cases (42). However, there is a relatively higher rate of sudden, unexpected death during infancy and early childhood (8,70). Cervicomedullary compression and its evaluation have been discussed by several authors (23a,27,41,63,71,76,104). The best predictors of the need for suboccipital decompression include lower limb hyperreflexion, central hypopnea on polysomnography, and reduced foramen magnum measurements (71). Brain stem compression may give rise to obstructive sleep apnea (105). Significant hydrocephaly (stepwise increase in the head growth slope) with neurologic signs and symptoms has occurred in a few instances (13,58,73,108) and is probably caused by cerebrospinal fluid obstruction at the level of the foramen magnum.

Most evidence to date seems to favor communicating hydrocephaly (40). Mueller et al (58) postulated two possibilities. First, early hydrocephaly may be caused by cerebrospinal fluid outlet obstruction

A B

Fig. 7–8. *Achondroplasia.* (A,B) Enlarged calvaria with frontal bossing, low nasal bridge, and midface recession. [From MM Cohen Jr, Mutations affecting craniofacial cartilage. In: Cartilage: Biomedical Aspects, Vol 3, Hall BK (ed), Academic Press, New York, 1983, p 191.]

resulting from a small posterior fossa that becomes compensated later in life secondary to bony structural maturation. Second, patients with achondroplasia may have obstruction of cerebrospinal fluid flow at the subarachnoid villi or in the venous sinuses secondary to retrograde pressure from marginal jugular veins. These could be compensated in size secondary to small jugular foramina that resulted from faulty endochondral ossification in the posterior fossa.

Pierre-Kahn et al (73) studied hydrocephaly in 25 achondroplastic patients and suggested that the hydrocephaly was related to constriction of the sigmoid sinus at the level of narrowed jugular foramina, resulting in a rise in intracranial venous pressure. They further noted that, in most instances, the hydrocephaly stabilized spontaneously in early life. Additional studies are necessary to determine if the jugular foramina are small or if their emissary vein foramina are enlarged in achondroplasia.

The narrow spinal canal predisposes to neurologic complications with age. Compression of the spinal cord and nerve rootlets results from osteophytes, prolapsed intervertebral disks, or deformed vertebral bodies (27,29,56,75,100,101).

Skeletal system. Enlarged calvaria and basilar kyphosis are constant features. The anterior cranial base length is normal, but the posterior cranial base length is shorter than normal (15). The foramen magnum is small (27,32). The maxilla is hypoplastic, resulting in midface deficiency and relative mandibular prognathism (15). The frontal and occipital bones and, in some cases, the temporal bones may be prominent (42,43). Partial occipitalization of the first cervical vertebra occurs in most cases.

The interpediculate distances progressively narrow from the upper to the lower lumbar spine, the pedicles are shortened in anteroposterior diameter, the posterior aspect of the vertebral bodies is concave, and the bony spinal canal diameters are decreased, particularly in the lumbar region (Fig. 7–9). Anterior wedging of the vertebral bodies (particularly in the region of the thoracolumbar junction) with resultant kyphosis may be prominent (42,43,87). Kyphosis occurs in about 20% and scoliosis in 7% (106). A thoracolumbar gibbus is more common in South African achondroplastic patients (6).

The lumbar spine appears to articulate low in relation to the crests of the iliac bone. The sacrum is narrow and horizontally oriented. The pelvis is broad and short. Narrowing of the pelvic inlet prevents vaginal delivery in pregnant achondroplastic females. The superior acetabular margins are oriented horizontally, and the sacrosciatic notch is acute (Figs. 7–9 and 7–10). The thoracic cage is relatively small in anteroposterior diameter (5,37,42,43). Legs are frequently bowed because of lax knee ligaments.

Limb bones are shortened in a rhizomelic pattern, which is more prominent in the upper extremities. There is incomplete extension at the elbows. The carpus is relatively large. The metacarpals and phalanges, although

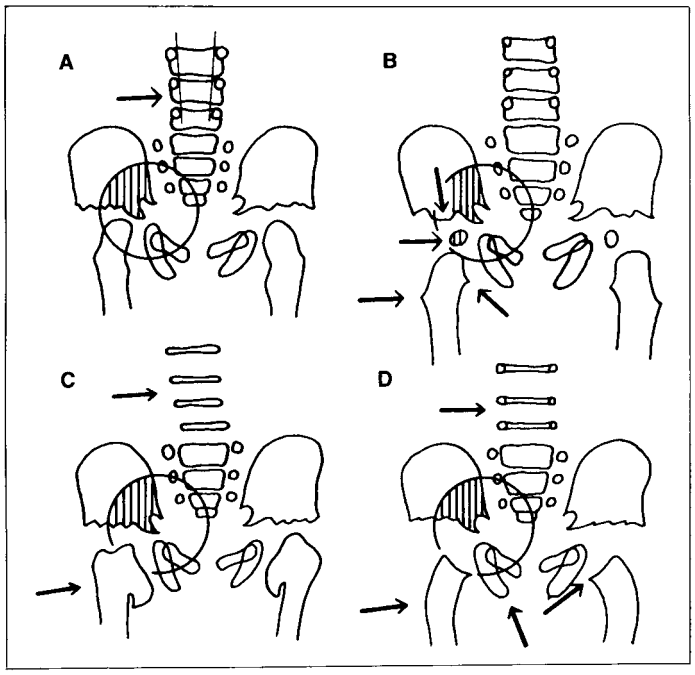
Fig. 7–9. *Achondroplasia.* Radiograph showing shortening of long bones, low articulation of lumbar spine in relation to iliac crest, short broad pelvis, and downward diminishing interpediculate distances in lumbar spine.

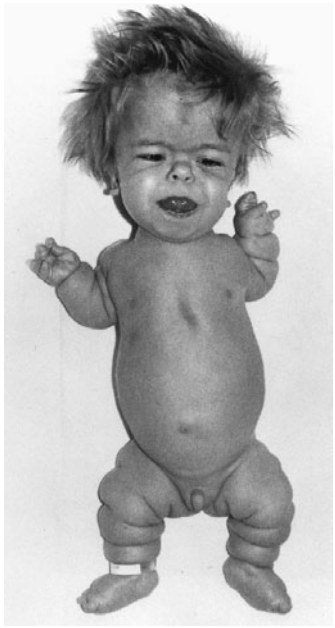
shortened, are disproportionately large in relation to the humerus, radius, and ulna. Metacarpophalangeal relations have been described in detail (39). Genua vara is found in 15% of cases (109). The fibula is overlong at the ankle compared to the tibia, leading in some cases to varus foot deformity. Elbow extension is limited.

Otolaryngologic findings. Otitis media is likely common during the first 6 years of life. Hall (25) surveyed 150 individuals with achondroplasia over age 18; 75% had a history of ear infections and 11% indicated that they had significant hearing loss. Among 88 patients studied by Glass et al (23), 97% reported having had ear infection and/or hearing loss; on audiometric testing, 72% had hearing loss of 22 dB or greater. Hunter et al (38) found an even higher rate of otitis media among 193 patients, varying in rate among different age classes and, in a questionnaire study of 437 adult patients, 17% of cases were reported to have chronic ear infections and 33% to have hearing impairment (48). In two studies of limited series of patients, most of whom were younger than 30 years, conductive hearing loss was noted in half; sensorineural and mixed hearing losses were also noted, but less frequently (23,62). The degree of hearing loss did not correlate with the abnormal temporal bone structure (86).

Differential diagnosis. Achondroplasia should be distinguished from *achondrogenesis, thanatophoric dysplasia, Ellis-van Creveld syndrome, metatropic dysplasia, diastrophic dysplasia, asphyxiating thoracic dystrophy, hypochondroplasia,* pseudoachondroplasia, *Nance-Sweeney chondrodysplasia,* Schmid type metaphyseal dysplasia, various spondyloepiphyseal and spondylometaphyseal dysplasias, and other types of short-limbed dwarfism (24,42,43,49,53,88,103) (Fig. 7–10B–D). The changes that distinguish heterozygous achondroplasia from homozygous achondroplasia and thanatophoric dysplasia reside largely in the vertebral column, the pelvis, and the limb bones (Fig. 7–10E,F). The differences have been elegantly discussed by Pauli et al (69).

Laboratory aids. Radiographic studies enable differentiation from other forms of dwarfism that simulate achondroplasia. Prenatal diagnosis





E

F

Fig. 7–10. *Achondroplasia.* Schematic drawing of pelvic features of (A) achondroplasia, (B) chondroectodermal dysplasia, (C) metatropic dysplasia, and (D) thanatophoric dysplasia. Deformity of acetabulum is nearly the same in all four conditions. In achondroplasia, interpediculate distances diminish downward. In chondroectodermal dysplasia, ossification centers of femora and spike-like exostoses at the trochanters are present. In metatropic dysplasia, reduced height of vertebral bodies, halberd form of femur, and, occasionally, scoliosis are seen. In thanatophoric dysplasia, vertebral bodies are flat, spike-like exostoses are present at the os pubis and at the femur, and the femur is bowed. (E,F) *Homozygous achondroplasia*. In E, note large head, small extremities, redundant skin folds, and narrow rib cage. Radiograph (F) shows small thoracic cage, marked platyspondyly, small iliac bones with scalloped lower margins, and short tubular bones, especially the humeri and femora. (A–D from K Gefferth, Prog Pediatr Radiol 4:137, 1973. E from RM Pauli et al, Am J Med Genet 16:459, 1983.)

by ultrasound has not been possible (19), although second-trimester ultrasound studies have been recorded on occasion (54). Bellus et al (7) reported first-trimester molecular diagnosis, emphasizing the importance for studies in couples at risk for homozygous offspring. Saitoh et al (83a) described prenatal diagnosis from maternal serum.

Hypochondroplasia

Hypochondroplasia is a common form of disproportionate short stature (Fig. 7–11) with relatively few clinical manifestations but with radiographic features similar to those found in achondroplasia, although milder in degree. Over a hundred cases have been recorded to date (3,8–13,15,19,20,25,29,32) and several excellent reviews are available (11,15,29). Inheritance is autosomal dominant. Most instances represent new mutations, but familial instances have been encountered (4,7,15,25,39). Hypochondroplasia has been found to be heterogeneous: in several patients mutations were found in fibroblast growth factor receptor (*FGFR*) type 3 (4,7,12,14,21,23,25) but other patients did not harbor a detectable mutation and several familial cases were unlinked to chromosome 4p (7,14,21,23,25,27). Mullis et al (18) reported linkage to 12q23 and suggested the insulin-like growth factor 1 gene as a candidate gene. The background of *FGFR3* is discussed in more detail in the section on achondroplasia (above).

In 43% to more than 50% of cases, a C-to-A or C-to-G mutation at position 1659 was reported, both leading to a lysine-for-asparagine substitution at codon 540 (4,7,21,22,23,25). Other mutations have been reported (4,7). All mutations were in the transmembrane domain of *FGFR3*. Clinically, no differences have been found in patients with different mutations in *FGFR3*. Some reports did not find clinical differences in patients linked and unlinked to 4p16.3 (4,7), others found differences: patients linked to *FGFR3* were found to have more often macrocephaly, large forehead, short hands, and disproportionate shortening of the back (22,23,25). A very severe mutation is that of Asn540Lys (10). This has been confirmed by R. Hennekam.

Diagnosis is difficult and is often made by exclusion. It is not commonly established in the newborn period (15), although Hall and Spranger (11) noted that 66% were macrocephalic at birth. Short stature is not usually recognized until approximately 22 months of age. Final height attainment varies between 128 and 153 cm (mean for males, 146 cm; mean for females, 137 cm) (2,3,10,15,29). Clinical and radiographic features are summarized in Table 7–3.

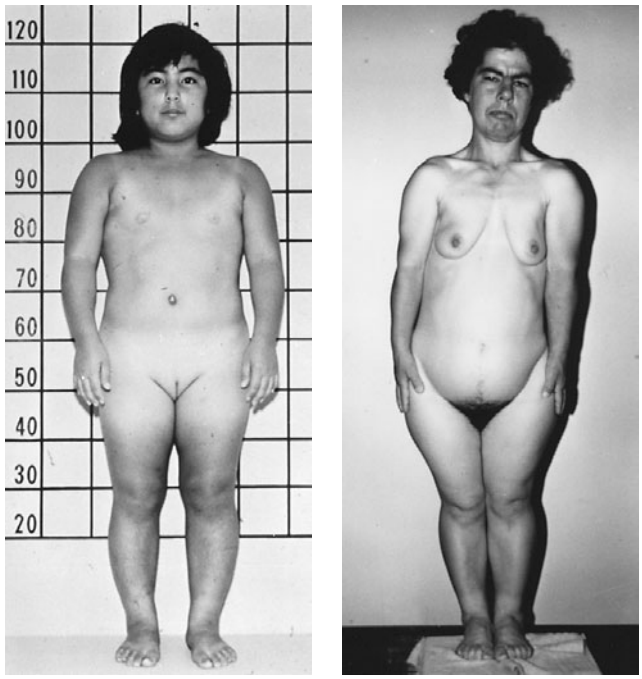

Fig. 7–11. *Hypochondroplasia.* (A,B) Disproportionately short limbs. (A courtesy of DL Rimoin, Los Angeles, California. B from MM Cohen Jr, The Child with Multiple Birth Defects, Raven Press, New York, 1982, p 103.)

The skull may be rectangular in shape with a slightly prominent forehead. Facial appearance is normal. Macrocephaly is present in 57% of all cases and in two-thirds of newborns. Cloverleaf skull has been found in one patient (1). Mental retardation is found in approximately 10% (10), but others have suggested this to be an overestimation (31). A family with an *FGFR3* mutation has been described in which one member had mild developmental delay, with the others being normal, which suggests the influence of other environmental or genetic factors (7).

Bowlegs appear in early childhood but tend to straighten spontaneously with age. The limbs are disproportionately short (100%), elbow extension is limited (100%), and brachydactyly is mild to moderate (97%). Lumbar lordosis is observed in about 35% of cases. Mild joint pain during exercise is often observed in adults (3,29). Patients may have a rather muscular appearance.

Radiographically, interpediculate distances are moderately narrowed, pedicles are shortened anteroposteriorly, and vertebral bodies of the lumbar spine have increased dorsal concavity. Tubular bones are shortened and relatively squared. The femoral neck is broad and short. The distal end of the fibula is elongated in relation to the tibia. The ilia are squared and shortened (3,11,15,19,29). Rarely, basilar impression may be found, as in achondroplasia (30).

For delivery, cesarean section may be necessary. Prenatal diagnosis has been reported in a fetus at risk for hypochondroplasia (13,28). Ultrasound examination at 22 weeks showed decreased length of limb bones by measurement in one fetus; the other was found to show a discrepancy at 35 weeks between limb length and head circumference.

Differential diagnosis. Differential diagnosis includes achondroplasia, which is similar but much more severe both clinically and radiographically. In achondroplasia, both the craniofacial appearance and the pelvic configuration are very distinctive in contrast to those in hypochondroplasia. In achondroplasia–hypochondroplasia compound, clinical and

Table 7–3. Clinical and radiographic features of hypochondroplasia

Striking features	Approximate percentage
Clinical	
Macrocephaly	57
Mental retardation	10
Disproportionately short limbs	100
Limited elbow extension	100
Mild-to-moderate brachydactyly	97
Lumbar lordosis	34
Tubular bones	
Short broad femoral neck	92
Short long bones with mild metaphyseal flare	100
Long distal portion of fibula	92
Long distal portion of ulna	73
Long ulnar styloid[a]	68
Lumbar spine	
Narrow or unchanged interpedicular distance	80
AP shortening of lumbar pedicles (lateral view)	89
Dorsal concavity (lateral view)	81
High vertebrae (lateral view)	33
Platyspondyly (lateral view)	37
Pelvis	
Squared shortened ilia	100

Adapted from BD Hall and J Spranger, Radiology 133:95, 1979 and NG Heselson et al, Clin Radiol 30:79, 1979.
[a] Presence related to age.

radiographic findings are different from those of achondroplasia or hypochondroplasia (16,26).

Long bone changes in hypochondroplasia may be similar to those in metaphyseal chondrodysplasia, Schmidt type, although the vertebral abnormalities of hypochondroplasia are not present in the Schmidt type.

Desch and Horton (6) reported an autosomal recessive bone dysplasia resembling hypochondroplasia. In the former condition, birth length was much less than normal, the interpediculate distances were normal, and the humeri were shortened with no significant shortening of the tibiae and the ulnae, no significant brachydactyly, and normal head circumference.

Finally, hypochondroplasia may be confused with familial short stature at the lower end of the normal curve in the general population.

Acrodysostosis

First reported by Arkless and Graham (2), Giedion (6), and Maroteaux and Malamut (10), acrodysostosis has undergone several reclassifications, finally emerging to stand on its own (13). It consists of short stature, severe brachydactyly, nasal hypoplasia, and varying degrees of mental retardation. Spinal stenosis and its complications have been a radiographic feature seen in 75% of cases (3) but only rarely is it symptomatic (7,9). About 85 cases have been reported to date.

Although most examples are sporadic, inheritance is autosomal dominant (1,5,8,10,14). New mutations are associated with advanced paternal age (7). The sibs born to normal parents possibly represent gonadal mosaicism (15). Normal Gs-α activity has been found (18).

The face is round, the nose is flat and short (Fig. 7–12). The cheeks are flat. Blue eyes have been noted in Japanese individuals (11).

Radiographic changes include brachycephaly, thick calvaria, hypoplastic nasal and maxillary bones, absent nasal spine, relative mandibular prognathism, peripheral dysostosis (short metacarpals, metatarsals, and phalanges), cone-shaped epiphyses, premature skeletal maturation, epiphyseal and vertebral stippling in infancy, narrow interpediculate distances, and relatively broad halluces (1,5–7,11,12,17) (Fig. 7–13).

Mental retardation has been found in almost 80% of patients. The hands and feet are less severely involved in pseudohypoparathyroidism and pseudopseudohypoparathyroidism. Endocrine abnormalities are not found in acrodysostosis (1). We believe that the case of Davies and Hughes (4) is not acrodysostosis. In at least one case, resemblance to Marshall syndrome was pointed out (16).

Acromesomelic dysplasia

In 1971, Maroteaux et al (20) defined a rare short-limbed dwarfism that they termed "acromesomelic dysplasia." There are earlier recorded cases (10,18), and an 11,000-year-old acromesomelic skeleton was exhumed in southern Italy (11). Approximately 40 examples of the disorder have been documented (1–5,7–9,14–16,21–26). There are two types of acromesomelic dysplasia: acromesomelic dysplasia in the strict sense, which has also been called the "(Maroteaux-) Campailla-Martinelli type," and a more severe Hunter-Thompson type (12,17), which resembles chondrodysplasia, Grebe type. Both severe Hunter-Thompson type and chondrodysplasia, Grebe type are caused by mutations in cartilage-derived morphogenetic protein (CDMP1) (28,29) located at 20q11.2. When mutated, the protein CDMP1 cannot be secreted. It produces a dominant negative effect by preventing secretion of other bone morphogenetic proteins (BMPs), probably by the formation of heterodimers (27,29). Mutations in CDMP1 may also cause a very mild phenotype in heterozygous expression, i.e., in autosomal dominant brachydactyly type C (29). Acromesomelic dysplasia was found to be linked to chromosome 9q12–22.2 in four families (12a,14). Kant et al (14) noticed that this is the same region in which familial hypomagnesemia was mapped, whereas Minty and Hall (21) reported a family with both disorders.

Diagnosis is usually not made until about 2 years of age. Inheritance is autosomal recessive. There has been parental consanguinity (3,20), and sibs have been affected (7,14,15,18,20,21,25). However, there is one report of acromesomelic dysplasia in a father and son (22).

Fig. 7–14. *Acromesomelic dysplasia.* Relatively large head, frontal bossing, low nasal bridge, short forearms and hands, and lumbar lordosis. (From M Raes et al, Helv Paediatr Acta 40:415, 1985.)

The disorder is characterized by disproportionate short stature. Adult height ranges from 94 to 123 cm. Puberty may be delayed. The fingers and toes are particularly abbreviated. The forearms are relatively shorter than the lower legs. The arms are often bowed whereas the legs are straight. The facies is characterized by frontal bossing, low nasal root, and slightly flattened midface (Figs. 7–14 and 7–15). Rarely, hydrocephaly with mild developmental delay (5) and corneal ulcers (4) are found. Low thoracic kyphosis and lumbar hyperlordosis are common. Hyperlaxity of joints, particularly of the hands and feet, is marked.

Radiologic changes include frontal bossing and marked occipital prominence and generalized shortening of long bones with metaphyseal flaring. The radii are bowed, and there is increased distance between the ulnae and carpal bones. The metacarpals, metatarsals, and phalanges are extremely short, the latter being cone shaped. There is premature fusion between epiphyses and metaphyses. Vertebral height is reduced, particularly in the thoracolumbar region with anterior beaking (Figs. 7–16 and 7–17).

Differential diagnosis includes *pseudohypoparathyroidism* and pseudoachondroplasia. In the former, the vertebral changes seen in acromesomelic dysplasia are absent. The nose is smaller and mental retardation is common. *Acrodysostosis* must also be excluded.

Some other unusual disorders with acromesomelia have been described. Israel and Vasan (13) noted a condition with acromesomelic

Fig. 7–15. *Acromesomelic dysplasia.* Broad hand with short, stubby fingers. (From M Raes et al, Helv Paediatr Acta 40:415, 1985.)

Fig. 7–16. *Acromesomelic dysplasia.* Short bent radius and ulna, and increased radioulnar distance. (From M Raes et al, Helv Paediatr Acta 40:415, 1985.)

dysplasia; bony abnormalities of the cervical spine, pelvis, ribs, and long bones; atrial septal defect (ASD), webbed esophagus; and stenosed larynx. The case was sporadic and chromosomes were normal. Leroy (19) observed two unrelated infants with acromesomelic dysplasia, growth and psychomotor retardation, synophrys, small nose, and flat face, giving a mild de Lange-like appearance. Ferraz et al (6) described a mother and son with acromesomelic dysplasia, as well as curved radii, marked shortening of the second and fifth finger, and angulation of the distal ulna in the mother. Pfeiffer et al (25) described an acromesomelic disorder with renal and facial changes. The head was large and there was congenital ptosis and telecanthus. Ureteral stenosis with hydronephrosis was seen. Bone abnormalities consisted of ulnar dysplasia, tibial hypoplasia, multiple synostoses of carpal and tarsal bones, proximal synostoses of metatarsals, and brachydactyly.

Acromicric dysplasia

In 1986, Maroteaux et al (4) described six isolated patients with short stature, mild facial anomalies, brachydactyly, and diminished joint movements (Fig. 7–18). Several authors described possible examples who, in addition, had symptoms of geleophysic dysplasia (2,3,5) or Moore-Federman syndrome (1a,6). It has been suggested that geleophysic and acromicric dysplasia are identical, allelic, or different disturbances in the same metabolic pathway (2,5,6). Faivre et al (1), in a survey of 18 examples, noted dominant transmission in three cases. The face shows narrow palpebral fissures and a short stubby nose with anteverted nostrils. One patient had cleft lip.

Height is far below the third centile. The limbs are short, but, in comparison, the hands and feet are even shorter. Flexion in fingers and toes may be limited (Fig. 7–18).

There are no major internal anomalies. One patient was noted to have atrial septal defect. None of the original patients showed any clinical symptom of a storage disorder. However, two patients with features that resembled those of both geleophysic and acromicric dysplasia had progressive thickening of cardiac valves (2,5) or enlarged liver and thickened skin (2). Histologically, there was considerable accumulation of glycogen in most chondrocytes (3,4); in another patient, this was lacking (2).

Radiologically, the metacarpals and phalanges are short and stubby with cone-shaped epiphyses. The proximal portion of the last four metacarpals is somewhat pointed with a notch at the base of the second (external) and fifth (internal) metacarpals. The femoral heads are slightly deformed, but otherwise, the long bones are normal. Bone age is delayed. The remainder of the skeletal frame is normal. There is no spondyloepimetaphyseal dysplasia.

Atelosteogenesis type I

Atelosteogenesis, a term derived from the Greek referring to incomplete bone formation and coined by Maroteaux et al (9), is a rare neonatally lethal chondrodysplasia characterized by marked rhizomelic shortening of limbs. Later, it became clear that atelosteogenesis encompasses a heterogeneous group of disorders with overlapping features (13). A dozen cases of atelosteogenesis type I have been reported, all isolated examples (1,2,5–15). Hence, the pattern of inheritance of the disorder remains uncertain. Each may represent a new autosomal dominant mutation or there may be an insufficient number of cases for affected sibs to have been born. Several cases, for instance, those of Maroteaux et al (9), are hard to classify and, furthermore, there may be variable expression. A comparison of atelosteogenesis types I, II, and III and Boomerang dysplasia is given in Table 7–4. The difference between type I and Boomerang dysplasia may be especially difficult (3,4). One case with type I was erroneously classified as type II (10). Atelosteogenesis type I has also been called "giant cell chondrodysplasia" and "spondylohumerofemoral hypoplasia" (11,12).

The facies is characterized by frontal bossing, prominent globes, edematous eyelids, depressed nasal bridge, hypoplastic nose, micrognathia, and short neck (Fig. 7–19). Some patients have cleft palate. Laryngeal stenosis has been described (1,15). The extremities are shortened rhizomelically and talipes is usually severe. Male infants have cryptorchidism. In some cases, there has been polyhydramnios.

Radiographically, there is hypoplasia of the distal humeri and often of the distal femora. The fibulae may be hypoplastic or absent. In some examples, the forearm bones may be hypoplastic. The vertebral bodies are hypoplastic with coronal clefts, and there is uneven ossification of most of the proximal and middle phalanges of hands and feet. The pubic bones may be small but otherwise the pelvis is essentially normal (Fig. 7–20).

Histopathologic changes include clusters of chondrocytes surrounded by fibrous capsules and zones containing degenerated chondrocytes and copious amounts of metachromatic material in the epiphyses and basal zone of the growth plate (1,9). Multinucleated giant cells may be scattered throughout the resting cartilage (12,13,15); however, they are not specific for the disorder (11,15).

Atelosteogenesis type II (De la Chapelle syndrome)

In 1972, De la Chapelle described a pair of sibs with a distinctive form of short-limb dwarfism, deficient ossification of different parts of the skeleton, cleft palate, and neonatal death (2). Whitley et al (13) reported another affected sib from the original family and a solitary case, and coined the term "De la Chapelle dysplasia," which was subsequently replaced by "atelosteogenesis type II" (11). Twenty cases have been described (2,5,6,8,10–13; RCM Hennekam, unpublished observations). Reviews were provided by Schrander-Stumpel (10), Sillence (12), and Newbury-Ecob (7). Inheritance is autosomal recessive (2). Chromosomal studies have yielded normal results. Mutations in the ubiquitously expressed sulphate transporter *DTDST*, located on chromosome 5q, and found to be responsible for diastrophic dysplasia and achondrogenesis type 1B were found in atelosteogenesis type II (3). For further discussion of the *DTDST* gene, the reader is referred to the diastrophic dysplasia section (below).

The facies is characterized by frontal bossing, flat nasal bridge, and short neck. About 50% of patients have cleft palate. The trunk and limbs are markedly shortened and incurved, the abdomen is protuberant. The thumbs and halluces are radially deviated ("hitchhiker" position) and the halluces and second toes are widely separated. Feet are held in the equinovarus position (Fig. 7–21A,B). Omphaloceles have been reported (12).

Radiographically, the vertebral bodies are moderately flattened. Some infants have mild scoliosis, but there is marked kyphosis of the cervical spine with hypoplastic/dysplastic changes and horizontal sacrum. The iliac bones are rounded with shortened sacrosciatic notches and flat acetabular roofs, sometimes with medial spiculae. The ischial and pubic bones are usually well formed with additional ossification centers. The limb bones are short, particularly proximally, with metaphyseal flaring. The end of the distal humerus manifests a U- or V-shaped depression and the distal femur can be rounded. The radius and tibia are particularly bowed. The distal ulna is often hypoplastic and the proximal ulna can be broad. The second and/or third metacarpals and the first and second metatarsals are usually larger than the remaining bones of the hand or foot. Some of the middle phalanges have double ossification centers (Fig. 7–21D–F). Bronchial rings are irregular in contour and, in some areas, there is increased perichondral fibrous tissue. The reserve zone of the cartilage can be attenuated with many cystic areas containing only radiating threads of matrix (Fig. 7–21C) (5).

Because of the "hitchhiker thumb and hallux," *diastrophic dysplasia* must be excluded (3,9). *Atelosteogenesis type I* can be excluded on histopathologic and radiologic grounds (Table 7–4). An unusual variant was reported by Herzberg et al (4), but because of the gestational age, adequate evaluation is difficult. A still different type was described by Brodie et al (1), which included mesomelia and distal tapering of the humerus, but with different histology and ultrastructural findings.

Atelosteogenesis type III

Stern et al (5) delineated a milder, usually nonlethal disorder with features overlapping those of atelosteogenesis type I and type II (Table 7–4). Several other cases have been reported (1–4). All were singletons, with males and females being equally affected, and no consanguinity was reported. There may be overlap with Larsen syndrome, with which it is possibly allelic (4). There is some suggestion of autosomal dominant inheritance (3).

The forehead is broad, the eyes are widely spaced, and the midface and especially the nose are hypoplastic (Fig. 7–22A). The nasal bridge is flat. Half of the patients have cleft palate. Laryngeal hypoplasia is common.

A B

Fig. 7–22. *Atelosteogenesis, type III*. (A) Broad forehead, widely spaced eyes, hypoplastic midface, especially the nose, and short limbs. (B) Marked shortness of femora, multiple joint dislocations, and talipes. (From HJ Stern et al, Am J Med Genet 36:183, 1990.)

Patients with atelosteogenesis type III show a short-limb dwarfism with prominent shortness of the humerus and femora, multiple joint dislocations, camptodactyly, ulnar deviation of fingers, and talipes (Fig. 7–22B). The tips of the fingers are broad, the nails are wide. Polydactyly has been reported (5). There may be cutaneous syndactyly of the second and third toes.

Radiologically, the calvaria is normal, and platyspondyly, scoliosis, coronal and sagittal clefting, and cervical segmentation defects are evident. The clavicles may be wavy or elongated. Both femurs and humeri show distal tapering. The tibia, radius, and ulna are bowed, and ossification of the fibula is absent. Metatarsals are short, proximal phalanges are squared, the middle phalanges are rounded, and the distal phalanges are widened. Histopathological studies did not show giant multinucleated chondrocytes, but only hypocellularity.

Lethal skeletal dysplasia with gracile bones (osteocraniostenosis)

In 1988, Maroteaux et al (6) described a lethal condition characterized by thin brittle bones. To date, about 15 cases of this possibly heterogeneous condition have been reported (1,1a,2,5–10). The sibs described by Dennis et al (3,4) probably represent another condition.

Although almost all cases have been sporadic, in some cases, there has been parental consanguinity (6), and siblings have been reported by Costa et al (2). Perhaps this represents somatic mosaicism.

Radiographic findings suggest two phenotypes. Type I is characterized by narrow metaphyses, mildly reduced mineralization of the calvaria, and deformed hands and feet. Type II exhibits relative flaring of the metaphyses, poor mineralization of the calvaria, and, rarely, cloverleaf skull, small mouth, small nose, hypoplastic supraorbital ridges, and asplenia/hyposplenia. Cases 1–4 of Maroteaux et al (6) and cases 1–3 of Verloes et al (10) are type II.

Boomerang dysplasia

The term "boomerang dysplasia" was coined by Tenconi et al (12) to describe a lethal short-limbed dwarfism. The name is reflective of the shape of the femur, ulna, and tibia (Figs. 7–23 and 7–24). Another example was reported earlier (5). In total, at least 10 patients have been reported (5–6,8–13). In four other cases, differentiation from atelosteogenesis type I (3,4) (Table 7–4), otopalatodigital syndrome type II (7), or Piepkorn syndrome (1) remains difficult. In describing a unique but related entity, Oostra et al (9) suggested that atelosteogenesis type I, Piepkorn dysplasia, and boomerang dysplasia constitute a family of skeletal dysplasias. It had been suggested earlier that the (female) infant with Piepkorn syndrome had, in fact, boomerang dysplasia (13). All but one were male, and all were isolated cases, except the male and his maternal

Fig. 7–23. *Boomerang dysplasia.* Facies similar to that seen in frontonasal malformation. In addition to short extremities, note four digits on each hand. (Courtesy of Y Sugiura, Nagoya, Japan.)

uncle reported in an abstract by Slaney et al (11), who suggested X-linked recessive inheritance.

Head circumference is large, the eyes hyperteloric, and the forehead is full. One patient had frontal encephalocele (13). The nasal root is broad, the nose small, the nostrils anteverted. The nasal septum and lateral cartilages are severely hypoplastic. The philtrum is prominent. The palate was cleft in one infant. Malar hypoplasia and micrognathia are present. The trunk is short, the abdomen prominent. Two patients had omphalocele. The limbs, particularly the upper limbs, exhibit rhizo- and mesomelic shortening with limited joint movement. The lower limbs are bowed anteriorly. The feet are in a calcaneovalgus position. Soft tissue syndactyly of the third and fourth fingers, hypoplasia of thumb nails, and partial duplication of the terminal phalanx of the index fingers are also found.

Radiographically, the radii and fibulae are missing, the ossification centers of the humeri are hypoplastic or missing, and the ulnae, femora, and tibiae are boomerang in shape. The metapodial bones are abnormal in form and the phalanges are not well ossified (Fig. 7–24B,C).

The bodies of the ilia are poorly formed and the pubic bones are absent. There are 13 pairs of ribs. Giant chondrocytes have been described (6,10).

Carpenter and Hunter (2) described a similar but nonetheless different case, which we find difficult to classify.

Fig. 7–25. *Burton syndrome.* Note pursed lips. (From BK Burton et al, J Pediatr 109:642, 1986.)

Burton syndrome

In 1986, Burton et al (1) reported male and female sibs with a Kniest-like skeletal dysplasia. In addition, there were microstomia, pursed lips, and dislocated lenses (Figs. 7–25 to 7–29). Lo et al (2) described a second, isolated patient without lens dislocation at 2 and 1/2 years.

Growth was at the fifth centile. The face, other than having mild exophthalmos and a small mouth with pursed lips, was not distinctive but looked somewhat like the Schwartz-Jampel syndrome facies. In the sibs, bilateral downward subluxation of the lenses was noted at the ages of 11 months and 2 years (Fig. 7–26).

The limbs were short and bowed, and the joints were stiff and enlarged (Fig. 7–27). Radiographically, the long bones were somewhat dumbbell shaped with flared metaphyses and mildly shortened diaphyses (Fig. 7–28). The thoracic and lumbar vertebral bodies were somewhat flattened, and cervical kyphosis and increased lumbosacral angle were also evident. The chest was rather bell shaped and the pelvis exhibited somewhat narrowed sacrosciatic notches with a notched lateral margin of the acetabula and wide ilia (Fig. 7–29).

On iliac crest biopsy the cartilage showed scattered, dense patches within the matrix with disturbed column formation (1). The chondrocytes appeared large and mature rather than degenerated and typically hypertrophic. Within the scattered dense patches there were collagen bundles that were 10–30 times broader than normal.

The condition should be differentiated from *Kniest dysplasia, Freeman-Sheldon syndrome, Schwartz-Jampel syndrome, Larsen syndrome,* and metatropic dysplasia.

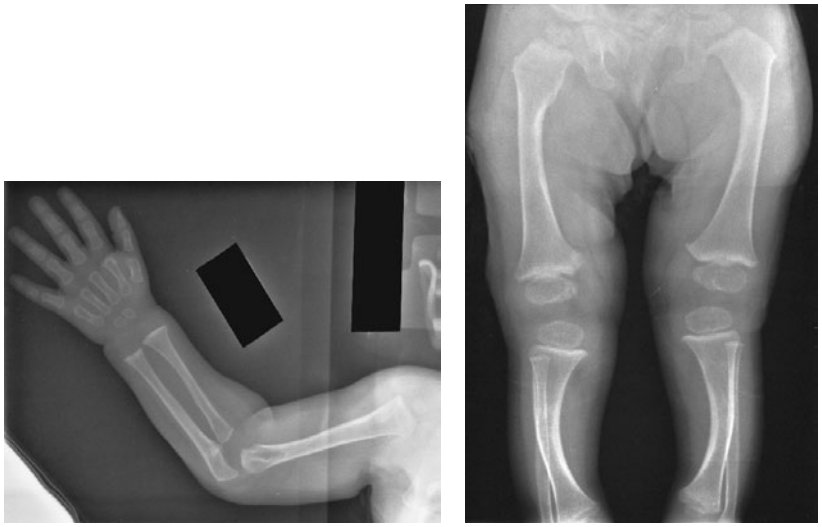
Campomelic dysplasia

Although described earlier by a number of authors (3,7,36), campomelic dysplasia (Figs. 7–30 and 7–31) was first recognized as an entity by Spranger et al (54) in 1970 and Maroteaux et al (35) in 1971. The name is derived from the Greek word "campto," meaning bent. Excellent reviews are available by Hall and Spranger (21), Beluffi and Fraccaro (6), Houston et al (24), and Mansour et al (33). Prevalence has been estimated from 1/100,000 births (55) to as high as 1.6/10,000 (44). At least 200 cases have been documented.

Early reports had assumed an autosomal recessive pattern of inheritance (13,15,21), mainly because of a slightly increased consanguinity rate and affected sibs (2,13,24,36,52,60,62,66). However, the number of affected sib pairs observed has been less than would be expected with an autosomal recessive condition (23,33); some patients were born to mildly affected parents (32,59), and affected half sibs have been born to apparently normal parents (64), all of which points to autosomal dominant inheritance. The chromosomal sex ratio is 1:1, and the phenotypic sex ratio is 3 F:1 M because of sex reversal in males (21,33). Sex-reversed infants are H-Y antigen negative (23,25,46).

There have been several reports of patients with a translocation or inversion involving chromosome 17q23.3–25.1 (33,34,43,61,68). Campomelic patients with a chromosome anomaly appear to have a much milder phenotype with less bowing. Location of the gene on 17q24.3 was favored by mutations that were detected in *SOX9* (8,28,37,57,63). The *SOX9* gene is a homolog of *SRY,* the mammalian Y-linked sex determining gene. *SOX9* is a transcription factor (67) expressed during chondrogenesis together with *COL2A1* (5,67) and during gonadal development (41). Complete deletion of the *SOX9* gene has been reported (45). Campomelic dysplasia without campomelia also maps to the *SOX9* gene (18,52a).

In about 50% of the cases, the child is either born dead or dies within the first 24 hr. Nearly all have succumbed by 10 months of age. A few have lived for many years (19,24,33). Hearing loss and mental retardation are common in all those that survive (24). At least 85% to 95% exhibit



A B

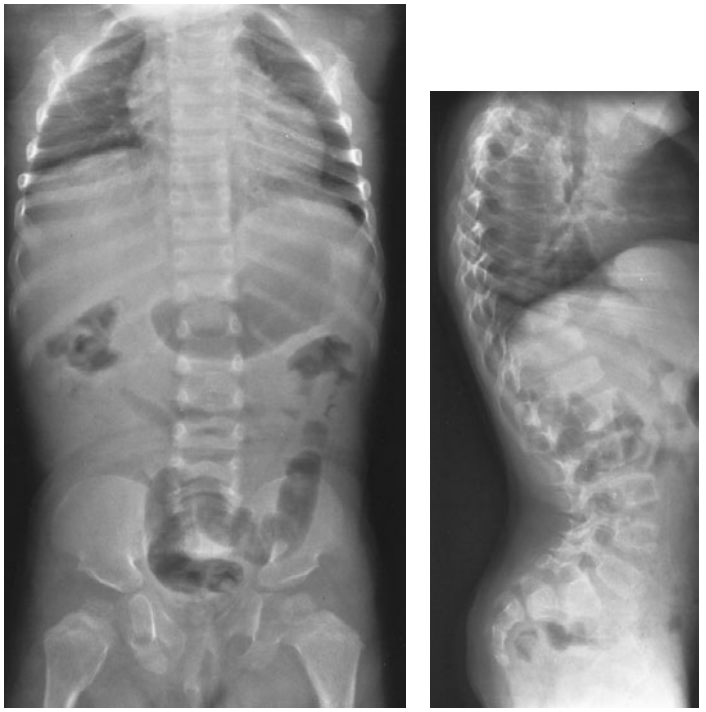
respiratory distress as a result of small thoracic cage, narrow larynx, hypoplastic trachea, and, possibly, CNS–based hypotonia. Polyhydramnios, beginning at about 32 weeks, is common.

Frequent craniofacial features are macrocephaly, dolichocephaly, large anterior fontanel and sutures, disproportionately small face, short narrow palpebral fissures, apparent hypertelorism, flat nasal bridge, low-set cartilage-poor pinnae, small nose with anteverted nostrils, long philtrum, small mouth, retroglossia, micrognathia, and short neck with redundant skin (39) (Fig. 7–30) (Table 7–5). Cleft palate is present in 65% to 80% of patients (6,33).

Fig. 7–29. *Burton syndrome.* (A,B) Thoracic and lumbar vertebral bodies are somewhat flattened. The chest is rather bell shaped and the pelvis exhibits somewhat narrowed sacrosciatic notches with notched lateral margin of acetabula and wide ilia. Note increased lumbosacral angle. (From BK Burton et al, J Pediatr 109:642, 1986.)



A B

The long bones of the lower extremities are bent, but to varied degrees. Cases without campomelia have been published (14,15,18,20,30,32, 43,69). The genesis of bowing and shortening of the lower limbs has been discussed by Lazjuk et al (29) and Pazzaglia and Beluffi (47). The bones of the upper extremities are mildly bowed in 20% to 25%. The elbows may be dislocated. Pretibial skin dimples over the most convex site are found in about 90%. Talipes equinovarus is a very common feature. There is often a wide space between the hallux and the second toe.

Radiographic changes include tall narrow orbits (70%–90%), hypoplastic bladeless scapulae (90%), small bell-shaped chest (70%–80%), nonmineralized sternum (80%), slender ribs (60%–85%), 11 ribs (55%–70%), and abnormal vertebral bodies (particularly cervical) with nonmineralized pedicles (80%). The mandible may be cleft (1). Bowed shortened tibias and femurs, hypoplastic fibulas, narrow iliac wings with increased acetabular angles, late developing pubic bones, vertical and widely spaced ischia, and dislocated hips are very common (Fig. 7–31). The proximal tibial and distal femoral epiphyses are absent in 80%–95% of patients. The talus is nonmineralized in 80%. The hands exhibit

Table 7–5. Frequency (%) of findings in campomelic dysplasia

Clinical findings	
Macrocephaly	87
Flat nasal bridge	90
Low-set ears	88
Cleft palate	66
Micrognathia	93
Congenital hip dislocation	82
Bowed femora	69
Bowed tibia	91
Pretibial skin dimples	88
Talipes equinovarus	94
Radiologic findings	
Hypoplastic facial bones	70
Hypoplastic scapulae	92
Small, bell-shaped chest	72
Slender ribs	61
Abnormal cervical vertebrae	77
Vertically narrow iliac wings	93
Dislocated hips	85
Bowed femora	90
Bowed tibiae	82
Delayed ossification of distal femoral epiphysis	81
Absent ossification of talus	81

A B C

Fig. 7–30. *Campomelic dysplasia.* (A–C) Note bent femora and tibiae, and micrognathia. The upper limbs are curved and there is a gap between the great toe and second toe in C. (A courtesy of JM Opitz, Helena, Montana. B courtesy of J Lindsten, Stockholm, Sweden. C courtesy of RE Stevenson, Greenwood, South Carolina.)

clinodactyly, brachydactyly, and small middle phalanges in 70% (6,21,33). Several cases of campomelic dysplasia without bowing (acampomelic) have been described (14,15,17,18,20,43,69).

Autopsy findings may show absence or hypoplasia of olfactory tracts or bulbs (25%), hydrocephalus (10%–25%), variable congenital heart anomalies [(VSD, ASD, PDA, tetralogy of Fallot, stenosis of aortic isthmus (20%–30%)], deficiency of laryngeal and tracheobronchial cartilages (30%–40%), and hydroureter and hydronephrosis (20%–30%) (50). Renal hypoplasia is also found. Sex reversal is frequent but not always completely so (10); some have ambiguous genitalia (46). Vascular anomalies, especially marked deficiency of the anterior tibial artery, have been described (48). The inner ears show no cartilage cells in the otic capsule and the ossicles are malformed (59).

Differential diagnosis. Kozlowski et al (27) described a few disorders with bent bones, but Hall and Spranger (22) listed almost 30 conditions having congenital bowing of long bones. Campomelic dysplasia must be distinguished from kyphomelic dysplasia and several other unusual conditions (49,51). Kyphomelic dysplasia is a somewhat heterogeneous group of disorders characterized by short, thick, and bent bones, generalized osteopenia, brown–green teeth, normal sclerae, and minimal fractures. In two cases, there was polyhydramnios. The changes resolve with time (22,49). Yet another autosomal recessively inherited disorder was described by Stüve and Wiedemann (9,12,26,53,56,58,65). The radiographic findings are different, and the feet are abnormally positioned. There is respiratory distress and recurrent periods of unexplained hyperthermia occur. In two patients, decreased activity of complexes I and IV of the mitochondrial respiratory chain was found (9). Several authors pointed to the have overlap between Stüve-Wiedemann syndrome and Schwartz-Jampel syndrome type 2 (12,53,58). Nakamura et al (42) described seven cases, including two sibs with congenital bowing of long bones of both upper and lower extremities, that improved with age. In addition, there were inconspicuous skin creases on the flexor side of elbows and knees and advanced bone age. Finally, there is another group of disorders that has scaphomacrocephaly, impaired CNS function, thin bones, bending limited to the femora, talipes, and, frequently, cleft palate (22). This form most closely resembles campomelic syndrome. A condition described by Stevenson (personal communication) (Figs. 7–30C and 7–31) may be a severe form of campomelic dysplasia.

Laboratory findings. The disorder has been diagnosed prenatally (4,11,66).

Cartilage-hair hypoplasia (McKusick-type metaphyseal dysplasia)

In 1964–1965, McKusick et al (46,47) described a syndrome in the Old-Order Amish that was characterized by short-limbed dwarfism and fine, sparse, light-colored hair. Subsequently, non-Amish patients with the disorder were reported (1,17,33,73). An increased birth prevalence has been reported in Finland (32,35,52). The incidence among the Old-Order Amish is estimated to be 1–2/1000 (carrier frequency 1:10) (47) and 1/23,000 in Finland (carrier frequency 1:76) (35). Less than 50 patients have been described among other populations (41).

Autosomal recessive inheritance has been established (47). However, the observed number of affected individuals is significantly less than would be expected on the basis of a recessive hypothesis, even when infant deaths are excluded (35,47). Considerable variability in expression has been noted, even within Amish kindreds (46). Some homozygotes may be so mildly affected that they are presumed to be healthy; this remains unproven, however (68,71).

The gene was assigned to chromosome 9p13 by linkage analysis (68). There is no evidence for genetic heterogeneity among Old-Order Amish, the Finns, or patients of other ethnic backgrounds (69). Single ancestral mutations probably account for the majority of patients among the Amish and Finns (41). Uniparental disomy was found in two families, and may explain the significant deficiency of affected family members (71). The gene itself remains unknown at present.

There are several excellent reviews, most notably those by Van der Burgt et al (73) and Mäkitie et al (40,41). Diagnosis may be very difficult in infancy (31).

Growth. Growth was studied in 108 Finnish patients (44). Mean male birth length was 45.8 ± 2.8 cm and mean female birth length was 44.8 ± 2.7 cm. Birth weight was 3360 ± 410 g for males and 3190 ±430 g for females. Final height attainment was 131 cm for males and 122.5 cm for females.

Facies and hair. The head is of normal size. The hair is blond, brittle, fine, silky, and sparse on the scalp and elsewhere on the body (40,46). About 15% of affected individuals are bald. Eyebrows, eyelashes, and beard are also sparse (Fig. 7–32). The diameter of the hair shaft is 50%–65% that of normal hair and there is no central pigment core (10,12,17, 30,34,46,47,79), although the latter finding is not a constant feature (76).

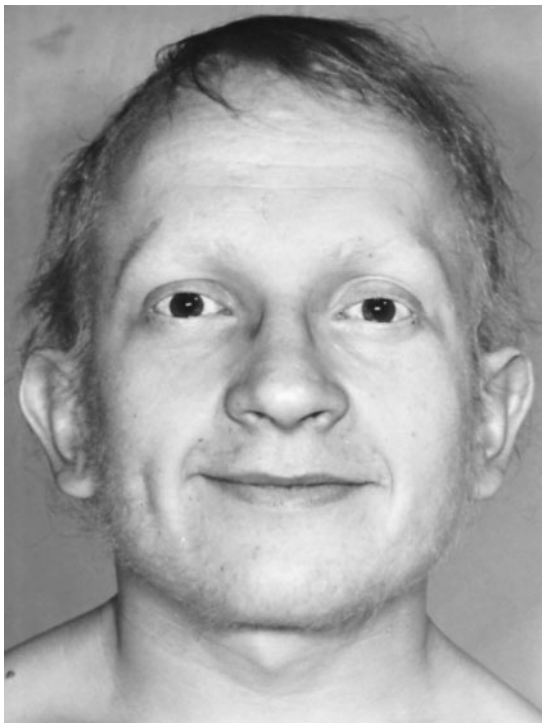
Skeletal alterations. The legs are relatively short, and the femurs are mildly bowed (Fig. 7–32B). The hands are short and pudgy (Fig. 7–33), and the fingernails and toenails are small (73). Some patients have marked hyperextensibility of joints, particularly of the hands, wrists, and feet. However, most are unable to fully extend their elbows. Several patients were noted to have been "floppy" babies (47). A narrow chest, increased lumbar lordosis, and mild scoliosis are common (40,73). Some patients have bowed legs, necessitating surgical correction (40).

Radiologically, irregularly scalloped metaphyses with sclerotic margins are noted (33) (Fig. 7–34). The metaphyseal changes are most pronounced in the knees and ankles; the irregularities disappear after closure of the epiphyses. Small, cloudy, cystic radiolucencies may be scattered throughout the metaphyses, particularly at the distal femoral metaphyses (Fig. 7–34B) (37,38,63). Epiphyses tend to be flattened or cone shaped (19a). There is often less expressed caudal widening of interpediculate distances, and about one-third of patients have mild odontoid hypoplasia. In general, spinal changes are minor. There is mild flaring of the lower rib cage. The sternum is prominent proximally and anteriorly angulated (19b). Vertebral height may be increased and mild lumbar lordosis may be found. The tibia is characteristically shorter than the fibula (Fig. 7–34). Cephalometric studies have not demonstrated striking abnormalities (57). The metacarpophalangeal pattern has been reported to be variable (73).

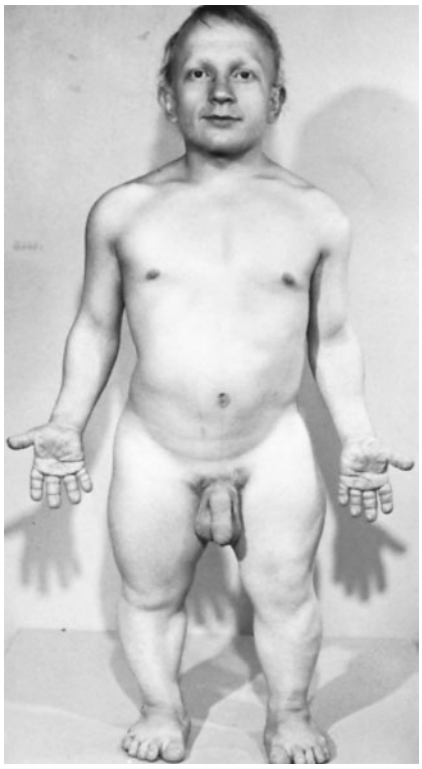
On microscopic examination of the costochondral junction, few cartilage cells are found; those present do not form orderly columns (47).

Infections. An important clinical feature of severe cartilage-hair hypoplasia is the unexplained susceptibility to severe varicella and other infections (1,25,28,40,46,47,73). Several patients have died from severe infections (40). The increased infection rate is mainly found in infancy and childhood. Despite persistently impaired cellular immunity, adults do not suffer from unusual infections. Chronic noncyclic neutropenia with maturation arrest has also been reported (1,8,34,40,47,73). Immunologic investigations in two children revealed persistent lymphopenia, diminished skin hypersensitivity, diminished responsiveness of their lymphocytes to phytohemagglutinin in vitro, and, in one child, delayed rejection of a skin allograft. Serum immunoglobulin levels were normal or elevated (34). Patients have not been able to synthesize antibodies to a variety of viral and bacterial antigens. It has been suggested that these persons have a distinct form of cellular immune defect that is responsible for their unusual susceptibility to varicella infection. Trojak et al (72), using mixed lymphocyte culture studies and mitogen-induced stimulation studies, found significant defects in several T-lymphocyte functions in Old-Order Amish patients. Similar abnormalities have been found in Finnish patients (42,55). These investigators concluded that impairment of cellular immunity was an integral part of the syndrome. Polmar and Pierce (54) found a defect in T-lymphocyte proliferation and concluded that it was not caused by excess suppressor cell activity or impaired accessory cell function. Defective proliferation was also found in B cells and fibroblasts. They also noted that individuals with the disorder had marked impairment of proliferation-dependent cytotoxic mechanism, whereas proliferation-independent natural killer cell activity was normal of even above normal. In two patients, bone narrow transplantation corrected the immune deficiency but not the skeletal dysplasia (5,24).

Smallpox vaccination and live polio vaccine should be avoided (60,73). In case of varicella infection, adequate therapeutic schemes are available (80).



A



B

Fig. 7–32. *Cartilage-hair hypoplasia.* (A) Note sparse blond hair and deficiency of eyebrows and eyelashes. (B) Marked shortening of extremities.

Malignancy. Among 110 patients, about 10% had one of the following malignancies: Hodgkin's disease, non-Hodgkin lymphomas, skin neoplasms, eye cancer, liver cancer, or leukemia (18,43,56). Other investigators have reported incidence of Hodgkin's disease (20,41), skin neoplasms, testicular tumor, and lymphosarcoma (41). Cases of anemia, varying from mild with spontaneous recovery to severe and with fatal outcome, have been reported (18,39,40,54,73).

Fig. 7–33. *Cartilage-hair hypoplasia.* Note short hands.

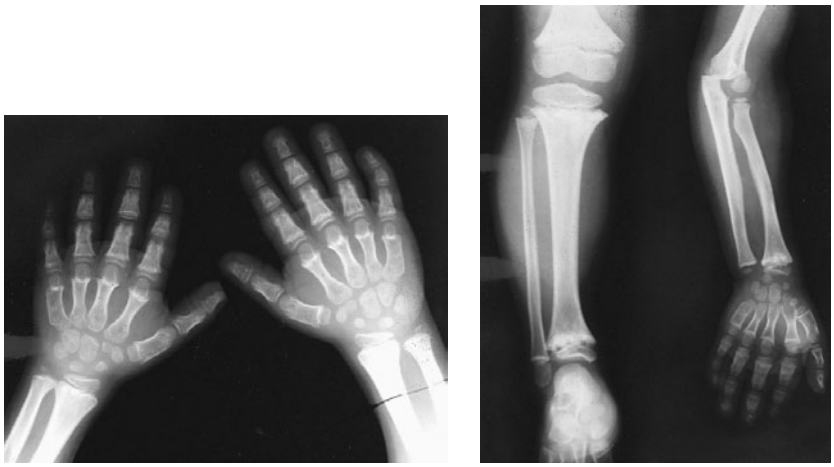
Other findings. Cesarean section is necessary for childbirth. Hirschsprung disease has been reported repeatedly in these patients (2,7,25,33,46,47,73); in the Finnish series, it was found in 7% of the patients (40). Both short-segment and total colon aganglionosis occur. Intestinal malabsorption was first thought to be very common, but further studies concluded that the malabsorption was likely secondary to gastrointestinal infections (34,40,47,73). Other rare symptoms include aseptic coxitis (2,40), esophageal atresia (40), unilateral facial nerve palsy with rudimentary ear (40), anosmia (40), and seizures (40).

Differential diagnosis. Fine blond hair may be seen in hypohidrotic ectodermal dysplasia (as well as in many other ectodermal dysplasia syndromes).

Disorders in which chondroosseous dysplasia is associated with abnormalities of immune function may be distinguished from cartilage-hair hypoplasia by radiologic examination (24,52). One of these disorders is the syndrome of chondroosseous dysplasia, adenosine deaminase deficiency, and severe combined immunodeficiency. (9,48). In cartilage-hair hypoplasia, adenosine deaminase levels have been reported to be normal (29) or increased (59). Gatti and associates (19) described a syndrome of lymphopenic agammaglobulinemia, short-limbed dwarfism, cutis laxa, alopecia of scalp, ichthyosiform erythroderma, and absence of hair and eyebrows. The disorder probably has autosomal recessive inheritance. Patients reported by McKusick and Cross (45) in an Old-Order Amish family had a skeletal dysplasia, ataxia telangiectasia, and Swiss-type agammaglobulinemia. The Schwachmann-Diamond syndrome (66,73) is characterized by metaphyseal chondrodysplasia, malabsorption, pancreatic insufficiency, and neutropenia. Blackfan-Diamond anemia has been described in cartilage-hair hypoplasia (22). Nezelof (51) described patients with T-cell deficiency and little or no abnormality of gamma globulin; the defect may be limited to the thymus. Some patients with the disorder (16) had metaphyseal dysostosis.

Achondroplasia and *hypophosphatasia* may be easily distinguished from cartilage-hair dysplasia on skeletal radiographs. In addition, patients with hypophosphatasia prematurely exfoliate deciduous teeth, mainly incisors and canines, during the first few years of life (6). Metaphyseal irregularities in cartilage-hair dysplasia are sharp, in contrast to the frayed and indistinct metaphyses in vitamin D–resistant rickets.

Cartilage-hair hypoplasia should be differentiated from other metaphyseal dysplasias. *Metaphyseal dysplasia, Jansen type*, is characterized by mental and motor retardation, abnormally shaped skull, hypertelorism, flexion deformities of many joints, beading at costochondral junctions, and gross metaphyseal widening (21,26,31,64). The immune system is normal. The pattern of inheritance is autosomal dominant. The mutated gene was found to be a PTH-PTHr8 receptor (61). Schmid-type metaphyseal dysplasia is characterized by normal face, mild growth retardation, and metaphyseal irregularities and widening that diminishes with age (11,32,58,62). In childhood, the capital femoral epiphysis is especially enlarged. The Schmid type is caused by mutations in type X collagen (13,77). Inheritance is autosomal dominant. Spahr-type metaphyseal dysplasia is an autosomal recessive entity with moderately short stature, bowed legs, waddling gate, increased lordosis, and metaphyseal widening (15,65). The capital femoral epiphyses are small.



A B

Fig. 7–34. *Cartilage-hair hypoplasia.* (A) Radiograph of hands showing scalloped metaphyses with sclerotic margins and flattened epiphyses. (B) Radiograph of long bones. Note metaphyseal irregularities. The tibia is characteristically shorter than the fibula.

Verloes et al (74) described six patients with similar bone changes but no hypotrichosis. Perhaps this is an allelic disorder.

Bellini et al (4) and Verloes et al (75) described two families with affected sibs with developmental delay, short stature, prominent forehead, hypoplastic midface with a broad nasal root and anteverted nares, and short fingers and toes. Radiographs showed distinctive widening of the metaphyses and epimetaphyseal fusion leading to V-shaped epiphyses. The hands and feet showed a picture similar to acrodysostosis. They suggested the name "acroscyphodysplasia" (75).

Bellini and Bardare (3) and Jequier et al (27) reported a metaphyseal chondrodysplasia with cone-shaped epiphyses and cupped metaphyses in tubular bones and in hands and feet, abnormally shaped vertebral bodies, odontoid hypoplasia, and alopecia. There was early growth but premature closure of epiphyses. Wiedemann and Spranger (78) described a similar metaphyseal dysplasia. Maroteaux et al (44) reported an entity with slight shortness and varus deformity of the lower limbs, and radiographically hypoplastic femoral necks and metaphyseal dysplasia. Stature was not affected. Because the symptoms regressed spontaneously, the authors called the entity "metaphyseal anadysplasia." Spranger (66) has described other metaphyseal dysplasias.

Laboratory aids. Steffensen and Østergaard (67), Van der Burgt et al (73), and others (53,55,72,76) have demonstrated selective dysfunction of cell-mediated immunity and inverted ratio of T-helper/T-suppressor cells. Prenatal diagnosis is discussed by Dungan et al (14) and Sulisalo et al (70).

Metaphyseal dysplasia, type Jansen

The Jansen type of metaphyseal dysplasia is a rare form of growth disorder showing progressive changes reminiscent of rickets or primary hyperparathyroidism. Reported for the first time by Jansen (9) in 1934, at least 16 cases have been subsequently reported (1–8,10–18).

Clinical findings have included severe short stature of postnatal onset, para-articular widening, short bowed limbs, ape-like stance, waddling gait, normal intelligence, and clinodactyly. The facies is characterized by prominent frontonasal and supraorbital ridges and zygomata. The eyes are often prominent in infancy. The mandible is markedly reduced in size (Fig. 7–35).

Fig. 7–35. *Metaphyseal dysplasia, type Jansen.* (A) Mother and daughter exhibiting extreme short stature. (B) Note short, bowed limbs.

C

Fig. 7–36. *Metaphyseal dysplasia, type Jansen.* (A–C) Short tubular bones, gross metaphyseal widening, enlarged epiphyseal centers of distal metacarpals, and irregular ossification. Knees show splaying and fragmentation of metaphyses and irregular ossification. The pelvis shows metaphyseal widening and irregularity, normal epiphyses, and bowing of femora. (From K Kruse and C Schutz, Eur J Pediatr 152:912, 1993.)

Radiographic alterations change with time. During infancy, there are diffuse demineralization and rickets-like findings in the metaphyses, cortical erosions, and increased subperiosteal bone formation. The epiphyses and diaphyses are normal. During childhood, the tubular bones are short and curved with wide, chaotically frayed and cupped metaphyses (Fig. 7–36). The fingers may be short and clubbed. Rib fractures have been documented. The long bones exhibit increased density. The calvaria and skull base are hyperostosed. The cranial sutures are wide in infancy and there may be choanal stenosis.

Inheritance is autosomal dominant, but most cases represent new mutations (3). Mutations involve a PTH-PTHrP receptor gene (15a).

Laboratory changes consist of hypercalcemia, hypercalciuria, elevated urinary phosphate, and cyclic AMP (2,4,6,7,9,13,17). There is no increased serum 1,25–dehydroxyvitamin D despite low to normal levels of parathormone (PTH) and PTH-related peptide. The parathyroid glands appear normal (6,7,17).

Table 7–6. Features of the three major forms of chondrodysplasia punctata

	X-linked dominant type	X-linked recessive type	Rhizomelic type
Head circumference	Normal for age	Mild microcephaly	Small for age
Nose	Hypoplastic	Hypoplastic	Hypoplastic
Cataracts	65%, often unilateral and asymmetric	In some cases, bilateral	65% bilateral and symmetric
Skin changes	Congenital ichthyosiform erythroderma; ichthyosis in older child; systematic atrophoderma, pseudopelade, coarse twisted scalp hair	Mild ichthyosis as neonate; sparse unruly hair	Dry scaly rash in 25%, hair normal
Contractures	Mild in 25%	Mild	Frequent, severe
Skeletal changes	Asymmetric limb shortening, usually femur and humerus; scoliosis after first year	Distal phalanx hypoplasia; carriers have broad wrists and short arms	Severe bilateral shortening of femur and/or humerus with severe metaphyseal changes
Stippling	Asymmetric involvement of long bones: paravertebral, laryngeal, tracheal	Bilateral symmetric involvement of long bones; paravertebral, laryngeal, tracheal	Proximal and distal humeri and femora, knee; no paravertebral stippling
Mental retardation	Normal to mildly retarded	Delay; hyperactivity, behavioral problems	Severely retarded; hypotonia
Prognosis	Good; lethal in males	Relatively good	Lethal, usually in first year
Inheritance	XLD	XLR	AR

Chondrodysplasia punctata (general)

Chondrodysplasia punctata is a term used for a heterogeneous group of skeletal dysplasias characterized by the radiographic appearance of punctate or stippled calcifications at long bone epiphyses during infancy. Thus, chondrodysplasia punctata is not a specific disease designation but is a radiographic sign evoking consideration of a spectrum of genetic and teratogen-induced disorders.

First described by Conradi (2) in 1914 and by Hünermann (4) in 1931, chondrodysplasia punctata was later split into two categories by Spranger et al (7), who differentiated the relatively mild and presumably autosomal dominant Conradi-Hünermann disease from lethal chondrodysplasia punctata, rhizomelic type. Burck (1) distinguished a hitherto sporadic form characterized by mesomelic shortening of the limbs and Sheffield et al (6) described a large series with an unusually mild picture. More recently, Curry et al (3) proposed an X-linked recessive chondrodysplasia punctata that may present as a chromosome microdeletion syndrome.

Thus, three major and at least two less frequent clinical entities have been distinguished on the basis of degree of skeletal aberration, presence of cataracts, and skin involvement (Table 7–6). Although these attempts to differentiate clinical phenotypes appear justified, there is uncertainty as to whether all phenotypic differences represent true genetic heterogeneity or are merely gradations in the variable expression of a single X-linked gene or gene complex. The heritable phenotypes must be further differentiated from the teratogenic effects of anticoagulant therapy with vitamin K antagonists (e.g., *Warfarin embryopathy*) and a number of other conditions in which transient epiphyseal stippling may occur.

Kelley et al (5) found abnormal sterol metabolism in some cases of chondrodysplasia punctata.

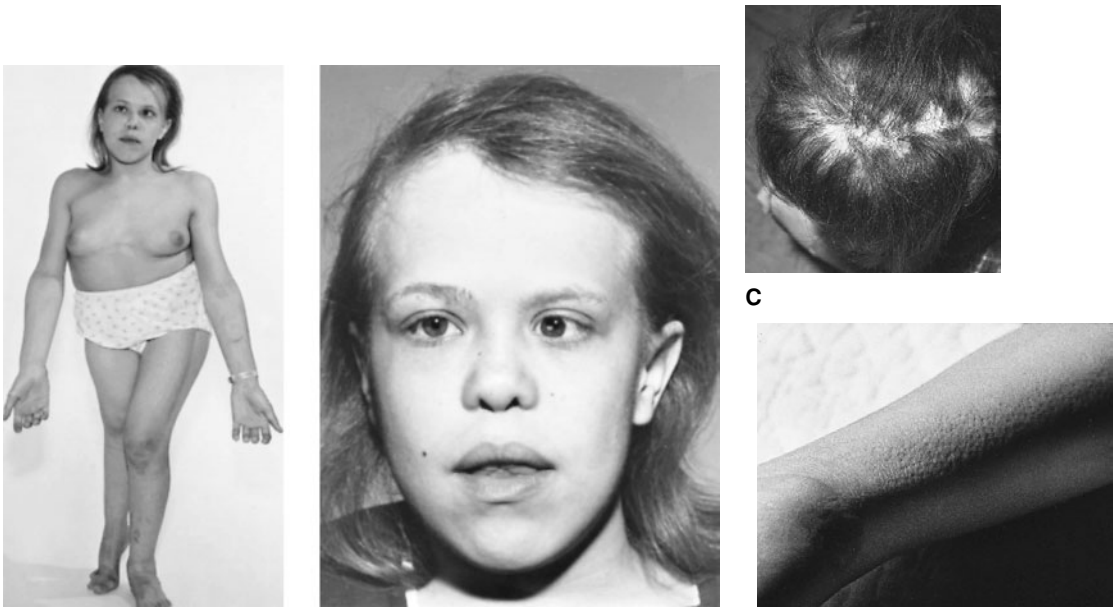
Conradi-Hünermann disease: X-linked dominant type. The eponym Conradi-Hünermann disease is frequently indiscriminately used for the group of chondrodysplasia punctatas, but it should be employed only for the X-linked dominant form (Figs. 7–37 and 7–38), which was first recognized by Happle et al (18,21) to be limited to females. The mother of an affected daughter may have mild manifestations, such as short stature or skin changes or cataracts (2,9,20,26,27,33,41). It has been proposed that this form accounts for at least 25% of cases (32), but our review suggests that all reported cases of Conradi-Hünermann syndrome, including the "autosomal dominant" cases, actually represent the X-linked dominant condition. The disorder occurs exclusively in females, because the underlying gene defect is lethal in hemizygous males (11). A stillborn male infant has been noted (3). A family with the X-linked dominant type has been reported in which an affected male was found to have XXY Klinefelter syndrome (41). The rare occurrence of the X-linked dominant type in males (18,47) can be best explained by a postzygotic mutation or a half-chromatid mutation, as first proposed by Lenz for incontinentia pigmenti (29). Other familial observations have been reported (2,10,16,32,39).

Following discovery of peroxisomal enzyme deficiencies in the rhizomelic type (23), similar abnormalities were reported in the X-linked dominant type (13,24,34). Already in 1983, Happle (20) suggested that the X-linked dominant type may have a murine homologue in the mouse mutant Bare Patches (*Bpa*). The name was derived from the skin abnormalities found in female mice of a particular strain after multiple doses of X-irradiation (30). The gene was mapped within Xq27–28 (22,30). The fact that peroxisomal anomalies were also found in Bpa mice (13) further suggested that the human *Bpa* gene was responsible for the X-linked dominant type. This has been echoed by Wilson and Aftimos (49). However, Traupe et al (45) excluded the region in three smaller families. They suggested the existence of an unstable premutation that can become silent in males (45). Kelley et al (28) found increased levels of 8-dehydrocholesterol, suggesting a sterol-Δ^8-isomerase deficiency as cause for the disorder. In 1999, Braverman et al (4) found that mutations in the gene encoding 3β-hydroxysteroid Δ^8, Δ^7-isomerase cause X-linked dominant Conradi-Hünerman syndrome. The gene is at Xp11.22–p11.23. Mosaicism has been reported (21).

The disorder is intermediate in severity with a good prognosis. Intelligence appears to be normal, although performance on specific tests may be impaired by poor vision and skeletal limitations on motor skills (32).

Facies. Frontal bossing is common, with macrocephaly being noted in several patients (7,12,14,16,21,25,40) (Fig. 7–37A,B). The nasal root is flat and broad (7,12). The face is often asymmetric because of hypoplasia of one side (14,21,33,39). The neck may be short (10,21,40).



A B C D

Fig. 7–37. *Chondrodysplasia punctata*, *X-linked dominant* (*Conradi-Hünermann*) *type.* (A) Height is reduced. Note disproportionate limb length and scoliosis. (B) Sparse hair, flat midface, anteverted nostrils, and cataract. (C) Patchy alopecia on scalp. (D) Skin changes. (From D Comings et al, J Pediatr 72:63, 1968.)

Eyes. Congenital diffuse cataracts have been observed in about 65% of patients. The cataracts may be unilateral (35%) or bilateral, often with asymmetric intensity (19) (Fig. 7–37B). Happle (19) pointed out that this exception to the general rule that hereditary cataracts tend to be bilateral and symmetrical is probably caused by lyonization. Microphthalmia and microcornea have also been reported (26,39).

Skin. Newborn patients exhibit ichthyosiform erythroderma with thick, adherent scales arrayed in a linear, blotchy pattern, presumably reflecting lyonization (26). The hyperkeratotic eruption is followed by systematized atrophoderma distributed in a mosaic pattern leaving patchy linear areas of alopecia on the scalp (Fig. 7–37C,D). A linear pattern of hyperpigmentation, which is not congruent with the pattern of hairlessness, has been observed and compared to incontinentia pigmenti (10). The nail plates are often flattened (12). Microscopic sections of the skin show a thin stratum granulosum. These skin changes can be distinguished from other forms of ichthyosis on the basis of histologic and ultrastructural criteria (6,13,17).

Fig. 7–38. *Chondrodysplasia punctata*, *X-linked dominant* (*Conradi-Hünermann*) *type.* Note severe scoliosis.

Musculoskeletal alterations. In infancy, punctate calcifications are scattered throughout the spinal column, costal cartilages, sternum, clavicles, scapulae, and in the epiphyseal centers of the extremities. Loss of the characteristic stippled epiphyses with time makes diagnosis difficult. In some individuals there is true dysplasia of vertebral bodies (7,10). Stature is usually reduced (1,40). Scoliosis or kyphoscoliosis with asymmetric shortening of limb bones, particularly the femur and humerus, is common (Fig. 7–38). Shortening of the limbs is asymmetrical. Flexion contractures involving the hip or knee joints (16), elbow (26,36), or fingers (10,20,33) and hip dysplasia (1,9,10,25,33,39) have been reported. Metapodial bones may also be involved (19,26). Some patients have exhibited postaxial supernumerary digits of the hands (19,32,36,38,39). Talipes is not uncommon (14,16,26).

Other manifestations. Mental retardation has been described (10) but is rare. Congenital paraplegia resulting from uncharacteristic maldevelopment of the spinal cord has been reported (9). Cardiovascular disorders, including peripheral pulmonary arterial stenosis (47), have been rarely mentioned (25,40).

Laboratory aids. Intrauterine radiographic examination of a pregnancy at 16 weeks failed to show diagnostic features, although the characteristic extensive calcifications in sites of endochondral bone formation were apparent by radiographic examination of the abortus. Prenatal sonographic diagnosis has been accomplished (37,48).

Chondrodysplasia punctata, rhizomelic type. This type, the most severe form of chondrodysplasia punctata, leads to death usually before the second year of life (Figs. 7–39 and 7–40), although much longer survival can occur (30). Familial occurrence has been reported (10,19,26,30), both sexes are equally affected, and parental consanguinity has been estimated at 8%–10%; all of these features point to autosomal recessive inheritance. Biochemical studies have indicated that this type results from a disorder of peroxisomal metabolism (14).

Patients exhibit profound deficiency of plasmalogen synthesis, the presence of unprocessed peroxisomal thiolase in the liver, reduced alkyldehydroxyacetone phosphate synthase activity in fibroblasts, and elevated phytanic acid levels in plasma and liver, indicating a reduction of phytanic acid oxidation to 1%–5% of controls (1,16,23). Other peroxisomal functions are normal. Additional information has been gained by complementation studies (13,16,20,23,25), in which fibroblasts from two different patients, both deficient in a peroxisomal process, are fused and the resulting multinucleated cells are examined. Restoration of activity can occur only if each cell line complements the gene product defective in the other. Moser et al (20) found at least 11 different groups, of which the rhizomelic type was one. Patients showed a homogeneous clinical picture, although a more mild picture does occur (2,20,22,26). Patients with isolated deficiency of alkyldihydroacetone phosphate synthase deficiency have the classic rhizomelic-type phenotype (29).

Three groups (3,21,24) have independently proven that the disorder is caused by mutations in one of the peroxisomal assembly proteins (peroxins), PEX7, located at 6q22–24. The *PEX* genes are required for import of matrix proteins into peroxisomes by peroxisome targeting signals (PTS) (3). *PEX7* encodes the receptor for one of these signals, PTS2. Different mutations in *PEX7* have been found in patients with the classic rhizomelic type (3,21,24). A founder effect and the structure of the gene have been dealt with at length (3a).

Facies. The face is symmetric, but notable for frontal bossing, flat nasal bridge, and small nares (Fig. 7–39).

Eyes. Cataracts observed in about two-thirds of the cases are usually bilateral and of equal density (25). Other lens abnormalities can occur (9).

Skin. At least 25% of patients have ichthyosis, which develops shortly after birth.

Musculoskeletal alterations. In contrast to the other types of chondrodysplasia punctata, there is severe congenital rhizomelic shortening of the extremities. Small head circumference tends to be present at birth and is a constant finding in older infants and children. Contractures have been noted in over 60% and foot deformities in about 10% of patients.

A B

Fig. 7–39. *Chondrodysplasia punctata*, *rhizomelic type.* Autosomal recessive form. (A) Flat midface and small upturned nose. (B) Deficient midface and posteriorly angulated ears.

Radiographic skeletal abnormalities include severe shortening, metaphyseal cupping, splaying, and disturbed ossification of the humerus and/or femur (Fig. 7–40). Epiphyseal and extraepiphyseal calcifications are usually severe (Fig. 7–41). Lateral views of the spine show a coronal cleft of the vertebral bodies (26). There are marked degenerative changes in resting chondrocytes (23).

Oral manifestations. Cleft palate (4,6,7,10,18,23,26) and submucous palatal cleft (1) have been noted in the rhizomelic type. There is one report of a patient with laryngeal atresia (27).

Other. Hearing loss (30), hypospadias (30), and magnetic resonance imaging (MRI) anomalies of the brain (31) have been described.

Laboratory aids. Prenatal diagnosis of the rhizomelic type is possible by sonography (30), peroxisomal investigations (12,15), and probably also by molecular study of *PEX7*, although this has not been reported yet.

Chondrodysplasia punctata, X-linked recessive type. An X-linked recessive disorder with chondrodysplasia punctata, ichthyosis, and mental retardation was reported by Curry et al (6). Cytogenetic studies revealed a small deletion at Xp22.32 in four affected males and in 11 of 25 apparently normal related females. Several other patients with interstitial deletion (3,4,13,14,16) or X-Y translocation involving Xp (1,2,13,21) have been reported. The presence of ichthyosis in affected males prompted biochemical studies that demonstrated functional deletion of three genes previously mapped in this region of the X chromosome, which corresponded to the observed deleted (steroid) sulfatase; Xg^a; and the M1C2X locus for expression of 12E7 antigen (2,6). Hence, it is a truly contiguous gene syndrome (3). It has been suggested that extensive calcification of blood vessels may play an important role in the pathology of this form (10). A genotype-phenotype study has been carried out (18). Heterozygous female carriers are clinically normal but, as a group, are slightly shorter, with broad wrists and short arms, in comparison to non-carrier relatives (1,2,6,20). After further refinement of the locus (7,11,12,14), Franco et al (8) were able to isolate the causative gene, *ARSE,* through positional cloning. It is an arylsulfatase enzyme that shows high sequence homology with steroid sulfatase. Point mutations were found in 5 of 27 patients by Franco et al (8). Parenti et al (15) described another mutation. It remains uncertain whether other genes in the critical region for the X-linked recessive type of chondrodysplasia punctata, named *ARSD* and *ARSF,* are also in part responsible for the symptoms in patients nullisomic for Xp22.3.

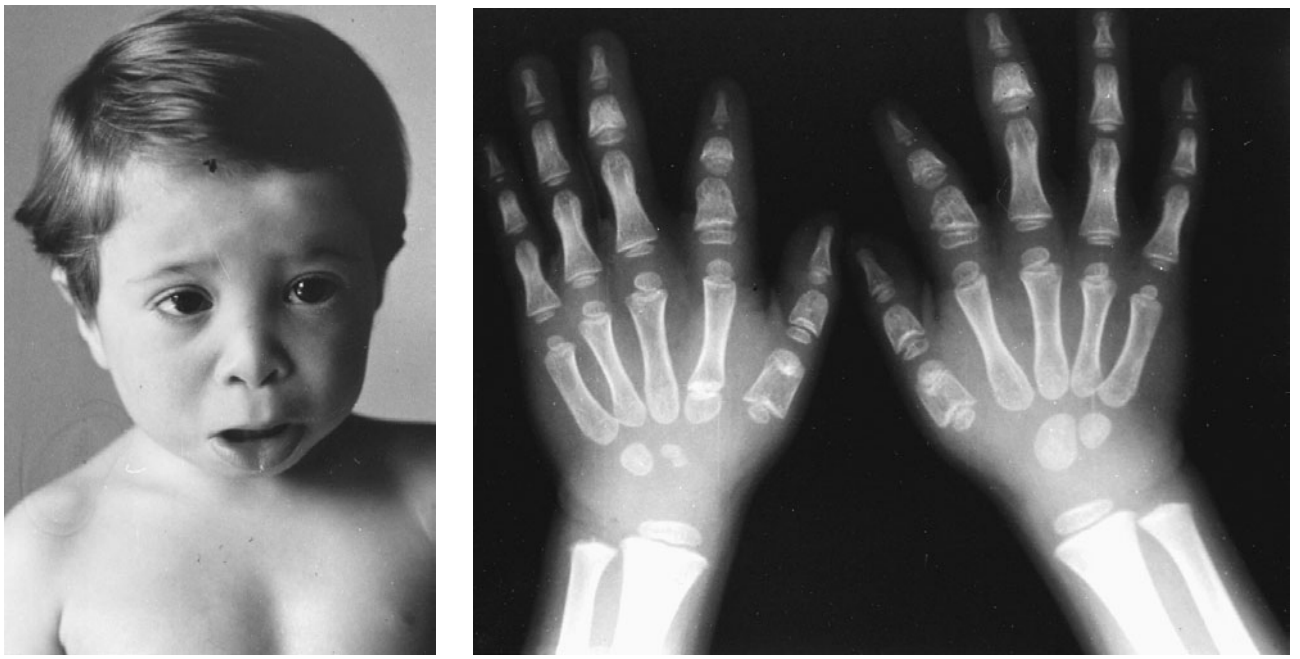
Chondrodysplasia punctata, Sheffield type may be in part caused by mutations in *ARSE*. As this latter entity is undoubtedly heterogeneous and the exact relationship between *ARSE* mutations and clinical picture remains uncertain, it is described separately.

Facies. Nasal hypoplasia was present in all children with some tendency toward improvement in later childhood (Fig. 7–42A). Sensorineural hearing loss may occur (4,6,15).

Eyes. Bilateral cataracts have been observed in some patients. One patient had optic nerve hypoplasia (16).

Skin. All patients had sparse and unruly hair with mild ichthyosis particularly over the chest, back of legs, neck, and axillae.

Musculoskeletal alterations. Bilaterally symmetric punctate stippling of multiple epiphyseal centers is characteristic, including the paravertebral epiphyses and those of the larynx, trachea, and long bones; these disappear relatively rapidly with age (17). Hypoplasia of the distal phalanges (brachytelephalangia) is common (Fig. 7–42B).



A B

Fig. 7–42. *Chondrodysplasia punctata*, *X-linked recessive type.* (A) Five-year-old boy with prominent forehead, underdeveloped flat nose, short columella, and long philtrum. (B) Note short first metacarpals, cone-shaped epiphyses, and short first and second proximal and middle phalanges. (From G Parenti et al, Am J Med Genet 73:139, 1997.)

Other. Mild mental retardation (1,2,4,13,16,21), hydronephrosis with multiple small cysts (4,21), and choanal atresia (4) have been reported.

Laboratory aids. Prenatal diagnosis has been accomplished (5).

Chondrodysplasia punctata, Sheffield type (and brachytelephalangic type). In 1976, Sheffield et al (7) described a series of 23 patients with an unusual mild type of chondrodysplasia punctata, characterized by failure to thrive, apparent developmental delay, Binder-like facial features, and punctate calcifications in the calcaneus and sometimes elsewhere. It seems very likely that this group of patients was heterogeneous. Norman et al (5) described another case. The so-called brachytelephalangic type of chondrodysplasia punctata (1,3,4) is probably the same entity. It has been suggested that some patients with Binder phenotype may in fact have chondrodysplasia punctata, Sheffield type (2,6).

The difference between the Sheffield and the X-linked recessive types can be difficult to determine. Indeed, in one case reported by Maroteaux (4), a mutation in the *ARSE* gene was found, as can be found in the X-linked recessive type. The X-linked recessive type is usually characterized by microdeletion at Xp22.3; the influences on the phenotype by nullisomy of other genes at Xp22.3 is uncertain. Therefore, it is prudent to keep the Sheffield type separate from the X-linked recessive type. In some patients of the Sheffield type, an autosomal recessive pattern of inheritance was suggested (5,8).

Most patients have low–normal birth weight. Growth velocity is mildly impaired thereafter. The nose is already characteristic at birth, showing a tip flattened by a shortened columella and depressed nasal bridge. The inadequate nasal airway can produce respiratory problems in the neonatal period. The nasal bridge fills out at a later age, but plastic surgery may still be warranted. Otherwise, the face is usually normal, although proptosis (3), nystagmus (7), and other usually mild dysmorphias (1) occur. The limbs can be normal, but brachydactyly with somewhat bulbous thumbs is not uncommon. Several patients had postaxial polydactyly (7).

Radiologically, fine stippling at birth is especially frequent in the calcaneus in a lateral view of the foot. Other sites can be tarsals, toes, sacrum, other vertebrae, proximal femora, proximal humeri, and laryngeal cartilages. Within 2 to 4 years most stippling is no longer visible. Sagittal clefts of the vertebral bodies and very small distal phalanges of all fingers can be found. The other phalanges and metacarpals can be shortened to a lesser extent (1,3,4).

Chondrodysplasia punctata, tibia-metacarpal type. In 1982, Burck (3) described two unrelated girls with a form of chondrodysplasia punctata characterized by marked mesomelic shortening of limbs, mild localized punctate epiphyseal calcifications, dislocation of radial heads and patellae, and characteristic face. In retrospect, the patients reported by Asanti and Heikel (1) and Haynes and Wangner (5) likely had the same entity. Several other patients have been reported (2,4,6–8), although the case described by Borochowitz (2) and by Fryburg and Kelly (4) had rhizomelic shortening instead of mesomelic shortening. Further related cases have been discussed (3,7); all have been sporadic. The symmetry and consistency of the symptoms make a genetic origin more likely. Peroxisomal studies were reportedly normal (4,8).

Patients show shortened limbs at birth, often more pronounced in the arms. With time, the shortening becomes more apparent. Facial features include flat face, flat nasal bridge, small nose, relatively long philtrum, small mouth, and micrognathia. Some patients have hypertelorism (3,7), thin vermilion borders of the lips (2,7), and cleft palate (7) or highly arched palate (2,7). No patient has had cataracts, one patient had atrophic facial skin changes (7). There is often bowing of upper or lower arms, which diminishes with age. A mild pectus excavatum, hyperlordosis, and mild hypomobility of the large joints have been described. The growth is moderately diminished (2–4 standard deviations below the mean); no adult height has been reported. Mental development is normal. No internal anomalies have been recorded.

Radiologically, the major symptoms are shortening of the tibiae and, to a lesser extent, the radii. In two cases, the shortening was more pronounced in the humeri. Distal ulnae may be hypoplastic and the fibulae very long. The metacarpals are short and show calcific stippling, especially the fourth. The distal phalanges may be short. The cervical vertebral bodies are underossified neonatally. Otherwise, the spine shows a coronal cleft indicating insufficient fusion of the anterior and posterior ossification centers. The ribs and pelvis are usually normal. Punctate calcifications are most prominent in the sacrum, metacarpals, carpals, and tarsals; this state appears with age. In some patients stippling was more widespread (4,5). Dislocations of patellae (3,8) and radii (3,7,8) have been recorded.

Other disorders with stippled epiphyses. Epiphyseal stippling in infancy is a nonspecific sign and may be seen in a variety of other disorders including Zellweger syndrome, different forms of adrenoleukodystrophy, other peroxisomal disorders (23), Blomstrand syndrome, cerebro-costo-mandibular syndrome (3), multiple epiphyseal dysplasia, kyphomelic dysplasia, acrodysostosis (22), Astley-Kendall syndrome (15), alcohol embryopathy, hydantoin embryopathy, coumarin embryopathy (7,13,24), maternal lupus erythematosus (2,6,20), chondritis secondary to bacteremia, I-cell disease, infantile sialic acid storage disease, G_{M1}-gangliosidosis, Smith-Lemli-Opitz syndrome, Keutel syndrome (5,14a), trisomy 18, trisomy 21, mosaic trisomy 9 (1), duplication of distal 16pter (9), deletion of 7q11 (16), and congenital hypothyroidism. Stippled epiphyses may be found in single digits (12) and in CHILD (*c*ongenital *h*emidysplasia, *i*chthyosiform erythroderma, *l*imb *d*efects) syndrome (8). Kozlowski and Majewski (10) have described a separate form of chondrodysplasia punctata (acrospondylar type) with mainly irregular calcifications at the base of metacarpals and metatarsals, and poorly ossified vertebrae with stippling, especially cervically. Toriello et al (21) reported a form with stippling of proximal humoral epiphyses, retarded bone age, coloboma of iris, some unusual facial features (brachycephaly, small nose, anteverted nares), and developmental delay. Ciske et al (4) reported a similar patient who had, in addition, an atrioventricular canal, coarctation of aorta, partial absence of the callosal body, small vermis, and enlarged ventricles. Refetoff et al (17) reported a family with the combination of stippled epiphyses, goiter with elevated protein-bound iodine (PBI), severe deafness, and mild dysmorphic features. Another form of epiphyseal stippling of especially the thorax, carpals, sacrum, proximal femoral epiphyses, and tarsals, together with osteoclastic hyperplasia, was reported by Shohat et al (18). Dappled diaphyseal dysplasia combines multifocal ossification of long bones of limbs, ribs, and pelvis with lethal short-limbed dwarfism (19). Mortier et al (14) reported stippled epiphyses with some similarity to the brachytelephalangic X-linked form. The child had cleft lip/palate, telecanthus, and aplasia cutis congenita of the scalp.

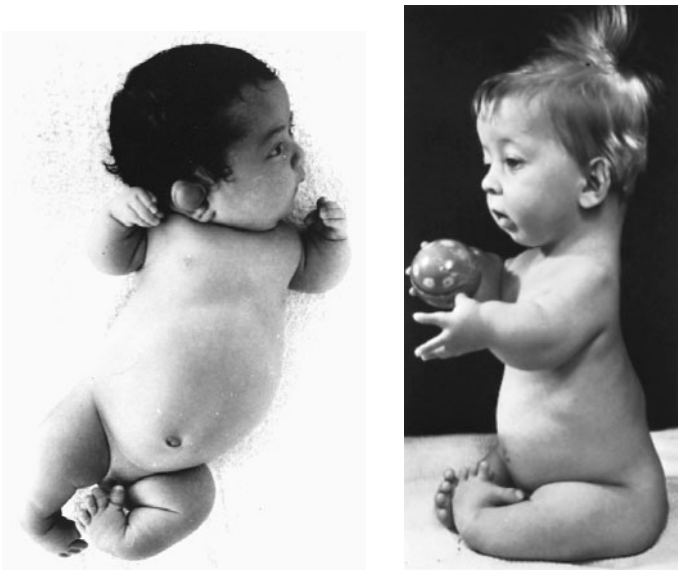
Diastrophic dysplasia

In 1960, Lamy and Maroteaux (27) used the term "diastrophic dwarfism" to describe a syndrome consisting of micromelic dwarfism, progressive scoliosis, bilateral talipes equinovarus, and various deformities of digits, hip dysplasia, characteristic external ear deformities, and, frequently, cleft palate (Figs. 7–43 to 7–45). Over 400 cases have been described, with over 150 of these coming from Finland (10,36). The incidence in Finland is estimated to be 1 in every 30,000 newborns (10). The syndrome has autosomal recessive inheritance (1). There is a founder effect in Finland (12a). Both sexes are equally affected. Prior to its delineation, cases in infants were generally classified as examples of "achondroplasia with clubbed feet," and in adults, as Morquio syndrome (5,24). Early examples are those of Arraga in 1897 [republished, see (29)], Schenk (38) in 1910, and Duken (5) in 1921.

The so-called diastrophic variant is presently considered to be a mild form of diastrophic dysplasia, reflecting the wide variability in phenotypic expression of this condition (9,15,26). Gustavson et al (8) have suggested that there are lethal and nonlethal forms, with the lethal form exhibiting lower birth weight, overlapping joints, dislocation of cervical spine, and, frequently, congenital heart disease. Fertility seems to be reduced (43).



A B

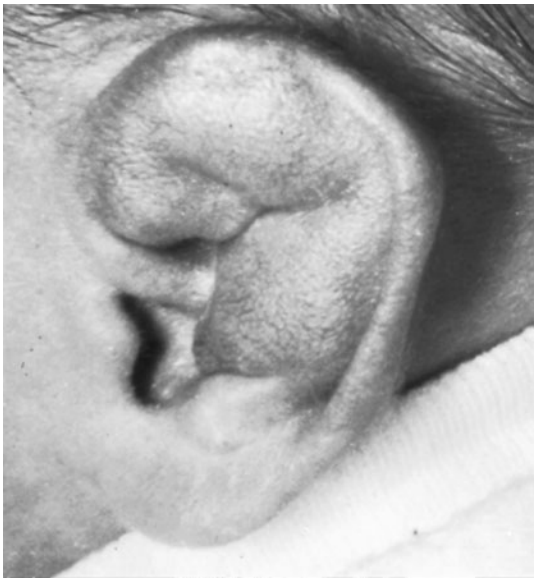
Fig. 7–43. *Diastrophic dysplasia.* (A) Micromelia, talipes equinovarus, and cystic ear. (B) Micromelic dwarfism, scoliosis, bilateral talipes equinovarus, and deviated thumbs and halluces. (A courtesy of C Gonzales, Sao Paulo, Brazil. In: MM Cohen Jr, The Child with Multiple Birth Defects, Raven Press, New York, 1982, p 104. B from J Spranger and H Gerken, Z Kinderheilkd 98:227, 1967.)

For a long time, the basic defect was considered to be a metabolic abnormality of the chondrocyte that induces cell death and/or defect in the synthesis of collagen or proteoglycan (16). Through work within the Finnish population, Hastbacka and co-workers (10) mapped the syndrome to chromosome 5q32. The same group of investigators cloned and sequenced the gene, which was named "diastrophic dysplasia sulfate transporter" (*DTDST*) (12). When mutated, sulfate uptake across the cell membrane is insufficient, leading to undersulfation of proteoglycans in cartilage. Mutations were found in patients with diastrophic dysplasia, achondrogenesis type 1B, and atelosteogenesis type 2 (40), thus constituting a separate bone dysplasia family. The severity of the phenotype within this bone dysplasia family correlates well with the predicted effect of mutations in *DTDST* (40). Rossi et al (37) described patients heterozygous for transporter gene mutations who showed features of both diastrophic dysplasia and atelosteogenesis type 2. A novel mutation for a broad bone variant has been found (31a).

About 25% of patients die in infancy of aspiration pneumonia or respiratory distress (glossoptosis, tracheomalacia). The somewhat hoarse cry, noted in several infants, may be related to abnormal laryngeal cartilages that may, in turn, reflect poor prognosis (43).

Facies. The face tends to be round with narrow nasal bridge, broad midnose, flared nostrils, and circumoral fullness (31,43) (Fig. 7–43). Bilateral but, at times, asymmetric deformity of the pinnae has been noted in over 80% of patients (43). It may be evident within the first few days or weeks of life as a cystic swelling from which serosanguineous fluid may be extracted (24,43) (Fig. 7–44). This resolves within a month, but the architecture of the pinnae becomes distorted with calcification of the cartilage. The external auditory canals may be narrowed. Cephalometric analysis has been performed (20–22).

Musculoskeletal alterations. Mesomelic dwarfism is a constant feature. Mean birth length is about 42 cm. Horton et al (17) and Mäkitie and Kaitila (30) established growth curves. Mean adult height in Finnish males is 136 cm (129–160 cm) and in females, 129 cm (90–143 cm); the Horton study showed height in males ranging from 86 to 127 cm and in females from 104 to 122 cm (17,30). The variability in growth failure was great even within sibships. Growth delay was aggravated



A

B

Fig. 7–44. *Diastrophic dysplasia.* (A) Cystic ear during hemorrhagic phase, which later resolves, leaving pinna calcified and distorted in form. (B) Hand and fingers are short, with thumb proximally placed.

in puberty by weak or absent pubertal growth spurt. There is shortening of all limbs (Fig. 7–43). Bilateral talipes equinovarus is severe, becomes worse with age, is resistant to treatment, and tends to recur after therapy. The patients bear their weight on their toes; thus walking is limited.

The thumbs are proximally inserted, hypermobile, and laterally displaced (hitchhiker's thumb) (14). The broad hands and shortened fingers often exhibit ulnar deviation. Frequent webbing, contractures, and fixation of the interphalangeal finger joints occur (Fig. 7–45). The metacarpophalangeal profile pattern has been discussed by Butler et al (3).

Scoliosis is not present at birth but is progressive, particularly in preadolescent years. It tends to become severe and rigid with a large rotary component (2,4,13,14,23,33). Kyphosis is occasionally associated. Lordosis is frequent and is not progressive (8). All patients reported by Herring (13) and Bethem et al (2) presented spina bifida occulta in the cervical spine. Flexion contracture and/or subluxation or dislocation, particularly of the hips and knees and, to a lesser extent, of the shoulders, are common and progressive, further reducing height (43). Inguinal hernia has also been described (42,43).

Radiographic changes include shortening and thickening of nearly all tubular bones. The epiphyses have delayed appearance and are flattened and distorted. With time, the metaphyses become widened, irregular, and deformed. The humerus is less shortened than the radius and ulna. The thumb is proximally placed, and the first metacarpal is small and rounded (Fig. 7–45A,B). Synostosis of the proximal interphalangeal joints is a constant feature. Carpal development is accelerated, but secondary centers for the metacarpals, metatarsals, and phalanges are retarded in appearance. The metacarpals are broader at the distal end than at the proximal end. The first metatarsal is broader and wider than the others (1,4,28,41,44) (Fig. 7–45C).

Dislocation or subluxation of hips and coxa vara are associated with flattening of the acetabular roof and delayed appearance and poor development of the capital femoral epiphysis. The patella is often subluxated. Progressive kyphosis of the cervical region of the spine, with subluxation of the second and third cervical vertebrae, is frequent and may result in spinal cord compression (2,13,25,28). The interpediculate distance tends to narrow below the third lumbar vertebra (2) (Fig. 7–45C–F). Death later in life results from progressive cervical kyphosis with medullary compression (25) (Fig. 7–45F). Intelligence is normal.

Precocious ossification of costal cartilages and calcification of pinnal cartilage occur in at least 80% of patients. Intracranial calcification has also been described (43).

Currarino (3a) pointed out that 50% of children have a double-layered manubrium sternum.

Histopathologic study has shown a generalized degenerative disorder of cartilage, with focal death of cells followed by matrix dissolution, cyst formation, fibrovascular scarring, and dystrophic ossification (34). Characteristic histopathologic findings include degeneration of chondrocytes, abnormal distribution of collagen in resting cartilage, and large cystic lesions in the resting cartilage which exhibits intracartilaginous ossification (16). Similar findings have been reported in fetuses (31).

Oral manifestations. The mouth is full and broad, with the lower lip slightly larger than the upper. Cleft palate has been found in 25%–60% of patients (1,20,28,37,42). Rintala et al (36) reported 43% of their patients with cleft palate and 32% with submucous palatal cleft. Oddly, this latter group did not have nasal speech. They further estimated that 10% had glossoptosis due to micrognathia. These investigators noted at a later time that 12 of 39 cases had cleft palate, and 11 had submucous cleft palate (21). Most patients have some degree of micrognathia. Teeth may be small (19). The abnormal size and shape of the vocal tract lead to hyponasality (22).

Differential diagnosis. The disorder may be confused with a plethora of chondrodysplastic and other disorders, such as arthrogryposis, *achondroplasia*, *atelosteogenesis type I*, and *cartilage-hair hypoplasia* (28,43). *Pseudodiastrophic dysplasia*, a rare recessive bone dysplasia, has a somewhat similar phenotype, but has interphalangeal joint dislocations and platyspondyly. The characteristic degeneration of cartilage is not evident.

Pinnal calcification can rarely be seen in other disorders such as ochronosis, Addison's disease, acromegaly, systemic chondromalacia, familial cold hypersensitivity (43), Nance-Sweeney chondrodysplasia, and *Keutel syndrome*.

Laboratory aids. Prenatal diagnosis has been made by ultrasonography (6,7,18,32) and with polymorphic DNA markers (11). In fetuses, scoliosis and joint contractures are usually absent (33).

Pseudodiastrophic dysplasia

In 1974, Burgio et al (2) were the first to describe an autosomal recessive condition that they called "pseudodiastrophic dwarfism." Eight additional patients have been reported (1,3,4,6,7). Although the clinical findings are somewhat similar to those of diastrophic dysplasia, distinct radiologic and chondroosseous histologic differences are evident. Furthermore, while diastrophic dysplasia has been shown to be caused by mutations in the diastrophic dysplasia sulfate transporter gene, this gene is not involved in pseudodiastrophic dysplasia (5).

There is rhizomelic shortening of the limbs and severe clubfoot deformity, but no "hitchhiker's thumb" (Figs. 7–46 and 7–47). The patients described by Burgio et al (2), Canki et al (3), Canki-Klain (4) and Fischetto et al (7) died within the first year of life. However, Eteson et al (6) reported two children over the age of 4, one of whom was later reported to be alive at 16 years (5), and Canki-Klain et al (4) described a child of almost 6 years.

Among the ten cases described to date, six had cleft palate. At birth, the cranium is enlarged with midface hypoplasia. The sclerae appear somewhat bluish. There is mild hypertelorism, flat nasal bridge, large malformed earlobes, and folded superior helices, dislocated elbows, interphalangeal dislocations, and clubfeet. Long clavicles, slightly short ribs with anterior flaring, and platyspondyly with scoliosis can be found. The pelvis appears normal with horizontal acetabular roofs and medial and lateral acetabular spikes. Rhizomelic shortening of limbs, elbow dislocations, and interphalangeal joint dislocations of the hands and clubfeet are characteristic. Later, in infancy and early childhood, the vertebral bodies

A B

Fig. 7–46. *Pseudodiastrophic dysplasia.* (A,B) Flat nasal bridge, short limbs, finger contractures, and clubfeet. (A from G-R Burgio et al, Arch Fr Paediatr 31:681, 1974. B from DE Eteson et al, J Pediatr 109:635, 1986.)

appear hypoplastic, and platyspondylic scoliosis progressively worsens. The sacrosciatic notches become smaller.

Radiographic features that distinguish the syndrome from that of diastrophic dysplasia are platyspondyly, rhizomelic shortness of limbs, and dislocation of elbow, knee, and proximal interphalangeal joints. The degeneration of cartilage, characteristic of diastrophic dysplasia, is not seen in pseudodiastrophic dysplasia, in which irregular myxoid degeneration with small cystic areas is seen. In pseudodiastrophic dysplasia there is no cystic enlargement of the pinnae.

Fig. 7–47. *Pseudodiastrophic dysplasia.* Radiograph of hand showing multiple interphalangeal and metacarpophalangeal joint dislocations with resultant ulnar and radial deviation of digits. (From DE Eteson et al, J Pediatr 109:635, 1986.)

Dyggve-Melchior-Clausen syndrome

This syndrome was first defined by Dyggve et al (6) in 1962, although earlier examples appear to have been published (9). It is a disorder of short-trunk dwarfism and mental retardation and has most often been mistaken for Morquio syndrome (Figs. 7–48 to 7–50). About 50 examples have been reported.

There is genetic heterogeneity, with both forms being autosomal recessive. One form is the Dyggve-Melchior-Clausen syndrome, and includes mental retardation (1–4,6,7,9,11,12,15,22–24); the other, which has no mental retardation, is commonly called "Smith-McCort" syndrome (8,10,13,14,16,21,23). X-linked inheritance has been suggested (5,26), but the patients in these reports probably had X-linked spondyloepiphyseal dysplasia, tarda type. Among those patients with mental retardation, several are Lebanese (4,15) or Moroccan (2,20) in origin. The high carrier frequency is probably the explanation for the unexpected recurrence in the son of a brother of affected sibs (RCM Hennekam, unpublished observation). Obligate heterozygotes are clinically normal. There is no clue regarding mapping of the gene.

Neonatal measurements are normal. Life span, apart from the risk of atlantoaxial instability, is normal. A summary of all major findings is provided in Table 7–7.

Facies. The face is coarse with a prominent mandible. Adults often have a receding forehead.

Table 7–7. Dyggve-Melchior-Clausen syndrome findings ($n = 44$)

Clinical findings	
Mental retardation	44/44
Short stature	44/44
Rhizomelia	27/30
Microcephaly	34/37
Short neck	27/29
Prominent sternum	36/39
Short thorax	39/40
Scoliosis	11/29
Increased lumbar lordosis	33/39
Restricted joint mobility	27/29
Genua valga	15/24
Waddling gait	31/33
Radiological findings	
Platyspondyly	43/44
Notched anterior vertebral bodies	37/40
Hypoplastic dens	26/27
Hypoplastic scapulae	27/29
Hypoplastic iliac bones	40/40
Lacy iliac crest	39/42
Dysplastic acetabulum	30/30
Short, broad phalanges	40/42
Delayed ossification of epiphyses	37/37

Adapted from FA Beemer and RCM Hennekam, T Kindergeneeskd 52:103, 1984.

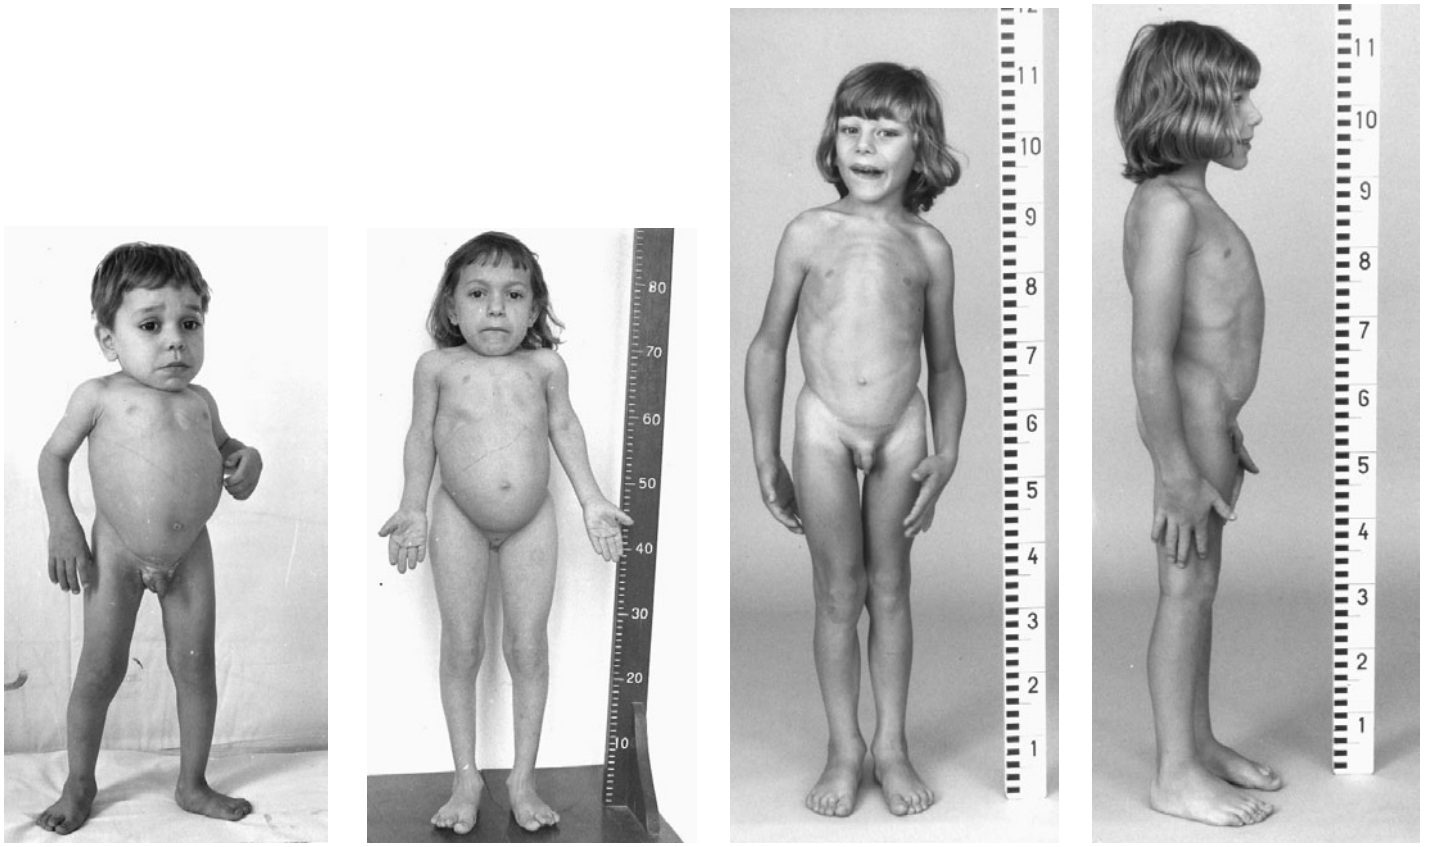

Fig. 7–48. *Dyggve-Melchior-Clausen syndrome.* (A–D) Short-trunk dwarfism. Ten-year-old male in C,D with short stature, protrusion of sternum, and thoracic kyphosis. (A,B from SPA Toledo et al, Am J Med Genet 4:255, 1979. C,D from R Schlaepfer et al, Helv Paediatr Acta 36:543, 1981.)

Fig. 7–49. *Dyggve-Melchior-Clausen syndrome.* (A) Platyspondyly with central indentation and ventral pointing. (B) Marked platyspondyly in older individual. (A from R Schlaepfer et al, Helv Paediatr Acta 36:543, 1981. B from HV Dyggve et al, Neuropadiatrie 8:429, 1977.)

Fig. 7–50. *Dyggve-Melchior-Clausen syndrome.* Short and broad iliac wings with lacy crests. Ischial and pubic bones are somewhat plump with flattened, poorly demarcated acetabula; hypoplasia and shortening of femoral necks are evident. (From HV Dyggve et al, Neuropadiatrie 8:429, 1977.)

Central nervous system. In the Dyggve-Melchior-Clausen form, milestones are delayed and progressive mental deficiency is mild to moderate (IQ 35–65); there is also microcephaly, with the adult head circumference rarely exceeding 47 cm. In the Smith-McCort type, head circumference is only mildly reduced (53–54 cm) and intelligence is normal.

Skeletal changes. Adult height ranges from 98 to 127 cm (mean 119 cm). By age 5–8 years, disproportionate stature becomes evident. The trunk and neck are short, the chest is barrel shaped with a protruding sternum, and thoracic kyphosis and lumbar lordosis occur (Fig. 7–48). Joint mobility is somewhat restricted. Atlantoaxial instability predisposes to spinal cord compression (15). There is rhizomelic limb shortening and genua valga. Most patients assume a crouching stance and walk with a waddling gait. The hands and feet are broad and may show camptodactyly.

Radiographic changes. These changes include disproportionately large facial bones with hyperpneumatization of paranasal sinuses and calvarial thickening in parietal and occipital regions. The vertebrae are flattened with irregular endplates and notching of the anterosuperior bodies in the lumbar region (Fig. 7–49). The odontoid process is often hypoplastic. The ilia are small and irregular with a wide pubic symphysis. The iliac crests have a lacy outline during childhood that becomes a nonspecific irregularity in adulthood (Fig. 7–50). The acetabula are sloping and dysplastic. The femoral heads are small, flattened, and usually dislocated. The shoulder joints are similarly affected. The humoral diaphysis is short and curved with distal metaphyseal flaring. The radial heads and olecranons are dysplastic and the metacarpals are shortened. The proximal row of carpal bones is small. Otherwise, the hand bones are essentially normal. The bones of the lower extremities are less severely affected (2–4,19,20,22,25). Usually patients do not have internal anomalies, although in one patient, valvular aortic stenosis was noted (17).

On light microscopy, resting cartilage cells show lacunae containing clusters of five or more chondrocytes in some areas. The cartilage matrix is very fibrous. Horton and Scott (11) described clusters of degenerating chondrocytes. Electron microscopic studies revealed that the chondrocytes exhibit cisternae of rough endoplasmic reticulum and vesicles coated with a smooth, single-layered membrane (8). Biochemical analysis of cartilage showed increased glucosaminoglycans (8). The findings in Smith-McCort syndrome are similar (16).

Differential diagnosis. In contrast to *Morquio syndrome*, no mucopolysaccharidurias and no corneal clouding occur. Normal hearing and teeth, microcephaly, and mental retardation are characteristic. The skeletal changes are truly different in spite of somewhat similar appearance (e.g., the lacy iliac crest, the eventually normal bones of the hands). There may be resemblance to *spondyloepiphyseal dysplasia*.

Laboratory aids. Some investigators have found elevated chondroitin sulfate-*N*-acetylgalactosamine 6-sulfate sulfatase and reduced aryl sulfatase glycoprotein-AMP metabolism (7). The uptake of radioactive sulfate (22) or results from other proteoglycan degradation studies (3) were normal. The increased pipecolic acid levels (18) were not found in other cases (RCM Hennekam, unpublished observations). Reliable prenatal diagnosis is currently not possible.

Dyssegmental dysplasia, type Silverman-Handmaker

Apparently, the first illustrated report of this bone dysplasia, which was lethal at birth, was that of Simmonds (15) who, in 1901, was trying to illustrate the value of radiographic diagnosis.

Almost 70 years were to pass before the second case of anisospondylic micromelic dwarfism was described by Silverman (14). There have been about 20 examples published under various terms (1–10,12–17), another possible case being that of Maisonneuve et al (11). Gorlin and Langer (5) described the early history of the disorder. Prabhu et al (13) provide a review. Inheritance is autosomal recessive (2,4,10,13). A defect in the *PAX1* gene should be looked for.

Polyhydramnios has been noted in about 25% of cases. Birth weight is generally normal but birth length is reduced as a result of short spine and curved lower limbs. The infants are either stillborn (40%) or live only a few days, although there are exceptions (2,13). Hydrocephaly and occipital encephalocele have been reported (1,8). In a few cases there was a defect in the occipital bone (1,6). Other CNS anomalies are polymicrogyria (6), Dandy-Walker malformation and cerebellar hypoplasia (1), and arachnoid cyst (13).

The facies is somewhat unusual. There is mild blepharophimosis, flat nasal bridge, hypoplastic supraorbital ridges, and dysplastc ears. The mandible is small and the neck remarkably short (Fig. 7–51). Cleft palate is reported in about one-half of the cases (1,8,12,13–16).

The chest is narrow. Reduced joint mobility is a constant feature. The limbs are short and curved (microcampomelia) with talipes equinovarus (Fig. 7–51). The fingers may wedge and the thumbs may be adducted. Lumbosacral kyphosis may be marked. Hirsutism has been present in about 90% of the cases. Inguinal and/or umbilical hernia have been

Fig. 7–51. *Dyssegmental dysplasia, type Silverman-Handmaker.* Abbreviated limbs, overlapping fingers with cortical thumbs, flat nose, and hirsutism of lower legs. [From RJ Gorlin and LO Langer Jr, Birth Defects 14 (6B):193, 1978.]

reported (8). In the few cases that have come to autopsy, hydroureter and hydronephrosis have been observed in the more severe examples (1,4,7,8,17). Patent ductus has been found in several patients (1,4,7,8). A longer-surviving patient had subluxated lenses at 6 weeks of age, and showed minimal developmental progress at 8 months (13).

Radiographically, short trunk and narrow thorax are evident. The vertebral bodies are of variable size, thickness, and width (anisospondyly). Most vertebral bodies consist of two or more ossified masses separated by vertical radiolucent clefts in lateral view (Figs. 7–52 and 7–53). The iliac bones have decreased vertical dimension with hypoplasia of the horizontal and inferior margins, giving them a rounded shape. The acetabula are small in comparison to the wide proximal femora. The sacrosciatic notches are narrow and deep. There is severe symmetric shortening of all tubular bones with marked metaphyseal flaring and cupping. The long bones may appear to be somewhat folded upon themselves, particularly the ulnae (Fig. 7–52). The scapulae are small and rounded in comparison to the wide humeral metaphyses. The radius is disproportionately short. The first metacarpals are particularly abbreviated.

Microscopically, a disturbance in enchondral ossification is apparent, including a lack of columnization, ballooning of cartilage cells, mucoid degeneration of resting cartilage, and prominent large, unfused calcospherites in the growth plate and calcifying zones. There is accumulation of acid mucopolysaccharides and no increase in collagen fibers (Fig. 7–54) (6,7). The disorder may have a disturbance in formation of α 1-collagen chains (17).

Differential diagnosis includes *Kniest syndrome and Burton syndrome*. More disturbed chondrocyte columnization is seen in Kniest syndrome, but the same "Swiss cheese" cystic changes are observed. Prenatal diagnosis by ultrasound has been accomplished (2,8,8a,9).

Fig. 7–52. *Dyssegmental dysplasia, type Silverman-Handmaker.* Radiograph showing severe symmetric shortening of all tubular bones with marked metaphyseal flaring and cupping. The ulnae appear to be somewhat folded on themselves. The trunk is short and the thorax narrow. Vertebral bodies are of variable sizes, thickness, and width. The iliac bones have decreased vertical dimensions with hypoplasia of the horizontal and inferior margins, giving them a rounded shape. Acetabula are small in comparison to the wide proximal femora. The sacrosciatic notches are narrow and deep.

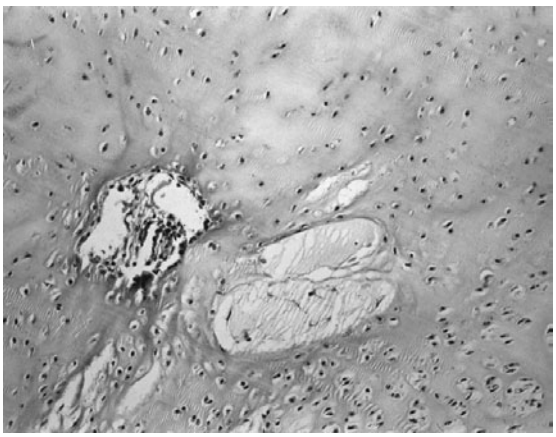
Dyssegmental dysplasia, type Rolland-Desbuquois

In 1972, Rolland et al (12) reported an infant with a short-limbed chondrodysplasia that resembled Kniest syndrome (Figs. 7–55 to 7–58). About 35 examples have been described by other authors (1–4,6). It is considered to be a mild form of dyssegmental dysplasia (1,3,8). The disorder is lethal in about 40% of patients, but many survive past infancy (7,9,10). Inheritance is autosomal recessive (1,3,12). All affected infants exhibit neonatal distress.

Fig. 7–54. *Dyssegmental dysplasia, type Silverman-Handmaker.* Puddle-like spaces in cartilage matrix.



A

B

Fig. 7–55. *Dyssegmental dysplasia, type Rolland-Desbuquois.* (A,B) Infant with hydrocephaly, occipital encephalocele, and short limbs. (From N Dinno et al, Eur J Pediatr 123:39, 1976.)

The facies is similar to that seen in dyssegmental dysplasia, type Silverman-Handmaker. The orbits are shallow. The face is round and flat with relative micrognathia. One infant manifested an occipital encephalocele (4), another an occipital defect (1), and two had hydrocephalus (4,6). One child had dislocated lenses (6), and two had glaucoma (8). Cleft palate has been found in most cases.

As in the Silverman-Handmaker type, there is microcampomelia, decreased joint mobility, narrow chest, and hirsutism. Hernia is noted in a few infants (1,6,12), but the radiologic changes are less severe. The long bones are short, broad, and bowed with some degree of metaphyseal widening. The pelvis appears essentially normal. Lateral spinal views demonstrate variability in size and shape of the vertebral bodies and prominent coronal clefting, but less than that seen in the Silverman-Handmaker type. There is accelerated carpal bone maturation (6). The ribs are short and flared (Figs. 7–56 to 7–58).

Chondroosseous morphology is characterized by patches of broad collagen fibers. The growth plate is normal but foamy Kniest-like changes may be observed in the resting cartilage cells. *COL2A1* mutations have not been found (8).

The disorder reported by Maroteaux et al (8) had Kniest-like features. Dyssegmental dysplasia, type Rolland-Desbuquois, should not be confused with the Larsen-like disorder that is referred to as "Desbuquois syndrome" (13). Desbuquois syndrome, which also has autosomal recessive inheritance, is characterized by short stature, flat midface, prominent eyes, short neck, narrow thorax, and joint laxity. Radiographic changes include osteoporosis, short long bones with broad metaphyses, prominent lesser trochanter, flat acetabular roof, advanced carpal and tarsal bone age, and supernumerary phalanges (2,5,13).

Ellis–van Creveld syndrome (chondroectodermal dysplasia)

Credit is given to Ellis and van Creveld (13) for describing the complete syndrome that bears their names and calling it "chondroectodermal dysplasia." The disorder, partially described in several earlier reports (1,4,28,33,52), consists of bilateral postaxial polydactyly of the hands, chondrodysplasia of long bones resulting in acromesomelic dwarfism, ectodermal dysplasia affecting nails and teeth, and congenital heart anomalies. The syndrome has autosomal recessive inheritance (25a,26,27,37). The gene is allelic with that of Weyers acrodental dysostosis (37a). Parental consanguinity has been confirmed in about 30% of cases (9,11,13,19,25a,29,37; RCM Hennekam, unpublished observations). Several authors have suggested that postaxial polydactyly may be a heterozygote manifestation of the syndrome (16,19,41), although this was not found in several other large pedigrees (9,25a,26). Ellis–van Creveld syndrome is the most common type of dwarfism among the Amish (25a,26). McKusick et al (25a,26) found 52 cases in 50 sibships among the Amish isolate of Lancaster County, Pennsylvania. The disorder has been reported in non-Amish populations as well (9,19,24). Birth prevalence has been estimated at 7/1,000,000 (42). There are about 300 reported cases.

The life expectancy is mainly determined by the congenital heart defect and the respiratory problems due to the thoracic cage deformity. The oldest living patient was 82 years of age (9). Nagai et al (30) reported a boy with symptoms fitting both Jeune syndrome (asphyxiating thoracic dysplasia) and Ellis–van Creveld syndrome. Polymeropoulos et al (34) have demonstrated linkage to chromosome 4p16. The gene, *EVC*, is a transcription factor having a leucine zipper (37a). Asphyxiating thoracic dystrophy and the short rib–polydactylies have been excluded from this region (24).

Facies. The facies is not especially characteristic except for a mild defect in the middle of the upper lip, which, although often present, is usually not striking. Some patients have been noted to have hypertelorism (9,43).

Skeletal anomalies. The extremities are often plump and markedly shortened progressively distalward, that is, from the trunk to the phalanges (Fig. 7–59). Bilateral postaxial hexadactyly is frequent (Fig. 7–60) and heptadactyly has also been noted (12). Frequently, the patient cannot make a tight fist. Less frequently there are extra toes (9,21,26,27). A wide space is often present between the hallux and the other toes (40). Genua valga (9,29), curvature of humerus, talipes equinovarus (9,47,49), talipes calcaneovalgus (11), and pectus carinatum with thoracic constriction (12,26,40) have also been reported.

Radiographically, the tubular bones are short and thickened. The diaphyseal ends of the humerus and the femur are plump. Shortening of the radius and ulna is even more marked than that of the humerus. The proximal end of the ulna and the distal end of the radius are unusually large, and the proximal end of the radius and the distal end of the ulna are unusually small (Fig. 7–61A,B). Duplication of the ulnar ossification center may be present in the first year of life (20). The widened end of the tibial shaft is irregular, and the ossification centers in the proximal epiphysis are hypoplastic (Fig. 7–61A,B). There is peaking of the proximal tibia, with a long lateral and a short medial slope, resulting in genua valga after the age of 6 years (26). The fibula is most severely shortened, being only about 50% of normal length (12). Syncarpalism (hamate and capitate), synmetacarpalism, and polymetacarpalism are frequent (5,9,21,26,29,31) (Fig. 7–61C,D). Cone-shaped epiphyses of the hands (type 37 of Giedion) are pathognomonic for the syndrome (18) (Fig. 7–61C).

In infancy, the pelvis is dysplastic with low iliac wings and hook-like downward projection of the medial acetabulum. The capital femoral epiphysis may ossify prematurely. In childhood, the pelvic shape normalizes. Histopathologic studies in three fetuses showed chondrocytic disorganization in the physeal growth zone, both in the long bones and vertebrae (36).

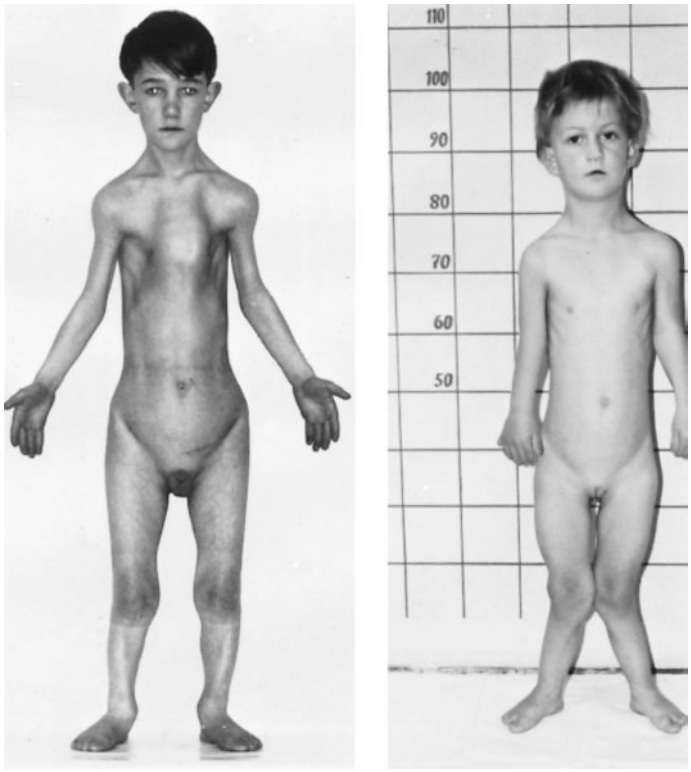

Fig. 7–59. *Ellis-van Creveld syndrome.* (A) Long thorax with pectus carinatum; mesomelia of lower extremities. (B) Compare phenotype with A. (A from GB Winter and M Geddes, Br Dent J 122:103, 1967. Fig. 7–60. *Ellis-van Creveld syndrome.* Digits are abbreviated, with hypoplastic nails. Note that digits have been amputated on ulnar side. (Courtesy of DH Altman, Miami, Florida.)

Fig. 7–61. *Ellis-van Creveld syndrome.* (A,B) Radiographs. Unusually large proximal end of ulna and distal end of radius, and unusually small proximal end of radius, as well as progressive shortening. The extra digit had been amputated shortly after birth. Also note peaking of proximal tibia. (C) Malformed middle phalanges with cone-shaped epiphysis of middle phalanx of fifth finger. Note extra finger on ulnar side, malformed fifth metacarpal, and capitate-hamate fusion. (D) Syncarpalism. (A,B courtesy of D Gutman and A Jungmann, Hadera, Israel. D courtesy of A Poznanski, Chicago, Illinois.)

Heart. Congenital heart defects are found in 50%–60% of patients (9,24), the most frequent defects being single atrium (40%) and endocardial cushion defect (14). Some patients have cor triloculare (29), atrioventricular canal (10,36), or even cor biloculare (40). Lynch et al (24) have reviewed the heart anomalies comprehensively.

Hair and nails. The hair, particularly the eyebrows and pubic hair, has been stated to be thin and sparse (13,21,26,29,50). However, RJ Gorlin has not been impressed that this is a feature. Nearly all patients have severe dystrophy of the fingernails, which are markedly hypoplastic, thin, and often wrinkled or spoon shaped (Fig. 7–60). Dermatoglyphic studies have shown an increased number of whorls (9).

Eyes. The eyes are usually normal, but esotropia (29) and congenital cataract (21,27) have been occasionally observed.

Genitourinary system. About one-third of male patients have genital anomalies. These anomalies have included cryptorchidism (13), mild epispadias (26,27), and hypospadias (26,48). Miscellaneous abnormalities of the urinary system have been reviewed by Rosemberg et al (37).

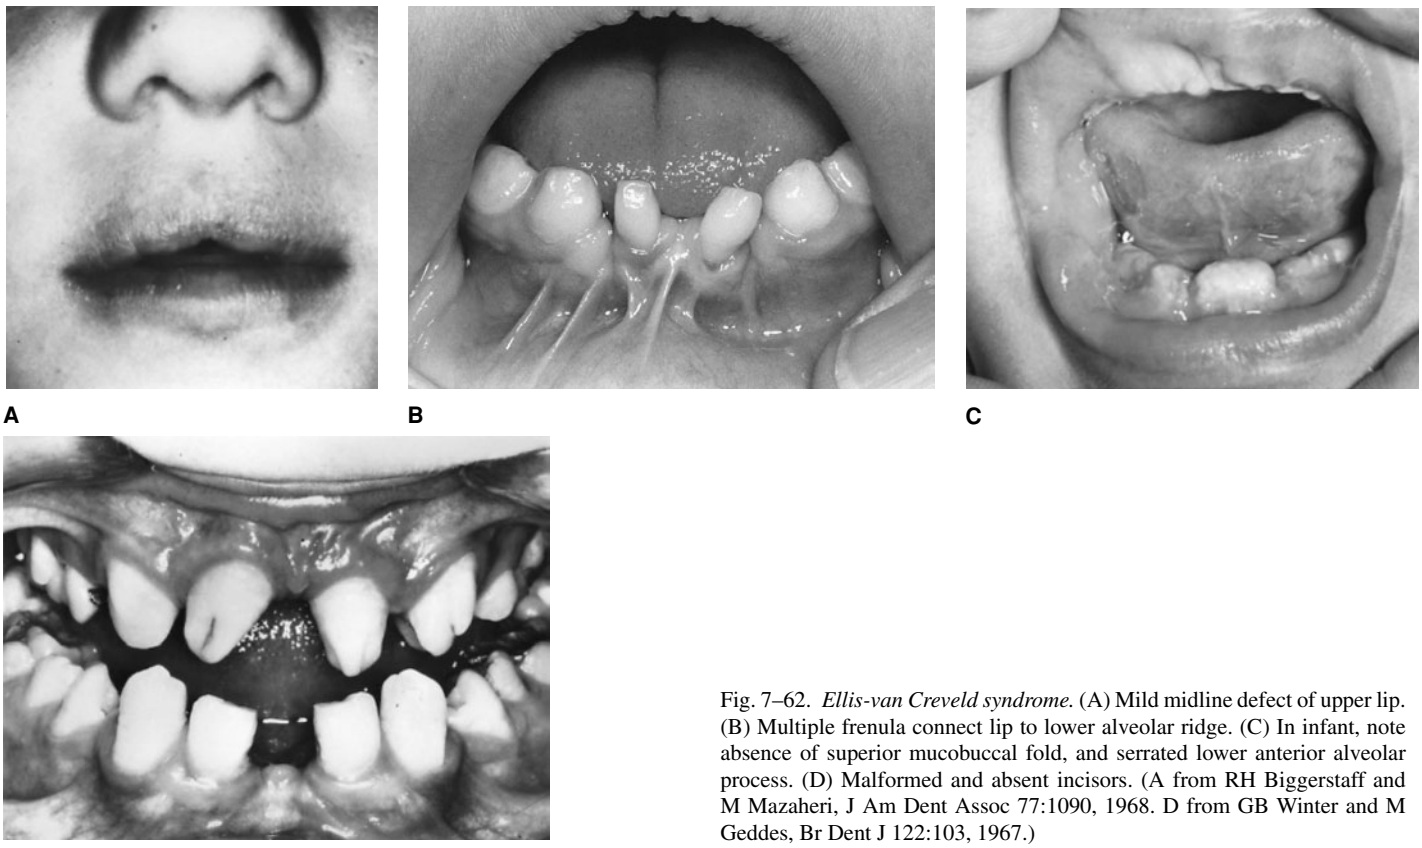

Fig. 7–62. *Ellis-van Creveld syndrome.* (A) Mild midline defect of upper lip. (B) Multiple frenula connect lip to lower alveolar ridge. (C) In infant, note absence of superior mucobuccal fold, and serrated lower anterior alveolar process. (D) Malformed and absent incisors. (A from RH Biggerstaff and M Mazaheri, J Am Dent Assoc 77:1090, 1968. D from GB Winter and M Geddes, Br Dent J 122:103, 1967.)

Central nervous system. Some patients are mentally retarded (32,48), but McKusick et al (26) have suggested that retardation is not an integral part of the disorder. Hydrocephaly has been noted is several instances (3,15). Other CNS anomalies have been reviewed by Rosemberg et al (37). Dandy-Walker malformation has been described (3,8,55).

Oral manifestations. The most striking and constant finding is fusion of the middle portion of the upper lip to the maxillary gingival margin so that no mucobuccal fold or sulcus is present anteriorly (2,9,11, 13,21,27,29,35,50). The middle portion of the upper lip appears to have a notch (2) (Fig. 7–62A). Natal teeth have been observed in at least 25% of patients and may be more frequent than reported. Congenitally missing teeth are also a constant finding, particularly in the mandibular anterior region (2,9,14,27,28,35,38,48) where the alveolar ridge is often serrated (2,11,13,40,47,54) (Fig. 7–62B,D). Notching of the lower alveolar process may represent continuation of the normal serrated condition of the gingiva from the third to the seventh month in utero (51) (Fig. 7–62C). Erupted teeth are usually small (2,27), have conical crowns, (2,9,12,13,28,53), and are irregularly spaced (2,13,14,28,53). Teeth that are not conical are somewhat bicuspid in form, with accentuated cuspal height and deep fissures (Fig. 7–62D). Supernumerary teeth have also been noted on occasion (21,35,38,53).

Differential diagnosis. It may be almost impossible to differentiate radiographically the Ellis-van Creveld syndrome from asphyxiating thoracic dystrophy (6,30,31). Patients may have identical changes in the hands, pelvis, and long bones. Differential diagnosis is based on the following clinical changes present in the Ellis-van Creveld syndrome: cardiac anomalies, nail hypoplasia, fusion of upper lip and gingiva, and, when present, neonatal teeth. Later in life, genua valga in Ellis-van Creveld syndrome and renal failure with hypertension in asphyxiating thoracic dystrophy help distinguish the two disorders.

The Ellis-van Creveld syndrome is differentiated from other chondrodystrophies such as achondroplasia, chondrodysplasia punctata, Morquio syndrome, and cartilage-hair dysplasia by its distinctive radiographic features. Fryns and Moerman (17) reported a newborn with an acromesomelic form of dwarfism that resembled the Ellis-van Creveld syndrome. Their case had in addition extensive vertebral segmentation defects.

Polydactyly and hypodontia or other dental anomalies have been seen in several generations without other apparent stigmata (46) and in association with acrodental dysostosis (Weyers) and trisomy 13. Postaxial polydactyly is also seen as a component of *Bardet-Biedl syndrome* (39). In combination with congenital heart defects and mucometrocolpos, the differentiation from McKusick-Kaufman syndrome may be difficult (54). An autosomal dominantly inherited disorder resembling both Ellis-van Creveld syndrome and *Weyers acrodental dysostosis* was mapped to chromosome 4p16. It was independently shown that Weyers acrodental dysostosis represents the heterozygous expression of the gene causing Ellis-van Creveld syndrome (22,37a).

Partial fusion of the upper lip as a result of hyperplastic frenula is seen in the *oro-facial-digital syndromes*. Natal teeth are observed in *pachyonychia congenita* and *Hallermann-Streiff syndrome*. Natal teeth may also occur alone and may, in some instances, be familial (23,44).

Laboratory aids. The disorder has been diagnosed prenatally by ultrasound and fetoscopy (7,15,25).

Fibrochondrogenesis

In 1978 and 1979, Lazzaroni-Fossati (8,9) described a neonatal lethal form of short-limb dwarfism, abnormally developed vertebrae, and abnormal facial appearance (Figs. 7–63 to 7–65). Nine additional examples have been reported (1–6,10,12). Inheritance is clearly autosomal recessive (1,2,8,12). Al-Gazali et al (1) provide an excellent review.

The face is round and flat with prominent eyes and anteverted nares. The mouth is often small. Cleft palate has been present in two patients (8,9,11) and in one case a severe micrognathia and bifid tongue were found (6). There is a narrow chest, moderately severe micromelia, and markedly enlarged joints. The head and trunk are proportionate. One patient had omphalocele.

Radiographically, the skull is relatively large with a large anterior fontanelle and hypoplastic facial bones. The clavicles are long and thin, the scapulae small. The ribs are short with wide, cupped anterior ends. The tubular bones are short and dumbbell shaped with metaphyseal flare and peripheral spurs. The vertebral bodies are flattened and project a diagnostic pear-shaped silhouette on lateral view. Two cases had ectopic extra-articular calcifications (1,5).

The ilia are small with narrow sacrosciatic notches and a medial acetabular spike. The ischia and pubic bones are short and relatively broad and the fibulae are short.

Fig. 7–63. *Fibrochondrogenesis.* Note round face, protuberant eyes, flat nasal root, anteverted nares, short neck, rhizomelic shortening of limbs, proportionate head, and trunk length. (From CB Whitley et al, Am J Med Genet 19:265, 1984.)

Fig. 7–64. *Fibrochondrogenesis.* Short ribs with flared and cupped anterior ends, small scapular bodies, platyspondyly, sagittal cleft in upper and mid-thoracic bodies, and small iliac bones with narrow sacrosciatic notches. Long tubular bones are short and broad with metaphyseal spurs. Proximal and distal ends of humeri and proximal ends of femora and tibiae are convex. (From CB Whitley et al, Am J Med Genet 19:265, 1984.)

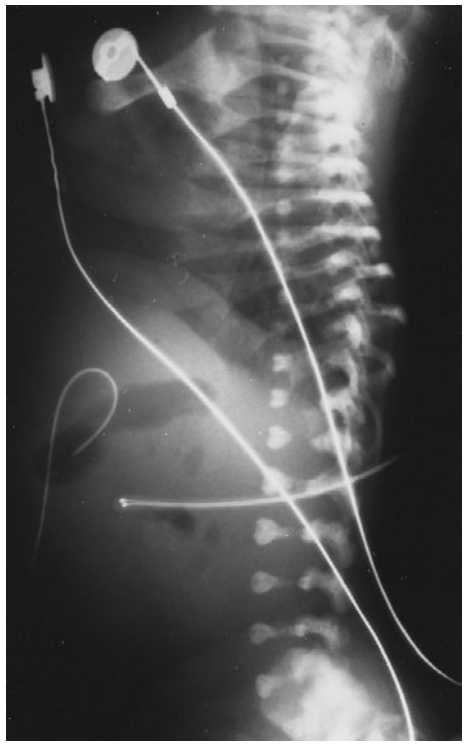

Fig. 7–65. *Fibrochondrogenesis.* Lateral spine showing pear-shaped silhouette due to ossification of only upper and mid-thoracic bodies. (From CB Whitley et al, Am J Med Genet 19:265, 1984.)

Cartilage histopathology is distinctive (6,10,12) (Fig. 7–66). The growth plate is disorganized with fibroblastic dysplasia of chondrocytes that are often clustered two to four cells per lacuna. Characteristic extracellular densely fibrous collagenic septa are evident. Ultrastructural studies show a paucity of endoplasmic reticulum in chondrocytes.

Fibrochondrogenesis should be differentiated from other perinatally lethal bone dysplasias, especially *Schneckenbecken dysplasia* and *Raine syndrome* (7). The latter syndrome has a similar external appearance, but radiologically shows a generalized sclerosis of long bones, ribs, and cranial base.

Prenatal diagnosis has been accomplished ultrasonographically (11).

Fig. 7–66. *Fibrochondrogenesis.* Columnar alignment of hypertrophic cells is distorted. Resting cartilage is composed of hypercellular, often spindle-shaped cells with hyperchromatic nuclei. (From CB Whitley et al, Am J Med Genet 19:265, 1984.)

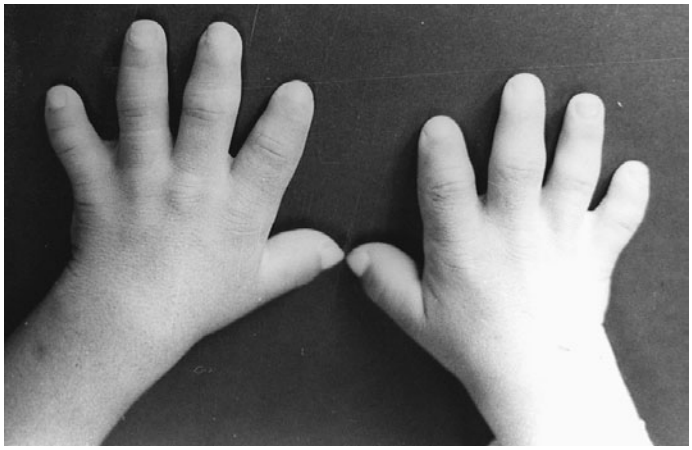
Geleophysic dysplasia

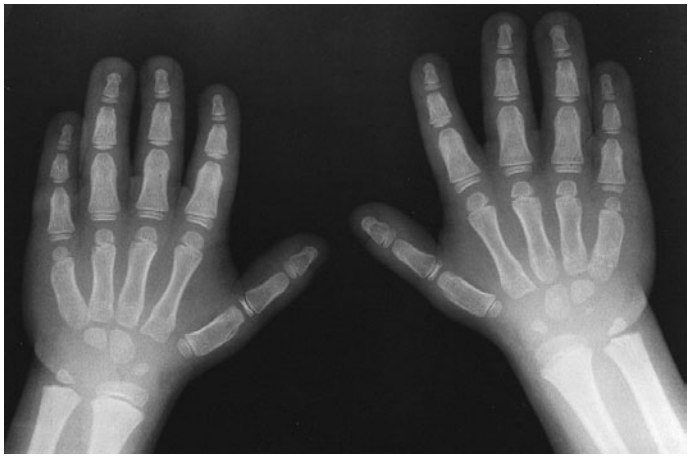
In 1971, Spranger et al (13) reported a skeletal disorder characterized by a happy-natured (geleophysic) face, short stature, and short hands and feet (Figs. 7–67 to 7–69). An early example is that of Vanace et al (17). At least 25 additional cases have been reported (4–12,14,16–18; RCM Hennekam, unpublished observation). Children with similar findings but with an unhappy face have also been noted (11,15). Inheritance is autosomal recessive (4,8,10,12,14,16). Shohat et al (12) found lysosomal vacuoles in skin epithelial cells and postulated a lysosomal storage disease. Death has occurred in several children under the age of 5 years (14,17).

Fig. 7–68. *Geleophysic dysplasia.* (A,B) Up-slanting palpebral fissures, full cheeks, long philtrum, and thin vermilion of upper lip resulting in pleasant facies. (A,B from JW Spranger et al, Am J Med Genet 19:489, 1984.)

A B



A



B

Fig. 7–69. *Geleophysic dysplasia.* (A) Brachydactyly. Note decreased finger extension. (B) Radiograph showing somewhat short and plump tubular bones. Shafts of first and fifth metacarpals and proximal and middle phalanges are widened. (A from CP Koiffmann et al, Am J Med Genet 19:483, 1984. B from JW Spranger et al, Am J Med Genet 19:489, 1984.)

The facies is indeed pleasant. The palpebral fissures are narrow and upward slanting, the cheeks full, and the philtrum long and flat. There is thin vermilion of the upper lip that, in most cases, is upturned. The mouth may be wide, and the neck is somewhat short (Fig. 7–68).

Height is usually far below the third centile, but a few authors have reported normal stature (8,11). The arms are somewhat short (Fig. 7–69A). There is joint limitation at the elbows, hips, and knees and decreased finger extension. All manifest a tiptoe gait as a result of pes equinovarus.

Progressive thickening of cardiac valves (70%) usually starts in late infancy or in childhood. Hepatomegaly and a thickened doughy skin are also characteristic (14). Tracheal narrowing has occurred in three cases (12,14,16).

Radiographically, tubular bones are somewhat short and plump, capital femoral epiphyses are short and irregular, and shafts of the first and fifth metacarpals and proximal and middle phalanges are widened (Fig. 7–69B). One patient developed Perthes disease (10).

Light microscopically, on iliac crest biopsy, the ground substance showed a reduction in mucopolysaccharides and incomplete modeling of the growth plate (8). Transmission electron microscopy showed numerous lysosomal-like storage vacuoles, several of which contained lamellar structures. These vacuoles were also found in skin fibroblasts (8,12). Metabolic studies have repeatedly given normal results.

Motor (4,12,14,17) and speech (4,10,13) delay are common. Late in infancy, recurrent respiratory and middle ear infections (50%) become more frequent. The liver is nearly always enlarged, with the hepatocytes having a vacuolated cytoplasm. There are umbilical and inguinal hernias (14). Death may result from infiltration of the mitral and aortic valves with an abnormal glycoprotein (14).

Prenatal diagnosis may be difficult, as limb shortening is sonographically detectable only after 28 weeks of gestation (9,10).

Acromicric dysplasia should be excluded from the diagnosis. In geleophysic dysplasia, the facial appearance is different. The liver is usually enlarged with some type of storage material (5,8,12,14,18), there is progressive thickening of heart valves with poor prognosis, and inheritance is autosomal recessive (2,5,10). Figuera (1,7) pointed to resemblance with Myhre syndrome and Hennekam et al (2) to similarity with Moore-Federman syndrome. Hopkin et al (3) described three unrelated cases with short stature, joint hypomobility, and short hands and feet, who facially resembled geleophysic dysplasia, but who had severe laryngeotracheal stenosis and no cardiac or hepatic enlargement.

Kniest dysplasia (metatropic dysplasia, type II)

The disorder described by Kniest (11) in 1952 is a form of generalized spondyloepimetaphyseal bone dysplasia with disproportionate dwarfism. Most patients have been isolated examples but several authors (7,10,15,16) have noted the disorder in two generations. Identical twins have been described (27). A lethal variant (30) and an autosomal recessive Kniest-like syndrome have been reported (26). Poole et al (22) demonstrated that the C-propeptide is missing in type II collagen. Indeed, *COL2A1* gene mutations were found in patients with Kniest syndrome

A B C

Fig. 7–70. *Kniest dysplasia.* (A,B) Five-year-old girl with flat midface, myopia, and cleft palate. At birth, legs were noted to be abnormally short and hips were stiff. Umbilical and inguinal hernia were repaired. (C) Six-year-old with short stature, protruding sternum, and large joints. Hips and knees flexed due to contractures. Note more severely affected face than in A. Patient also had myopia and cleft palate. (Courtesy of J Spranger, Mainz, Germany.)

(34,35). Collagen type II is a molecule that forms trimeric fibrils and has a large, central triple-helical domain. The gene is located at chromosome 12q13–14. Most cases of Kniest dysplasia are caused by small deletions in the *COL2A1* gene, especially in exon 12 (4,33,36). This causes incorporation of shortened chains into the fibrils and, therefore, malalignment of cross-linking sites. Mutations in the *COL2A1* gene may cause a spectrum of phenotypes, varying from achondrogenesis to Stickler syndrome (4). Mosaicism for a dominantly acting mutation may manifest as Stickler syndrome or mild spondyloepiphyseal dysplasia (31), which may be important for counseling parents of a child with Kniest dysplasia. An excellent review of the molecular findings is that of Faber et al (2a).

Several authors (14,15) have confused the condition with metatropic dysplasia, type I. Spranger et al (32) gave a historical view, a follow-up of the original patient, and described the molecular defect in that patient.

Facies. The face is round, the midface is flat, and the nasal bridge depressed, giving the eyes a somewhat exophthalmic appearance (Fig. 7–70). The nostrils may be anteverted. The neck is usually short. The head appears to sit on the thorax. Severe myopia and lattice degeneration with or without retinal detachment and/or cataract formation have been present in about 40% of cases, as has cleft palate (2,10,25,28). A large series was studied by Maumenee and Traboulsi (17). Mawn et al (18) reviewed all skeletal dysplasias that manifest congenital glaucoma. Conduction and/or sensorineural hearing loss, a frequent finding, may develop before puberty. Recurrent otitis media and respiratory infections are common.

Musculoskeletal alterations. At birth, cleft palate, clubfoot, and prominent knees may be noted (2,5,21,28,29). Lordosis, dorsal kyphosis, and tibial bowing usually develop within the first few years of life. The child may not sit and walk until ages 2 and 3, respectively. By that time, most joints become progressively enlarged and stiff. The gait is waddling. Movement at the metacarpophalangeal joint is normal, but the child cannot make a fist. The fifth fingers are generally not involved. The palms may have a violaceous hue. The elbows, wrists, and knees become particularly enlarged, and flexion and extension of most joints become progressively reduced. The feet are flat and turned out. Hernia is frequent. Adult height ranges between 105 and 145 cm.

Radiographically, the neurocranium is large in comparison with the facial skeleton. The anterior fontanel is late to close. The cranial base angle is flattened and the sella turcica is anteriorly displaced. The odontoid is short and wide (5,10,27). Occipitoatlantal instability may occur (19). Platyspondyly, particularly of the upper thoracic part of the spine, is severe. The vertebrae exhibit vertical clefts. The long bones are somewhat short, slightly bowed, and have flared metaphyses. The epiphyses are large (20), irregular, and punctate. The hands show epiphyseal and carpal retardation with generalized osteopenia. Later, the carpal bones assume bizarre shapes and sizes. The iliac bones are small, particularly in relation to the large capital femoral epiphysis and proximal femoral metaphysis. The pubic rami are poorly ossified. The femoral capital epiphysis forms late, the neck is wide and short with a poorly osssified central area, and there may be coxa vara. The trochanter is prominent (12,13) (Fig. 7–71).

Histopathologic examination of the bones has shown that the soft, crumbly cartilage contains large chondrocytes that lie in a very loosely woven matrix containing numerous empty spaces ("Swiss cheese cartilage") (Fig. 7–72) (2,3,6,23,24). Ultrastructural studies of cartilage cells have shown dilated cisternae of endoplastic reticulum, a finding noted in other skeletal dysplasias. Vacuolar degeneration of extralacunar matrix is found in the area of the resting cartilage adjacent to the growth plate (8). The collagen fibrils are fragmented and disintegrated, resulting in a web-like pattern and large, open, cyst-like spaces (6).

In differential diagnosis, *dyssegmental dysplasia, type Rolland-Desbuquois, spondyloepiphyseal dysplasia congenita,* and *Burton syndrome* should be excluded. Type II collagenopathies include achondrogenesis, type II, hypochondrogenesis, spondyloepiphyseal dysplasia congenita, Kniest dysplasia, Stickler syndrome, spondylometaphyseal dysplasia of the Strudwick type, and AD spondyloarthropathy. The nature of the mutations and their location determine the phenotypic differences. Premature stop codons leading to less type II collagen are milder, whereas point mutations that involve folding and mutations near the carboxy-terminal end result in severe phenotypes (4).

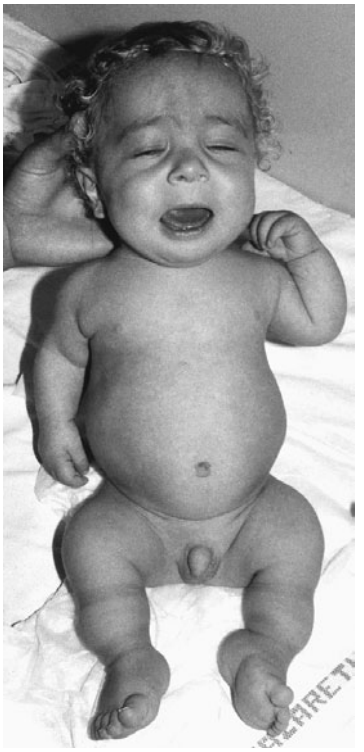

Fig. 7–73. *Kyphomelic dysplasia.* Note long philtrum, small chin, small limbs and trunk, and bowed femora. (From PD Turnpenny et al, J Med Genet 27:269, 1990.)

Kyphomelic dysplasia

Kyphomelic dysplasia was first described by Hall and Spranger (5) and Khajavi et al (7) in 1975–76 as a variant of campomelic dysplasia. In 1983, Maclean et al (9) recognized it to be a distinct entity and proposed the name "kyphomelic dysplasia" (the Greek word "kyphos" means bent forward). Fourteen patients are known (1–5,7,9,10,13,15–18; RCM Hennekam, unpublished observation). Because of four affected sib pairs (1,3,13,15) and no vertical transmission, autosomal recessive inheritance is likely. However, there is a 10 M:1 F sex predilection. An adult has been reported (13a). In one family, a mother had brachydactyly type E (1). Chromosomes have been normal. A type I collagen defect has been found (N. Robin, personal communication, 2000).

The patients have normal intelligence. The major findings are generalized shortness of both the limbs and trunk, normal head size, hypoplastic midface, long philtrum, cleft palate (15%), and short chin (Fig. 7–73). The chest is small and narrow, and most patients have restricted joint mobility. The hands and feet are normal, although clinodactyly has been described. Skin dimples are present over the bony prominences such as the greater trochanters.

Radiographically, all patients have very short femora with marked bowing and metaphyseal flaring (Fig. 7–74). Other frequent findings are short, flared ribs (100%), mild bowing of humeri, tibiae, and radii (75%), and platyspondyly (50%). Increased acetabular angles, Perthes-like changes (10,13), 11 pair of ribs (20%), and underossification of proximal tibial epiphyses are less common. The limb bowing and other radiographic features tend to improve with age. There is considerable variability in features (2).

One patient died because of pure red cell aplasia (17), one patient had severe combined immune deficiency (3), and another developed aplastic anemia and late-onset severe combined immune deficiency (RCM Hennekam, unpublished observation).

Prenatal diagnosis has been accomplished (1). Kyphomelic dysplasia can be readily distinguished from *campomelic dysplasia* by the extraskeletal manifestations, mental retardation, ambiguous genitalia, and severe tibial bowing and hypoplastic scapulae in the latter. The differentiation from *femoral hypoplasia-unusual facies syndrome* can be difficult (14), the hypoplasia of the femora being the most important difference. Several single case reports are available describing patients with related entities (6,8,11). *Antley-Bixler syndrome* and Stüve-Wiedemann

Fig. 7–74. *Kyphomelic dysplasia.* Radiograph showing severely bowed femora, unossification of proximal tibiae, and increased acetabular angles. [From D Viljoen and P Beighton, Dysmorphol Clin Genet 1(4):136, 1988.]

dysplasia should be excluded. A benign form of angulation of long bones associated with shortening of soft tissues was reported by Nakamura et al (12) in sibs.

Lethal short-limbed dysplasias

There are a great number of rare types of lethal short-limbed dysplasias. They may be grouped into platyspondylic types, short-rib types, fragmented bones types, osteosclerotic types, and a miscellaneous group (Table 7–8). The conditions should be distinguished from achondrogenesis, hypophosphatasia, fibrochondrogenesis, atelosteogenesis, thanatophoric dysplasia, boomerang dysplasia, Caffey-Silverman dysplasia prenatal type, de la Chapelle dysplasia, Piepkorn dysplasia (73,91), and Schneckenbecken dysplasia. Prenatal diagnosis has been accomplished for most entities (14,25,26,28,37,70,88,98).

Table 7–8. Perinatally lethal short-limbed skeletal dysplasias

Entity	McKusick no.	Inheritance
With platyspondyly		
Torrance type	151210	Sporadic
San Diego type	270230	Sporadic
Calgary type	—	Sporadic

Holmgren-Connor dysplasia	273680	AR

[a] Asphyxiating thoracic dysplasia (Jeune syndrome) and Ellis-Van Creveld syndrome are also characterized by short ribs, but are not tabulated here as they are not universally perinatally lethal.

[b] We object to naming a condition in humans after a character in videogames (Pacman dysplasia).

Lethal short-limbed dysplasia with platyspondyly. This is a heterogeneous group of lethal spondyloepimetaphyseal dysplasias, all characterized by expressed platyspondyly, varying involvement of epiphyses and metaphyses, and different histology. This naming is according to geographic location of the first authors, except for fibrochondrogenesis. The Shiraz type and fibrochondrogenesis are autosomal recessive; all other cases have been sporadic. The sporadic cases are probably autosomal dominant and lethal (69a).

Torrance type. Horton et al (45) described a single patient with a narrow thorax and protuberant abdomen—there were no additional clinical data—and Nishimura et al (68) and Van der Harten et al (92) described still other patients. The radiographic data were similar to those found in thanatophoric dysplasia, including short ribs and short tubular bones, but with diminished ossification of the cranial base, more extreme hypoplasia of vertebral bodies (disclike), wider sacrosciatic notches, and wider, more tubular-formed long bones showing metaphyseal enlargement and cupping. There was no proximal tibial hypoplasia or disproportionate widening of the fibula, as found in thanatophoric dysplasia.

Histologic analysis showed a relatively normal growth plate but with abnormal incorporation of degenerating chondrocytes in metaphyseal bone (92). The resting cartilage appeared hypercellular. Protein studies showed overmodification of type II collagen (35), but no mutations were found, so this finding may be a secondary effect.

San Diego type. The clinical features and radiographic changes of this variant were reported to be not distinguishable from those in Torrance type (45). The single reported case was identified because of

the histologic features: the growth plate was abnormal in poor column formation and there was a lack of ingrowth of chondrocytes in metaphyseal bone. The resting cartilage showed normal cellularity, although cells were larger than normal (92). This disorder is caused by mutations in *FGFR3* (13a).

Calgary type. A single case with another platyspondylic form of short-limbed dwarfism was described as having bilateral cleft lip and palate, normal trunk, small chest, rhizomelic shortening of limbs, and small hands and feet (74). There were no internal anomalies detected. Radiologically, there was osteopenia of tubular bones and pelvis, platyspondyly, short ribs, broad clavicles, hypoplastic scapulae, flared irregular metaphyses, and shortened, angulated diaphyses. Histologic changes were found both in growth plate, bone, and resting cartilage, suggesting involvement of both chondrocytes and osteoblasts.

Luton type. Winter and Thompson (97) described yet another type in a single case. The clinical features were hydramnios, low birth weight, macrocephaly, midface hypoplasia, slightly bifid nasal tip, intact palate, severe shortening of all limbs with extremely short, stubby, and tapering fingers, small chest, and protuberant abdomen. Visceral anomalies were confined to a dilated hypertrophied bladder; the brain was normal. Radiographic findings for the spine resembled those for the Torrance and San Diego types, but the long bones were less abnormal, showing shortening and splayed metaphyses. There was suggestion of spur formation especially of the femur and humerus. The pelvis was small and had flat acetabular roofs, round iliac bones, but no narrow sacrosciatic notches.

Histologically, the growth plate showed regular columns but with focal disorganization and ingrowth of degenerating chondrocytes in the newly formed bone. Some poorly organized fibrovascular tissue was seen intervening between resting cartilage and bone. The resting cartilage was hypercellular, with large ballooned chondrocytes, the ground substance showed patchy lobulation.

Yamagata type. Akaba et al (1a) described a case with frontal bossing, cloudy corneae, low nasal bridge, small thorax, and rhizomelic micromelia. The patient also had hypoplastic callosal body and larynx stenosis. Radiographic findings included extremely severe platyspondyly, short skull base, hypoplastic ilia, Madelung-like deformities, and delayed epiphyseal ossification.

Perth type. Goldblatt and Knowles (38) gave a detailed description of another sporadic case. Unusual clinical features were hydrocephaly, craniosynostosis of lambdoid and sagittal sutures, and unilateral cystic renal dysplasia. The radiographs resembled those of the other platyspondylic short-limbed dwarfisms, except for localized expansion at the angles. The resting cartilage was hypercellular and extensively vascularized. The columnization was poor, but chondrocytes were of good size.

Shiraz type. Sedaghatian (80) described two children from an Iranian family in which probably other cases had been born. Six other examples were reported (15,29,71,72). Autosomal recessive inheritance is likely. Clinical features are postnatal rhythm disturbances, hypotonia, and neonatal death. In one case, hyperphosphatemia was found. Facial features are not remarkable, except for posteriorly angulated or low-set ears. All limbs show rhizomelic shortness. In one case, clubfeet were present (71). Internal anomalies have been atrial septal defect (72), porencephaly (29), and partial lissencephaly (71). Radiologic changes include moderate platyspondyly, metaphyseal cupping, flaring, and irregularity of long and short tubular bones, disproportionately long fibula, and delayed ossification. The iliac crests are lace-like with sclerosis. Histologic studies show a long hypertrophic zone with dense hypertrophic cells and little intervening matrix (15,71,72). The hypertrophic cells often extend into the metaphysis. The chondroosseous morphology somewhat resembles that found in hypophosphatasia, but alkaline phosphatase levels have been normal.

Fig. 7–75. *Short rib-polydactyly syndrome*, *type I* (*Saldino-Noonan*). Note micromelia, narrow chest, protuberant abdomen, and postaxial polydactyly. The forehead is prominent and the nose is wide with low nasal bridge; the nostrils are anteverted. (From M Richardson et al, J Pediatr 91:467, 1977.)

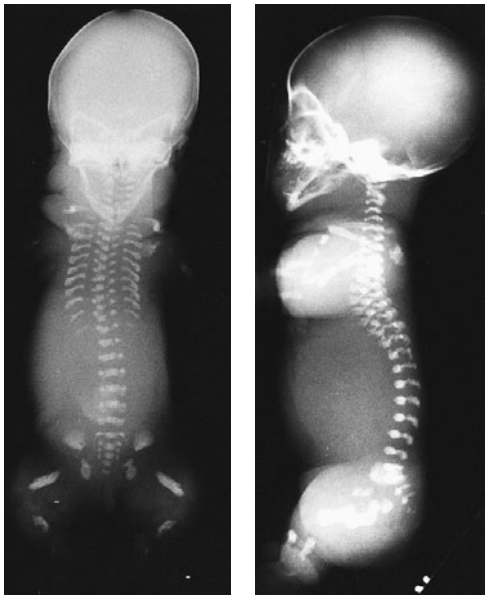
Short-rib syndromes. Although these syndromes have been separated into specific entities, there is evidence of some degree of a continuous phenotypic spectrum (11a).

Type I (Saldino-Noonan type). In 1972, Saldino and Noonan (79) first reported a short-rib syndrome clinically characterized by severe micromelia, narrow chest, protuberant abdomen, and postaxial polydactyly (Fig. 7–75). Radiographs showed very short ribs, small pelvic bones, square-shaped vertebral bodies, hypoplastic cervical spine, markedly shortened long tubular bones with pointed ends, notched tibiae, absent fibulae, and generalized underossification (Fig. 7–76). Reports of several additional patients have been published (9,27,39,77–79,83–87). It may represent a continuous spectrum (79a).

Prenatally, there is oligohydramnios or polyhydramnios, and hydrops. Cleft lip or palate has been reported (39,78), the tongue may be cleft, and the alveolar ridges are furrowed (79). The polydactyly (six or seven digits are frequently found) is postaxial, usually asymmetric, and more often on the hands. It is often accompanied by cutaneous syndactyly. Visceral anomalies include hypoplastic lungs and atresia of esophagus, duodenum, and anus. The intestines are short and malrotated. Various heart anomalies have been documented (transposition of great vessels, VSD, double-outlet left ventricle, endocardial cushion defect, persistence of left superior vena cava) (27). The kidneys may be absent, dysplastic, or cystic, and the ureters and bladder may be hypoplastic. The urethrovaginal opening is small, the uterus is absent or double. Several males with 46,XY karyotype had ambiguous genitalia (9,87). Other anomalies include agenesis of the gallbladder and fibrosis of the pancreas (9,77,78). Histological findings are available (83,84).

Inheritance is autosomal recessive, but all severely affected cases are clinically female, which is due at least in part to failure of secondary sexual differentiation (85). Affected sibs have been described (39,77,78), with marked concordance in radiological features.

Type II (Majewski type). In 1971, Majewski et al (60) described four newborns with a short rib–polydactyly syndrome and added 13 nearly identical cases from the nineteenth century literature. After delineation of the short rib syndrome type I by Saldino and Noonan (79), Spranger



A B

Fig. 7–76. *Short rib-polydactyly syndrome, type I (Saldino-Noonan).* (A,B) The ribs are remarkably short, the ilia abnormally contoured, the femora peg shaped, the tibiae notched, and the vertebral bodies small and flattened. (Courtesy of AL Baudet, Houston, Texas.)

et al (87) concluded that only case 1 of Majewski et al had the short rib syndrome type II, and added one case of their own. The other three cases described by Majewski et al (60) had, in fact, type I. About 40 examples have been described (8,17,24,60,64,65,69,81,85,87,90). Several other possible cases from older literature have been summarized (60,87). The characteristics of type II are hydrops fetalis, short and narrow thorax, protuberant abdomen, short limbs, and pre- and postaxial polysyndactyly (Figs. 7–77 to 7–80). Inheritance is autosomal recessive (17,87). Urioste et al (90) described pericentric inversion of chromosome 4. The cause is unknown, although the resemblance with the severe form of Smith-Lemli-Opitz syndrome and hydrolethalus syndrome warrants studies of cholesterol metabolism. Prenatal diagnosis has been accomplished several times.

Fig. 7–77. *Short rib-polydactyly syndrome*, *type II* (*Majewski*). (A,B) Affected sibs. Note midline cleft of upper lip, short limbs, narrow chest, and polysyndactyly. (From T Motegi et al, Hum Genet 49:269, 1979.)

A B

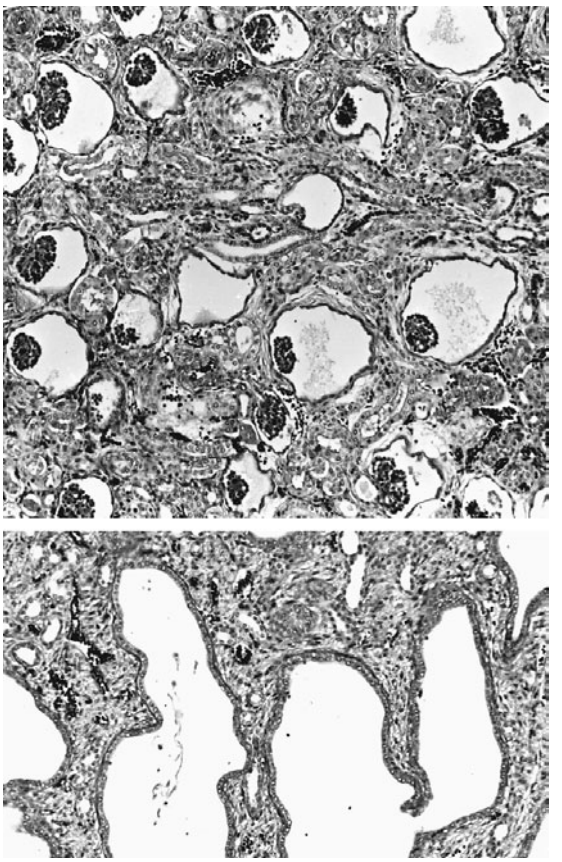
Fig. 7–78. *Short rib-polydactyly syndrome*, *type II* (*Majewski*). (A,B) Median cleft lip and somewhat malformed pinnae. (Courtesy of JS Fitzsimmons, J Med Genet 19:141, 1982.)

Usually there is polyhydramnios. The infants are either stillborn or die shortly after birth. Some may have hydrocephaly (81), cebocephaly (69), deep-set eyes, notching of the mid-upper lip, cleft lip and palate (8,17,60,81,85,87), bifid or trifid tongue (8,60,64,90), ankyloglossia (60,69,85), notched gingiva (24), natal teeth (24,64), and somewhat malformed pinnae (69,81). The epiglottis, larynx, and lungs are hypoplastic. Several cases had intestinal malrotation, fibrocystic pancreas, enlarged

Fig. 7–79. *Short rib-polydactyly syndrome, type II* (*Majewski*). Cortex (top) and medulla (bottom) of kidney showing multiple glomerular cysts and focal cystic dilatation of distal tubules. (From T Motegi et al, Hum Genet 49:269, 1979.)



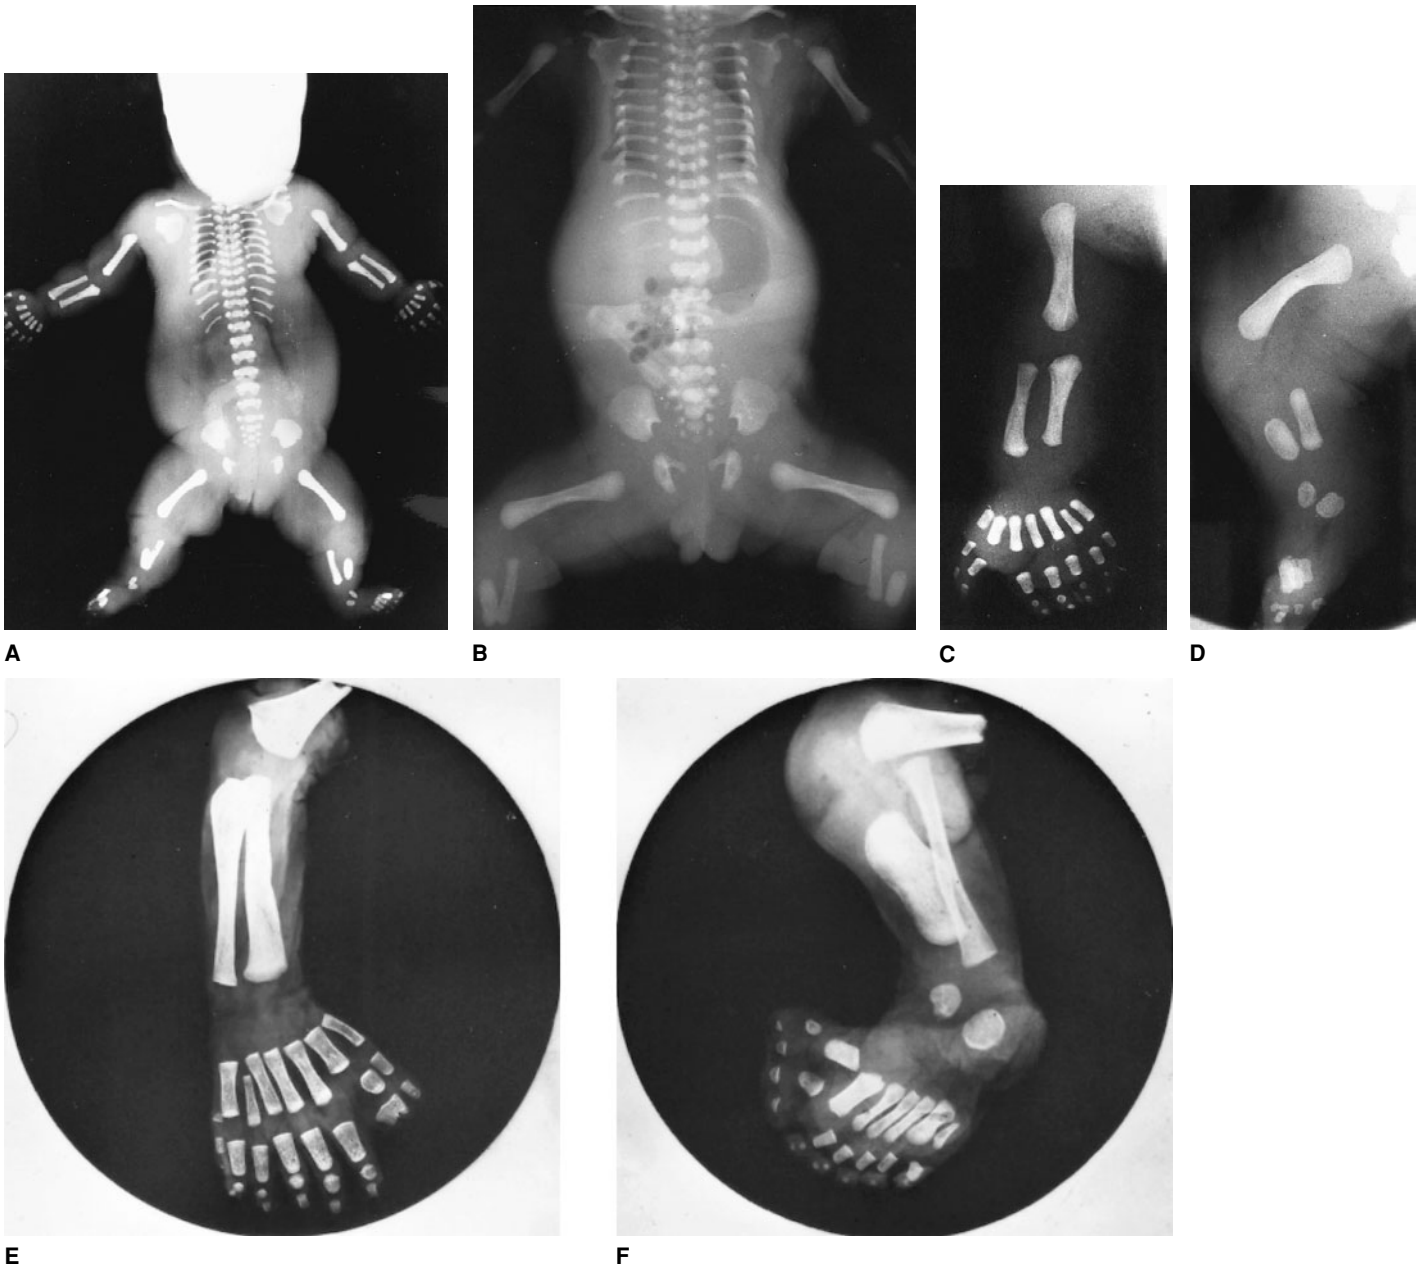


Fig. 7–80. *Short rib-polydactyly syndrome, type II* (*Majewski*). (A) Micromelia. (B) Short ribs, normal pelvis, and very abbreviated tibiae. (C) Shortened humerus, radius and ulna, and pre- and postaxial polydactyly. (D) Shortened femur and lower leg bones, particularly the tibia. (E,F) Compare with C and D. (B,C,D, courtesy of H Jorulf, Uppsala, Sweden. E,F from E Pitschi, Thesis, Zürich, 1904–1905.)

portal areas in the liver, and imperforate anus. Cardiac anomalies include persistent superior vena cava, truncus arteriosus, total anomalous pulmonary venous return, ASD, tetralogy of Fallot, and coarctation of aorta. Genitourinary anomalies include small or absent urogenital opening, hypospadias, micropenis, ambiguous genitalia, cryptorchidism, septate or hypoplastic uterus, and septate or rudimentary vagina. The kidneys are hypoplastic with multiple glomerular cysts and focal dilatation of distal tubules. Shortening of the limbs is mesomelic, especially the lower limbs. The degree of polysyndactyly is extremely variable, with up to nine digits per extremity.

Radiographs show very short horizontal ribs, preaxial and postaxial polydactyly, and short oval tibiae. The ilia appear to be essentially normal, and the vertebral bodies are square shaped and somewhat hypoplastic, especially in the thoracic and cervical spine. Ossification of the proximal epiphyses of the humeri and femora is premature, and sternal bone age may be advanced. The middle and distal phalanges are poorly ossified. In two unrelated cases, an occipital bone defect was found, as in hydrolethalus syndrome (81).

Type III (Verma-Naumoff type). Yet another lethal autosomal recessively inherited short rib syndrome was suggested by Verma et al (94) and Naumoff et al (67). Over 30 examples have been published (1b,7,9,11,26,42,52,58,67,84,85,94,98). Types I and III have many clinical and radiographic features in common and are differentiated by the configuration of the end of long bones and less severe changes in the ilia. Several authors have expressed doubts regarding the separation of the two types (9,40,84,85) and have suggested that they are allelic disorders, but other investigators (98) have rejected this fusion. Biochemical or molecular studies will have to settle this. Ho et al (43a) have further suggested that Jeune asphyxiating thoracic dystrophy is a variant.

The external clinical features in type III are indistinguishable from those in type I (Fig. 7–81). Polydactyly is an inconsistent feature and is

A B

Fig. 7–81. *Short rib-polydactyly syndrome, type III* (*Naumoff*). (A) Clinical phenotype strikingly similar to type I (Majewski). (B) Changes in ilia and long bones are less severe than in type I. (From R Bernstein et al, J Med Genet 22:46, 1985.)

often asymmetric. Visceral anomalies are often less extensive in type III; cardiac malformations are especially less common. Coarctation of the aorta, hypoplastic left or right heart, transposition of great vessels and cor biloculare have been noted. Ambiguous genitalia, including persistent cloaca, and less severe anomalies of the genitalia have been described.

Radiographic changes include very short ribs, short cranial base, mild platyspondyly with irregular outlines of vertebral bodies, hypoplasia of cervical spine, and horizontal trident-shaped acetabular margins with well-developed ischial and pubic bones. The metaphyses of long bones are widened, especially that of the tibia, and longitudinal spurring is found at the margin of the metaphyses of the distal humeri and proximal and distal radii and femora. Corticomedullary demarcation is marked. All hand bones are short and show changes similar to those in the long bones but the changes in the hand are less well marked. Histological changes have been reported to be similar to (9,40,83,85) or different from (99) the findings in type I.

Autosomal recessive inheritance is indicated by multiple instances of consanguinity, affected sibships, and segregation ratio (85).

Type IV (Beemer-Langer type). In 1983, Beemer, Langer, and coworkers (6) delineated another type of short rib syndrome. In retrospect, the cases described by Black et al (11) and Le Marec et al (54) are earlier examples. In total, 34 cases have been described (5,6,10,13,18,19,21,31, 32,41,43,46,54,56,59,89,93,96,100). Consanguinity in several instances and the occurrence of six pairs of affected sibs of both sexes fit autosomal recessive inheritance. In one case, a de novo paracentric inversion mosaicism involving 17q21 and 17q23 was found (18). Most affected infants are stillborn or die within hours after birth, but survival until 8 sweeks has been described (10).

Major clinical characteristics include hydrops and ascites, macrocephaly, prominent forehead, flat nasal bridge, median cleft upper lip and palate, narrow thorax, protuberant abdomen, omphalocele, short limbs, and sometimes preaxial polydactyly (Fig. 7–82). Cardiac anomalies have included preductal coarctation of the aorta, atrial and ventricular septal defect, and transposition of great vessels. There is often intestinal malrotation. The genitalia can be hypoplastic or ambiguous. Almost atretic ear canals (6), anophthalmia (21), additional oral frenula and hamartoma of the tongue and gingiva (10,31,43,54,56), and milia (56) are less frequent facial findings. Renal agenesis; hydronephrosis; atresia of ureteropelvic junction; renal cysts; fetal renal lobulations; intrahepatic bile duct cysts; ectopic pancreas; pancreatic cysts; polysplenia; lung hypoplasia, sometimes with segmentation defects; rudimentary epiglottis; and pyloric stenosis, in immature as well as premature stillborns, have been reported. Lurie (59) summarized brain malformations, which included hydrocephaly, Dandy-Walker malformation, agenesis of callosal body, hypothalamic hamartoblastoma, polymicrogyria, cerebellar hypoplasia, holoprosencephaly, aplastic optic and olfactory nerves, and occipital encephaloceles.

The radiologic signs include very short ribs, mild platyspondyly, highly placed clavicles, small scapulae, small iliac bones, and short and often bowed long bones with normal metaphyses. The tibiae are often longer than the fibulae and are not ovoid; this constitutes the major point of difference with type II (41,59). All small tubular bones are shortened (Fig. 7–82B,C).

The short rib syndromes must be differentiated from *orofacial digital syndromes*, *hydrolethalus syndrome*, *Smith-Lemli-Opitz syndrome*, *Jeune syndrome*, and *Ellis-van Creveld syndrome*. There are several reports of short rib syndromes that we cannot classify with certainty (14,34,47,90,98,101). In one report, a pericentric inversion including as a breakpoint chromosome 4p16, i.e., the locus for *FGFR3,* was detected (90).

Lethal short-limbed dysplasias with decreased bone density

Epiphyseal stippling–osteoclast hyperplasia. Shohat et al (82) described a single patient with a lethal skeletal dysplasia characterized by osteopenia, short long bones, distinct epiphyseal stippling, and increased number of osteoclasts in histological studies. Two siblings of different sex with the same signs were described (95), which suggests autosomal recessive inheritance. The cause has been suggested to be a deficiency of an osteoclast-inhibiting factor (95).

Both sibs were detected prenatally by sonography, and the pregnancy was terminated. The single patient died shortly after birth. One of the sibs was normocephalic, the other microcephalic. Hypotelorism, cloudy corneae, and short limbs with prominent genua vara were described. No major internal anomalies were present. Radiological changes included generalized osteopenia, with periosteal cloaking in one case. Stippling was found in the proximal femoral epiphysis, sacrum, and talus, in the calcaneus and cuboid bones, and, in one patient, also in the hands. There was rhizomelic and mesomelic shortening, with dense metaphyses and bowing of the femora. Platyspondyly and clefting of the vertebrae were present. Another case has been added (59a).

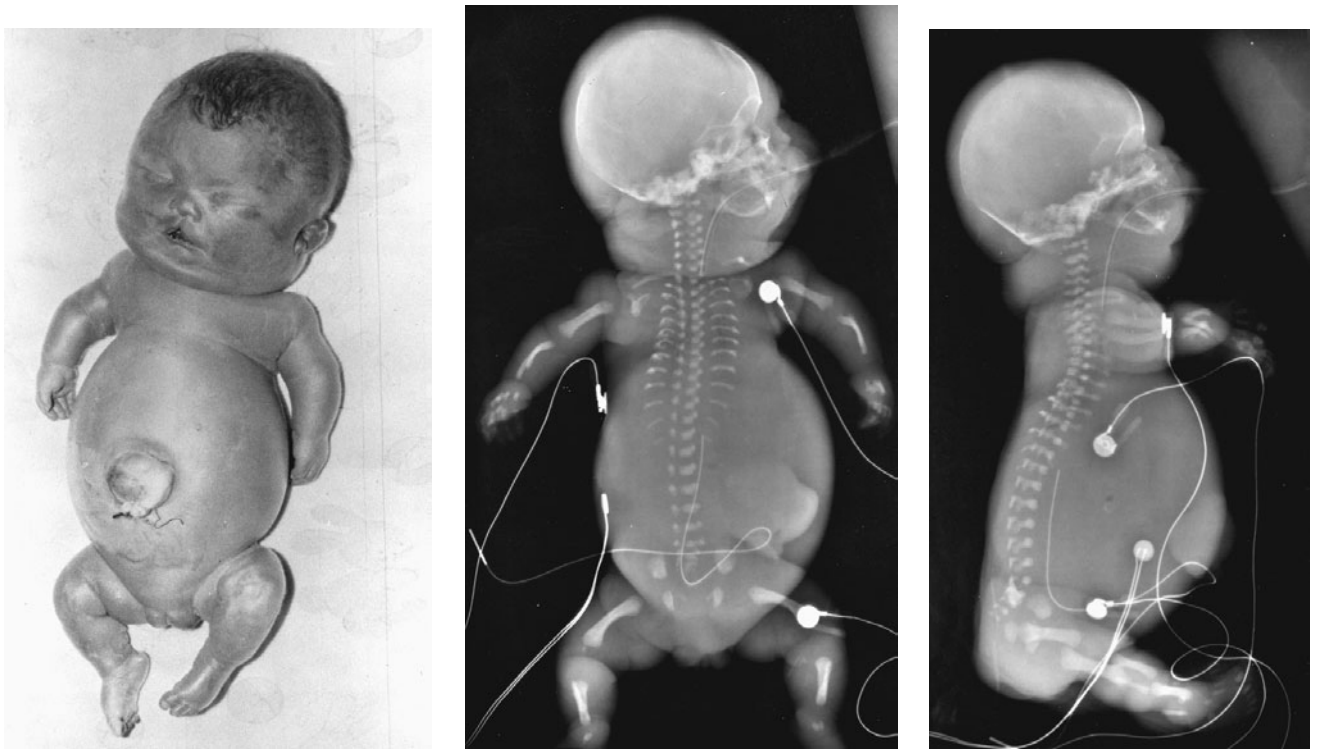
Morphological studies showed that the bone marrow was largely replaced by fibrous tissue, especially in the metaphyses, containing numerous normal-appearing osteoclasts and giant multinucleated osteoclast-like cells. The ultrastructural bone and cartilage morphology was normal.

The entity should be differentiated from *mucolipidosis type 2*, the various forms of *chondrodysplasia punctata*, and neonatal hyperparathyroidism.

Piepkorn dysplasia. Piepkorn et al (73) described a severely dysplastic infant with a marked lack of ossification of all bones except the clavicle. There was polyhydramnios, and the arms and legs were flipper-like. The palate was cleft. Persistence of left superior vena cava and urogenital abnormalities were also evident (Fig. 7–83). An old specimen was noted (70a).

Lethal short-limbed dysplasias with increased bone density

Blomstrand dysplasia. Blomstrand et al (12) described a lethal skeletal dysplasia that was especially characterized by increased bone density and advanced bone age. In total, 10 cases have been reported (12, 25,36,48,55,57,70,86,102), one of which was diagnosed in a 130-year-old museum specimen (70). In five of the six described families, the parents were consanguineous, and in four families, more than one child was affected, indicating autosomal recessive inheritance. The cause is



A B C

Fig. 7–82. *Lethal short-limbed dysplasia, type Beemer-Winter.* (A) Generalized edema, large head with flat face, broad nasal base, median cleft of upper lip, small edematous pinnae, short narrow thorax, and distended abdomen with omphalocele. (B,C) Short horizontal ribs, high clavicles, relatively normal ilia, and metaphyses of abbreviated long bones. There is no polydactyly of the hands or feet. (From FA Beemer et al, Am J Med Genet 14:115, 1983.)

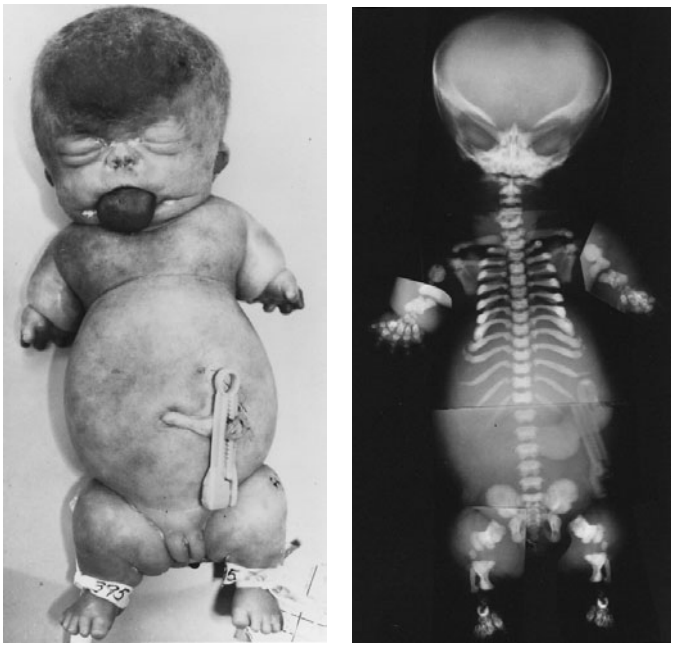
a missense mutation in the gene coding for the receptor for PTH/PTH-related peptide (48,103). There appears to be heterogeneity (70b).

All affected infants were born immaturely or prematurely, and were stillborn or died shortly after birth. Clinical characteristics are polyhydramnios, and hydrops that may distort the face and give the impression of a low nasal bridge and very small nose, widely spaced protruding eyes, long philtrum, large tongue, and small chin (Fig. 7–84). The limbs are

Fig. 7–83. *Lethal short-limbed dysplasia, type Piepkorn.* (A,B) Note flipper-like arms and legs, and marked lack of ossification of all bones except clavicles. (From M Piepkorn et al, Teratology 16:345, 1977.)

A B

Fig. 7–84. *Lethal short-limbed dysplsia, type Blomstrand.* (A) Note low nasal bridge, macroglossia, short limbs, and narrow chest with large abdomen. (B) Long narrow thorax, widened anterior ribs, and severely abbreviated long bones with flared cupped metaphyses. Note extremely advanced bone age. (From S Blomstrand et al, Pediatr Radiol 15:141, 1985.)



A B

Fig. 7–85. *Lethal short-limbed dysplasia, type Raine.* (A,B) Large bulging fontanelles, marked exophthalmos, midface hypoplasia, triangular mouth, and micrognathia. (C,D) Generalized osteosclerosis and slightly hypoplastic vertebral bodies with short anterior-posterior diameter. (From AE Kan and K Kozlowski, Am J Med Genet 43:860, 1992.)

short and broad, with normal-sized hands and feet without polydactyly. Internal organs have been normal except for hypoplastic lungs, malrotation of bowel, and preductal aortic coarctation. Radiography has shown a small facial skeleton, short skull base, long, narrow thorax showing widening of the anterior rib ends, thick clavicles, and mild platyspondyly, with the sacral and coccygeal vertebrae already being ossified. In general, ossification is well advanced. The hyoid bones and thyroid cartilages are ossified, and in one patient, mineralized teeth were found in the hypoplastic mandible (57). The long bones are extremely short with marked metaphyseal flaring and cupping and fragmented irregular capital femoral epiphyses. The radii and ulnae may show acute bowing. Ossification of carpal, metacarpal, tarsal, and metatarsal bones is also advanced. Histologically, acceleration of enchondral ossification in the tubular bones, is apparent, as well as large epiphyseal ossification centers (57). In two families, hemosiderosis of the liver was found (25,55). The marrow space has been found to be reduced to a great extent, which probably explains this feature and the anemic hydrops. Ultrastructural studies have shown a high number of chondrocytes with pyknosis or karyorrhexis and altered rough endoplasmic reticulum, and unequal fibers in the bone matrix (57).

Raine syndrome. In 1989, Raine et al (75) described a newborn lethal disorder characterized by microcephaly, exophthalmos, hypoplastic nose, cleft palate, and diffuse osteosclerosis (Fig. 7–85). Several additional cases were reported thereafter (1–3,49,50,76). No sex predilection has been reported. Parents have been consanguineous (2,3,50,71a,80a) and affected sibs have been noted (76), indicating autosomal recessive inheritance. FitzPatrick et al (33) drew attention to a cholesterol metabolism disturbance, desmosterolosis, but follow-up studies in one patient (49) failed to show accumulation of desmosterol. There is some evidence that the gene maps to 7p (47a).

Nearly all patients have died shortly after birth from lung hypoplasia, but some have lived a few months (3,76). Striking facial characteristics are microcephaly, wide anterior and posterior fontanels and sagittal, lambdoidal, and metopic sutures (coronal sutures are ridged), midface hypoplasia with marked exophthalmos due to very shallow orbits, nasal hypoplasia with misshapen and anteverted nares, bowed upper lip, causing the mouth to be triangular, sunken midface, micrognathia, and low-set, dysplastic ears. The sunken nasal bridge allows the forehead to extend over the nose like a shelf. The soft palate and uvula may be cleft (2,3,75,80a); the gingiva are hyperplastic with gingival nodules. Atretic or stenotic choanae have been found (1–3,49,50). The neck is short, but otherwise no external anomalies have been described.

Radiologically, a generalized increased bone density is prominent, with extensive periosteal thickening of long bones and ribs. Corticomedullary demarcation is poor; the size of ribs and long bones is normal. The thorax is narrow. The ribs can show vertical lines suggestive of fractures (49,50), but no fractures are found histologically. The lateral ends of the clavicles and distal phalanges are hypoplastic. The cranial vault is retarded in ossification, but the bone that is present is markedly sclerotic. The vertebral bodies may be slightly hypoplastic.

Necropsy has shown hypoplastic lungs, hyperplastic adrenals, but otherwise normal viscera. The brain may show calcifications, or small areas of gliosis with mineralization of the periventricular white matter basal ganglia and tentorium cerebelli (2,3). In one patient an ovary was calcified (49). Bone histology showed no abnormality of cartilage and growth plates, and normal enchondral ossification. There was a striking periosteal reaction with accumulated amorphous ground substance–like, Alcian blue–positive mucoid material arranged in globular masses among calcospherites of varying size and a large number of neutral lipid droplets in multinucleated giant cells (49), which likely were osteoclasts. Osteoblasts and fibroblasts were normal.

The differential diagnosis includes *achondrogenesis, Blomstrand dysplasia, Koide dysplasia* (9), and a dysplasia reported by Kozlowski et al (53).

Koide dysplasia. Koide dysplasia is a lethal short-limbed dwarfism characterized by midface hypoplasia, prominent nasal bones, severe platyspondyly, diminished ossification in the sacral region with some punctate calcifications, markedly trident pelvis, extreme hypoplasia of the iliac wings, and micromelic hypoplasia (51) (Fig. 7–86). The distal humeri are pointed. Kozlowski et al (53) described another lethal skeletal dysplasia with macrocephaly, midface hypoplasia, micromelia, protuberant abdomen, and edematous scalp and scrotum. Radiographs showed long, distally hooked clavicles, thin ribs, platyspondyly, and rhizomelia.

Lethal short-limbed dysplasia with fragmented bones

Astley-Kendall dysplasia. Astley-Kendall dysplasia was first described in 1980 (4) and is especially characterized by absent ossification of the cranial vault and multifocal ossification elsewhere. Elcioglu

A B C

Fig. 7–86. *Lethal short-limbed dysplasia, type Koide.* (A) Micromelia, large head, flat facies, large abdomen. (B,C) Radiographs showing short ribs, platyspondyly, crenated ilia, and less severely involved long bones. Note distally tapered humeri. (From T Koide, Pediatr Radiol 13:102, 1983.)

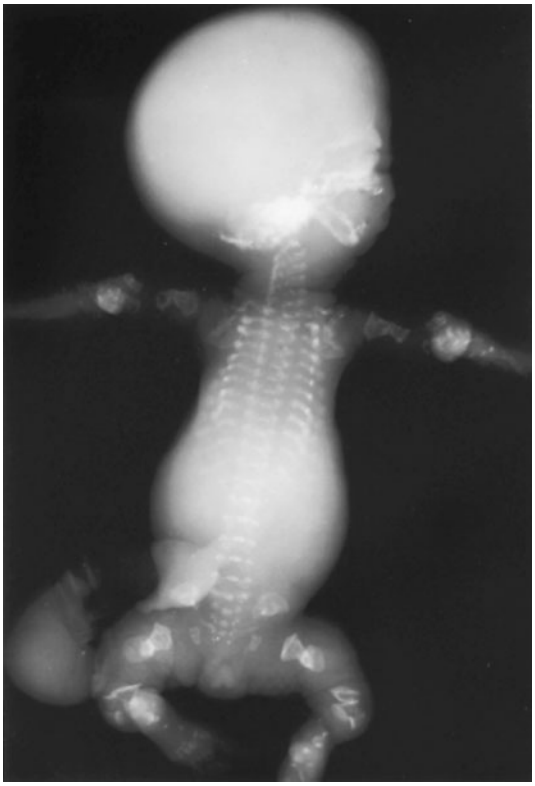
and Hall (30) and Colavita and Kozlowski (22) described other examples. Nairn and Chapman (66) reported three female sibs, but it has been suggested that these were examples of dappled diaphyseal dysplasia. Inheritance is presumed to be autosomal recessive.

The condition is lethal, either prenatally or shortly after birth. Except for a small thorax and short limbs, no other external or visceral anomalies have been reported. Radiologic changes (Fig. 7–87) include barely calcified calvaria with multiple wormian bones, well-developed base of the skull and facial bones, multiple areas of ectopic ossification centers in the spine but almost absent ossification elsewhere in the spine, and platyspondyly. The ribs are short and thin, with flaring ends and some transverse defects suggesting intrauterine fracturing. Multiple ossification centers are seen in the hands, feet, scapulae, and ischia. The ilia are crescentic in shape. In addition to being stippled, the long bones are short and sometimes bowed; the metaphyses are flared.

Histopathologic changes consist of dystrophic globular calcification within the epiphyses, vacuolated chondrocytes, widened lacunae, and disorganized growth plate (30).

Differential diagnosis includes *dappled diaphyseal dysplasia*, *Greenberg dysplasia*, *osteogenesis imperfecta type II*, different types of *chondrodysplasia punctata*, and *metatropic dysplasia*.

Fig. 7–87. *Lethal short-limbed dysplasia, type Astley-Kendall.* Note barely calcified calvaria, shortened extremities with transverse defects of humeri, femora, and tibiae with flared metaphyses, short ribs, space between ribs and vertebral bodies, platyspondyly, and crescent-shaped ilia. (From R Astley and AC Kendall, Ann Radiol 23:121, 1980.)

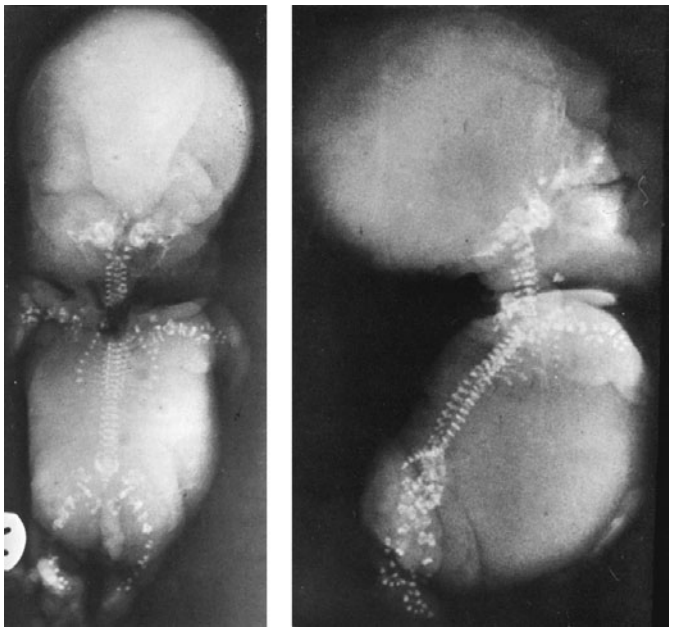


Dappled diaphyseal dysplasia. This condition was recognized by Carty et al (16). In retrospect, the three sibs described by Nairn and Chapman (66) may have had the same entity. Another case was only sparsely illustrated (86). Clinical characteristics are polyhydramnios, hydrops, and extremely short limbs. One patient had situs inversus. Radiographs have shown rudimentary calcification of the cranium and multifocal ossification of the long bones, which thus appear to be fragmented (Fig. 7–88). The epiphyses and diaphyses could not be distinguished. Multicentric ossification is also present in the scapulae, pelvis, and facial bones. Platyspondyly can be marked. The tubular bones of the hands and feet are unossified.

Microscopic examination shows no recognizable chondroosseous transformation or trabecular formation. Because three sibs were born to consanguineous parents, autosomal recessive inheritance is likely (66).

Greenberg dysplasia. In 1988, Greenberg et al (40) reported two sibs, the offspring of consanguineous parents, with a poorly ossified skull vault, mottled appearance of the long bones, and a lethal course. Spranger and Maroteaux (86) briefly reported another example, and Chitayat et al (20) and Gorlin have seen similar cases. It has been suggested that Greenberg dysplasia is a milder form of dappled diaphyseal dysplasia (86). Inheritance appears to be autosomal recessive (20). Kelley et al (49a) have demonstrated that the disorder is due to deficiency of sterol-delta 14-reductase.

Clinical features are polyhydramnios, hydrops fetalis, narrow thorax, rhizomelic shortened limbs, and broad hands with short fingers. The tissues may be fragile. Radiographically, the membranous bones of the skull are extremely poorly ossified, but the skull base is dense (Fig. 7–89). Midface hypoplasia is severe. The cervical vertebrae appear moth-eaten, otherwise there is platyspondyly with multiple ossification centers of the vertebral bodies and poor pedicular and laminar development. There can be calcifications near the larynx and trachea. The ribs exhibit unusual



A B

Fig. 7–88. *Lethal short-limbed dwarfism, type Carty* (*dappled diaphyseal dysplasia*). (A,B) Long bones and pelvis are replaced by multiple small ossified foci. The cranium is very poorly calcified. Note narrow rib cage and platyspondyly. Because of similar changes, the ribs appear fractured. (From H Carty et al, Rofo Fortschr Geb Rontgenstr Neuen Bildgeb Verfahr 150:228, 1989.)

ossification gaps with an anterior ossified, tail-like extension. The iliac wings are moth-eaten, the pubic bones and ilia are lace-like. Most long bones are mottled, being most pronounced at the ends of the bones. Clavicles are elongated.

Microscopically, chondroosseous changes are characterized by marked disorganization of tissue with interspersed masses of cartilage, bone, and mesenchymal tissues.

Lethal short-limbed dysplasia: miscellaneous type

Holmgren-Connor dysplasia. Holmgren et al (44), Connor et al (23), and Maroteaux et al (61) described an autosomal recessive severe micromelic dysplasia with slightly incurved limbs, hyperlaxity of extremities, disproportionately large skull, slightly flattened nasal bridge, and, in some cases, congenital heart defects. Most of the patients succumbed from respiratory distress within hours or days of birth or during the first weeks of life.

Radiographs show short long bones with incurved diaphyses, especially the femora, enlarged and slightly irregular metaphyses, striking well-developed and rounded lower femoral epiphysis, short, square iliac wings with a wide iliac angle, and short ribs with wide and somewhat irregular anterior ends (Fig. 7–90).

Histologically, the upper tibial growth cartilage has an irregular arrangement of cells, demasked fine fibers in the matrix, short primary trabeculae, and closure of some of the vascular lacunae by bony bridging.

Megepiphyseal dysplasia

Gorlin et al (1) described a male with cleft palate, dislocated lenses, deafness, somatic and mental retardation, epicanthal folds, and snub nose. Striking were the enlarged joints (shoulders, elbows, hips, knees, ankles). Radiographic study showed marked shortening of long bones, with flared metaphyses and extremely large proximal and distal epiphyses. The carpal bones were large (Fig. 7–91).

Homocystinuria, found on biochemical study, would account for the dislocated lenses and the mental retardation, but the skeletal alterations were unique. The child was a product of father–daughter incest. The disorder, made homozygous by the incest, is possibly the same as bone dysplasia, midface hypoplasia, and deafness (OSMED). The patient described by McAlister et al (2) may have had the same disorder. The facies and skin, however, resemble those of gerodermia osteodysplasticum.

Metatropic dysplasia

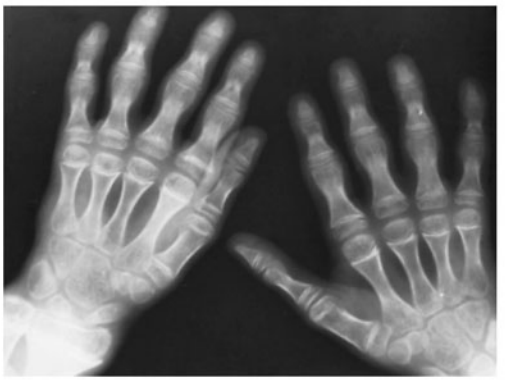
Metatropic dysplasia was first described in 1966 by Maroteaux, Spranger, and Wiedemann (9). The name is derived from the Greek "metatropos,"

A

B

C

D



E

Fig. 7–91. *Megepiphyseal dysplasia.* (A) Bizarre facies marked by circumferential staphyloma and retrousse nose with anteverted nostrils. Note enlarged joints. (B) Huge epiphyses, with widened metaphyses of shortened long bones. (C) Markedly enlarged femoral heads, and trochanters. (D) Anterior wedging of several lumbar vertebrae. (E) Note flattened epiphyses of metacarpals, and large carpal bones.

meaning changing patterns. The main characteristics are long trunk and short limbs at birth, with subsequent development of short-trunk dwarfism because of progressive kyphoscoliosis (Figs. 7–92 and 7–93). About 50 cases have been described. An early patient may be that of Kaufmann in 1893 and Johannessen in 1898 (1). Another earlier case is that of de Groot (4) in 1951. There is some evidence for heterogeneity (1). There may be a perinatally lethal type I (12) and a nonlethal type II. Because of the occurrence of the lethal type in sibs of unaffected parents, autosomal recessive inheritance has been suggested. However, because the 14 known cases with the lethal type had 1 affected sib and at least 12 unaffected sibs, and no consanguinity has been reported, autosomal dominant inheritance is more probable, the occurrence in sibs being explained by germline mosaicism. Beck et al (1) further suggested that the nonlethal type is inherited as either autosomal recessive or dominant; as with the lethal type, autosomal dominant inheritance with (rarely) parental germline mosaicism seems more probable. Transmission of the disorder from an affected father to daughter has been described (1).

Skeleton. At birth, infants' length is normal or slightly above the mean (13) because of an unusually long trunk (Fig. 7–92). With time, the trunk becomes significantly shortened. At birth or within the first year of life, diminished joint mobility in most larger joints and hypermobility in the small joints can be found (1,9). The face has been described as being normal, with deep-set eyes and prominent nose, prognathism, or depressed nasal bridge (1–5,9,11,13). Several patients were macrocephalic, showing enlarged ventricles on CT scans (13). The chest may be narrow (2,13), thus respiratory problems may develop. Significant kyphoscoliosis develops (Fig. 7–93), which can be aggravated by hypopharyngeal air flow obstruction (2). No significant internal anomalies have been reported (10). Mental development is normal.

Radiologically, a major finding is the flattened and irregular vertebral bodies (Fig. 7–94). Already at birth, vertebral ossification is diminished, and defective ossification may remain clear until the end of puberty (13). The odontoid process can be hypoplastic; Shohat et al (13) found that this was associated with marked atlantoaxial subluxation. This can cause significant cord compression and even lead to dislocation (2,13), necessitating early surgical fusion. The thorax is narrow, and the ribs are short with distal splaying. The pelvis shows crescent-shaped iliac crests, and the lower portions of the ilia can be markedly hypoplastic, giving rise to wider horizontal iliac wings and shorter vertical wings. All long bones are shortened, and at birth the metaphyses are already grossly expanded

A B

Fig. 7–92. *Metatropic dysplasia.* (A,B) Note extremely long trunk, cat-back formation, and small tail-like appendage.

("mushrooming"). The femora may show a dumbbell shape. The tubular bones of hands and feet undergo epimetaphyseal changes.

Histologically, the major findings are absence of formation of normal spongiosa in metaphyses, islands of dysplastic chondrocytes in metaphyses and epiphyses, and disproportionate growth of long bones—i.e., arrest of endochondral growth and persistence of circumferential growth (3).

Other findings. Rarely, other symptoms have been reported, such as dilated ventricles that may need shunting (13), cleft palate (7,12), abnormal lungs, thyroid agenesis (10a), and sensorineural hearing loss (8).

Laboratory aids. Prenatal diagnosis of the severe lethal type has been accomplished at 20 weeks of gestation by ultrasound (8).

Nance-Sweeney chondrodysplasia

Nance and Sweeney (2) noted a chondrodysplasia characterized by short stature, cleft palate, and subcutaneous calcification (Fig. 7–95). Cousins were similarly affected and there was parental consanguinity, indicating autosomal recessive inheritance. Rosser et al (4) described another case, although comparison is hindered by the great difference in age between the two cases.

It has been suggested that the disorder is the same as bone dysplasia, midface hypoplasia, and deafness (homozygous OSMED) (1) although in the latter disorder subcutaneous calcifications are not present and epiphyses are large (4). The term "Nance-Sweeney chondrodysplasia" has also been discouraged by Spranger (5).

The facial characteristics included prominent forehead, flat nasal bridge, anteverted nares, cleft palate, and some micrognathia. The hearing loss was sensorineural.

The subcutaneous calcifications were in the abdominal wall and extremities (4) and in the external ears, ribs, hands, and epiphyseal centers of humerus, scapula, and femur (2). The skin was thick and leathery in the adult (2). Intelligence was normal. The adult height was 130 cm.

The radiographs at a young age showed small capital femoral epiphyses, shortening of all long bones with flared metaphyses and wide flattened epiphyses, and mild platyspondyly.

In the differential diagnosis, the condition reported by Oranje et al (3) should be considered. They reported a single patient with subcutaneous calcifications and metaphyseal dysplasia, but without midface hypoplasia, cleft palate, or hearing loss.

Opsismodysplasia

In 1984, Maroteaux et al (3), employed the term "opsismodysplasia" ("opsismos" in Greek means late or delayed) to describe a rhizomicromelic dwarfism originally reported by Zonana et al (8) in 1977. In total, 11 patients have been reported in detail (1,3,4,6–8) and others have been briefly mentioned (2,3,5). The occurrence in sibs of different sex (3,6) and parental consanguinity (1,4,6) point to autosomal recessive inheritance. Several patients died in infancy or childhood because of respiratory complications due to narrow thoracic cage and hypotonia. A boy in adolescence is known (4). Mental development is normal. Santos and Saraiva (4) provide an excellent review.

The disorder is recognizable at birth and characterized by short stature, hypotonia, and short hands with digits of equal length. The thumbs and halluces tend to be wide. The head is large, the forehead is high and bossed with large anterior and posterior fontanels. The nose is small with anteverted nostrils and the philtrum is long (Fig. 7–96). The thorax is short and narrow, the abdomen protuberant. Herniae (3,8), hydrocephaly (8), and genital hypoplasia (4) have been reported.

Radiographic changes include severe bone retardation (delayed appearance of distal femoral and proximal tibial epiphyses), shortness of long bones with short, thick diaphyses, and irregular cup-shaped metaphyses, those of the metacarpals and metatarsals being especially concave (Fig. 7–97). The pelvis somewhat resembles that of asphyxiating thoracic dysplasia, showing square iliac bones, lateral and medial spurs, and horizontal acetabular roofs. The vertebral bodies are thin and lamellar. Ossification of the base of the skull and cervical vertebral bodies can also be severely delayed. Histologically, the cartilage shows a wide and irregular hypertrophic zone with thick connective tissue septa, balloon-shaped cells having abnormal lacunae, and irregular calcification and vascular invasion (3). Immunohistochemical studies have shown type I collagen (in lieu of type II) in the hypertrophic zone in the growth cartilage.

Osteoglophonic dysplasia

The term "osteoglophonic dysplasia," derived from the Greek and meaning hollowed-out bone, was introduced by Spranger (see 1); however, strictly translated, "osteoglyphic" would be a better term (4). The disorder is a distinctive skeletal dysplasia characterized by disproportionate short stature, craniosynostosis, unerupted teeth, multiple lucent metaphyseal defects, and anterior beaking of vertebral bodies (Figs. 7–98 to 7–100). Osteoglophonic dysplasia was first described by Fairbank (3) in 1958 as a case report of *acrocephaly with abnormalities of the extremities,* and several other examples have been reported since that time (1,1a,2,4–10). Because the disorder affects patients of both sexes and vertical transmission, including a father–son transmission (6,7), has occurred, autosomal dominant inheritance is suggested. The cause is unknown, although the finding of mutations in the fibroblast growth factor receptors in other entities showing craniosynostosis and skeletal dysplasia warrants similar studies in osteoglophonic dysplasia (9).

Intelligence is normal, although several patients were first thought to be retarded. Two patients died in infancy (8,10) from respiratory problems. Another patient died of pneumonia at age 27 years (MM Cohen Jr, unpublished observation). Both Beighton (1a) and Sklower Brooks (9) provide good reviews.

Craniofacial findings. Craniosynostosis has occurred in all cases to date, and multiple sutures are usually involved. Head shape may be brachycephalic, oxycephalic, or cloverleaf (6). Hydrocephaly occurred in one instance (6). Facial features include frontal bossing, shallow orbits with maxillary hypoplasia, proptosis, hypertelorism, low nasal bridge, anteverted nares, and mandibular prognathism. Radiographically, there are multiple unerupted teeth.

Musculoskeletal findings. Shortening of the extremities may be noted at birth but becomes increasingly apparent in childhood. Adult height has been between 97 and 146 cm. The long bones are undermodeled with generalized osteoporosis, cortical thickening, and loss of normal trabecular patterning. Lucent, fibrous, dysplasia-like changes are present throughout the metaphyses and are most prominent in the distal femurs and proximal tibias. The tubular bones of the extremities are short and broad; markedly dysplastic changes are observed in the epiphyseal ossification centers. Maltese cross changes have been reported in the phalanges (10). Pseudarthroses, fractures, and nonossifying fibromata have been noted (1a,9). In the spine, platyspondyly with anterior projection of the vertebral bodies is a prominent feature. In affected adults, resolved lucent defects result in grossly distorted, somewhat widened, and somewhat cystic-appearing metaphyses in many long bones. Other features include symmetrical flattening and lateral migration of the femoral heads, dysplastic and dislocated humeral heads, type B brachydactyly, hypoplastic or absent middle phalanges in the feet, and thoracolumbar scoliosis. Otherwise, the spinal curve is usually normal.

Other findings. Instances of cryptorchidism and inguinal hernia have been noted (6,9). A patient with classic findings of osteoglophonic dysplasia studied by MM Cohen, Jr had, in addition, documented renal phosphate wasting and osteomalacia. Serum calcium, serum phosphorus, and alkaline phosphatase concentrations have been within normal limits in all cases except for the one instance with renal phosphate wasting, noted above.

Differential diagnosis. The disorder should be differentiated from *hypophosphatasia.*

Schneckenbecken dysplasia

Graf et al (5), in 1972, and Laxova et al (7), in 1973, reported a lethal neonatal disorder described as thanatophoric dysplasia. A similar condition was described in 1986 by Knowles et al (6) and by Borochowitz et al (1). Inheritance is autosomal recessive. Affected sibs and parental consanguinity have been documented (1,5–7).

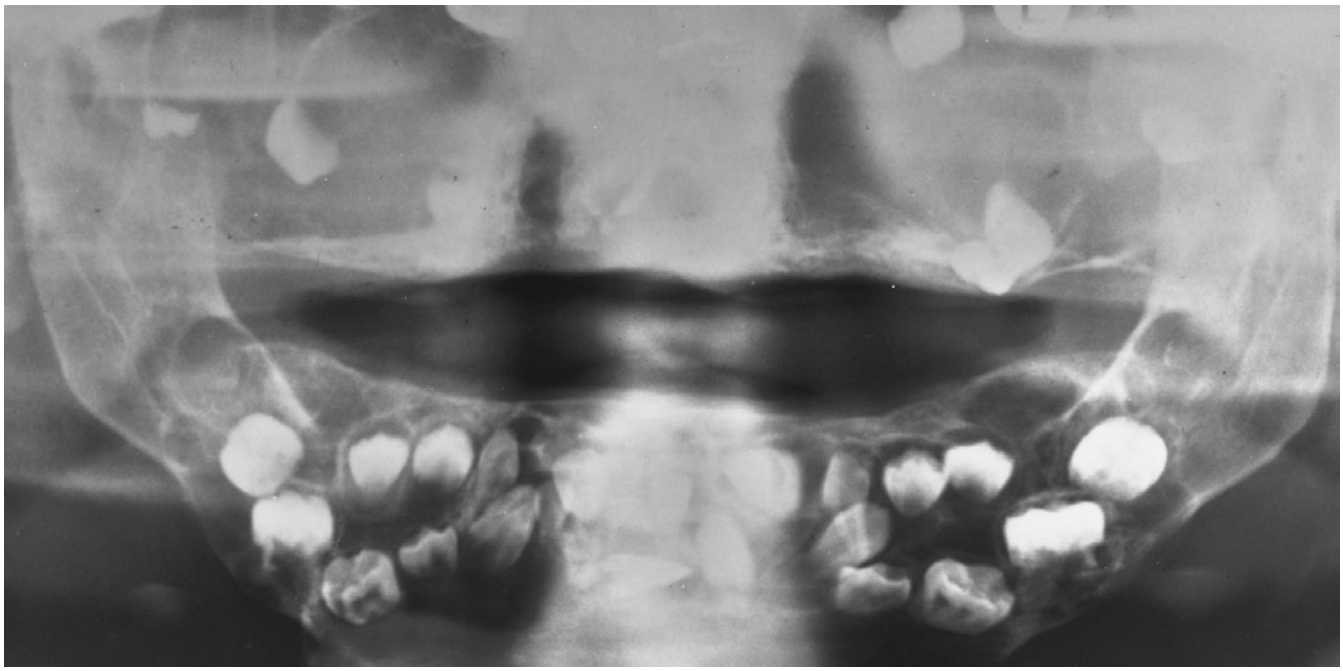

Fig. 7–100. *Osteoglophonic dysplasia.* Unerupted teeth.

The infants were edematous, and hydramnios was an almost constant feature. The head was large, the neck was short, and the face exhibited midfacial flattening (1–10). Two children had cleft palate (1,8).

The long bones were short with thick, dumbbell-like metaphyses. The clavicles had a handlebar form and the scapulae were hypoplastic. The vertebral bodies were flat and the ribs were short and splayed. The ischia were short, vertical, and precociously ossified. There was a snail-like appearance to the ilia, hence the term "Schneckenbecken" from the German. The pubic bones were hypoplastic (Figs. 7–101 and 7–102). The ankle bones were precociously ossified with three ossification centers. Brachydactyly was evident. Microscopically, the cartilage exhibited increased cellular density and hypervascularity, with each chondrocyte containing a large round central nucleus (6). Horseshoe kidneys, hydroureters, and hydronephrosis were found (5).

The disorder should be differentiated from *thanatophoric dysplasia, achondrogenesis,* and *fibrochondrogenesis.*

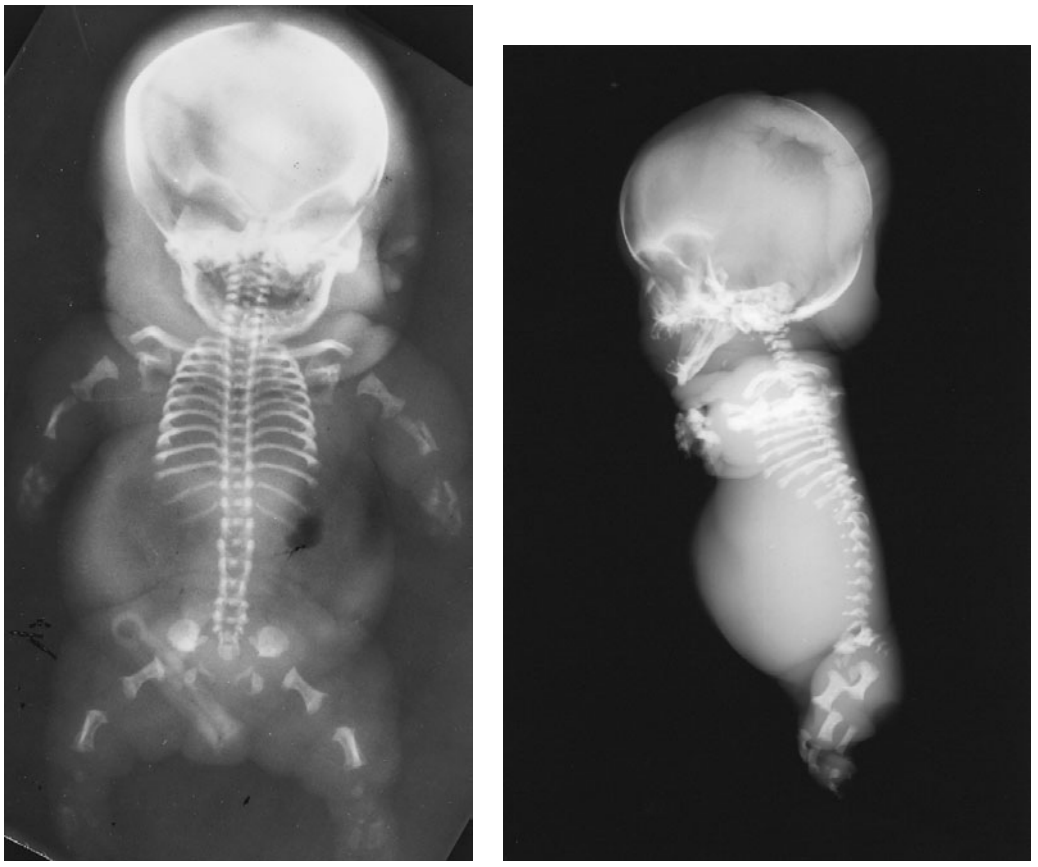
Spondylo(meta)(epiphyseal) dysplasias

The spondylo(meta)(epiphyseal) dysplasias comprise a huge group of skeletal dysplasias sharing anomalies of the vertebral column, metaphyses, and epiphyses of the long bones in a variable combination. Some are detectable at birth, in others the full (often radiologic) picture emerges only in childhood or later in life. There are entities in which the signs are confined to the skeleton and others with extraskeletal signs. A summary of the most important entities is provided in Table 7–9. Two entities (spondyloepiphyseal dysplasia congenita and spondyloepimetaphyseal dysplasia with joint laxity) are described in further detail; for the other entities, the reader is referred to the original references (Table 7–9).

Spondyloepiphyseal dysplasia congenita. Spondyloepiphyseal dysplasia (SED) congenita, first described by Spranger and Wiedemann in 1966 (92), is characterized by short stature, myopia, cleft palate, and radiographic anomalies of the vertebrae, epiphyses, and (to a lesser extent) the metaphyses. Prevalence is approximately 1/100,000 (96,105). The disorder has autosomal dominant inheritance (46,89,92), with unexpected recurrence being explained by germline mosaicism (42). It can be grouped together with Kniest dysplasia; achondrogenesis type II; hypochondrogenesis; Stickler syndrome; spondyloepimetaphyseal dysplasia (SEMD), Strudwick type (100); SED tarda (7,25,81); and SED with brachydactyly (84) as type II collagenopathies (8,74,75,93). This grouping is discussed in more detail in the section describing Kniest dysplasia (above). Mutations in the *COL2A1* gene have been found (23,60), with deletions, duplications, amino acid substitutions, and exon-skipping mutations occurring (99).

Clinical findings. Short stature leads to final height attainment of 84–128 cm (47,105). There is disproportionate shortness of neck and trunk, and coxa vara. The head appears to sit upon the trunk and is often held in retroflexion (Fig. 7–103), requiring stabilization of the cervical spine in some patients (60). The extremities are proportionately shortened but the hands and feet are normal. The chest is small and bell shaped and the abdomen protuberant. Stiffness, limitations at the hips, and waddling gait are evident. Most patients exhibit pectus carinatum, moderate thoracic kyphoscoliosis, and, in particular, lumbar lordosis. Talipes varus occurs in about 10%–15% of cases. Nonprogressive myopia of five diopters



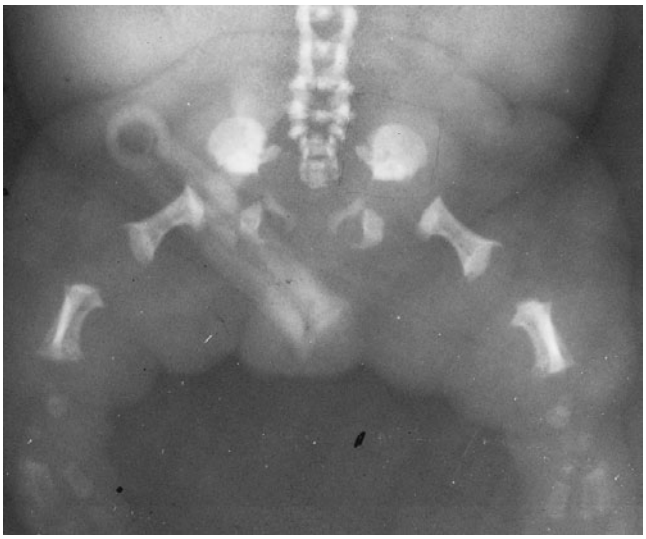
A B

Fig. 7–101. *Schneckenbecken dysplasia.* (A) Short long bones with enlarged metaphyses, handle bar-shaped clavicles, hypoplastic scapulae, flattened vertebral bodies, short splayed ribs, and abnormal ilia. (B) Extreme platyspondyly. Note lordosis of lumbosacral region and short ribs. (B courtesy of PGJ Nikkels, Utrecht, The Netherlands.)

or greater has been documented in about half of the children. In those with high myopia, vitreoretinal degeneration is encountered. Retinal detachment is rare (40,105), despite earlier reports (89,92).

Moderately severe (30–60 dB) sensorineural hearing loss, especially marked in the high tones, occurs in about 30% of patients (72). Cleft palate is noted in about 15%–20% (10,46,56,65,72,89,97,105). Mental deficiency has been rarely documented (10,72).

Fig. 7–102. *Schneckenbecken dysplasia.* Enlarged radiograph showing snail-like ilia (Schneckenbecken). (From Z Borochowitz et al, Am J Med Genet 25:47, 1986.)



Radiographic findings. In the affected infant, vertebral bodies appear ovoid on lateral view (Fig. 7–104). The odontoid is usually hypoplastic and may dislocate. As the child matures, there is platyspondyly with posterior wedging of vertebral bodies. Mild to moderate metaphyseal alterations are noted in the long bones of infants. Ossification of the sternum, pubic bones (Fig. 7–105), distal femoral and proximal tibial epiphyses, talus (Fig. 7–106), and calcaneus is retarded. The iliac bones are hypoplastic. The upper femoral epiphyses are small and deformed, late to develop, and in the coxa vara position (Fig. 7–107) (55,68,90,92). Humeral pseudoarthrosis has been reported in a mother and child (35a).

Differential diagnosis. Spondyloepiphyseal dysplasia congenita should be differentiated from *Kniest dysplasia*, *Stickler syndrome*, *Morquio syndrome*, and many of the other disorders mentioned in Table 7–9. Epiphyseal dysplasia can be secondary to congenital hypothyroidism (28). Cervical kyphosis is seen in numerous disorders, both lethal and nonlethal. The lethal forms include *atelosteogenesis II*, *campomelic dysplasia*, and a Larsen-like syndrome; the nonlethal ones include *diastrophic dysplasia*, *Larsen syndrome*, oto-facio-cervical syndrome of Fara, *Rolland-Desbuquois syndrome*, *Burton syndrome*, Berk-Tabatznik syndrome, and dominant cervical kyphosis (84a).

Spondyloepimetaphyseal dysplasia with joint laxity. Beighton and Kozlowski (1) first defined this entity in Afrikaners in 1980. Subsequently, about 25 patients with the disorder have been reported (1–4,6, 8,9,11,12,14–18; RCM Hennekam, unpublished observations). An early example is that of Maloney (12). Farag et al (9) noted an affected sibship with consanguinity. Torrington and Beighton (17) were able to trace the origin of the disorder in eight South African families to two females. Inheritance is autosomal recessive (3). Linkage studies have excluded *COL1A1*, *COL1A2*, *COL2A1*, *COL10A1*, fibrillin and elastin (4). It has been suggested that the defect lies in the processing of collagen or other components of connective tissue (4).

The syndrome, evident at birth, is manifested by dwarfism, articular hypermobility, spinal malalignment, thoracic asymmetry, bilateral dislocation of radial heads, and talipes equinovarus (Fig. 7–108). The hips are dislocated in about 30% of patients and there is genua valga in 80%. The terminal phalanges, particularly of the thumbs, are spatulate. A more or less specific profile of the metacarpophalangeal pattern is available (1). Spine malalignment is progressive (11). Paraplegia or early death from cardiorespiratory failure is common. Congenital heart anomalies (VSD, ASD) have been found in 30% of patients.

The face tends to be oval and flat with protuberant eyes, blue sclerae, and long philtrum. Cleft palate is present in 30%. The skin is somewhat hyperelastic with a doughy consistency. Rare symptoms have included mental retardation, myopia, lens dislocation, Hirschsprung disease, and megaureter (4).

The tissues are not fragile and healing is unimpaired, which allows surgical procedures without specific precautions. The spinal malalignment is very refractory to treatment. Despite bracing and internal fixation, children often develop spinal cord compression, paraplegia, and cardiorespiratory embarrassment. Beighton et al (4) reported that 10 affected children died within the first two decades; 2 adults were still alive.

The differential diagnosis includes *diastrophic dysplasia,* especially in the neonatal period, *Larsen syndrome, Ehlers-Danlos syndrome, articular type,* and the many other forms of spondyloepimetaphyseal dysplasia (Table 7–9). Goldblatt et al (10) reported a still different autosomal recessive entity that had, in addition to skeletal symptoms, dentinogenesis imperfecta. Growth was below the third centile. Mild brachydactyly, genua vara, and genua recurvata were evident. Radiographic changes included short long bones, broad cupped metaphyses, and "banana peel" configuration of distal radius. Iliac wings were flared, the sciatic notch was small, acetabular roof horizontal, and vertebral bodies were biconvex. A type II

collagen defect was found (5). Phaoke et al (13) reported a neonate with multiple joint dislocations, short stature, metaphyseal dysplasia, deficient calcification of the neurocranium, natal tooth, and lymphedema. Castriota-Scanderbeg et al (7) described a newborn with mild short-limb dwarfism without metaphyseal changes, but with joint dislocations, and severe immunodeficiency.

Thanatophoric dysplasia

Thanatophoric dysplasia, first described by Maroteaux et al (66,67), is almost always incompatible with life. The word "thanatophoros," from the Greek, means death-bringing. The condition is characterized by marked shortening of the extremities with numerous skin folds, relatively normal trunk length, narrow thorax, and either disproportionately large head with frontal bossing, protruding eyes, and low nasal bridge or, less commonly, cloverleaf skull. Many articles on the subject have appeared dealing with a variety of different topics, including frequency (12,17,19), affected sibs (30,76), monozygotic twins (20,43,64,86,89), sibs misdiagnosed as having thanatophoric dysplasia (36,39,87), differential diagnosis (1,18,24,32,35,58,69,81,88), separate types of thanatophoric dysplasia (59,73), radiologic features (59), histopathology of long bones (75,81,82,102), cloverleaf skull heterogeneity (20,52,69,78,83), cloverleaf skull histopathology (7,53), neuropathology (21,41,101), and prenatal diagnosis (11,12,22,27).

Although usually lethal at birth, long-term (150–170 days) survival has been reported (3,59,70,94). More than 150 cases have been described to date. An early case with cloverleaf skull is that of Vrolik (98) in 1849.

Epidemiology. Connor et al (19) found a birth prevalence of 1/42,221 and suggested a mutation rate of $11.8 \pm 4.1 \times 10^{-6}$ mutations per gene per generation. Stoll et al (95) and Cobben et al (17) reported a birth prevalence of 1/25,000. Orioli et al (74) found a birth prevalence of all lethal skeletal dysplasias of 1/10,000. Hall (38) noted a propensity of births during the summer and early fall.

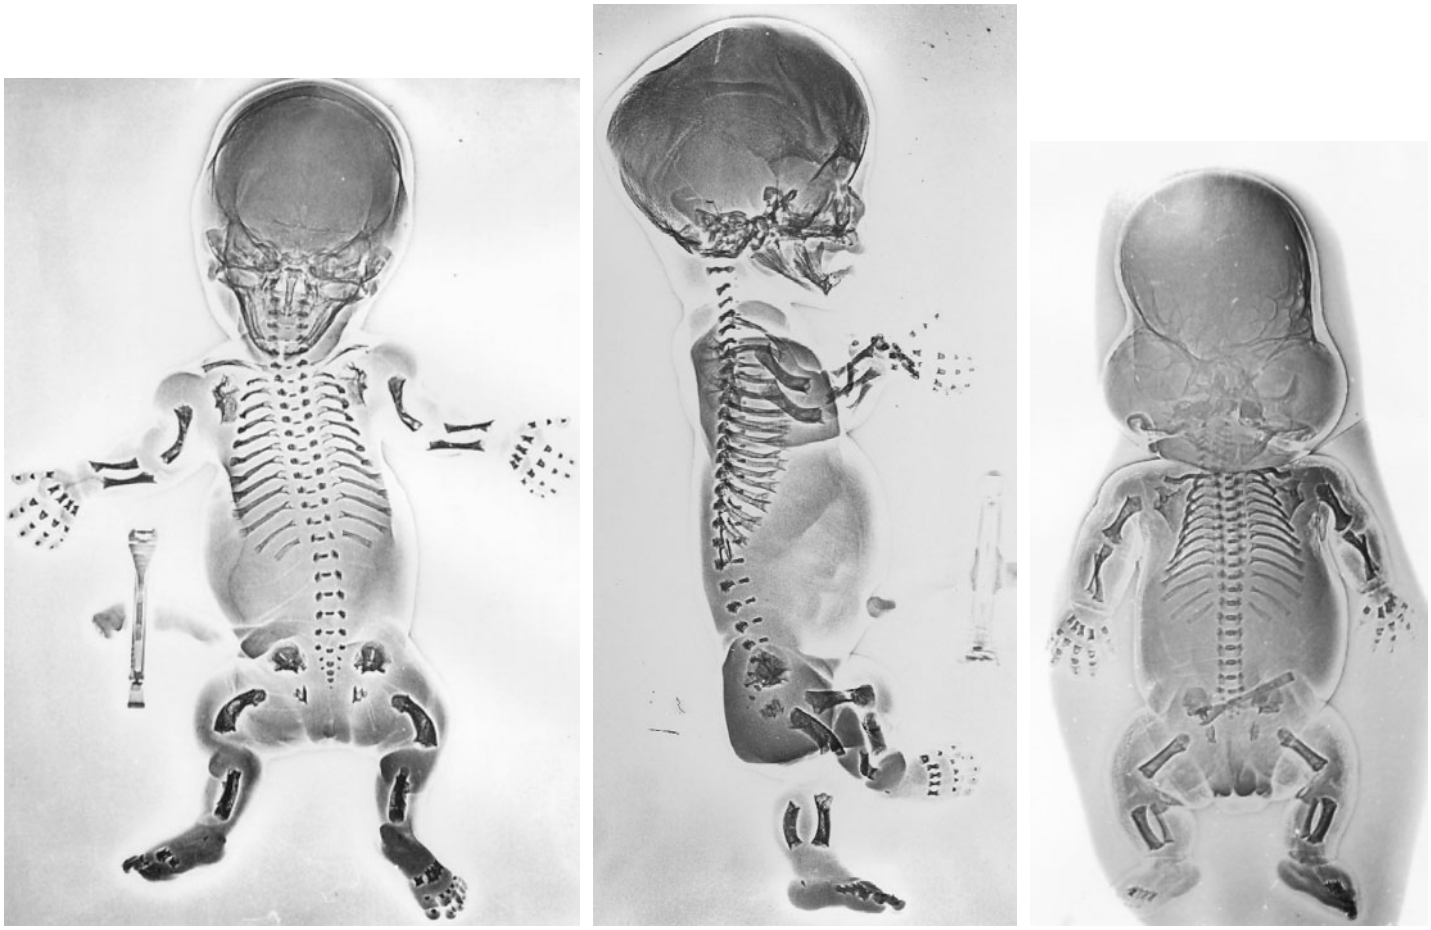
Histology and pathogenesis. Endochondral ossification is severely disturbed in thanatophoric dysplasia. This is manifested by abnormal columnization, maturation, and hypertrophy of chondrocytes in the growth plates (82,102). Cultured fibroblasts from patients with achondroplasia can be distinguished from normal fibroblasts on the basis of total intracellular mucopolysaccharide content and the relative proportion of dermatan sulfate (23). Ornoy et al (75) studied light microscopic and transmission and scanning electron microscopic findings in 13 cases and found that in growth plates, areas with less abnormal cartilage and bone alternated with areas of severely abnormal cartilage and bone. They suggested that the pathogenesis of the skeletal abnormalities is based on focal replacement of the growth plate and periosteum by persisting abnormal, mesenchymal-like tissue from which the abnormal bone originates. Their findings were confirmed by Brenner et al (9).

Nosology and genetics. Langer et al (59) distinguished two types of thanatophoric dysplasia (Figs. 7–109 to 7–113). In type 1, the long tubular bones, particularly the femora, are curved and the vertebral bodies are very flat (Fig. 7–109A,B). In type 2, the femora are straight, the vertebral bodies are not as flat as in type 1, and cloverleaf skull is virtually always present (Figs. 7–109C and 7–113). Type 2 is less common than type 1 (2,5,7,46,47,54,55). In contrast, type 1 occurs without cloverleaf skull in the vast majority of cases, and, when occasionally present, it is mild. Although Langer et al (59) noted some overlap in the diagnostic criteria of type 1 and type 2, they suggested that, on the basis of the evidence available to date, thanatophoric dysplasia represents two closely related but separate entities rather than variable expression of a single entity. However, Horton et al (43) reported monozygotic twins with type 1, discordant for (mild) cloverleaf skull.

The cause for both types of thanatophoric dysplasia was found to be mutations at different sites in *FGFR3* (6,13,72,84,85,96). Because mutations were found in many patients but not in all, genetic heterogeneity is suggested. Additional indication for heterogeneity was found by in vitro studies of clonal growth of chondrocytes, in which different responses of chondrocytes were found (9). The background of the FGFRs is described in the section on achondroplasia (above). *FGFR3* expression in cartilage and bone has been shown to be activated (25,71). Most patients with type 1 have Arg248Cys substitution, and all patients with type 2 had Lys650Glu substitution (96,100). Other mutations have been reported (6,85,96,100). All mutations have been de novo. Wilcox et al (100) studied 91 cases and found a *FGFR3* mutation in all of them. Cloverleaf skull can be present in cases with different mutations. Histologic findings were not conclusive for dividing patients into different groups, suggesting the influence of other genetic, environmental, or stochastic factors. Both types represent lethal autosomal dominant mutations. This is further supported by the finding of advanced paternal age (68) and its occurrence in identical twins (103). The affected sibs with type 2 thanatophoric dysplasia reported by Partington et al (76) could be explained on the basis of gonadal mosaicism. The overall recurrence risk is very low (43,89). Although several claims have been made about affected sibs with presumed thanatophoric dysplasia, subsequent radiographic and histologic studies have demonstrated that these infants had other types of lethal short-limbed dwarfism (43,81,82,92).

Natural history. Thanatophoric infants are either stillborn or survive for a few days and, on occasion, for several months, usually succumbing to respiratory distress that can be explained in most instances by the narrow thorax, muscular hypotonia, and alterations in bronchial cartilages. Survival beyond 1 year has rarely been observed (3,56a,59,64,70,94). Langer et al (59) noted a patient who survived to 19 years of age. Baker et al (3) reported a patient 9 years of age who had the Arg248Cys substitution commonly found in type 1. He and others (56a,64) developed acanthosis nigricans, which also occurs in Crouzon syndrome when caused by a *FGFR3* mutation. He was very severely mentally retarded. For further discussion, see the section on *unique skeletal dysplasia, developmental delay, and acanthosis nigricans, (SADDAN)* (below). In approximately 70% of cases, there is a history of hydramnios. At least one-third of thanatophoric infants are premature and born by breech presentation (81).

Craniofacial features. In type 1 thanatophoric dysplasia, the head is disproportionately large, with head circumference being as large as



A B C

Fig. 7–109. (A,B) *Thanatophoric dysplasia* (*curved bone type*). Xeroradiograph showing midfacial hypoplasia, micrognathia, narrow thorax, very short ribs, hypoplastic flattened vertebral bodies, abbreviated long bones, curved humeri and femora, short metapodial bones, and phalanges. (C) *Thanatophoric dysplasia with cloverleaf skull*. Note cloverleaf skull, abnormal clavicles and ribs, hypoplastic vertebrae, small pelvic bones, abbreviated long bones, and small bones of extremities. In contrast to classic thanatophoric dysplasia, the femora and humeri are straight with irregular metaphyseal plates. (From R Elejalde, Am J Med Genet 22:669, 1985.)

40 cm. Characteristic features usually include frontal bossing, protruding eyes, and low nasal bridge (Fig. 7–110). Cloverleaf skull anomaly is found in type 2 (Fig. 7–113). Histologic study of the cranial base demonstrates disarrayed chondrocytes (7). In detailed anatomic and histologic study, Kokich et al (53) showed that the synchondroses, usually present at birth, between the presphenoid, basioccipital, exoccipital, and supraoccipital components of the skeletal floor were absent; the cranial base was completely united as one bone. This results in dramatic foreshortening of the cranial base. In some cloverleaf skulls, the sagittal and lambdoidal sutures are synostosed (7,76). In others, coronal, sagittal, and lambdoidal sutures are involved (53). In cases of type 1 thanatophoric dysplasia without premature synostosis involving the cranial vault (18,59), the trilobular skull configuration is usually absent or minimally manifested. This severe cloverleaf skull anomaly is probably not dependent on the dysplastic changes in the cranial base per se, but results from the restricting influence of the particular pattern of prematurely synostosed cranial sutures on the normal expansion of the brain.

Neuropathology. Neuropathologic study of several cases has demonstrated abnormally deep sulci in the temporal lobe, dysgenesis of the parahippocampal area, agenesis of Ammon's horn, and periventricular heterotopia limited to the temporal lobe with polymicrogyria in the adjacent area. These findings were present in thanatophoric dysplasia both with and without cloverleaf skull (21,41,52,101)

Hydrocephaly is a common finding in thanatophoric dysplasia with cloverleaf skull. Diverticulum formation in areas of focal temporal dysplasia has been reported in one instance (41), as was spinal cord injury due to neural arch stenosis (29).

Other abnormalities. Low-frequency findings in thanatophoric dysplasia may include cleft lip/palate (37), congenital heart defects (47), soft tissue syndactyly of fingers and toes (10), and adenomyosis of the pyloric muscular layer (93). Acanthosis nigricans may develop in those patients who live longer (3).

Prenatal diagnosis. Prenatal diagnosis on the basis of ultrasonic and radiographic findings has been reported in several instances (8,11, 12,22,27,28). Since almost all examples of thanatophoric dysplasia are sporadic, it has not been possible to single out couples at risk. Thus, early prenatal diagnosis, which is theoretically possible, has not been the rule.

Differential diagnosis. Differential diagnosis of thanatophoric dysplasia includes *heterozygous achondroplasia*, *homozygous achondroplasia*, different types of *achondrogenesis*, severe *hypophosphatasia*, and different short limb syndromes (81,92). The cloverleaf skull malformation is known to be both etiologically and pathogenetically heterogeneous.

Unique skeletal dysplasia, developmental delay, and acanthosis nigricans (SADDAN)

In 1999, Tavormina et al (4) and Bellus et al (2) described a syndrome they called "SADDAN," standing for *S*evere *A*chondroplasia, *D*evelopmental *D*elay, and *A*canthosis *N*igricans. The severity of the phenotype can perhaps be thought of as less severe than thanatophoric dysplasia but more marked than achondroplasia. The term "SADDAN" will become established because the precedent has been set (2,4). However, we are concerned that the term "severe achondroplasia" may be misleading because one might think that the disorder is really achondroplasia but of a more severe degree than usual.

The mutation involves the same FGFR3 amino acid residue (650) affected in thanatophoric dysplasia type 2, but instead of the usual thanatophoric dysplasia type 2 mutation (Lys650Glu), a methionine is substituted (Lys650Met) for a lysine. Furthermore, the nucleotide change (1949A→T) is adjacent to the one for thanatophoric dysplasia, type 2 (1948A→G). The Lys650Met mutation has constitutive receptor kinase activity that is three times greater than that observed for Lys650Glu (4).

Those individuals with the mutation usually survive into adulthood, although a V-P shunt may be necessary (2).

The phenotype closely resembles that of achondroplasia.

Skin. Acanthosis nigricans develops during infancy and first involves the neck, axilla, groin, and dorsum of the hand and progresses with time to involve the back, chest, and palms (Fig. 7–114A–C). The epidermal layer is somewhat thicker than that found in other disorders with acanthosis nigricans. Insulin resistance is not the cause of acanthosis nigricans in SADDAN (2,4).

Skeletal system. The skull is large with frontal bossing and midface hypoplasia. The sinuses are prominently pneumatized and the calvaria is asymmetrically thickened. There has been no evidence of craniosynostosis (Fig. 7–114D). G Bellus suggested that cementomas are present in the jaws (August, 2000).

The spine exhibits platyspondyly and narrowing of the interpediculate distances caudally. In adults, the vertebral bodies are high and square with severe anterior scalloping, extreme kyphosis, and exaggerated lumbar lordosis. The ribs are shorter and the chest circumference smaller than in achondroplasia (2).

In newborns, the pelvis is thanatophoric dysplasia–like with extremely short iliac bones and very narrow sacrosciatic notches. With growth, the pelvis becomes more achondroplasia-like with flattening of the acetabular roof (2).

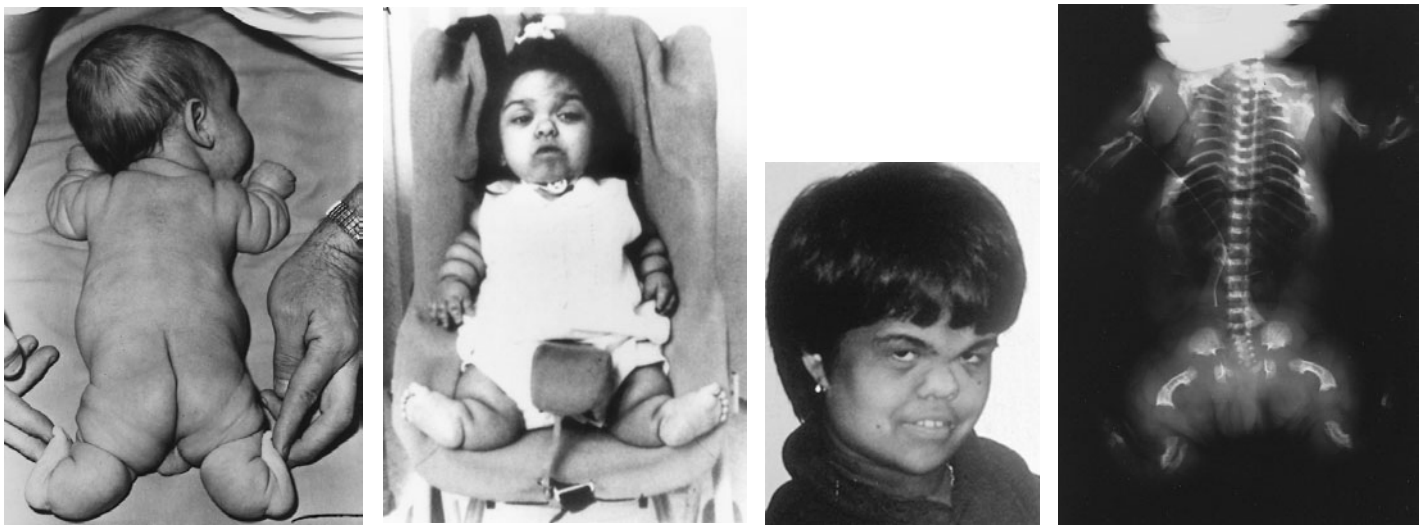
Long bone changes are dramatic in newborns and are thanatophoric dysplasia–like. Femoral bowing is severe and bowing of the tibia and fibula may be observed. The humerus tends to be larger than that found in thanatophoric dysplasia type 1. The radius is short with dislocation of the head, and there is compensatory bowing of the ulna. During infancy, short metacarpals and broad phalanges are neither thanatophoric dysplasia–like nor achondroplasia-like (2).

The histopathologic changes found at the costochondral junction are similar to those found in thanatophoric dysplasia, type 1.

Central nervous system. Generalized seizures during infancy, various degrees of hydrocephalus, and cervical spine stenosis have been reported (2). These features can also be found in rare instances of thanatophoric dysplasia survivors (1,3). Other findings in SADDAN include a very thin splenium of the corpus callosum and a paucity of white matter with prominence of the ventricles and sulci. These abnormalities are not found in achondroplasia.

In the surviving patients with SADDAN, developmental delay has been noted (2).

Acanthosis nigricans may also be seen in *crouzonodermoskeletal syndrome, Beare-Stevenson cutis gyrata syndrome*, and in rare cases of thanatophoric dysplasia, type 1 with extended survival (1).



A B C D

Fig. 7–114. *Unique skeletal dysplasia, developmental delay, and acanthosis nigricans (SADDAN).* (A) Six-month-old showing unusual curvature of lower legs, large head, and excessive skin folds. (B) Note redundant skin folds, bent lower limbs, and acanthosis nigricans. (C) Facies similar to that in achondroplasia. Note acanthosis nigricans. (D) Neonatal radiograph showing severe bowing of femora and reverse bowing of tibiae. Femora and pelvis are very similar to that of thanatophoric dysplasia, type 1, but platyspondyly is not as severe. (A,B,D from GA Bellus et al, Am J Med Genet 85:53, 1999. C courtesy of G Bellus, Denver, Colorado.)

Spondyloepiphyseal dysplasia, craniosynostosis, cataracts, cleft palate, and mental retardation

Nishimura et al (1) reported four Japanese sibs with spondyloepiphyseal dysplasia, craniosynostosis, cataracts, mental retardation, and cleft palate (Figs. 7–115 and 116). Inheritance appears to be autosomal recessive. The cataracts, possibly congenital, became evident during early childhood.

Radiologic changes included coronal synostosis, mild epiphyseal dysplasia, particularly of the distal tibiae, strikingly delayed patellar ossification, mild metaphyseal splaying, hypoplastic ilia with iliac flare, and platyspondyly with ovoid or posteriorly humped vertebral bodies.

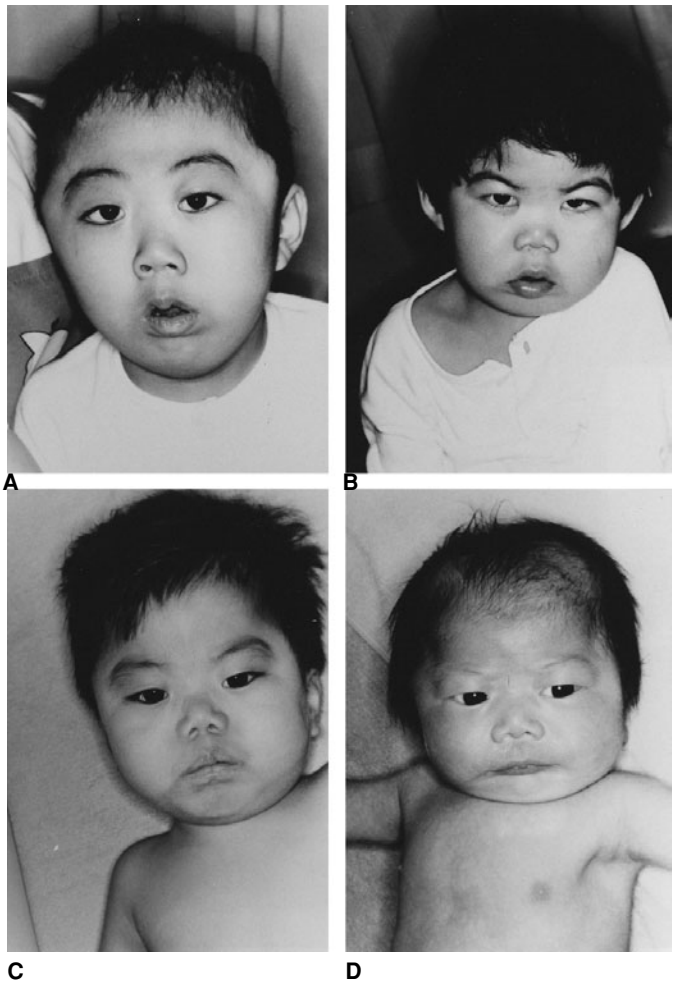
Cerebro-ocular-dental-auricular-skeletal (CODAS) syndrome

The CODAS syndrome is a rare multiple congenital anomalies syndrome comprising unusual facies, unusual skeletal changes, and unusual teeth (1–3). Two patients were of Mennonite ancestry. Inheritance may be autosomal recessive.

Fig. 7–115. *Spondyloepiphyseal dysplasia, craniosynostosis, cataracts, cleft palate, and mental retardation.* (A–D) Facies of four sibs showing flattened facies, depressed nasal bridge, and small nose with anteverted nares. (From G Nishimura et al, Am J Med Genet 77:1, 1998.)



A B C D

Fig. 7–116. *Spondyloepiphyseal dysplasia, craniosynostosis, cataracts, cleft palate, and mental retardation.* Patient 1, shown in Figure 7–115A, with kyphosis, sloping forehead, and brachycephaly. (Courtesy of G Nishimura, Tochigi, Japan.)

The facies is characterized by grooved nose, bilateral ptosis, congenital cataracts, facial hypotonia, anteverted nares, epicanthic folds, and overfolded and crumpled pinnae (Fig. 7–117).

Skeletal changes included short humeri, genua valga, pes planus, delayed bone age, coronal clefts of lumbar vertebrae, epiphyseal dysplasia, marked joint laxity with dislocation, proximally placed thumbs, and squared ilia. Stature is short.

The teeth, both deciduous and permanent, exhibited enamel projections from the cusp tips.

Multicentric osteolysis,Torg-like

Several disorders of multicentric osteolysis have recessive inheritance. The syndromes of Torg, Winchester, Thieffrey-Kohler, and François principally involve the carpal, tarsal, and interphalangeal joints. Progressive bone loss and crippling arthritic deformities mimic severe juvenile rheumatoid arthritis. Al-Mayouf et al (2) and Al Aqeel et al (1) collectively described 12 patients from seven unrelated Saudi Arabian families. Inheritance is clearly autosomal recessive.

All patients had distal arthropathy. Ten patients presented with deformed hands and about half of these exhibited pain in the hands. Involvement of the extremities began in the first few months of life.

Radiographically, osteopenia and undertubulation of bones affected the distal more than the proximal areas and the upper limbs more severely than the lower limbs. Osteolysis was also seen in carpal and tarsal bones. Common findings were sclerotic cranial sutures, brachycephaly, and broad medial clavicles. Stature was short.

Large, painful, fibrocollagenous palmar and plantar pads were evident as well as mild hirsutism of the body.

Facial changes including high forehead and proptosis are seen as well as narrow nasal bridge, bulbous nose, and micrognathia. Normal intelligence and normal renal function separated this form of multicentric osteolysis from several others.

There is marked similarity to the patient described by Torg et al (8). A facies similar to that seen in this syndrome was reported by Szoke et al (7) and others (4–6). The same facial changes were reported in the autosomal dominant form noted by Carnevale et al (3).

"Baby rattle" pelvis dysplasia

Cormier-Daire et al (1) described a lethal skeletal dysplasia having distinct radiologic and chondro-osseous morphologic features. Clinically, the limbs were severely shortened. The fontanelles were very large, the midface hypoplastic, and the belly protuberant (Fig. 7–118A).

The humeri of the limbs had bifid distal ends and the vertebral bodies were unossified. The most striking feature from which the name is derived is the "baby rattle" pelvic configuration with tall and broad ilia (Fig. 7–118B).

Microscopic examination of long bones showed absent enchondral ossification, regions of mesenchymal within resting cartilage, and abnormal mesenchymal ossification.

Achondrogenesis, pyknoachondrogenesis, *atelosteogenesis II,* and *Greenberg dysplasia* must be excluded.

Chapter 8
Syndromes Affecting Bone: Craniotubular Bone Disorders

General considerations

There has been much confusion attendant to genetic disorders of bone characterized by modeling errors of tubular and cranial bones. Gorlin et al (3) divided craniotubular dysplasias into Pyle disease, craniometaphyseal dysplasia, craniodiaphyseal dysplasia, frontometaphyseal dysplasia, Schwarz-Lélek syndrome, dysosteosclerosis, and oculodentoosseous dysplasia. The craniotubular hyperostoses consist of Van Buchem disease, sclerosteosis, congenital hyperphosphatasia, autosomal dominant osteosclerosis, and Camurati-Engelmann disease. Later, Gorlin (2) thought that Lélek's report represented an example of craniometaphyseal dysplasia or possibly an entity unto its own, and considered the report of Schwarz to be an example of craniometadiaphyseal dysplasia. Furthermore, Pyle disease was no longer considered a craniotubular bone disorder as the skull is so mildly involved. More extensive discussions may be found in Beighton and Cremin (1) and Whyte (4).

Craniometaphyseal dysplasia

This disorder, often erroneously reported as Pyle disease, is characterized by unusual facies and club-shaped metaphyseal flaring of long bones. Autosomal dominant (1–6,8,10–12,14–29) and, less frequently, autosomal recessive (31–36,38–45) inheritance patterns have been observed. Extreme variability in the dominant form does not allow for differentiation from the recessive form, whereas the latter appears to be somewhat less variable. Although recessive cases generally appear to be more severe than dominant examples, in a sporadic case it is not possible to clinically distinguish between the two forms (19,37). We cannot classify the cases of Girdwood et al (33) and Sinow et al (43) into either the dominant or recessive type. The case of Schaefer et al (23) surely must represent the autosomal dominant form of craniometaphyseal dysplasia. The cases of Kienböck (15) appear to represent various disorders. About 80 cases have been reported, with most being of the autosomal dominant type (vide infra). Recent reviews are those of Beighton (1) and Richards (21). There appears to be altered bone turnover (7,9,11,30), and stature and intellect are normal. A gene for the dominant form has been mapped to chromosome 5p15.2–p14.1 (20). The recessive form has been mapped to 6q21–q22 (34a).

Usually within the first year of life, rarely at birth, the root of the nose begins to broaden and an elevated wing of bone gradually extends bilaterally over the nasal bridge to the zygomas. With age, this pattern may regress. Increasing bony sclerosis narrows the nasal lumen, leading to obstruction, with resultant mouth breathing (2,22) (Figs. 8–1A–C and 8–2).

Bony overgrowth and sclerosis of the skull base result in variable compression of cranial nerves VII and VIII. Peripheral facial nerve paralysis, headache, or vertigo occur in about 30% of patients (2,5,16). Hypertelorism is a constant feature, and nystagmus is common. Rarely, there is visual loss because of optic atrophy (12,16); this suggests bony encroachment on the optic foramina. The alveolar ridges may be thickened and the teeth malaligned. Occasionally there is delayed eruption of permanent teeth.

Bony alterations in the temporal bone and pyramid produce mixed hearing loss that becomes evident in childhood in about one-half the cases. Chronic otitis media is common. Encroachment is slowly progressive until there is moderate to severe (30–90 dB) hearing loss by the fourth decade (2,5,13,16).

Hyperostosis and sclerosis involve the frontal and occipital portions of the calvaria, skull base, and, less often, mandible. There is increased bone deposit on the walls of the paranasal sinuses and underpneumatization of mastoid cells. Most marked is frontonasal hyperostosis (Fig. 8–1D). The ribs are wide and dense. Long bones have a club-shaped metaphyseal flare that is far milder than that seen in Pyle disease and may be minimal during the first years of life. Cortical hyperostosis of diaphyses is noted in the young, but it disappears with age. Short tubular bones exhibit the same changes as those noted in long bones (Fig. 8–1E,F).

While one cannot differentiate between dominant or recessive inheritance in the isolated patient, separation from those with Pyle disease and craniodiaphyseal dysplasia is usually clinically easy. Reardon et al (41), however, have pointed out the difficulty of diagnosis in some cases.

Craniodiaphyseal dysplasia

Joseph et al (10) first used the term "craniodiaphyseal dysplasia" to designate a severe bone disorder characterized by massive generalized hyperostosis and sclerosis, involving in particular the skull and facial bones (Fig. 8–3A–D). They noted the similarities with the case reported previously by Halliday (8). In total, 15 patients have been described (1,3,5,8–18,20,22). The patient described by Gemmell (6) may have had a mild form of the disease and the patient described by Schaefer et al (19) and again by Thurnau et al (21) most probably had autosomal dominant craniometaphyseal dysplasia. All cases are sporadic, except for the sib pair described by de Souza (4) whose diagnosis may be more compatible with Van Buchem disease (3). Parental consanguinity was described once (8). Inheritance may be autosomal dominant, with all cases representing spontaneous mutations. Brueton and Winter (3) provide an excellent review. The movie *Mask* was about a patient with craniodiaphyseal dysplasia.

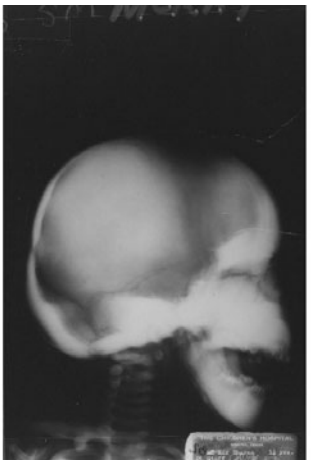
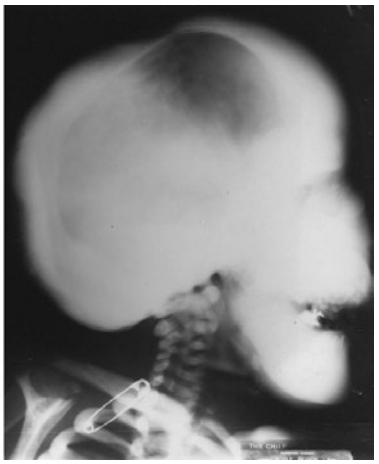
B



C



D

E

Fig. 8–3. *Craniodiaphyseal dysplasia*. (A) Five-year-old showing marked enlargement of cranium, facial bones, and mandible. Note severe ocular hypertelorism and dental malocclusion. (B–D) Lateral radiographs at 3 1/2 months, 18 months, and 5 years showing progression of hyperostosis. Note absence of paranasal sinuses and mastoids. (E) Osteoporosis, "policeman's nightstick" appearance, lack of normal modeling. (A–D from RI Macpherson, J Can Assoc Radiol 25:22, 1974. E from E Stransky et al, Ann Paediatr 199:393, 1962.)

Already in infancy some facial abnormalities are evident, but within a few years, facial and cranial thickening, distortion, and enlargement become more expressed (3). Nasal obstruction and recurrent upper respiratory infections appear within the first few years or even first few months of life, often before the characteristic facial appearance is clear. Marked bony thickening, hypertelorism, paranasal bossing, nasal flattening, and severe dental malocclusion and maleruption of teeth generally follow. Bilateral choanal stenosis can be demonstrated within the first few years. All patients develop lacrimal duct obstruction resulting from bony overgrowth, and most have diminished visual acuity or blindness and progressive hearing impairment as a result of compression of cranial nerves. Seizures may occur (8,20).

Developmental milestones are delayed (6,8,20), but this delay is probably at least in part due to diminished sensory perceptions. Many patients complain of early morning headaches (13). Lack of sexual maturity has been reported (20), and growth is retarded (6,10,14,20). Right ventricular cardiac failure occurs (16,20), and early death is common (8,11,16,20). Histologically, facial bone fragments show dense hyalinized fibrous tissue within the periosteum, containing focal cell clusters of fibrocytes and lymphocytes (15). Bony trabeculae are very thick and have very thick uncalcified osteoid seams (1,15).

Radiographically, the whole skull, including the neurocranium and the facial bones as well as mandible, are severely sclerotic and hyperostotic. The paranasal sinuses and mastoids do not develop. There is moderate thickening and marked sclerosis of the ribs and clavicles. The long tubular bones do not exhibit metaphyseal flare, but rather have a variable cylindrical shape ("policeman's nightstick shape") and show diaphyseal endostosis (Fig. 8–3E). The short tubular bones of the hands

and feet, particularly the first metapodial, also exhibit cylinderization. Spinal sclerosis is more marked in the vertebral arches than in the vertebral bodies (3). Tucker et al (22) have described the radiographic changes that occur over time.

Several investigators have found elevated levels of serum alkaline phosphatase but normal levels of calcium and phosphorus (1,9–11,14, 16–18,20,22). No reliable prenatal diagnosis is available.

The differential diagnosis includes *Van Buchem disease, Camurati-Engelmann disease*, and *craniometaphyseal dysplasia*.

Craniometadiaphyseal dysplasia, wormian bone type

Craniometadiaphyseal dysplasia was first described by Schwarz (5) as a distinct syndrome comprising mild sclerosis of the skull base, marked frontal bossing, and abnormal modeling of the tubular bones (Fig. 8–4). Affected sibs reported by Williams et al (6) were also reported in more detail by Langer et al (2). The patient described by Lélek (3) was first thought to have the same entity, but probably had craniometaphyseal dysplasia (1). Therefore, the eponym "Schwarz-Lélek syndrome" (1) is no longer used and has been replaced by the term "craniometadiaphyseal dysplasia." Another case was reported by Santolaya et al (4). The occurrence of affected sibs and parental consanguinity points to autosomal recessive inheritance (2,4,6).

Clinically, the skull circumference is large, often above the 98th centile. The closure of the anterior fontanel is delayed. The forehead is prominent, the eyes are relatively large with downward-slanting palpebral fissures, the malar bones are hypoplastic, and the jaw protrudes (Fig. 8–4A). The palate is high, and two patients have had natal teeth (2,6). Increased caries (5) and dental hypoplasia (2,4,6) have been described.

The lower limbs may be bowed, and all patients had coxa valga (Fig. 8–4B). One patient (5) had short stature. All patients had sustained multiple fractures that caused severe scoliosis, chest deformity, and a distorted pelvis in one adolescent patient (5).

Radiographically, the changes in the humerus, hands, clavicles, and ribs resemble those found in Pyle disease—i.e., absence of normal diaphyseal constriction, poor metaphyseal flaring, and widened short tubular bones (4). The cortex is thin, the bones, osteoporotic. In infancy, there is delayed ossification of the cranial vault, causing a large anterior fontanel and thinning of the calvaria with wormian bones. Hyperostosis and mild sclerosis of the skull base as well as of the maxilla and mandible are present. The paranasal sinuses are obliterated. Occipital horns were noted in three patients (2,5,6). In some patients a moderately increased alkaline phosphatase level was found (4,5).

Osteopetrosis

Osteopetrosis is a group of disorders characterized by failure of resorption of the primary spongiosa by osteoclasts, resulting in increased osseous density in which cortical and cancellous bone cannot be distinguished radiographically. Histologically, there is an increased number of osteoclasts (14,29,50,63).

Osteopetrosis has been traditionally divided into two groups: congenital or malignant autosomal recessive type and adult or benign autosomal dominant form. However, there is considerable further genetic heterogeneity: (*a*) severe autosomal recessive osteopetrosis (Albers-Schönberg disease, precocious type); (*b*) mild autosomal recessive osteopetrosis (intermediate type); (*c*) autosomal recessive osteopetrosis with renal tubular acidosis (carbonic anhydrase II deficiency), and (*d*) benign autosomal dominant osteopetrosis (delayed type). Still other forms likely exist. All forms appear to be due to defects in osteoclastic resorption (71a).

Severe autosomal recessive osteopetrosis (Albers-Schönberg disease). This disorder is characterized by increased density of nearly all bones and the following complications that occur from failure of resorption of the primary spongiosa and its resultant persistence: anemia, hepatosplenomegaly, blindness, deafness, facial paralysis, and osteomyelitis (28,48). Over 500 cases have been reported. The exact incidence is unknown, but it has been estimated to be 1:200,000 (39), with a higher incidence occurring in Costa Rica (48) and Saudi Arabia (28). Bollerslev and Anderson (8) estimated that 5.5 in 100,000 persons in Denmark have the disorder. Autosomal recessive inheritance with frequent occurrence in sibs and consanguinity has been demonstrated (19,48). The recessive disorder was mapped at chromosome 11q13 (34). Mutations in the TCIRG1 osteoblast-specific unit of the vacuolar protein pump have been

Fig. 8–4. *Craniometadiaphyseal dysplasia, wormian bone type*. (A) Brothers at age 5 and 3 years, respectively. Note large head and parietal bulging. Older sib shows a prominent forehead, depressed nasal bones, prominent eyes with slight downward slant of palpebral fissures, and malar hypoplasia. (B) Two-year-old with unossified area in the superior anterior, and posterior parietal areas. Multiple wormian bones are present in occipital, temporal, and posterior parietal bones. (C) Bones are wide and lack normal diaphyseal constriction. (D,E) Long tubular bones of upper limbs. Wide diaphysis not showing the usual constriction. Lack of the normal metaphyseal flaring and thin cortices. (A,D,E from JM Santolaya et al, Am J Med Genet 77:241, 1998. B,C from LO Langer et al, Skeletal Radiol 20:37, 1991.)

found (25a,42a). The pathogenesis remains unknown. A deficiency in the macrophage-colony stimulating factor (M-CSF) type 1 has been suspected, but has since been found to be unlikely (28,34,56). Pathogenic mechanisms have been extensively discussed by Reeves et al (60), Whyte (77), and Lajeunesse et al (44).

Without treatment, life span is greatly reduced and rarely exceeds a few years (28). After allogeneic bone marrow transplantation, the chances for survival are much better, although a considerable number of patients still die in early childhood (27). Other treatment strategies have been tried (42).

Clinical findings. All tubular bones may be involved, but growth is usually normal. The skull is thickened and dense, mainly at its base, but the calvaria, mastoid bones, and paranasal sinuses are poorly aerated, and the facial bones appear denser than normal (58) (Fig. 8–5A,B). Especially revealing are the MRI studies (16a).

Defective vision and nystagmus are extremely common and are the first symptom (at a median age of 2 months) in half of the patients (15,28). Optic atrophy eventuating from pressure of bone on optic veins is a relatively common complication (1,36). In some cases a primary retinal degeneration exists, indicating possible heterogeneity (49,62). Facial paralysis results from the pressure of dense bone on the foramen of the seventh cranial nerve (6,45). Mental retardation occurs in about 20% of patients (45). Between 25% and 50% of patients have moderate mixed sensorineural and conductive hearing loss, beginning in infancy (5,39,53). The audiograms have been compared to those found in otosclerosis (25). In about half the cases there is a history of otitis media (79a). Temporal bone changes include a small middle ear cavity lined by hypertrophic mucosa, small fallopian canal, and abnormal, sclerotic bone covering the otic capsule (33). The ossicles lack medullary cavities. Intracerebral calcifications at birth have been described (57).

Musculoskeletal findings. The bones are extremely uniformly dense but not distorted in form. The epiphyses, metaphyses, and diaphyses are similarly affected. The cortical and cancellous bones are indistinguishable radiographically (Fig. 8–5C). Alternate radiolucent bands can be seen in the metaphyses and diaphyses of long bones (26). Fractures are common. Because of upward slanting of the greater sphenoid wings, a "space alien" appearance may be noted in the frontal view (23). Older children may show a "hair-on-end" phenomenon in the calvaria. Prenatal X-ray diagnosis has been accomplished (54).

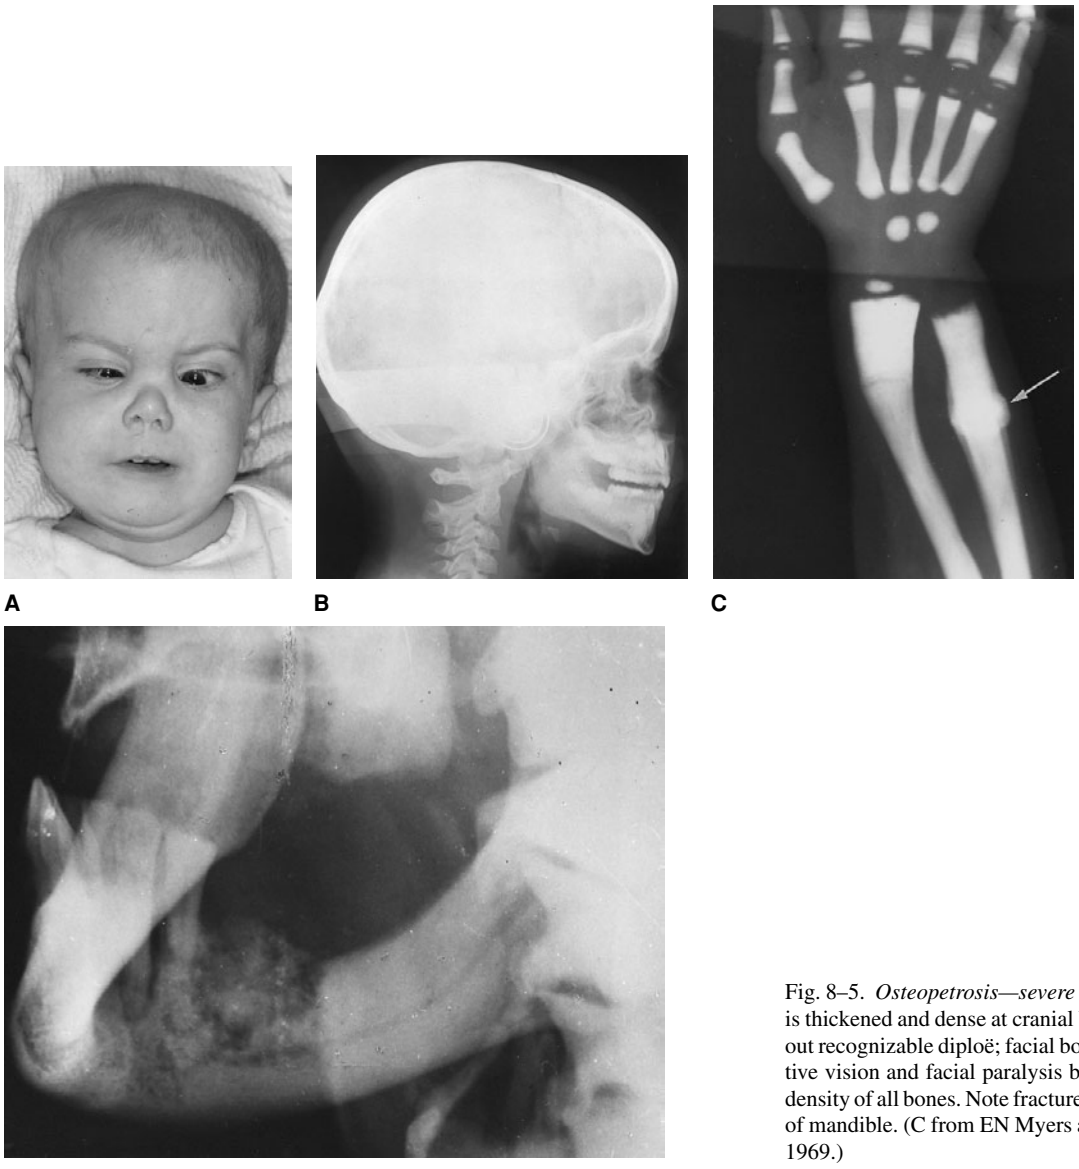

Fig. 8–5. *Osteopetrosis—severe autosomal recessive form.* (A,B) Skull is thickened and dense at cranial base; calvaria is involved as well without recognizable diploë; facial bones appear denser than normal. Defective vision and facial paralysis become evident. (C) Marked increased density of all bones. Note fractures of radius and ulna. (D) Osteomyelitis of mandible. (C from EN Myers and S Stool, Arch Otolaryngol 89:460, 1969.)

Hematopoietic findings. Although the liver and spleen are normal at birth, in over 50% of cases they enlarge in childhood because of extramedullary hematopoiesis. Hemolytic anemia and thrombocytopenia are found in 65% of cases (38), and generalized lymphadenopathy has been noted in about 20%.

Oral manifestations. Osteomyelitis of the jaws, presumably the result of deficient blood supply, seems to be a significant complication of dental extraction (20,80). It may lead to extraoral fistulas. Primary molars and all permanent teeth are greatly distorted and remain totally or partially embedded in basal bone (7). Ankylosis of cementum to bone has been described (82). The teeth appear to be secondarily affected by failure of bone resorption and/or osteomyelitis (Fig. 8–5D). Many authors have remarked on the high incidence of dental caries.

Other findings. Uncommonly described findings are hydrocephaly necessitating drainage (28), Hirschsprung disease (19), and symptoms of neuronal storage disease (38,47,70), indicating further heterogeneity. El Khazen et al (21) described an unusually severe form in which there were in utero fractures, hip dislocation, hydrocephaly, and hypoplasia of the cerebellum. No osteoclasts were found. Monaghan et al (52) described a case with generalized osteosclerosis in infancy that resolved spontaneously within 2 years.

Laboratory findings. Prenatal diagnosis has been accomplished radiologically (54).

Mild autosomal recessive osteopetrosis. This form is rare. It is characterized by short stature, increased upper/lower segment ratio, mandibular prognathism, fractures following minimal trauma, and mild to moderate anemia with extramedullary hematopoiesis, unerupted teeth, and osteomyelitis (4,5,18,32,33,35,40,41,72).

The occurrence in sibs and parental consanguinity indicate autosomal recessive inheritance. Kahler et al (40) have nicely summarized the published cases. This group is probably heterogeneous. Several cases with mental retardation cannot be accurately classified (26,37) but they may represent the disorder discussed below. Horton et al (35) found a decreased number of osteoclasts.

Autosomal recessive osteopetrosis with renal tubular acidosis. At least 30 patients have been reported with short stature (−2 SD to −4 SD), mild to severe mental retardation, basal ganglia calcification, visual impairment, mixed renal tubular acidosis, osteomalacia, extramedullary hematopoiesis, hepatosplenomegaly, pancytopenia, and sensorineural hearing loss (13,31,46,55,59,64,73,78). Improvement of symptoms occurs in time, except for the mental retardation. A deficiency

Fig. 8–6. *Osteopetrosis, autosomal dominant types*. (A) Cranium in type 1. There is pronounced osteosclerosis and enlarged thickness of cranial vault. Trigeminal nerves involved. Conductive hearing loss was common. (B) Cranium in type 2. Osteosclerosis is more pronounced at base. Facial nerves involved. (C,D) Spine. Type 2, in contrast to type 1, has rugger jersey appearance. (E) Pelvis. Endobones in type 2. (A–E from J Bollerslev and PE Anderson, Jr, Bone 9:7, 1988.)

of carbonic anhydrase II has been demonstrated in erythrocytes (64). Heterozygotes have one-half the enzyme levels (67).

The disorder is especially common among Arabs (55,64), but it has been found in Japanese individuals (2,65). The gene has been mapped to 8q22 (53,61). A point mutation is found at an invariant histidine residue His107Tyr (73).

Benign autosomal dominant osteopetrosis. The dominant forms of osteopetrosis are more common than the recessive forms and are not associated with hepatosplenomegaly, anemia, blindness, or mental retardation. At least 40% of cases are asymptomatic, and are diagnosed radiologically (39). The condition has been localized at chromosome 1p21, near M-CSF (74). It usually appears somewhat later in life than the autosomal recessive types (7,11,12), and it appears to be heterogeneous (3,6a,75). Type I is rarely associated with fractures after minor trauma (9,39,43,44,68,83), whereas fractures occur in about 60% of patients with type II (6b,9,24,39). Walpole et al (75) described a family with autosomal dominant osteopetrosis type II, in which an infant had symptoms fitting the severe autosomal recessive type. Thomson (71) described a mentally retarded, blind patient.

Clinical findings. The condition appears silently within the first few years of life, being manifest by increased radiopacity of the skull. Not uncommonly, it is discovered on routine X-ray films of the chest or on radiographic survey of a family of a known patient (Fig. 8–6). In type I there are sclerosis and thickening of the calvaria, no endplate

Table 8–1. Autosomal dominant osteopetrosis

Changes	Type I	Type II
Skull	Thick vault	Dense base
Spine	Variable sclerosis	"Sandwich" vertebrae
Pelvis	No subcrestal sclerosis	Subcrestal sclerosis
Serum acid phosphatase	Normal	Elevated
Osteoclasts	Reduced in size and number	Increased in size and number and in number of nuclei
Fractures	Few %	60%

sclerosis of vertebral bodies, and no "bone-within-bone" appearance in the ilia, whereas in type II, the base of the skull is thickened, and endplate thickening of vertebral bodies ("sandwich vertebrae") and iliac "bone-within-bone" appearance occur (7–12). Osteomyelitis of the mandible occurs in 10%–30% of cases (20,39), as do cranial nerve palsies of cranial nerves II, III, and VII (16,30,39,63,76). In type I there is more often involvement of cranial nerve V with narrowing of the internal auditory meatus (8,51); in type II, cranial nerve VII is far more often affected. Conductive hearing loss is associated with type I (12,30,39) (Table 8–1).

Radiologic findings. Increased density is most marked at the diaphyseal ends of long bones, gradually extending to the epiphyses and to the marrow cavity (39). The times of initiation of calcification and closure of the epiphyses are not altered. There is usually some lack of remodeling, particularly in the femur and tibia. Nearly all bones are ultimately involved. The "sandwich" vertebrae in type II form early in the course of the disease as a result of calcification of the upper and lower surfaces (Fig. 8–6D,E). In the skull, there is thickening of the vault (type I) or base (type II) with clubbing of the anterior and posterior clinoid processes. The sinuses become involved and ultimately disappear. The head is not enlarged.

Elevated levels of serum acid phosphatase have been noted type II (39,44,63) as well as elevated levels of serum creatinine kinase BB (81).

Diagnosis. A contiguous gene syndrome has been described by Zannoli et al (personal communication, July, 2000). It consists of Binder phenotype, obesity, rugger-jersey vertebrae, and Scheuermann disease sign and maps to chromosome 1p21.

Oculodentoosseous dysplasia (oculodentodigital syndrome)

Although reported as early as 1920 by Lohmann (27) and independently by several other investigators (3,29,35), Meyer-Schwickerath et al (28), in 1957, were the first to fully describe a syndrome characterized by narrow nose with hypoplastic alae and thin nostrils, microcornea with iris anomalies, syndactyly and/or camptodactyly of postaxial fingers, hypoplasia or aplasia of the middle phalanx of the fifth fingers and toes, and enamel hypoplasia. About 150 cases have been reported to date (Fig. 8–7).

The syndrome has autosomal dominant inheritance (9,34,37). New mutations represent approximately 50% of cases (37) or 75% of all reported families (38). Jones et al (23) found advanced age in fathers of isolated cases of the disorder. Although affected sibs with normal parents have been described (10,14), these cases can be attributed to the widely variable expressivity of the disorder also within a family (30,32,37,41). Shapiro et al (41) reported a large pedigree in which genetic anticipation might be present, especially in neurologic symptoms. These authors noted several other reported families who suggest anticipation (1,9,24,30,49) and expressed the view that the entity may be caused by expanded trinucleotide repeat sequences. Brueton et al (5) described a family with cutaneous syndactyly of the fourth and fifth fingers (syndactyly type III), craniofacial symptoms fitting oculodentodigital syndrome, but no ocular or dental anomalies, and suggested that syndactyly type III is part of the same spectrum, possibly being allelic or part of a contiguous gene syndrome. Gladwin et al (16) and Boyadjiev et al (4) mapped oculodentodigital syndrome to 6q22–23 and found the same locus involved in the family described by Brueton et al (5). This finding suggests that isolated syndactyly type III is located in the same region as well (39).

Craniofacial findings. Short, narrow palpebral fissures, epicanthal folds, and long, thin nose with prominent nasal bridge and hypoplastic alae nasi comprise a characteristic physiognomy (Fig. 8–7A). The head circumference may be somewhat reduced (26,37,42) and hyperostosis of the skull has been reported (8,34,37).The pinnae may be somewhat abnormally modeled and/or outstanding. Conduction hearing loss has been described in a number of cases (12,14,23,31,37,44), in part because of recurrent otitis media. Dry, lusterless hair that fails to grow to normal length has been described in about 30% of cases (17,19,26,28,34,42). One author noted microscopic changes of monilethrix and pili annuli (44).

Ocular findings. Striking eye changes consist of short, narrow palpebral apertures, microcornea (6–9 mm in diameter), and epicanthal folds in childhood (9,11,13,25,31). The oft-quoted findings of hypertelorism and microphthalmia are spurious (11,13). The pupil may be eccentric and the iris may consist of fine porous spongy tissue. Between the frill and the pupillary rim are crypts and lacunae, and the iris frill may overlie the pupillary rim. Remnants of the pupillary membrane may be present along the iris margin rather than across the pupil (8,10,17,19,28). A number of patients have exhibited strabismus or secondary glaucoma

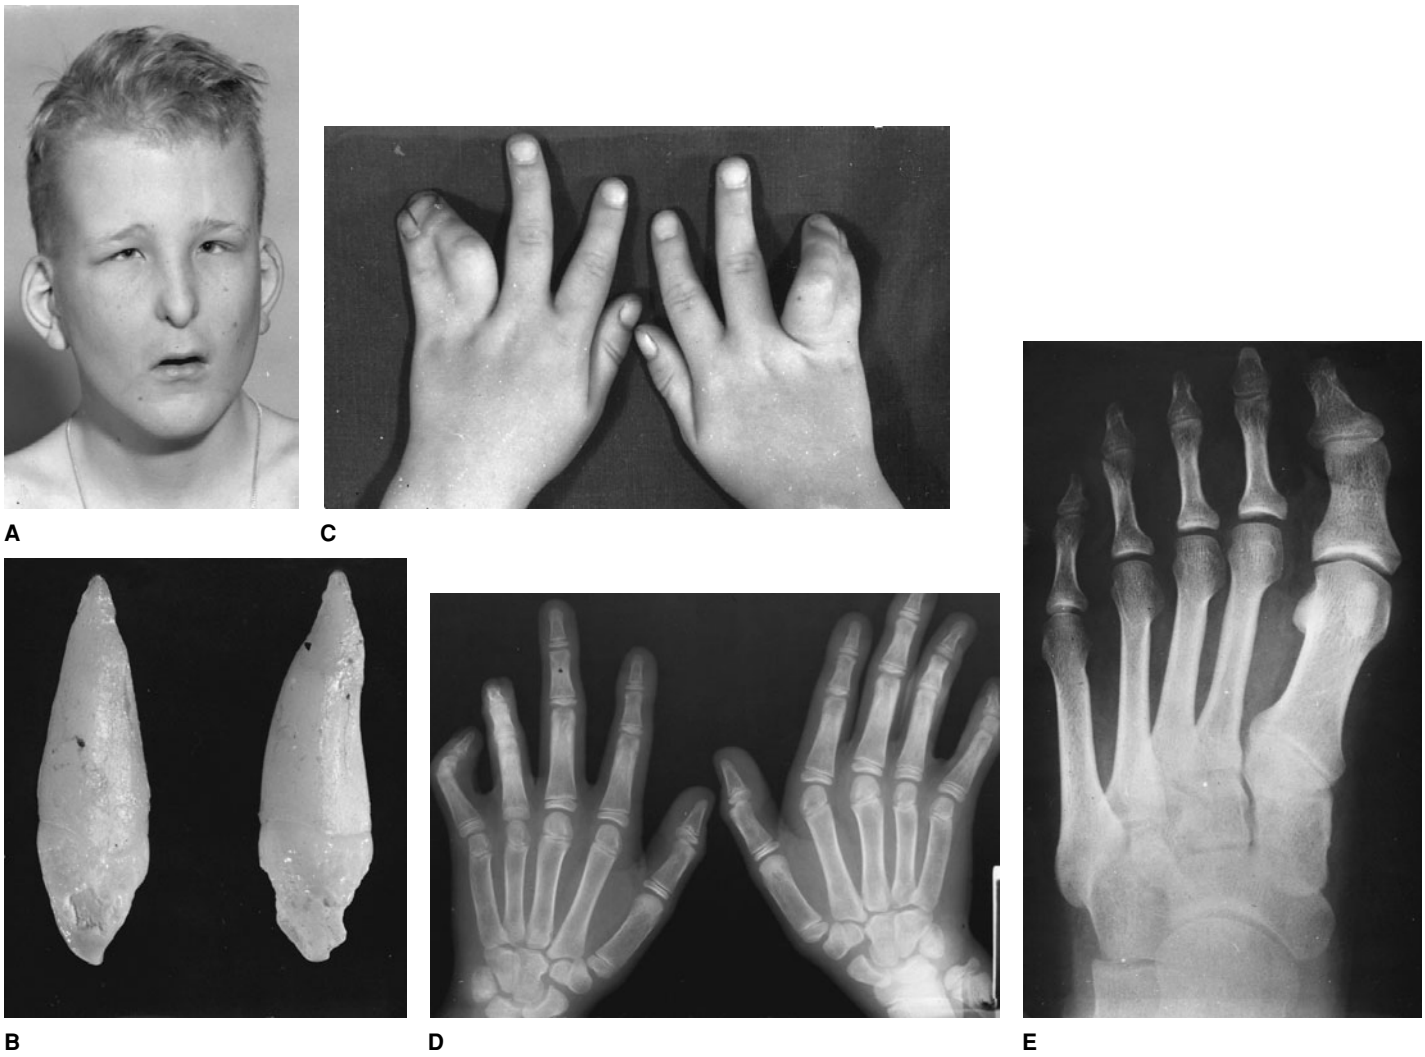

Fig. 8–7. *Oculodentoosseous dysplasia* (*oculodentodigital syndrome*). (A) Characteristic facies showing microcornea and lack of nasal alar flare. (B) Note marked hypoplasia of enamel. (C) Soft tissue syndactyly and ulnar deviation of the fourth and fifth digits. (D) Note poor modeling of metacarpals, abbreviated middle phalanx of fifth finger, and camptodactyly of left fifth finger. There is a mild cone-shaped epiphysis of distal thumb phalanx. (E) Note missing middle phalanges of toes. (A from RJ Gorlin et al, J Pediatr 63:69, 1963. C from SH Reisner et al, Am J Dis Child 118:600, 1969.)

(11,16,24,35,43,46). There may be an increase in the number of disc vessels (24). Persistent hyperplastic primary vitreous has been noted on two occasions (19,45). Radiographically, orbital hypotelorism has been demonstrated in 40% of cases (13). Gutierrez-Dias et al (19) have tabulated the various eye findings in the syndrome.

Musculoskeletal findings. Most patients have a gracile build. Camptodactyly of the fifth or, less often, of the fourth fingers is a common finding (Fig. 8–7C). Clinically, the fifth finger appears to be shortened. Bilateral syndactyly of the fourth and fifth fingers (rarely the third) along with ulnar clinodactyly and syndactyly of the third and fourth toes is often present (35,37,49) (Fig. 8–7E).

Radiographically, the middle phalanx of the fifth finger is cuboid or deltoid or occasionally absent (44) (Fig. 8–7D). The feet, which are clinically normal, exhibit aplasia or hypoplasia of the middle phalanx of one or more toes (Fig. 8–7E). In at least one case, there was postaxial hexadactyly of toes (25). Lack of modeling of the metaphyseal area of the long bones is relatively common (8,9,12,17,26,36).

Oral findings. Generalized enamel hypoplasia has been noted by a number of investigators (10,12,37,38,42) (Fig. 8–7B). The teeth may have a yellowish-brown color (38). Scheutzel (38) described the histopathological changes in the enamel and dentin. The alveolar ridge of the mandible may be wider than normal (6,17,24,36,47). Cleft lip/palate (12,14,30,31,47, RJ Gorlin, personal communication, 2000) and microdontia (11,21,31,47) have been observed by several authors.

Other findings. Cox et al (7) first drew attention to the neurological anomalies. Spastic paraparesis, sometimes progressive (2,4,16,18,20, 30–32,40,42), cerebral white matter anomalies (15,18,20,31,41), basal ganglia calcifications (1), ataxia (37), intention tremor (41), neurogenic bladder disturbances (31,32,41), abnormal visually–evoked and brainstem auditory–evoked potentials (41), epilepsy (32), migraine (31), and learning disabilities (24,31,32) have all been described.

Differential diagnosis. A child with many similar stigmata but with rudimentary dry and brittle nails was described by Whitwell (48). Hypoplasia of the alae nasi can be found in the *oral-facial-digital syndromes* and in *Hallerman-Streiff syndrome*. Although the eye anomalies appear to be similar to those observed in *Rieger syndrome*, there is neither microcornea nor enamel hypoplasia in the latter. Tooth formation is suppressed. Microcornea in combination with glaucoma, epicanthal folds, absent frontal sinuses, and hyperkeratosis of the palms may exhibit autosomal dominant inheritance (22).

Frontometaphyseal dysplasia

In 1969, Gorlin and Cohen (11) separated frontometaphyseal dysplasia from other craniotubular dysplasias. The condition consists of pronounced bony supraorbital ridge, mixed hearing loss, and generalized skeletal dysplasia. About 30 cases were subsequently described (1–10,12–21,23–26,28–32). A probable earlier example is that of Lischi (22).

Inheritance appears to be X-linked with variable expression in carrier females (3,9,10,12,14). Although some authors have suggested autosomal dominant inheritance (4,17,32), there has been no male-to-male transmission. No case with a chromosomal anomaly has been described. Verloes et al (30) opined that frontometaphyseal dysplasia, Melnick-Needles syndrome, and otopalatodigital I and II are variants of a single disorder.

Craniofacial features. The marked supraorbital ridge, wide nasal bridge, downward slanting palpebral fissures, and small pointed chin give the patient a striking appearance. Enlargement of the supraorbital ridge becomes evident before puberty (6) (Fig. 8–8). Progressive mixed hearing loss is commonly present (2,11,28,31,32). Missing permanent teeth and retained deciduous teeth have been found (2,6,11).

Musculoskeletal system. There is both primary and secondary wasting of hand muscles (6,8,12). Dorsiflexion of the wrist and extension of the elbows are reduced, with pronation and supination being extremely limited. Flexion deformities of the fingers and ulnar deviation of the wrist are progressive. Finger mobility is essentially limited to the metacarpophalangeal joints. The thumbs tend to be broad. Hammertoes have also been noted (11).

Radiographic findings. A thick, torus-like frontal ridge, absence of frontal sinuses, "Hershey-kiss" or "top-of-the-mosque" defects of supraorbital rims, arched superior border of maxillary sinuses, short maxilla, elongated cranial base, and antegonial notching of the mandible with marked hypoplasia of the angle and condyloid process have been described (2,11,13,16,18,19,28). A mandibular spur has been reported to be characteristic (10).

The foramen magnum is greatly enlarged, and numerous vertebral anomalies have been noted: the odontoid process is located too far anteriorly, the atlas has no posterior arch, the lumbar vertebrae are flattened, the second and third cervical vertebrae are fused, and the third and fourth vertebrae are subluxated. The shoulders may be highly positioned. Scoliosis is usually marked with resultant shortening of the trunk. The long bones manifest increased density in the diaphyseal region, with lack of modeling in the metaphyseal area producing an Erlenmeyer flask deformity. The legs may be laterally bowed. Marked flaring of the iliac bones

Fig. 8–8. *Frontometaphyseal dysplasia*. (A) Marked supraorbital ridge, wide nasal bridge, and small pointed chin give patient a striking appearance. (B) Wasting of interosseous muscles of hands, ulnar deviation of fingers. (C) Radiograph showing supraorbital torus, hypoplasia and dysplasia of mandible, and cervical anomalies. (D) Generalized lack of modeling of long bones. (E) Marked flaring of iliac bones, widened femoral necks. (F) Missing permanent teeth, retained deciduous teeth, teeth without conical crown form in 18-year-old patient. (A,D from RJ Gorlin and MM Cohen Jr, Am J Dis Child 118:487, 1969.)

and coxa valga have been noted, as well as fused and eroded carpal bones, wide, elongated middle phalanges, and increased interpediculate distances in the lumbar region of the spine (6,11,14,18,28,32). The ribs and vertebrae are irregularly contoured (13) and the lower ribs are "coat hanger" in form. A characteristic metacarpophalangeal profile has been suggested (14).

Other findings. Urinary tract anomalies, mainly hydroureter and hydronephrosis (8,16,17,28), but also bilateral renal duplication (10) and obstructive airway disease (2,8,11,20,21,28) are common complications. Several patients have had cryptorchidism (3,8). Accompanying heart defects have included atrial septum defects (2,6,10), pulmonary stenosis (2,10), pulmonary and tricuspid atresia (10), and mitral valve prolapse (26). One patient had an esophageal atresia with a fistula (9). Bands of soft tissue extending from the medial edge of the scapula to the vertebral column have also been found (29). Hirsutism of the buttocks and thighs is common.

Differential diagnosis. Frontometaphyseal dysplasia should be distinguished from *craniometaphyseal dysplasia* (27), *craniodiaphyseal dysplasia, otopalatodigital syndrome type I* (6), and *Melnick-Needles syndrome* (5). The diagnosis may be difficult in the newborn period, and rests on the increased bone density, rib configuration, widened metaphyses, and externally rotated iliac bones (10,25).

Dysosteosclerosis

Dysosteosclerosis, a term first employed by Spranger et al (16) in 1968, was described as early as 1933 by Ellis (2). Additional examples have been described (1,3–5,6,8–12,14,17–20). Affected sibs (2,3,10,17) and parental consanguinity (2,3,5,14,20) indicate autosomal recessive inheritance. However, there appears to be an X-linked recessive form (13), and some of the isolated male cases may be examples of the X-linked form. The patient reported by Ventruto et al (20) as having craniometaphyseal dysplasia surely has dysosteosclerosis.

Craniofacial findings. The anterior fontanel tends to remain open. Frontal and biparietal bossing and a narrow chin are characteristic (Fig. 8–9). Oligodontia, poorly calcified teeth with late eruption and ankylosis, and premature tooth loss have been described (9,13,14,18,19). Natal teeth have also been noted (4). During early childhood, there may be cranial nerve involvement, such as optic atrophy, abducens palsy, and facial paralysis. Some degree of spasticity and exaggerated reflexes have been evident (1–3,8,14). Other patients have manifested progressive mental retardation (1), progressive otosclerosis (8), or intracerebral calcifications (1).

Musculoskeletal findings. The patient is short and there is a tendency to bone fractures (8,16,17). The limbs are disproportionately shortened in comparison to the trunk and somewhat bowed. Pectus carinatum has been noted in several patients. Macular atrophy of the skin has been found in several cases (2,3,13,14,18).

Radiographically, the calvaria and skull base are thickened. There is sclerosis of the orbital roofs, absent paranasal sinuses, and constriction of the foramina. The clavicles, scapulae, and ribs are sclerotic. The vertebral bodies are flattened and irregularly dense. Long tubular bones are bent in the region of the shortened, thickened diaphyses. The metaphyses are bottle shaped. The epiphyses and metaphyses are sclerotic, but the submetaphyseal areas are clear and their trabecular structure is coarse and irregular. Short tubular bones exhibit similar changes. Iliac bones are hypoplastic and sclerotic. Osteomyelitis of the mandible has been noted (11).

Microscopic study of the growth plates suggests that the metaphyses are filled with irregular trabeculae consisting mainly of cartilaginous matrix with few chondrocytes (7).

Van Buchem disease and pseudo-Van Buchem disease

Van Buchem disease (generalized cortical hyperostosis) is characterized by osteosclerosis of the skull, mandible, clavicles, and ribs and by hyperplasia of the diaphyseal cortex of the long and short bones. An extensive monograph is the 1976 study by Van Buchem et al (17). The total number of reported patients is 26 (1–3,6–18), with 15 of them belonging to the family originally described by Van Buchem (15,16) (Fig. 8–10A–E).

The disorder exhibits autosomal recessive inheritance. The family described by Dixon et al (4) had a different disorder, one that we have seen in affected sibs and have termed this "pseudo–Van Buchem disease" (Fig. 8–10F–H). Several other patients reported to have Van Buchem disease probably had endosteal hyperostosis, Worth type (5,13). It has been suggested that Van Buchem disease in The Netherlands and sclerosteosis in South Africa are, in fact, the same disorder, the differences being explained by an additional epistatic gene in South Africa (1). A genome-wide search in the original family has shown linkage to chromosome 17q12–q21 (19). The increased bone density is due to a deficiency of a novel secreted protein (SOST)(1).

Craniofacial findings. Facial changes develop slowly, but usually become apparent before the second decade (Fig. 8–10A–E). A most striking finding is a wide and thickened mandible, suggesting acromegaly. Rarely, skull circumference is enlarged. Occasionally there is mild exophthalmos. Patients experience headache, unilateral or, rarely, bilateral facial paralysis, and optic atrophy. Facial palsy may be the initial finding (7). Progressive sensorineural or mixed hearing loss often starts during puberty (18). Surgical decompression has been attempted (13).

Musculoskeletal findings. Radiographic changes include progressive thickening of the calvaria and increased density of the skull base. The body of the mandible is greatly enlarged in all measurements; the angle is obtuse. CT scanning of the skull can be useful in preparation of neurosurgical interventions (3). The long tubular bones exhibit diaphyseal thickening and are rough textured. The cortical hyperostosis is predominantly endosteal in character. In severe cases, the medullary cavity is occluded. The transverse diameter of the diaphysis is normal or increased. Elevated serum alkaline phosphatase levels have been noted in most cases (3,16). An aneurysmal bone cyst has been reported in the para-acetabular area (20).

Sclerosteosis

This disorder was described as early as 1929 by Hirsch (16). Several other reports of the disorder (10,11,13,15,17–19,21,22,26,27) antedate Hansen's (14) definition of sclerosteosis. The disorder is characterized by generalized osteosclerosis with hyperostosis of the calvaria, mandible, clavicles, and pelvis similar to that seen in Van Buchem disease. Usually there are syndactyly and other abnormalities of the digits (Fig. 8–11). The disorder appears to be one of osteoblast hyperactivity (23). Beighton (3) provides a good review.

Sclerosteosis has autosomal recessive inheritance. Most patients have been South African of Dutch ancestry (4,7,12,18). The gene has been mapped to 17q12–q21, to the same region as for van Buchem disease (1). Thus, the two disorders are probably allelic. Its frequency there has been estimated to be about 1/60,000 Afrikaners (4). It has been seen in Japan (24), Spain (9), the United States (15,17,23), Senegal (25), and Brazil (21). It is due to loss of SOST gene product (8). Possibly 90 cases have been reported. It has been alleged that heterozygote detection may be possible on the basis of increased calvarial width and density (3,7).

The typical facies, evident by the age of 5 years, is characterized by frontal prominence, hypertelorism, and broad flat nasal root (20). The mandible is prognathic, broadened and squared, and dental malocclusion is frequent. The face may be distorted with relative midfacial hypoplasia. Head circumference is enlarged. In most cases, mixed hearing loss appears in childhood (20). Facial nerve paralysis, transient in infancy, is common in adulthood (10,11). Characteristically, it is unilateral for many years. There is increased intracranial pressure in 80% of cases (5,7,23). Ataxia has been reported (18,23). Exophthalmos, optic atrophy, reduced visual fields, convergent strabismus, nystagmus, chronic headache, and decreased sensory function of the trigeminal nerve have been described in adults. Visual loss occurs in 30%. Only rarely, however, is there total blindness. Several patients have died suddenly from impaction of the medulla in the foramen magnum (5,12).

Body height is over 180 cm in 70% of patients. In about 75%, asymmetric partial or complete cutaneous syndactyly of the index and middle

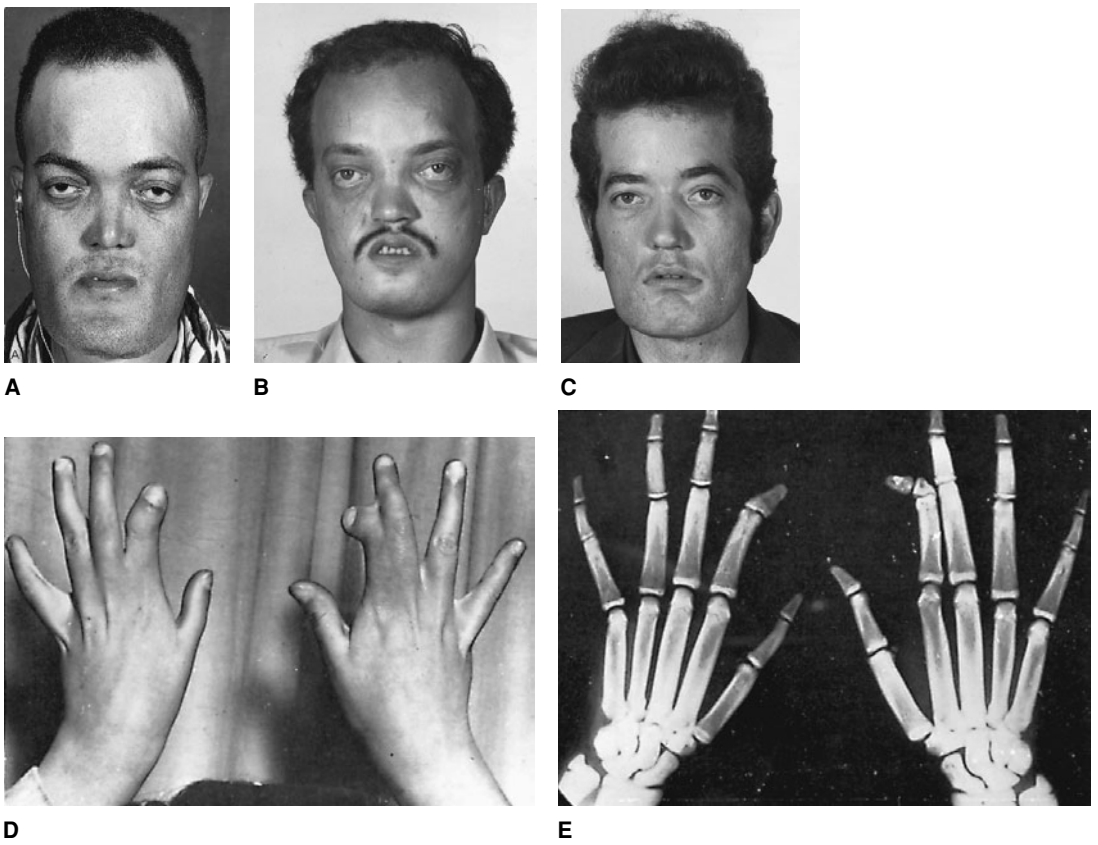

Fig. 8–11. *Sclerosteosis*. (A) There is marked mandibular growth following puberty; mandible assumes square form. Mixed hearing loss, facial palsy, headache, exophthalmos, and blindness are common complications. (B) Exophthalmos and facial palsy. Lips cannot close over teeth. (C) Grossly enlarged cranial vault and mandible. Expressionless facies is due to seventh nerve involvement. (D) Soft tissue syndactyly of second and third fingers was present bilaterally. Third and fourth fingers were partly fused unilaterally. (E) Radiograph shows hypoplasia or absence of middle phalanx of second digit together with radial deviation of terminal phalanx. (A courtesy of CJ Witkop Jr, Minneapolis, Minnesota. B,C from H Hamersma, Laryngoscope 80:1518, 1970. D,E from AS Truswell, J Bone Joint Surg Br 40:208, 1958.)

fingers occurs. There may be radial deviation of the distal phalanx of the index fingers. The nails on the involved digits are hypoplastic in 80% of patients. Height may be is correlated with syndactyly.

Radiographically, the calvaria becomes thickened and sclerotic in infancy. This gradually increases until about the age of 30 years. The base is dense and the foramina obliterated. The mandible is massive, prognathic, and often asymmetric, with an obtuse angle. The clavicles and ribs are broad and dense because of cortical thickening. The scapulae, pelvis, and vertebral endplates and pedicles are uniformly sclerotic. The tubular bones, in addition to having increased density, exhibit a lack of diaphyseal modeling. The index finger may have no middle phalanx or only a small triangular bone (delta phalanx), producing radial deviation. Bony syndactyly may involve the second and third fingers (6).

Microscopic study of the bone reveals only increased density with osteoblastic hyperactivity (23).

Patients with *Van Buchem disease*, most of whom are of Dutch ancestry, tend to be of normal height and never have involvement of digits. Sclerosteosis tends to be more severe in its manifestations. Hearing loss (90%) and raised intracranial pressure (80%) are more common in patients with sclerosteosis than in those with Van Buchem disease. Beighton et al (8), having examined 80 Afrikaners with sclerosteosis in South Africa and 15 patients with Van Buchem disease in The Netherlands, posited that they are the same disorder, the difference being the occurrence of an additional epistatic gene in South Africa.

Autosomal dominant osteosclerosis (endosteal hyperostosis, Worth type)

Clinical manifestation of this disorder is essentially limited to a square jaw—i.e., a widened and deepened mandible with increased gonial angle (1–16,18–20) (Fig. 8–12). We are not certain how to classify the case of Scott and Gautby (17). The changes begin at puberty and plateau with cessation of growth. Possibly, torus palatinus is more frequently associated with the condition (3,10,15,19,20).

Radiographically, endosteal sclerosis of the neurocranium is evident with loss of the diploë, osteosclerosis, and hyperostosis of the mandible as well as absence of the normal antegonial notches, endosteal sclerosis of the diaphyses of long bones (including metacarpals and metatarsals), and osteosclerosis of the pelvis. The vertebral bodies, ribs, and clavicles are involved to a minor degree.

In contrast to *Van Buchem disease*, there is usually no compression of cranial nerves as a result of foraminal encroachment or elevation of serum alkaline phosphatase, but exceptions do exist (1,3,9,11,14). Autosomal dominant inheritance has been reported (7). *Autosomal dominant osteopetrosis* is not associated with enlarged mandible, and furthermore, skeletal involvement is generalized.

Progressive diaphyseal dysplasia (Camurati-Engelmann disease)

Progressive diaphyseal dysplasia is a sclerotic and hyperostotic disorder of bone. Originally reported by Cockayne (5) in 1920, it was defined by Camurati (3) in 1922 and by Engelmann (9) in 1929. More than 200 cases have been reported (22). The prevalence has been estimated to be lower than 1 in 1,000,000 births (25).

Inheritance is autosomal dominant with considerable variation in expression (4,22,25). There appears to be anticipation (25,25a) and genetic homogeneity (1a,5a). Families with more severely affected parents have been reported (24). The gene has been mapped to 19q13.1–q13.3 (10,16a). Domain specific mutations in the gene for transforming growth factor β-1 (TGFβ1) are responsible (16b). A question has been raised regarding its relation to Ribbing disease (20a). A remarkable example was reported by Clybouw et al (4), who described a fully affected child, a symptomless mother without anomalies on X-rays but with a focus of increased osteoblastic activity at the base of the skull, and a grandfather with all major radiologic features but a normal bone scintigraphy. New

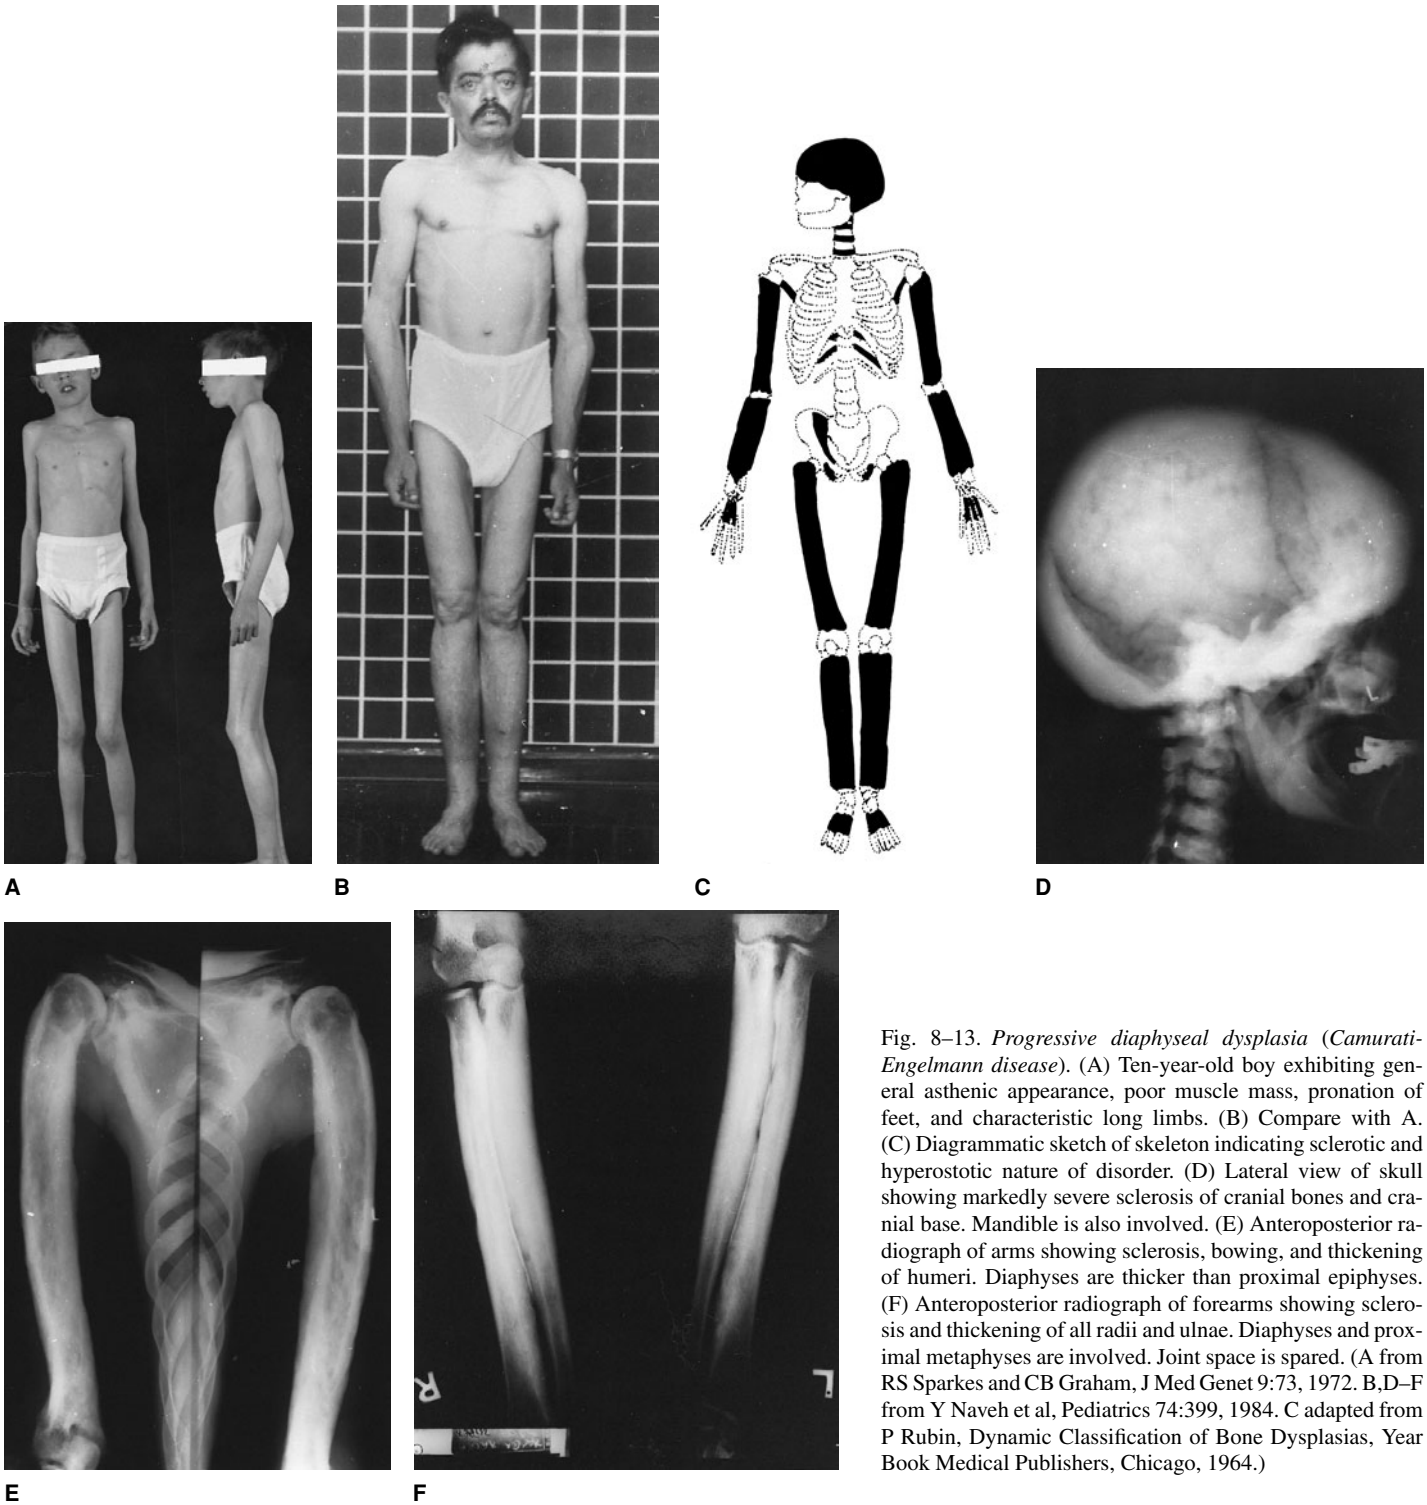

Fig. 8–13. *Progressive diaphyseal dysplasia* (*Camurati-Engelmann disease*). (A) Ten-year-old boy exhibiting general asthenic appearance, poor muscle mass, pronation of feet, and characteristic long limbs. (B) Compare with A. (C) Diagrammatic sketch of skeleton indicating sclerotic and hyperostotic nature of disorder. (D) Lateral view of skull showing markedly severe sclerosis of cranial bones and cranial base. Mandible is also involved. (E) Anteroposterior radiograph of arms showing sclerosis, bowing, and thickening of humeri. Diaphyses are thicker than proximal epiphyses. (F) Anteroposterior radiograph of forearms showing sclerosis and thickening of all radii and ulnae. Diaphyses and proximal metaphyses are involved. Joint space is spared. (A from RS Sparkes and CB Graham, J Med Genet 9:73, 1972. B,D–F from Y Naveh et al, Pediatrics 74:399, 1984. C adapted from P Rubin, Dynamic Classification of Bone Dysplasias, Year Book Medical Publishers, Chicago, 1964.)

mutations have been stated to account for about 50% of cases, but the experience described by Clybouw et al (4) indicates that this may be too high. Hence, a combined radiologic and scintigraphic evaluation of first-degree relatives is needed to investigate whether Camurati-Engelmann disease is present or not. Ghosal et al (11) and, subsequently, Oszoylu (23) and Gümrük et al (13) described diaphyseal dysplasia associated with anemia, which appears to be a separate autosomal recessive entity. Bone marrow suppression and elevated levels of IgG and IgA have been recorded.

The most common clinical findings include delayed ambulation, bone pain, generalized neuromuscular weakness, flat feet, broad-based waddling gait, and thin musculature with disproportionately long limbs and bowed tibiae. Symptoms can manifest as early as the third to fifth year of life, although the mean age for full development of the disorder is about 15–20 years (17,22,25,33). Genua vara, genua valga, lumbar lordosis, or scoliosis may occur. Less often there is hepatosplenomegaly (6) (Fig. 8–13). Secondary sexual development is poor.

Some patients exhibit frontal bossing, exophthalmos, papilledema, epiphora, optic atrophy, and headache (8,18,20,22,31). Luxation of the globe has been reported. Mixed hearing loss has been noted in 5%–7% of patients (6–8,15,21,29,30,32), and sometimes diminishes after decompression procedures (15). Stapes fixation has also been

found (16). The external auditory canals can be nearly occluded by bony overgrowth (27). The vestibular nerve can be compressed (14). Neurological manifestations include cranial nerve dysfunction and pain (1,27,28). Cerebellar herniation into the foramen magnum may be life-threatening (27). Grey et al (12) have reported a remarkable follow-up of 45 years.

Radiographically, symmetric, irregular, spindle-shaped, sclerotic cortical thickening of the mid-diaphyses of the long tubular bones and narrowing of the medullary cavities are evident. With age, the process extends proximally and distally toward the metaphyses, which are rarely involved; the epiphyses are not affected. The base of the skull and calvaria are sclerotic in 70% of cases (Fig. 8–13D). The cervical vertebrae, clavicles, pelvic bones, hand and foot bones, and ribs are affected in about 20%. The mandible is sclerotic in 25% and occasionally is significantly enlarged (6,8,21,24).

Serum alkaline phosphatase and urinary hydroxyproline levels and the erythrocyte sedimentation rate may be elevated (28); carnitine levels may be lowered (2). The scintigraphic changes are striking and do not always correlate with radiographic changes (4,19,26).

Osteopathia striata with cranial sclerosis

In 1924, the Dutch radiologist Voorhoeve was the first to describe a syndrome of cranial sclerosis with osteopathia striata (32). Approximately 45 individuals have been reported (1–34). Most authors have favored autosomal dominant inheritance for this disorder (2,7,8,10,16,20,22,26,29, 32,34), with male-to-male transmission being poorly documented (16,32). We would opt for X-linked dominant inheritance, as do Pellegrino et al (26), Bueno et al (4), and Behninger and Rott (2a). There is a 2.5:1 female sex predilection (13). Intrafamilial variation in expression may complicate genetic counseling (6,29). The syndrome has been well reviewed by König et al (20).

The cranium is usually biparietally enlarged. This is evident at birth but is frequently mildly progressive so that adult head circumference is often 60–65 cm. The facies appears somewhat squared. Nasal obstruction may be evident in infancy (3,12,16,25). There is frontal bossing, the nasal bridge is broad, and the eyes appear wide set (28) (Fig. 8–14). Ankylosis of the temporomandibular joint has been noted (2a). Hearing loss, present in almost half the cases, is usually mixed and quite variable in degree, and often involves the low frequencies (13,18,20,29). Some patients have facial palsy (12,20,21); other cranial nerves may also be involved (6,10,13). Some investigators have suggested that narrowing of the cranial foramina is the cause of the palsy(10); others have suggested that the often transitional character better fits involvement of other factors such as vascular compromise (20). Mild and sometimes moderate mental retardation occurs in about 20% of cases (2,3,12,16,18,20,25,29,31,33). Brain studies are normal (2) or show atrophy (28), callosal body hypoplasia (26), or hydrocephaly (20,26). It remains uncertain whether the alobar holoprosencephaly found in one of the affected family members described by Savarirayan et al (29) was part of the entity or was a coincidence. Cleft palate or bifid uvula has been noted in 40% of cases (2,3,5,7,12,18,20–22, 26,27,30,31,33). Cataracts and abbreviated tooth roots or unerupted teeth have also been noted (3,12,27; RJ Gorlin, unpublished observations). Radiographically, there is scoliosis and hyperostosis of the cranial vault and a marked increase in density of the cranial base (Fig. 8–14B,C). This may be progressive in childhood (13,20,28) or stationary in adulthood (12).

G

Fig. 8–14. *Osteopathia striata with cranial sclerosis*. (A) Facies appears somewhat squared with frontal bossing, broad nasal bridge, and the appearance of wideset eyes. (B,C) Markedly thickened sclerotic areas in cranial vault and base with particularly dense petrous portion of temporal bone. Note rudimentary paranasal sinuses and mastoids. (D) Abbreviated tooth roots. (E) Dense linear striations parallel to long axis are present in femur, tibia, fibula. (F) Note combed appearance of radius and ulna. (G) Characteristic striations present in proximal end of each femur and numerous areas of bone condensation are present in acetabula and ischia. (B,C,E–G from PA Schnyder, Skeletal Radiol 5:19, 1980.)

The sinuses may be obscured and the mastoid air cells diminished. The anterior fontanel closes late (7). Radionuclear studies show an increased tracer uptake, suggestive of an active metabolic process (10,13). The long bones and iliac wings appear combed with fine, uniform, linear striation, hence the name *osteopathia striata*. It is particularly clear in the metaphyses (Fig. 8–14E–G). Similar striations may be present in the ribs parallel to the long axis (29). Some have general increased bone density. Spina bifida occulta in the lumbar region is common (16,33). A few patients have scoliosis (16,30,33). The clavicles are sometimes straight with broad endings (13,20,27,34). Nakamura et al (23) described a single case with recurrent fractures and metaphyseal undermodeling.

Ventricular (6,21,24,26,29) or atrial septal defect (20,26), pulmonic stenosis (8), postaxial polydactyly (6), transient cardiac murmurs (31,33), syndactyly between the fourth and fifth toes (6), duodenal web (1), cystic kidneys, micropenis, omphalocele, and malrotation of the gut all occur (20,26,29). Some patients are described as being hypotonic (21,27,33,35).

Prenatal diagnosis has been accomplished (34) through echocardiographic measurement of the head circumference. However, macrocephaly may develop only in the second or third trimester (20,26).

Hyperphosphatasemia

Variously described under designations such as juvenile Paget's disease, osteochalasia desmalis familiaris, familial osteoectasia with macrocranium, fragile bones with macrocranium, and hereditary chronic hyperphosphatasemia, this disorder was first described by Sorrel and LeGrand-Lambling (20) in 1938 and Choremis et al (5) in 1958. It has been well reviewed by Fanconi et al (12) and Spindler et al (21).

The condition has autosomal recessive inheritance (3,10,11,14,23,24). About half of the patients have been of Puerto Rican origin (1,2,11, 22,24).

The syndrome is characterized by fever, bone pain, and swelling of the extremities during the first year of life (8). Later, enlargement of the calvaria and often numerous fractures and bending of the bones of the extremities occur, particularly anterior bowing of the legs and general broadening of the diaphyseal areas of tubular bones (Fig. 8–15). However, healing is normal. Headache and hypertension are frequent (15,16). Cardiomegaly has been described (14). The sclerae may be blue (11), but are usually normal in color. Intelligence is normal. Progressive mixed hearing loss is commonly diminished and angioid streaking of the retina has been reported (11,16,24). The skin exhibits pseudoxanthoma elasticum (7,9,13,16,19). A single patient developed multiple osteogenic sarcoma of the skull (17).

Histologically, there is intensive metaplastic fibrous bone formation as well as increased osteoblastic and osteoclastic activity that is very similar to that seen in Paget's disease but without typical mosaic or regression lines.

Since chondral ossification is not markedly disturbed (epiphyses are normally formed and the joints are not involved), growth is not seriously diminished. Muscle weakness is frequent, which retards walking, running, and jumping.

Radiographic examination of the skull reveals changes ("cotton ball patches") remarkably like those seen in Paget's disease. There is flattening of vertebral bodies. Long bones exhibit bending, overcylindricalization, and generalized cortical widening. The bone trabeculation is coarse and bone density diminished. Short bones are involved to a lesser degree, mostly on the endosteal side. The facial bones, except in the patient reported by Marshall (15), have not been involved. Scintigraphic changes are striking (14). Teeth are shed early due to root resorption (11).

The blood picture is generally normal, although anemia was described in Swoboda's (23) patients. Serum alkaline phosphatase levels (normal 25) may exceed 500 King-Armstrong units (KAU) (16). Serum acid phosphatase is also elevated (normal 1.5–3.5 KAU) as well as urinary hydroxyproline and leucine aminopeptidase (6).

Diaphyseal medullary stenosis and malignant fibrous histiocytoma (Arnold-Hardcastle syndrome)

A bone dysplasia characterized by abnormalities of cortical growth including diaphyseal medullary stenosis with overlying endosteal thickening and scalloping, metaphyseal striations, infarctions, and sclerotic areas of bone was first reported by Arnold (1) in 1973. The lower extremities are more often involved than the upper extremities. The skull, axial skeleton, and short tubular bones are spared.

Clinical features include pathologic fractures with poor healing and nonunion with painful debilitation. The legs become bowed. Usually between 20 and 50 years of age, aggressive malignant fibrous histocytoma develops. Other families have been reported (3,6). At least 25 examples are known (6). Presenile cataracts have been noted (1,3). Mental retardation was evident in sisters (3).

Autosomal dominant inheritance with variable expression has been found (1). The gene maps to 9p21–p22 (4,5). The mechanism by which the cancer is produced is not known (2). Thallium scanning has been advocated for diagnosis.

Chapter 9
Syndromes Affecting Bone: Other Skeletal Dysplasias

Autosomal recessive mesomelic dwarfism

Reardon et al (1) described a brother and sister, the offspring of second-cousin Pakistani parents. At birth, short angulated lower limbs and forearms with dimpling of the overlying skin were noted, as well as cleft palate and microretrognathia.

Psychomotor development was normal. In addition to marked mesomelic shortness and bowing, there was bilateral camptodactyly of the third, fourth, and fifth fingers. Elbow extension was limited.

Radiographic changes revealed mild generalized platyspondyly with slight irregularity of vertebral endplates of the upper lumbar region with mild posterior scalloping. Flaring of the distal humeral and radial metaphyses was noted. The radius and ulna were short, with marked bowing of the proximal ulna with a bony spur at the apex. The radial head was dislocated, and the distal radial epiphysis was flat. The first metacarpal was abbreviated. Lateral clavicular "hooks" were noted. Flat, irregularly ossified capital femoral epiphyses with broad femoral necks and flared irregular metaphyses were noted. The tibiae and fibulae were short, with anterior bowing and skin dimpling at the apices over the midshaft of the tibiae and fibulae. The talus was unusually formed.

Inheritance is apparently autosomal recessive.

Other mesomelic disorders include Reinhardt-Pfeiffer syndrome, Langer syndrome, Nievergelt syndrome, and autosomal recessive *Robinow syndrome*.

Calvarial doughnut lesions, osteoporosis, and dentigerous cysts

In 1969, Keats and Holt (8) reported multiple round calvarial radiolucencies surrounded by dense rings of sclerotic bone (doughnut lesions) (Fig. 9–1). Similar examples were described under a variety of names by a number of other authors (1–7,9,10,12,13). Inheritance is autosomal dominant (3,4,10,12). A good review is by Baumgartner et al (4a).

In addition to the calvarial doughnut lesions, there have been osteoporosis, moderate bone fragility, coarse trabeculae, and diaphyseal undermodeling of long bones (1,6,10,12). Multiple fractures occur in early childhood (2,6,13). The calvarial lesions manifest as progressively enlarging skull bumps in adolescence. "Bone within bone" appearance in the vertebral bodies has been noted (2).

Both the jaw and calvarial lesions consist of fibroosseous changes. Colavita et al (6) described dentinogenesis imperfecta with cysts surrounding the roots of several teeth. There may be jaw infection (1).

Histologically, the lesions represent a fibrous nidus surrounded by sclerotic bone, essentially a fibrous dysplasia. Serum alkaline phosphatase has been elevated (1,4,6,10,13).

The disorder should be differentiated from calvarial hyperostosis (11).

Campomelia, cervical lymphocele, polysplenia, multicystic dysplastic kidneys, and cleft lip or palate (Cumming syndrome)

Cumming et al (1), in 1986, reported an infant with campomelia, polycystic renal disease, cervical lymphocele, and polysplenia. Additional

cases were presented by Urioste et al (5), Ming et al (3), Dibbern et al (2), and Pérez del Rio et al (4).

In addition to generalized edema and cervical hygroma, all had a short bell-shaped chest. Cystic pancreas (3–5), polycystic liver (1,2,4,5), and cystic kidney disease (1–5) were described. All had short limbs with campomelia and short hands. Some had absent phalanges (3,5). Cutaneous syndactyly of toes (5) was described as well as talipes equinovarus. Cleft palate (1,2) and cleft lip (3,5) have been noted.

Affected female siblings were reported by Urioste et al (5). Inheritance may be autosomal recessive.

Cleidocranial dysplasia

More than 1000 cases of cleidocranial dysplasia have been documented since the reports of Martin (46) in 1765 and Meckel (47) in 1760. It possibly was first manifest in Neanderthal man (24). Scheuthauer (62) accurately described the syndrome in 1871. The Museum of Pathological Anatomy in Vienna harbors a well-preserved skeleton (2). Marie and Sainton (45), in 1897, reported the combination of aplasia or hypoplasia of one or both clavicles, exaggerated development of the transverse diameter of the cranium, and delayed ossification of fontanels. They named the syndrome "cleidocranial dysostosis." The largest known kindred consists of more than 250 affected persons (34,57).

Many extensive reviews and analyses of the syndrome have been carried out, and over 100 associated anomalies have been recorded (9,12,13,15,26,48,49). A classic anatomic study is that of Hultkrantz (32), a good clinical review is that of Schuch and Fleischer-Peters (63), and an excellent historical review was carried out by Soule (68).

The syndrome has autosomal dominant inheritance (5,6,14,15, 48,57,63). It has been suggested that 20%–40% represent new mutations (14,63). Nienhaus et al (53) described a classically affected individual with a de novo pericentric inversion of chromosome 6. Narahara et al (52) found a balanced translocation between chromosome 6p and 18q in another patient. Two groups independently found linkage to 6p21 (13,50), and, in one family, a microdeletion was found (45). After refinement of the localization (21), mutations were found in the CBFA1 gene (51). The CBFA1 gene controls differentiation of precursor cells into osteoblasts (49). The Core-Binding Factor A (CBFA) consists of three different genes, and belongs to the Runt domain gene family (56). In mice, CBFA1 is initially expressed in mesenchymal condensations of the developing skeleton and activity is later restricted to osteoblasts (10), and is important for osteoblast differentiation (55). Mice deficient for CBFA1 showed features comparable with cleidocranial dysplasia in humans (55,65). Hence, the disorder is likely to be caused by haploinsufficiency for the CBFA1 gene, resulting in disturbed terminal differentiation of osteoblasts (56). There may, however, be genetic heterogeneity (3). Some mutations may cause only dental anomalies (56).

There are several reports of affected sibs born to normal parents, which may be explained by germline mosaicism (14,23,75), although this has not yet been proved by molecular studies. Genotype-phenotype correlation has been discussed (76).

Facies and general appearance. The appearance is generally pathognomonic (Figs. 9–2 and 9–3). Affected individuals are usually short, with males averaging 156.6 to 168.8 cm and females 144.6 to 148.5 cm (32,34,38). The skull is brachycephalic, with pronounced frontal and parietal bossing, and the maxilla and zygomas are hypoplastic; thus, the face appears small. The nose is broad at the base, with the bridge depressed. There is hypertelorism. The neck appears long, and the shoulders are narrow and droop markedly.

Cranium. The skull is large and short with biparietal bossing; the cephalic index is usually in excess of 80. In most patients, a groove, overlying the metopic suture, extends from the nasion to the sagittal suture. Closure of the anterior fontanel and sagittal and metopic sutures is delayed, often for life (70). There is segmental calvarial thickening in the supraorbital portion of the frontal bone, the squama of the temporal bones,

and the occipital bone above the inion. Secondary centers of ossification appear in the suture lines, and many wormian bones are formed (70,73) (Fig. 9–4). In extreme cases, the parietal bones are not present at birth (69). The cranial base has short sagittal diameter (59). Mandibular length is increased and the maxilla is short vertically (59). The foramen magnum, which is large, often exhibits defects in the posterior wall (68). Paranasal sinuses (5,19,39) and mastoids (73) are often underdeveloped or absent. Cephalometric changes of the skull are carefully described by Jensen and Kreiborg (36–41), Hirschfelder et al (30), and Ishii et al (33).

Clavicle. Clavicles are absent unilaterally or bilaterally in about 10% (67); more frequently, they are defective at the acromial end (26,34). The clavicles of some patients have a central gap (pseudoarthrosis), with bone replacement by fibrous connective tissue (15) (Fig. 9–5A–C). When the defect is unilateral, it is more frequently on the right side (35).

Deficiency of the clavicle is responsible for the long appearance of the neck and the narrow sloping shoulders. The range of shoulder movements permitted by this bony defect is often remarkable, frequently allowing the individual to approximate the shoulders in front of the chest. This ability is not always recognized by the patient, nor are the parents of an affected child necessarily aware of it (Fig. 9–2).

In this syndrome, there are variations in size, origin, and insertion of muscles related to the clavicles, especially the sternocleidomastoid, trapezius, deltoid, and pectoralis major, yet function is remarkably good (14).

Other skeletal deformities. Although cleidocranial dysplasia was originally believed to involve only bones of membraneous origin, involvement of endochondral bones has been recognized since Fitchet's (14) report. The most frequent abnormalities include delayed closure of the pubic symphysis, coxa vara, or (less often) coxa valga with lateral notching of the capital femoral epiphysis (26,35), cone-shaped thorax, spina bifida occulta of the cervical, thoracic, or lumbar regions of the spine, lumbar spondylolysis, pseudoepiphyses at the base of the metacarpal, abnormally pointed terminal phalangeal tufts of the hands and feet, short broad thumbs, long second metacarpal, short middle phalanges and metatarsals/tarsals III–V, and cone-shaped epiphyses of the distal phalanges. Reduced pelvic diameter requires cesarean section in about 35% of affected women (Fig. 9–5D) (35).

Other findings. Conduction hearing impediment (17,18,29,53) has been described. Although mental development is usually normal, several patients with mild delay have been reported (23,53,63).

Oral manifestations. The palate is highly arched. Submucous cleft palate and complete cleft of the hard and soft palates have been described (73). Delayed union at the mandibular symphysis is characteristic. Many patients may show a deficient ossification of the hyoid bone (34,38,58). Development of the premaxilla is poor, and since growth of the mandible is usually normal, relative prognathism results (67). Newborns may have prolonged feeding problems (6).

The literature presents a rather chaotic picture of the dentition, including multiple supernumerary (average−5) teeth (Fig. 9–6A), multiple crown and root abnormalities, crypt formation around impacted teeth, ectopic localization of teeth, and lack of tooth eruption (19,20,54,59, 60,71,73). The extra teeth are most often in the mandibular premolar and maxillary incisor areas (59). It is known that extraction of deciduous teeth does not promote eruption of permanent teeth (73). Rushton (60) and others (4,25,31,67,74) studied teeth microscopically and observed that roots lacked a layer of cellular cementum (Fig. 9–6B). Fleischer-Peters (16) suggested that the greater than normal bone density of the jaws might inhibit tooth eruption. Rushton (60) and Hitchin (31) attributed noneruption of teeth to failure of bone to resorb. Jensen and Kreiborg (36) and coworkers (44) carried out a study of 20 patients (most followed longitudinally), utilizing cephalograms, panorex and intraoral X rays, intraoral photographs, and surgically removed teeth. They found that the dental lamina produced normal primary teeth and permanent tooth crowns. The primary teeth erupted, but not the permanent teeth, except for first molars and occasionally other teeth. Following normal development of the permanent crowns, the dental lamina was reactivated to form supernumerary teeth. These occurred with highest frequency in the maxillary central incisor area and canine regions. The bizarre supernumerary crown and root morphology appeared to be related to spacial crowding. Deciduous root resorption is extremely delayed or arrested, and can probably be explained by diminished bone resorption. Abnormalities of root morphology in the permanent dentition appear secondary to arrested eruption.

Differential diagnosis. Although the facies as well as body habitus are characteristic, brachycephaly and frontal bossing may suggest rickets, prenatal syphilis, *achondroplasia*, hydrocephaly, *osteogenesis imperfecta*, and *pycnodysostosis*. A deficient premaxilla may also be seen in *Apert syndrome* and in *Crouzon syndrome*. Depressed nasal bridge is seen in *hypohidrotic ectodermal dysplasia, Stickler syndrome*, and prenatal syphilis. The appearance of the shoulders is similar to that seen in intrauterine or natal fracture. *Mandibuloacral dysplasia* is characterized by mild cranial and clavicular dysplasia, but lacks the dental abnormalities

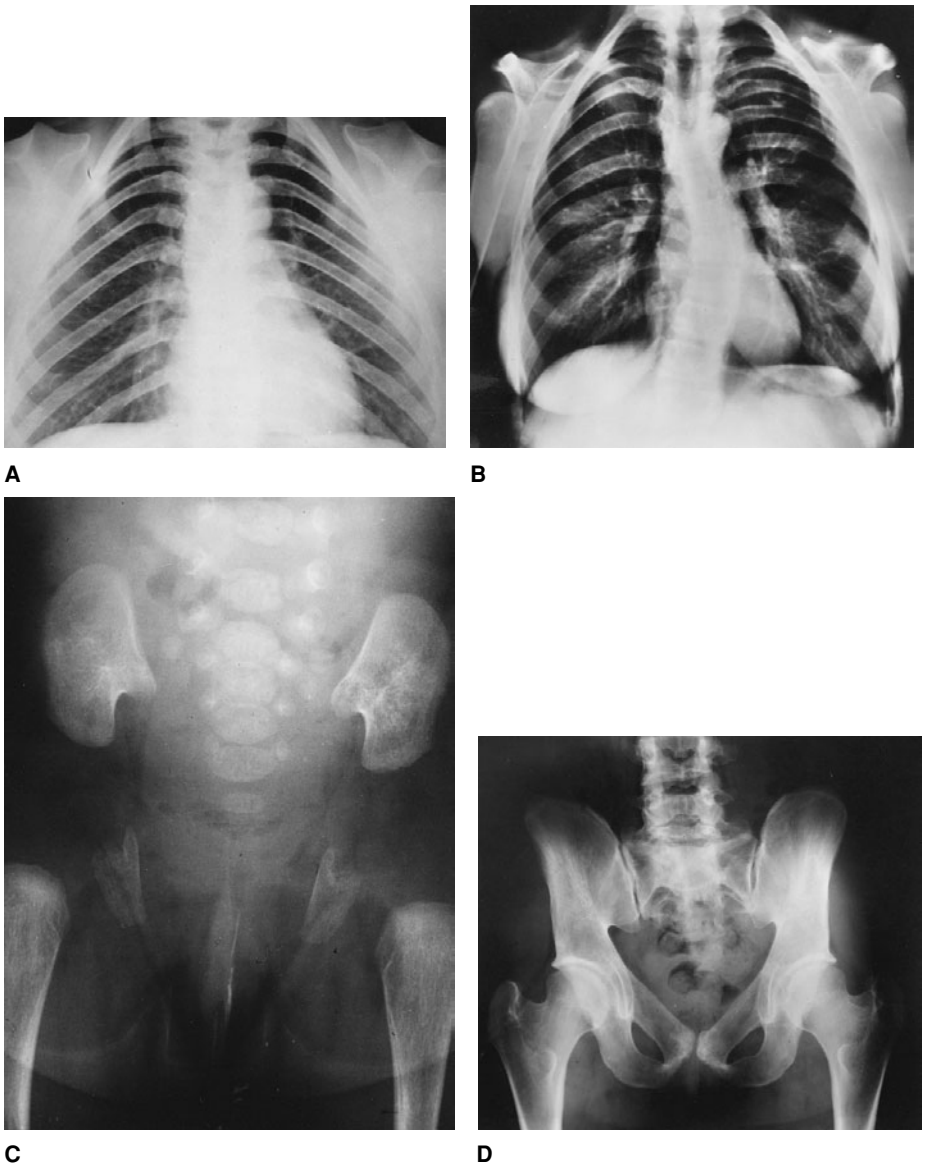

Fig. 9–5. *Cleidocranial dysplasia.* (A,B) Radiographs demonstrating bilateral aplasia of clavicles. (C,D) Pelvic abnormalities (D from M Forland, Am J Med 33:792, 1962.)

seen in cleidocranial dysplasia. In *Hajdu-Cheney syndrome* (acroosteolysis), clavicular demineralization, cranial dysplasia, and severe acroosteolysis occur, but the dental abnormalities found in cleidocranial dysplasia are absent.

Goodman et al (23) reported a disorder resembling cleidocranial dysplasia in three male offspring of two consanguineous matings. These patients had short stature, brachycephaly, open fontanels, bilateral absence of clavicles, wormian bones, nail dysplasia, and radiologic abnormalities of the spine and pelvis. Inheritance was compatible with an autosomal or X-linked recessive disorder.

The *Yunis-Varón syndrome* is characterized by absent clavicles, macrocrania, diastasis of sutures, micrognathia, absent thumbs and distal phalanges of fingers, hypoplasia of the proximal phalanx and absence of the distal phalanx of great toes, pelvic dysplasia, bilateral hip dislocation, and retracted and poorly delineated lips. Inheritance is autosomal recessive. Also, patients with enlarged parietal foramina, macrocephaly, occipital hair tuft, and lateral clavicular aplasia have been described by several investigators (11,22,27); this condition is probably autosomal dominant.

Postnatal clavicular hypoplasia or dysgenesis occurs in *progeria*, disorders of acroosteolysis, and possibly *pycnodysostosis*. Congenital clavicular dysplasia may occur in many disorders reviewed by Hall (27), including *focal dermal hypoplasia, dup(11q) syndrome, dup 20p syndrome, dup8q22 syndrome, Floating-Harbor syndrome*, and *Antley-Bixler syndrome*. Isolated pseudoarthrosis of the right clavicle as an isolated phenomenon is relatively common and largely limited to females. Crane and Heise (8) reported a lethal, autosomal recessive condition characterized by poorly mineralized calvaria, cleft lip and palate, micrognathia, upturned nares, ocular hypertelorism, depressed nasal bridge, and hypoplastic, posteriorly angulated, and low-set helices. In addition, absent cervical vertebrae and clavicles, talipes equinovarus, soft-tissue syndactyly of fingers and toes, short penis, and undescended testes were noted. Barnicoat et al (1) described a fetus with similar features and discussed the resemblance with aminopterin syndrome sine aminopterin.

Wallis et al (71) reported autosomal dominant inheritance of lateral clavicular defects and rhizomelic short stature (cleidorhizomelic syndrome).

Absence of clavicles, anal atresia, and psoriasis-like lesions were reported in sibs by Fukuda et al (20). The affected boy also had hypospadias and urethrorectal fistula. His sister had rectovaginal fistula. The boy's teeth were described as cone shaped with enamel hypoplasia. The parents were normal.

A particular variant, in which there were dolichocephaly, severe lordosis, generalized joint hypermobility, and dystrophic toenails, was described by Winkler (72). RJ Gorlin has seen another patient with the disorder. Patients with cleidofacial dysplasia (42) lack clavicles bilaterally, are microbrachycephalic, have exophthalmos with hypoplasia of lids, and are mentally retarded; inheritance is autosomal recessive.

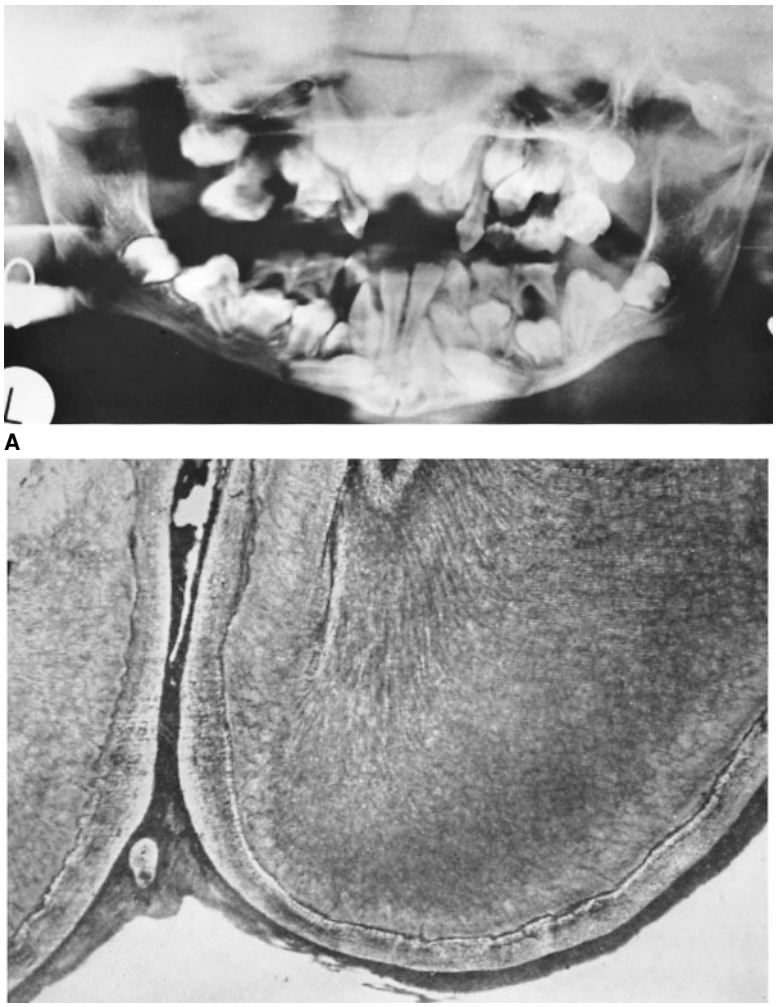

Fig. 9–6. *Cleidocranial dysplasia.* (A) Panorex showing multiple supernumerary, unerupted teeth. (B) Tooth roots, exhibiting complete absence of cellular cementum. (A from A Fleischer-Peters, Stoma (Heidelb) 23:212, 1970. B from M Rushton, Br Dent J 100:81, 1956.)

Silverman and Reiley (66) described spondylomegepiphyseal metaphyseal dysplasia, an autosomal recessive condition similar to cleidocranial dysplasia, but without its cranial and clavicular features.

Delayed ossification of the pubic ramus can also occur in a number of conditions: prematurity, *del(4p) syndrome*, Sjögren-Larsson syndrome, *campomelic dysplasia, spondyloepiphyseal dysplasia congenita* (7), and epispadias.

RJ Gorlin and MM Cohen Jr have seen a girl with congenital absence of both clavicles and sternum and contractures of the fingers. Failure of eruption of most permanent teeth has also been reported as an autosomal dominant trait (64). It also occurs in *GAPO syndrome*.

Clavicular hypoplasia has been seen in combination with zygomatic arch hypoplasia, microcornea, and stellate irides (55a).

Wormian bones are seen in a number of disorders, among them *pycnodysostosis, osteogenesis imperfecta*, hypothyroidism, and *Hajdu-Cheney syndrome*.

Laboratory aids. The disorder has been diagnosed prenatally with ultrasound (28,69a). The advent of molecular studies should allow prenatal studies through mutation analysis of CBFA1.

Dysplastic clavicles, sparse hair, and digital anomalies (Yunis-Varón syndrome)

Yunis and Varón (13), in 1980, described five children with prenatal and postnatal growth deficiency, hypoplastic clavicles, absence of thumbs and halluces, and distal aphalangia. About 15 cases have been reported to date (2,3,5,6,8–11, RCM Hennekam, unpublished observation, 1999). We are uncertain how to classify the case of Adés et al (1), and the pairs of sibs described by Garrett et al (4) have been compared to the skeletal dysplasia reported by Kozlowski et al (7). The child reported by Hughes and Partington (6) and reviewed by Lapeer and Fransman (8) is mildly affected.

Inheritance is autosomal recessive. Parental consanguinity has been reported, and there have been several affected siblings (4,5,11). Hennekam and Vermeulen-Meiners (5) suggested mild heterozygote expression, but

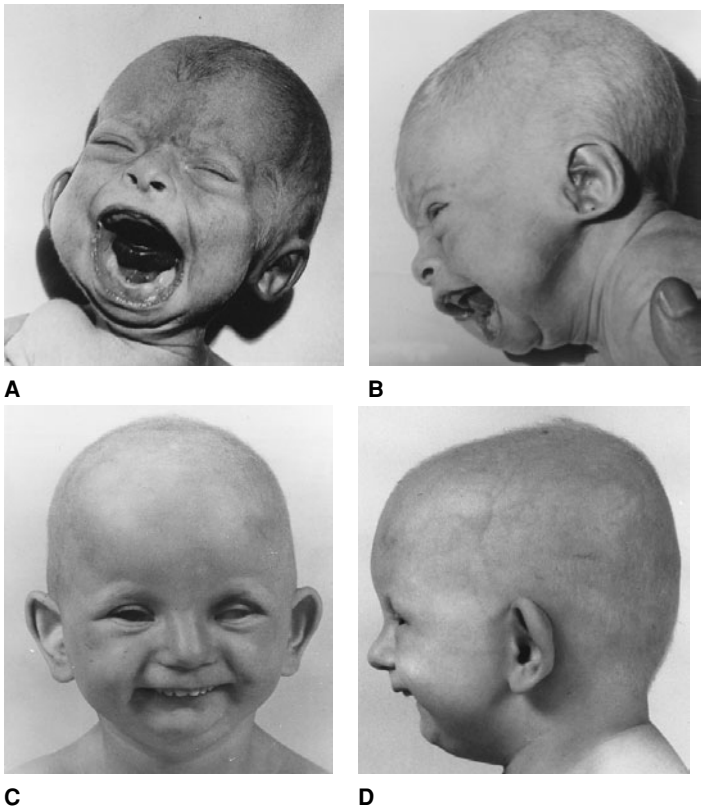

Fig. 9–7. *Dysplastic clavicles, sparse hair, and digital anomalies (Yunis-Varón syndrome).* (A–D) Dolichocephaly with sparse hair, eyebrows, and lashes, outstanding pinnae with wide concha, thin lips, and micrognathia. (A,B from E Yunis and H Varón, Am J Dis Child 134:649, 1980. C,D from HE Hughes and MW Partington, Am J Med Genet 14:539, 1983.)

this has not been found by others (11). In 80% the condition has been lethal before 6 months (11). Walch et al (12) suggested that the syndrome is a lysosomal disorder.

Microcephaly has been found in 40%. Wide sutures and large fontanels are constant features. The facial bones are hypoplastic and the scalp hair is sparse. The eyes tend to be small but proptotic (4,5,12). The pinnae are microtic or dysplastic. One case had severe hearing impairment (11). The nostrils are anteverted. The upper lip is short and the lower jaw small. The skin of the neck appears loose (Fig. 9–7).

The nipples have been absent in a few patients (4,5,12), and pyloric stenosis occurs (11).

The thumbs and great toes are hypoplastic or aplastic (Fig. 9–8). Most have transverse palmar creases. The fingers and toes are short and pointed with hypoplastic or aplastic nails.

Radiographically, there is unusual skull mineralization, wide fontanels and sutures, hypoplastic facial bones, micrognathia, and cystic dental follicles. Clavicles have been missing in 70%. Other skeletal changes include absent sternal ossification, flattened acetabula, and dislocated hips (Fig. 9–9). Constant features are aplasia of thumbs and halluces and distal digits of the toes and middle and distal phalanges of fingers (Fig. 9–10). The diaphyses of long bones have occasionally been thin and constricted. Dworzak et al (3) reported on PAS-positive storage material in vacuoles in heart, muscle, brain, and fibroblasts.

Male infants born to mothers with *Melnick-Needles syndrome* have hypoplastic thumbs and halluces.

Fibrodysplasia ossificans progressiva

Fibrodysplasia ossificans progressiva (FOP) is a rare autosomal dominant disorder of connective tissue with progressive ectopic ossification of tendons, ligaments, facial and skeletal muscles, characteristic skeletal malformations including malformations of the hallux and reduction defects of all digits, hearing loss, and baldness. Progressive disability due to ectopic calcification is erratic, but severe restriction of movement eventually occurs, especially in the shoulders and spine. The condition was first recorded by Guy Patin in 1692 (37). The term *myositis ossificans progressiva* is said to have been assigned by von Dusch in 1868 (33). Since connective tissue is primarily affected, especially aponeuroses, fasciae, and tendons, the term *myositis* is no longer appropriate. In 1918, Rosenstirn (42) analyzed 200 cases; by 1982, an excess of 550 instances had been noted (11), and since then more than 150 additional cases have been published (3,4,7,8,14,19–22,35,36,39,45–50). A few large series of cases are available (8,12,33,35,41,49,53). Whites are reported most commonly, but a number of black patients have also been observed (9,46). A racial or ethnic predilection has not been reported.

Genetics. About 95% of the cases are sporadic (12,25,33,41,54). Autosomal dominant inheritance is based on several instances of parent-to-child and male-to-male transmission (5,14,19,20,25) and on concordant monozygotic twins (18,55). A gene called *noggin* has been mapped to 4q27–q31 (18a,31a,56). Most cases arise as new mutations. A significant paternal age effect for new mutations has been demonstrated (11,40,54). Genetic fitness is close to zero, physical disability probably being the main reason (21,53), although infertility has been suggested (54). Other families link to 17q21–q22 (32).

Evidence indicates that when the FOP gene is transmitted through two or more generations, penetrance is complete. However, variable expressivity is observed with respect to skeletal malformations and the extent of ectopic ossification. On occasion, a parent has exhibited only the characteristic skeletal malformations, with the child expressing the full FOP phenotype with ectopic ossification (25,50). There is evidence for genetic heterogeneity (32). The occurrence in two half sisters has been explained by maternal gonadal mosaicism (21). Although a distorted sex ratio has been suggested (33), other studies have not confirmed this, and it seems to be caused by problems of sample size and ascertainment bias.

Connor and Evans (11), attempting complete ascertainment of FOP in the United Kingdom, indicated a point prevalence of 0.61×10^{-6}. They also calculated a direct estimate of the mutation rate: 1.8×10^{-6} mutations per gene per generation, a rate compatible with other known human mutations. A useful review was provided by Buyse et al (6).

Pathogenesis. FOP is a distinctive histopathologic entity that can be differentiated from other soft-tissue lesions that ossify, such as myositis ossificans, extraosseous osteosarcoma, and osseous metaplasia. Early FOP is characterized by multifocal, interconnecting nodules of spindle-shaped, fibroblast-like cells in a distinctive connective tissue matrix with bone spicules occupying the central area. The histologic picture of such an early lesion can be misinterpreted as fibromatosis or sarcoma (26). Foci of chondroid differentiation may sometimes be observed. Lesions evolve to become mature lamellar bone with adipose and hematopoietic tissue in the cancellous spaces; the rim of fibroblast-like cells is no longer evident. Such pathologic features suggest that the spindle-shaped cells, like periosteum, are precursors of the osseous tissue found in FOP lesions (15). In general, lesional biopsies are not needed to reach the diagnosis FOP. In fact, biopsies are contraindicated as these exacerbate the condition (26,41).

Attempts to understand pathogenesis have viewed FOP lesions as a reaction to dystrophic calcification (43,47,48). Biochemical studies have shown normal calcium and phosphate balance, normal levels of parathyroid hormone, normal tubular handling of phosphate, and normal responsiveness to parathyroid stimulation (9,38). Skin fibroblast studies using a fluorometric assay system have shown normal qualitative and quantitative regulation of alkaline phosphatase (10).

Clinical evidence indicates that lesions tend to be located near flat bones that are formed primarily by membranous ossification. Lack of involvement of the abdominal wall, perineum, and internal viscera strongly suggests multifocal rather than truly systemic disturbance.

In 1990, Kaplan et al (24) reevaluated the data on the natural history of FOP and discovered the similarity between FOP and the anomalies induced by mutations in the decapentaplegic (dpp) gene in Drosophila. The Drosophila dpp gene shows strong homology with the human bone morphogenetic protein (BMP) gene (27), which raised the possibility that FOP is caused by mutations in BMP, especially BMP4. The BMPs are potent bone-inducing morphogens that participate in the developmental organization of the skeleton. Overexpression in lymphocytes of BMP4 and its mRNA was found in patients with FOP recently (44), but it remains

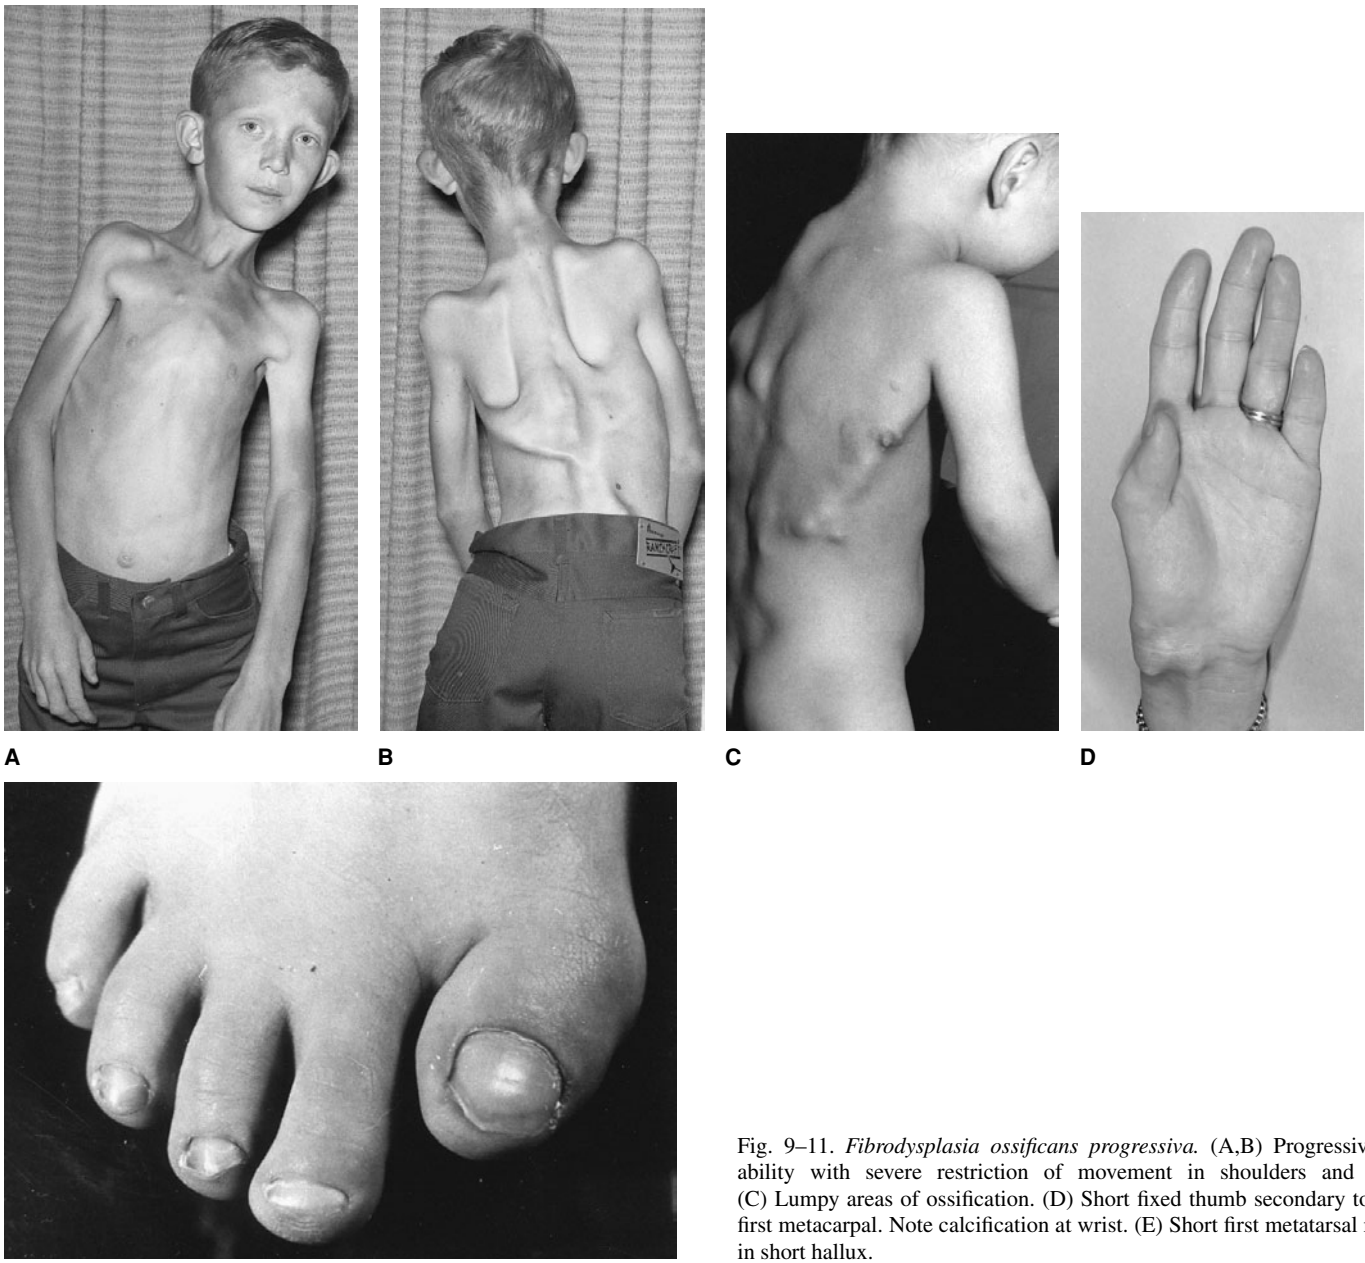

Fig. 9–11. *Fibrodysplasia ossificans progressiva.* (A,B) Progressive disability with severe restriction of movement in shoulders and spine. (C) Lumpy areas of ossification. (D) Short fixed thumb secondary to short first metacarpal. Note calcification at wrist. (E) Short first metatarsal results in short hallux.

uncertain whether this is a primary or secondary event. BMP4 is located at chromosome 14q22–q23.

Musculoskeletal findings. All patients have skeletal abnormalities of the hallux (Figs. 9–11E and 9–12C) that are present at birth and vary from short halluces consisting of a single phalanx, to normal length halluces that are stiff from early childhood and show progressive osseous fusion, hallux valgus, sometimes with osteophytic lipping. Variable other reduction defects have been observed (12,16,52). Other skeletal abnormalities include short thumbs due to short first metacarpals (Figs. 9–11D and 9–12B); clinodactyly of fifth fingers; short broad femoral necks; abnormal cervical vertebrae with small bodies, large pedicles, and large spinous processes; progressive bony ankylosis of the cervical spine (Fig. 9–11A–C); widened metaphyses; and, occasionally, exostoses of the proximal tibiae (12,33,36,41,45). Although regular CT scanning or MRI studies are not indicated, it is important to distinguish the nonspecific findings from those found in soft-tissue tumors, to prevent invasive procedures (7,28) (Table 9–1). Enchondroma has been described (51) but is likely to be coincidental. Limb swelling may be considerable (34).

Ectopic ossification is progressive and begins in early childhood (mean age of 5 years) (8) (Fig. 9–12). The site of onset is most commonly the neck or paraspinal region (spine, shoulder girdle) and less commonly the head or limbs. When new lumps appear, reddening of the overlying skin may occur and pain may sometimes be present. Certain areas within the connective tissue are prone to ossification, especially the paraspinal muscles, limb girdle muscles, and the muscles of mastication. Permanent restriction of mandibular opening has been noted in over 50% and usually presents during adolescence following dental treatment, especially mandibular block anesthesia (7a,31). Involvement of joint capsules, ligaments, and plantar fasciae is common. The progress of ossification proceeds according to characteristic anatomical patterns: dorsal to ventral, cranial to caudal, axial to appendicular, and proximal to distal (8,12). The diaphragm, extraocular muscles, heart, and smooth muscles are spared from ossification. In FOP patients, various factors are known to precipitate ectopic ossification, such as muscle trauma, biopsy, surgical procedures to excise ectopic bone, intramuscular injections, careless venipuncture, and dental treatment (12,29,33,41,46). All patients eventually develop restriction of movement and physical

handicap: by the age of 15 years, 95% of a group of 44 patients had severe restricted mobility of the upper limbs (8). Episodes of ossification and subsequent disability are characteristically erratic. The disorder is known to have long periods of inactivity. Although ectopic ossification is most marked prior to puberty, new lumps may occur during the sixth and seventh decades. Chest wall fixation may lead to diminished pulmonary reserve, and most patients eventually die from respiratory failure (13). Although several treatment strategies have been tried, none has proven to be completely effective (3,4,6). Avoidance of trauma is paramount.

Table 9–1. Features of fibrodysplasia ossificans progressiva[a]

Feature	Percentage
Abnormal hallux	100
Type I (one phalanx)	79
Type II (two phalanges with progressive bony fusion)	9
Type III (two phalanges with osteophytic lipping)	6
Type IV (variable reduction defects)	6
Short thumbs secondary to short first metacarpals	59
Clinodactyly, fifth finger	44
Short broad femoral necks	55
Ectopic calcification, site of onset	
Neck	38
Paraspinal region	32
Head	9
Limbs	12
Joint involvement	
Spine	100
Shoulder	100
Elbow	55
Wrist	7
Hip	59
Knee	38
Ankle	32
Temporomandibular	71
Hearing loss[b]	24
Diffuse thinning of hair[c]	24
Mental deficiency	6

[a] Adapted from data in JM Connor and DAP Evans, J Bone Joint Surg Br 64:76, 1982.
[b] Of these 63% were conductive.
[c] Of these 75% were female.

Other findings. Baldness occurs in approximately 25% of all patients, becoming evident in middle age, and in the majority of females. It appears to be a primary feature of FOP. Mental deficiency is found only as a low-frequency abnormality (12,33). Hearing loss has been reported in at least 25% of patients (10,33,41); in two-thirds, it is conductive; in one-third, sensorineural. It may manifest in infancy to late childhood.

Differential diagnosis. Delayed diagnosis is commonplace in patients with FOP even though they have characteristic skeletal malformations (6,49). Common misdiagnoses are hallux valgus, diaphyseal aclasia, *Klippel-Feil anomaly*, and various forms of arthrogryposis. Swellings, depending upon their site, may be mistaken for lymphadenopathy, sarcoma, or even mumps (9). A number of entities have similarities to FOP, including osseous metaplasia (49), *Albright hereditary osteodystrophy*, extraskeletal osteosarcoma (2,49), dermatomyositis, myositis ossificans with a previous history of trauma (1,35), and bone formation occurring with pilomatrixoma (16).

Laboratory aids. Diagnosis depends on clinical and radiographic demonstration of characteristic skeletal malformations. Routine laboratory tests are usually normal (48); biopsy of lumps should be avoided (26,41), as should careless venipuncture, intramuscular injections, and surgery to excise ectopic bone. Dental treatment should be carried out cautiously and anesthesiologists should be aware of the possibility of atlantoaxial subluxation and also that intubation may be technically difficult because of fixation of the jaws (12,30,31).

CT scanning, ultrasonography, and scintigraphy have all been employed in diagnosis (17).

Hajdu-Cheney syndrome (acroosteolysis)

The Hajdu-Cheney syndrome consists of dissolution of the terminal phalanges, bizarrely shaped skull, premature loss of teeth, and short stature (Figs. 9–13 to 9–17). It was first described by Hajdu and Kauntze (18) in 1948. Cheney (6) reported familial occurrence in 1965.

The syndrome has autosomal dominant inheritance with very variable expressivity (6,11,35,54,60), but the vast majority have been isolated examples. About 50 patients have been described (1–6,8–14,17,18,20–22, 24–26,28,35,36,38–43,45,46,49,50,52–55,57,58,60–63). A few examples are less certain (34,37). We cannot identify some presumed cases (48). No patient with a chromosome defect has been described, nor is there any clue regarding the gene(s) involved. Crifasi et al (8) provide a useful tabulation of patients.

Facies. The face is characteristic (Figs. 9–13 and 9–14). The head appears disproportionately large. The scalp hair and eyebrows are thick and coarse with synophrys. The hair is low on the forehead and nape. The outer supraorbital ridges are often enlarged. There may be mild exophthalmos and hypertelorism. The midface is somewhat hypoplastic and the philtrum is long. The lower third of the face is shortened, probably in large part due to premature loss of teeth. The mouth tends to be small and the chin usually recedes, although prognathism has been described (18). The neck is often short. The ears are low-set. Conduction

Fig. 9–14. *Hajdu-Cheney syndrome*. (A) Ten-year-old boy exhibiting shortness of stature, hirsutism, genua valga, unusual facial appearance. (B) Compare with 18-year-old boy. Note similar, somewhat more square-appearing face, bushy eyebrows, and subluxation of radial head. (A from J Herrmann et al, Z Kinderheilkd 114:93, 1973. B from A Matisonn and F Ziady S Afr Med J 47:2060, 1973.)

A B

(1,8,9,18,49,54,57,58,60) and sensorineural (14,20,55) hearing loss have been noted in a number of cases. Myopia, epicanthal folds, nystagmus, reduced visual fields, abducens palsy, disk pallor, morning glory pupil, and optic atrophy have been found (1,2,14,18,22,57,60). One patient had cataract (25).

Skin. Generalized hirsutism is relatively frequent. The skin may be somewhat more elastic than normal (22,37). The nails are often wider than they are long and may become coarse and curved (1,2,11,25,37). Prominent sweat pores in axillae, groin, and neck have been reported (1). Kaler et al (24) described concomitant psoriasis; Nishimura et al (39) described the skin as being coarse and scaly.

Central nervous system. A serious complication can result from impaction of the cerebellum into the foramen magnum (18,22,27,35,45, 49,60). This can cause occipital headache, hydrocephaly, and progressive neurologic deterioration with involvement of the lower cranial nerves (gruff or low-pitched voice, paralyzed palate, anesthesia of pharynx)

Fig. 9–15. *Hajdu-Cheney syndrome*. Bathrocephaly with many wormian bones in suture lines, depressed anterior fontanel, and basilar impression. (From WD Cheney, Am J Roentgenol 94:595, 1965.)

Fig. 9–16. *Hajdu-Cheney syndrome.* (A) Abbreviated terminal phalanges. (B) Lytic alterations of terminal phalanges. (A from A Matisson and F Ziady, S Afr Med J 47:2060, 1973. B From WD Cheney, Am J Roentgenol 94:595, 1965.)

and cerebellar dysfunction (1,2,8,20,22,25,27,28,43,45,57,58,60). Seventh nerve palsy has also been noted (2), as were anosmia (8), trigeminal neuralgia (38), vocal cord paralysis (14), and syringomyelia (50).

Musculoskeletal alterations. Progressive basilar invagination, dolichocephaly, and unusual protuberance of the squamous portion of the occipital bone (bathrocephaly) are striking. Widening of the metopic, coronal, and lambdoidal sutures with multiple wormian bones and depression at the anterior fontanel are evident in most patients (Fig. 9–15). The frontal sinuses are absent and the maxillary antra underdeveloped. The sella turcica is enlarged, elongated (J-shaped), and wide open with slender clinoids (Fig. 9–15). The anterior nasal spine resorbs (54). The mandibular condyles are positioned anterior to the glenoid fossae and there may be resorption of the condylar heads (2) or mandibular rami (16). The mandibular chin button is often missing.

Adult height has ranged from 140 to 157 cm but decreases with age (11). This is in part due to progressive kyphosis and/or scoliosis, marked osteoporosis (40), and compression of thoracic vertebrae. There is associated pain (5,6,18) due, in part, to compression fractures of the spine. Extension and flexion of the neck are often limited (21). The superior and inferior surfaces of the vertebrae are concave, assuming a "fish-bone" shape (60). The cervical spine is often straighter than normal (4,52). Syringohydromyelia has been reported (1,39). Intervertebral disks may appear denser than the vertebral bodies.

Shortening and clubbing due to resorption of the distal portion of fingers and toes, primarily the former, begin around the third or fourth year of life. In severe cases, the middle phalanges can be involved (6,10,11). The terminal portion of the thumb is especially abbreviated (6,42,54) (Fig. 9–16). All joints are somewhat hyperflexible, especially the interphalangeal joints. Hip dislocation has been reported (3). Pain or paresthesia may be experienced in the joints, especially on motion (49). Genua valga is frequent. Long bones, metacarpals, and metatarsals often fracture (4,6,10,39,42,45,47). The metaphyseal area of metapodial bones tends to undergo dissolution. Narrowing of the metacarpophalangeal and/or metatarsophalangeal spaces (6,9,17,18,47) and osteolysis of the radial head (18,55) have been documented. The tibiae and fibulae may be somewhat curved, and some patients have a proximal anterior tibial groove. Some patients have exhibited fusion of the dorsal processes of the third to fifth cervical vertebrae. Radial dislocation has also been noted (1,14,25,35,41,61). Clubfeet (1,2,8,37,47,57) and umbilical and/or inguinal hernia (1,25,49,57) have been reported in a few cases.

Fig. 9–17. *Hajdu-Cheney syndrome*. Early loss of teeth due to periodontal disease.

Genitourinary findings. Anomalies have included renal cortical cysts (2,8,13,14,25,32,45,61), glomerulonephritis (45), urinary reflux (14,25,58), hypogonadism (1,2,35,41), cryptorchidism (1,22,25), and hypospadias (8,61). The polycystic kidneys may lead to hypertension and early chronic renal failure (13,14,25,45).

Other findings. VSD (1,8,49,54), patent ductus arteriosus (1,3, 25,61), aortic and mitral regurgitations and aortic stenosis (24), and malrotation of the bowel (25,43,54) have been reported.

Oral manifestations. Early loss of teeth due to periodontal disease with marked resorption of the alveolar ridges within 6 months after loss of teeth is an almost constant feature (2) (Fig. 9–17). Permanent teeth are often impacted. Malocclusion is constant. Molar roots may be resorbed (2,10,42). Cleft palate, cleft uvula, and velopharyngeal incompetence have been mentioned (4,8,25,27,45,49,60). The mandible, small in childhood, may become relatively prognathic with age (57).

Differential diagnosis. The term "acroosteolysis" is used nonspecifically to refer to dissolution of the terminal phalanges of the hands and feet. Acroosteolysis may also be seen in *pycnodysostosis, progeria, mandibuloacral dysplasia, epidermolysis bullosa, Murray-Puretić-Drescher syndrome, Winchester syndrome*, Gorham disease, scleroderma, syringomyelia, leprosy, syphilis, psoriasis, trauma, dominant acroosteolysis, neurogenic ulcerative acropathy, manual exposure to polyvinyl chloride intoxication, and a host of other disorders (7,11,15,19,23,26,29–33, 48,59).

The *serpentine fibula syndrome* (12) has been suggested to be allelic to Hajdu-Cheney syndrome (13,25,44). There is also resemblance with *Melnick-Needles*, and *Ter Haar syndrome* (51,56). Rosser et al (46) provide a useful comparison with the latter entities. A very severe case of massive osteolysis, in part, resembled Hajdu-Cheney syndrome (31).

Laboratory aids. Several investigators (4,22,35,55) described somewhat elevated serum alkaline phosphatase levels but others have noted normal values (11,57). Vanek (55) found elevated acid phosphatase. Brown et al (4) noted elevated plasma beta-glucuronidase activity. Growth hormone deficiency has been found but needs confirmation (47).

Infantile cortical hyperostosis (Caffey-Silverman syndrome)

Although infantile cortical hyperostosis was originally described by Röske (36) in 1930, it was not until 1945–1946 that the clinical and radiographic studies of Caffey and Silverman (11) and of Smyth et al (42) called attention to it. The disorder affects infants under 6 months of age and is generally a benign and self-limited disorder. Its most constant features are bilateral swelling over the mandible or other bones, radiographic evidence of new bone formation in the area, hyperirritability, and mild fever. At least 250 cases have been recorded. A number of large series have been published (10,18–20,22,38) and, although sporadic cases have far outnumbered familial cases, autosomal dominant inheritance with incomplete penetrance and variable expression has been repeatedly demonstrated (1,4,15,17,19,20,34,38,43,46). It has been stated that the sporadic form has occurred less frequently during the last decades (32).

Saul et al (38) and MacLachlan et al (32) indicated that familial infantile cortical hyperostosis differed in several respects from sporadic examples, the former having an earlier onset of disease (24% at birth),

less frequent mandibular, ulnar, and clavicular involvement, no involvement of ribs and scapulae, and more frequent lower extremity involvement. Onset in the sporadic form is at 10 weeks, a bit later than the 7 weeks in the familial form (32). The disorder has been observed as late as 20 months after birth (20,25,27). Blank (6) indicated that some unexplained episodes of pain and cortical thickening in older children may represent recurrences in patients in whom the infantile phase of the disease has not been severe enough to call attention to it. A severe prenatal form is likely to exist (2,14,28,30,31,48), characterized by polyhydramnios, extensive skeletal involvement but with relative sparing of the clavicles, hands, and feet, edematous and sometimes short extremities, and frequent intrauterine or early neonatal death (48). Most cases with this form are sporadic, but familial occurrence has been described (14,48) and autosomal recessive inheritance can not be excluded. In one case (31), elevated IgA and C-reactive protein levels at cordocentesis pointed to an infectious cause.

Cayler and Peterson (12) estimated that the disorder was present in 3 of every 1000 registered patients under 6 months of age. It has been suggested that pathogenesis is based on congenital abnormality of the vessels supplying the periosteum of the involved bones, hypoxia effecting focal necrosis of the overlying soft tissue, resulting in new subperiosteal bone formation (40,41). A dog model exists (32).

Here the sporadic and autosomal dominant cases will be described collectively.

Facies. Because of the swelling, the facies is so striking that the condition may be diagnosed with considerable assurance even prior to confirmatory X-ray evidence (24). The swelling is symmetric and located over the body and ramus of the mandible (Fig. 9–18). Pallor is often observed as well.

Soft tissues. The condition is initiated by tender, soft-tissue swelling over the face, around the orbits, thorax, or extremities; this swelling often undergoes remission and exacerbation (33). It is firm, brawny, and often so painful as to cause pseudoparalysis of an extremity (41). It is not accompanied by redness or increased heat.

Fever and irritability. Pain, fever of mild degree, and hyperirritability are seen in at least two-thirds of the patients (10,41). These signs commonly precede the appearance of the swelling and bone involvement. One or all may, however, be absent. Anemia, leukocytosis, and elevation of the sedimentation rate occur in more than half the patients (22,50).

Fig. 9–18. *Infantile cortical hyperostosis*. Note bilateral swellings over ramus of mandible.

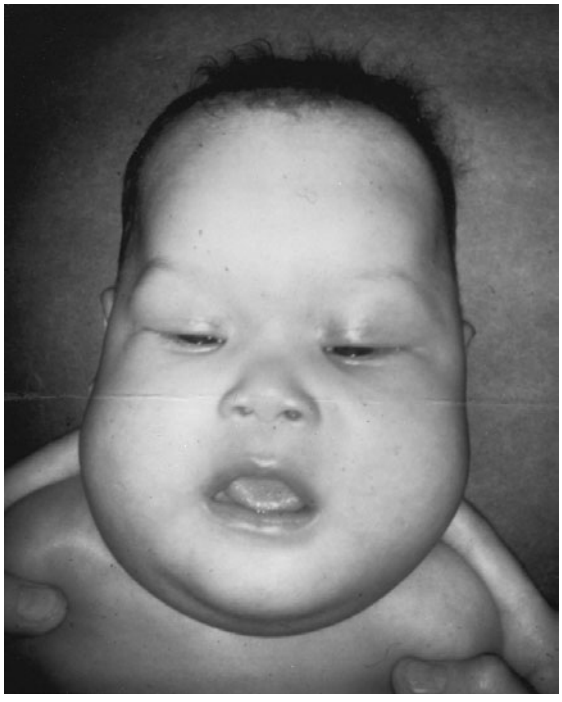

Fig. 9–19. *Infantile cortical hyperostosis.* Symmetric mandibular enlargement 6 months after onset of the disorder. (From PM Burbank et al, Oral Surg 11:1126, 1958.)

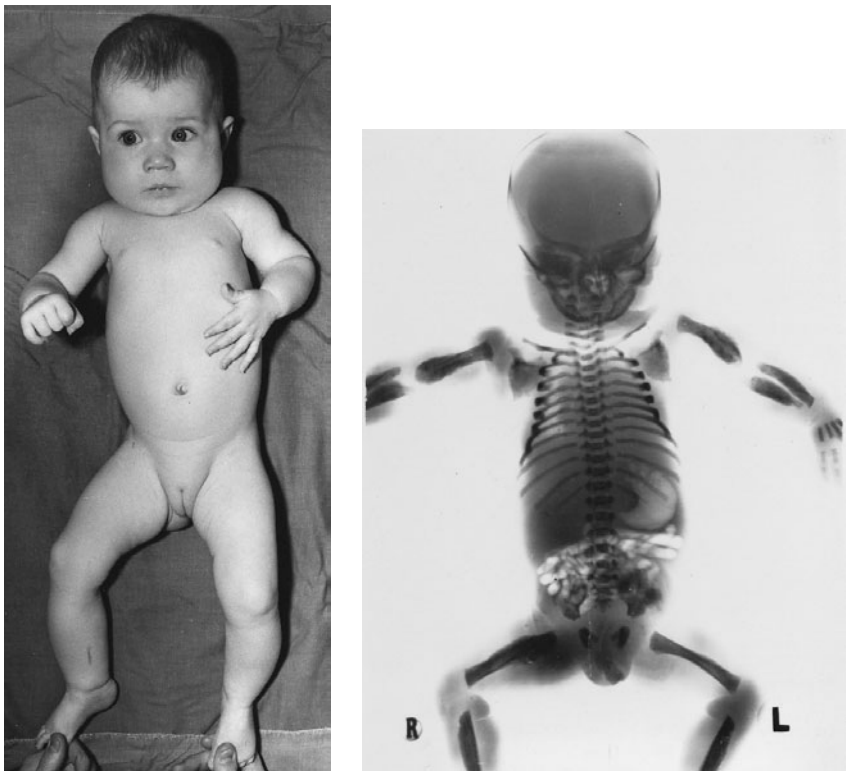
Skeletal system. The most frequently affected bone is the mandible, at least three of every four patients experiencing mandibular enlargement (Fig. 9–19). Less commonly involved are the clavicle, tibia, ulna, femur, rib, humerus, maxilla, and fibula (10,21–23,41,45,50). MRI studies have not had additional value (37). Usually several bones are affected at the same time (Fig. 9–20). As noted above, in the autosomal dominant form, the mandible, ulna, and clavicle are less often involved than in the sporadic form and the ribs and scapulae almost never (32). Lachaux et al (29) described sibs in whom the lesions were largely confined to the skull, sparing the mandible. New periosteal bone formation, appearing most often during the ninth week, undergoes resolution slowly. Though complete clinical resolution takes place within 3 to 30 months (average, 9 months), radiographic evidence may persist for many years (11,35). Bone bridges between the radius and ulna and between ribs have been described (11). Leg length inequality (11,23) and forward bowing of the tibia (20,25,32,49) are common. Pleural effusion has been reported in cases in which there has been rib involvement (11). Later recurrences of the disorder, although uncommon, have been described (6,8,22,35).

Oral manifestations. The oral findings have been discussed, in part, above. Involvement of the mandible was formerly thought to be necessary for diagnosis of the condition, but analysis of large series of cases has revealed that this is not so (41). Nevertheless, swelling of the jaws is the most common presenting sign. In a follow-up survey of 11 cases, Burbank et al (10) demonstrated that in six cases the mandible was the only bone involved. Follow-up showed that the fever had no effect on the enamel or on the eruption sequence. However, 8 of the 11 patients had radiographic evidence of residual bony asymmetry of the mandible at the angle and ramus, and some had severe malocclusion. Dysphagia has been noted (39).

Pathology. Several microscopic studies have been performed (8,9,35), the most comprehensive being that of Eversole et al (16), and are characterized by periosteal reactive bone formation associated with resorption of the immediate underlying cortex. In the early stages, foci of polymorphonuclear neutrophilic leukocytes are seen within the periosteum. The periosteum is swollen and mucoid in appearance, losing its well-defined limits and blending into the muscle, fascia, and tendons. At this stage, there is some resemblance to osteosarcoma, and erroneous diagnosis and treatment may result. The small arteries of the periosteum



A B

Fig. 9–20. *Infantile cortical hyperostosis.* (A) Involvement of mandible and lower extremities. (B) Thickening of periosteum and new bone formation in long bones. (A from JW Gerrard et al, J Pediatr 59:543, 1961.)

and overlying soft tissue show intimal proliferation. In the later stages, poorly vascularized and incompletely structured new bone is laid down. Neither hemorrhage nor inflammation is seen at this stage (22).

Differential diagnosis. Bocian et al (7) reported a newly recognized skeletal dysplasia that simulates infantile cortical hyperostosis, but differs in absence of induration, redness or tenderness over affected bones, absence of fever, and presence of transient neonatal cholestatic jaundice. Bowing of the lower extremities persisted after infancy. Inheritance is probably autosomal recessive. Also to be considered are epidemic parotitis (mumps), vaccinial and pyogenic osteomyelitis, parotid tumor, rickets, congenital syphilis, *osteogenesis imperfecta*, subperiosteal hematoma, scurvy, and vitamin A intoxication (13,25).

Kozlowski and Tsuruta (26), in 1989, described a seemingly new form of lethal neonatal dwarfism, which they called *dysplastic cortical hyperostosis*, that resembles the severe perinatal type of Caffey-Silverman syndrome. It was characterized by generalized symmetric cortical thickening and sclerosis of the long bones. The ribs appeared somewhat wavy. To be excluded are *I-cell disease* and G_{M1} *gangliosidosis.*

Laboratory aids. Radiographic study not only of the mandible but of the chest and long bones confirms the clinical impression. Serum alkaline phosphatase is elevated in cases with marked bone deposition (22). In over 80%, the sedimentation rate is elevated. Anemia and leukocytosis are common. Elevated IgM and thrombocytopenia have also been noted (44,47). Prenatal diagnosis by radiography (2,3,5,28,30) and echography (31,43), using bowing of the tibia and an irregular cortex of the long bones as indices, has been accomplished. The variable severity and onset possibly only late in the third trimester make prenatal studies less reliable.

Kenny-Caffey syndrome (tubular stenosis, Sanjad-Sakati syndrome)

Kenny and Linarelli (15) and Caffey (5) first described the syndrome of proportional growth retardation with macrocephaly, low birthweight, and episodic hypocalcemia with hyperphosphatemia leading to tetany. About 50 cases have been reported (1–25,27,28). Genetic heterogeneity appears likely (23). Vertical transmission was described three times (15,19,25), but multiple affected children born to normal parents (10,16,21,22) and consanguinity in 17 families (1,3,10,16,21,22) point to autosomal recessive inheritance. In one family, deletion at chromosome 22q11 was detected both in the four affected sibs and in their clinically unaffected mother (15). The finding was not confirmed in another, unrelated patient (28). The autosomal recessive form, known as Sanjad-Sakati syndrome, probably originated from the Mediterranean area. It maps to 1q42–q43 (2,6,20). Diaz et al (7) indicated that Sanjad-Sakati syndrome and recessive Kenny-Caffey syndrome are allelic. Patients with the recessive disorder show mental retardation, more obvious prenatal growth retardation, microcephaly, severe micrognathia, large low-set pinnae, deep-set eyes, small hands and feet, cryptorchidism, and micropenis (12,14,24), compared to those with the dominant form with normal intelligence, only postnatal growth retardation, macrocephaly, and dense bones. Patients with the recessive disorder are usually identified by neonatal seizures, tetany, or apnea due to hypocalcemia. Some exhibit immune deficits that result in neonatal sepsis or repeated infections. We cannot agree that the patient described by Wilson et al (27) has the disorder. Khan et al (16) provide a useful review.

The facies is only mildly dysmorphic. There are frontal bossing, high hairline, and diminished eyebrows and lashes (Fig. 9–21A,B). Ocular findings, found in 80%, have ranged from uncomplicated microphthalmia and hyperopia to extreme pseudopapilledema, vascular tortuosity, optic atrophy, and macular clouding (9). Corneal and retinal calcification has been seen on autopsy (4,18). Intracranial calcifications have been reported (4,22). Delayed tooth eruption and extensive caries can be present (16,22).

Adult height has ranged from 121 to 152 cm (18). The shafts of the long bones are narrow, with cortical thickening and stenosis of the medullary cavities (17) (Fig. 9–21C–E). Bone age is delayed in about 60%. There is mild brachymetacarpalia. Delayed closure of the anterior fontanel is very common in Western cases (90%) but rare in cases from the Middle East. Wide metopic suture with absent diploic spaces can be seen in about 80%. The patients of Majewski et al (19) lacked medullary stenosis. Mental development is usually normal, except in cases from the Middle East (16).

Episodic hypocalcemic tetany has been noted in about 70% (8,16,26), usually in cases with hypoparathyroidism. Anemia has been documented in about 30% (10). Growth hormone studies have been normal (18,19,22). Hoffman et al (13) reported two cases with microorchidism, of whom one patient had elevated levels of follicle-stimulating hormone with normal testosterone, and the other had Leydig cell hyperplasia.

A B

Fig. 9–22. *Lenz-Majewski syndrome*. (A,B) Note disproportionately large head contrasting with reduced trunk and limbs. Note prominent veins and syndactyly in A. (From M Robinow, J Pediatr 91:417, 1977.)

Lenz-Majewski syndrome

The syndrome characterized by large head, characteristic facies, loose skin, mental retardation, and skeletal findings (Figs. 9–22 to 9–25) was first reported by Braham (1) in 1969. This report went largely ignored until the entity was rediscovered by Lenz and Majewski (7) in 1974 and updated in 2000 (8). Eleven reported examples were reviewed in 1983 by Gorlin and Whitley (4). Additional examples are those of Elefant et al (3) and Chrzanowska et al (2).

All cases have been isolated. Paternal age appears advanced (4). Chromosome studies have been normal.

Facies. The head appears disproportionately enlarged with large fontanels and widely separated sutures that close late. The size of the head contrasts sharply with the reduced trunk and limbs (Figs. 9–22 and 9–23). Prominent veins, especially in the scalp, are evident. The ears are very large and floppy. Choanal atresia or stenosis and nasolacrimal duct obstruction are common. Hypertelorism is evident.

Fig. 9–23. *Lenz-Majewski syndrome*. Disproportionately large craniofacies. (A) Age 8 months. Note thin atrophic skin with prominent veins. (B) Note hypertelorism. (B from M Robinow, J Pediatr 91:417, 1977.)

A B

Fig. 9–24. *Lenz-Majewski syndrome*. Loose and wrinkled atrophic skin of hands with short digits and partial syndactyly.

Musculoskeletal. Inguinal hernia is common. The digits are hyperflexible and there may be generalized hypotonia (5). Radiographic features include progressive sclerosis of the skull (especially at the base), facial bones, and vertebrae. The clavicles and ribs are broad. The middle phalanges are short or absent. The long bones exhibit diaphyseal undermodeling and midshaft cortical thickening. However, there is marked hypostosis of the metaphyses and epiphyses. In general, skeletal maturation is retarded (Fig. 9–25).

Genitourinary. Cryptorchidism has been a uniform finding in affected males. Hypospadias and/or chordee have been noted (6,11). The anus may be anteriorly displaced.

Central nervous system. All children with the disorder have been mentally retarded, intelligence quotients ranging from 20 to 40. Sensorineural hearing loss is frequent. Agenesis of the corpus callosum has been seen (11).

Skin. The skin is thin, loose, wrinkled, and atrophic (Fig. 9–24). Veins, especially in the scalp, are prominent and cutis marmorata is evident (5). Proximal interdigital webbing of the fingers is frequent (4).

Oral manifestations. Tooth enamel has been defective in all patients. No microscopic studies have been carried out.

Differential diagnosis. Radiographically the disorders most often mistaken for Lenz-Majewski syndrome are *craniometaphyseal dysplasia* and *craniodiaphyseal dysplasia*. In contrast to those disorders, there does not appear to be any impairment of cranial nerves. One example was thought to represent *Camurati-Engelmann syndrome* (1). Nishimura et al (9) described a boy with a disorder that overlapped Lenz-Majewski syndrome, who lacked the diaphyseal hyperostosis and had, in addition, proximal symphalangism.

Laboratory aids. While alkaline phosphatase levels have been elevated in some cases (4,10), the significance is not known.

Mandibuloacral dysplasia

Cavallazzi et al (1), in 1960, were probably the first to report a syndrome characterized by short stature, delayed cranial suture closure, mandibular hypoplasia, dysplastic clavicles, abbreviated club-shaped terminal phalanges, acroosteolysis, and atrophy of skin over the hands and feet (Figs. 9–26 to 9–28), as an atypical form of cleidocranial dysplasia. Others reported cases but did not associate the disorder with that in Cavallazzi's patient or mistakenly classified their patients as examples of Werner syndrome (2,15), acrogeria (10,13), geroderma osteodysplastica (20), pycnodysostosis (14), and Hutchinson-Gilford progeria (3,16,18,26). Young et al (30) coined the name for this disorder. Danks et al (5) employed the term *craniomandibular dermatodysostosis* to describe the same condition. A total of 30 cases has been published (6a,19,24,27,28). The patient reported by Schrander-Stumpel et al (23) has an unusual severe presentation and may have another entity, possibly a collagen disorder. Toriello (27) provides a good review. The occurrence of the disorder in sibs strongly suggests autosomal recessive inheritance [12(sib mentioned in 24),16,17,19,21,25,27a,29,31]. Reports describe possible consanguinity (19,25,31). The disorder has an apparently high frequency in Italians (25). Onset of symptoms is usually between 3 and 14 years, but neonatal lethal cases are known (12,24). In some cases, the phenotype is unusually severe (5,20,23,27). Intelligence is normal.

Facies. The eyes are prominent. The nose is sharp or pointed (Fig. 9–26A–C). With age, the face becomes pinched. The scalp hair becomes sparse and lusterless, usually without graying, by the third decade, revealing the scalp veins. Some patients have alopecia (17,18). The mandible becomes progressively smaller and more recessed. Cataracts (6), hearing loss (6), and a high nasal voice (17,23) are unusual features.

Musculoskeletal. Stature is usually reduced by 3 SD, although this is not always the case (6,17,23,29). There appears to be progressive stiffness of joints and swelling, and redness may occur. The shoulders become narrow, usually by the end of the first decade (Fig. 9–26A–D). The hands and feet appear small. The terminal phalanges are short and club-shaped, which, together with cutaneous atrophy, cause them to appear spatulate (Fig. 9–28).

Radiographic changes include slow osteolysis of the mandibular body and ramus, resulting in micrognathia with antegonial notching, delayed cranial suture closure and fontanel, numerous wormian bones, and acroosteodysplasia of fingers and toes (27) (Fig. 9–27). Clavicular osteolysis is progressive, eventuating in severe hypoplasia or aplasia. Delayed ossification of carpal bones is evident.

Variable findings include abnormal modeling of femur, humerus, and tibia with patchy thickening of cortex, hypoplasia of first through fourth ribs (25,29,31), coxa valga (21), avascular necrosis of femoral head (21), fish-mouthed vertebral bodies, and scoliosis (30). In one patient, MRI studies showed cortical atrophy (6). A follow-up of the patient reported by Danks et al (5) showed striking metaphyseal changes (27).

Skin. The skin over the hands and feet becomes atrophic and mottled giving a poikilodermatous appearance at about two years of age (Fig. 9–28). A mottled brown skin rash may extend over the trunk and extremities (6,9,14,17,20,23,29,30). Subcutaneous fat is diminished over the distal extremities, causing the veins and tendons to become evident. Fat deposits are marked over the abdomen (14,29). Calcium deposits frequently extrude from the scalp, ears, elbows, and, especially, fingertips. Plantar hyperkeratoses have been noted (15). The nails become brittle.

Oral manifestations. Mandibular hypoplasia with inability to open the mouth widely has been a common feature. Crowding of the mandibular teeth with absence of cellular cementum has been demonstrated (5). The roots are hypoplastic. The teeth are lost during adolescence (17,25,29,31).

Other findings. Renal failure due to focal sclerosis (5,27) or focal tubular atrophy (6), hepatomegaly (6), anemia (31), glandular hypospadias (24), and delayed or absent sexual maturation (2,17,25,30) have been reported. At follow-up (27), one patient (5) proved to need a tracheostomy for airway difficulties.

Differential diagnosis. Similar cutaneous changes are seen in *progeria* and *Werner syndrome. Cleidocranial dysplasia* should easily be excluded. Acrometagyria (7,8) is probably a still different disorder (27).

Laboratory findings. Diabetes mellitus has been described (6,15). More extensive glucose metabolism studies showed a severe insulin resistance, which placed mandibuloacral dysplasia in the group of partial lipodystrophies (4,6). However, this seems not to have been present in other patients (25,29). It has been suggested that type III collagen anomalies may be present (3). Premature adrenocortical dysfunction has been found in one patient (16a).

Marfan syndrome

The main features of Marfan syndrome include disproportionate skeletal growth with dolichostenomelia, ectopia lentis, and fusiform and dissecting aneurysms of the aorta. Marfan syndrome was first mentioned in the fifth century in the Babylonian Talmud. The French pediatrician Antoine-Bernard Marfan described a 5-year-old girl with skeletal manifestations of the disorder that now bears his name (89). It has been suggested that Abraham Lincoln had Marfan syndrome (56). Lincoln was known to have a Marfan-like habitus, and his son, Tad, had a flat face with cleft palate, raising the possibility of Stickler syndrome (64). A case has been made for Marfan's original patient having cystathionine synthase deficiency (homocystinuria) (13), but the most convincing argument has been made for congenital contractural arachnodactyly (9). The famous violin virtuoso Nicolo Paganini had long fingers and hyperextensible joints that were said to be attributable to Marfan syndrome (132). In 1986, the U.S. volleyball star Flo Hyman died from a ruptured aortic aneurysm associated with Marfan syndrome. This tragic event focused widespread public attention on the syndrome for the first time (60). The Dutch ophthalmologist Weve (159) was the first to demonstrate the autosomal dominant pattern of inheritance, and also suggested it to be a disorder of mesodermal tissues. A major contribution was made in 1955 by McKusick (94), who established the nosology of the heritable disorders of connective tissue.

Marfan syndrome has autosomal dominant inheritance with extremely high penetrance. Indeed, not a single case with nonpenetrance has ever been reliably documented. A patient who was asymmetrically affected is probably an example of somatic mosaicism (19). An example of gonadal mosaicism has been published (122). Affected sibs born to unaffected parents may well be explained by insufficiently detailed investigations of the parents, although genetic heterogeneity cannot be discarded (21,47). The homozygous state is lethal (21,133). The reported number of sporadic cases varies from 25% to 35% (88,103,106,115,116). Advanced paternal age at the time of conception was found to be associated with sporadic cases (88), although this was not found in another study (106). The earlier estimate of the prevalence of 4–6 per 100,000 (116) is probably an underestimate (115). The frequency is now estimated to be about 1 per 10,000 (60,114,115).

In 1990, the disorder was mapped to chromosome 15q21 (72). In that same year, Godfrey et al (53) and Hollister et al (67) reported diminished amounts of microfibrils in the skin of Marfan patients. Eventually, Dietz et al (39) reported that mutations in fibrillin type I gene cause the disorder. Fibrillin is a large glycoprotein and a major component of microfibrils, which interacts with elastin in elastic fibers and has anchoring functions in other tissues (97,109). Microfibrillin assembly is disturbed in Marfan syndrome (74,124a). The structure of the fibrillin gene is complex (110 kb, 65 exons, 10 kb of coding sequence) and has epidermal growth factor (EGF)-like domains and transforming growth factor (TGF)-like domains. Multiple mutations of all sorts have been found (38,73), confirming intragenic heterogeneity. No clear genotype–phenotype correlation exists (5,12,38), with the exception of mutations in the EGF domain 24–26, which are mainly found in severe, neonatal, sporadic Marfan patients (73,98). Two "hot spots" have been found in the fibrillin 1 gene in neonatal Marfan syndrome. The mutations often involve exons 24–27 with skipping of exons 31 or 32 (16).

Fibrillin-1 mutations are not restricted to patients with Marfan syndrome but can also be found in patients with familial aortic aneurysms, familial ectopia lentis, Shprintzen-Goldberg syndrome, the Mass phenotype (38,73), autosomal dominant Weill-Marchesani syndrome (160), and even familial tall stature (99). The so-called neonatal Marfan syndrome is not a separate entity, but is also caused by fibrillin-1 mutations (18,62,73,98). Hence, the presence of a mutation in the fibrillin-1 gene in itself is not a proof for the existence of Marfan syndrome.

In a related protein, fibrillin-2, located at chromosome 5q (151), mutations give rise to congenital contractural arachnodactyly (Beals syndrome) (112).

It still remains possible that Marfan syndrome has a heterogeneous cause: in a large French family with skeletal and cardiovascular anomalies fitting the diagnosis, but without the characteristic eye symptoms, linkage with the fibrillin genes was excluded (14), and a possible second locus has been mapped at 3p24.2–25 (28). Bonneau et al (15) described a neonate with a Marfan phenotype and cutis laxa, who had recurrent chromosome breaks at 7q31.3–32, possibly disrupting laminin B1. In another neonate with a Marfan phenotype, a mitochondrial complex I deficiency was found (23).

Animal models of the Marfan syndrome are available (12).

Criteria. In 1986, criteria for the diagnosis of Marfan syndrome were published (10). Over time, both emerging weaknesses in these criteria and molecular progress urged revision, which was published as the Ghent criteria (Table 9–2) (34). In general, at least two specific studies are required for the diagnosis: careful cardiac evaluation, including echocardiography, and slit-lamp examination of the eyes (114,117). In cases in which the diagnosis remains doubtful, radiographs of the pelvis to ascertain protrusio acetabulae, and (especially) MRI or CT of the lower vertebral column for lumbosacral dural ectasia, can be useful to establish diagnosis. In children, the criteria may not be met on first investigation, and establishing the diagnosis may need follow-up of years (85). Although many authors have tried to establish a radiographic criterion for arachnodactyly (metacarpal index), this is of very limited value and precision (149). The thumb (Steinberg) sign (the entire nail of the thumb projects beyond the ulnar border of the hand when the hand is clenched without assistance) and wrist (Walker-Murdock) sign (the thumb overlaps the terminal phalanx of the fifth digit when grasping the contralateral wrist) are more simple and more helpful, but are also subject to interpretation and are of limited value in differentiating Marfan syndrome from other hypermobility conditions (116,156) (Fig. 9–31C,D). In any patient, homocystinuria should be ruled out.

Table 9–2. Diagnostic criteria for Marfan syndrome

Family History

Major criteria
Having a parent, child, or sib who meets these diagnostic criteria independently:
Presence of a mutation in FBN1 known to cause the Marfan syndrome; or
Presence of a haplotype around FBN1, inherited by descent, known to be associated with unequivocally diagnosed Marfan syndrome in the family.

Minor criteria
None

For the family history to be contributory, one of the major criteria must be present.

Skeletal System

Major criterion—Presence of at least four of the following manifestations:
Pectus carinatum
Pectus excavatum requiring surgery
Reduced upper to lower segment ratio or arm span to height ratio greater than 20°
Positive wrist and thumb signs
Scoliosis or spondylolithesis.
Reduced extension of elbows (<170°)
Medial displacement of the medial malleolus causing pes planus
Protrusio acetabulae of any degree (ascertained on X ray)

Minor criteria
Pectus excavatum of moderate severity
Joint hypermobility
Highly arched palate with dental crowding
Facial appearance (dolichocephaly, malar hypoplasia, enophthalmos, retrognathia, down-slanting palpebral fissures)

For the skeletal system to be involved, at least two components comprising the major criterion or one component comprising the major criterion plus two minor criteria must be present.

Ocular System

Major criterion
Ectopia lentis

Minor criteria
Abnormally flat cornea (as measured by keratometry)
Increased axial length of globe (as measured by ultrasound)
Hypoplastic iris or hypoplastic ciliary muscle causing decreased miosis

For the ocular system to be involved, at least two of the minor criteria must be present.

Cardiovascular System

Major criteria
Dilatation of ascending aorta with or without aortic regurgitation and involving at least the sinuses of Valsalva; or
Dissection of the ascending aorta

Minor criteria
Mitral valve prolapse with or without mitral valve regurgitation
Dilatation of main pulmonary artery, in absence of valvular or peripheral pulmonic stenosis or any other obvious cause, below the age of 40 years;
Calcification of the mitral annulus below the age of 40 years; or dilatation or dissection of the descending thoracic or abdominal aorta below the age of 50 years

For the cardiovascular system to be involved, a major criterion or only 1 of the minor criteria must be present.

Pulmonary System

Major criteria
None

Minor criteria
Spontaneous pneumothorax, or
Apical blebs (ascertained by chest radiography)

For the pulmonary system to be involved, one of the minor criteria must be present.

Table 9–2. (*cont.*)

Dura

Major criterion
Lumbosacral dural ectasia by CT or MRI

Minor criteria
None

Skin and Integument

Major criteria
None.

Minor criteria
Striae atrophicae (stretch marks) not associated with marked weight changes, pregnancy or repetitive stress, or
Recurrent or incisional herniae
For the skin and integument to be involved, the major criterion or one of the minor criteria must be present.
Requirements of the diagnosis of Marfan syndrome
For the index case
Major criteria in at least two different organ systems and involvement of a third organ system
For a family member
Presence of a major criterion in the family history and one major criterion in an organ system and involvement of a second organ system.

Adapted from A De Paepe et al, Am J Med Genet 62:417, 1996.

Extensive long-term study of the natural history was reported by Marsalese et al (92) and Sun et al (144). The frequencies of major symptoms are shown in Table 9–3. A health supervision scheme has been proposed (36).

Craniofacial features. Dolichocephaly usually occurs with prominent supraorbital ridges (Fig. 9–29). This can result in a characteristic long face with deeply set eyes (due to decreased retrobulbar tissue) (104), prominent brows, downslanting palpebral fissures, hypoplastic malar eminences, and retrognathia (34,111) (Fig. 9–30).

Although earlier authors estimated the prevalence of a high palatal vault to be between 15% and 40%, some have observed this condition in all their patients (88,156). Cleft palate or bifid uvula has been reported in several instances (88). The teeth have been noted to be long and narrow and frequently maloccluded (31,156). Mandibular prognathism is common and temporomandibular joint disease is found more frequently than expected. Large maxillary sinuses may be noted radiographically (7).

Table 9–3. Characteristics of Marfan syndrome[a] ($n = 50$)

Clinical feature	%
Ocular	70
Ectopia lentis	60
Myopia	34
Cardiovascular	98
Prosthetic aortic valve	10
Aortic enlargement	84
Mitral valve prolapse	58
Musculoskeletal	100
Arachnodactyly	88
Upper/lower segment at least 2 SD below mean for age	77
Pectus deformity	68
High, narrow palate	60
Height greater than 95th centile for age	58
Hyperextensible joints	56
Vertebral column deformity	44
Pes planus	44
Striae distensae	24
Inguinal hernia	22
Family history	85
Additional documented cases of Marfan syndrome	85
Sporadic cases (new mutations)	15
Unclear or unknown pedigree	6

[a] From RE Pyeritz and VA McKusick, N Engl J Med 300:772, 1979.

Fig. 9–29. *Marfan syndrome*. Patient has dolichostenomelia, arachnodactyly, scoliosis, pectus excavatum, and bilaterally subluxated lenses. (From N Tuna and AP Thal, Circulation 24:1154, 1961.)

Musculoskeletal system. Dolichostenomelia, defined by an upper segment–to–lower segment ratio (US/LS) of at least 2 SD below the mean, or arm-span-to-height ratio of at least 1.05, is found in 76% (116). Arachnodactyly occurs in 88% (Figs. 9–29 and 9–31A,B). Pectus excavatum, especially when asymmetric with the left costochondral junction more anterior, is most characteristic. Other features include pectus excavatum (6) and weakness of joint capsules manifested by pes planus (44%) and hyperextensibility of joints (56%) with recurrent dislocation (mainly first metacarpal-phalangeal joint and patellae) (108) (Fig. 9–31C,D). As joint hypermobility is common in the general population, it has by itself little diagnostic specificity. The elbows may show a limited extension in late childhood or thereafter (140). In coexistence with joint hypermobility elsewhere, this sign is more specific. Joint complaints are common at all ages. In later life, secondary arthritic changes occur commonly. Scoliosis may develop in childhood and worsen during periods of rapid growth, such as puberty (124,141), and can be accompanied by a thoracic or thoracolumbar kyphosis. More often, however, the physiologic thoracic kyphosis has disappeared or even a thoracic lordosis occurs. Spondylolisthesis is found in about 6% (141,146). Enlarged vertebrae and widened spinal cord have also been noted (116). The frequency of osteoporosis in older patients remains uncertain (59). An abnormally deep hip socket is very frequent (81) but is generally asymptomatic. The skull shows often dolichocephaly.

Fig. 9–30. *Marfan syndrome.* Enophthalmos, downward-slanted palpebral fissures, malar hypoplasia, narrow maxilla, retrognathia.

Ocular changes. Ectopia lentis, resulting from lax suspensory ligaments, is found in 50%–80% and is almost always bilateral and symmetrical (22,32,77,93). Dislocations are not found at birth, but are noted first at 10–14 days of age. They tend to progress in infancy and early childhood, and in early puberty. The direction of dislocation is upward in about 75% (93,104,106,116). The zonular fibers remain intact, permitting normal accommodation. Some degree of backward dislocation is frequently found. Anterior dislocation may cause glaucoma, but most cases of glaucoma are the result of surgical extirpation rather than acute blockage of the anterior chamber. Subluxation of the lens often causes the iris to flutter as the lens accommodates (iridodonesis). An enlarged axial diameter (especially above 25 mm) is responsible for the increased tendency to myopia that occurs most often in the first two decades.

An increased corneal diameter occasionally gives the appearance of megalocornea. The radius of curvature of the cornea can be studied by keratometry, and mostly shows corneal flattening. The degree of reduction in curvature is positively correlated with the presence of ectopia lentis (93). Hypopigmentation of the posterior iris epithelial layer permits transillumination of the iris in 10% (120). Dilatation of the pupil is often difficult because of hypoplasia of the ciliary muscle. Increased size of the eyeglobe accounts for choroid thinning, apparent microphakia, and blue sclerae. Ocular changes are also found in the anterior chamber angle, ciliary body, and pupil (3). The most frequent cause of visual loss is amblyopia from delayed refraction or inadequate correction of myopia; the visual loss is usually reversible. More than 80% of patients have normal vision, even with dislocated lenses. Rarely, Rieger anomaly has been noted (61). It is still uncertain whether early nuclear cataract and open-angle glaucoma occur more frequently in Marfan syndrome (34,70).

Cardiovascular abnormalities. Cystic necrosis of the vascular media leads to diffuse, progressive dilatation of the ascending aorta (123). The resulting aneurysm can be associated with increasing aortic regurgitation and congestive heart failure or dissection and rupture (43). Together, these constitute the leading causes of death in affected individuals. Before the development of an effective procedure for presymptomatic, elective repair of the aorta, the average age of death was 32 years (17,57,102), but during the last decades a considerable improvement in life expectancy has been reached, mainly due to prophylactic medication (136), prophylactic surgical interventions (138), and better survival after cardiosurgery (4,11,30,58,84).

Echocardiographic evidence of mitral valve prolapse is found in 68% (37,51,52,90,91,117). Valvular abnormalities may be present at birth and aortic dilatation is detectable by echosonography from early infancy (140). Mitral valve prolapse is also found in the majority of children (50%–80%) (117,140). Progressive mitral valvular dysfunction and potentially malignant ventricular dysrhythmias do occur in children (22,100,138). Exceptionally, aortic dissection has been reported to occur already at 5 years of age (128).

In adults, significant auscultatory signs are found in only one-third to one-half of cases, whereas abnormal echocardiograms are found in the majority (80%–95%). Characteristically, the aortic root diameter is above the upper limit of normal (approximately 38 mm) and there is mitral valve prolapse and left atrial dilatation (65). Nomograms for the upper normal limits for age and body size have been developed (125–127). Symptomatic aortic regurgitation, which is found in less than 25% of patients, and aneurysmal dissection are both associated with dilatation of the aortic root beyond 55 mm (29,110,116,117,129). The strongest

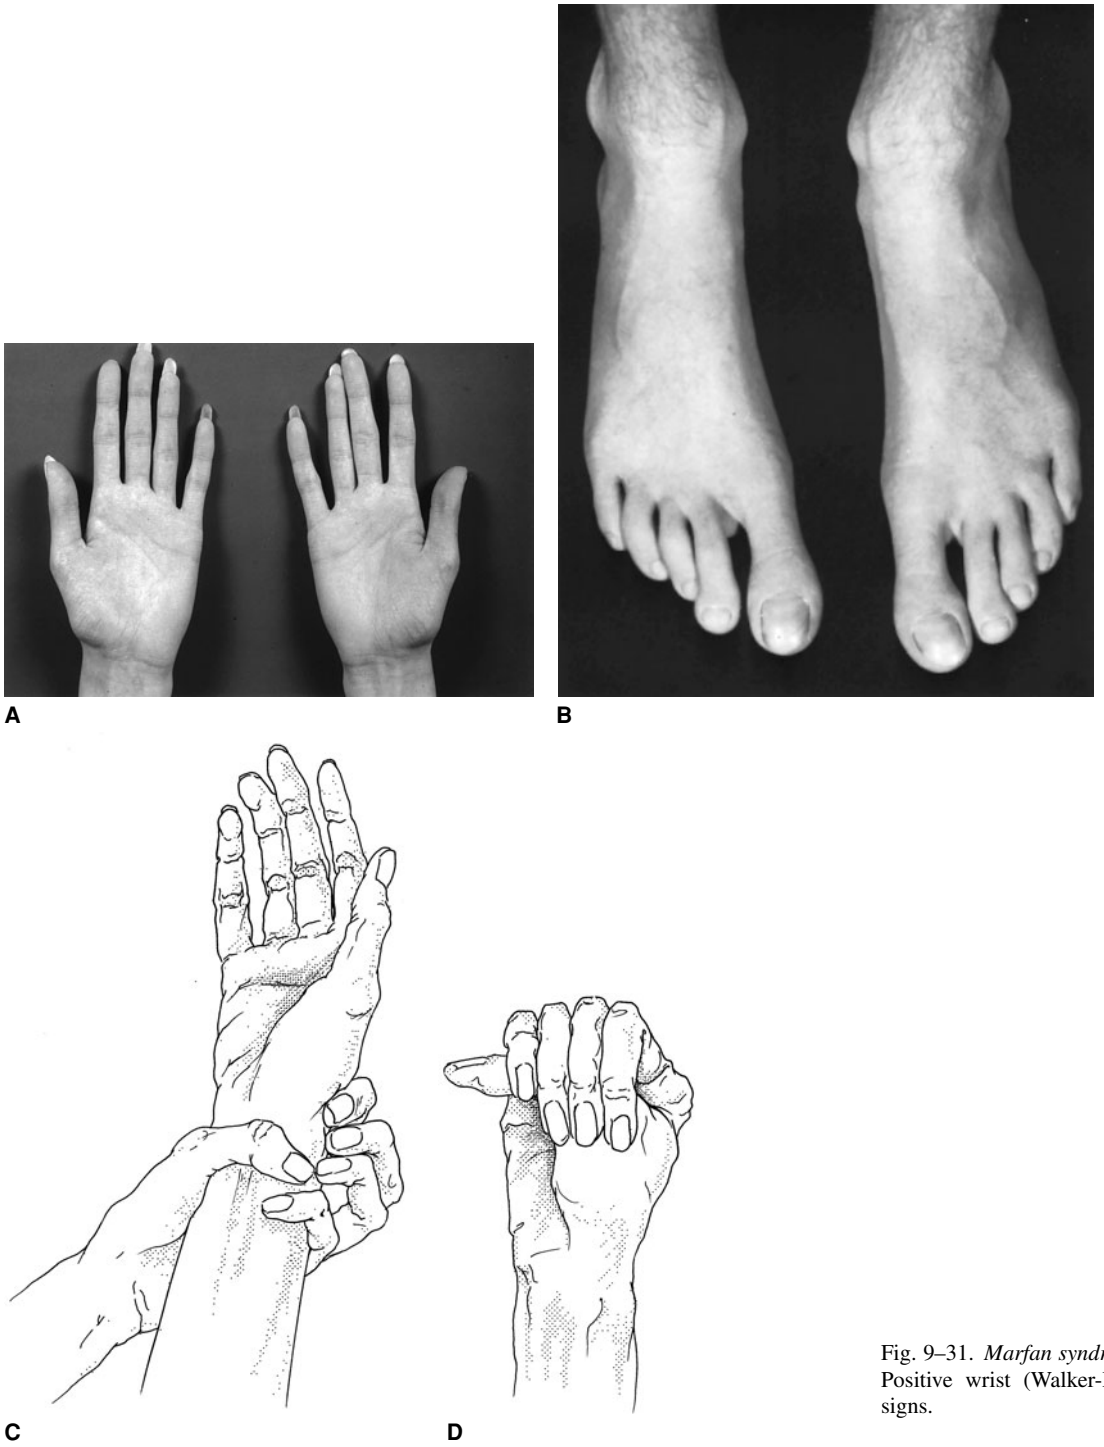

Fig. 9–31. *Marfan syndrome*. (A,B) Arachnodactyly. (C,D) Positive wrist (Walker-Murdock) and thumb (Steinburg) signs.

predictors of dissection of the ascending aorta are the actual size of the aortic diameter and a history of dissection in a relative (106,115). DeSanctis et al (35) published an excellent review of aortic dissection. Serious cardiovascular complications during pregnancy are also more likely with dilatation greater than 40 mm (45,69,80,86,101,113,115). The risk is greatest during the last trimester of pregnancy and first weeks after delivery.

Obstetric complication are otherwise not more frequent (86).

Other reported cardiovascular complications include acute aortic valve prolapse (20), bicuspid aortic valve (50), aneurysms of the descending aorta or pulmonary artery (40), renal vein thrombosis (2), and aneurysms of the abdominal aorta (82,153). As with all patients with valvular disease, there is an increased risk of bacterial endocarditis. Although an increased risk for intracranial aneurysms has been reported, this was not confirmed in a larger study (152).

Pulmonary pathology. Because of the connective tissue defect, the tall asthenic habitus, and the frequency of thoracic cage deformities, affected individuals are at increased risk for spontaneous pneumothorax. Although the frequency is low (4.4%), recurrence is likely unless the underlying lesion, usually an apical bulla, is resected. Pulmonary infections and chronic emphysematous changes occur with increased frequency (41,147). The pulmonary vital capacity is generally reduced even in patients without thoracic distortion, adding significantly to the anesthetic risk (63,143,154,161).

Skin and integument. Connective tissue involvement leads to increased frequency of striae distensae (24%), arising around puberty, and mainly on the shoulders, lumbar region, and thighs (27). Striae gravidarum can be masked in women with Marfan syndrome (115). Inguinal herniae (22%) and recurrence after standard surgical therapy are common. Hernias of other structures have also been described (135), including paraesophageal hernias in newborns (107). Miescher elastomata, especially on the neck, may also be found (116).

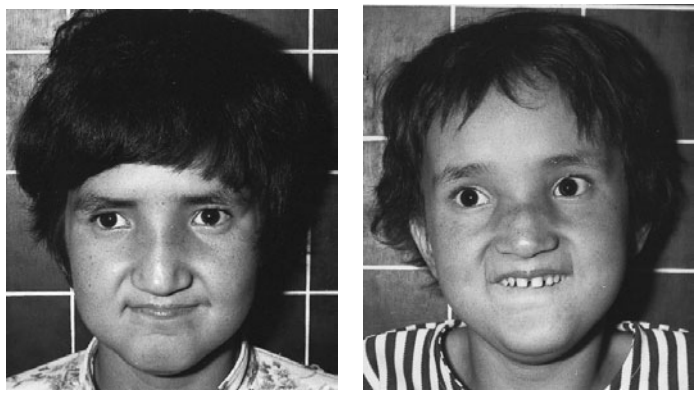
Miscellaneous findings. Abnormalities of the central nervous system, presumably of connective tissue origin, include dural ectasia, sacral meningocele, and dilated cisterna magna, but neurological manifestations are rare (24,66,114). Dural ectasia in the lumbosacral region is very common in Marfan syndrome, but may be found in disorders such as *neurofibromatosis, Ehlers-Danlos syndrome*, and ankylosing spondylitis (1a,119).

Other symptoms in Marfan syndrome are nephrotic syndrome (2,130), possibly due to glomerular basement membrane alterations, medullary sponge kidney (131), hematologic abnormalities (44,68), primary hypogonadism (50), myopathic symptoms due to a diminished amount of skeletal muscles (55), sleep apnea (25), diminished amount of subcutaneous fat (106,115), biliary tract anomalies (96), and alopecia (162). Neuropsychological studies showed problems with sustained visual attention and visual construction abilities, which could not be explained by reduced visual acuity, but otherwise normal intelligence (83). The meaning of the report of schizophrenia in five Marfan patients is uncertain (139).

Differential diagnosis. A Marfan-like habitus may be observed in *homocystinuria* (cystathionine synthase deficiency), congenital contractural arachnodactyly (9), Marfanoid hypermobility syndrome (155), eunuchoidism, *Klinefelter syndrome, XXY syndrome*, sickle-cell anemia, *multiple endocrine adenomatosis, type IIb*, and occasionally in *nevoid basal cell carcinoma syndrome.* Marfan-like habitus may also be a feature in some cases of *Stickler syndrome* (64). Other symptoms of Marfan syndrome may also be seen in other disorders. In *Shprintzen-Goldberg syndrome* (137), arachnodactyly is associated with craniosynostosis, mental deficiency, ocular proptosis, micrognathia, and other features. Furlong et al (49) reported a patient with typical characteristics of Marfan syndrome, but additionally had craniosynostosis, hypospadias, spondylolisthesis, and absence of ectopia lentis. Clunie and Mason (26) described three sibs, products of a consanguineous union; Marfan-like habitus and multiple inguinal and femoral hernias were described. Jaffer and Beighton (71) noted a patient with arachnodactyly, pectus carinatum, spondylolisthesis, joint laxity, and mental deficiency. Lujan et al (87) and Fryns and Buttiens (48) reported an X-linked disorder characterized by Marfan-like habitus, large head, mental retardation, long narrow face, highly arched palate, small mandible, atrial septal defect, and other anomalies. Tamminga et al (145) reported an infant with a Marfan-like phenotype, congenital contractures, microspherophakia, optic nerve colobomas, prolapse of mitral and tricuspid valves, cerebral white matter hypoplasia, and spinal axonopathy. Currarino and Friedman (33) reported a severe form of congenital contractural arachnodactyly associated with unusual histopathologic changes in the metaphyses and epiphyses together with other anomalies such as ankyloblepharon, esophageal atresia with tracheo-esophageal fistula, duodenal atresia, and vertebral malformations. They suggested that congenital contractural arachnodactyly may be etiologically heterogeneous.

Fragoso and Cantú (46) described four sibs with psychomotor retardation, flat and coarse facies, dolichocephaly, low posterior hairline, synophrys, hypertelorism, broad nose with bifid columella, malar hypoplasia, small mouth, and large ears (Fig. 9–32). Musculoskeletal alterations included pectus excavatum, muscle hypoplasia, dolichostenomelia, osteopenia, and thin metapodial bones, phalanges, and ribs. Inheritance is probably autosomal recessive.

Thieffry-Kohler syndrome (148), a dubious entity, has been characterized by Marfan-like appearance, frontal bossing, micrognathia, mild scoliosis, pes cavus, overlapping toes, and plantar cysts. Bone destruction of the wrists and ankles, beginning with the carpal and tarsal bones and spreading to involve adjacent bones, occurred during childhood and progressed, with painless, at times asymmetric, osteolysis. Serum alkaline phosphatase and hydroxyproline levels were elevated.



A B

Fig. 9–32. *Coarse facies, Marfanoid habitus, and mental retardation*. (A,B) Facies of two of four affected sibs. In addition to mental retardation, all have flat coarsened facies, synophrys, hypertelorism, esotropia, broad nose, short philtrum, somewhat small mouth. (From R Fragoso and JM Cantú, Clin Genet 25:187, 1984.)

The Mirhosseini syndrome is characterized by microcephaly, severe mental deficiency, pigmentary retinal degeneration, cataracts, hyperextensible joints, arachnodactyly, and mild scoliosis (95). Inheritance is autosomal recessive.

Ectopia lentis may occur in Weill-Marchesani syndrome, congenital contractural arachnodactyly (8), *Ehlers-Danlos syndromes*, *homocystinuria*, *osteogenesis imperfecta*, and as an isolated autosomal recessive trait. In homocystinuria, the lens tends to dislocate, nasally, inferonasally, or inferiorly (32). Shawaf et al (134) reported a Lebanese family with ectopia lentis, spontaneous filtering blebs, and mild craniofacial dysmorphism. Aortic dilatation is also seen in Erdheim's cystic mediconecrosis and in tertiary syphilis (150). Joint hypermobility is seen in a number of disorders, including *osteogenesis imperfecta,* the *Ehlers-Danlos syndromes, homocystinuria, Stickler syndrome*, and Marfanoid hypermobility syndrome (64,155).

Mitral valve prolapse may occur in *cutis laxa syndromes, Ehlers-Danlos syndromes, osteogenesis imperfecta, Stickler syndrome, fragile X syndrome*, contractural arachnodactyly, and a host of other conditions reviewed in the third edition of this text.

Laboratory aids. Preimplantation (75) and prenatal (54,121,157) diagnosis by molecular studies have been accomplished. During the third trimester, diagnosis can be strongly suspected on the basis of ultrasonographic analysis of limb lengths (78). Some parents may benefit from emotional preparation for the birth of an affected child (68).

Lumbosacral dural sac dimensions can be measured by MRI. Dural ectasia is a good marker for Marfan syndrome (106a).

McCune-Albright syndrome

The McCune-Albright syndrome is characterized by (a) polyostotic fibrous dysplasia, (b) multiple areas of cutaneous light brown pigmentation or café-au-lait spots, and (c) autonomous hyperfunction of one or more endocrine glands, especially gonads and thyroid (Figs. 9–33 to 9–35). The syndrome was delineated by McCune (48) and McCune and Bruch (49) in 1936 and 1937 and by Albright et al (2,3) in 1937 and 1938, although it was described as early as 1922 by Weil (72). It has been suggested that cases 5, 6, and 7 of von Recklinghausen may possibly represent examples of this syndrome rather than neurofibromatosis (18). Because of multiple endocrine gland dysfunctions, the syndrome has been included as one of the multiple endocrine adenomatoses. The most extensive review is that of Danon and Crawford (18). Cohen and Howell (15a) describe the molecular aspects of the syndrome.

Virtually all cases described to date have been isolated examples. Hibbs and Rush (36) reported a woman with skin pigmentation, possible sexual precocity, and bone lesions consistent with fibrous dysplasia; a daughter had multiple cystic bone lesions, but no endocrine or skin manifestations. Firat and Stutzman (25) described a mother and daughter with hyperparathyroidism, cystic lesions of bone, but no skin or other endocrine abnormalities. Bone biopsy in the mother was consistent with fibrous dysplasia. Alvarez-Arratia et al (4) described a woman with bone lesions, skin hyperpigmentation, and diabetes mellitus and thyroid enlargement, who had 11 relatives with café-au-lait spots and, in some, mild skeletal symptoms. The syndrome has also been observed in one of monozygotic twins (21,40). An analysis of 32 cases was published by De Sanctis et al (19a) in 1999.

Happle (34) postulated an autosomal dominant lethal gene as the cause, resulting in loss of the zygote in utero. Mutated cells are thought to survive only when occurring together with normal cells in the mosaic state. The disorder may result from a gametic half chromatid mutation or from an early somatic mutation. Danon and Crawford (18) suggested that functional failure of receptor complexes might underlie the syndrome. Weinstein et al (73) proved this by showing activating missense mutations at codon 201 of the *GNAS1* gene encoding the α subunit of the stimulatory G protein, located at chromosome 20q13.2, in a mosaic state. The G (guanine nucleotide binding) proteins form a superfamily of signal-transducing proteins that mediate numerous transmembrane hormonal and sensory processes (42). The proteins have a heterotrimeric structure, of which the alpha subunits have intrinsic GTPase activity and probably allow for functional specificity of each G protein (74). The (stimulatory) Gs alpha protein couples receptors causing activation of adenylate cyclase and thereby increases the synthesis of cyclic AMP (Fig. 9–33). Mutations in the Gs alpha protein are found in various degrees in different tissues (13,20,61,62,64,65,73), and somatic mosaicism can account for the great clinical variation in the disorder (69). Possibly, similar isolated organ defects can be explained this way (45,52,60). Studying bone marrow, Bianco et al (8) found two different genotypes within single fibrous dysplastic lesions, which is in accord with the hypothesis put forward by Happle (34). The same *GNAS1* mutations occur in isolated fibrous dysplasia (8a).

Features of the syndrome occur with variable frequency. Diagnosis is made with certainty if all three principal features are present, but should

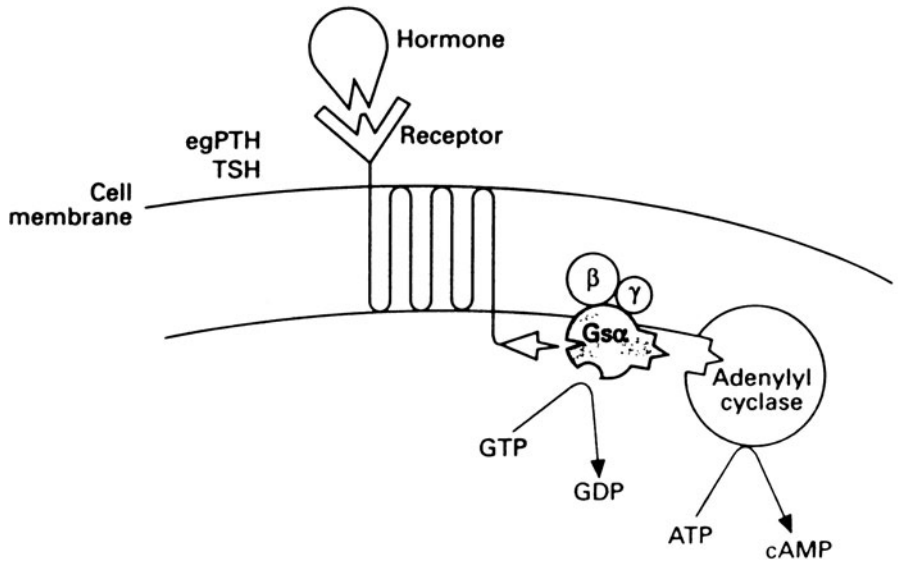

Fig. 9–33. *Hormone receptor-Gs-adenylyl cyclase pathway.* Parathormone, like TSH and several other hormones, exerts its effects by stimulating adenylate cyclase to produce a second messenger cAMP. The receptor is coupled to adenylate cyclase by a signal-transducing protein, Gs, one of a large family of heterotrimeric GTP binding G Proteins. Note that Gs is composed of α, β, and γ subunits, the subunit determining both effector and receptor specificity. (From LC Wilson and RC Trembath, J Med Genet 31: 779, 1994.)

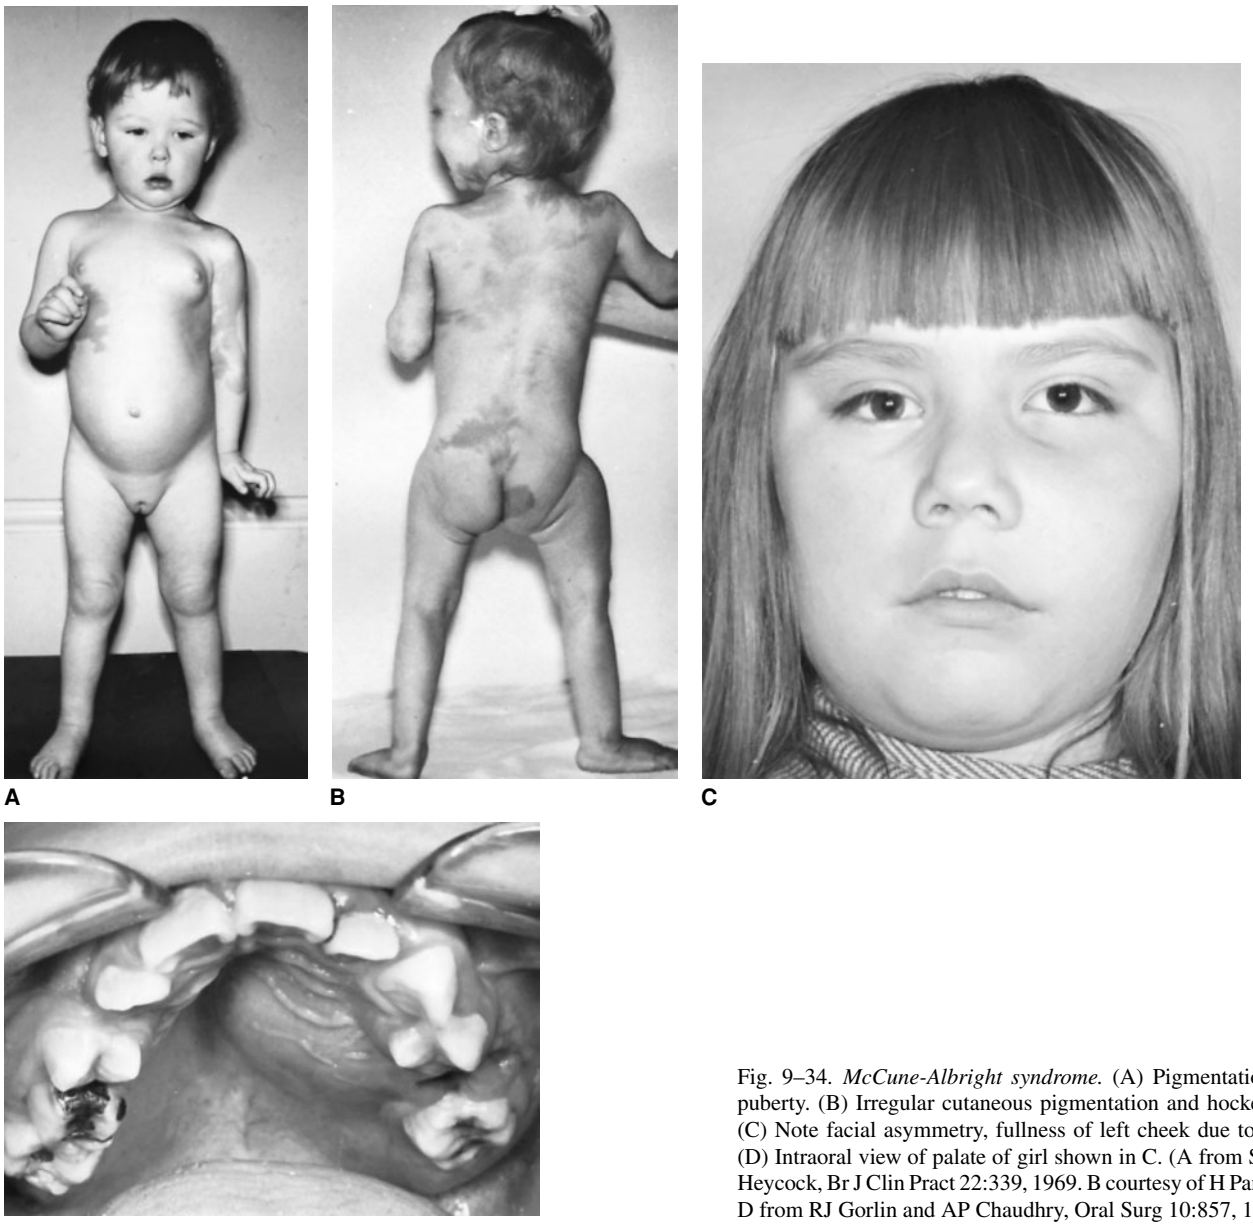

Fig. 9–34. *McCune-Albright syndrome.* (A) Pigmentation and precocious puberty. (B) Irregular cutaneous pigmentation and hockey-stick deformity. (C) Note facial asymmetry, fullness of left cheek due to fibrous dysplasia. (D) Intraoral view of palate of girl shown in C. (A from S Agarwala and JB Heycock, Br J Clin Pract 22:339, 1969. B courtesy of H Pande, Oslo, Norway. D from RJ Gorlin and AP Chaudhry, Oral Surg 10:857, 1957.)

also be considered with two features because each has special characteristics seldom encountered in other disorders. The presence of any one of the three features should prompt a search for one or both of the other features of the syndrome. In the series of Harris et al (35), about 38% had bone involvement alone, 40% had two features, and 22% had the full-blown syndrome. Pritchard (53) found cutaneous pigmentation in 43% ($n = 181$). Approximately 45% of affected females exhibit sexual precocity, but only 6% of affected males have this feature. Of patients referred for sexual precocity, only 8% have McCune-Albright syndrome (56) and only 3% of patients with polyostotic fibrous dysplasia have McCune-Albright syndrome (18).

Skeletal manifestations. Although any bone may be involved, the long bones are most frequently affected, especially the upper end of the femur. Bowing resembling a hockey stick may be produced, resulting in leg-length discrepancy (Fig. 9–34A,B). Limp, leg pain, or fracture is the presenting complaint in about 70% (35). Other bones affected, in descending order of frequency, are the tibia, fibula, pelvis, humerus, radius, and ulna. Bilateral involvement occurs in about half the cases (9,22) (Fig. 9–35A,B). Occasionally, a single bone is involved. Incipient bowing of the legs may be seen as early as the first year of life and nearly always appears before the end of the first decade (48,49). The process may be asymptomatic or accompanied by pain and fracture. Fractures may be multiple and recurrent. At least 85% have one fracture, and over 40% have three or more (5,35). Occasionally, bones on only one side of the body may be involved (53). Scintigraphic studies have been reported (51).

Bone is replaced by a yellowish to red-brown fibrous tissue, its composition varying greatly in different parts of the body. It may be rich or poor in cells. The stroma may vary from a finely fibrillar one with a loose whorled arrangement to one that is densely collagenous. Some areas appear edematous, with numerous small cystic spaces. Foci of hemorrhage and multinucleated giant cells may be observed. The trabeculae are irregular in form, and occasionally a few fragments of cartilage are present (Fig. 9–35C).

Facial asymmetry occurs in about 25% (Fig. 9–34C,D) and may be accompanied by protrusion of an eye with associated visual disturbances in some instances (22,53,69). The bony lesions of the skull and facial skeleton, in contrast to the cystic lesions of long bones, are hyperostotic (Fig. 9–35B). The skull base becomes thickened and dense, bulging upward into the cranial cavity (17). The calvaria may also become

A

C

Fig. 9–35. *McCune-Albright syndrome.* (A) Thickening and pseudocystic involvement of tibia and fibula. (B) Hyperostotic involvement of maxillary sinus by fibrous dysplasia. (C) C-shaped trabeculae composed of metaplastic woven or fiber bone in fibrous connective tissue stroma.

thickened, with marked occipital and frontal bulging. Bossing may be asymmetric, with unilateral, and occasionally bilateral, obliteration of the sinuses and nasal passages. Overgrowth of bone around foramina may result in deafness and blindness. Furin et al (28) reported an intracranial frontoethmoid mucocele.

The jaws may be enlarged, expanded, and distorted (14). Radiographic examination may show a dense mass, especially in the maxilla, extending into and obliterating the sinuses and expanding the buccal plate in the tuberosity areas, or there may be a radiolucent area, more common in the mandible, similar to that seen in long bones. Often there is loss of trabeculae and a "ground-glass" appearance on radiographic examination (18,35,53,77).

Cutaneous manifestations. Pigmentation is of the café-au-lait type (7,55,58). Well-defined, generally unilateral, irregular macular spots are scattered over the forehead, nuchal area, and buttocks. Only rarely are the face, lips, or mucosa affected (10,30,57) (Fig. 9–34A,B). The hyperpigmentation may follow Blaschko's lines (55).

There appears to be a correlation between the amount of pigmentation and the degree of bone involvement (7). It has been stated that

pigmentation is more frequent on the side of unilateral bone involvement, although this has been denied (36). The pigment appears from the fourth month to the second year of life. In a few patients, it has become evident a few weeks postnatally (6). In one patient, symptoms resembling epidermal naevus syndrome were found (76).

Endocrine manifestations. Endocrine abnormalities, reviewed elsewhere (3,9,15,18,19,24,29,32,36,46–50), are characterized by autonomous hyperfunction and, to date, no instances of extraglandular trophic influences mediating hypersecretion have been identified. In affected patients, any given endocrine gland may function normally. At autopsy, characteristic endocrine nodular hyperplasia may be found that did not give rise to clinical signs of hyperfunction during life. In fact, endocrine organs, in spite of autonomy, may function so nearly normally that their independence is not recognized until appropriate tests have been performed. Sexual precocity is the most common endocrine manifestation, especially in females (Fig. 9–34A). It is generally manifest earlier in girls than in boys. Menarche is reached between 1 and 5 years of age in 50% and between 6 and 10 years in another 33% (9). However, vaginal bleeding may occur within the first few months or even the first few days of life (2,3,6,32). It is usually irregular, lasts from 2 to 4 days, and may, on occasion, be profuse. Breast development and pubic and axillary hair appear after menarche, usually from the fifth to the tenth year, but may be manifest as early as birth (48,49). Hypertrophy of the internal (26) and external (2,3) genitalia occurs. It is remarkable that affected women can be fertile (18,32). In males with sexual precocity, enlargement of the penis and testes is accompanied by growth of pubic hair, suggesting hyperfunction of both spermatic tubules and Leydig cells (18,32). Precocious puberty in males may be accompanied by gynecomastia (22,53). Acromegaly or gigantism has been described (1,37,69).

Hyperthyroidism is present in about 20%, occurring at an early age (3,49,53,57,59,78). The sex distribution is approximately equal. Thyrotoxic manifestations such as irritability, poor weight gain, and growth failure have been described during infancy, as early as 3 months in one instance (59). With untreated sexual precocity or hyperthyroidism, skeletal maturation is often rapid and premature closure of the epiphyses may result, producing short stature in adulthood.Various other endocrine disorders have also been noted, including Cushing's syndrome, hypersomatotropinism, hyperprolactinemia, hyperparathyroidism, thyroid storms after surgery, and hypophosphatemic vitamin D–resistant rickets or osteomalacia without hypercalcemia or elevated parathyroid hormone levels (15,18,22,24,33,39,56).

Central nervous system. Although the overwhelming majority of patients have normal intelligence, mental deficiency has been reported in a few instances (2,15,18). It may be secondary to factors such as prematurity, hypercorticalism, or grossly malformed skull. The significance of mental retardation in others remains unclear. In the original description of Albright et al (2), an accessory mammillary body was found at autopsy. However, no other patient has exhibited this finding.

Neoplasms. Malignancies are rarely described. The most unusual malignancy recorded to date has been carcinoma of the breast in an 11-year-old girl. Endometrial carcinoma (18) and maxillary osteosarcoma (4) have also been recorded. Instances of sarcoma arising in areas of fibrous dysplasia have been secondary to radiation therapy (35). Other neoplasms have been observed in patients with isolated polyostotic fibrous dysplasia, but could conceivably occur as components of McCune-Albright syndrome. Multiple intramuscular myxomas have been noted in a number of such patients (22,27,29,41,67,75). This is known as *Mazabraud syndrome* and may be associated with osteogenic sarcoma (38,44). Reticuloendothelial hyperplasia with lymphoid and myeloid metaplasia has been described (59). Leukemia (23), osteoma of the skin (63), osteosarcoma (68), and meningioma (23) have also been noted.

Other findings. At autopsy, the thymus and spleen are frequently hyperplastic, but the significance of this finding is unknown (18).

Differential diagnosis. Fibrous dysplasia may occur without McCune-Albright syndrome. The overwhelming majority of cases are monostotic; polyostotic involvement occurs much less frequently and, of these, only 3% have McCune-Albright syndrome (11,18,25,35,71). Radiographically, bone lesions should be distinguished from those of hyperparathyroidism, histiocytosis X, multiple myeloma, Paget disease of bone, neurofibromatosis, and giant cell tumor. It is unfortunate that some authors have referred to cherubism, an autosomal dominant disorder, as "familial fibrous dysplasia of the jaws," a designation it does not merit. *Jaffe-Campanacci syndrome* consists of café-au-lait macules with nonossifying fibromas of long bones and giant cell granulomas of the jaws (50,66). Some have mental retardation and hypogonadism and/or cryptorchidism (12,36).

Cole et al (16) described a congenital disorder of bone with unusual facial appearance, bone fragility, hyperphosphatasemia, and hypophosphatemia—a condition they called panostotic fibrous dysplasia. Viljoen et al (70) described a patient with polyostotic fibrous dysplasia without skin or hormonal abnormalities, who showed extensive cranial hyperostosis. A five-generation family with a craniofacial fibrous dysplasia was reported by Reitzik and Lownie (54).

Skin pigmentation is also seen in *neurofibromatosis.* "Coast of California" contour is typical of neurofibromatosis and a markedly irregular outline ("Coast of Maine") usually occurs with McCune-Albright syndrome; exceptions have been noted (31). Giant pigment granules, characteristically seen in malpighian cells or melanocytes in neurofibromatosis, are very rare in McCune-Albright syndrome (7,25). Precocious puberty occurs in the adrenogenital syndrome, with ovarian granulosa cell tumor, and occasionally in *Peutz-Jeghers syndrome.*

Laboratory aids. Radiographic studies are useful for fibrous dysplastic lesions, advanced bone age, and for occasional findings such as rickets, osteomalacia, or osteoporosis. Serum alkaline phosphatase is elevated in about 50% (53). Appropriate endocrine investigations should be carried out.

Fig. 9–36. *Melnick-Needles syndrome.* Dysplastic habitus, foot dysplasia. (From N Moelter and A Walther, Monatsschr Kinderheilkd 123:178, 1975.)

Melnick-Needles syndrome (osteodysplasty)

In 1966, Melnick and Needles (32) described a syndrome characterized by generalized bone dysplasia and abnormal facies (Figs. 9–36 to 9–38). About 50 cases have been reported to date (3,4,7,8,10,12,20, 23,24,26,27,29–31,34,35,37,39,42,45–47,51–53). In all but five examples, the patients were females, with about one-half the cases representing new mutations. In only five kindreds was there transmission from one generation to another (10,15,26,32,35,48) although the symptoms in the boy reported by Neou et al (35) were so mild as to make the diagnosis doubtful. Male patients, originally reported to be affected by Melnick and Needles (32), on follow-up were found to be normal (15). Several males born to normal parents had the same degree of expression as that of affected females (13,18,22,23,33,45,47,53); and five affected females had male stillborn infants with a distinct embryopathy (9,23,44,51,54) characterized by exophthalmos, omphalocele and/or malrotation of the gut, and skeletal anomalies (thin calvaria with stellate ossification pattern, cervical lordosis, cervicothoracic kyphosis, thoracolumbar lordosis, thin irregular ribs, curved long bones with sheathing, and hypoplasia or absence of thumbs and halluces (Fig. 9–39). Less certain example are those of Deleporte et al (6) and Gardner et al (14). Several cases (2,41,49) cannot be accepted as examples of Melnick-Needles syndrome on either clinical or radiographic grounds or due to inadequate documentation. Others (40) clearly have frontometaphyseal dysplasia. A disorder first reported by ter Haar et al (20,43), although having somewhat similar clinical but far less severe radiographic features, is a separate entity with autosomal recessive inheritance. The condition reported in twins by Kozlowski et al (21) as being a possible new syndrome, was probably reported later by Adés et al (1) as examples of Shprintzen-Goldberg syndrome, and may, in fact, have Melnick-Needles syndrome.

Gorlin and Knier (15) indicated that Melnick-Needles syndrome has X-linked dominant inheritance lethal in the male. Verloes et al (50) have opined that *frontometaphyseal dysplasia, otopalatodigital syndromes* I *and* II, and *Melnick-Needles syndrome* were but variants of the same disorder.

The pathogenesis is unknown, but it is thought to be a connective tissue disorder. Svejcar (42) reported increased collagen content in affected bones, and dense collagenous tissue was found at the constrictions in the ribs, and abnormal fibrovascular sites within epiphyses (33,51).

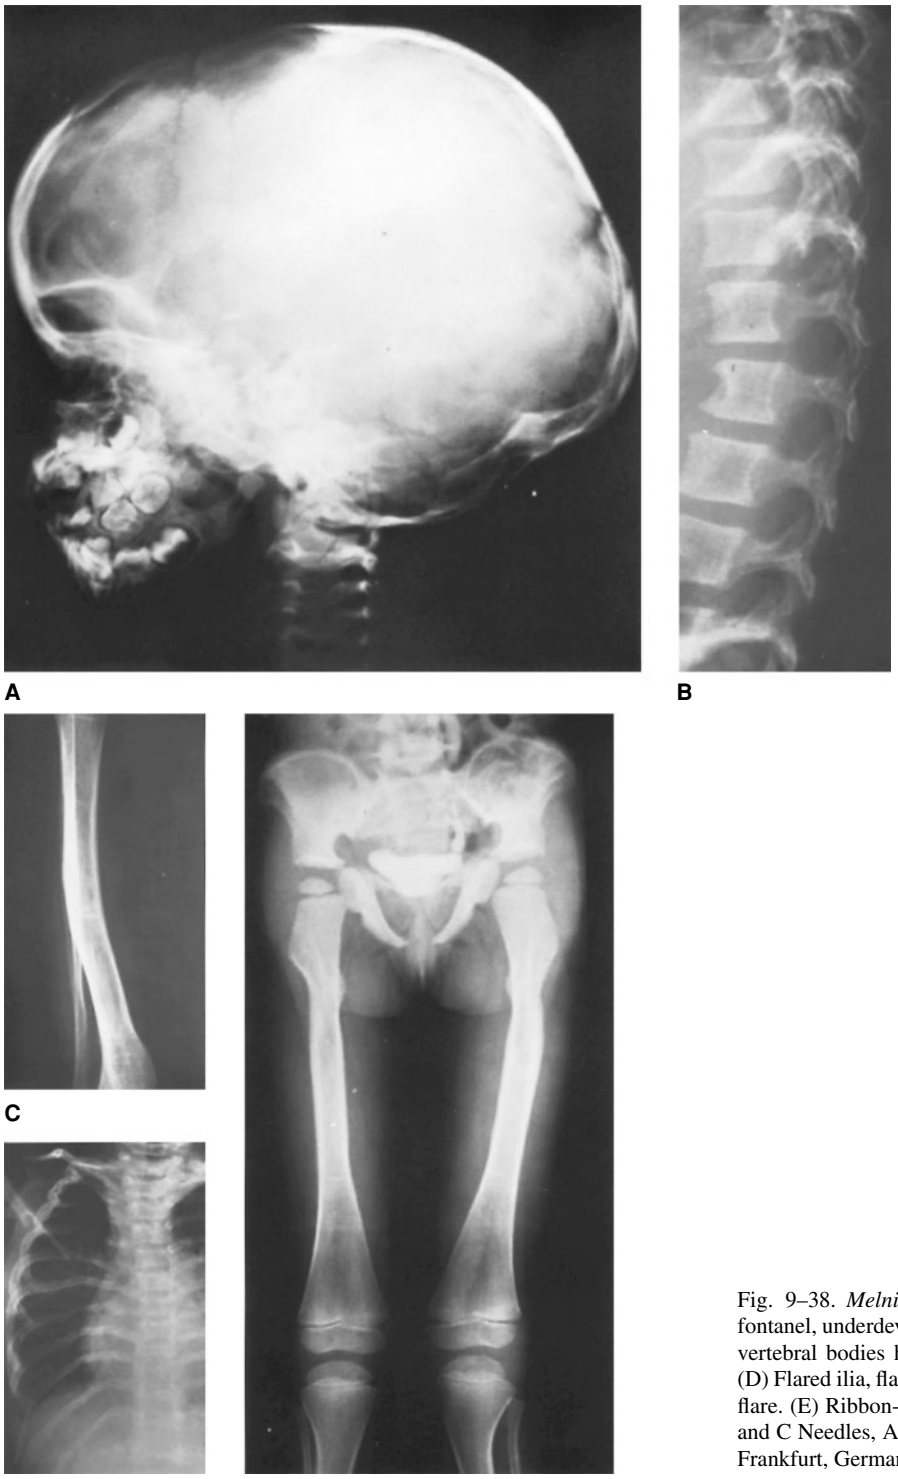

Fig. 9–38. *Melnick-Needles syndrome.* (A) Delayed closure of anterior fontanel, underdevelopment of paranasal sinuses. (B) Disproportionately tall vertebral bodies having anterior concavity. (C) S-shaped bowing of tibia. (D) Flared ilia, flat acetabula, tapered ischial bones, coxa valga, metaphyseal flare. (E) Ribbon-like ribs with cortical irregularities. (A,D from J Melnick and C Needles, Am J Roentgenol 97:39, 1966. B,C,E courtesy of B Leiber, Frankfurt, Germany.)

Early childhood is marked by recurrent respiratory and ear infections. Height and weight are usually below the 10th centile. The patients tend to remain thin. The breasts are very small and sexual hair is sparse (10,39). Mild developmental delay occurs (10,35).

Facies. The facies is characterized by high somewhat hirsute forehead, somewhat prominent supraorbital ridges, prominent eyes, full cheeks, large pinnae, and marked micrognathia (Fig. 9–37). Strabismus (8,33,36,52) and blue sclerae (3) have also been reported, and squamous cell carcinomas in another (32).

Skeletal alterations. The neck is long, the chest is narrow, and the upper arms and terminal digits are often short. There is valgus deformity at the elbows and extension is often diminished. Mild pectus excavatum has been noted in over 50% of the cases (10,20,33,52). About 35% exhibit delay in motor development and abnormal gait. Dorsal kyphosis and/or scoliosis are relatively common. Most patients exhibit genua valga, and about one-third have pes planus or valgus. Some have dislocated hips.

Radiographically, the calvaria often has digital markings. There is delayed closure of the anterior fontanel. The skull base and mastoid processes are sclerosed. There is mildly increased interorbital distance. The paranasal sinuses tend to remain underdeveloped. The mandible is small with scalloped rami and lack of coronoid processes (16,17,38). The mandibular bone is so thin that retromolar lucencies have been confused with cysts (10).

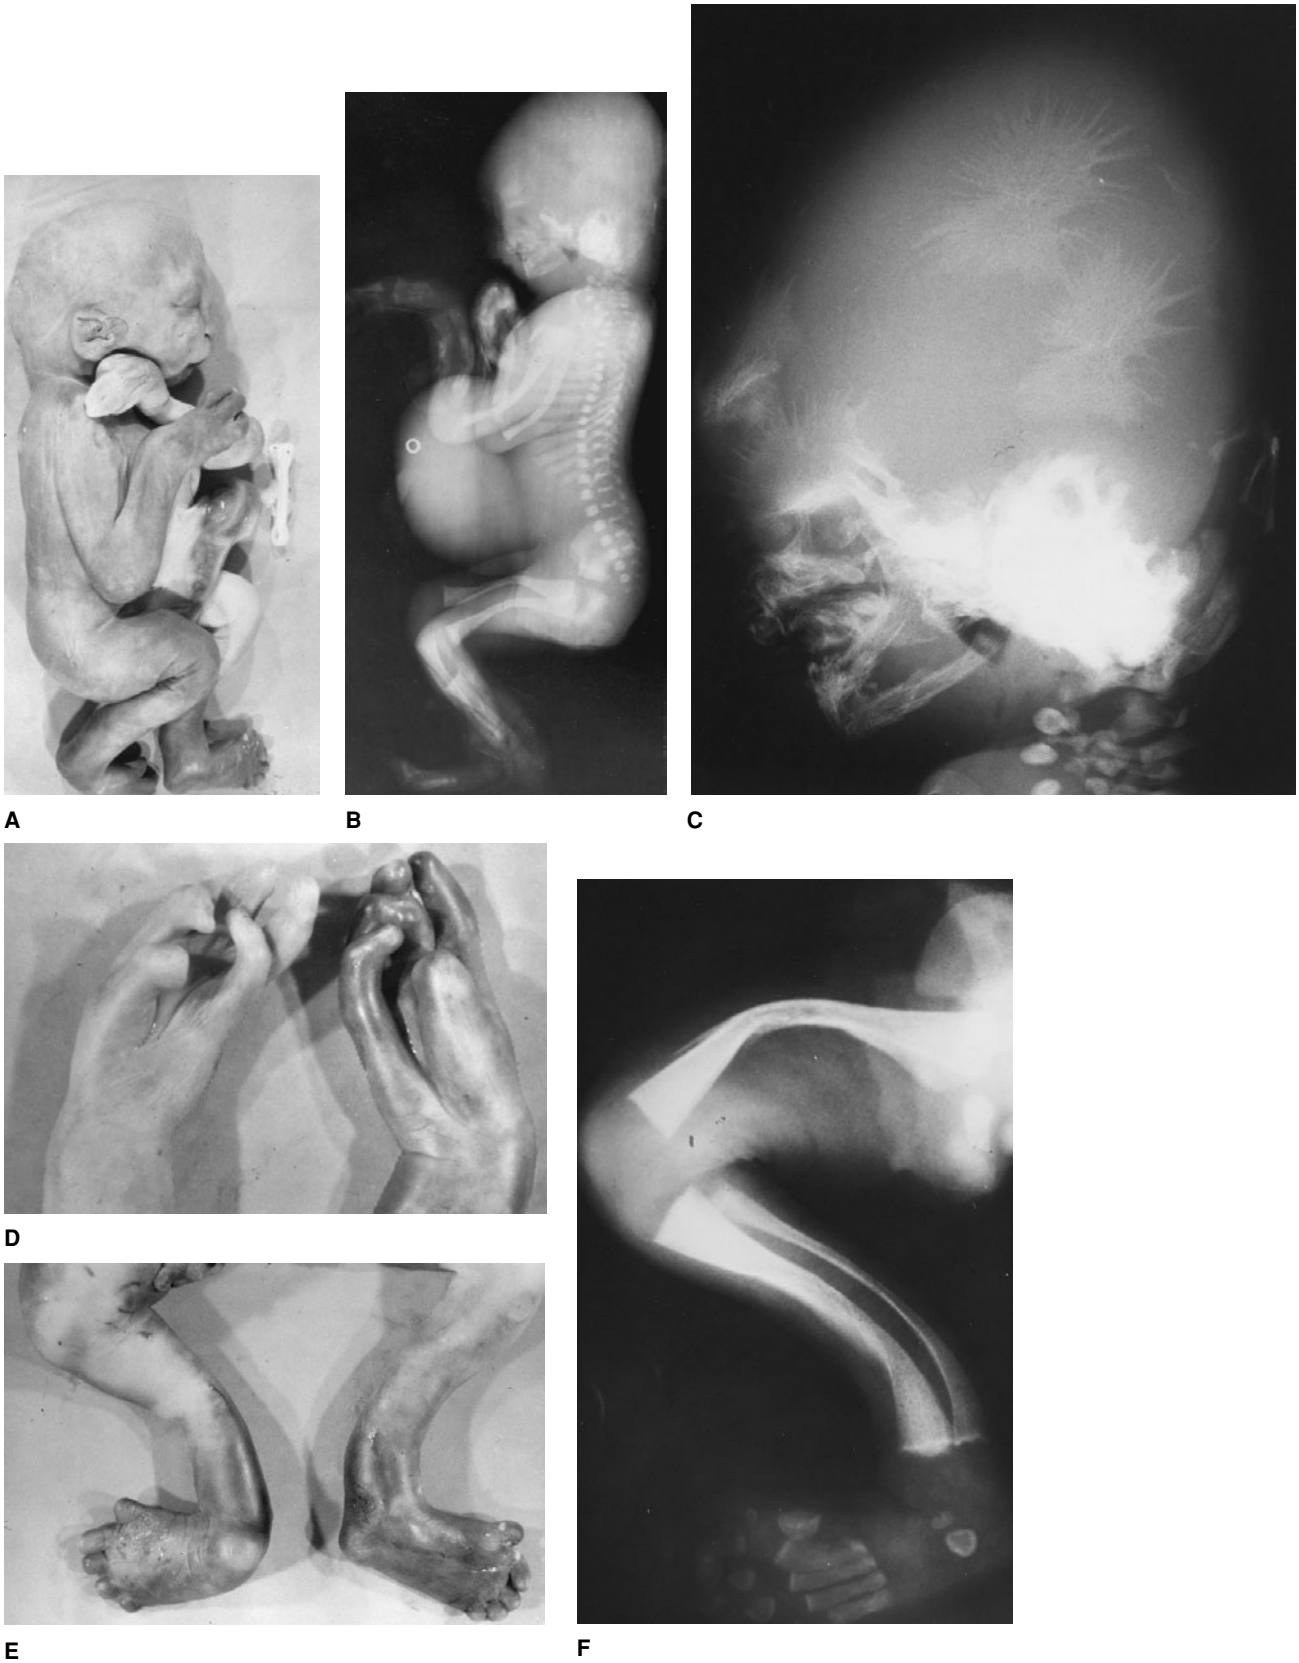

Fig. 9–39. *Melnick-Needles syndrome embryopthy.* (A–C) Male stillborn, mother affected. Note exophthalmos, omphalocele, thin calvaria with stellate ossification pattern, cervical lordosis, cervicothoracic kyphosis, thoracolumbar lordosis, and thin irregular ribs. (D–F) Curved long bones with sheathing, hypoplasia or absence of thumbs and halluces. (A courtesy of M Barr, Ann Arbor, Michigan. B,C, from G Theander and O Ekberg, Acta Radiol Diagn 22:369, 1981.)

All vertebral bodies are unusually tall, especially those of the axis, atlas, and occipital condyles (Fig. 9–38B). The thoracic vertebrae exhibit an anterior concavity with double beaking. Decreased disc space has been found in the lumbar area. The clavicles have cortical irregularity with flaring. Sternal ossification is delayed. The scapulae are hypoplastic.

Most striking are the changes in long bones. Bowing of the radius and tibia produces an S-shaped appearance. The metaphyses at the proximal and distal ends of the humerus, fibula, and tibia are flared. The terminal phalanges are short and thick, especially those of the thumbs. Cone-shaped epiphyses are found in the middle phalanx of the abbreviated fifth fingers and in the terminal phalanx of the thumbs (12,26,32,45). Coxa valga is marked. The iliac bones are flared at the crest and constricted in the supraacetabular area, whereas the ischial bones are tapered. The ribs are ribbon-like, with cortical irregularity (Fig. 9–38).

Other findings. Ureterovesicular obstruction has been documented in several cases (3,8,10,20,32,45) that were reviewed by Lamontagne (26). Fryns et al (13) reported hyperlaxity in affected males, and Krüger et al (24) noted mitral and tricuspidal valve prolapse. Pulmonary hypertension (20), tetralogy of Fallot (9), and noncompaction of the ventricular myocardium (52) have been found.

Oral manifestations. Micrognathia and marked malocclusion are constant features. Some have delayed tooth eruption (13).

Differential diagnosis. The radiographic features are so distinctive as to differentiate this syndrome from all other disorders in which there is delayed closure of the anterior fontanel. The *serpentine fibula-polycystic kidney syndrome,* characterized by overly long curved fibulas but without several of the skeletal abnormalities of Melnick-Needles syndrome, was reported by Dereymaeker et al (7, Case 1), Exner (11), and Majewski et al (28). However, it seems likely that this is the same disorder.

Melnick-Needles syndrome needs to be separated from *Hajdu-Cheney syndrome, frontometaphyseal dysplasia,* and *otopalatodigital syndrome*. A suggestion has been made that the latter entity is allelic to Melnick-Needles syndrome (37). Billette de Villemeur et al (5) described an entity first reported by Bowen, characterized by congenital glaucoma, exophthalmos, facial anomalies, and cardiac malformations, that superficially may resemble the lethal form of the entity in males. Radiographs were normal, however, and autosomal recessive inheritance was suggested.

Laboratory findings. Prenatal diagnosis has been carried out by ultrasonography (25).

Osteochondrodysplasia with hypertrichosis (Cantú syndrome)

Cantú et al (2) described two sibs and two unrelated patients with congenital generalized hypertrichosis, coarse facies, cardiomegaly, and mild generalized skeletal dysplasia, including osteoporosis and delayed bone age. The same group of authors described four other unrelated patients and follow-up of one of the original patients (3). Nevin et al (5) described a single case, Rosser et al (7), three unrelated cases, and Robertson et al (6), a case. Parental consanguinity was present once (7), and affected sibs were described (2), pointing to a possible autosomal recessive inheritance. However, some cases (especially Case 3 from the Rosser report) resemble the entity described by Irvine et al (4), which was considered different because of the absence of skeletal anomalies, and which has autosomal dominant inheritance. Dominant inheritance was noted by Lazalde et al (4a). The occurrence of idiopathic cardiac effusions both in one of the original patients (3), in the patient of Nevin et al (5), and in one of the patients described by Irvine et al (4) form another point of overlap. Baumeister et al (1) provides guidelines for management of hypertrichosis.

Hypertrichosis is congenital, and changes from lanugo to terminal hair. It continues to grow. Only palms, soles, and mucosae are spared. Facial features (Fig. 9–40) include prominent forehead, epicanthal folds, long curly eyelashes, anteverted nostrils, long philtrum, and thick lips. Some patients have gingival hypertrophy (7) or macrocephaly (3,5). Birth weight can be elevated. Some have a short neck and narrow thorax. Cardiac problems were serious pericardial effusions necessitating surgery (3,5), congenital hypertrophy of left ventricle (2), patent ductus arteriosus (7), and idiopathic intermittent cardiac failure (7). One patient had primary lymphedema (3). Mentation has been normal or mildly delayed.

Radiologically, most patients had wide metaphyses, a delayed bone age, and generalized osteopenia. Other radiologic symptoms are wide ribs, platyspondyly, hypoplastic ischiopubic rami, coxa valga, and long bones with Erlenmeyer flask shape (Fig. 9–41). Megaepiphyses have also been noted (2a).

Pachydermoperiostosis [Touraine-Solente-Golé syndrome, primary (idiopathic) hypertrophic osteoarthropathy]

Pachydermoperiostosis is characterized by coarsening of facial features with thickening and furrowing of the face, forehead, and scalp, and clubbing of the digits with periosteal new bone formation (Fig. 9–42 to 9–44). Touraine et al (54), in 1935, first recognized pachydermoperiostosis as a distinct clinical entity, although examples were noted as early as 1868 by Friedreich (16). Other early cases are those of Unna (55) and Grönberg (18). An excellent review is that of Thappa et al (50a).

Most reports have been isolated cases of the condition. However, kindred have been reported in which the disorder appears to be autosomal dominant with variable expressivity (26,27,29,35–37,41,44,56,58), but only 12%–15% of the affected are females (36,44). Anticipation has been suggested (36). The disorder usually appears in the second decade of life (5,15,19,22,23,25,32,36,38,40,43,45,46,53). The cause of pachydermoperiostosis remains uncertain. It has been found that there are high concentrations of nuclear steroid receptors and very low concentrations

of epidermal growth factor receptors (3) suggesting an increased tissue sensitivity to circulating sex hormones and enhanced production of transforming growth factor alpha. Silveira et al (47) discussed the possible role of vascular endothelial growth factor. The role of the increased peripheral blood flow (13,41) and platelet activation (11) remains uncertain. Connective tissue studies (39) showed accumulation of acidic mucopolysaccharides and some fibrillar material in the dermis. Matucci-Cerinic et al (36) and Jansen et al (27) provide useful reviews.

Facies, skin, and skin appendages. Thickening of the skin occurs over the face, forehead, scalp, hands, and feet. The face is drawn into thick folds, producing creasing or furrowing that causes the patient to look worried or angry, as well as prematurely aged (5,14,20,28,34,37,43,57). The nasolabial folds become deep (Fig. 9–42A,B). Thickening of the scalp tends to produce a corrugated surface or cutis verticis gyrata (18,55), although groups of patients without this characteristic have been described (19,36,52).

The skin has been reported to be greasy or oily (5,18,23,38, 46,50). The dilated sebaceous pores are filled with plugs of sebum that can be easily expressed (18) (Fig. 9–42C). Acne may be marked (25). Pseudoptosis, caused by thickening of the eyelids, may be so severe as to impair vision (5,19,28,50). Skin biopsy shows sebaceous gland hyperplasia, thickening of the stratum corneum, and perivascular round-cell infiltrates (18,36,41,57). The nails may be thick and curved (40). Hyperhidrosis of the hands and feet (1,19,20,23,25,36) is common. Multiple basal cell carcinomas were found in one case (52) and squamous cell carcinomas in another (31).

Fig. 9–44. *Pachydermoperiostosis.* (A) Note thickening and increased density of proximal phalanges and metacarpals, and periosteal thickening of radius. (B) Marked periosteal proliferation along entire length of tibia and fibula. (A from G Pietruschka et al, Klin Monatsbl Augenheilkd 154:525, 1969. B courtesy of A Susmano, Chicago, Illinois.)

A B

Skeletal alterations. Bone changes affect primarily the long tubular bones, metacarpals, metatarsals, and proximal phalanges (18,20, 25,30,36,37,52,58) (Figs. 9–43 and 9–44). Enlargement may be painful (3,6,25,29,30,36). The ends of the fingers and toes become thickened during the second decade of life (18,20) and may become very bulbous (16,19,36,46,52,58) (Fig. 9–43). This clubbing is produced by soft-tissue hyperplasia, which stops abruptly at the distal interphalangeal joints. A diffuse irregular periosteal ossification increases the circumference of the affected bones and results in loss of normal tubulation of long bones. Acroosteolysis in the hands and feet has been described (3,19,36). Bone marrow failure due to massive endosteal hyperostosis has occurred (36).

Joint effusions of the knees (20,25,30,38) and ossification of ligaments and tendons (19) lead to ankylosis of joints (19). The clavicles, patellas, and pubis may also be affected, but the carpal and tarsal bones, sella turcica, and articular surfaces are spared. The skull is usually not affected, but the posterior half of the calvarium has been described as thickened (46). Some patients have pretibial edema (3) as in thyroid disorders. Enlargement of the wrists and knees has been noted (6,19,20).

Hypertrophic gastritis (57) and gastric ulcers (36) occur more frequently than in the general population, and also Crohn's disease has been found within a family (8).

Differential diagnosis. All clinical aspects of pachydermoperiostosis have been described in secondary (pulmonary) hypertrophic osteoarthropathy (21). Patients with pulmonary hypertrophic osteoarthropathy lack a family history of the disorder but have a primary neoplasm, usually bronchogenic carcinoma. There appears to be increased blood flow in pulmonary osteoarthropathy (17), in contrast to reduced flow in pachydermoperiostosis (13,27,41).

In acromegaly, there is enlargement of the hands and feet, and thickening of the skin, particularly of the face (47,48,57). The mandible, nose, sella turcica, supraorbital ridges, and tongue are also enlarged, findings not seen in pachydermoperiostosis.

Thyroid acropathy may follow medical or surgical treatment of hyperthyroidism. As in pachydermoperiostosis, the distal parts of the limbs may be come enlarged, and clubbing of the fingers and toes may occur (12). There may be subperiosteal new bone formation in the hands. Severe exophthalmos and pretibial myxedema may be present, together with high levels of long-acting thyroid stimulator in the serum of such patients.

Simple hereditary clubbing (acropathy) has been described (10). Rimoin (41) has suggested that hereditary acropathy may be an incomplete form of pachydermoperiostosis.

Rosenthal and Kloepfer (42) and Harbison and Nice (22) described a combination of cutis verticis gyrata, corneal leukoma, marked supraorbital ridging, and enlarged frontal and sphenoid sinuses as an autosomal dominant syndrome in a large kindred; the cranium was thickened in some patients, but no periosteal reaction was seen along the shafts of long bones.

Members of the kindred reported by Boylen and Blackard (4) as pachydermoperiostosis had hyperthyroidism. They had coarse prominent facial features, frontal bossing, furrowing of the skin over the forehead, and large hands. Corneal leukomas were also found. The proband had no significant clubbing of the hands, but other members of the family exhibited this characteristic. There were no periosteal changes in the long bones, but radiographs of the proband's hands showed several cystic lesions. Inheritance was autosomal dominant. *Beare-Stevenson cutis gyrata syndrome* (2) should also be excluded.

A patient reported by Vogl and Goldfischer (58) had oily and thickened facial skin, deep folds on the forehead, deep nasolabial folds, and clubbing of fingers and toes. Onset of these changes was noted by the patient at about age 40. No evidence of periosteal proliferation was found. Familial idiopathic osteoarthropathy of childhood (7,9) is an autosomal recessive disorder characterized by eczema, clubbing of fingers, large hands and feet, thick arms and legs due to periosteal new bone formation, and persistent anterior fontanel. Onset has been reported during the second year of life.

The patient reported by Herbert and Fessel (24) had large, unusually shaped extremities since birth, which increased in thickness during adolescence, periosteal new bone formation affecting the distal ends of some of the long bones and clubbing of all fingers and toes, thickening of the skin of the lower legs, and acroosteolysis of the distal phalanges of the fingers and toes; there was no hyperhidrosis or cutis verticis gyrata, and facial features were normal.

Leibowitz and Kalk (33) reported a patient with coarsening of facial features beginning at puberty, cutis verticis gyrata, acneiform eruption on the face, unilateral ptosis, and prominent nasolabial folds; there was no clubbing or periostosis. The patient had depressed urinary excretion of 17-hydroxy- and corticosteroids, depressed response to thyrotropin-releasing hormone, and aminoaciduria.

Sirinavin et al (49) reported a 12-year-old girl, born to a consanguineous couple, with clubbing of fingers and toes since 7 months of age, hyperhidrosis of hands and feet, slightly tender and swollen distal phalanges, dystrophic nails, thickening of soft tissues of knees and ankles, generalized osteoposis, joint effusion in knees, and acroosteolysis. Although other skeletal abnormalities were present, subperiosteal ossification was not found.

Thomas (51) described a 22-year-old male with marked clubbing of fingers and toes of unknown onset and mild periosteal thickening of the tibias and forearms; the remainder of the physical examination was unremarkable. His father had similar hand and foot abnormalities.

Pycnodysostosis

Maroteaux and Lamy (32) and Andrén et al (2), in 1962, defined pycnodysostosis (the Greek word *pyknos* meaning "thick, stocky") as a syndrome consisting of short stature, osteopetrosis, abbreviated terminal phalanges, cranial anomalies, such as persistence of fontanels and failure of closure of cranial sutures, and hypoplasia of the mandibular angle.

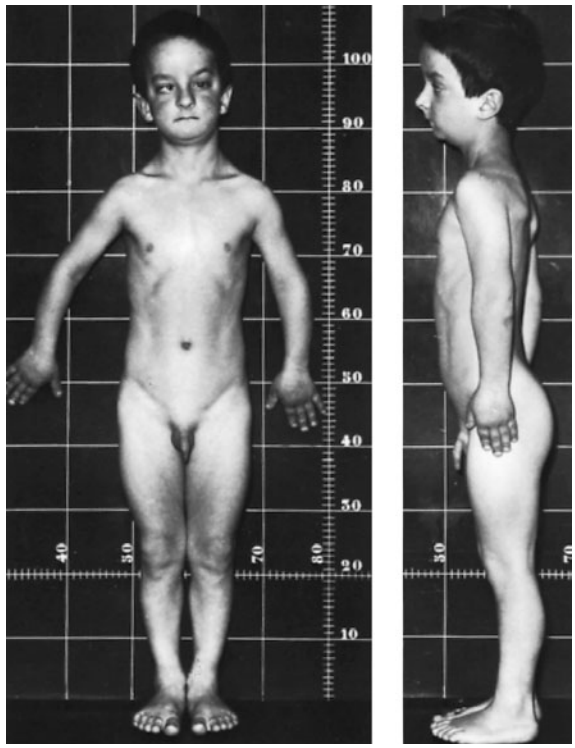

Fig. 9–45. *Pycnodysostosis.* (A,B) Eight-year-old boy with short stature, exophthalmos, and small mandible. (From A Giedion and M Zachmann, Helv Paediatr Acta 21:412, 1966.)

Several cases of the syndrome were published as examples of other disorders, chiefly osteopetrosis (1,40) and cleidocranial dysplasia (37,523). The first documented case is that of Montanari (37) in 1923. About 125 cases have been reported (26,41,48).

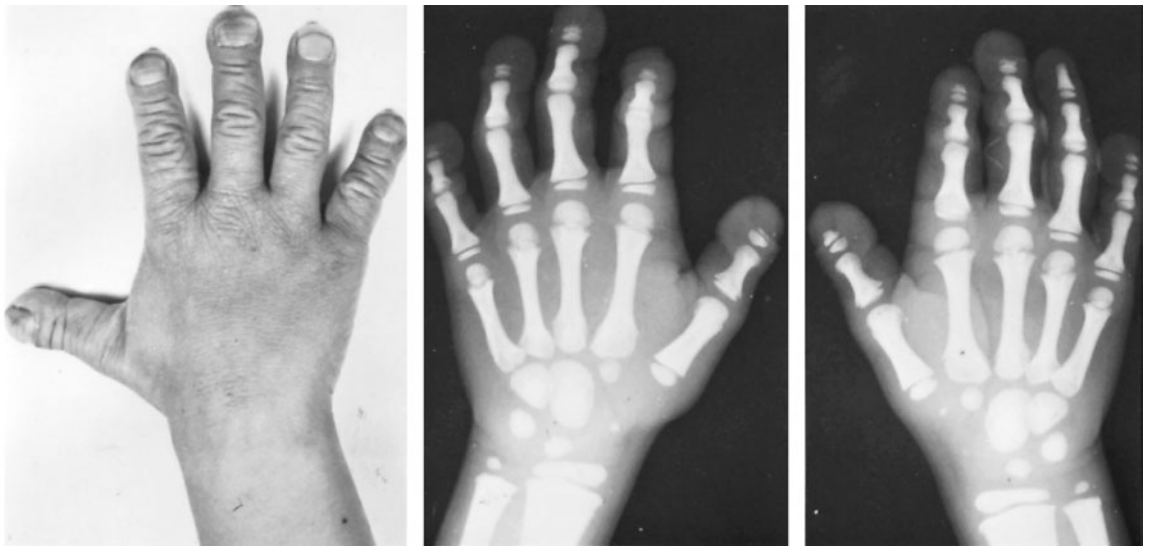
Affected sibs have been noted in many instances (1,12,30,35,37, 40,41,43,47,49,52,53). The syndrome has also been seen in identical twins (2). Parental consanguinity has been noted in more than 30% (44,48). Autosomal recessive inheritance is indicated. The disorder is more common in Japanese (38). Through a pooling strategy (41) and homozygosity mapping (18,19), the gene was located at chromosome 1q21. Gelb et al (20) found mutations in the cysteine protease gene cathepsin K. This is a lysosomal protease with high expression in osteoclasts, which secretes the enzyme for bone matrix degradation. Hence, pycnodysostosis is a lysosomal disorder caused by defective tissue-specific expression of cathepsin K (20,21a,22a).

A patient with pycnodysostosis due to paternal uniparental disomy of the 1q21 region has been described (21). It has been suggested that Toulouse-Lautrec had the syndrome (22,33), but a detailed study of pertinent data has shed doubts on this suggestion (17). The patient reported by Roth (42) does not have pycnodysostosis.

Mental development is normal, although exceptions have been described (5,26).

Facies. The head appears large because of occipital bulging. A large beaked nose with mild exophthalmos, deep nasolabial skin folds, and micrognathia are characteristic (Fig. 9–45). The micrognathia, together with the relatively long soft palate, can be severe enough to cause chronic respiratory airway obstruction (16). Several patients have developed sensorineural deafness (15,35). Mocan et al (36) described a hemangioma of the skull.

Skeletal alterations. Because of shortness of the extremities, adult height is reduced to 135–160 cm. Soliman et al (46) and Darcan et al (10) described defective growth hormone levels and improved growth after growth hormone supplementation. The trunk is not shortened but often exhibits marked pectus excavatum. The terminal phalanges are



A B C

Fig. 9–46. *Pycnodysostosis*. (A–C) Terminal digits of fingers reduced and widened. Nails often overlap ends of fingers. Note increased bone density, acroosteolysis of terminal phalanges, also pointed terminal phalanx. (From SE Shuler, Arch Dis Child 38:620, 1963.)

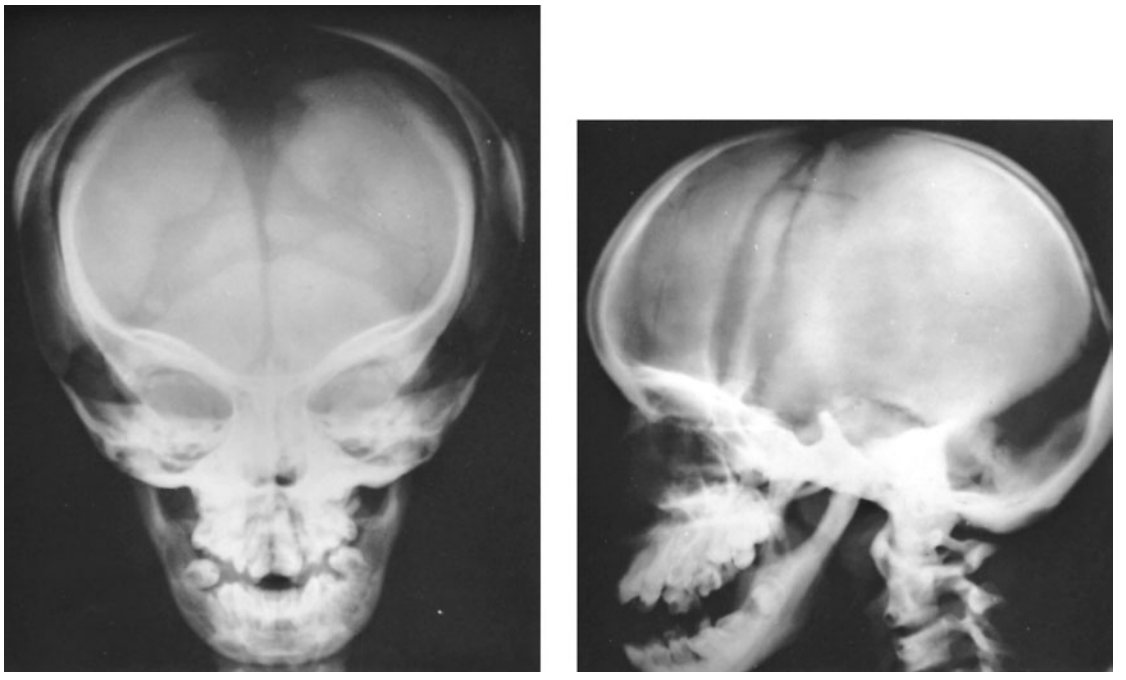
underdeveloped and widened and often present a drumstick appearance (Fig. 9–46 A–C). The nails may be thin and hypoplastic.

The acromial end of the clavicle is usually somewhat hypoplastic (2,45,48,52). Bilateral genua valga is frequent. Partial disappearance of the hyoid bone has been reported (51). In one report, indifference to bone-related pain was noted (12).

On radiographic examination, the skull is dolichocephalic with frontal and occipital bossing (1,20,49). Most cranial sutures and fontanels are open, especially the parietooccipital. The bones of the calvaria are thin, dense, and without diploic markings. Wormian bones are commonly observed (2,12,15,43,44,47). Craniosynostosis has been reported rarely (6). The frontal sinuses are consistently absent, and other paranasal sinuses are hypoplastic or missing. The mastoid air cells are often not pneumatized (2,43,44,52) (Fig. 9–47).

There is increased radiopacity of all bones, but especially of the long bones, spine, and cranial base. Through densitometry, Karkabi et al (24) found the increased bone density to be mainly in the trabecular bone and not in the cortical bone. Spondylolysis of cervical vertebra has been described (9,12,48). Bone fragility is increased, over 70% having multiple fractures during their lifetime (5,35,50). The terminal phalanges of the fingers and toes exhibit fragmentation of the heads with preservation of the bases, osteolysis of the unguiculate portions, or narrowing of the ends

Fig. 9–47. *Pycnodysostosis.* Radiographs. (A,B) Absence of fusion of sutures and closure of fontanels. Increased bone density and absence of mandibular angle. (From SE Shuler, Arch Dis Child 38:620, 1963.)



A B

of otherwise normal terminal phalanges (4,25). Brachymesophalangy of the fifth fingers, less often of the index finger, is a common finding. The fourth metatarsal is occasionally abbreviated (48).

Microscopic studies of the involved bones (45,47,49) have shown reduction in osteoclastic and osteoblastic activity, with reduced rates of bone formation and resorption. The bone has been found to be markedly sclerotic. Electron microscopic studies have demonstrated that osteoclasts have diminished or even inactive secretory functions (34).

Eyes. The eyes may be somewhat exophthalmic (1,48,49,52) with blue sclerae (53).

Oral manifestations. Obtuse mandibular angle is a constant feature. Facial bones are often underdeveloped, with relative mandibular prognathism (2,38,52,54). Oral and dental anomalies include premature or delayed eruption (1,13,14,21,48,54), ectopic teeth (14), enamel hypoplasia (15,40,49), malposed teeth (7,13,35,48,49), grooved palate (35,38,48,49), and sometimes cleft palate (15). The soft palate tends to be long (38,55). Lacey et al (28) described a patient with short and blunted tooth roots and multiple congenitally missing permanent tooth germs. Several patients developed osteomyelitis of the mandible after tooth extractions (23,35,43), which may be related to the impaired monocyte killing activity (24).

Differential diagnosis. Acquired acroosteolysis may occur in workers synthesizing polyvinyl chloride (31) and in a host of other disorders: psoriasis, various collagen disorders, thermal injury, hyperparathyroidism, and in guitar players (11). Lamy and Maroteaux (29) described isolated autosomal dominant acroosteolysis. Differential diagnosis includes *osteopetrosis, Hajdu-Cheney syndrome*, and *mandibuloacral dysplasia*.

Hajdu-Cheney syndrome is associated with progressive reduced height, kyphosis, bathrocephaly, basilar impression, numerous wormian bones, absence of frontal sinuses, and fusion of the spinous processes of the cervical vertebrae. The terminal phalanges are shortened and often exhibit tenderness, pain, and paresthesia. The alveolar process often is markedly atrophic, but the mandibular angle is not missing as in pycnodysostosis. It has autosomal dominant inheritance.

Stanescu osteosclerosis syndrome, a rare form of craniofacial dysostosis, inherited as an autosomal dominant trait, is characterized by small skull, thin cranial bone, depressions over the frontoparietal and occipitoparietal sutures, poorly developed mandible with obtuse angle, exophthalmos, and very short limbs with massive thick cortices.

Mandibuloacral dysplasia resembles pycnodysostosis in delayed closure of skull sutures, wormian bones, and hypoplasia of terminal phalanges, but there is no increase in bone density or aplasia of the mandibular angle. Instead there is antegonial mandibular notching, stiff joints, and cutaneous atrophy.

Laboratory aids. Reduced serum alkaline phosphatase has been found in a few cases (49,53). Cabrejas et al (8) described increased intestinal calcium absorption and diminished exchangeable calcium pool turnover as well as diminished bone accretion rate. Hepatosplenomegaly, thrombocytopenia, and iron deficiency anemia also have been found (4,5,27,30,34,39). Monocyte function tests showed normal phagocytic activity and impaired killing activity (24).

Osteosclerosis syndrome, Stanescu type

Osteosclerosis, Stanescu type, is characterized by short stature, hypoplastic midface, prognathism, long thorax, lack of pneumatization of frontal and sphenoidal bones, and dense cortices of long bones (Figs. 9–48 to 9–50). In the family first reported by Stanescu et al (5) and later by Maximilian et al (4), 14 individuals were affected. Dipierri and Guzman (1) described an affected mother and daughter, and Horovitz et al (3) expanded the phenotype in describing a mother and son and 11 other possibly affected family members, which allowed inclusion of the sporadic case reported by Hall (2) despite lack of brachydactyly and severe involvement of the spine and thorax.

Horovitz et al (3) provided a good review. Generally, patients have short stature due to shortened limbs. They may have prominent forehead, ocular hypertelorism, and exophthalmos. The malar bones are usually hypoplastic. The nasal base can be wide, and the nares prominent. The palate is shallow; the teeth are abnormally implanted and show increased caries due to insufficient enamel formation. The jaw may be relatively large.
